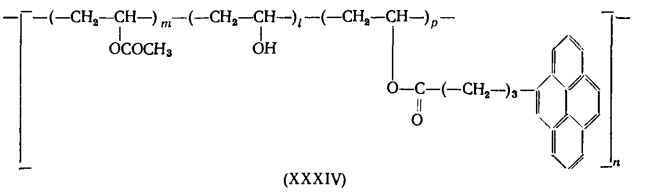
The fluorescence spectra of the pyrene-containing polymers (XXXIII) are more complex (Fig.8). Evidently, depending on the concentration of the solution, either only monomer fluorescence bands due to the pyrene groups with λ_{max} = 376, 395, and 415 nm are present in the spectra or they are accompanied by the excimer band with λ_{max} = 495 nm. The authors[59,60] observed a direct linear relation between the ratio I_e/I_m and the concentration of an aqueous solution of the polymer (XXXIII). When water was replaced by a more viscous solvent (ethylene glycol) a sharp decrease of the intensity of the excimer glow was observed, while the intensity of the monomer fluorescence bands was unchanged. Evidently the increased viscosity of the solvent diminishes the rate constant for the intramolecular formation of excimers, which agrees with a diffusion-controlled mechanism.

The latter conclusion has also been confirmed by the results of Cuniberti and Perico,[61] who investigated a partly hydrolysed poly(vinyl acetate) (XXXIV) treated with 4-(3-pyrenyl)butyric acid in THF in the presence of trifluoroacetic anhydride at 50 °C. This method made it possible to obtain a polymer with an average spacing between the pyrenyl groups equivalent to approximately 200 units:



It follows from the fluorescence spectra of solutions of the polymer (XXXIV) in methanol and ethylene glycol that both a monomer emission with λ_{max} = 396 nm and an excimer emission with λ_{max} = 480 nm are observed in the former solvent. In the more viscous ethylene glycol the excimer fluorescence is absent. A dependence of the ratio I_e/I_m on the viscosity of the medium has been observed for mixtures of solvents of similar types.[61]

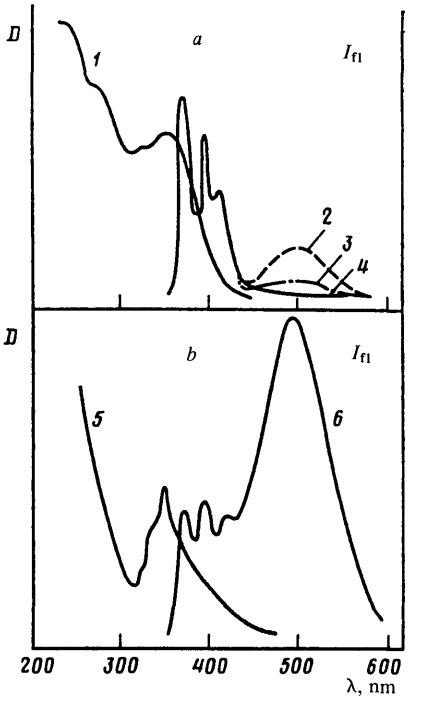


Figure 8. Absorption (curves *1* and *5*) and fluorescence (curves *2*, *3*, *4*, and *6*) spectra: *a*) of aqueous solutions of the pyrene-containing polymer (XXXIII) at concentrations of 0.28 M (curve *2*), 0.14 M (curve *3*), and 0.017 M (curves *1* and *4*); *b*) of a film of the polymer (XXXIII) (curves *5* and *6*).[60]

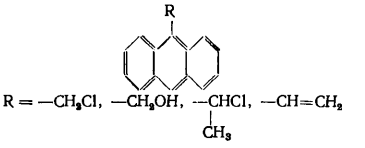
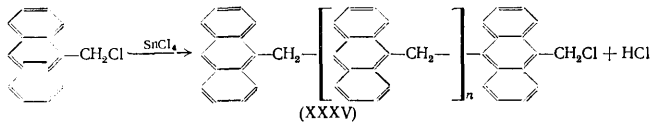
The Friedel–Crafts reaction of anthracene derivatives with the benzene rings of the macromolecules proved to be a fairly convenient method of synthesis of fluorescent polymers by polymer-analogue transformation.[51,62] It has been suggested that derivatives of the type



be used as the anthracene compounds. Their reaction with phenyl-containing polymers of the polystyrene, poly-α-methylstyrene, poly(benzyl vinyl ether), or poly(benzyl propenyl ether) was carried out at room temperature or at −78 °C for 0.5–360 h using $SnCl_4$ or boron trifluoride as the catalysts.[62] The polymers formed contain from 0.2 to 83 anthracene groups per 1000 polymer units and possess fluorescence properties close to those of the model benzylanthracene (the bands in the fluorescence spectrum of a solution in toluene at λ_{max} = 395, 425, and 440 nm).

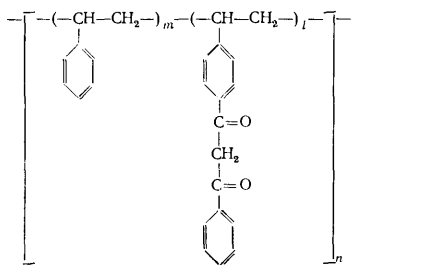
It was shown[62] that polycondensation processes occur simultaneously with alkylation under the conditions of the Friedel–Crafts reaction:



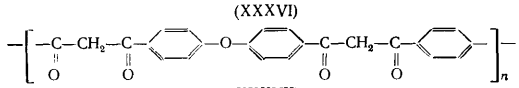
(XXXV)

Thus in the absence of the phenyl-containing polymer, the homopolycondensation of 9-chloromethylanthracene gives rise to the polymer (XXXV) MW = 1500) in 85% yield, the fluorescence spectrum of its solution in toluene containing a short-wavelength band at λ_{max} = 420 nm and a long-wavelength band at λ_{max} = 445 nm, which slowly descends to 560 nm. Homopolycondensation reduces the yield of the alkylation reaction and can lead to the addition of groups of the type of (XXXV) to the phenyl-containing polymer, which is reflected in the fluorescence spectra.

Extremely interesting fluorescent polymers, the method of synthesis of which can also be regarded as approximately polymer-analogue transformations, have been described.[65] These compounds are chelate europium complexes of macromolecules containing β-diketone units as ligands: poly-*p*-benzoylstyrene (XXXVI) and polyaryl-β-diketone (XXXVII):



(XXXVI)



(XXXVII)

The polymers (XXXVI) were synthesised by the reaction of partly acetylated styrene with methyl benzoate in the presence of sodium amide in THF at 50 °C. The europium(III) complexes were obtained by mixing 1–2% solutions of the polymers in THF with a solution of europium trichloride in a THF–methanol mixture.

The interest in the polymeric complexes of the lanthanides is associated primarily with their intense monochromatic fluorescence. This property makes it possible to employ such complexes as the active media in laser technology, their operating characteristics being in a number of instances superior to those of traditional materials for analogous purposes.[5]

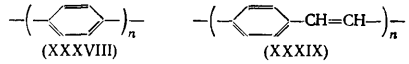
The chelate complexes of the polymers (XXXVI) and (XXXVII) are thermally stable but begin to decompose at 350 °C. The structure of the chelates has been investigated by infrared spectroscopy. It has been noted that the infrared spectrum of the polymer (XXXVII) has in the main an enolic structure with a broad absorption band in the region of 1350–1600 cm^{-1}.[65] When a chelate ring with Eu^{3+} is formed, a new intense band, corresponding to the asymmetric and symmetric vibrations of the C=O bonds and having a resonance structure appears in the spectrum at 1400–1530 cm^{-1}. The Eu^{3+} ions involved in complexes with the polymers (XXXVI) and (XXXVII) undergo radiative deactivation on excitation with light in the range of frequencies characteristic of inorganic crystals. The fluorescence spectra of the complexes contain two bands: one with a maximum at 613 nm, due to the $^5D_0 \rightarrow {}^7F_2$ transition, and the other, low-intensity band with a maximum at 580 nm, associated with the forbidden transition $^5D_0 \rightarrow {}^7F_0$. The intensity of the first fluorescence band of the complexes derived from the polymer (XXXVI) increases linearly with increase of the Eu^{3+} concentration to 3 wt.% and then remains constant. These complexes exhibit a fluorescence which is 20–30 times more intense that that of the complexes with the polymer (XXXVII) (containing 1% of Eu^{3+}). The authors[65] believe that this is due to the fact that, when the β-diketone groups are incorporated in the polymer chain, the formation of complex coordinate bonds between the Eu atoms and the β-diketone may be hindered by steric restrictions and by the decrease in the number of rotational degrees of freedom.

Since the fluorescent macromolecules arising in polymer-analogue transformations are in most cases polymers obtained by polymerisation methods, the rules governing their luminescence-spectroscopic properties are those noted in a review.[1] In the case of polymers the processes involving the transfer and migration of energy from the sites where it is absorbed to the sections of the macromolecule where the proximity and parallel arrangement of the planes of the chromophoric fragments promote the formation of excimers take place more or less effectively. A consequence of these processes is the presence in the fluorescence spectra of the polymers, together with the monomer emission band whose position and character are determined primarily by the nature of the chromophore, also of one or several excimer emission bands. In those cases where the absence of excimer emission may be regarded as proved, there is a great likelihood that no electronic excitation energy migration takes place along the polymer chain. One of the possible causes of the low capacity of such polymers for the formation of excimers is the increased flexibility of the macrochains, which disturbs the required planarity in the arrangement of the chromophores.

IV. AROMATIC FLUORESCENT POLYMERS

1. Carbochain Polymers

Aromatic carbochain polymers have been thoroughly investigated from the standpoint of light absorption properties, but their fluorescent characteristics have been investigated to a much lesser extent. An empirical rule established for linear polyenes and poly-*p*-phenylenes[66] (XXXVIII) is valid also for poly-*p*-xylidenes (XXXIX):[67]



(XXXVIII) (XXXIX)

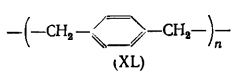
It states that, with increase in the length of the conjugated chain, the energy of the light quantum required for the excitation of the π-electron system diminishes and a bathochromic shift of the long-wavelength absorption band is

observed; after the chain has attained a specific length, the bathochromic shift ceases.[68,69] This shows that the fragment of the macromolecule which behaves as the chromophoric group is consistent with the model in which the number of conjugated π-bonds is less than the number equivalent to the length of the polymer chain. The chromophoric group of the polymer (XXXIX) is approximately equivalent to 3–4 elementary units of the macromolecule.[67]

The fluorescence properties of the polymers (XXXVIII) and (XXXIX) have been investigated.[70,71] A bathochromic shift of the fluorescence band has been observed for the poly-*p*-phenylene (XXXVIII) as its concentration in solution increases, without an appreciable change in the form of the absorption spectra,[70] which is associated with the major role of the energy transfer processes, whose intensity grows as the concentration of the solution rises. At concentrations above 10^{-3} M the energy transfer becomes so effective that quenching of the fluorescence is observed. The study of the effect of quenching agents such as tetracyanoethylene, chloranil, trinitrobenzene, dimethylamine, aminostyrene, and triethylamine on the luminescence of solutions of poly-*p*-phenylene (XXXVIII) showed that, when the absorption spectrum of the quenching agent overlaps the emission spectrum of the polymer, the quenching of the fluorescence can be accounted for by the Forster dipole–dipole energy transfer mechanism. This phenomenon occurs when chloranil is used as the quenching agent. On the other hand, when the absorption spectrum of the quenching agent and the emission spectrum with the polymer do not overlap, then the quenching takes place via a mechanism involving the migration of energy over a short distance or via the formation of donor–acceptor complexes. The latter occurs when aminostyrene, dimethylamine, or triethylamine are used as the quenching agents.

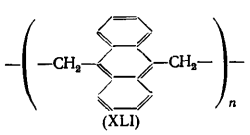
The study of the electronic absorption and emission spectra of polyphenylenes permits a detailed analysis of the mechanism of photoconduction in these polymers.[72]

The light absorption and luminescence properties of polymers with one or two methylene groups between the aromatic rings have been studied.[73–77] The electronic absorption spectra of poly-*p*-xylylene (XL) are characterised by a low-intensity band in the range 260–280 nm:[73,74]



(XL)

The phosphor-containing polymers of the type of poly-9,10-dimethyleneanthracene (XLI), obtained by the pyrolysis of 9,10-dichloromethylanthracene via the stage involving the formation of 9,10-anthraquinodimethane as an intermediate, are of more interest from the standpoint of optical properties:[75]



(XLI)

Fig.9 presents the absorption spectra of the initial 9,10-dichloromethylanthracene at 20 °C, of 9,10-anthraquinodimethane at −196 °C, and of the polymer (XLI) at 20 °C. Evidently the bands in the range 330–420 nm, which are characteristic of the anthracene nucleus, vanish almost completely on passing from 9,10-dichloromethylanthracene to 9,10-anthraquinodimethane. The spectrum of the latter contains only an intense band in the range 270–290 nm associated with the absorption by the anthraquinodimethane chromophore. As this compound is heated from −196 °C to room temperature, the intense absorption band at 291 nm disappears and a band with a maximum at 260 nm as well as a series of bands in the range 330–430 nm appear, confirming the structure of the polymer (XLI) formed.

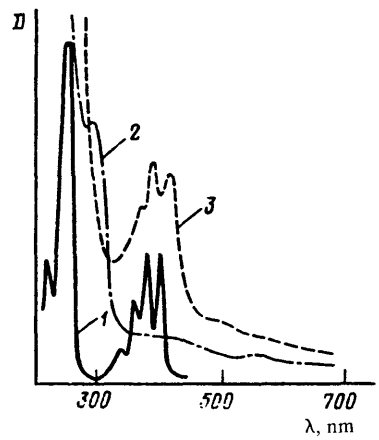


Figure 9. Absorption spectra of a solution of 9,10-dichloromethylanthracene in n-heptane at 20 °C (curve *1*), of 9,10-anthraquinodimethane deposited on a support at −196 °C (curve *2*), and of the polymer (XLI) on a support at 20 °C (curve 3).[75]

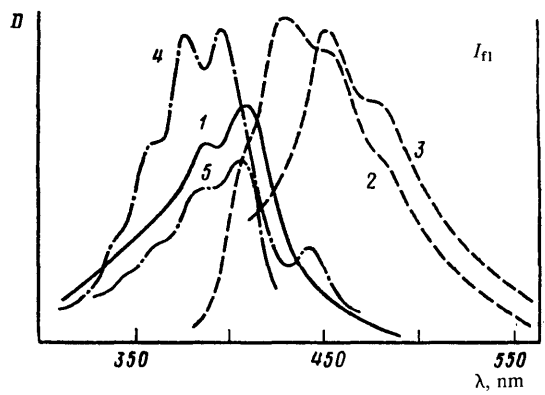

Figure 10. Electronic spectra of a solution of the polymer (XLI) in dimethylformamide: *1*) absorption spectrum; *2*) and *3*) fluorescence spectra (λ_{exc} = 365 and 412 nm respectively); *4*) and *5*) fluorescence excitation spectra for maxima at 432 and 482 nm respectively.[75]

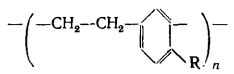
It has been shown[75] that the solid polymer (XLI) does not fluoresce, while its solutions in DMF are characterised by an intense fluorescence. Fig.10 presents the absorption and fluorescence spectra of solutions of the polymer (XLI)

as well as the fluorescence excitation spectra for λ_{max} = 432 and 482 nm. The dependence of the type of the emission spectrum of the solution on the wavelength of the exciting light indicates the presence of two luminescence centres, which is confirmed by the parameters of the fluorescence excitation spectra. It has been suggested[75] that a short-wavelength luminescence centre with λ_{max} = 432 nm is typical of the polymer (XLI). The long-wavelength luminescence centre with λ_{max} = 482 nm is apparently associated either with the presence in the test solution of polymeric associated species or with the presence of low-molecular-weight admixtures of the type of dianthrylethylene derivatives.[4]

The absence of an appreciable fluorescence of the solid phase can also be explained by the admixture of dianthrylethylenes. A characteristic feature of the molecular structure of dianthrylethylene is that they consist of open chains in which there is steric hindrance to the conjugation of π-electron systems or "overlap zones".[78] The presence of such zones significantly diminishes the intensity of the fluorescence of certain dianthrylethylenes compared with the other anthracene derivatives.

Polymers with two methylene groups between the benzene rings in compound (XLII) have been investigated by absorption and luminescence spectroscopy:[76,77]



(XLII)

They have been synthesised by the reaction of 1,2-dichloroethane with substituted benzenes in the presence of $AlCl_3$ as the catalyst.[79] It has been observed that, together with the band at 260 nm corresponding to the π–π* electronic transition in the benzene ring, the absorption spectra also contain bands in the range 300–400 nm, reflecting the vibronic interaction between the ring and the substituent, as well as the bands in the range 450–500 nm due to intermolecular interaction. It has been observed[76] that the intensity of the π–π* transition in these polymers is determined by the excitation vector, whose magnitude depends on the nature of the substituent R.

Summarising the data on the electronic and vibrational absorption spectra of polyarylenealkyls,[80] the author concludes that, as a consequence of intramolecular and intermolecular interactions, a many-centre type of bond arises in the polymers (XLII). According to the existing ideas,[81] the interpretation of the observed EPR absorption signal in these polymers cannot be accepted as correct and the EPR signal is apparently due to the presence of paramagnetic impurities in the polymer. In view of the foregoing, the author's conclusion[76] that the structure of the polymers (XLII) is intermediate between the conjugated and non-conjugated types also appears to be incorrect.

Kozyreva's study[77] was devoted to the observation of the low-temperature luminescence of the polymers (XLII) in the solid phase and in solutions. The phosphorescence of these compounds has been noted, the decrease of the luminescence intensity during the first instants after the removal of the light source being described by a relation of the hyperbolic and then exponential type. On the basis of data which in our view require revision, the author[77] classifies the polymers (XLII) as crystalline phosphors in terms of the type of their luminescence and suggests that they exist in the liquid crystal state at low temperatures.

Thus the observed spectroscopic properties of polyarylenealkyls are as yet not entirely reliable and require revision. Overall, one should note that the available literature data for the luminescence-spectroscopic properties of carbochain aromatic polymers are fragmentary and require further investigations.

2. Heterochain Aromatic Polymers

The optical properties of heterochain aromatic polymers have been studied in greater detail than the properties of the carbochain polymers. There are literature data obtained in investigations of the luminescence-spectroscopic characteristics of aromatic polyethers,[82] poly-Schiff bases,[83–85] polyamides,[86–89] and polyureas.[86,90]

The study of polyoxy-(2,6-dimethyl)-1,4-phenylene by luminescence spectroscopy showed[82] that it exhibits an intrinsic fluorescence in the form of solutions and films in the ultraviolet region (λ_{max} = 320 nm) and an impurity luminescence in the visible part of the spectrum (λ_{max} = 550 nm), the intensity of the latter diminishing on photolysis of the polymer.

The luminescence-spectroscopic properties of poly-Schiff bases and of model compounds have been investigated by D'Alelio et al[83] and by Vasilenko and co-workers.[84,85] In their studies of the absorption and fluorescence spectra of arylazomethines, Vasilenko and co-workers[84,85] observed that protonation imparts to their molecules a planar configuration and hence diminishes the probability of the radiationless deactivation of the S_1 state. It has been shown[91,92] that the fluorescence process in the free bases of arylazomethines is suppressed by the radiationless internal conversion, whose rate constant has been estimated as 10^{12} s^{-1} for *N*-benzylideneaniline. After comparing the absorption spectra of the hydrocarbon and sulphuric acid solutions of *N*-benzylideneaniline, Vasilenko and co-workers[84,85] concluded that in the protonated form of this molecule the π-electrons are strongly bound and are excluded from the π-electron system of the arylazomethine, as a consequence of which the long-wavelength band in the spectrum of the acid solution undergoes a 25 nm bathochromic shift.

Continuing their investigation of the luminescence-spectroscopic properties of arylazomethines in relation to poly-Schiff bases and a number of model compounds such as the product of the condensation of *m*-phenylenediamine with isophthalic aldehyde [compound (XLIII)] or benzaldehyde [compound (XLIV)] and also the product of the condensation of *p*-phenylenediamine with terephthalic aldehyde [compound (XLV)] or cinnamaldehyde [compound (XLVI)], Vasilenko and co-workers[84,85] observed that the characteristic features of the optical behaviour of *N*-benzylideneaniline discovered in various media persist on passing to more complex systems (Fig.11*a*). Evidently in the case of the solution in sulphuric acid the absorption spectra of the polymer (XLIII) and the model (XLIV) are similar (λ_{max} = 340 nm for the long-wavelength band), whereas for the solution of compound (XLIV) in a non-polar solvent (cyclohexane) λ_{max} = 330 nm.[85] Consequently both the polymers and low-molecular-weight bis(arylazomethine) derivatives are protonated at the nitrogen atoms in sulphuric acid, like *N*-benzylideneaniline, which activates the fluorescence of the test systems.

Fig.11*a* shows that the fluorescence spectra of compounds (XLIII) and (XLIV) are similar and have a resolved vibrational structure with 1300–1000 cm^{-1} gaps between the bands. Analogous conclusions can be reached from the analysis of the absorption and low-temperature fluorescence spectra of the polymer (XLV) and the model (XLVI) (Fig.11*b*). Comparison of the spectra in Figs.11*a* and 11*b* shows that, on passing from the *m*-isomers of the polymeric and model arylazomethines to the *p*-isomers, the long-wavelength

absorption band and all the bands in the fluorescence spectrum are seen to undergo a bathochromic shift; the luminescence intensity of the powdered polymer specimens increases in the same sequence.

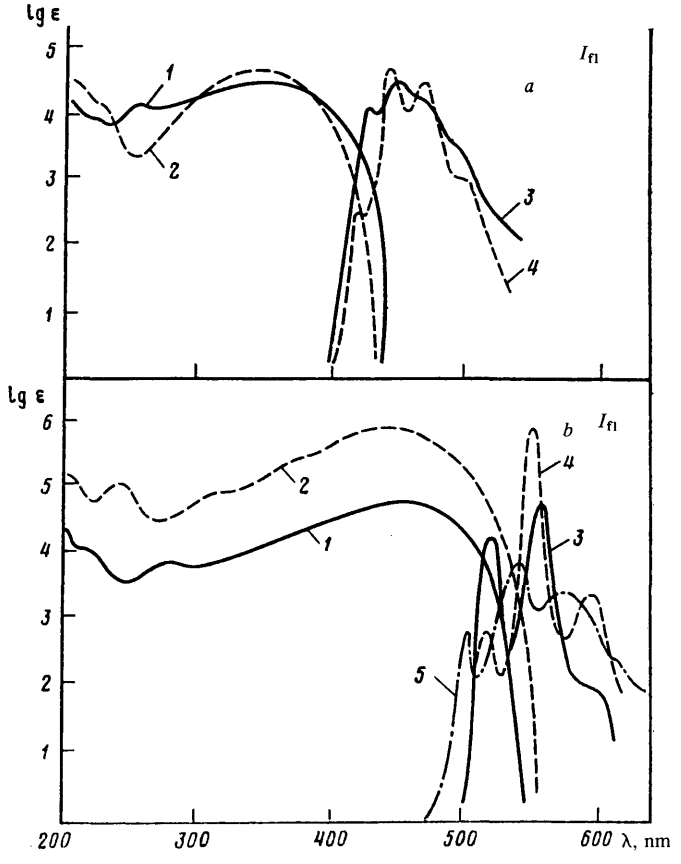


Figure 11. *a*) Absorption spectra at 20 °C (curves *1* and *2*) and fluorescence spectra at −196 °C (curves *3* and *4*) of solutions of the polymer (XLIII) (curves *1* and *3*) and the model (XLIV) (curves *2* and *4*) in concentrated H_2SO_4; *b*) absorption spectra at 20 °C (curves *1* and *2*) and fluorescence spectra at −196 °C (curves *3* and *4*) of solutions of the polymer (XLV) (curves *1* and *3*) and the model (XLVI) (curves *2* and *4*) in H_2SO_4 and the fluorescence spectrum of a powder of the polymer (XLV) at −196 °C (curve *5*).[85]

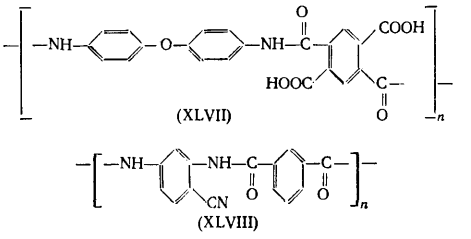
It is known[93] that the poly-Schiff bases derived from benzil and *p*-phenylenediamine have a resistivity of ~10^{12} Ω cm in the dark and an activation energy for conduction in the range 0.1–0.3 eV. In our view, one of the urgent problems, which have been only partly solved for the low-molecular-weight photoconductors,[94] is the establishment of a correlation between the fluorescence and photoconductivity of the polymer systems.

We shall consider the luminescence properties of aromatic polyamides. It is usually suggested[95] that unsubstituted polyamides of the type of poly-*m*-phenyleneisophthalamide exhibit a blue fluorescence with λ_{max} = 445 nm, caused by the presence of impurities in the polymer. When certain substituents are introduced into the aromatic rings of the polyamides, an intrinsic fluorescence appears. Thus a film of the polyamidoacid (XLVII) fluoresces with λ_{max} = 470 nm, while the polycyanamide (XLVIII) fluoresces with λ_{max} = 425 nm:[96,97]



The first studies on the optical properties of phosphor-containing aromatic polyamides and polyureas date back to the middle 1970's.[86,87,90] The polarised fluorescence of the polyamidoacid (XLIX), containing a luminescent label in the main polymer chain, has been investigated.[87] Unfortunately the authors do not quote data concerning the nature and types of binding of the phosphor fragments in the chain.[87] It is only stated that each label is enclosed between flexible hinged C–O–C junctions and that there is one label for each 300 amidoacid units. The data for solutions of the polymer (XLIX) in DMF and in DMF–glycerol mixtures revealed a linear relation between the reciprocal of the polarisation of the luminescence and T/η, where T is the temperature and η the viscosity of the solvent.

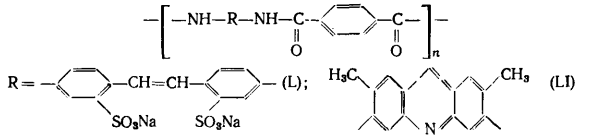
Having calculated the diffusion parameters, the authors[87] concluded that the macromolecules of the polymer (XLIX) exhibit an appreciable kinetic flexibility compared with carbochain polymers. It has been shown that the main inhibiting factor in the kinetically flexible chain of the polyamidoacid is the external viscous friction of the units against solvent molecules.

The synthesis and fluorescence properties of aromatic polyamides and polyureas with three types of phosphor fragments in the chain have been described.[86,90] The polymers were obtained by the interfacial polycondensation of Acridine Yellow, thionine, or the sodium salt of 4,4′-diaminostilbene-2,2′-disulphonic acid with acid dichlorides such as terephthaloyl chloride and sebacyl chloride or with 2,4-tolylene di-isocyanate.

Apart from the synthesis of fluorescent polymers and the comparison of their optical properties with those of the initial phosphor diamines, the authors[86] were also interested in the polyelectrolyte character of all the polyamides and polyureas investigated. The polymers synthesised do not melt up to 300 °C and are soluble in water (polymers with stilbene units in the chain) or in *NN*-dimethylacetamide and DMF (polymers with acridine and thionine units).

A detailed study of the fluorescence properties of the polymer solutions showed that the positions of the maxima in their fluorescence spectra and their fluorescence intensity depend significantly on the concentration of the solution. Thus, for the polymers with stilbene and acridine units, the maximum in the fluorescence spectrum undergoes an appreciable hypsochromic shift (by 20–40 nm depending on the type of polymer) and the concentration of the polymer in solution diminishes from 10^{-3} to 10^{-7} M (calculated in terms of the concentration of phosphor groups). The fluorescence intensity diminishes in the same sequence by a factor of 10–25 for the stilbene-containing polymers and by a factor of 150–300 for the acridine-containing polymers.

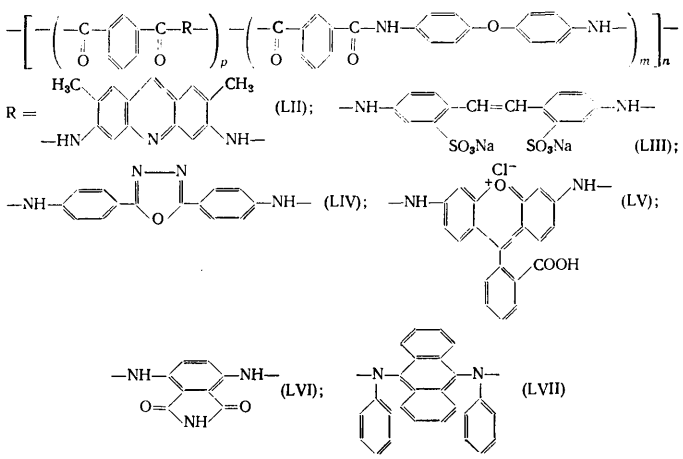
Comparison of the fluorescence characteristics of the initial phosphors and the corresponding polymers showed that the position of the maximum in the fluorescence spectra is determined by the type of polymer. For example, whereas the sodium salt of 4,4'-diaminostilbene-2,2'-disulphonic acid luminesces with λ_{max} = 444 nm in aqueous solution at a concentration of 10^{-4} M, polyureas luminesce with λ_{max} = 440 nm at the same concentration of phosphor groups, while the emission from the dissolved polyamide based on terephthaloyl chloride (L) is at 504 nm:



The authors believe[86] that the appreciable bathochromic shift of the fluorescence band in the spectrum of the last polymer relative to the initial diamine is associated with the increased length of the conjugation chain in it. To a lesser extent, this effect is manifested in acridine-containing polymers: a band with λ_{max} = 510 nm is characteristic of the fluorescence spectra of solutions of the polyamide (LI) based on terephthaloyl chloride (compared with λ_{max} = 500 nm for solutions of Acridine Yellow).

An interesting result of the study of Uno and Kondo[86] is data showing a decreased intensity of the fluorescence of solutions of the polymers (L) and (LI) compared with the solutions of the initial phosphors under ultraviolet irradiation. It was observed that, after irradiation for 1.5 h, the intensity of the fluorescence of solutions of the sodium salt of 4,4'-diaminostilbene-2,2'-disulphonic acid falls by 56.0%, while that of solutions of the corresponding polyamide (L) falls by only 26.7%. For Acridine Yellow and the polyamide (LI), the corresponding figures are 18.4% and 6.5% respectively. The authors[86] correctly attribute the lower photoconductivity of solutions of the stilbene monomer compared with the polymer (L) to the effective *cis–trans* photoisomerisation of the former compound under irradiation conditions. The complete lack of data concerning the absorption and fluorescence spectra of the polymer specimens in the form of films is one of the disadvantages of the study by Uno and Kondo.[86]

Polyamides with a structure similar to that of the polymers described above, containing acridine [polymer (LII)], stilbene [polymer (LIII)], and diphenyloxadiazole [polymer (LIV)] units in the chain have been obtained by the present author and his co-workers:[88,89]



The proposed method of synthesis involving the polycondensation in solution of a mixture of di(aminophenyl) ether and the phosphor diamine with isophthaloyl chloride made it possible to obtain polymers with a fairly high molecular weight, in contrast to interfacial polycondensation.[86,90] Furthermore it permitted the variation of the content of the phosphor groups in the chain within broad limits by altering the ratio of the initial diamines.

The real content of the chromophoric groups in the polyamides (LII) and (LIV) was determined spectrophotometrically—from the intensities of the absorption bands with maxima at 468, 360, and 342 nm respectively.[89] It was found that the experimental concentration of the chromophoric groups is several times lower than expected on the basis of the molar ratios of the diamines used for the polycondensation. The evident cause of this discrepancy is the low reactivity of the initial phosphor diamines, as a result of which a considerable proportion of the latter fail to react.

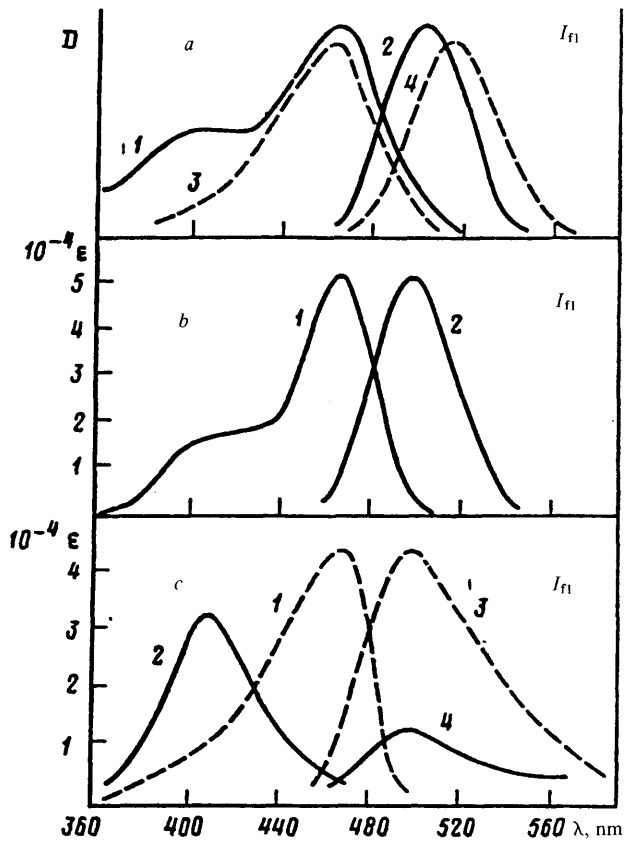


Figure 12. Absorption and fluorescence spectra of acridine-containing compounds: *a*) absorption (curves *1* and *3*) and fluorescence (curves *2* and *4*) spectra of a solution of the polyamide (LII) ($p:m$ = 1:110) in *N*-methylpyrrolidinone (curves *1* and *2*) and in the form of a film (curves *3* and *4*); *b*) absorption (curve *1*) and fluorescence (curve *2*) spectra of a solution of the polymer (LVIII) in *N*-methylpyrrolidinone; *c*) absorption (curves *1* and *2*) and fluorescence (curves *3* and *4*) spectra of solutions of Acridine Yellow in ethanol (curves *1* and *3*) and dimethylformamide (curves *2* and *4*).[89]

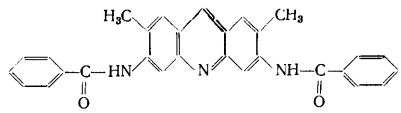
Fig.12*a* presents the absorption and fluorescence spectra of the polyamide (LII), with acridine units in the chain, in the form of a film and a solution in *N*-methylpyrrolidinone. The absorption and fluorescence spectra of the model diamide (LVIII) were studied simultaneously (Fig.12*b*).



(LVIII)

It follows from Fig.12 that the long-wavelength absorption and fluorescence bands of the polymer are similar to the corresponding bands of the model compound (LVIII). These data serve as an adequate basis for the assignment of the observed absorption and emission bands of the test polymer to the acridine unit.

The band with the maximum at 410 nm in the absorption spectra of solutions of the polyamide (LII) with acridine units must be attributed to the interchain association of these units. It is known[98] that acridine dyes such as Acridine Yellow tend to self-associate in solutions and the tendency is determined by the nature of the solvent. Thus it has been found that in solutions in DMF the compound is present mainly in the form of associated species characterised by an absorption maximum at 410 nm (Fig.12*b*). In the course of measurements of the absorption spectra of polyamides with different contents of Acridine Yellow fragments, it was found that a decrease in their concentration reduces the optical density ratio D_{410}/D_{465}. Spectroscopic studies of the absorption and fluorescence of solutions and films of polyamides modified by stilbene and diphenyloxadiazole units yielded analogous results.

It follows from data for the fluorescence of polyamide films that the intensity of their emission falls appreciably with increased content of the phosphor groups in the chain, which may be due to both the association of these groups and to the manifestation of the concentration-induced quenching of the fluorescence.[89]

The question of the influence of the phosphor groups in the polyamide chains on the resistance of the latter to ultraviolet irradiation is of independent interest. It is known[99] that the addition of organic phosphors increases in many instances the resistance of polymers to the action of light. After irradiation of polymer films with the unfiltered light of a DRSh-500 lamp for 2 h, it was found that the values of η_{log} for solutions of the polyamides (LII), (LIII), and (LIV) are 74, 85, and 35% respectively relative to the initial value of η_{log}.[89] After the photoageing under the same conditions of a polyamide having an analogous structure but without phosphor groups, η_{log} was found to amount to 61% of the initial value.

It is seen from the data presented that the introduction of acridine and stilbene units increases the photostability of polyamides, while the introduction of diphenyloxadiazole fragments reduces it. A possible explanation of the protective effect of the phosphor fragments may be the fact that the excitation energy of the macromolecules is transferred to these fragments, which have low-lying S_1 levels, and is emitted in the form of the $S_1 \rightarrow S_0$ fluorescence. This protective mechanism may not operate in the diphenyloxadiazole-containing polyamide, where the S_1 levels are too high.

The present author and his co-workers[88,89] synthesised also a whole series of film-forming aromatic polyamides with rhodamine [compound (LV)], 3,6-diaminophthalimide [compound (LVI)], and 9,10-dianilinoanthracene [compound (LVII)] phosphor units, present in the residue of the diamine component, or the 9,10-diphenylanthracene-*pp'*-dicarboxylic acid (LIX) units in the acid component. Most of the features found in the variation of the properties of the polyamides (LII) and (LIII), for example, the increase of η_{log} with decreased content of the phosphor fragments in the chain or the weakening of the fluorescence intensity of the films with increased concentration of these fragments, are also observed with the polyamides (LIV)–(LVII) and (LIX).

As an example, Fig.13 presents the absorption and fluorescence spectra of solutions and films of the polyamides (LVII) and (LIX) and also solutions of the corresponding monomers—9,10-dianilinoanthracene and 9,10-diphenylanthracene-*pp'*-dicarboxylic acid. It follows from the results of the study of the luminescence-spectroscopic properties of these compounds and also the polyamides (LV) and (LVI) and the corresponding monomers that the chromophoric fragments are responsible for the fluorescence and long-wavelength absorption of the polymers (LV)–(LVII) and (LIX).

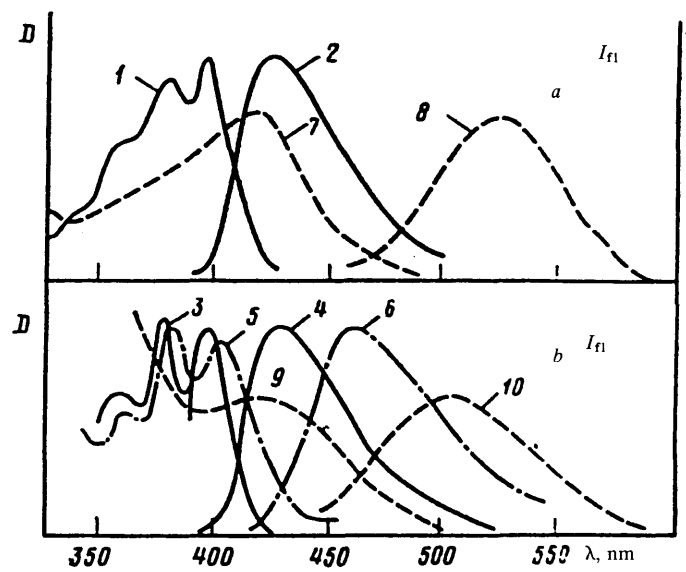


Figure 13. *a*) Absorption (curves *1* and *7*) and emission (curves *2* and *8*) spectra of solutions of 9,10-diphenylanthracene-*pp'*-dicarboxylic acid (curves *1* and *2*) and 9,10-dianilinoanthracene (curves *7* and *8*) in dimethylacetamide; *b*) absorption (curves *3*, *5*, and *9*) and emission (curves *4*, *6*, and *10*) spectra of a film of the polyamide (LIX) (curves *5* and *6*) and solutions in dimethylacetamide of the polyamides (LIX) (curves *3* and *4*) and (LVII) (curves *9* and *10*); for the polyamide (LVII), $p:m = 1:10$.[88]

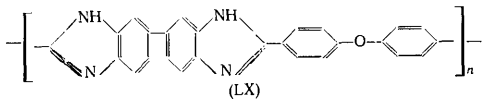
Certain representatives of the polyamides (LII)–(LIX), capable of forming transparent intensely fluorescent films, are promising as scintillating materials suitable for recording of the tracks of α- and β-particles and neutrons and for X-ray dosimetry.[4]

3. Polyheteroarylenes

Aromatic polymers with a heterocyclic fragment in the chain, which possess very effective mechanical and dielectric properties and a high thermal stability, belong to the class of polymers which have been least investigated from the standpoint of their light absorption and fluorescence properties. There have been only a few studies of the spectroscopic properties of polybenzimidazoles,[100] polybenzoxazoles,[101,102] polyimides,[96,103,104] polyhexazocyclanes,[105] and polymeric bipyridylium salts.[106]

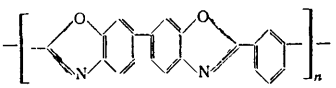
It has been stated in a report[100] that solutions of the polybenzimidazole (LX) in *NN*-dimethylacetamide and formic acid fluoresce in the blue part of the spectrum.



(LX)

The spectroscopic properties of the polymer (LX) were compared with those of the model bis-*p*-(2-benzimidazolyl)-phenyl ether (Fig.14). It was found that the fluorescence of the model is determined by the radiative transitions from the 0–0, 0–1, and 0–2 vibrational levels of the excited ^1L_b state of the benzimidazole ring, while the fluorescence spectrum of the polymer (LX) has a vibrational structure; λ_{max} = 394 and 413 nm. In addition to the monomer luminescence band, the emission spectra of solutions of the polymer (LX) and of the model compound in formic acid contain a longer-wavelength band at 460 nm associated with the fluorescence of the intermolecular associated species, which undergoes a bathochromic shift with increase in the concentration of the solution.

The available information in the literature about the fluorescence properties of polybenzoxazoles is even more scanty. Thus an intense green fluorescence of films of the polymer (LXI) with λ_{max} = 490 and 520 nm has been mentioned;[101,102] the authors confined themselves to the measurement of the emission spectrum without attempting to account for its origin.



(LXI)

The possibility of the fluorescence of aromatic polyimides of different structure has been discussed by the present author and his co-workers.[96,103,104] They showed that, regardless of the presence of phosphor fragments in the chain, the quenching of the fluorescence associated with the nature of the diimide unit is observed in polypyromellitimides. In the study of the spectroscopic characteristics of the model compound *NN'*-dimethylpyromellitimide (LXII) it was observed[96] that this product does not fluoresce at room temperature (in solution) and exhibits an intense phosphorescence at −196°. The absorption and phosphorescence spectroscopic data suggested a scheme for the arrangement of the energy levels in the molecule of (LXII), the characteristic details of which are a low-lying $T_{\pi\pi^*}$ level (20000 cm^{-1}) and the fact that the energy of the $S_{n\pi^*}$ state is intermediate between those of the $S_{\pi\pi^*}$ and $T_{\pi\pi^*}$ states. It is known[69] that molecules with this arrangement of levels do not fluoresce. The quenching of their fluorescence is associated with the probability of a radiationless intersystem crossing from the $S_{n\pi^*}$ level to the $T_{\pi\pi^*}$ level.

The energies of the $S_{n\pi^*}$ and $T_{n\pi^*}$ levels of compound (LXII) can increase on protonation of the pyromellitimide ring. Indeed, it has been shown[96] that in solution in concentrated sulphuric acid the intersystem crossing process becomes unlikely as a consequence of the increase in the energy of the $S_{n\pi^*}$ state, which has been confirmed by the appearance of an intense green fluorescence of compound (LXII) under these conditions.

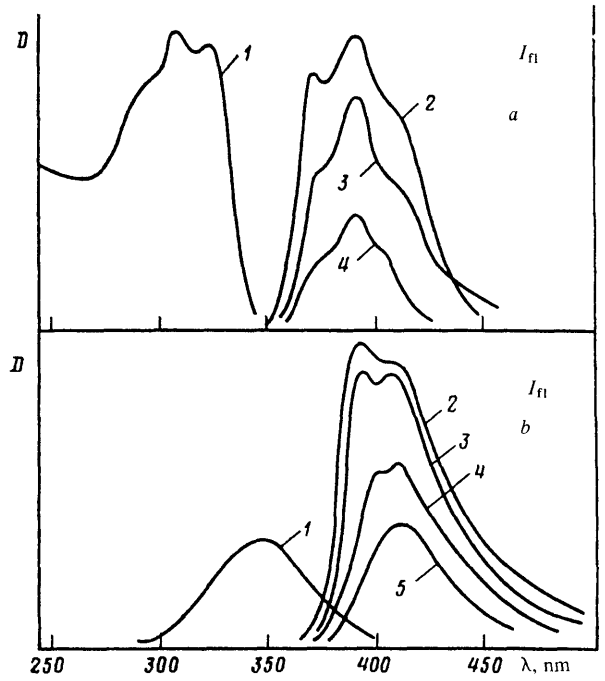


Figure 14. a) Absorption (curve *1*) and fluorescence (curves *2–4*) spectra of solutions of bis-*p*-(2-benzimidazolyl)-phenyl ether in dimethylacetamide at concentrations of 7.9 × 10^{-4} g ml^{-1} (curve *2*), 3.2 × 10^{-3} g ml^{-1} (curve *3*), and 6.3 × 10^{-3} g ml^{-1} (curve *4*); b) absorption (curve *1*) and fluorescence (curves *2–5*) spectra of solutions of the polymer (LX) in dimethylacetamide at concentrations of 4.6 × 10^{-6} g ml^{-1} (curve *2*), 1.5 × 10^{-4} g ml^{-1} (curve *3*), 4.3 × 10^{-4} g ml^{-1} (curve *4*), and 5.2 × 10^{-3} g ml^{-1} (curve *5*).[100]

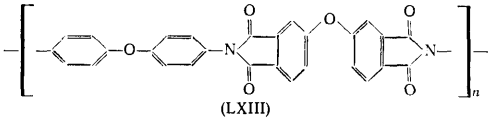
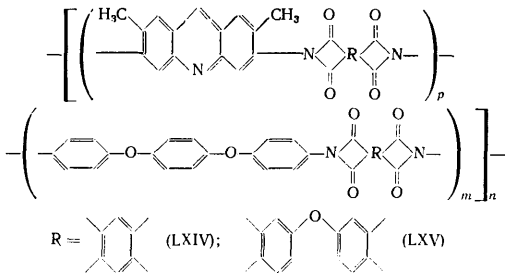
Thus the quenching of the fluorescence in polypyromellitimides is due to the presence of low-lying $n\pi^*$ levels. The appearance of fluorescence in aromatic polyimides requires that a diimide component with higher $S_{n\pi^*}$ and $T_{n\pi^*}$ levels be introduced into their composition. For example, the polyimides based on the dianhydride of oxydi(benzene-3,4-dicarboxylic acid) such as the polymer (LXIII) exhibit an appreciable blue fluorescence:[103]



(LXIII)

A comparative study of the spectroscopic properties of the polypyromellitimides (LXIV) and the polyimides (LXV) with acridine fragments in the chain has been carried out.[104]

The polymers were synthesised by the low-temperature polycondensation of a mixture of Acridine Yellow and the di(4-aminophenyl) ether of hydroquinone with the dianhydrides of the corresponding tetracarboxylic acids with subsequent thermal polycyclodehydration of the prepolymer films:



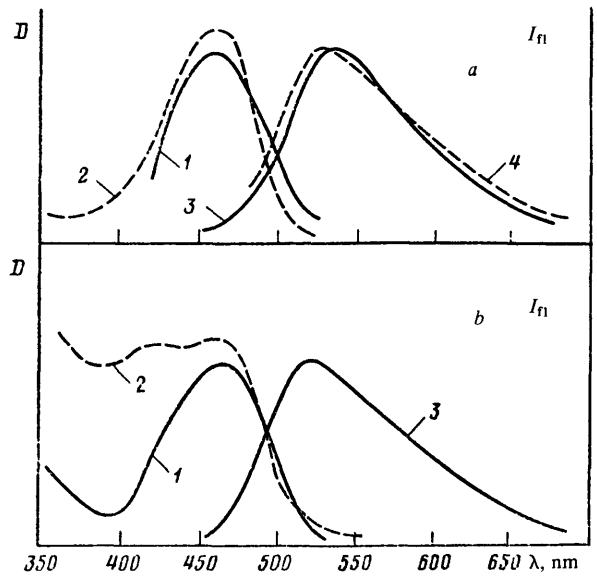


Figure 15. *a*) Absorption (curves *1* and *2*) and emission (curves *3* and *4*) spectra of films of the prepolymer for the polyimide (LXV) (curves *1* and *3*) and the prepolymer for the polyimide (LXIV) (curves *2* and *4*); *b*) absorption (curves *1* and *2*) and emission (curve *3*) spectra of films of the polyimides (LXV) (curves *1* and *3*) and (LXIV) (curve *2*); in all cases $p:m = 1:3$.[104]

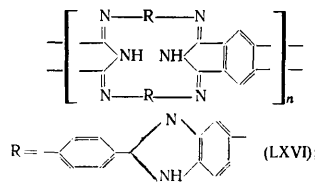
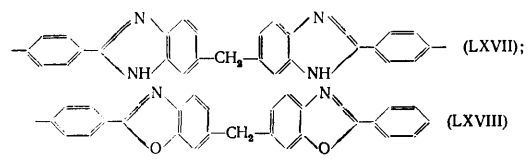
Acridine-containing polyamidoacids showed an intense green fluorescence with λ_{max} = 500 nm in solutions and a yellow-green fluorescence with λ_{max} = 530–540 nm in films (Fig.15*a*). Fig.15, which presents the absorption and emission spectra of films of the polyimides (LXIV) and (LXV) as well as the corresponding polyamidoacids, shows that the nature of the dianhydride component has little influence on the spectroscopic properties of the prepolymers. On the other hand, the luminescence-spectroscopic characteristics of the polyimides depend strongly on the character of the diimide fragment (Fig.15*b*). Whereas the absorption spectra of the polyimide (LXV) contain only one band with λ_{max} = 460 nm, in the spectra of the polyimide (LXIV) an absorption band with a maximum at 415 nm, associated with the aggregation of the acridine fragments, appears. Regardless of the ratio $p:m$, all the polyimides (LXV) showed an intense fluorescence with λ_{max} = 515–525 nm, whereas the polyimides (LXIV) did not fluoresce.[104]

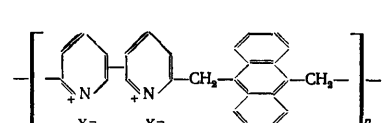
The aim of the synthesis of the acridine-containing polyimide (LXV) as well as other polyheteroarylenes–polyhexazocyclanes (LXVI)–(LXVIII), described by the present author and his co-workers,[105] was the preparation of polymeric phosphors with yellow and orange luminescence, which are of interest for the preparation of scintillating materials:[108]





The polymers (LXVI)–(LXVIII) were synthesised by the polycondensation of pyromellitonitrile with diamines of the phenylbenzimidazole and phenylbenzoxazole series in phenol. It was found that the absorption and fluorescence spectra of these polymers as well as the model hexazocyclanes of analogous structure contain bands in the ultraviolet region associated with the electronic transitions in the phenylbenzimidazole and phenylbenzoxazole fragments; in addition, the fluorescence spectra contain longer-wavelength bands at 540–650 nm associated with charge transfer from the electron-donating chromophoric fragment to the electron-accepting isoindole fragment.

In conclusion we shall consider the absorption and fluorescence properties of polymeric bipyridylium salts (polyviologens) (LXIX), obtained[106] by the Menshutkin reaction of 2,2'- or 4,4'-bipyridyl with 9,10-dihalogenmethylanthracenes in methanol, DMF, or dimethyl sulphoxide at 30–70 °C. The solubility in water and intense fluorescence of these polymers make it possible to use them as luminescent probes for the investigation of biological membranes:[63]



(LXIX)
X=Cl, Br .

The absorption and emission spectra of solutions of the polymers (LXIX) as well as the model (9-methyl)-10-anthrylmethylpyridinium halides (LXX) and the initial 9,10-dihalogenomethylanthracenes (Fig.16) have been investigated. It was found that the absorption spectra of the corresponding chloro- and bromo-compounds have a resolved structure typical for anthracene derivatives; the absorption spectra are fairly close to one another as regards the shape of the bands and their relative positions. On the other hand, appreciable differences were noted in the fluorescence

properties of the monomers, the model compound (LXX), and the polymers (LXIX). Thus, whereas 9,10-dichloromethylanthracene and the corresponding model compound exhibit a weak fluorescence in the crystalline form and in solution, the polyviologens show a bright fluorescence both in the solid state and in solution. Furthermore, 9,10-dibromomethylanthracene and the corresponding model compound do not fluoresce at all either in the solid state or in solution at room temperature, while the bromine-containing polyviologen (LXIX, X = Br) exhibits an intense fluorescence under these conditions.

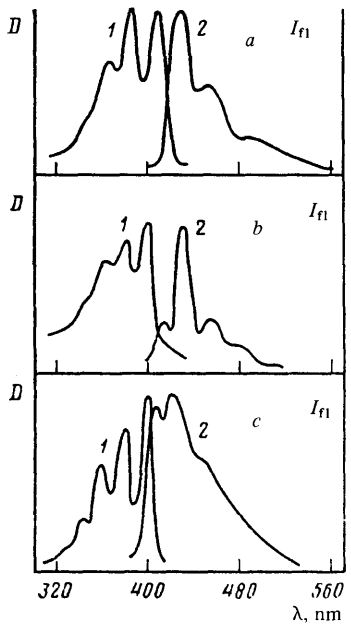


Figure 16. Absorption (curve *1*) and fluorescence (curve *2*) spectra of solutions in dimethylformamide: *a*) of 9,10-dichloromethylanthracene; *b*) of the model compound (LXX, X = Cl); *c*) the polyviologen (LXIX, X = Cl).[106]

The present author and his co-workers[106] suggested as an explanation of the observed differences that in dichloromethylanthracene and especially in dibromomethylanthracene the probability of the radiationless transitions from the S_1 to the T_1 level increases as a consequence of the strong spin–orbital interaction and such transitions are responsible for the quenching of the fluorescence. Halide ions have been detected in polymers in the vicinity of the nitrogen atoms of the bipyridyl residues, which tends to increase the number of vibrational degrees of freedom, reduces the probability of radiationless transitions, and thereby increases the fluorescence quantum yield. The differences between the emission spectra of the polymers (LXIX) and the corresponding model compounds (LXX) are apparently associated with the fact that the bipyridylium salts,[107] which do not contain anthracene fragments, have fluorescence spectra with a set of intense bands in the range 400–450 nm, in contrast to pyridinium salts.

Thus the examples examined above show that, among heterocyclic aromatic polymers, the luminescence-spectroscopic properties have been more or less investigated only for polyimides. The properties of other polyheteroarylenes have been either very little investigated (polybenzimidazoles, polybenzoxazoles, and polyhexazocyclanes) or not at all (polyoxadiazoles, polyquinoxalines, polyquinazolinones, and a whole series of other polymers). At the same time the study of the fluorescence characteristics of these polymers is of undoubted interest, since it is known[4] that many of their low-molecular-weight analogues exhibit an intense fluorescence.

---o0o---

Summarising the available information about the fluorescence characteristics of condensation polymers, one may conclude that the introduction of phosphor fragments into the composition of the macromolecules can lead to the preparation of materials with an intense luminescence and in many cases with a high photostability and photosensitivity. The specific synthesis of such polymers, which have a high fluorescence quantum yield in the required spectral range, makes it possible to create promising materials for the needs of scintillation and laser technology, for the preparation of migration-resistant luminescent varnishes and dyes, and for medical and biological research. The study of the behaviour of polymers with fluorescent labels in the chain by optical molecular spectroscopic methods enables us to obtain new information, which is either totally unobtainable or obtainable with difficulty by other procedures, about the dynamic mobility of macromolecules in the solution, about the conformational structure of polymers, etc.

Functional Derivatives of Polyisobutene

Yu.A.Sangalov and Yu.B.Yasman

The methods of synthesis of isobutene polymers with end groups of different types are examined. It is shown that advances in the synthesis of these compounds are associated with the progress in the field of the regulation of the cationic polymerisation and copolymerisation of isobutene and the degradation of isobutene polymers and copolymers. Examples of the employment of functional derivatives of isobutene polymers in various branches of technology are presented. The bibliography includes 102 references.

I. INTRODUCTION

Polyisobutene (PIB) and its copolymers (PIBC) together with dienes occupy an outstanding position among polyolefins as regards the volume in which they are manufactured and used. This is due to the availability of the raw materials and the valuable properties of the polymer. "Defect-free" PIB molecules exhibit a relatively high resistance to chemical and physical influences and are irreplaceable as corrosion resistant hermetic sealing compounds, additives, oils, and other materials.[1] On the other hand, the chemical inertness of PIB hinders the introduction of functional groups into the polymer chain. It is known that the introduction of such groups significantly expands the applications of hydrocarbon elastomers to which PIB also belongs.[2]

During the last 5–10 years numerous publications devoted to the synthesis of PIB with specified end groups by the cationic polymerisation of isobutene (IB), oxidative degradation of PIBC with dienes, and other procedures have appeared. The introduction of reactive groups into PIB and their subsequent reactions lead to the formation of products with polar groups, for example, with antioxidant fragments, graft and block copolymers, etc. i.e. to the variation of the properties of PIB over a wide range of molecular weights. This leads to new applications of PIB.

The aim of this review is the systematic account and a survey of the literature data concerning the method of synthesis of functional derivatives of PIB with specified end groups and new applications of the modified PIB.

II. METHODS FOR THE INTRODUCTION OF FUNCTIONAL GROUPS INTO ISOBUTENE POLYMERS DURING POLYMERISATION

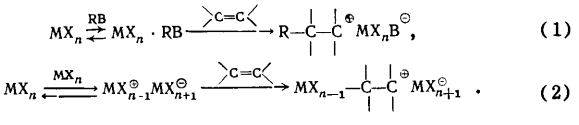
Until recently it was believed that the PIB obtained by the polymerisation of IB under the influence of acid catalysts contain mainly t-butyl and unsaturated fragments at the end of the chain.[3] However, the latest investigations of the low-temperature cationic polymerisation of IB in the presence of complex catalysts and (or) specially introduced additives indicated the possibility of forming PIB with end groups different from those indicated above.[4] Here and henceforth these products are treated as functional derivatives of PIB. In terms of their origin, the end groups in PIB can be divided by convention into "head" groups (formed in the polymer chain initiation and transfer stages), and "tail" groups (formed in chain termination steps). Serious obstacles to the introduction of functional groups into PIB during the cationic polymerisation of IB arise from the high reactivity of the intermediate carbonium ions, the high fluidity, and the difficulty of controlling the PIB formation processes. The short lifetime of the carbonium ion centres rules out the possibility of polymerisation via the "living chain" mechanism,[5] which is the traditional method for the introduction of tail functional groups into polymers based on anionically active monomers.[6,7]

The synthesis of PIB with specified end groups was a consequence of a deeper understanding of the mechanism of the cationic polymerisation of IB and, in particular, of the chemistry of the chain initiation and termination reactions, as well as the application of modern methods for the quantitative analysis of polymers.

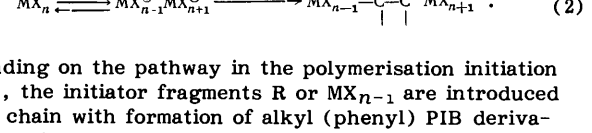
In contrast to Brønsted acids, which lead to the formation of low-molecular-weight products alone[3] and carboxylate salts which are relatively inactive in polymerisation,[4] Lewis acids and complexes based on them show a high reactivity in the polymerisation of IB, creating difficulties in the regulation of the process as a whole and of its individual elementary stages.

When strong Lewis acids (MX_n) are used as the catalyst, their interaction with the monomers and additives (the cocatalyst RB) determines the different initiation pathways and hence also the nature of the head groups (Scheme 1).

Scheme 1



(1)



(2)

Depending on the pathway in the polymerisation initiation reaction, the initiator fragments R or MX_{n-1} are introduced into the chain with formation of alkyl (phenyl) PIB derivatives [reaction (1)] or polymeric organometallic compounds [reaction (2)] respectively. The predominance of a particular reaction pathway depends on the nature of the Lewis acid, the cocatalyst, their concentrations, and the polymerisation conditions.[4] As a rule, these reactions occur under conditions which absolutely rule out the presence of traces of proton-donating compounds in the system. However, such purity has been achieved only in isolated studies using

special vacuum apparatus and the most sophisticated experimental techniques.[4,8,9] In the polymerisation of IB in the presence of traditional catalysts ($AlCl_3$ and BF_3 containing admixtures of proton donors HB) the head t-butyl groups are formed both in the initiation of the process by protons [reaction (1)] and in the chain transfer to the monomer [reaction (2)] while the tail C–C bonds arise only in the chain termination by reactions (3) (Scheme 2).

Scheme 2

$$HB + MX_n + C_4H_8 \rightarrow \quad t\text{-}C_4H_9^{\oplus}MX_nB^{\ominus}, \qquad (1)$$

$$t\text{-}C_4H_9^{\oplus}MX_nB^{\ominus} + nC_4H_8 \rightarrow \quad t\text{-}C_4H_9(C_4H_8)_n^{\oplus}MX_nB^{\ominus}, \qquad (2)$$

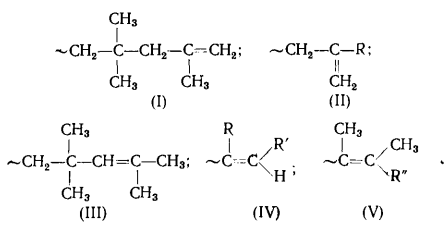
$$t\text{-}C_4H_9(C_4H_8)_n^{\oplus}MX_nB^{\ominus} + C_4H_8 \rightarrow \quad t\text{-}C_4H_9(C_4H_8)_kC_4H_7 + \quad t\text{-}C_4H_9^{\oplus}MX_nB^{\ominus}, \qquad (3)$$

where reactions (1), (2), and (3) are elementary initiation, propagation, and termination steps and $k = n - 1$.

Since reactions (1) and (3) take place even when aprotic cocatalysts are used (Cl_2, RCl, etc.[4]), the introduction of head groups other than t-butyl groups into PIB presents certain difficulties associated both with the elimination of the influence of proton-donating impurities and with the selection of catalytic systems or additives which prevent chain transfer to the monomer.

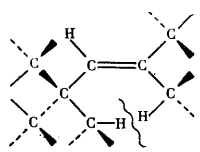
Bearing in mind the decisive contribution of the polymer chain termination reaction to the formation of head and tail groups in PIB,[9,10] it is useful to consider the characteristic features of this reaction.

A characteristic feature of the cationic polymerisation of IB in the presence of the majority of acid catalysts is intense chain transfer to the monomer [reaction (2), Scheme 2].[8] Quantitative and qualitative analysis of the end groups in PIB established that on average there is one C=C bond per macromolecule.[11,12] According to ^1H NMR data,[12] the unsaturated groups in PIB can be represented by structures (I)–(V) with structures (III) and (IV) predominating:



These results significantly supplement and correct the investigations in which mainly vinylidene C=C bonds were detected by infrared spectroscopy.[13]

The ratio of trisubstituted and vinylidene C=C bonds in IB dimerisation and trimerisation processes is probably controlled by steric factors.[9] The transition state in the formation of structure (III) is slightly compressed owing to the interaction of the hydrogen atoms of the methyl groups not linked by chemical bonds:



The two hydrogen atoms shown below this scheme tend to approach one another as soon as a double bond is formed. In contrast to this, the transition state in the formation of structure (I) is much less deformed, which compensates for the difference between the heats of formation of the olefins. When the internal stress cannot be relieved by the rotation of the interaction groups, compound (I) is formed in this case as the main product (Table 1).

Table 1. Characteristics of unsaturated PIB.

Catalyst + additive	M_n^*	Content of C=C bonds, % of theoretical		Method of determination**	Refs.
		tri-substituted	vinylidene

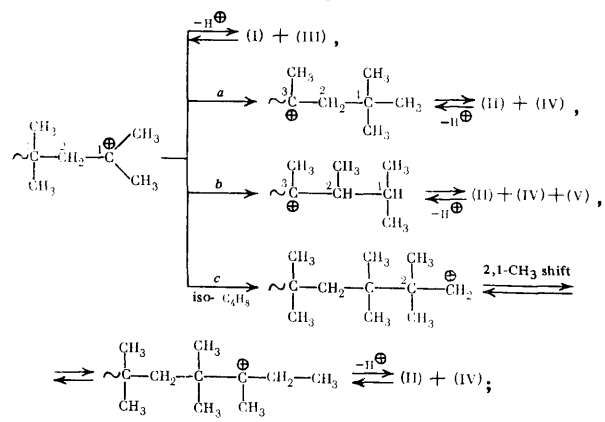
RCl–BCl_3–$CH_3CN(C_2H_5)_2$	500	0	100	1	[14]

*M_n represents the number-average molecular weights of the PIB.
**1) ^1H NMR; 2) infrared spectroscopy; 3) ozonolysis.

Depending on the polymerisation conditions and the nature of the catalysts, the ratio of the trisubstituted and vinylidene double bonds in PIB varies within wide limits.

Compounds (I) and (III), formed initially in the PIB obtained in the presence of BF_3, can probably undergo a skeletal rearrangement and isomerisation to compounds (II), (IV), and (V) (Scheme 3, *a* and *b*), which agrees with the results of studies of the model system tri-isobutylene + $AlBr_3$ + DBr.[15] The conclusion that compound (V) is formed is based on the fact that the unsaturation detected by ^1H NMR (which is insensitive to tetrasubstituted C=C bonds) is much less marked than the unsaturation measured by hydrogenation methods. The low content of vinylidene C=C bonds and the predominance of compound (IV) among the trisubstituted olefins in the PIB obtained in the presence of $AlCl_3$ are probably associated with multistage polymer chain termination. According to Puskas et al.[12] and Slobodin and Matusevich,[16] it includes the anomalous "tail to tail" addition of isobutene and the subsequent methyl shift (Scheme 3, *c*).

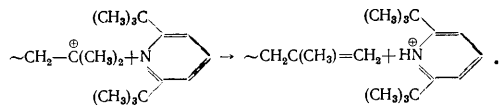
Scheme 3



a) 1,3-CH_3 shift; *b*) 1,2-H and 1,2-CH_3 shifts; *c*) anomalous "tail to tail" addition of isobutene; the symbol ~ denotes the PIB chain.

The anomalously high content of compound (I) in the PIB obtained in the presence of 2,6-di-t-butylpyridine (Table 1) is a consequence of the complete suppression of the reaction involving chain transfer to the monomer. The aromatic base then serves as a kind of trap,[17,18] which selectively abstracts a proton from the CH_3 group of the growing carbonium ion and does not interact with the sterically less accessible protons of the CH_2 groups (Scheme 4).

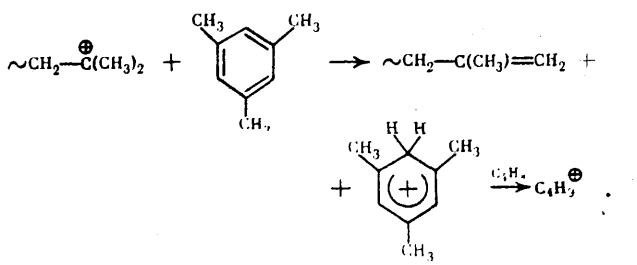
Scheme 4



Apart from its influence on the character of the terminal double bonds, 2,6-di-t-butylpyridine promotes an increase of the molecular weight of the PIB (by an order of magnitude) and a narrowing of its polydispersity (by a factor of 2–3).

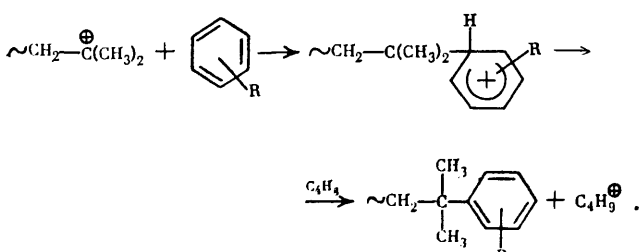
Other sterically hindered aromatic compounds such as 2,4,6-tri-t-butylphenol[19] and 1,3,5-trimethylbenzene[20] can behave in the isobutene polymerisation reaction as mediators in the chain transfer step to the monomer in accordance with Scheme 5 and can broaden the molecular weight distribution.

Scheme 5



In the polymerisation of isobutene in the presence of anisole,[21] 2-alkyl- and 2,4-dialkyl-phenols,[19,22] and certain methylbenzenes,[20] the chain transfer to the monomer is accompanied by the alkylation of the aromatic compounds by the growing carbonium ion with formation of aromatic polyisobutene compounds in accordance with Scheme 6:

Scheme 6



The molecular weight of the functional PIB derivatives is determined by the process temperature and varies from 400 to 200000. The relative contents of the unsaturated and aromatic groups in PIB depends on the ratio of the rates of the competing reactions, which is to a large extent determined by the nature of the catalyst and of the aromatic hydrocarbon (Table 2).

The relative rate constants for the transfer of the polymer chain to methylbenzenes increase with increasing basicity of the aromatic hydrocarbons in the sequence toluene < *m*-xylene < hemimellitol.[20] The presence of aromatic fragments in PIB has been demonstrated by ^1H and ^{13}C NMR and by the EPR of the phenoxy-radicals, obtained on oxidation of the polymers by PbO_2,[19] and by ultraviolet spectroscopy in combination with gel-permeation chromatography.[22] The maximum content of the aromatic end groups in the products has been obtained by polymerisation in the presence of 2,6-dialkylphenols.[19] The contribution of the alkylation reaction increases at lower temperatures and in the presence of the $SnCl_4$ catalyst it becomes dominant.

Table 2. Methods of synthesis of polyisobutene with aromatic end fragments at −78 °C.

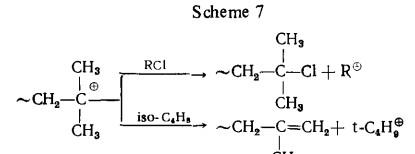
*MW = molecular weight. **Ar = aromatic fragments.
+25 °C. *−70 °C.

Another example of the use of reactions involving chain transfer to a specially introduced reagent in order to obtain a tail functional group other than an unsaturated group (suppression of chain transfer to the monomer) is provided by the polymerisation of IB in the presence of alkyl chlorides. As in the case of aromatic compounds,[20] alkyl chlorides participate in the competitive (relative to the monomer) interaction with the growing centre, leading to the formation of PIB with end fragments in accordance with Scheme 7:

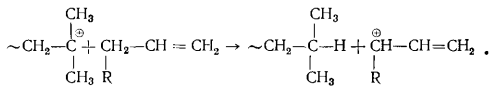
Scheme 7



The ratio of the products[24] is determined by the relative concentrations of RCl and the monomer and by the rate constants for the corresponding reactions. However, the increase in the concentration of RCl entails not only an increase in the chlorine content in the polymer with retention of a high yield of the product[25] but also a significant decrease of its molecular weight. In contrast to RCl (a pure chain transfer agent), α-olefins (chain terminating agents) do not

influence the molecular weight of the product, but significantly reduce the yield (the length of the kinetic chain) as a consequence of the allyl termination reaction[26] with formation of saturated PIB in accordance with Scheme 8:

Scheme 8



Many compounds exhibit both effects to a greater or lesser extent, the effects being quantitatively expressed in terms of empirical poisoning and chain transfer coefficients (Table 3). The knowledge of these quantities provide valuable information about the character of the polymer chain termination reaction under the influence of various additives, which determine the number, size, and nature of the end groups in the PIB molecules formed.

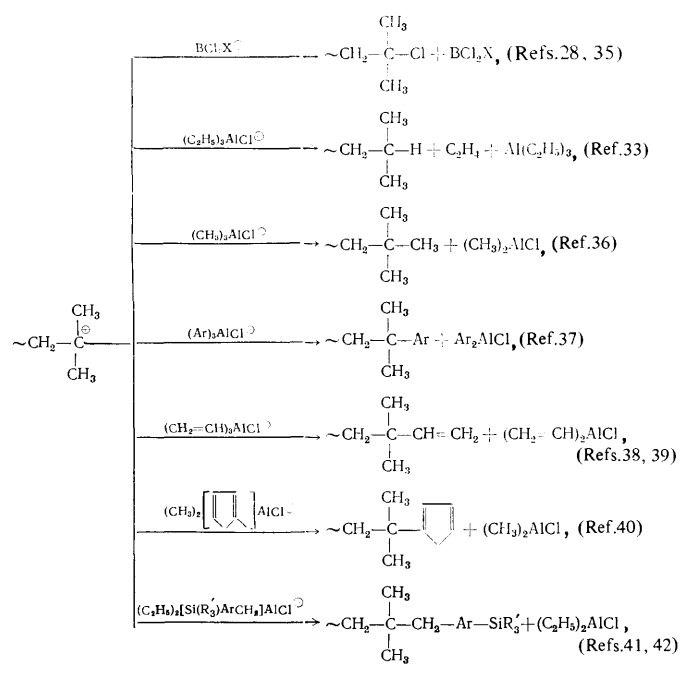
*Initiator—$AlCl_3$ in CH_3Cl; solvent—n-pentane; −78 °C.

Wider possibilities, from the standpoint of the preparation of functional PIB derivatives, arise from the chain termination reaction at the initiator fragment. Depending on the nature of the complex initiator $MX_n + R^{\delta+}B^{\delta-}$, one distinguishes termination by a Lewis acid fragment X (for the systems $BCl_3 + H_2O$,[28] $R_2AlCl + RCl$,[28] and $R_2AlCl + Cl_2$ [29]) and termination by the cocatalyst B fragment (for the combination $TiCl_4 + H_2O$, $TiCl_4 + CCl_3COOH$, and $SnCl_4 + C_6H_5OH$ [4,30,31]). The pathways followed in the above polymer chain termination reactions depend on the strength of the donor–acceptor interactions of the components of the initiating system. When it is high ($BF_3 + H_2O$), chain transfer to the monomer with retention of the BF_3OH^- counterion is preferable, as stated above.[12] With decrease in the stability of the complex initiators (based on titanium and tin compounds), the initiation and chain termination proceed with participation of the activated Lewis acid RB, i.e. the cocatalyst behaves as a kind of telogen, forming head and tail groups in the PIB. An additional complexity from the standpoint of the formation of end groups of a specified kind is introduced by systems of the type indicated above, which permit different pathways in the fragmentation of RB, for example, the dissociation of the C–O and O–H bonds in ROH.[32]

Comparison of the experimental and calculated (quantum-chemical analysis of the $\equiv C^+$ or MX_n complex with alcohols by the CNDO/2 method in terms of the Santry–Pople–Segal parametrisation) data shows that the pathway in the fragmentation of ROH bound in a complex depends on the nature of R and the strength of the acid. An increase in the acidity of MX_n and in the degree of branching of the group R promotes the preferential fragmentation of the alcohol at the C–O bond with incorporation of the OH group in the polymer.[32] For $SnCl_4 + C_6H_5OH$,[31] chain termination via the elimination of phenoxy-groups is determined primarily by the effect of the $(p-p)_\pi$ conjugation of the oxygen atom with the aromatic ring, which hinders the rupture of the C(phenyl)–oxygen bond. Since the elimination of the ligands from the MX_nB^- counterion depends on the energy of their binding to the metal and on the stability of the Lewis acid formed, it is possible for the ligand X to be eliminated and then incorporated in the polymer chain in the form of an end group. Reactions of this type occur when relatively weak Lewis acids (BCl_3, R_2AlCl) are used as initiating systems.[28] Numerous model investigations carried out on di- and triisobutenes[33] in the presence of catalysts–cocatalyst systems[34] and also the results of the physicochemical analysis of the polymers established that Cl and R are eliminated from the $[BCl_3R]^-$ and $[R_3AlCl]^-$ counterions respectively in accordance with the scheme:

Scheme 9



where X = OH, Cl, etc., R′ are alkyl radicals, and Ar are fragments of aromatic hydrocarbons.

Because of the absence of chain transfer to IB, the use of these catalysts in absolutely dry systems leads to extensive possibilities not only for the introduction of the specified tail groups into the PIB but also for the synthesis of PIB with functional head groups. The combination of controlled initiation and chain termination methods in the polymerisation of isobutene leads to monofunctional and αω-bifunctional PIB depending on the conditions[37] (Table 4).

Table 4. The synthesis of certain αω-bifunctional PIB.

Initiating system	T, °C	10^{-3}MW of PIB	αω-Bifunctional PIB	Refs.
Cl_2+BCl_3	−40 — −100	—	$Cl-CH_2-C(CH_3)_2-PIB-CH_2-C(CH_3)_2-Cl$	[43]
$CH_2=CH-CH(CH_3)Cl+Al(CH=CH_2)_3$	−30 — −75	—	$CH_2=CH-CH(CH_3)-PIB-CH=CH_2$	[38]
$(CH_3)_2C=CH-CH_2Cl+BCl_3$	−50	9.3—14.3	$(CH_3)_2C=CH-CH_2-PIB-C(CH_3)_2Cl$	[44]
$Cl-C(CH_3)_2-(CH_2)_3-C(CH_3)_2-Cl+(C_6H_5)_3Al$	−10 — −70	9.0—22.0	$C_6H_5-PIB-C_6H_5$	[45]
$Cl-C(CH_3)_2-C_6H_4-C(CH_3)_2-Cl+BCl_3$	−30 — −70	3.1—100.0	$Cl-C(CH_3)_2-CH_2-PIB-C(CH_3)_2-C_6H_4-C(CH_3)_2-PIB-CH_2-C(CH_3)_2-Cl$	[46, 47]

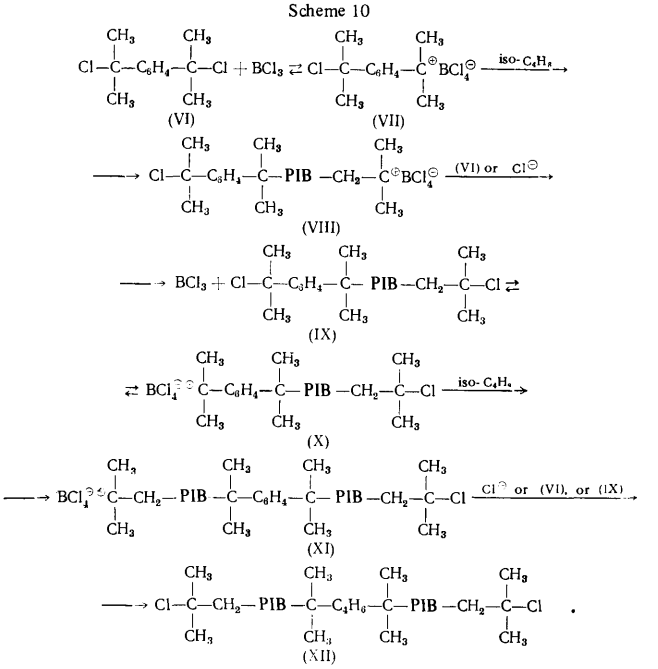
The formation reactions of αω-divinyl-PIB, and α-chloro-ω-vinyl-PIB are based on the principle of controlled chain initiation and termination by the Cl, $CH_2=CH-CH(CH_3)$, and $(CH_3)_2C=CH-CH_2$ cations in the first stage and fragment anions Cl and $CH=CH_2$ in the second respectively. It has been shown[38] that in such cases polymerisation is initiated slowly owing to the greater stability of the primary cationic species compared with the growing PIB carbonium ion. In contrast to the systems indicated, the dihalides combine the functions of the initiator and chain transfer agent. The degree of chain transfer to the monomer in the system is slight, while chain transfer to *p*-bicumenyl chloride is the dominant polymer chain termination reaction.[48,49]

The reactions (Scheme 10) result in the formation of bifunctional PIB containing in the middle of the chain one *p*-phenylene group and two terminal Cl atoms.[46]

The scheme for the formation of αω-dichloro-PIB resembles the cationic telomerisation reaction of isobutene,[50—52] but the products differ by significantly higher molecular weights and have a narrow molecular weight distribution with a width of 1.46—1.70.[47,53]

It is noteworthy that a number of patents deal with the synthesis of PIB having specified end groups. However, owing to the lack of a detailed specification of the experimental conditions, their value is reduced and they are therefore not quoted here.

Scheme 10

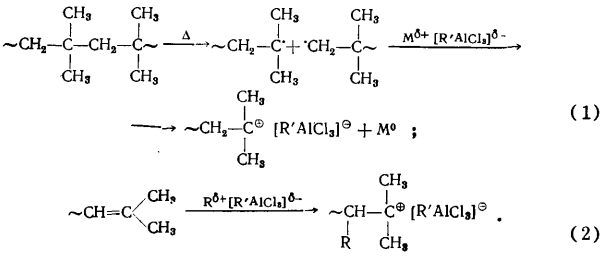


III. DEGRADATION AS A METHOD OF SYNTHESIS OF FUNCTIONAL DERIVATIVES OF ISOBUTENE POLYMERS

The degradation of PIB and PIBC was investigated previously only with the aim of demonstrating the structure (composition) of the compounds[54,55] or to estimate the stability of PIB in relation to various physical influences.[56—58] The free-radical decomposition of PIB proceeds with formation of a complex range of products.[59,60] Furthermore, specific degradation of polymers can serve as a convenient method of synthesis of functional PIB.

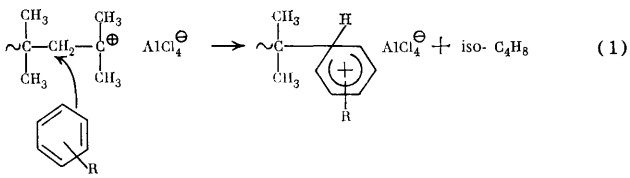
The thermocatalytic degradation of PIB via a mechanism involving depolymerisation under the influence of aluminium chloride complexes has been described.[61—63] Depending on the conditions, it is initiated in accordance with a "random law" via the homolytic dissociation of a C—C bond of the polymer with subsequent redox interaction of the polymer radical and the cation of the complex [Scheme (11), reaction (1)] or in accordance with the "end group" law via the interaction of the complex with the terminal C—C bond of the polymer [reaction (2)]:

Scheme 11



The reaction obeys the general rules for electrophilic processes and in the presence of aromatic hydrocarbons can take place at temperatures below the ceiling temperature for the decomposition of PIB, which is 50 °C.[64-66] The study of the decomposition of PIB in the range from -78° to 200 °C, catalysed by aluminium chloride, showed[64] that the polymer with terminal C=C and C–Cl bonds undergoes degradation from the end of the chain in the presence of ring-alkylating methyl- and isopropyl-benzenes with formation of aromatic polyisobutylene compounds having the general formula $C_4H_9(C_4H_8)_{6-10}C_6H_4$ and t-butyl derivatives of alkylbenzenes. The activating role of the aromatic hydrocarbon in reducing the PIB decomposition temperature below the limiting temperature apparently consists in promoting the fragmentation of the PIB macrocations at the preterminal C–C bond in the coupled alkylation reaction [Scheme 12, reaction (1)] and in binding the IB evolved by alkylating the alkylbenzene with the olefin [reaction (2)]:

Scheme 12



(1)

(2)

When sterically hindered aromatic compounds (mesitylene, tri-isopropylbenzene) are used and also when the reactions are carried out in the absence of alkylbenzenes, the PIB remains indifferent to the action of an acid catalyst under the experimental conditions at temperatures below 50 °C.[64]

More extensive possibilities for the introduction of functional groups into PIB in the degradation process arise from the oxidative cleavage of polymers or copolymers with dienes either at the C=C bonds[67,68] or at the aromatic fragment in the centre of the PIB chain[69] (Table 5).

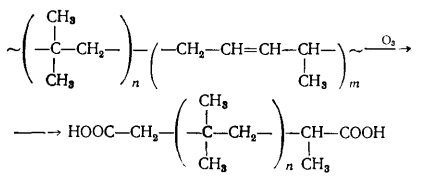
Table 5. The synthesis of αω-bifunctional PIB derivatives by the oxidative cleavage of polymers.

Polymer	Oxidant	Functional derivative	Refs.
$C_6H_{6-n}[C(CH_3)_2$— PIB —$C(CH_3)_2$·.Cl]$_n$, where n = 2, 3	$CF_3COOH-H_2O_2$	HOOC— PIB —COOH	[69]
Isobutene-piperylene copolymer	O_3 + pyridine	HOOC— PIB —COOH	[67, 70]
Ditto	O_3	OCH— PIB —COOH	[71]
"	RuO_4 + co-oxidant	HOOC— PIB —COOH	[72]
Isobutene-2,3-dimethylbuta-1,3-diene copolymer	RuO_4 + co-oxidant	CH_3—C(=O)— PIB —C(=O)—CH_3	[72]
Isobutene-isoprene copolymer	O_3	CH_3—C(=O)— PIB —COOH	[69]

The oxidation of linear and three-arm star PIB having the general formula $C_6H_{6-n}[C(CH_3)_2$–PIB–$C(CH_3)_2Cl]_n$, where n = 2 or 3, with the $CF_3COOH-H_2O_2$ mixture in the CCl_4-H_2O two-phase system at 60 °C lowers the molecular weight of the polymer by a factor of two (for n = 2) or three (for n = 3) as a result of the cleavage of the aromatic ring and the formation of PIB with terminal ~COOH groups.[69]

When high-molecular-weight PIBC, containing 2–4 wt.% of piperylene, are ozonised in the presence of pyridine, PIB with molecular weights of 1800–4000, containing up to 1.8 COOH groups per macromolecule, are formed[67] in accordance with the scheme:

Scheme 13



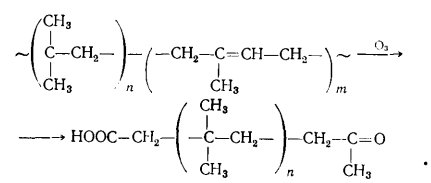
The preparation of these products includes three stages: (1) cleavage of the double bonds with formation of aldehyde and acid groups; (2) oxidation of the aldehydes to acids and peracids; (3) reduction of the peracids to acids.

For the process to be selective, it is necessary to maintain an equimolar ratio of ozone to the diene fragments in the polymer. When this ratio is disturbed, either the degradation of the isobutene chain takes place in the presence of an excess of ozone or the copolymer undergoes incomplete degradation at the diene units if there is insufficient oxidant.[73]

In the controlled ozonisation of PIBC with piperylene in the absence of pyridine, aldehydoacids are formed,[71] while in the presence of pyridine the products are dicarboxylic.[67, 68,70] As a result of a detailed study of the ozonolytic degradation of PIBC with piperylene, the Enjay Company (USA) developed the industrial manufacture of liquid PIB with terminal carboxy-groups.[67] The nature of the terminal functional groups introduced into PIB by this method is determined not only by the ozonolysis conditions but also by the type of the diene fragment in the copolymer.[68]

When isobutene copolymers are ozonised with subsequent thermal decomposition of the ozonides, ketoacids are formed[74] via the scheme

Scheme 14



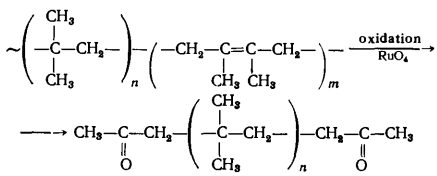
A decrease in the electronegativity of the substituent at the double bond in the copolymer increases its reactivity with respect to ozone (Table 6).

Table 6. The rate constants for the addition of ozone to the double bond in PIBC with dienes.[74]

Copolymer	10^{-5} k, litre mole^{-1} s^{-1}
PIBC with isoprene	10.0
PIBC with penta-1,3-diene	2.9
Brominated PIBC with isoprene	1.0
Chlorinated PIBC with isoprene	0.8

For example, the preparative possibilities of the synthesis of functional PIB derivatives in the course of oxidative degradation are extended when PIBC with 2,3-dimethylbuta-1,3-diene are used. [72] Their oxidation in the presence of catalytic amounts of RuO_4 gives rise to almost quantitative yields of diketones (Scheme 15):

Scheme 15



When the distribution of diene units with the 1,4-configuration in the copolymer is statistical, their content determines the average molecular weight of the degradation products (Table 7). The nature of the diene fragments in the copolymer does not affect the character of the molecular weight distribution of the PIB, which is narrower than in the initial polymer (the M_w/M_n ratio varies from 1.15 to 1.4).

Table 7. The properties of the initial copolymers and the products of their oxidative degradation. [71]

Initial copolymer				Functional PIB derivative	
$10^{-4}\cdot\bar{M}_v$	$\bar{M}_w/\bar{M}_n$	content of diene, mole %	F, wt.%	$\bar{M}_n$	f
Isoprene					
60	—	1.2	20.6	4800	0.81
65	1.8	1.2	20.6	4150	0.9
40	2.84	2.2	17.6	2500	0.92
53	—	6.3	10.3	1080	0.95
Penta-1,3-diene					
38	—	2.3	10.0	2400*	0.97*
38	—	2.3	10.0	2350	1.85
40	—	1.8	—	3500	1.88
35	—	3.6	12.0	1700	1.9
45	2.54	2.0	—	2900*	0.95*
45	2.54	2.0	—	2900	1.9

Notation: $\bar{M}_v$ is the viscosity-average molecular weight, $\bar{M}_w/\bar{M}_n$ the width of the molecular weight distribution, F the content of vinyl units relative to the total number of C=C bonds, and f the functionality with respect to the carboxy-group [number of carboxy-groups per unit].
*Obtained on ozonolysis in the presence of pyridine.

The functionality with respect to the carboxy-group [the number of carboxy-groups per unit] varies from 0.81 to 1.9 as a function of the conditions in the synthesis and the products contain mono-, bi-, and poly-functional derivatives of PIB (Table 8). The presence of "anomalous" fractions with a **functionality** in excess of one (in the case of a ketoacid) or more than two (in the case of a dicarboxylic acid) is due to the deviations from the 1,4-structure of the copolymer [71] in the course of the cationic copolymerisation of the diene with IB. The presence of diene units with 1,2- and 3,4-configurations in the copolymer (Table 7) leads to the formation of formaldehyde and formic acid in the ozonolysis products in accordance with Scheme 16:

Scheme 16

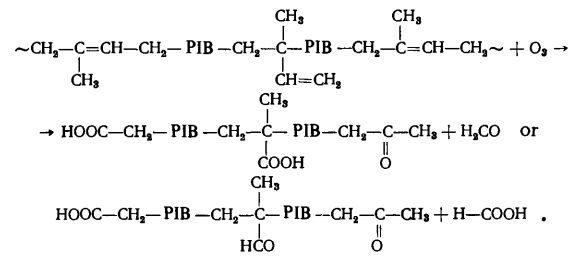


Table 8. Characteristics of carboxyl-containing PIB. [71]

Functional PIB derivative	$\bar{M}_n$	Content of fractions (wt.%) for different functionalities					
		0	1	>1	2	2*	>2
HOOC—PIB —C(=O)—CH$_3$	4800	12.48	70.0	17.5	—	—	—
HOOC—PIB —C(=O)—CH$_3$	2300	6.23	70.63	—	5.87	17.25	—
HOOC—PIB —COOH	2300	6.23	18.3	—	70.85	—	4.62

*Relative to aldehyde groups.

Thus the nature and the number of functional groups in the PIB obtained by the oxidative degradation of the products of the cationic polymerisation and copolymerisation of IB depend to a large extent on the composition and structure of the initial polymers. The development of this method of synthesis of functional derivatives of PIB is therefore associated with the improvement of procedures for the regulation of both the oxidative degradation and copolymerisation processes.

IV. REACTIONS OF ISOBUTENE POLYMERS VIA END GROUPS

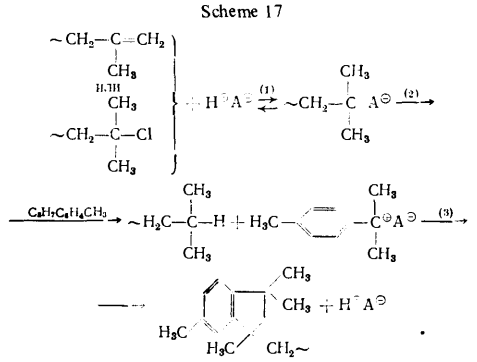
The PIB with one or two reactive end groups obtained in polymerisation or degradation processes are modified by polymer-analogue transformations in order to obtain other functional PIB derivatives (Table 9). These reactions are carried out under conditions which rule out the decomposition and cross-linking of the PIB macrochains. The presence of even one C=C terminal bond in low-molecular-weight PIB makes it possible to introduce into the polymer various groups (chlorine, aromatic groups, etc.).

In contrast to IB, which combines quantitatively with HCl, PIB with a molecular weight of 800 is only partially hydrochlorinated (in solution in toluene the degree of conversion of PIB after 3 h is not more than 50% at 0 °C), while in aliphatic solvents it is totally inactive. [75] With increase in solvent polarity or in the presence of weak Lewis acids ($FeCl_3$, $SnCl_4$, etc.) the degree of conversion of PIB with respect to the end group increases to 86%.

The alkylation of aromatic hydrocarbons (benzene, toluene, [64] and phenol) by PIB with terminal C=C and C–Cl bonds on treatment with acid catalysts leads to the formation of aromatic polyisobutene compounds. In the case of 1-isopropyl-4-methylbenzene, ionic hdyrogenation of PIB takes place under these conditions [77] in accordance with Scheme 17,

which involves the formation of a macrocation [reaction (1)], hydride transfer [reaction (2)], and cycloalkylation of the aromatic ring attached to the second generation carbonium ion [reaction (3)]:

Scheme 17



In contrast to catalytic hydrogenation by molecular hydrogen under severe conditions,[78] the ionic hydrogenation reaction takes place at room temperature without high pressure and leads to the formation of PIB with isobutyl and indan groups at the end of the chain in equimolar proportions. The presence of the latter in the products has been demonstrated by ultraviolet spectroscopy and model reactions of di-isobutylene.[79]

The high-molecular-weight alkenylsuccinic anhydride has been obtained in yields up to 58% by the condensation of an unsaturated PIB (molecular weight 800–1000) with maleic anhydride (230 °C, 10 h).[80] Reactions involving hydrosilylation with trichlorosilane and alkylchlorosilanes in the presence of the H_2PtCl_6 catalyst with formation of Si–Cl and (on reduction) Si–H groups are of interest.[51] Various sulphur-containing PIB derivatives can be obtained by the addition of sulphur dichloride, 4-chloro-5-chlorosulphenyl-3-methyltetrahydrophthalic anhydride, or 9-chloro-10-chlorosulphenylstearic acid.[82] PIB chlorination, sulphonation, oxidation, and epoxidation reactions, accompanied not only by the modification of the terminal C=C bonds but also by a change in the chemical nature of the chain are likewise known.[1] Analogous reactions can evidently be achieved with αω-divinyl-PIB obtained by the dehydrochlorination of αω-dichloro-PIB in the presence of $t\text{-}C_4H_9OK$.[83] It has been shown[84] that the epoxidation of PIB containing the vinyl C=C bonds at the end of the chain with the aid of *m*-ClC_6H_4COOOH and subsequent treatment with $ZnBr_2$ lead to a polymeric dialdehyde.

An important intermediate in the synthesis of functional PIB is a carboxyl-containing polymer obtained in the oxidative degradation of PIBC containing dienes[74] or on oxidation in the presence of RuO_4 of PIB with aromatic fragments at the ends of the chain.[86] When αω-dicarboxy-PIB is treated with thionyl chloride, it is readily converted into the corresponding bifunctional acid chloride.[74,86] PIB with carboxy-acid chloride groups have been used for the synthesis of low-molecular-weight polymers with hydroxy-, phenolic, phosphorus-containing, amine, and amidoamine reactive end groups (Table 9). A method of synthesis of dihydroxy-PIB by the hydroboration of αω-divinyl-PIB with subsequent oxidation in an alkaline medium has been described.[85] The product reacts further with isocyanates,[85,89] chlorosilanes,[85] and other reagents. This extends the series of functional PIB. However, one should note that the use of methods for introducing functional groups into high-molecular-weight PIB obtained beforehand is sometimes restricted by the decrease in the reactivity of the end groups with increasing molecular weight of the polymer[79,90] or by the decomposition of the polymer chain under the reaction conditions.[64] These features distinguish the reactions of PIB involving end groups from the reactions of its low-molecular-weight analogues.

Table 9. Modification of PIB via end groups.

V. APPLICATIONS OF THE FUNCTIONAL DERIVATIVES OF ISOBUTENE POLYMERS

The employment of functional derivatives of PIB in the traditional applications of PIB which have a single double bond at the end of the chain (electrically insulating oils, components of inorganic and synthetic oils, additives to such oils, cooling and lubricating liquids, and ingredients of compound preparations for different purposes[1,91,92]) is of great practical interest. This is because the introduction of functional groups into PIB by the methods described above results in a significant improvement of certain useful properties of the polymer. For example, low-molecular-weight PIB containing heteroatomic fragments at the ends of the chain are characterised by an increased resistance to oxidation compared with unsaturated PIB (octol) (Table 10).

Table 10. Oxidation of functional derivatives of low-molecular-weight PIB at 200 °C and an O_2 pressure of 250 mmHg.[74]

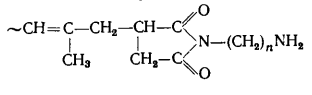
End groups in PIB	Inductive period in oxidation reaction, min
t-C_4H_9~, ~$C(CH_3)=CH_2$, ~$HC=C(CH_3)_2$	0
~COOH, ~$C(O)CH_3$	10
~OH	35
~NH_2	45
~$C(O)SP(O)(OR)_2$	55
~C_6H_4OH	135

The products of the hydrogenation of PIB [79] and aromatic polyisobutene compounds[22,93] exhibit a high resistance to mechano- and thermo-oxidative degradation. The presence of phenolic fragments in the functional PIB derivatives imparts to them the properties of antioxidants.[22]

PIB with terminal carbonyl and carboxy-groups, used as viscosity controlling additives to oils, show a greater thickening capacity than their unsaturated analogues. Functional derivatives of PIB increase the viscosity index without influencing the setting temperature of the petroleum oil and improve its thermal and mechanical stability.[94]

Polyisobutylene with phosphorodithioate end groups (1.5 wt.% of phosphorus and 2.7 wt.% of sulphur) show a polyfunctional activity in lubricating oils, exhibiting not only thickening but also antioxidant, antitear, and antiwear properties. Additives of this type can be regarded as essential materials for creating lubricating oil compositions with improved properties and with a reduced number of components. The high thermo-oxidative stability of these polymers is associated with the formation of phosphorodithioate radicals, which inhibit the decomposition of PIB.[88]

Ashless additives, which are the products of the interaction of polyisobutylenesuccinic anhydride with amines, i.e.



have found extensive applications. A characteristic feature of succinimide additives to motor oils is their effective detergent and dispersing action.[95]

The employment of PIB with carboxy- and keto-end groups as plasticising additives to rubbers makes it possible to improve the frost resistance and the physicomechanical properties of vulcanised chloroprene rubber.[96]

Oils based on aromatic polyisobutylene compounds are distinguished by a low setting temperature.[20] Saturated PIB are also used as lubricating materials in various branches of industry, medicine, and cosmetics.[78]

An advantage of hydrogenated PIB is that, when they are employed as dielectric fluids, the useful life of condensers is 3–4 times longer than in the case where octol (unsaturated PIB) is used as the condenser oil.[79]

High-molecular-weight PIB has a high chemical stability and resistance to ageing but is inadequately compatible with inorganic fillers. Since polymers are used in mixtures with fillers in techniques designed to protect against corrosion and to ensure hermetic seals,[92] the presence of functional groups in PIB is important for the improvement of the compatibility of the mixture components. Functional derivatives of PIB are of greatest interest for the preparation of various gasket and film materials and also compound mixtures, hermetic seals, non-drying putty, adhesive tapes, greases, and dyes, among other general purpose technical materials. By altering the polarity of the macromolecules as a result of the introduction of functional end groups into PIB, it is apparently possible to eliminate also the disadvantage of polyisobutene hermetic seals such as low cohesive strength and instability in relation to oils, fats, lubricants, and many solvents.[92]

Examples of the effective employment of PIB with carboxylic end groups for the modification of polymeric composites based on the acrylonitrile-butadiene-styrene copolymer, which are produced industrially, have been described.[97]

Apart from the traditional applications of PIB, the synthesis of their functional derivatives gives rise to prospects for the creation of liquid rubbers of a new type.[2] The combination of the saturation of the isobutene chain, which imparts a high chemical stability, impermeability to gases, and compatibility with certain polymers to articles based on high-molecular-weight polymers with the advantages arising from the ease of working with liquid rubbers containing highly reactive groups should ensure a wide variety of applications of these compounds. The hardening of oligoisobutenedicarboxylic acid by epoxy-compounds in the presence of tertiary amines as catalysts is accompanied by the formation of rubbers with a regular three-dimensional network.[90]

The presence of the reactive acid chloride group in PIB permits the subsequent grafting of starch via the CH_2OH groups[98] and also the preparation of a PIB block copolymer with polystyrene by reaction with the "living" polymer.[86]

Depending on the number and nature of the reactive groups, functional derivatives of PIB can be used as prepolymers in the synthesis of block copolymer of the type PIB-A, A-PIB-A, and $(PIB)_nA_m$, where A are blocks of a polymer differing in its nature from PIB. For example, the diblock (PIB–PST) and triblock (PST–PIB–PST) copolymers have been obtained by initiating the cationic polymerisation of styrene with alkyl derivatives under the influence of the PIB-Cl + alkylaluminium halide macromolecular initiator.[99]

Monofunctional PIB with a terminal chlorine atom attached to a teritary carbon atom reacts to form an IB block copolymer with styrene having a molecular weight up to 80000–100000 with a conversion up to 98% after the addition of $Al(C_2H_5)_2Cl$ and styrene.[100] Functional derivatives of diblock copolymers of isobutene with styrene or α-methylstyrene have been synthesised by an analogous procedure. PIB with a molecular weight from 9300 to 14300, having a tertiary Cl atom at one end of the chain and the $(CH_3)_2C=CH-CH_2$~ or $CH_2=CH-C(CH_3)_2$~ group at the other, was used as the prepolymer.[37] It has been shown[101] that chain transfer to α-methylstyrene with formation of a homopolymer does not occur in this instance and the product is characterised by a unimodal molecular weight distribution.

The reaction of bifunctional PIB having terminal chlorine atoms (whose molecular weights are in the range 30000–100000) with α-methylstyrene in the presence of $(C_2H_5)_2AlCl$ leads to a triblock copolymer consisting of a central PIB block and two terminal poly-α-methylstyrene blocks.[48]

The polymeric Grignard reagent synthesised on the basis of αω-dichloro-PIB has been used to prepare a new poly(isobutene–block–methyl methacrylate) block copolymer[43] in accordance with the scheme

Scheme 18

$$\mathrm{ClCH_2{-}C(CH_3)_2{-}PIB{-}CH_2{-}C(CH_3)_2Cl} \xrightarrow[2)\ Mg\ (THF)]{1)\ CH_3OH(HCl)} \longrightarrow$$
$$\longrightarrow \mathrm{ClMg{-}CH_2{-}C(CH_3)_2{-}PIB{-}CH_2{-}C(CH_3){=}CH_2} \xrightarrow{MMA} \longrightarrow$$
$$\longrightarrow \sim\mathrm{PMMA{-}CH_2{-}C(CH_3)_2{-}PIB{-}CH_2{-}C(CH_3)_2{=}CH_2}\ ,$$

where MMA is methyl methacrylate and PMMA is poly(methyl methacrylate).

By virtue of the presence of polystyrene, poly-α-methylstyrene, poly(methyl methacrylate), and other blocks in the products, they have the properties of thermoelastoplastics.[43] This leads to promising new applications of isobutene polymers.

The methods for the introduction of functional end groups into PIB reflects the characteristic features of the synthesis and properties of the polymer. The inapplicability to PIB of the method for the introduction of functional groups traditional for polymers based on anion-active monomers and based on the principle of "living polymerisation" as well as the limited possibility for polymer-analogue transformations via the terminal double bond have given rise to the use of new procedures. These include the cationic polymerisation of IB, regulated at the level of elementary chain intitiation and termination (transfer) stages, using specially selected complex catalysts, weak electron-donating compounds (chain transfer agents), proton traps, etc., which makes it possible to synthesise PIB with specified functional groups at the end of the chain. The picturesque term "molecular engineering" given to this method for the introduction of functional groups into PIB [102] neatly reflects the high level of the solution of the problem: together with the specified functionality and the distribution of functional groups, a specific molecular weight, molecular weight distribution, and microstructure of the polymer are ensured. In other words, one is dealing with the synthesis of functional derivatives of PIB regulated at different levels.

By means of further development of research into the controlled cationic polymerisation of IB in the absence of protic initiation and chain transfer to the monomer, it is possible to approach and even surpass the synthetic possibilities of "living" systems as regards the preparation of a wide variety of block and grafted copolymers.[102]

The synthesis of cationic copolymers (susceptible to regulation) of IB with diene (1,4-addition) and triene (1,6-addition) monomers and subsequent oxidative degradation under specially selected conditions also lead to extensive possibilities for the synthesis of functional PIB derivatives. Despite the large number of stages involved and their complexity, the oxidative degradation methods can compete successfully with polymerisation procedures for the synthesis of functional PIB derivatives, particularly in the synthesis of high-molecular-weight dihydric alcohols and dicarboxylic acids. The range of chemical reactions and applications of PIB as hermetic seals, oils, additives, etc. can be significantly extended by modifying the polymer at the end groups. The presence of reactive groups in functional PIB derivatives makes it possible to combine this polymer chemically with "incompatible" plastics and elastomers to form polymeric products with a unique set of properties.

Paramagnetic d^1-Complexes of Biscyclopentadienylvanadium

G.A.Razuvaev, G.A.Abakumov, and V.K.Cherkasov

Electron paramagnetic resonance data for the Cp_2V d^1-complexes are surveyed and the dependence of the EPR parameters for the complexes on their molecular and electronic structure is discussed. Examples of the use of the EPR method for the determination of the structures of labile Cp_2V d^1-complexes, formed as intermediates in various reactions, are considered. The bibliography includes 59 references.

CONTENTS

III. The EPR parameters and structure of Cp_2V d^1-complexes 728
IV. EPR study of Cp_2V d^1-complexes in solution 732

I. INTRODUCTION

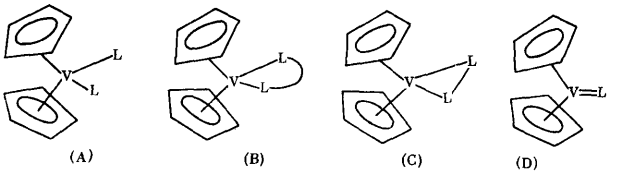
The electron paramagnetic resonance method is widely used for the solution of various problems in the chemistry of organometallic compounds (OMC), including the determination of their molecular and electronic structures. We believe that this aspect of the application of the EPR method to the OMC chemistry is most important and interesting. Unfortunately, the EPR study of paramagnetic OMC is frequently undertaken with the utilitarian aim of obtaining the spectroscopic characteristics of the given specific compounds. For this reason, most of the available EPR information obtained in OMC chemistry is concerned with specific species, is of an unrelated character, and is relatively unsuitable for the solution of problems involving the determination of the electronic and molecular structures of OMC because success in research of this kind is impossible without the elucidation of the influence of the ligand environment on the EPR parameters.

In the present review an attempt is made to survey EPR data obtained for the Cp_2V d^1-complexes: the spectroscopic parameters are compared with the available information about the molecular and electronic structures of these complexes; certain rules governing the variation of the EPR parameters as a function of the nature of additional ligands attached to Cp_2V are discussed; the relations found between the EPR parameters and the structure are used to determine the structures of labile Cp_2V d^1-complexes formed as intermediates in various reactions involving Cp_2V and its derivatives.

II. THE EPR SPECTRA OF Cp_2V d^1-COMPLEXES

1. Types of Cp_2V d^1-Complexes. General Information about the Molecular and Electronic Structures

A paramagnetic 17-electron vanadium d^1-complex incorporating Cp_2V can be formally produced from the 15-electron complex Cp_2V by adding to the latter either two one-electron ligands or one two-electron ligand. The first variant can be achieved in only one way—as a result of the formation of two σ-bonds between Cp_2V and two one-electron ligands (A).



(A) (B) (C) (D)

Depending on their nature (structure), the two-electron ligand can be linked to vanadium in three different ways. Bidentate chelate ligands (formally η^2-ligands), in which the atoms bound directly to vanadium are not linked to one another, form complexes of type (B) which differ little from complexes of type (A) (in terms of the character of the V–L bond) and can be regarded as d^1-complexes with two one-electron η^1-ligands. Bidentate ligands in which the atoms bound to vanadium are linked directly to one another form on addition to Cp_2V a three-membered metallocycle. In the resulting d^1-complex a two-electron η^2-ligand (C) is bound to Cp_2V. The third "terminal" type of binding of the two-electron ligand to Cp_2V leads to d^1-complexes with a two-electron η^1-ligand (D).

The majority of the known Cp_2V d^1-complexes belong to the first two types [(A) and (B)]. The one-electron η^1-ligand which enters into the composition of type (A) complexes can be of a wide variety of types: the halogens (Cl, Br, and I), the pseudohalogens (CN, OCN, SCN, SeCN, and N_3), carboxy-compounds (OCOPh), alkyls (Me, Et, CH_2Ph, and CH_2SiMe_3), hydrogen, element-containing groups (SiR_3, GeR_3, SnR_3, and SR), etc. The complex can contain both two identical and two different additional ligands. In complexes of type (B) the ligands bound to vanadium may be various chelate species forming four-, five-, and six-membered rings; their coordinating atoms may be C, O, N, and S.

The two-electron ligands in the main react with Cp_2V to form complexes of type (C) (η^2-ligands). A fairly large number of such complexes are known in which the ligands are alkenes EtOC(O)C(H) = C(H)C(O)OEt, F_3CFC = $CFCF_3$), alkynes (PhC≡CPh, $C_6F_5C{\equiv}CC_6F_5$, etc.), diazenes (PhN=NPh), heterocumulenes ($Ph_2C{=}C{=}O$, Ph–N=C=O, S=C=S). Among complexes of type (D) described in the literature, one may refer to compounds with carbon monoxide, isonitriles, and nitrenes.

The classification of complexes of type (C) and (D) as d^1-complexes still remains controversial. Thus the authors of a review[1] regard Cp_2V complexes with ligands of this kind as d^3-complexes, assuming that the ligands in them are neutral and that the formal oxidation state of vanadium in the complexes is +2. This view has been confirmed by the results of quantum-chemical calculations, from which it follows that the highest fully occupied molecular orbital in the complexes involves a large contribution by the d orbitals of the atom.[2] On the other hand, the results of calculations indicate an appreciable decrease of the energy of this orbital compared with the initial d^3-complex (Cp_2V), i.e. the transformation of this orbital from non-bonding to bonding. The available data concerning the molecular structure of certain d^1-complexes with η^2-ligands[3-5] also show that the alkene and alkyne molecules coordinated to Cp_2V undergo appreciable deformations, the resulting structures approaching those of alkanes and alkenes respectively. The V–C bond lengths in these complexes are comparable to those of the normal V–C σ-bonds. Thus the binding of vanadium to the carbon atoms in the complexes of type (C) differs little in its character from the σ-binding in complexes of types (A) and (B). In order to compare the properties of different 17-electron Cp_2V complexes, in the present review compounds of types (C) and (D) will be considered together with those of types (A) and (B) and will be classified as d^1-complexes.

The general features of the molecular and electronic structures of the Cp_2V d^1-complexes are well known. Admittedly, this claim refers to a large extent to complexes of type (A) (with two one-electron ligands), for which fairly reliable quantum-chemical calculations have been performed,[6,7] whose results agree well with EPR experimental data for diamagnetically diluted single crystals.[8,9] As regards complexes of the other three types, their electronic structures can be inferred on the basis of a qualitative "angular sandwich" structural model[2] and also on the basis of the available data for the molecular structure of such complexes. Here one should naturally take into account the similarities and differences in the structures of complexes of different types and the character of the bond linking the additional ligand to Cp_2V.

In conformity with the available data, the general features of the structure of Cp_2V d^1-complexes are as follows. Their molecular geometry is described in an idealised manner by C_{2v} symmetry with a twofold symmetry axis, which coincides with the X axis (for the arrangement of the coordinate axes illustrated in Fig.1). In the presence of different additional ligands, the symmetry of the complex decreases to C_2.[2] For the arrangement of coordinate axes shown in Fig.1, the lines joining vanadium to the centres of the Cp ligands are in the xy plane and the bonding to the additional ligands L is in the xz plane. In this case the unpaired electron is located in the molecular orbital with a_1 symmetry. In terms of its character, this orbital is non-bonding with a dominant contribution from the d_{z^2} orbital of vanadium. Taking into account the ligand contribution, the expression for the molecular orbital of the electron (MO_e) can be formulated as follows:

$$\varphi^e_{a_1} = \alpha(d_{z^2},\ d_{x^2-y^2}) + (1-\alpha)^{1/2}\varphi_L, \qquad (1)$$

where α and $(1-\alpha)^{1/2}$ are the coefficients of the orbitals forming part of the composition of MO_e and ϕ_L is the combined orbital of the ligands with a^1 symmetry.

According to the results of quantum-chemical calculations,[6,7] the contribution of the vanadium orbitals (d orbitals) is from 58 to 72% depending on the nature of the additional ligands, the contribution of the ligand orbitals (p_π orbitals) is 23–37%, and the contribution of the orbitals of the Cp ligand does not exceed 5%. It is striking that MO_e contains virtually no contribution from the s orbitals of the ligands (< 1%). An interesting feature of the Cp_2V d^1-complexes is the dependence of the relative contributions of the d_{z^2} and $d_{x^2-y^2}$ orbitals of vanadium on the nature of the additional ligands. This dependence is manifested very distinctly in the anisotropic EPR spectra and will be discussed in detail when such spectra are considered.

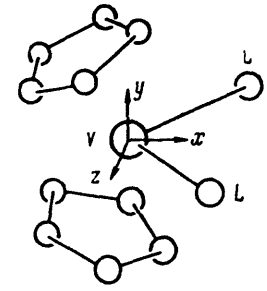


Figure 1. The molecular geometry and disposition of the coordinate axes in Cp_2V d^1-complexes.[20]

2. Isotropic EPR Spectra of Cp_2V d^1-Complexes

The isotropic parameters of the EPR spectra of d^1-complexes of various types are presented in Table 1. The data in this table show that, depending on the nature of the additional ligands bound to vanadium, the isotropic parameters vary within wide limits. The constants for the hyperfine interaction with the ^{51}V nucleus (99.9%; $J = 7/2$; $\mu = 5.1392$) $A_i(V)$ vary from -23 to -80 G and the g_i range from 1.965 to 2.025. Comparative analysis of the isotropic parameters of the spectra of the Cp_2V d^1-complexes makes it possible to discover certain relations governing their variation as a function of the properties of the additional ligand. These relations are clearly illustrated by the "field" of the values of g_i and $A_i(^{51}V)$ in which the majority of the known Cp_2V d^1-complexes are represented (Fig.2).

Virtually all d^1-complexes of type (A) (two one-electron ligands) fit on a straight line (linear correlation between g_i and A_i), constituting one group. An analogous relation has been observed for d^1-complexes of type (B) (chelating two-electron ligands); the straight line combining these complexes has approximately the same slope but differs in the linear term. For complexes of type (C) (two-electron η^2-ligand), the hyperfine interaction constant A_i varies very slightly with L, remaining virtually invariant. An analogous tendency has been noted for complexes of type (D) (two-electron η^1-ligand), but the number of examples of complexes of this type is small. Cp_2V complexes with carbon-containing additional ligands, in which the coordination is via carbon atoms [dialkyl derivatives of type (A), alkene and alkyne complexes of type (C), and carbonyl and isonitrile complexes of type (D)] constitute yet another group of d^1-complexes with its own linear relation between the isotropic parameters.

The groups enumerated include almost all Cp_2V d^1-complexes for which the parameters of the isotropic EPR spectra are known.

It is striking that the composition of the groups combining complexes in terms of the isotropic parameters of the EPR spectra is consistent with the formal types of these complexes based on the nature of the binding of the additional ligands to Cp_2V (see Section I). This indicates, on the one hand, the similarity of the molecular and electronic structures of isotypical complexes within each group and, on the other hand, differences between the complexes in different groups (different types). The correlation between the parameters of the carbon-containing d^1-complexes of different types emphasises common features in the electronic structures of all the Cp_2V d^1-complexes. The relation between the spectroscopic parameters and molecular electronic structures of Cp_2V d^1-complexes appears most distinctly in the analysis of anisotropic EPR spectra.

3. Anisotropic EPR Spectra of Cp_2V d^1-Complexes

Anisotropic EPR spectra have been investigated for a much smaller number of Cp_2V d^1-complexes than the isotropic spectra although the information obtained from the analysis of the former makes it possible to understand certain important details of the electronic and molecular structures of these complexes (the composition of the molecular orbital of the unpaired electron, the relative energy of the lowest occupied and unoccupied MO, and the geometry of the complex). Table 2 presents anisotropic EPR spectroscopic parameters of Cp_2V d^1-complexes. The majority of the data quoted were found in the study of "vitrified" solutions and only the data concerning Cp_2VCl_2 and Cp_2VS_5 have been obtained in experiments with diamagnetically diluted single crystals.[8,9]

It follows from Table 2 that the $\bar{g}$ and $\bar{T}$ tensors for all the d^1-complexes have orthorhombic symmetry (the principal components of the $\bar{g}$ and $\bar{T}$ tensors are not the same). The anisotropic EPR spectra of the series of Cp_2V d^1-complexes were interpreted incorrectly in a number of studies[29,31,36] based on the hypothesis of axial symmetry of the $\bar{g}$ and $\bar{T}$ tensors, the authors failing to take into account the z components of the two tensors.

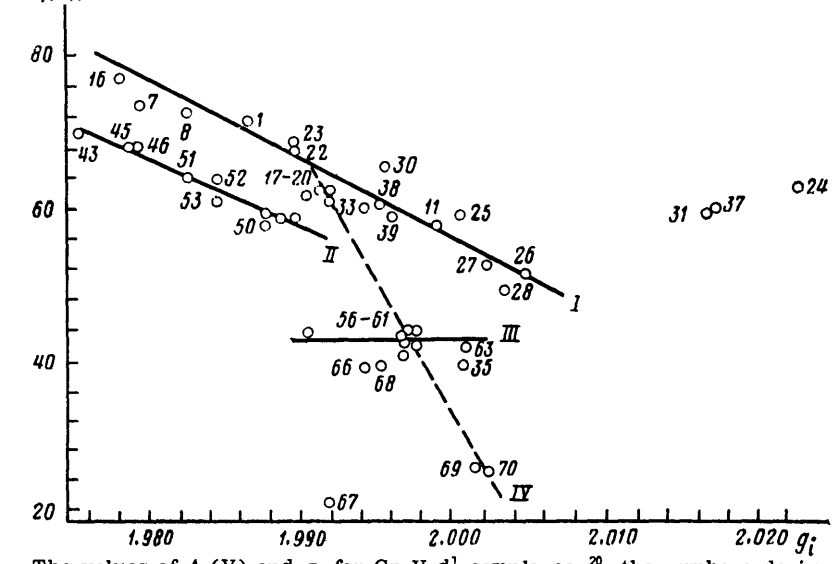

Figure 2. The values of A_i(V) and g_i for Cp_2V d^1-complexes;[20] the numbers designating the circles correspond to the numbers of the complexes in Table 1.

The interpretation of the anisotropic EPR spectra using a quantum-chemical model was first achieved for Cp_2VCl_2 in a study[37] whose authors established that the unpaired electron in Cp_2VCl_2 is located in a molecular orbital with a_1 symmetry, comprising the $3d_{z^2}$ and $3d_{x^2-y^2}$ orbitals of the metal atom. However, since the crystal structure of the matrix (Cp_2TiCl_2) was unknown at the time, it was impossible to determine the correct orientation of the axes of the $\bar{g}$ and $\bar{T}$ tensors relative to the crystal. Somewhat later a complete analysis of the anisotropic EPR spectra was carried out for a series of Cp_2V and Cp_2Nb d^1-complexes obtained in vitrified solutions.[6] Despite the fact that the initial orientation of the axes of the $\bar{g}$ and $\bar{T}$ tensors in the above investigation was selected incorrectly (the z axis coincided with the C_{2v} symmetry axis), the data obtained by the authors for the composition of the unpaired electron orbital and other details of the electronic structure differ little from the more accurate results obtained later[8,9] and based on a comparison of the parameters of the anisotropic EPR spectra of a diamagnetically diluted Cp_2VCl_2 single crystal with the quantum-chemical calculations for this complex by the Fenske–Hall method.[7] A somewhat simplified model, based on the conclusions reached in the studies listed above, as well as the investigation of Lauher and Hoffman[2] devoted to a qualitative consideration of the binding of ligands of different types in "angular sandwiches", has been used in the present review for the interpretation of the anisotropic EPR spectra of Cp_2V d^1-complexes with different ligands.

If one uses Eqn.(1) for the unpaired electron MO, then, resorting to the ligand field approximation and assuming that the contributions of the orbitals and additional ligands to the ground state are small, the principal components of the $\bar{g}$ and $\bar{T}$ tensors for the Cp_2V d^1-complexes with C_{2v} symmetry can be expressed as follows:[6,7]

$$g_x = g_0 - 2\lambda(a\cdot 3^{1/2} + b)^2\left[\frac{P^*_{b_1}}{\Delta E(\varphi^*_{b_1} \leftarrow \varphi^c_{a_1})} - \frac{1 - P^*_{b_1}}{\Delta E(\varphi^e_{a_1} \leftarrow \varphi_{b_1})}\right], \quad (2a)$$

$$g_y = g_0 - 2\lambda(a\cdot 3^{1/2} - b)^2\left[\frac{P^*_{b_2}}{\Delta E(\varphi^*_{b_2} \leftarrow \varphi^c_{a_1})} - \frac{1 - P^*_{b_2}}{\Delta E(\varphi^e_{a_1} \leftarrow \varphi_{b_2})}\right], \quad (2b)$$

$$g_z = g_0 \quad (2c)$$

$$T_x = -K + P\left[-\frac{2}{7}(a^2 - b^2) + \frac{4\cdot 3^{1/2}}{7}ab\right], \quad (3a)$$

$$T_y = -K + P\left[-\frac{2}{7}(a^2 - b^2) + \frac{4\cdot 3^{1/2}}{7}ab\right], \quad (3b)$$

$$T_z = -K + P\left[\frac{4}{7}(a^2 - b^2)\right], \quad (3c)$$

where $P = g_0 q^{51}_N \beta\beta_N \langle r^{-3}\rangle$ is the dipolar contribution, $K = -g_0 g^{51}_N \beta\beta_n \times 2/3\chi$ the contact contribution to the hyperfine interaction (HFI) with the ^{51}V nucleus, λ the spin–spin orbit coupling constant for ^{51}V, $g_0 = 2.0023$ the g-factor for the free electron, $\phi^e_{a_1}$ the molecular orbital of the unpaired electron, ϕ_{b_1} and ϕ_{b_2} are the highest fully occupied orbitals with b_1 and b_2 symmetry, $\phi^*_{b_1}$ and $\phi^*_{b_2}$ the lowest unoccupied orbitals with the same symmetries, and a and b are coefficients of the d_{z^2} and $d_{x^2-y^2}$ vanadium orbitals. The form of Eqns.(3a)–(3c) for different values of the components of the $\bar{T}$ tensor has been simplified for their more complete expression,[7] omitting small terms whose contribution to T_x, T_y, and T_z is less than 1%. On the other hand, additional terms, taking into account the spin–orbit coupling between $\phi^e_{a_1}$ and the highest fully occupied orbitals ϕ_{b_1} and ϕ_{b_2} have been introduced into the expressions for g_x and g_y, as was done by Stewart and Porte.[6] The discussion below will make clear the importance of these terms for the explanation of the values of the $\bar{g}$ tensor, especially in the case of the Cp_2V d^1-complexes with neutral η^1- and η^2-ligands.

According to Eqn.(2c), the g_z component for the Cp_2V d^1-complexes should be close to $g_0 = 2.0023$ and the T_z component should be largest, bearing in mind that all the quantities T_x, T_y, T_z, and A_i are negative. In view of these features of the z components of the $\bar{g}$ and $\bar{T}$ tensors, their assignment in the experimental spectra does not present major difficulties. The assignment of two other components, based solely on EPR spectra, is impossible, since the signs of the coefficients a and b for the metal d orbitals incorporated in $\phi^e_{a_1}$ cannot be determined from the EPR experiment. The quantum-chemical calculations[6,7] for Cp_2V d^1-complexes of types (A) and (B) yield the opposite signs for a and b, i.e. for complexes of these types $T_x > T_y$. The relative values of g_x and g_y are determined not only by the signs of the coefficients a and b but also by the relative magnitudes of the terms expressing the spin–orbital coupling of $\phi^e_{a_1}$ for the lowest unoccupied and highest fully occupied MO ($\phi^*_{b_1}$, $\phi^*_{b_2}$, ϕ_{b_1}, ϕ_{b_2}).

III. THE EPR PARAMETERS AND STRUCTURE OF Cp_2V d^1-COMPLEXES

1. Dependence of the Components of the $\bar{g}$ and $\bar{T}$ Tensors on the Structure of the Cp_2V d^1-Complexes

When use is made of the qualitative scheme proposed by Lauher and Hoffman[2] for the description of the binding of the Cp_2M fragment to the additional ligands in "angular sandwiches", then comparison of the molecular diagrams for complexes of types (A), (C), and (D) (Fig.3) can reveal significant differences, which determine the electronic structure of these complexes and hence also the parameters of the anisotropic EPR spectra.

(1) In conformity with C_{2v} molecular symmetry (with the choice of coordinate axes shown in Fig.1), the highest fully occupied MO in the complexes of all three types is an orbital with b_2 symmetry consisting mainly of contributions from the dxz orbital of vanadium and the b_2 orbital of the ligand (or ligands) and virtually lacking any contribution from the Cp ligands.

(2) The highest fully occupied and lowest unoccupied MO with b_1 symmetry consists predominantly of the d_{yz} orbital of the vanadium atom and the b_1 group orbitals of the Cp ligands and have virtually no contribution due to the orbitals of the additional ligands.

(3) In contrast to complexes of type (A), in which the b_2 orbital of the ligands is a b_2 group orbital consisting of the σ orbitals (p or s) of the ligands, in complexes of types (C) and (D) the b_2 orbital of the ligand is an antibonding orbital of a neutral ligand. As a consequence, both its energy and the energy of the b_2 orbital of the complex produced from it on formation of a bond is significantly higher than the energy of the initial σ orbitals of the one-electron ligands and the MO of the same symmetry in complexes of type (A).

The factors noted above entail two conclusions concerning the properties of the principal components of the $\bar{g}$ tensor of Cp_2V d^1-complexes. Firstly the g_x component of the $\bar{g}$ tensor must show very little sensitivity to the nature of the

additional ligands, since, as a consequence of spin–orbit coupling, the a_1 orbital of the unpaired electron becomes mixed in this instance with the MO having b_1 symmetry, which contains no contribution from the additional ligands and therefore both its energy and its composition change little when such ligands are replaced. Conversely, the g_y component must be very sensitive to changes in the properties of additional ligands, because the angular momentum operator L_y mixes the a_1 orbital of the unpaired electron with the b_2 orbital, whose energy and composition are determined by the interactions of the d_{xz} orbital of vanadium with the b_2 orbital of the ligand (or ligands). Secondly the g_y component may be greater than $g_0 = 2.0023$, since the appreciable difference between the energies of the initial b_2 orbitals of the ligands should lead to a significant difference between the energies of the MO with b_2 symmetry (ϕ_{b_2} and $\phi^*_{b_2}$) depending on the type of ligands.

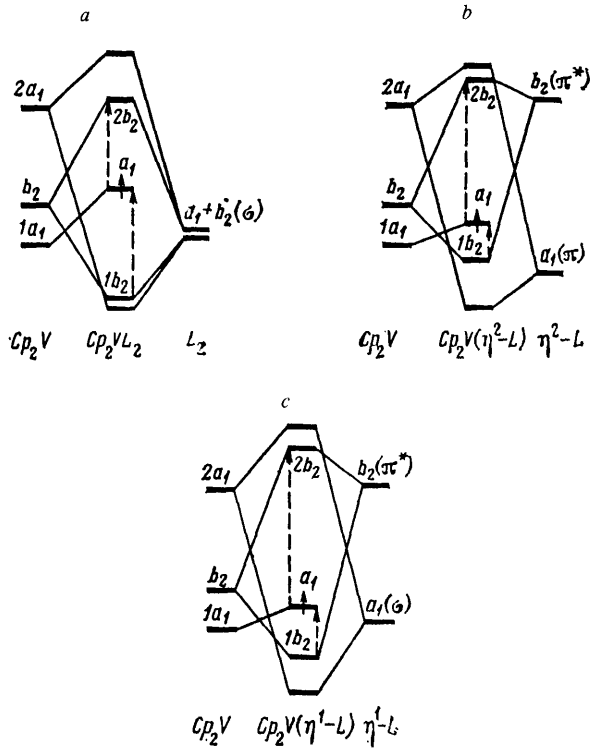

Figure 3. A qualitative energy level diagram for molecular orbitals with a_1 and b_2 symmetry in Cp_2V d^1-complexes: *a*) complexes of type (A); *b*) complexes of type (C); *c*) complexes of type (D).[20,28]

In complexes of type (A) the energy of the initial b_2 group orbital of the ligands is lower than the energy of the d_{xz} orbital of the Cp_2V complex (see Fig.3), as a result of which the energy difference ΔE between $\phi^e_{a_1}$ and ϕ_{b_2} is greater than that between $\phi^e_{a_1}$ and $\phi^*_{b_2}$, i.e. the electronic transitions predominate in the spin–orbit coupling over the "hole" transitions. Another situation arises in complexes of types (C) and (D). The high energy of the antibonding b_2 orbitals in the neutral alkene, alkyne, and CO ligands causes a shift of the energy of the b_2 and b^*_2 MO relative to the MO of the unpaired electron such that ΔE between $\phi^e_{a_1}$ and $\phi^*_{b_2}$ becomes greater than that between $\phi^e_{a_1}$ and ϕ_{b_2}, as a result of which the "hole" transitions make a greater contribution to g_y than the electronic transitions.

Unfortunately there are no literature data on the photoelectron spectra of the Cp_2V d^1-complexes of different types but such information does exist for the analogous Cp_2Mo complexes. It follows from the data of Green et al.[38] that the energy difference ΔE between the MO with a_1 symmetry, occupied in the given instance by a pair of electrons, and the orbital with b_2 symmetry (in the original study this orbital was assigned to b_1 symmetry as a result of a different type of indexing of the coordinate axes) in the complexes $Cp_2Mo(CO)$ and $Cp_2Mo(C_2H_4)$ is 0.9 eV, while in the complexes Cp_2MoMe_2 and Cp_2MoH_2 the energy differences are 2.5 and 2.2 eV respectively. At the same time, the long-wavelength transition in the electronic spectrum of Cp_2VCl_2, for example, corresponding to the excitation of the unpaired electron from the a_1 orbital to the b^*_2 orbital, is characterised by an intermediate energy of approximately 1.5 eV.[9]

On the basis of the model for binding of the additional ligands in the Cp_2V d^1-complexes considered above, the component of the $\bar{g}$ tensor greater than g_0 can be defined as the g_y component. This fact was taken into account in the compilation of Table 2, where, in contrast to the original communication,[5] the g_x and g_y components have been assigned in conformity with the model described above. Here the corresponding components of the $\bar{T}$ tensor naturally also undergo a change in indexing in such a way that $|T_x| > |T_y|$, in contrast to $|T_x| < |T_y|$ for the Cp_2V d^1-complexes of type (A). It follows from Eqns.(3a) and (3b) that the relative values of the components T_x and T_y depend only on the relative signs of the coefficients *a* and *b* defining the contribution of the vanadium d_{z^2} and $d_{x^2-y^2}$ orbitals to the MO of the unpaired electron.

Quantum-chemical calculations for the Cp_2V d^1-complexes of types (C) and (D) have not been made. As mentioned previously, calculations for the type (A) complexes lead to the conclusion that *a* and *b* have opposite signs, which is responsible for the relation $|T_x| < |T_y|$. The authors of a study[5] devoted to the analysis of the anisotropic EPR spectra of Cp_2V d^1-complexes with alkenes, alkynes, and azobenzene assume that the coefficients *a* and *b* for complexes of this type also have the opposite signs, whence follows the relation $|T_x| < |T_y|$. However, the authors[5] fail to give a correct explanation of the relation $g_x > g_y$ which follows from the preceding relation.

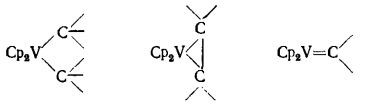
As shown above, the relation $g_y > g_0 > g_x$ between the components of the $\bar{g}$ tensor agrees best with the electronic structure of the d^1-complexes of types (C) and (D). In order to account for the relation $|T_x| > |T_y|$ associated with the above relation, one must assume that in complexes of these types the coefficients *a* and *b* have the same sign. This hypothesis agrees well with the dependence of the L–V–L valence angle on the population of the MO with a_1 symmetry known for "angular sandwiches".

The change in the relative signs of the coefficients *a* and *b* has the simple physical significance of a change in the spatial distribution of the electron density in the a_1 MO. As was correctly noted by Petersen and Dahl,[8] when $a < 0$ and $b > 0$, a small positive contribution of the $d_{x^2-y^2}$ orbital corresponds to an increase of the electron density within the L–V–L angle (along the *x* axis) and to its corresponding

decrease in the direction of the normal to the L–V–L plane (along the y axis) compared with the "pure" d_{z^2} orbital (Fig.1). The dependence of the L–M–L valence angle on the population of the MO with a_1 symmetry has been established for the Cp_2M d^0-, d^1-, and d^2-complexes: the angle L–M–L diminishes with increasing population, i.e. in this case the electronic factor (the population of the non-bonding orbital) influences the parameter of the molecular structure (the valence angle). It is natural to expect that this influence should be reciprocal, i.e. that a change in the valence angle should entail a redistribution of the spatial electron density in the a_1 MO.

It has been shown[7–9] that a simple criterion of the spatial distribution of electron density in this orbital in the transition metal d^1-complexes, especially for Cp_2V, may be the quantity a^2/b^2 determined from the anisotropic parameters of the EPR spectra. For a series of Cp_2V d^1-complexes of type (A), these quantities have been calculated.[7] Their values, which vary in the range 7.7–20, indicate the predominant contribution of the d_{z^2} orbital with a small admixture of the $d_{x^2-y^2}$ orbital. Later,[5,28] in the analysis of the EPR spectra recorded in "vitrified" toluene, it was established that the contribution of the small $d_{x^2-y^2}$ orbital for complexes of type (C) with two-electron η^2-ligands is significantly reduced ($a^2/b^2 = 70–250$), i.e. the MO of the unpaired electron is an almost pure d_{z^2} orbital.

Comparison with the available X-ray diffraction data for the structures of complexes of both types enabled the authors[5,28] to formulate a conclusion concerning the molecular structure of the complex (the L–V–L valence angle) and its electronic structure (the spatial distribution of the electron density in the a_1 MO). However for complexes of type (D) (for example, Cp_2VCO and Cp_2VCNR) a discrepancy is observed between a^2/b^2 and the L–V–L angle within the framework of this simple relation. Indeed complexes of type (D) can be regarded as limiting in the series established in accordance with a decreasing C–V–C valence angle:



(A); ~ 87° (C); 35 – 39° (D); 0°.

For complexes of type (D), in which the η-ligand is located on the x axis, the C–V–C valence angle can be regarded as zero, whence it follows that $a^2/b^2 \to \infty$, in conflict with experiment [for example, $a^2/b^2 = 13.4$ for $Cp_2V(CO)$].[28]

The conflict can be readily resolved if it is assumed that a and b have the same sign in conformity with the model of the binding of the ligands in complexes of type (C) and (D). Despite the identical values of a^2/b^2 for complexes of types (A) and (D), here the spatial distribution of electron density in the MO of the unpaired electron is significantly different. The positive sign of the $d_{x^2-y^2}$ orbital would then correspond to a decrease of electron density along the x axis and its corresponding increase along the y axis, as should be also the case under the conditions of the limiting decrease of the L–V–L valence angle.

2. Dependence of the Isotropic Hyperfine Interaction Constant A_i(V) on the Nature of the Ligand

As already mentioned, the Cp_2V d^1-complexes of types (A) and (B) differ from the complexes of types (C) and (D) by the dependence of the hyperfine interaction (HFI) constant on the nature of the additional one-electron ligands. The change in the quantity A_i(M) in transition metal complexes, where the unpaired electron is in a d orbital, has been attributed in EPR theory to the possible operation of two mechanisms: (1) the spin polarisation of the inner s orbitals and (2) the mixing of the MO_e with a MO of the complex having a suitable symmetry, in which there is a large contribution by the s orbital of the metal. In those cases where spin polarisation predominates, a correlation is observed between the change in the effective charge on the central atom (or the charge in the covalence of the metal–ligand bonds) and the quantity A_i;[99] under these conditions, an increase of the covalence of the bond entails an increase in the positive contribution to the A_i for transition elements of the first series. Bearing in mind the negative sign of A_i, for ^{51}V this should entail a decrease of $|A_i(V)|$. This type of linear relation had been noted earlier for titanium, vanadium, etc. complexes.[1] In the Cp_2V d^1-complexes of type (A), this mechanism is likewise the main one, since a linear correlation has been observed for such complexes between $|A_i(V)|$ and the sum $\sum_L (\chi_V - \chi_L)$ (Fig.4), which characterises the amount of ionic character (the covalence) of the V–L bonds. One should note that the correlation under discussion is observed when a rough approximation is used: the values of χ for the ligand atoms directly linked to vanadium are employed as the χ_L.

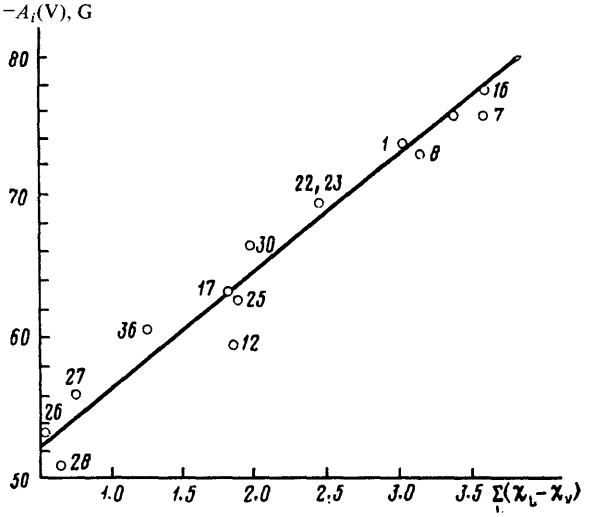


Figure 4. Dependence of the constant A_i(V) for Cp_2V d^1-complexes on the electronegativity of the ligands χ_L (χ is the Pauling electronegativity)[20] (for the significance of the numbering of the circles, see Table 1).

The linear relation between $\sum_L (\chi_V - \chi_L)$ and $|A_i|$ in a series of isostructural (within the limits of the immediate coordination environment of the vanadium atom) d^1-complexes of type (A) permits the conclusion that the HFI A_i(V) constants are additive. This makes it possible, in turn, to identify the ligands bound to vanadium in the complex from its EPR spectrum. As an illustration, Table 3 presents the experimental and calculated A_i(V) for certain mixed complexes

of the type $Cp_2VL_1L_2$; these values agree well with one another. As an example of the application of the rule of the additivity of the $A_i(V)$ for the identification of the Cp_2V d^1-complexes, one may consider the complex $Cp_2V(CN)(NCS)$ described by Morán and Fernandez.[13] The authors assumed that the complex has a structure corresponding to the presence of the isothiocyanato-ligand with a V–N bond. However, the value $|A_i(V)| = 59.43$ for this complex corresponds much better to the thiocyanato-complex $Cp_2V(CN)(SCN)$ with a V–S bond.

Table 3. Experimental isotropic parameters of the EPR spectra of certain Cp_2V d^1-complexes and the spectra calculated assuming additivity.[20]

Complex	g_i^e	$\|A_i(^{51}V)\|^e$	g_i^c	$\|A_i(^{51}V)\|^c$
$Cp_2V(Cl)Me$	1.9900	69.2	1.9898	68.7
$Cp_2V(Cl)CH_2SiMe_3$	1.9900	70.0	1.9896	69.4
$Cp_2V(Cl)SnEt_3$	1.9946	62.0	1.9954	62.2
$Cp_2V(Cl)GeEt_3$	1.9956	66.8	1.9950	64.9
$Cp_2V(CN)(NCS)$	1.9810	59.4	1.9900	66.7
$Cp_2V(CN)(SCN)$	—	—	1.9970	61.4
$Cp_2V(CH_2SiMe_3)SnEt_3$	1.9964	60 8	1.9979	57.5

*The experimental and calculated parameters are designated by the superscripts e and c respectively.

The additivity rule holds also for g_i for type (A) d^1-complexes, but with a lower degree of precision. The explanation is that, apart from the influence of the effective charge on vanadium, which alters the spin–orbit coupling constant, the quantity g_i is acted upon by at least two [sic] further factors: the contribution to g_i by the spin–orbit coupling. Both these factors also change on passing from one ligand to another and, although the overall trend in the variation of g_i is maintained (Fig.2), the overall operation of the three factors enumerated above complicates the character of the dependence of g_i on $\sum_L(\chi_V - \chi_L)$.

On passing from complexes of type (A) to those of types (C) and (D), the quantity $A_i(^{51}V)$ increases in succession and there is also a successive rise in g_i.[20] These changes are particularly clear in the carbon-containing d^1-complexes $Cp_2V(Alk)_2$, $Cp_2V(en)$, $Cp_2V(CO)$. Bearing in mind the negative sign of $A_i(V)$, its increase can be accounted for either by a decrease of spin density in the inner *s* orbitals of the vanadium or by an increase in the positive sign of the contribution of the 4*s* orbital to $A_i(V)$.

The amount of ionic character (covalence) of the V–L bonds can change on replacement of two one-electron ligands by one two-electron ligand with the same coordinating atom (carbon), but it is not possible to estimate it by a simple procedure, as has been done for complexes of type (A). One should only note that the approximation based on the use of the electronegativities of the coordinating atoms lacks significance in the given instance.

The most probable cause of the decrease of $|A_i(^{51}V)|$ on passing from complexes of type (A) to those of type (C) and further to complexes of type (D) may be the increase of the contribution of the 4s orbital to MO_e as a consequence of the mixing of the latter with a MO orbital of the same symmetry in which there is a large contribution by the 4*s* orbital. In the Cp_2V d^1-complexes there exist orbitals with a_1 symmetry, which are involved in the binding of the ligands L to Cp_2V and whose energies are close to that of MO_e. The effectiveness of their mixing with MO_e depends on the energy difference between the orbitals $\phi^e_{a_1}$ and ϕ_{a_1}, which should change following the replacement of ligands. If one takes into account the fact that, according to the results of quantum-chemical calculations[7] for the complex Cp_2VCl_2, the contribution of the 4*s* orbital of vanadium to MO_e is less than 1%, then the observed change in A_i for complexes of type (C) must be due to the increase of this contribution up to 2%, while that for the complexes of type (D) is caused by an increase up to 4%. (The value of A_i in the case of one unpaired electron in the 4*s* orbital of ^{51}V, quoted by Goodman and Raynor,[1] was used to calculate the amount of the admixture of the 4*s* orbital).

3. Hyperfine Interaction with Magnetic Nuclei of the Ligands in the Cp_2V d^1-Complexes

The idea of the transfer of spin density to the ligands in paramagnetic transition metal complexes has long been adopted in coordination chemistry. The fact that hyperfine interaction with the magnetic nuclei of the ligands has been observed by EPR has considerably promoted the development of this concept. Quantum-chemical calculations for the Cp_2V d^1-complexes yield high contributions of the ligands to MO_e. For the p_π orbitals of Cl or SH in Cp_2VCl_2 and $Cp_2V(SH)_2$, the contribution is approximately 22%.[7] However, hyperfine interaction with the magnetic ^{35}Cl and ^{37}Cl nuclei in the EPR spectrum of Cp_2VCl_2 as well as with the ^{79}Br and ^{81}Br nuclei in the Cp_2VBr_2 spectrum has not been observed,[9–12] but in a whole series of other complexes, where L = H, Me, Et, CH_2SiME_3, $SnET_3$, or $HgGe(C_6F_5)_3$ (Table 1), the change in spin density on the ligands has been confirmed experimentally by the presence of a signal due to the hyperfine interaction with the ^1H, ^{117}Sn, ^{119}Sn, ^{199}Hg, and ^{201}Hg nuclei in the EPR spectra. The hyperfine interaction with the ^{31}P and ^{75}As nuclei has been observed[29,30] in type (B) complexes, where the ligands were dialkyl phosphorodithioates and dialkyl arsenodithioates. For complexes of types (C) and (D), hyperfine interaction with the magnetic nuclei of the ligands was not observed. One should note that the additional hyperfine interaction with the magnetic nuclei of the ligands makes it possible to identify Cp_2V d^1-complexes with a high degree of reliability on the basis of their isotropic EPR spectra as a consequence of the highly characteristic nature of the latter. As an example, Fig.5 presents the isotropic EPR spectra of certain Cp_2V d^1-complexes.

The spin densities in the *s* orbitals of the ligands calculated from the experimental HFI constants are 2.9% (H), 2.7% (Me), and 1.9–2.5% ($SnEt_3$). Thus the overall spin density should not exceed 6% in the presence of two such ligands at the vanadium atom. According to the results of quantum-chemical calculations by a number of workers[6,7] for the Cp_2Ti, Cp_2V, Cp_2Cr, and Cp_2MO d^1-complexes, the contribution of the ligand *s* and *p* orbitals to MO_e is very insignificant. When these data are used as the starting point, one may conclude that the principal mechanism of the transfer of spin density to the α-atoms of the σ-bonded ligands is the

spin polarisation of the V–L–σ bonds under the influence of the unpaired electron in the *d* orbitals (the d_{z^2} orbital) of vanadium.

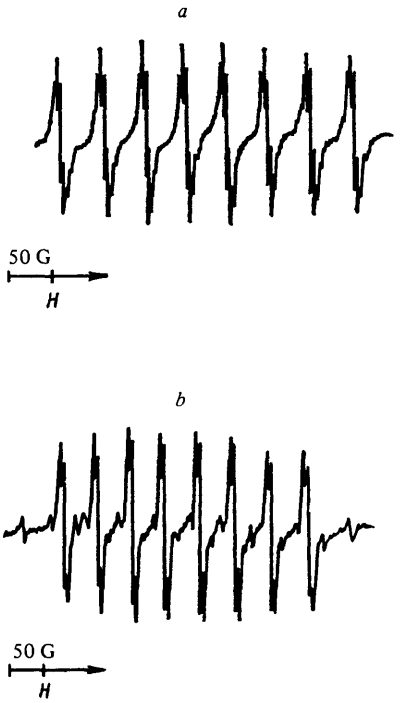

Figure 5. Isotropic EPR spectra of Cp_2V d^1-complexes: *a*) Cp_2VMe_2; *b*) $Cp_2V(CH_2SiMe_3)(SnEt_3)$ (toluene, 25 °C).[23]

In those cases where the α-atom of the ligands have p_π orbitals with a symmetry suitable for interaction with MO_e, a spin density should appear at the nucleus of the ligand atom as a result of the direct interaction between the ligand orbitals and the d_{z^2} orbital of the metal. Since in this case the binding to the metal is also achieved via the p_σ orbitals, the isotropic constant for the hyperfine interaction with the magnetic nuclei of the ligands is determined by the overall spin density of two different *p* orbitals of the ligand: p_π and p_σ. The two contributions have the opposite signs, because the direct delocalisation of the unpaired electron over the ligand leads to the appearance of a positive spin density in the p_π orbital, while spin polarisation induces a negative spin density in the p_σ orbital. An appreciable hyperfine interaction with the ^{35}Cl, ^{37}Cl, ^{79}Br, and ^{81}Br nuclei is absent in the complexes Cp_2VCl_2 and Cp_2VBr_2,[9–12] which indicates a low overall spin density in the *p* orbitals of these ligands, i.e. approximately equal contributions by each mechanism. If it is assumed (and this assumption is fairly valid) that the spin polarisation of the σ-bonds induces approximately equal spin densities in the orbitals (*s* and *p*) involved in the binding regardless of their nature, then it follows from the equality $\rho_{p_\pi} = \rho_{p_\sigma}$ that the overall contribution of the p_π orbitals of the ligands to the MO_e for the Cp_2V d^1-complexes should not exceed 6%. This differs significantly from the calculated data for Cp_2VCl_2 (22%) and Cp_2VS_5 (21%) obtained by Petersen et al.,[7] but agrees with the calculated data for the series of Cp_2V d^1-complexes quoted by Stewart and Porte.[6]

It is noteworthy that hyperfine interaction with the magnetic Cl and Br nuclei has been observed experimentally in the EPR spectra of the isoelectronic cationic complexes Cp_2Mo^+ and Cp_2W^+ and is appreciable: $A(Cl) = 3.1$ G and $A(Br) = 15.0$ and 21.9 G.[40] The spin polarisation contribution should not change significantly on passing from Cp_2V to the Cp_2Mo^+ and Cp_2W^+ complexes and the increase of $A(Cl)$ and $A(Br)$ should therefore be attributed to an increase in the direct contribution of the p_π orbitals of the halogens to MO_e. This conclusion agrees with the results of a calculation[7] indicating an increase in the contribution of the p_π ligand orbitals to MO_e for Cp_2MoCl_2 relative to Cp_2VCl_2.

Spin density can be transferred to the β-atoms of the ligands (the protons of the methyl and methylene groups in alkyl ligands) from the central atom via a mechanism similar to that of hyperconjugation in organic π-radicals.[41] This is indicated by the values of $A(H_\beta)$ which are comparable to $A(H_\alpha)$ for the hydride complex; in the case of the spin polarisation mechanism, the $A(H_\beta)$ must be much smaller, because the spin polarisation rapidly decays with increase of the number of "spin polarised" σ-bonds.

IV. EPR STUDY OF Cp_2V d^1-COMPLEXES IN SOLUTION

The data presented show that there is a close relation between EPR spectroscopic parameters and the structure of the Cp_2V d^1-complexes, which in some cases has a simple significance. This permits the EPR identification of the relatively unstable Cp_2V d^1-complexes formed as intermediates in various reactions and also determination of their structures.

1. Oxidative Addition to Cp_2V ($d^3 \rightarrow d^1$ Reactions)

Oxidative addition is the most typical reaction for Cp_2V. A wide variety of reagents, namely variable-valence metal salts, alkyl halides, chalcogenides, organic disulphides, alkynes, alkenes, and many other compounds interact with Cp_2V to form d^1-complexes (sometimes d^2-complexes). We may note that a large number of Cp_2V d^1-complexes with heterocumulenes have been synthesised and investigated during the last ten years by Floriani and co-workers (see, for example, Pasquali et al.[42]).

One of the first reactions involving oxidative addition to Cp_2V investigated was that with alkyl halides. A study[43] of the interaction of Cp_2V with MeI, EtBr, and $PhCH_2Cl$ led to the conclusion that the reaction proceeds in accordance with the equation

$$2Cp_2V + X-R \rightarrow Cp_2V-R + Cp_2V-X,$$

possibly via the intermediate formation of the extremely unstable complex $Cp_2V\begin{smallmatrix}R\\X\end{smallmatrix}$. Treatment of Cp_2V–R with an excess of R–X for a long time led to the appearance of Cp_2VX and R–R. The authors did not use the EPR method in their investigations, which apparently retarded for more than ten years the synthesis of dialkyl and alkyl halide Cp_2V d^1-complexes. The results of the above study[43] also apparently promoted the firm establishment of the idea that the high lability of such Cp_2V derivatives is due to the steric strain at the central atom.[44]

In reality, as shown[45] by monitoring the reaction of Cp_2V with RX with the aid of EPR, the latter proceeds in a more complex manner (Scheme 1):

Scheme 1

$$Cp_2V\langle^{R}_{R} + Cp_2VX;$$

$$(c)\uparrow Cp_2VR$$

$$Cp_2V + X{-}R \xrightarrow{(a)} Cp_2V\langle^{R}_{X} \xrightarrow[(b)]{Cp_2V} Cp_2V{-}R + Cp_2V{-}X;$$

$$(d)\downarrow$$

$$Cp_2V{-}X + [\dot{R}].$$

The first stage of the reaction is the synchronous oxidative addition of a molecule of RX to Cp_2V with formation of the alkyl halide d^1-complex $Cp_2V\langle^{R}_{X}$, which is stable. The difficulty of detecting it in solution by traditional methods is due to the reaction conditions and not to its increased lability. The presence in solution of Cp_2V, with which $Cp_2V\langle^{R}_{X}$ reacts very rapidly yielding Cp_2VR and Cp_2VX, is the main cause of the extremely low stationary concentration of $Cp_2V\langle^{R}_{X}$.[45] Under specially selected conditions, all the stages of the reaction can be realised separately. Thus slow dropwise addition at reduced temperatures (between -30° and -50 °C) of a solution of Cp_2V to a solution of RX taken in a large excess (more than 100-fold) makes it possible to reduce significantly the rate of the second stage (*b*) and promotes a steady detection of $Cp_2V\langle^{R}_{X}$ in solution by EPR.

We may note that, when alkyl iodides (MeI and Me_3SiCH_2I) are employed under the usual conditions, the interaction of Cp_2V with RX in stoichiometric proportions leads to the formation of appreciable amounts of the dialkyl complex Cp_2VR, which can be unambiguously identified from the EPR spectrum. It has been established, also by EPR, that it is formed as a result of the interaction of $Cp_2V\langle^{R}_{X}$ with Cp_2VR [stage (*c*)], accumulating in solution in the course of the reaction. The observation of this reaction made it possible to develop a new method of synthesis of dialkyl Cp_2V d^1-complexes, previously difficult to obtain, using Cp_2V and an alkyl halide as the starting materials.[45]

Another example of oxidative addition to Cp_2V, the understanding of the detailed mechanism of which would be impossible without the application of the EPR method, is provided by the interaction of Cp_2V with organic and organoelemental derivatives of cadmium and mercury. As early as 1975, it was shown[46] that the reaction of Cp_2V with $Cd(GeR_3)_2$ leads to the formation of Cp_2VGeR_3. The reaction mechanisms were assumed to involve the insertion of Cp_2V in the Cd–Ge bond (which is equivalent to oxidative addition to Cp_2V) with subsequent elimination of metallic cadmium and GeR_3. In a study[16] of the interaction of Cp_2V with $CdMe_2$, $CdEt_2$, $Cd(CH_2Ph)_2$, and $CdPh_2$ by EPR, the formation of Cp_2V d^1-complexes of the type Cp_2VR_2 was recorded. One of the complexes, namely dimethylvanadocene Cp_2VMe_2, was isolated in a crystalline form and thus proved to be the first reliably demonstrated dialkyl Cp_2V d^1-complex. Together with the data of Razuvaev et al.,[46] the results of this study led to the establishment of a scheme for the interaction of Cp_2V with organic and organoelemental derivatives of cadmium (Scheme 2):

Scheme 2

$$Cp_2V + X{-}Cd{-}X \rightarrow \left[Cp_2V\langle^{CdX}_{X}\right] \begin{cases} \rightarrow Cp_2V{-}X + Cd + [\dot{X}]; \\ \rightarrow Cp_2V\langle^{X}_{X} + Cd. \end{cases}$$

The primary product, a d^1-complex with a V–Cd bond, is merely a tentative intermediate in the above scheme. The final proof of the mechanism illustrated in Scheme 2 has been obtained recently[24] in a study of the reaction of Cp_2V with $Hg[Ge(C_6F_5)_3]_2$. As in the case of the reaction with Cp_2VGeR_3, the final product in this instance is the d^2-complex $Cp_2VGe(C_6F_5)_3$. A d^1-complex, which is a product of the oxidative addition of the organobimetallic derivative to Cp_2V, was detected by EPR in the course of the reaction. The presence of the mercury-containing substituent in this complex follows unambiguously from the analysis of the hyperfine structure of the EPR spectrum, which contains "satellite" components due to the interaction of the unpaired electron with magnetic Hg isotopes (Fig. 6).

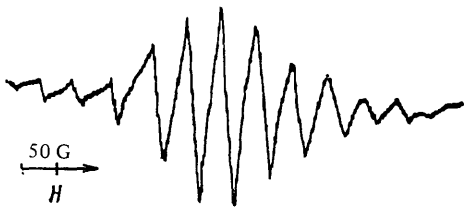

Figure 6. Isotropic EPR spectrum of $Cp_2V[Ge(C_6F_5)_3]$. $.HgGe(C_6F_5)_3$ (toluene, 10 °C).[24]

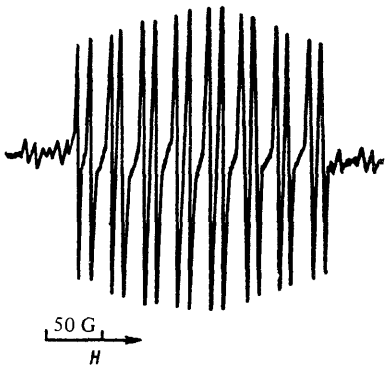

Figure 7. Isotropic EPR spectrum of $Cp_2V(H)SnEt_3$ (toluene, 25 °C).[23]

The first hydride d^1-complex $Cp_2V{-}Cp_2V(H)SnEt_3$, obtained as an intermediate in the reaction of Cp_2V with $HSnEt_3$, was detected by EPR.[23] The parameters of the observed EPR spectrum (Fig. 7) [g_i = 2.0007; $A_i(V)$ = -41.6 G; A_H = 14.6 G; A_{Sn} = 143 G] define unambiguously

the composition of the complex. Judging from the parameters of the anisotropic EPR spectrum, its structure is unusual for d^1-complexes with two η^1-ligands. The principal components of the $\bar{g}$ and $\bar{T}$ tensors of this complex differ appreciably from values typical for type (A) d^1-complexes and are close to the corresponding parameters of the type (C) d^1-complexes.

As mentioned above (in Section III), there is a relation between the spectroscopic parameters of the Cp_2V d^1-complexes and the structure, in particular the L–V–L valence angle. The d^1-complexes of type (C) usually differ from the d^1-complexes of type (A) by significantly smaller L–V–L valence angles. Judging from the EPR parameters, the compound $Cp_2V(H)SnEt_2$ should also differ in its structure from the usual d^1-complexes with two one-electron ligands, having a reduced L–V–L valence angle. This may be caused by the formation of an intramolecular bridging hydride bond H...Sn. The conclusions concerning the structure of the complex $Cp_2V(H)SnEt_3$, derived from the analysis of the spectroscopic data, cannot be tested by X-ray diffraction, since the complex investigated cannot be isolated from the reaction medium. However, a similar intramolecular hydride bond, leading to a decrease of the H–Nb–Sn valence angle to 58°, has been recently observed in a study of the complex $(Cp_2NbH)_2SnClEt$ by X-ray diffraction.[47]

In the presence of $HSnEt_3$ the hydride Cp_2V d^1-complex is converted, as shown by EPR, into a new d^1-complex containing two $SnEt_3$ groups, namely $Cp_2V(SnEt_3)$. This is indicated by the hyperfine structure of the EPR spectrum, corresponding to the interaction of the unpaired electron with the two equivalent tin nuclei.[23] The complex $Cp_2V.(SnEt_3)_2$ is also unstable and is converted after a time into Cp_2VSnEt_3 and hexaethyldistannane.[23]

The reaction of Cp_2V with $HSnEt_3$, investigated by EPR, is also of interest, because its mechanism may be similar in many details to the mechanism of the reaction of Cp_2V with alkanes (activation of C–H bonds[48]). Intermediates, with a structure analogous to that of the hydride complex $Cp_2V(H).SnEt_3$, have been postulated[48] in the reaction

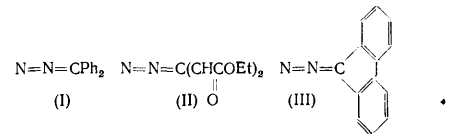
$$Cp_2V + CH_4 \rightarrow Cp_2V\begin{matrix}H\\Me\end{matrix}.$$

The existence of the fairly stable complex $Cp_2V(H)SnEt_3$ makes this hypothesis quite probable. We may note that the reaction of Cp_2V with $HSiCl_3$ described by Cardoso et al.,[49] which leads to the formation of a d^1-complex, can also proceed via the intermediate formation of a hydride silyl d^1-complex.

As already mentioned, the carbene-like properties of Cp^2V are very strikingly manifested in reactions with various substrates containing double and triple bonds. Many d^1-complexes of this type have been isolated in a pure state and their structures have been determined by X-ray diffraction. In all cases where the structure and EPR parameters of the complexes are known, complete agreement between them has been found. On the other hand, in certain EPR investigations of Cp_2V d^1-complexes the conclusions reached concerning the structure of the complexes are not entirely correct. Some of these controversial conclusions are discussed below.

It has been demonstrated convincingly[50] that the conclusions reached in an earlier investigation[51] of the structure of Cp_2V were based on an erroneous experiment. The isotropic EPR spectrum with $g_i = 2.00$ and $A_i(^{51}V) = 27.4$ G observed by the authors,[51] could not have been due to Cp_2V and must have been caused by the presence of an impurity. However, Prins[50] was also unable to assign the given spectrum to any one complex. On the basis of the conclusions reached in the present review, one may decide that the impurity signal, erroneously attributed to Cp_2V, referred to the Cp_2V d^1-complex of type (C) containing a two-electron η^2-ligand. It is difficult to arrive at conclusions about the nature of this ligand, since the experimental conditions are not fully known; it is quite likely that it might have been a carbene or a carbene-like ligand.

In considering reactions involving the oxidative addition of neutral ligands to Cp_2V one must deal with the study[35] of the interaction of Cp_2V with substituted diazomethanes:

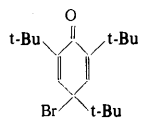


(I) (II) (III)

Depending on the diazomethane employed, EPR spectra of two types were observed: a spectrum with $g_i = 1.9918$ and $A_i(^{51}V) = 23$ G for (I) and one with $g_i = 1.9942$ (II) and 1.9953 (III) and $A_i(V) = 41$ G for (II) and (III). Despite the difference between the parameters, the authors[35] assigned the observed EPR spectra to g^1-complexes of one type, explaining the difference indicated in the spectra by the different degrees of delocalisation of the unpaired electron over the ligand. However, as shown above (Section II), the nature of the ligand in Cp_2V d^1-complexes of types (C) and (D) does not influence their EPR parameters to such a great extent (particularly as regards A_i). The observed difference between the constants $A_i(V)$ therefore requires a different explanation. The most natural cause of the difference between the EPR spectra is, in our view, the fact that they arise from complexes of different types. Judging from the value of $A_i(V)$, compound (I) is a type (D) d^1-complex with a two-electron η^1-ligand. Compounds (II) and (III) are type (C) d^1-complexes with a two-electron η^2-ligand.

2. Oxidation Reactions of Cp_2V d^2-Complexes ($d^2 \rightarrow d^1$ Reactions

The EPR method has been used particularly successfully in the study of reactions of the type $d^2 \rightarrow d^1$, namely reactions involving the oxidation of Cp_2V d^2-complexes. Compounds of the type Cp_2VX, where X = Cl, Br, alkyl, GeR_3, SnR_3, etc., are readily oxidised to Cp_2V d^1-complexes by various halogen-containing reagents, both inorganic and organic. The formal oxidation state of vanadium then increases from +3 to +4. The oxidation of Cp_2VCl, Cp_2VBr, Cp_2VMe, $Cp_2VCH_2SiMe_3$, Cp_2VGeEt_3, Cp_2VSnEt_3, and other Cp_2V d^2-complexes by reagents such as Ph_3CCl,

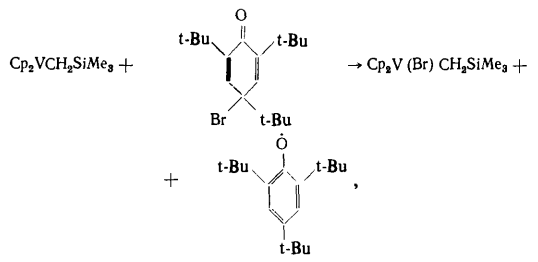


CuCl, $CuCl_2$, AgCl, AgBr, and Cp_2VCl_2 with formation of the corresponding Cp_2V d^1-complexes has been investigated[12,18,23] by EPR:

$$Cp_2VCl + Ph_3CCl \rightarrow Cp_2VCl_2 + Ph_3\dot{C}, \quad (4)$$

$$Cp_2VBr + CuCl \rightarrow Cp_2VBrCl + Cu, \quad (5)$$

$$Cp_2VMe + AgCl \rightarrow Cp_2V(Cl)Me + Ag, \quad (6)$$

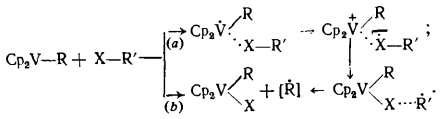


(7)

$$Cp_2VGeEt_3 + Cp_2VCl_2 \rightarrow Cp_2V(Cl)GeEt_3 + Cp_2VCl. \quad (8)$$

The occurrence of reactions (4) and (7), in which the oxidant is reduced to an organic free radical, clearly indicates a one-electron mechanism of the oxidation reaction. The oxidation-reduction reaction via a mechanism involving inner-sphere (bridge-type) one-electron transfer (with transfer of the bridging ligand) appears to be the most likely. This mechanism is formally equivalent to the transfer of a halogen atom [Scheme 3, pathway (*b*)].

Scheme 3



Reactions (4)–(8) indicate a high "affinity" of the Cp_2V d^2-complexes for one-electron reagents; free radicals may also be included among them. Hitherto there has been virtually no information in the literature about the reactions of Cp_2V d^2-complexes with free radicals. An exception is the study of Morán and Gayoso,[14] who showed that nitric oxide (NO), which is a stable radical, reacts with Cp_2VCl and Cp_2VBr, forming the d^1-complexes $Cp_2V(Cl)NO$ and $Cp_2V(Br)NO$ respectively. The study of the interaction of the Cp_2V d^2-complexes with free radicals is of undoubted interest, since reactions of this kind have been little investigated.

The oxidation-reduction reactions between Cp_2V d^2- and d^1-complexes, for example reaction (8), occupy a special place among the $d^2 \rightarrow d^1$ reactions. The complex Cp_2VCl_2 can also oxidise monoalkyl derivatives of the type Cp_2VR.[18] The mechanism of these reactions is evidently similar to that illustrated in Scheme 3. Mixed alkyl halide Cp_2V d^1-complexes can also participate in the oxidation-reduction $d^2 \rightarrow d^1$ reactions as oxidants. For example, $Cp_2V(Cl)Me$ can oxidise Cp_2VGeEt_3 and Cp_2VSnEt_3 to the corresponding d^1-complexes, being reduced at the same time to Cp_2VMe:[23]

$$Cp_2V\begin{matrix}Me\\Cl\end{matrix} + Cp_2V{-}R' \rightarrow Cp_2V{-}Me + Cp_2V\begin{matrix}R'\\Cl\end{matrix}. \quad (9)$$

The reaction between Cp_2V and alkyl halide d^1-complexes and alkyl d^2-complexes, which results in the formation of dialkyl d^1-complexes and monohalide d^2-complexes, proceeds differently:[18]

$$Cp_2V\begin{matrix}Cl\\R\end{matrix} + Cp_2V{-}R' \rightarrow Cp_2V\begin{matrix}R'\\R\end{matrix} + Cp_2VCl. \quad (10)$$

In terms of its formal features, reaction (10) is an exchange reaction in which the halogen in the d^1-complex is replaced by an alkyl group. However, its mechanism is evidently more complex and requires additional study.

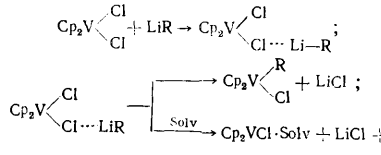
Investigation of reactions (4)–(10) by EPR showed that they are in many instances quantitative and can be used as preparative methods for the synthesis of mixed alkyl halide and dialkyl Cp_2V d^1-complex.[18] In the EPR variant, reactions of the type $d^2 \rightarrow d^1$ can be used as tests for the detection of Cp_2V d^2-complexes in solution. In particular, the formation of $Cp_2VGe(C_6F_5)_3$ and Cp_2VGePh_3 in the reactions of Cp_2V with $Hg[Ge(C_6F_5)_3]_2$ and $Hg(GePh_3)_2$ has been demonstrated in this way.[24]

3. Cp_2 d^1-Complexes in Exchange Reactions ($d^1 \rightarrow d^1$ Reactions)

The reactions of Cp_2VCl_2 with organometallic compounds, in particular with lithium, cadmium and aluminium compounds, have been most thoroughly investigated among processes of the type $d^1 \rightarrow d^1$ studied by EPR. Attempts to employ organolithium compounds for the synthesis of dialkyl complexes in solvating solvents have been frequently undertaken by various groups of investigators,[52] but they all gave a negative result—the reaction products were Cp_2V d^2-complexes, i.e. Cp_2VCl was reduced by LiR. These data served as a basis for the idea that the dialkyl Cp_2V d^1-complexes are unstable due to the steric hindrance around the central atom.[44]

The synthesis of Cp_2VMe_2, Cp_2VEt_2, and $Cp_2V(CH_2Ph)_2$ by the reaction of Cp_2V with organocadmium compounds showed that this concept is erroneous, after which Cp_2VMe_2 was also obtained by the exchange reaction from Cp_2VCl_2 and MeLi but in toluene instead of tetrahydrofuran.[53] There is no explanation in the literature of this type of strong dependence of the reaction pathway on the nature of the solvent. We believe that the main cause may be the influence of the solvating solvent on the intermediate complex formed in the first reaction stage (see Scheme 4).

Scheme 4



A second pathway, involving the oxidation-reduction reaction leading to the reduction of Cp_2VCl_2 to Cp_2VCl, competes in the presence of a solvating solvent, for example THF, with the "normal" pathway corresponding to the formal substitution of Cl^- by R^-. The solvation of the vanadium atom in the resulting d^2-complex by the solvent, which undoubtedly enters into the composition of the outer coordination sphere also of the initial compound Cp_2VCl_2, should play an important role in this process. Use of non-solvating solvents (for example toluene, as in the study of Foust and Rausch[53]) promotes the "normal" course of reaction.

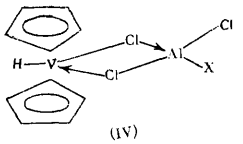
The OMC of cadmium and aluminium are also capable of interacting with Cp_2VCl_2, forming exchange products. The reaction of Cp_2VCl_2 with Et_2AlCl and other aluminium OMC has been studied in greatest detail. The EPR spectrum of the dialkyl vanadocene derivative has in fact been observed for the first time in one of these reactions. This concerns an EPR study[54] of a catalytic system based on Cp_2VCl_2 and an organoaluminium compound in which EPR spectra with a parameter $g_i = 1.992$ and $A_i \cong 62$ G, which evidently refer, as is now evident, to Cp_2VMe_2 and Cp_2VEt_2, were recorded. These products are obtained following the complete ligand exchange between Cp_2VCl_2 and the organoaluminium compound:

$$Cp_2VCl_2 + 2R_2AlCl \rightarrow Cp_2VR_2 + RAlCl_2 \quad (11)$$

Mixed alkyl halide Cp_2V d^1-complexes are also formed in such

reactions after the replacement of one halogen atom by an alkyl group.

A study of the reaction of Cp_2VCl_2 with Et_2AlCl led[54] to the observation of yet another unidentified EPR spectrum with the parameters $g_i = 1.997$ and $A_i = -39.5$ G. The same signal was later recorded in another study.[55] Having investigated in detail the isotropic and anisotropic EPR spectra, the authors[55] concluded that the EPR spectrum refers to a hydrido Cp_2V complex having the following structure:



(IV)

This hypothesis of such an unusual structure with parallel cyclopentadienyl rings is based on the "anomalous", from the authors' points of view,[55] parameters of the EPR spectrum of this complex compared with other Cp_2V d^1-complexes ($Cp_2.VCl_2$ and Cp_2VR_2). The disappearance of the isotropic EPR spectrum of the complex (IV) on treatment with THF or pyridine and the appearance of a new EPR spectrum with the parameters $g_i = 1.988$ and $A_i(^{51}V) = 70.3$ G was explained[55] by the conversion of compound (IV) into the hydrochloride d^1-complex $Cp_2V(H)Cl$ and was also regarded as evidence in support of the structure (IV), which the authors proposed. Treatment of a solution containing $Cp_2V(H)Cl$ with HCl led to the appearance of the spectrum of Cp_2VCl_2, while treatment with Et_2AlCl led to the spectrum of Cp_2VEt_2.

Comparison of the spectroscopic parameters quoted by Evans et al.[55] and the corresponding parameters of the EPR spectra of d^1-complexes of type (C) (with one two-electron η^2-ligand) and the known hydride Cp_2V and Cp_2Nb d^1-complexes, as well as the analysis of the chemical behaviour of the complexes showed that the interpretation of the two EPR spectra observed initially was erroneous.

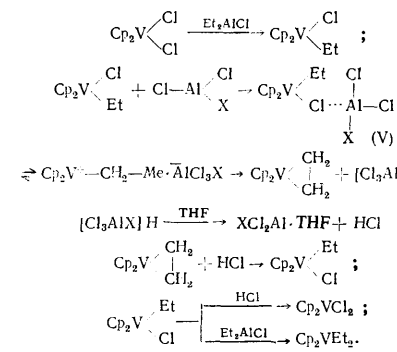
In the first place, in terms of their isotropic and anisotropic parameters [$g_i = 1.996$, $A_i(V) = -41.1$ G, $g_x = 2.001$, $g_y = 1.987$, $g_z = 2.000$, $T_x = -63.7$ G, $T_y = -70.5$ G, and $T_z = +1.09$ G], the primary EPR spectrum corresponds most closely to a Cp_2V d^1-complex with a two-electron η^2-ligand. Furthermore, one can assume that in the complex (IV) the hyperfine interaction with the hydrogen atom is weak and is therefore not manifested in the EPR spectrum (complexes of this type are unknown). As regards the complex $Cp_2V(H)Cl$, the absence from its spectrum of evidence for its hyperfine interaction with the ^1H nucleus is difficult to account for, since the $A(H)$ constants for the EPR spectra of other similar complexes [$Cp_2V(H)SnEt_3$ [23] and $Cp_2Nb(H)Cl$ [56]] are fairly large (>10 G) and the corresponding hyperfine structure should have been observed.

The absence of such hyperfine structure in the EPR spectra indicates an incorrect interpretation of the latter. The parameters of this spectrum correspond exactly to those of the spectrum of the known $Cp_2V(Cl)Et$ d^1-complex within the limits of the error of the measurement.

The new interpretation of the EPR spectra observed in the reaction of Cp_2VCl_2 with Et_2AlCl leads to a different mechanism for this reaction (Scheme 5), which differs from that proposed by Evans et al.[55]

The interaction of the reactants in the first stage of the reaction (the presence of small amounts of Et_2AlCl) leads to the replacement of one chlorine atom at the vanadium atom by the ethyl group with formation of the complex $Cp_2V(Cl)Et$, which can exist in solution both in a free state and in the form of a complex with an $XAlCl_2$ molecule. (The ability of Cp_2VCl_2 to form complexes with $AlCl_3$ is known[54]). An analogous complex, consisting of the reaction products, is formed on interaction of Cp_2VCl_2 with $Cd(GeR_3)_2$.[57] It is noteworthy that in solution $Cp_2V(Cl)GeR_3$ and its complex $Cp_2V(Cl)GeR_3.Cd(Cl)GeR_3$ are spectroscopically indistinguishable. Under the reaction conditions (with a hexane–CH_2Cl_2 mixture as the solvent), the complex (V) undergoes partial dissociation; proton transfer from $Cp_2V^+-CH_2-Me$ to $AlCl_3X^-$, which is evidently a stronger Lewis base than the ethylene complex formed, completes the process. In our view the "anomalous" EPR spectrum is in fact due to the ethylene Cp_2V d^1-complex.

Scheme 5



Under the influence of THF and the solution, the hydrogen chloride bound in the complex is liberated and reacts with the ethylene complex, converting it into $Cp_2V(Cl)Et$. Subsequent treatment with HCl converts $Cp_2V(Cl)Et$ into Cp_2VCl_2, while on interaction with Et_2AlCl alkylation proceeds further with formation of Cp_2VEt_2. The proposed mechanism undoubtedly requires special experimental confirmation, but it is much more consistent with the EPR data.[54,55] The results of a study[58] in which analogous reactions were observed between Cp_2MoCl_2 and Et_2AlCl may serve as its indirect confirmation.

Yet another interesting variety of $d^1 \rightarrow d^1$ reactions has been discovered[23] by EPR in a study of the interaction of Cp_2VEt_2 and $Cp_2V(CH_2SiMe_3)_2$ with $HSnEt_3$. This interaction leads to the formation of mixed d^1-complexes of the type $Cp_2V(R)SnEt_3$ under mild conditions. The second alkyl group is also not substituted under more severe conditions (−20 °C)—up to the decomposition temperatures of the initial dialkyl complexes. The mechanism of this reaction is still obscure and requires further study.

- - - o 0 o - - -

In conclusion one should note that the EPR method will undoubtedly prove useful in the study of the structures of new Cp_2V d^1-complexes, whose chemistry is at present developing vigorously. Thus, much interesting information can be obtained from the study of the reactions, mentioned in this review, of Cp_2V with heterocumulenes which are coordinated to vanadium and in many cases undergo a series of consecutive reactions of the type $d^1 \rightarrow d^1$. Another interesting aspect of the chemistry of Cp_2V, involving reactions with unsaturated compounds containing Si=C, Si=Si, and Ge=Ge bonds, has so far been almost completely uninvestigated. It is to be expected that the high reactivity of Cp_2V with respect to multiple bonds will lead in this instance to the formation of complexes of type (C) with η^2-coordinated two-electron ligands, whose structure can be determined from the EPR parameters.

In the methodological sense, the conclusions reached in this review concerning the relation between the EPR parameters of the Cp_2V d^1-complexes and their structure can also be used in the study of the d^1-complexes of other transition metals (Ti, Zr, Hf, Nb, Ta, Mo, and W).

The Stability of Organometallic Compounds During Their Synthesis and Decomposition

G.A.Domrachev, L.N.Zakharov, and Yu.A.Shevelev

Various aspects of the stability of organometallic compounds on the basis of the concept of the stability and structure of material systems are considered. The energy and steric factors in stability are discussed.
The bibliography includes 127 references.

I. INTRODUCTION

The problem of the stability of organometallic compounds (OMC) arose during the dawn of the development of organometallic chemistry as a specific problem in the synthesis of OMC of non-transition[1] and transition[2] metals. A large number of thermally stable organoelemental compounds have been obtained with non-transition metals and non-metals. As regards transition metals, stable compounds have been obtained only in studies on the synthesis of polyaryl derivatives of chromium,[3] molybdenum,[4] and tungsten.[5] However, owing to the difficulty of the synthesis, further studies on these compounds were not performed up to 1954–1955. During these years polyphenylchromium compounds were again synthesised, their reductive decomposition was investigated, and their sandwich structure was confirmed.[6]

During the 1940s–1950s, the view arose that fully alkylated OMC of *d* and *f* elements are unstable and involatile on the basis of Nesmeyanov's,[7] Cotton's,[2] and Jaffé's[8] generalisations (the Mendeleev–Grosse–Nesmeyanov rule). Since the discovery[9] of biscyclopentadienyliron Cp_2Fe, having the sandwich structure, aromatic character, and a high stability (thermal, oxidative, etc.) the problem of the stability of OMC, particularly those of transition metals, has undergone a new development. Stable and volatile OMC of transition metals with many-centre bonds, the so-called polyhapto-(η^n)-derivatives of π-electron ligands and metals were synthesised.

At approximately the same time, Chatt's concept[10] of the stability of transition metal OMC containing a two-centre two-electron σ-bond with an alkyl or aryl ligand and having an electron shell of the next inert gas in Mendeleev's Table, built up by the electrons of electron-donating ligands (phosphines, etc.), was published. These views were confirmed by a series of experimental studies designed to synthesise σ-derivatives of platinum, palladium, and other metals.[11] Somewhat later, after the publication of the communications by Ziegler and Natta on the catalysis of the polymerisation of olefins,[12] experimental studies on the synthesis of alkyl (methyl, ethyl, etc.) derivatives of transition metals (titanium, chromium, manganese, etc.[11]) were published. Various investigators explained the low thermal stabilities of these compounds either in terms of thermodynamic or kinetic instability.

In their investigations of the problem of the kinetic stabilisation of σ-derivatives of transition metals, Wilkinson,[13] and Lappert and co-workers[14] achieved considerable successes in the synthesis of thermally stable OMC using bulky sterically hindered alkyl groups without C–H bonds in the β-position (in order to prevent the olefin-hydride decomposition of the OMC).

The problem of the stability of non-transition metal OMC has not arisen in quite such an acute form as for transition metals with the exception of the question of the stability of extravalence compounds, such as the pentacovalent derivatives of Group VA elements, and the question of the possibility of the olefin-hydride decomposition of OMC, for example, those of aluminium.

Studies on the radical decomposition *in vacuo* of lead, tin, and other metal alkyls,[15] on the photodecomposition in the gas phase of lead, mercury, and other metal alkyls,[16] and on the thermal reactions of alkyl and phenyl compounds of mercury, lead, tin in the condensed phase under hydrogen pressure in the presence and absence of catalysts, which have been described by Razuvaev,[17] may be regarded as some of the first investigations designed to determine the stability of non-transition metal OMC not as regards the possibility of their synthesis in principle but as regards the pathways and ease of decomposition of the OMC. Subsequently these studies were extended to the thermal and photochemical reactions of non-transition metal OMC in solution[18] and their aim became the demonstration of the formation of free radicals and their involvement in the reactions.[19]

In recent years the problem of the stability of OMC in relation to various decomposition processes arose anew in connection with the practical employment of OMC—for the preparation in the course of their decomposition of inorganic coatings and materials,[20,21] for the preparation of gaseous metals from OMC as active substances in gas lasers,[22,23] and also in connection with the extensive possibilities of the new methods of synthesis of OMC (the direct synthesis of OMC by the cocondensation of metal vapours with organic compounds,[24,25] the electrochemical synthesis of OMC,[26] the

radiation-chemical synthesis of OMC,[27] the plasma-chemical synthesis[28] and decomposition[29] of OMC in the gas phase). The application of these methods is frequently complicated by the instability of the OMC under the conditions of their synthesis or use, which gives rise to the necessity for the determination of the stability of OMC in various processes and under various conditions.

In the chemical literature there is no single combined approach to the problem of the stability of OMC. The authors only partially discussed the thermodynamic or kinetic aspect, the quantum-chemical aspect of the stability of OMC was considered in isolation from the former, and there have been virtually no studies on the stability of OMC under real non-equilibrium conditions in the presence of mass and energy fluxes. The aim of the present review is to consider critically, from a single standpoint, the concept of the stability of an isolated OMC molecule and also of systems incorporating OMC and their decomposition products in various states of aggregation, the energy and steric factors in the stability of OMC, and their manifestations under various conditions. Different aspects of the stability of OMC in the OMC synthetic and decomposition processes occurring under the following conditions are considered: thermal reactions involving uncharged (neutral) OMC species and the decomposition products; electron impact under the influence of an electric current with participation of charged (ionised) species; the effect of electromagnetic radiation with different energies and intensities (including laser radiation).

1. The Concept of the Stability of OMC

The concept of the stability of the state of a material system in time and space is fundamental. Its essential feature for a system of atoms or molecules having a definite order in space is the ability of the system to exist, subject to the influence of internal and external forces, in an equilibrium which corresponds to a definite energy level and their ability to return to a state of equilibrium after any kind of perturbation. The stability of the system in relation to various perturbations is almost always different and depends on the nature and character of the perturbations. When the latter is not specified, the stability of the system in relation to any perturbations is implied.

The set of stable bonds in a system of atoms and molecules ensuring the integrity and identity of the system itself in space and in time, constitutes the concept of the structure of the system. Hence the stability of the structure of a system is a characteristic of the stability of the system as a whole.

The stability of the structure of OMC is determined by two factors—energy and steric factors. The state of the system, for example an OMC molecule, is described by the solution of the Schroedinger equation, in which the eigenvalues of the energy (the energy factor) and the coordinate-temporal wave eigenfunctions (the steric factor) play equivalent roles. The eigenvalues of the energy and the steric localisation—delocalisation of the wave functions of the molecule can help to explain the energy and steric-specific features of the stability of OMC (for stationary time-independent solutions). Accordingly, in the analysis of the stability of OMC it is useful to consider in succession the energy and steric OMC stability factors in relation to various types of perturbations of the system or in relation to various types of OMC synthetic and decomposition reactions, in particular, the relation between the structure of OMC (the molecular structure, the structure of the condensed state) and stability and its influence on the reaction mechanism.

It is possible to differentiate four general aspects of the study of the stability of OMC, covering the molecular and electronic structures of OMC, all possible states of aggregation of OMC, their dynamics, and their interaction with fluxes (energy and mass fluxes): (1) the stability of an isolated OMC molecule (quantum-chemical stability); (2) the stability of systems incorporating OMC and their decomposition products in definite states of aggregation and at equilibrium (thermodynamic stability); (3) the dynamic stability of thermodynamically reversible systems incorporating OMC and their decomposition products in definite states of aggregation at equilibrium and in the vicinity of equilibrium and the rate of approach to equilibrium by the system (kinetic stability); (4) dynamic stability of thermodynamically irreversible systems consisting of OMC and their decomposition products in definite states of aggregation in the presence of mass and energy fluxes both near and far from thermodynamic equilibrium (the formation and stability of dissipative structures, macrokinetic aspect).

The first two aspects refer to the description of systems having a time-independent spatial structure, while the second two characterise the stability of systems with a time-dependent spatial-temporal structure.

II. QUANTUM-CHEMICAL STABILITY

We shall consider the quantum-chemical stability of OMC, concentrating attention initially on the energy factor (the stability of the electronic structure of the OMC molecule) and on the steric factor (the stability of the molecular structure of the OMC) and also on the description of the possible states of OMC with the aid of potential energy surfaces, the description including both factors. In conclusion we shall discuss the main types of possible perturbations of the OMC molecule which determine its stability.

The main criterion of the possible existence of an isolated OMC molecule (*in vacuo*) is the quantum-chemical stability. A quantum-chemical estimation of the stability of the OMC molecule presupposes the consideration of electron shell stability (the electronic configuration, structure) of the molecule relative to the stability of the electron shells of isolated molecules (species) of the decomposition products considered in valence states. Overall, the quantum-chemical stability of OMC is determined,[30] firstly, by the electronic configuration (structure), of the OMC molecule, i.e. the distribution of electrons among the bonding, non-bonding, and antibonding MO; secondly, the binding energy in each MO, i.e. the decrease of the energy of the bonding MO relative to the energy of the constituent orbitals of the isolated fragments; thirdly, the non-bonding interactions (usually repulsive), which characterise the steric hindrance in the OMC molecule and determine its steric structure.

There exist a series of theoretical and empirical criteria of electron shell stability in OMC and their molecules, characterising their quantum-chemical stability. For the majority of ions of the elements in the Periodic System, metal carbonyls, and the OMC of non-transition and transition metals, there exists a rule which states that a closed electron shell is stable. For compounds having a central atom of an element, the most stable (closed) electron shell is that which attains the electronic structure of the shell of the next inert gas in Mendeleev's Table by employing electrons of all the ligands involved in the bonds with the element (the extension of Sidgwick's rule[31] to ions). The most stable compounds are formed precisely in conformity with the "inert gas rule" (for example, ferrocene, dibenzenechromium, virtually all the

transition metal carbonyls, especially mixed cyclopentadienyl- or arene-metal carbonyls, etc.), although there exist many exceptions to this rule. The inert gas rule is the overall consequence of Hund's rule,[32] which states that unoccupied, half-occupied, and wholly occupied subshells are stable (the *s*, *p*, *d*, and *f* shells).

In organic complexes of metals and in OMC molecules this stability criterion leads to the stabilisation of both low-spin and high-spin states, for example, in $(C_5H_5)_2Mn$ stabilisation of the configuration with maximum spin (five unpaired electrons) is energetically favourable, whereas in ferrocene as well as in the ferrocenium cation, which is isoelectronic with manganocene, stabilisation of the low spin configuration is observed.

A special case of the overall effect of the stabilisation of the electronic structures of derivatives of non-transition elements is the octet rule (involving the s^2p^6 electronic configuration).[30]

Mendeleev's remark, contained in the early editions of "Principles of Chemistry" (up to the eighth),[33] namely that only the elements in the odd series are capable of forming organometallic compounds and that, when an element forms a hydrogen compound EH_x, it also forms organometallic compounds ER_x, constitutes one of the first formulations of the OMC stability rules. Grosse[34] assumed that only the elements whose valence electrons are located in levels with the same principal quantum number, i.e. non-transition elements, give rise to typical alkyl compounds.

On the basis of a survey of extensive experimental data, Nesmeyanov[7] formulated the following rule: "alkyl groups are bound fairly stably to an element only via *sp*-valence levels. The presence in the atoms of even unused *d* or *f* valence electrons cause a sharp weakening of the stability of the resulting alkyl derivatives, renders them atypical and involatile, and altogether prevents their existence". In his generalisations,[7,35] Nesmeyanov discussed the thermal instability and stability of OMC, which he estimated either on the basis of the possibility of the existence of compounds at room temperature or at the decomposition temperature.

The Mendeleev–Grosse–Nesmeyanov rule has received a theoretical quantum-chemical justification in Jaffé's studies.[8] According to Jaffé, the M–C σ-bonds are weaker for transition metals than for all the principal elements and their strength increases with increasing *s* character of the hybrid carbon orbitals of the group linked to the metal: sp^3 (alkyls) < sp^2 (aryls) < *sp* (acetylides). When aryl groups are bound to transition metals, there is a possibility of additional strengthening of the bond and there is also the formation of π-bonds, both donor–acceptor Ar → M bonds of the types $2p_\pi \rightarrow np_\pi$ and $2p_\pi \rightarrow (n-1)d_\pi$ (for transition metals) or $2p_\pi \rightarrow nd_\pi$ (for non-transition elements), and dative M → Ar bonds (via the pairs of electrons of the d_π orbitals of the metal). In the experimental studies of Chatt and co-workers[10] on the stability of organic derivatives of Group VIII metals it was established that the OMC is stable in relation to thermal dissociation when all the bonding MO are populated by pairs of electrons, for example, the electrons of phosphine, amine, or carbonyl ligands. In this case the carbon-transition metal σ-bond is stabilised and there is a possibility of isolating stable OMC, for example, $CH_3Mn(CO)_5$, $Alk_2Ni(PR_3)_2$, etc.

The OMC stability rules quoted above refer to the degree of population of the bonding, non-bonding, and anti-bonding MO. If all the bonding MO are populated by electron pairs and the non-bonding MO, if such exist, are not orbitals of the π-system but constitute the orbitals of unshared electron pairs of the ligand heteroatoms or the orbitals of the electrons in the metal atom which are non-bonding in relation to ligands, then such an electronic configuration (structure) of the OMC should be stable in the quantum-chemical aspect (analogously to Hückel's rule concerning the stability of aromatic systems). The stability of the electronic structure of OMC, expressed in terms of these theoretical and empirical rules, is based on the fact that, on formation of the entire system of chemical bonds in the molecule between the metal and the ligands, there is an overall energy decrease of all the electrons in the molecule relative to the isolated ligands and the metal atom. This decrease corresponds to the stabilisation of the electron shell both via the formation of chemical bonds and because the closed electron shell is favoured by energy factors.

The methods of ultraviolet, X-ray, and photoelectron (PES) spectroscopy[36] make it possible to determine experimentally the vertical and adiabatic ionisation potentials of the molecules and to find the sequence of energy levels of the electrons involved in the M–C, C–C, C–H, etc. bonds and also of the non-bonding electrons of the metals, which yields complete information about the energy distribution of the electrons in OMC. On the basis of experimental studies of mononuclear and polynuclear OMC of non-transition and transition metals,[37–39] the sequences of the energy levels of the electrons in OMC have been established. Under the conditions where Koopman's theorem is applicable, this yields an idea about the sequence of the energies of the one-electron molecular orbitals[40] and, when Koopman's theorem is inapplicable, it yields the sequence of the energies of the multielectron levels of the molecule.

The non-bonding electrons of the metal are usually located in the highest of the occupied MO and below these are the MO which correspond to the electrons involved in the metal–metal σ-bonds or the metal–ligand δ- and π-bonds. These are followed by the strong bonding MO corresponding to the metal–ligand (group) σ-bonds and the σ-bonds within the ligands (C–C and C–H).

Consideration of the OMC stepwise dissociation (decomposition) process shows that each reaction stage can be modelled by means of a two-particle approximation and, by analogy with diatomic molecules, one can assume that the dependence of the energy on the metal–ligand distance is described by a potential curve resembling the Morse curve. In this case one can speak of the dissociation energies of specific bonds (D_1, D_2, etc.) formed by the metal-containing fragment of the OMC molecule and the ligand:

$$R_nM \rightarrow R_{n-1}M \ldots R \xrightarrow{D_1} R_{n-1}M + R;$$
$$R_{n-1}M \rightarrow R_{n-2}M \ldots R \xrightarrow{D_2} R_{n-2}M + R \quad \text{etc.}$$

The quantities D_n are determined by mass-spectrometric or thermochemical methods. The average bond dissociation energies *D*, determined experimentally for the gas-phase total dissociation of the OMC, are used in many cases as a measure of the strength of the metal–ligand bond in the OMC:[41–43]

$$R_nM\,(\text{gas}) \overset{n\bar{D}}{\rightleftarrows} M\,(\text{gas}) + nR\,(\text{gas}). \qquad (1)$$

For the majority of the metals investigated, the values of D_n or *D* are always much greater than zero and usually amount to between 20 and 100 kcal mol^{-1} and more.[41–43] Consequently the formation of isolated OMC molecules is energetically favourable. On the other hand, the stability of the molecules produced depends on the stability of the electronic structure acquired by the metal in the OMC and on the stability of the steric molecular structure of the OMC.

Proceeding now to the consideration of the stability of the molecular structure of OMC, we may note that the latter depends on the spatial distribution of the electron density associated with the chemical bonds, the unshared electron

pairs, and the non-valence interactions between ligands which are not linked by bonds, i.e. on the steric factor. When the non-valence interactions do not give rise to steric hindrance to the formation of the molecular structure, the stability of the latter is determined by the extent to which the corresponding spatial distribution of electron density and the atomic nuclei is energetically favourable, this being determined by the structure of the electron shells of the OMC, the metal atom, and the ligands.

If the ligands form chemical bonds with the metal via one of their sp^3, sp^2, or sp orbitals, then the electronic structure of the OMC of non-transition and transition metals represents[44] a set of two-electron two-centre σ-bonds, one of which is localised on each ligand. The number of such bonds, their spatial distribution, and the stability of the OMC are determined by the structure of the electron shell of the metal, the number of valence electrons, and the number and type of unoccupied atomic orbitals (AO) of the metal. For ligands with sp^2 and sp valence orbitals, weak or strong π-bonds,[44] involved in p_π–p_π or p_π–d_π interactions, may be formed in addition to the σ-bonds. In order to find the most stable configurations of molecules of the type MR_n use is made of Pauling's[45] and Murrell's[46] maximum overlap method, which has been successfully developed by other workers.[47–49]

Organic ligands containing an unsaturated π-electron system (η^n-ligands: alkenes, alkynes, allyl, cyclobutadiene, cyclopentadiene and cyclopentadienyl, benzene, etc.) give rise to considerable possibilities for the formation of many-centre metal–ligand bonds in OMC molecules. Many-centre two-electron σ-, π-, and δ-bonds are usually formed along the principal symmetry axis of the ligand and in the case of transition metals such organic derivatives have a sandwich structure.[11]

The strength of the bonds between polyhapto-ligands and transition metal atoms is determined by the total number of two-electron many-centre bonds formed with the given ligand and reaches a maximum on formation of the maximum number of the possible bonds. With increase of the metal–ligand distance, the strength of the π- and especially δ-bonds diminishes sharply in contrast to the σ-bond, which acts over a longer range.[50]

The nature of the bonds between polyhapto-ligands and non-transition metals such as silicon, germanium, and tin is close to that of the analogous bonds with transition metals, i.e. also delocalised over the ligand,[51,52] although, by virtue of the lack of the ability of the electron shells of these metals to form many-centre π- and δ-bonds, they are comparatively weak σ-bonds.[51]

The stability of OMC containing bonds between polyhapto-ligands and transition metals is frequently strikingly high. Compounds in the molecules of which all the bonding MO are occupied by pairs of electrons (in many cases such filling of the MO corresponds to the inert gas rule) are especially stable.

The spatial distribution of the many-centre bonds in the OMC molecule depends, analogously to the two-centre σ-bonds, on the electronic structure of the metal and also on the presence or absence of steric hindrance owing to the repulsion of the non-bonded ligands (the effect of the latter is the steric and energetic non-equivalence of the ligands and of their bonds with the metal, for example, the existence of different numbers of η^5- and η^1-C_5H_5 ligands in compounds of the type $(C_5H_5)_4M$ (M = Ti, Zr, or Hf),[53] etc.

Overall, the delocalisation of electrons over many centres, which leads to the formation of a many-centre transition metal–ligand bond, increases significantly the stability of OMC. Stabilisation of labile metal–carbon bonds also results from the formation of a chelate ring via a neighbouring (usually in the β-position within the substituent group or in the *ortho*-position in a phenyl substituent) electron-donating group of the type of $\ddot{N}R_2$, $\ddot{O}R$, and $\ddot{P}R_2$.[54]

The next type of intramolecular interactions influencing the stability of OMC molecules are the so-called additional interactions, intermediate between valence (bonding) and non-valence (repulsive) interactions.[55] By binding the metal atom to the substituent group (ligand) or the ligands to one another, these interactions increase the quantum-chemical stability of the OMC, as happens, for example, in the case of $[(C_6F_5)_3Ge]_2Hg$.[56]

As already mentioned, the non-bonding interactions, namely the repulsions between the substituent groups (ligands) not linked by valence bonds, the unshared electron pairs, and atomic nuclei, play an important role in the formation of the molecular structure of the OMC and its stability. They can influence appreciably the extent of the bonding and additional interactions up to complete blocking of the possibility of bond formation. The non-bonding interactions in the OMC molecule lead, on the one hand, to the steric shielding of the metal atom (or a group of metal atoms in polynuclear OMC and metal clusters) by substituents (ligands) (this characteristic of the OMC molecule will be used subsequently when the stability of the state of aggregation of the OMC are considered) and, on the other hand, such interactions can lead to steric hindrance to the formation of metal–ligand bonds. The first effect always increases the stability of the state of aggregation of OMC (see below), while the second reduces the stability of the OMC molecule.

The influence of non-bonding interactions (steric effects) on the molecular structure of the OMC and its stability has been noted in many communications (see, for example, Wilkinson[13] and Davidson et al[14]), but few systematic studies of this problem have been made, (see, for example, Refs.57–60).

There exist several methods for the quantitative estimation of the bulk of the substituents (ligands) and hence of the extent of non-bonding interactions in OMC molecules.[58–60] One of these, described by the present authors,[58] consists in calculating the solid angles formed by the substituents (ligands) with the vertex at the metal atom (Fig.1*a*). Cylindrical projections of the molecule can be usefully employed for such purposes in the molecules of polynuclear OMC containing chains of metal atoms.[58] It is possible to use the method proposed also for transition metal clusters. Fig.1*b* presents the dependence of the solid angles q on the M–X distance, where X is an atom of the substituent (ligand) linked to the metal atom M (for certain ligands). The sum of the solid angles for all the substituents (ligands) in the molecule

$$Q = \sum_{i=1}^{n} q_i,$$

where n is the number of substituents (ligands) in the molecule, can be used for the *a priori* estimation of the possible existence of molecules from the standpoint of steric hindrance due to non-bonding interactions, because this sum should be less than or equal to half the solid angle 4π. The quantity $Q > 4\pi$ indicates the possibility of steric hindrance and hence a low probability of formation or stability of the suggested OMC molecule. Conversely, the quantity $Q < 4\pi$ indicates the absence of steric hindrance to the formation of the molecule and at the same time characterises the degree of shielding of the metal atom in the latter by the substituents (ligands).

The energy and steric factors together determine the electronic and steric molecular structures of the OMC and their separation in merely methodological in character. Indeed,

the set of solutions of the Schrödinger equation with variation of the steric parameters (coordinates of the atoms or fragments of the OMC molecule) defines the potential energy surface (PES), describing all the states of the OMC molecule in terms of spatial coordinates. Equilibrium interatomic (interfragment) distances, which correspond to equilibrium between the forces of attraction and repulsion between the fragments of the molecule, correspond to the minimum on the PES (i.e. to a stable state of the OMC). Allowance for the non-bonding interactions of the non-bonded fragments of the OMC molecule in the calculation of the PES makes it possible to estimate the most favourable steric molecular structure of the OMC[61] and hence obtain an idea about the stability of the molecule.

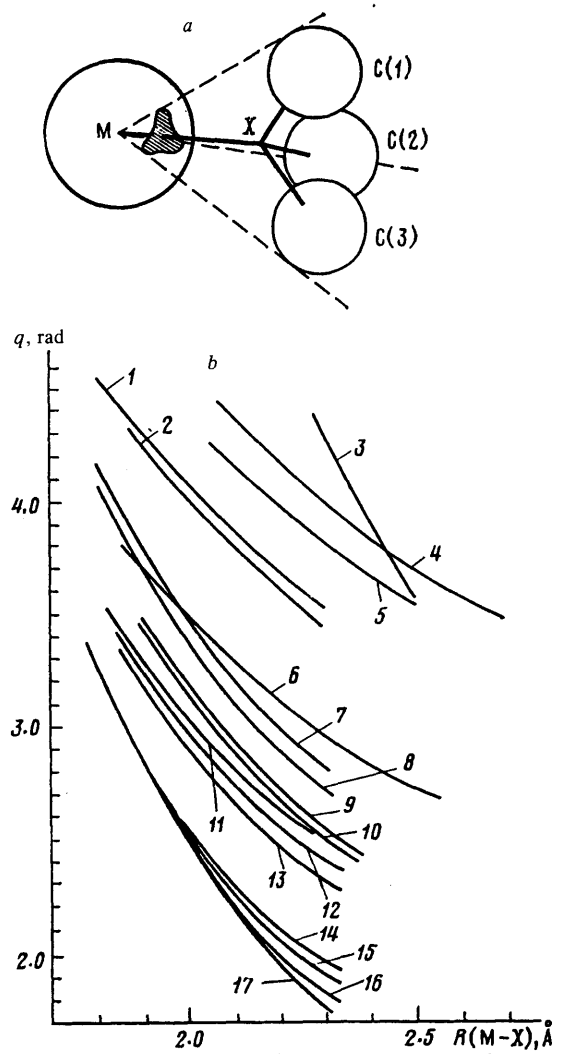

Figure 1. *a*) Scheme illustrating the structure of the solid angle *q* made by the substituent; *b*) dependence of the solid angle *q* on the distance R(M–X) for certain common substituents and ligands (an ideal tetrahedral or planar-trigonal coordination has been assumed for the atom X of the substituent).[58] Substituents: 1) CPh_3; 2) $CH(SiMe_3)_2$; 3) η^5-Cp; 4) $SiPh_3^F$; 5) $Si(t\text{-}Bu)_3$; 6) PPh_3; 7) CH_2CMe_3; 8) 2,4,6-$Me_3C_6H_2$; 9) CH_2SiMe_3; 10) CF_2CF_3; 11) CCl_3; 12) CMe_3; 13) ferrocenyl; 14) η^1-Ph; 15) CF_3; 16) η^1-Cp; 17) Me, Et.

The stability of the electronic structure of the molecule on the PES is determined by the extent to which the transition of the electronic structure of the OMC from the surface corresponding to the ground electronic state to one corresponding to excited electronic states, including dissociative states, is hindered. Molecules, for which the intersection of the PES for the ground state with the PES for the excited states requires a considerable energy expenditure and deformation of the molecule (which is extremely probable for steep walls of the potential well on the PES of the OMC) apparently have stable electronic and molecular structures. In those cases where a potential well with sloping walls corresponds to the ground state of the OMC and, at the same time the PES for the ground state has no close intersections with the PES for the excited electronic states, the electronic structure of the OMC is stable and the molecular structure is labile relative to changes in the distances between the fragments.

We shall now consider the susceptibility of the OMC molecule to perturbations in the structure, which displace it from its position of stable equilibrium. The response of the OMC molecule to perturbation depends both on the type of the latter and on the nature of the bonds in the molecule. The following principal types of perturbations in the OMC molecular structure, characterising its stability, can be differentiated: (1) movement of a fragment and ligand forming part of the OMC molecule, which leads to homopolar bond dissociation with formation of neutral species; (2) movement of a fragment and ligand forming part of the OMC molecule leading to heteropolar bond dissociation with formation of charged species (ions) with opposite charges; (3) shifts of electron density and nuclei in the OMC molecule in opposite directions leading to the ionisation of the molecule to give the cation OMC^+ and an electron (characterised by the OMC ionisation potential and the redox potential in solution).

From general considerations, it is easy to conclude that the polarity of the metal–ligand bonds in the OMC as well as the bond energies play an important role in determining the ease of each of the three perturbation processes. A number of conclusions concerning the polarity of the bonds and the character of the MO in the OMC of non-transition and transition metals can be arrived at by assuming, in conformity with the Koopman's theorem,[40] that the one-electron MO may be responsible for the ionisation potentials of the molecule.[21]

A characteristic feature of non-transition metals whose ionisation potentials (IP_M) are of the order 4–8 eV is the reaction with organic radicals, whose ionisation potentials (IP_R) are about 8–10 eV, to form OMC which have $IP_{OMC} > IP_M$ (for $IP_R > IP_M$) in the absence of non-bonding electrons in the metal and a populated d^{10} shell in post-transition metals (Fig.2*a*).[21] As a consequence of the electropositivity of the metal, the contribution of the substituent orbital to the populated bonding MO is higher than would correspond to the formation of a polar M–R bond with a negative charge on the substituent. For similar ionisation potentials $IP_M \cong IP_R$, the M–R bond is significantly non-polar (covalent), although $IP_{OMC} > IP_M \cong IP_R$. For metals and substituents for which $IP_M > IP_R$, the negative charge of the dipole of the M–R polar bond is localised at the metal atom and the bonding MO involves a predominant contribution by the atomic orbital of the metal.

For transition metals having $IP_M \cong 7$–8 eV combined with organic π–η^n-ligands, for which $IP_R = 8$–9 eV, the situation is somewhat altered. Since transition metals have *d* electrons and unfilled atomic orbitals, while the π–η^n-ligands have filled and unfilled MO, it follows that, together with covalent bonds, there is a possibility of the formation of both donor–acceptor and dative bonds (Fig.2*b*).[21] The formation of donor–acceptor bonds, using the electron pairs of the ligands

and the AO of the metal, requires, as an essential condition, the rearrangement of the electron shell of the metal with liberation of the lowest AO having the appropriate symmetry and the filling, as a rule, of the d_δ and d_σ orbitals of the metals, among which the d_δ orbitals are involved in the formation of dative bonds with the antibonding MO of the ligands.

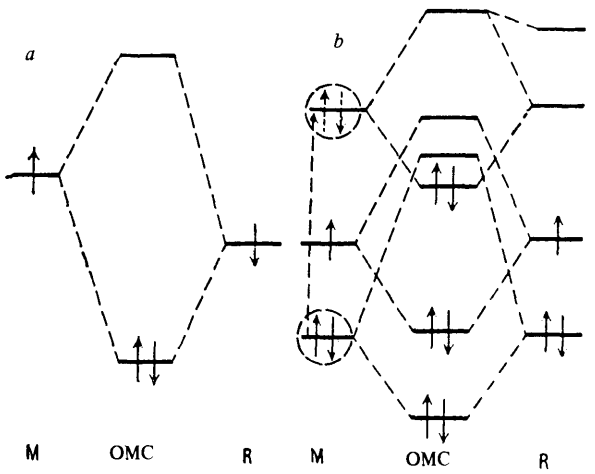

Figure 2. Molecular orbital diagrams for the OMC of non-transition (*a*) and transition (*b*) metals;[21] M = metal; R = substituent or ligand; the dashed arrow denotes the rearrangement of the electron shell.

In most cases the lowest bonding MO of the OMC molecule, corresponding to the donor–acceptor bonds, involve a large contribution by the ligand MO; MO with moderate energies, corresponding to covalent bonds, involve approximately equal contributions by the AO of the metal and the MO of the ligands, while the highest MO usually have the character of non-bonding or weakly bonding MO localised at the metal, since $IP_M \cong 7-8$ eV and the ionisation potential of the antibonding ligand MO is usually ~3–4 eV. Hence one can reach two conclusions. Firstly, since the formation of the optimum number of bonds ensuring the minimum energy of the OMC molecule requires a rearrangement of the ground electronic state of the transition metal to give an excited state, the upper electrons should be distributed in higher energy levels than the electrons of the free metal atom and should be non-bonding or weakly bonding in character. Secondly, the effective charge on the metal atom can be estimated from the energies of these non-bonding electrons. A survey of data for the IP_{OMC} of transitions metals[21,41] shows that $IP_{OMC} \leq IP_M$. This indicates an insignificant deviation of the charge on the metal from zero, which has in fact been confirmed by calculations yielding results close to the experimental data, for example, for ferrocene[62] and dibenzenechromium.[63–66] Thus, predominantly non-polar (covalent) bonds are observed in many η^n-derivatives of transition metals, with the exception of a number of compounds of the type of manganocene and cyclopentadienyl derivatives of the lanthanides, as a consequence of the mutual compensation of the shifts of electron density owing to donor-acceptor and dative interactions.

Having adopted the polarity of the metal–ligand (substituent) bond as the factor influencing the ease of both dissociation [homopolar (2) or heteropolar (3)] and ionisation processes, we shall now consider the characteristics of the energy relations of these processes.[66–73] If it is assumed that the OMC contains a polar $M^{\delta+}-R^{\delta-}$ bond, then its possible dissociation processes can be formulated as follows:

$$M^{\delta+}—R^{\delta-} \rightarrow M^0—R^0 \rightarrow M^0+R^0; \quad (2)$$

$$M^{\delta+}—R^{\delta-} \rightarrow F^+ + R^-. \quad (3)$$

Dissociation via scheme (2) should be accompanied by the abolition of the polar bond in the course of its dissociation.[20,21,66,73] Estimation of the energy of the displacement of the electron pair in the polar bond (the ionic component ΔE) by the method of Razuvaev et al[20] showed that different M–R bonds have different values of ΔE. Small, nearly zero values of ΔE are favourable for reaction (2), while higher values of ΔE hinder it.[20] Conversely, higher values of ΔE favour reaction (3) while low values hinder it. The ionisation process is promoted by low values of IP_{OMC} and also by high energies of the exciting quanta. The conditions associated with thermal reactions or multiquantum infrared excitation correspond to the first type of perturbation, which is milder and leads to homopolar dissociation. As a consequence of the greater strength of the more ionic bond, reaction (3) is promoted as a result of excitation by higher energy quanta (electron impact and ultraviolet, X-ray, and γ-ray quanta) or by the delocalisation of the separating charges on solvation and on exposure to an electric current in solution.[67–71]

III. THERMODYNAMIC STABILITY

The quantum-chemical stability of the OMC considered above determines the possibility, in principle, of the formation and existence of an isolated OMC molecule. If such a possibility exists, then the set of molecules forming a definite state of aggregation of the given substance can be stable in relation to any one decomposition process under some conditions, while under others it is unstable. The state of equilibrium in the thermodynamically reversible OMC $\rightleftarrows$ decomposition product system, the decomposition products involving different combinations of states of aggregation, is a measure of the thermodynamic stability of the OMC in relation to any decomposition process and is determined by the sign and magnitude of the change in the Gibbs free energy ΔG in this process.

The thermodynamic stability of coordination and organometallic compounds in relation to heteropolar dissociation into gaseous or solvated ions, i.e.

$$R_nM \rightleftarrows nR^- + M^{n+} \quad (4)$$

differs significantly from that for the homopolar dissociation into gaseous or solvated uncharges species (decomposition products):

$$R_nM \rightleftarrows nR + M. \quad (5)$$

Since reaction (4) in the gas phase involves charge separation, it is very greatly hindered by energy factors, i.e. it has high values of ΔH and is facilitated by solvation of the ions in solution. (There exists an extensive literature on the stability of coordination compounds in solution in relation

to reaction (4).[67-71] In view of the much lower values of ΔH, in the gas phase at temperatures up to ~1000° virtually the only dissociation process is the homopolar reaction (5).

Accordingly, the thermal stability, frequently discussed as a general characteristic of the OMC,[7,35,72] should be defined as the stability of OMC in relation to reaction (5) in all the aspects (quantum-chemical, etc.) discussed in this review. As a criterion of the thermal stability of OMC in its thermodynamic aspect, one must consider the presence of equilibrium in the homopolar bond dissociation process,[20,73] with formation of uncharged species: the metal and radicals (for ligands with an odd number of electrons involved in the formation of the bond) or molecules (for ligands with an even number of electrons participating in the formation of the bond). The reverse reaction in this case involves the synthesis of OMC from the decomposition products.

For a general consideration of the thermodynamic stability of OMC in thermal processes, we shall examine three main cases:

$$R_nM\ (gas) \rightleftarrows nR\ (gas) + M\ (gas), \quad (6)$$

$$R_nM\ (cond.) \rightleftarrows nR\ (cond.) + M\ (gas), \quad (7)$$

$$R_nM\ (gas) \rightleftarrows nR\ (gas) + M\ (solid), \quad (8)$$

where (gas), (cond.), and (solid) denote respectively the gas, condensed, and crystalline phases.

The homogeneous gas-phase process (6), under conditions where the states of the reactant obey the relations for ideal gases, is an analogue of the homopolar dissociation process (2), considered in its quantum-chemical aspect for the isolated states of the reactants. Because of this, the dissociation energies (D_n and $\bar{D}$) are identical with the dissociation enthalpy ΔH_D^0 for reaction (5). In describing the equilibrium in the decomposition reaction of polyatomic OMC molecules, one frequently employs the average enthalpy and entropy of dissociation of the metal–ligand bond. The results of the measurements of the energies and entropies of dissociation of the metal–organic ligand or radical bond have been discussed.[41-43,74-76]

Comparison of the enthalpy (ΔH) and entropy ($T\Delta S$) contributions to the Gibbs free energy (ΔG) of dissociation via reaction (6) for virtually all the known and investigated OMC[74] has shown that under standard conditions the contribution of the entropy term is only 5–30% of ΔH. Bearing in mind that the dissociation energies of all the bonds are positive[75] and that the entropy change on dissociation is likewise positive,[74] one may conclude that ΔG for all OMC dissociation processes in the gaseous state with formation of gaseous decomposition products and the metal vapour is always positive under standard conditions. Consequently almost all the OMC investigated hitherto are thermodynamically stable in relation to the gas-phase dissociation process at 298.15 K and a pressure of 1 atm. These conclusions confirm indirectly the results of extensive synthetic studies[24,25] during the last 10–15 years on the reactions of atomic (gaseous) metals with organic compounds when they are subjected to cocondensation at low temperatures.

With increase of temperature (at a constant pressure $p = 1$ atm), the contribution of the entropy term rises and at a specific temperature $T_{p,gas}$ the free energy ΔG of the dissociation reaction (6) becomes zero and then negative. Starting from this temperature, the OMC decomposition process becomes thermodynamically probable. The temperature $T_{p,gas}$ can be adopted as the temperature of the "onset" of the gas-phase OMC decomposition reaction characterising the thermal stability of the OMC in relation to the gas-phase decomposition reaction (6).

An estimate of the influence of pressure on the thermal stability of OMC has shown[21] that (1) at an elevated pressure the thermal thermodynamic stability of OMC is higher than at a reduced pressure; (2) the OMC thermal decomposition processes at a reduced pressure should occur at lower temperatures than at elevated pressures. These conclusions have been demonstrated qualitatively by known facts, namely that dibenzenetungsten(0) and dibenzenemolybdenum(0) decompose in a high vacuum at much lower temperatures than in a closed volume under the pressure of both decomposition products.[77,78]

Systematic studies have been made on the dependence of the dissociation energies[75] and dissociation entropies[74] of chemical bonds on the atomic numbers of the elements. It has been shown that the average dissociation energies $\bar{D}$ for compounds of non-transition elements within one Group in the Periodic System with carbon diminish with increase of the atomic number of the element, while for compounds of transition metals the opposite relation is observed: the average dissociation energy of the σ-bonds increases with increasing atomic number of the element down the Group.[75] This is also true of biscyclopentadienyl compounds, carbonyls, and other types of compounds of transition metals. On moving along the 3*d* series of transition metals, $\bar{D}$ diminishes with increasing atomic number of the element.[75,76] For the same non-transition element M in the analogous compounds, the values of D decrease in the following sequence as R is varied: Ar > Alk > Ph > Me > Et ≅ n-Pr ≅ n-Bu.[43]

The average M–C bond dissociation energies for non-transition elements reach a maximum on moving along the Period for Group IV elements.[43] The increase of $\bar{D}$(M–Alk) after the introduction of electron-accepting substituents into the OMC molecule, of the type $Alk_{n-m}MX_m$, where X = Cl, Br, I, or OH, compared with Alk_nM is of interest.[43] For the organobimetallic compounds $Alk_3M–MAlk_3$, the dissociation energies $\bar{D}$(M–Alk) are equal to those in Alk_4M; the metal–metal bond dissociation energies in compounds of the type $Alk_3M–MAlk_3$, which have been investigated, diminish in the sequence Si–Si > Ge–Ge > Sn–Sn,[43,76] while for the $M_{non\text{-}trans}–M_{trans}$ bonds [in compounds of the type $CpM_{trans}(CO)_3–M_{non\text{-}trans}Me_3$] the values of $\bar{D}$ lie in the sequence Cr–Ge < Cr–Sn < Mo–Ge < W–Ge < Mo–Sn < W–Sn, i.e. $\bar{D}$ increases with increasing atomic numbers of both metals, which is characteristic of transition metal OMC and not of non-transition metal OMC.

Analysis of the dependence of the average bond dissociation entropy on the position of the element in the Periodic System has shown[74,75] that $\Delta\bar{S}$(M–C) varies within much narrower limits than $\bar{D}$(M–C) and is in the range 15–45 cal mol^{-1} K^{-1}, the greatest number of values of $\Delta\bar{S}$ obtained lying in the range 30–40 cal mol^{-1} K^{-1}. Here $\Delta\bar{S}$(M–C) for the same Group of the Periodic System and isotypical compounds decreases with increasing atomic number, the effect being less pronounced for the heavier transition metals. The effect has been attributed[74,75] to the variation of the atomic radius of the metals in the Periodic System.

The $\Delta\bar{S}$(M–C) and $\bar{D}$(M–C) data can be used to calculate the average Gibbs free energies of dissociation of the bonds $\Delta\bar{G}$(M–C),[74] which may serve as a criterion of the stability of the OMC and the M–C bonds in them under standard conditions. The ΔG(M–C) for the OMC of non-transition and transition elements have been compared.[75,76]

Estimates of ΔG^0 [21,76,79] for the reactions

$$M\ (gas) + 2(C_5H_{5+n})\ (gas) \rightleftarrows (C_5H_5)_2M\ (gas) + nH_2\ (gas);$$

$$M{=}V,\ Cr,\ Mn,\ Fe,\ Co,\ Ni;\ n{=}0,\ 1,\ 3,\ 5.$$

$$Cr\ (gas) + 2(C_6H_6)\ (gas) \rightleftarrows (C_6H_6)_2Cr\ (gas).$$

show that the equilibrium in the gas-phase reactions with a

gaseous metal, involving synthesis and decomposition, is almost always displaced towards synthesis regardless of whether gas-phase radicals or stable organic compounds of the type of benzene or cyclopentadiene participate in the reaction. Although the entropy term contributes significantly to ΔG at elevated temperatues, the differences between the average M–C bond dissociation energies for different elements, the characteristic features of the variation of which were indicated above, should exhibit a marked influence.

On passing to heterogeneous OMC synthesis and decomposition processes (7) and (8), one should note the importance of considering the energy relations and the structures of the condensed phases of the reactants. If the condensed phase (crystal) has a molecular type of packing, then the contributions of ΔH and ΔS for the condensed phase of the OMC and the organic compounds, which occur in different parts of the reaction equation, partly cancel out and the position of the thermodynamic equilibrium in the synthesis-decomposition reaction involving the gaseous metal does not vary very markedly.[25,79] Specific features can be introduced only by intermolecular interactions in the condensed OMC phase additional to the van der Waals interactions. If the synthesis-decomposition reaction of the gaseous OMC with formation of gaseous organic decomposition products and the solid metal [Eqn.(8)] is considered, it is noted that the state of thermodynamic equilibrium in the reaction differs significantly from that for a purely gas-phase reaction. In the reaction involving the formation of the solid metal, for which this phase state is standard, the enthalpy of atomisation of the solid metal ΔH_f[M(gas)], i.e. the term which made a positive contribution to ΔG when the decomposition reaction was considered, giving rise to $\Delta G > 0$, virtually disappears and the state of equilibrium becomes markedly dependent on the enthalpy of formation of the decomposition products and on the entropy terms. Cases may be observed where $\Delta G > 0$ and $\Delta G < 0$, depending on ΔH_f[M)gas)] and other factors, for different OMC where the state of equilibrium of the gas-phase reaction is displaced towards synthesis.[21,25,79–81]

The radical change in the thermodynamic equilibrium and hence in the thermodynamic stability of OMC in the synthesis-decomposition reaction of dibenzenechromium(0) may be regarded as a classical example. While the equilibrium in the gas-phase reaction under standard conditions is displaced towards synthesis (see above), the equilibrium in the reaction involving the solid chromium phase is almost always displaced towards decomposition[21] under the same (standard) conditions:

$$(C_6H_6)_2Cr\ (gas) \rightleftarrows Cr\ (solid) + 2(C_6H_6)\ (gas).$$

Thus dibenzenechromium(0) is thermodynamically unstable in relation to the gas-phase decomposition with formation of solid metallic chromium. Such instability is manifested to an even greater extent for the bisarene derivatives of refractory metals, such as vanadium,[82] molybdenum,[77] tungsten,[78] titanium, niobium, and tantalum[83] as a consequence of the extremely high enthalpy of atomisation of the metals ΔH_f[M(gas)].

In the general case, for reactions involving the segregation of the solid metal, equilibrium should be attained at lower temperatures than for a purely gas-phase reaction.

For non-transition metals, for which the values of ΔH_f[M(gas)] are as a rule much lower, a shift of the equilibrium in the synthesis-decomposition reaction with participation of the solid metal towards synthesis is more likely,[80] as, for example, has been frequently observed for OMC of aluminium and certain other metals[81] and is also known from Paneth's classical studies on the reactions of free radicals with metallic mirrors.[15]

Thus the thermal thermodynamic stability of OMC is different for different decomposition reactions and is determined both by the thermodynamics of the OMC itself and by the phase state and the thermodynamic characteristics of the decomposition products.

In view of the foregoing, one may conclude that the thermodynamic stability of OMC in relation to the gas-phase decomposition process characterises, as it were, the possibility of the existence of the OMC in the gas phase (in the molecular form) and is thus close to the definition of the quantum-chemical stability, but refers solely to the set of OMC molecules in equilibrium with their decomposition products.

The thermodynamic stability of OMC in relation to the decomposition process with formation of the solid metal is more closely related to the definition of thermal stability in a real thermal decomposition process used to deposit coatings from the vapour phase and is more likely to characterise the reactivity of OMC than the possibility of the existence of OMC of the given type. The thermodynamic equilibrium between the solid metal and the gaseous OMC is attained more readily with increase of the surface area of the solid phase. It is noteworthy that the state of equilibrium for the solid metal and the condensed states of the OMC and the organic compound is likewise determined mainly by the high value of ΔH_f[M(gas)] and characterises the stability of the condensed state of the OMC in equilibrium with the solid metal. The majority of the OMC of refractory transition metals are thermodynamically unstable in these processes under standard conditions.[21,77–79,82] The thermodynamic instability of the OMC in relation to a specific decomposition process can be compensated by the kinetic stability and conversely, by virtue of the kinetic instability, in certain processes the thermodynamic stability may not be of decisive importance and the equilibrium (reversibility) of the process may be disturbed as a consequence of the operation of kinetic factors.

The transition from the gaseous to condensed (liquid or solid) states of the OMC is characterised by a significant change in the structure of the OMC. Apart from the molecular structure, the latter includes the relative disposition of the molecules, reflecting the intermolecular bonds (their packing).

Analogously to the way in which the molecular structure characterises the steric factor in electronic-nuclear interactions in the molecule, the structure of the condensed state of the OMC characterises the steric factor in the electronic-nuclear interactions in the set of molecules comprising the given states.

We shall consider the general types of the possible interactions between the OMC molecules in the condensed state: substituent (ligand)–substituent (ligand) (R ... R), substituent (ligand)–metal (R ... M), and metal–metal (M–M). The R ... R interactions are characteristic of organic chemistry, while the R ... M and M–M interactions constitute the specific features of the OMC.

The R ... R interactions are of the van der Waals type with energies up to 5 kcal mol^{-1}; their capacity for the formation of bonds is a maximum over a range of distances of ~2.5–3.5 Å.[84] These interactions determine the structure of molecular crystals.[84]

The intermolecular coordinate bonds with energies of ~3–10 kcal mol^{-1},[85] which lead to the formation of oligomeric and polymeric structures,[85–87] belong to the class of R ... M interactions. In the limit, these interactions can result in the formation of the R–M chemical bonds. This is confirmed, for example, by the oligomeric and polymeric structures of metal alkoxides or β-diketonates.[86]

The metal–metal interactions can also lead to the association of the molecules in the given state of aggregation. Thus many instances of the formation of infinite chains of OMC molecules and crystals with metal–metal bonds are known (see, for example, Ibers et al.[88]). The energy of these interactions is low compared with that of the M–M chemical bond (for example, the Rh–Rh bond energy is 18 kcal mol^{-1} [89]). The upper limit of the distances corresponding to the M–M chemical binding (~3–3.5 Å[88]) is comparable to the R ... R intermolecular contacts.

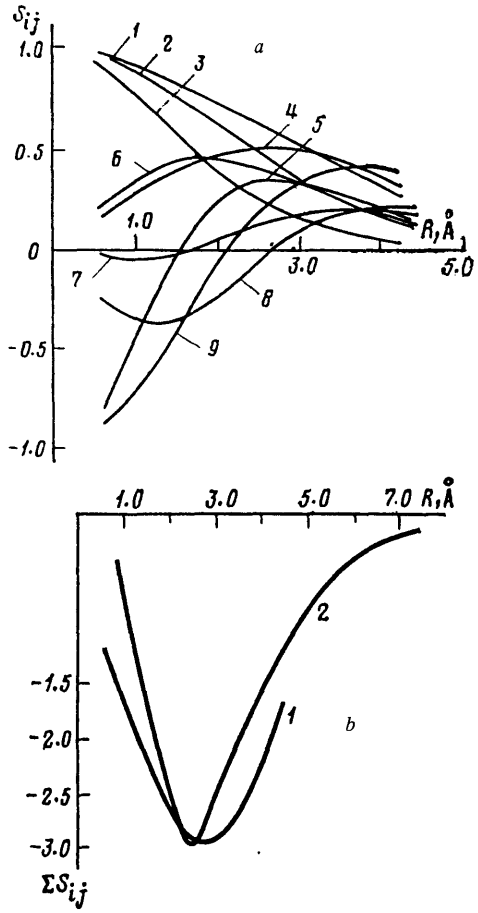

Figure 3. *a*) Dependence of the overlap integrals S_{ij} on the interatomic distance R in the Cr_2 molecule. The curves correspond to the following interactions: 1) 4*s*–4*s*; 2) $4p_\pi$–$4p_\pi$; 3) $3d_\sigma$–$3d_\sigma$; 4) 4*s*–4*p*; 5) $3d_\pi$–$3d_\pi$; 6) $3d_\pi$–$4p_\pi$; 7) $3d_\sigma$–4*s*; 8) $3d_\sigma$–$4p_\sigma$; 9) $4p_\sigma$–$4p_\sigma$; *b*) dependence of the sum ΣS_{ij} (curve *1*) and the potential of the Cr_2 molecule (curve *2*), calculated from experimental data in the form of the Morse potential, on the interatomic distance R in the Cr_2 molecule. Curves *1* and *2* have been normalised with respect to the minimum in curve *1*.

Analysis of the overlap integrals S_{ij} for the M–M bonds[90] has shown that for heavy metals the M–M interaction over distances of ~3–4 Å is still more intense and passes through a maximum for p_σ–p_σ, etc. Fig. 3 presents the values of S_{ij} based on the data of Batsanov and Zvyagina[90] and the semi-empirical Morse potential[91] for the Cr ... Cr interactions. In contrast to the "short range" Cr–C interaction, the Cr–Cr interactions are of the "long range" type and are characterised by a relatively broad minimum, which is due partly to a change in the contributions of different atomic orbitals of the metal.

All these factors confirm that it is legitimate to take into account the possibility of the formation of M–M bonds in considering the intermolecular interactions in OMC. The R ... R interactions have the character of boundary interactions and, in contrast to the R ... M and M–M interactions, are obligatory constituent elements of the intermolecular interactions in the condensed state of OMC.

On the basis of the foregoing, it is possible to trace the influence of the structure on the stability of the condensed state of OMC in relation to synthesis-decomposition processes, important for OMC and characteristic of such compounds, such as the formation of polynuclear OMC, metal clusters, and the solid metal from mononuclear OMC.

An estimate of the thermodynamic stability of the structure of the condensed state of OMC in relation to the formation in the latter of M–M bonds (apart from the intermolecular R ... R bonds) represents in essence an estimate of the stability of the structure of mononuclear OMC in relation to the formation of polynuclear OMC containing metal–metal bonds.

We shall estimate the contributions of the enthalpy and entropy terms to the ΔG of the transition from the structure of the OMC with intermolecular R ... R bonds to the structure with intermolecular R ... R and M–M bonds.

The enthalpy of the process consists of the changes in ΔH corresponding to the formation of M–M bonds and to the modification under these conditions of the intermolecular and intramolecular R ... R interactions. Overall, the intermolecular M–M interactions are energetically more favourable than the R ... R interactions. Consequently, in the absence of hindrance to the formation of M–M bonds by the R ... R interactions, the thermodynamic equilibrium is displaced towards the formation of the OMC structure with M–M bonds. The intermolecular (intramolecular) repulsion, which increases rapidly with decrease of the R...R distances, exerts the opposite influence and can render the formation of M–M bonds thermodynamically impossible.

The entropy term hinders the formation of M–M bonds, because the entropy of the system falls when they are formed ($\Delta S < 0$). ΔS depends directly on the steric hindrance to the formation of M–M bonds both by the molecular structure of the OMC and by the molecular packing: the greater the hindrance, the higher the value of ΔS.

Thus the structure of the condensed state of the OMC with intermolecular R...R bonds is more stable in relation to the OMC structure with intermolecular R...R and M–M bonds the greater the steric hindrance to the formation of these bonds by the intermolecular or intramolecular R...R interactions, in particular the higher the degree of shielding of the metal atom or the active centres in the substituents (ligands). Consequently, by creating a hindrance due to intramolecular and intermolecular non-bonding interactions, it is possible to achieve the stabilisation of the structure with R...R bonds relative to the formation of M–M bonds in the latter.

IV. KINETIC STABILITY

Since all real processes take place over a period of time, a significant factor determining the stability of OMC is the kinetics of the synthesis-decomposition reactions, the

principal features of which constitute the foundations of the concept of the kinetic stability and instability of OMC. Analogously to the previous two aspects of the consideration of the stability of OMC, the kinetic stability is determined for different processes involving perturbations in the state of equilibrium (the synthesis-decomposition of OMC). Under the conditions of the thermal processes (6)–(8), the kinetic stabiiity is one of the important components which determine the thermal stability of the OMC.

In order to determine the principal characteristics of the thermal kinetic stability of OMC, we shall consider the features of the gas-phase OMC synthesis-decomposition reaction:

$$R_nM \rightleftarrows R_{n-1}M + R \rightleftarrows R_{n-2}M + 2R \rightleftarrows \ldots \rightleftarrows M + nR.$$

Assuming that each of the consecutive stages presented above can determine the overall rate, consideration of the case where $n = 1$ or of the overall process

$$R_nM \rightleftarrows nR + M.$$

will not be an unduly drastic simplification. For $n = 1$, the process reduces to the dissociation reaction of diatomic molecules and the recombination of two atoms (or radicals), which have been thoroughly described in the literature.[92–95]

It is known from the theory of absolute reaction rates[96,97] that the intermediate activated state in the forward dissociation reaction and in the reverse recombination reaction is the same:

$$R{-}M \underset{k_2}{\overset{k_1}{\rightleftarrows}} [R{-}M]^{\neq} \rightleftarrows R + M.$$

However, the rates of the forward and reverse reactions can differ appreciably.

The forward dissociation reaction is a unimolecular process,[92] while the reverse reaction is a bimolecular process. The rate of the unimolecular dissociation reaction of RM may be determined by the rates of its two stages: (1) the activation process with formation of the intermediate activated state $[R{-}M]^{\neq}$ and (2) the transition of the activated state $[R{-}M]^{\neq}$ through the barrier with formation of the decomposition products.[96,97]

When equilibrium thermodynamics is used in the activated complex theory for the determination of the decomposition reaction rate constant, the latter is given by the following expression (the Arrhenius law):[92,93,96,97]

$$k = \varkappa \frac{kT}{h} e^{-\Delta G^{\neq}/RT} = \varkappa \frac{kT}{h} e^{\Delta S^{\neq}/R} \cdot e^{-\Delta H^{\neq}/RT},$$

where $\Delta G^{\neq}$, $\Delta S^{\neq}$, and $\Delta H^{\neq}$ are respectively the changes in the Gibbs free energy, entropy, and enthalpy of activation.

According to Moin,[98] $\Delta H^{\neq}$ is determined as the difference between the sums of the dissociation energies of the bonds being ruptured ΣD_r and the dissociation energies of the activated bonds $\Sigma D^{\neq}$:

$$\Delta H^{\neq} = \Sigma D_r - \Sigma D^{\neq}.$$

The factor kT/h characterises the frequencies of the collisions of the molecules during activation and increases with increase of temperature and pressure in gas-phase reactions.

The factor $e^{\Delta S^{\neq}/R}$ characterises the efficiency of the molecular collisions leading to reaction (the probability factor). The activation entropy $\Delta S^{\neq}$ then depends on the redistribution of energy between the different degrees of freedom in the activated state and is determined by the symmetry, i.e. by the steric structure of the OMC.

These kinetic features are valid both for the forward decomposition reaction and for the reverse synthesis reaction (recombination). The difference between the rates of the forward and reverse reactions is caused by the differences in the frequency and probability factors and in $\Delta H^{\neq}$. The kinetic conditions for the OMC thermal decomposition reactions and the reverse synthetic reactions have therefore proved to be such that the rate of one of the reactions is higher or lower than the other by any orders of magnitude.

The low overall OMC pressures *in vacuo* of the low OMC partial pressures in the carrier gas, used in carrying out the OMC thermal decomposition process, favour thermal decomposition at a higher rate and conversely they hinder the reverse synthetic reaction, which is significant only at high pressures, where the probabilities of binary and ternary collisions become appreciable.

Nevertheless the kinetic instability of OMC in the gas phase determined above is not decisive under the usual conditions at low temperatures where the rates of decomposition of OMC are low. Therefore, even in the presence of the solid metal, when the OMC may be thermodynamically unstable, as happens, for example, in the case of dibenzenechromium(0),[79] the OMC possesses kinetic stability as a consequence of the low rates of its decomposition; in other words, under these conditions the thermodynamic equilibrium is not established because of kinetic limitations. On the other hand, with increase of temperature the reaction rates also increase, which leads both to the rapid attainment of a state which is thermodynamically stable under the given conditions and to the manifestation of the kinetic instability of the OMC. These features can be clearly seen in relation to the synthesis-decomposition reactions of dibenzenechromium(0).[21,79]

Despite the thermodynamic stability of dibenzenechromium(0) in relation to the gas-phase decomposition reaction, it is kinetically unstable in the gas phase reaction because the forward decomposition reaction is a unimolecular process, while the synthetic reaction is a termolecular process or consists of two consecutive bimolecular processes, whose probability is low at reduced pressure compared with that of the unimolecular process. Since the rate of the forward gas-phase decomposition reaction of dibenzenechromium(0) should be much higher than the rate of the reverse synthetic reaction, an appreciable concentration of chromium atoms is established in the system. In view of the higher probability of a binary collision than a ternary collision, atomic chromium may recombine in binary collisions. If there is a possibility of removing the Cr–Cr bond energy to a third species or to the wall (support), the equilibrium in the recombination reaction shifts towards the formation of metallic clusters and ultimately of the solid metallic phase. Thus the kinetic conditions in the forward and reverse reactions may promote a shift of the reaction equilibrium to a thermodynamically unstable state—towards decomposition in the gas-phase reaction.

The appearance of the nuclei of metallic clusters and the solid phase during the process modifies the gas-phase reaction, so that the latter becomes a reaction with formation of the solid metal for which the fundamentally stable state is a dissociative state (decomposition).

Analysis of the conditions for the kinetic stability of gaseous substances and in particular of the OMC has shown that the stability increases with decrease of temperature and increase of pressure in the OMC $\rightleftarrows$ decomposition product system.[21]

From the standpoint of the influence of the structure on the kinetic stability of OMC, it is interesting to examine the effect of structure on the individual factors influencing the reaction rate constant. The factor kT/h is independent of the nature of the reactants and the activated state;[97] virtually the entire structural "load" is carried by the entropy (probability) factor $e^{\Delta S^{\neq}/R}$. If the structure of

the intermediate activated state differs little from that of the initial molecules, $\Delta S^{\neq}$ is low and the reaction rate falls. When the structure of the intermediate activated state of the complex is close to that of the decomposition products, $\Delta S^{\neq}$ is almost equal to the entropy of reaction ΔS and may be large and positive. If the intermediate activated state or the final products have a greater number of bonds than the initial reactants, $\Delta S^{\neq}$ may be negative, which diminishes the pre-exponential factor, although the formation of new bonds entails a decrease of the activation energy for the reaction (isokinetic law). Overall, the following statement may be made concerning the influence of structure on the entropy factor in the OMC thermal decomposition rate constant: the greater the rearrangement of the structure of the initial OMC in the intermediate activated state and the closer it is to that of the final products, the higher the decomposition reaction rate constant and the lower the kinetic stability of the OMC. Virtually no systematic estimates of $\Delta S^{\neq}$ for the OMC thermal decomposition reactions exist as yet; one can only point to a few investigations.[20,21]

The problem of the kinetic stability of OMC involves yet another important question, namely that of the efficiency of the activation energy transfer to the bond being ruptured, which depends on the distribution and the possibilities for the redistribution of the activation energy among the electronic, vibrational, and rotational degrees of freedom of the OMC molecule. The structure of the OMC may play a dual role in the redistribution of energy among the degrees of freedom and in its localisation in one of the stretching vibrations. If the OMC contain groups and fragments whose vibrations and rotations are of the type of symmetric or asymmetric tops, which interact strongly with other molecular vibrations, in particular, with the stretching vibrations responsible for the dissociation process, then in these molecules the activation energy is readily localised precisely in such torsional vibrations or rotations of the fragments and the probability of its localisation in the stretching vibration should be lower than in the molecules where such possibilities are absent.

Substituents and ligands of this type are, for example, the neopentyl (CH_2CMe_3), trimethylsilyl ($SiMe_3$), trimethylsilylmethyl (CH_2SiMe_3), benzyl (CH_2Ph), diphenylmethyl ($CHPh_2$), triphenylmethyl (CPh_3), adamantyl, cyclohexyl, norbornyl, cyanomethyl (CH_2CN), polychloromethyl ($CH_{3-n}Cl_n$), perfluoroalkyl (for example, CF_3), and other groups as well as ligands: $:C{\rightleftarrows}O$, $:PF_3$, and $:P(OR)_3$, where R = methyl, ethyl, phenyl, *o*-biphenylyl, etc.

Apart from their fairly high efficiency in delocalising the activation energy over the molecule, such substituents and ligands are able to shield the reaction centre, i.e. the metal–substituent (ligand) bond, from direct activation by virtue of their steric structure. The transmission of activation via the above groups to this bond is relatively ineffective as a consequence of the presence of a large number of high-energy vibrations in these fragments compared with the low-frequency stretching vibrations of the metal–substituent (ligand) bond and owing to the absence of the possibility of complex formation for the substituent. Such complex formation is possible for substituents of the type of allyl, alkynyl, and others as a consequence of a "viscous" ["non-elastic" (Editor of Translation)] collision with the multiple bond or collisions of substituted groups with hydroxy-, amino-, and other groups active in the formation of hydrogen bonds.

The steric shielding by the above substituents (ligands) of the central metal atom is such that the OMC molecule constitutes, as it were, an elastic sphere which is difficult to deform by compression and extension. Bearing in mind the chemical inertness of such substituents (ligands) in relation to both similar reagents and functional reagents, it is possible to account for the appreciable kinetic stability of OMC of this kind. A large number of kinetically stable OMC with substituents and ligands of the sort described have been obtained by Wilkinson and other workers.[13,14]

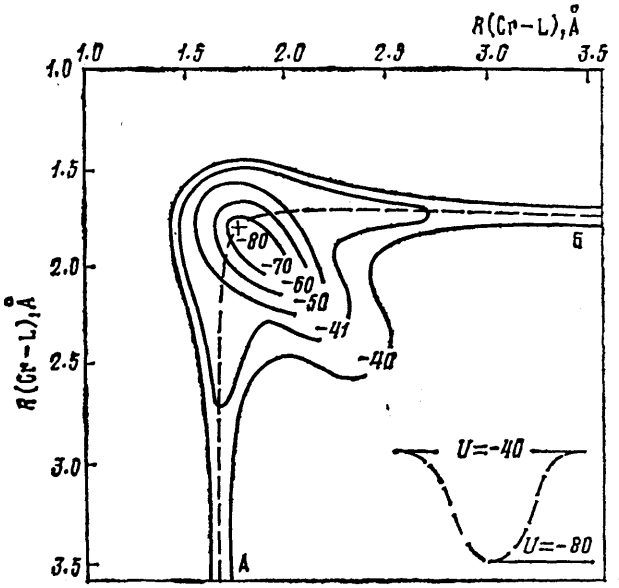

Figure 4. The potential energy surface for linear $(\eta^6\text{-L})_2Cr$ molecules, where L = C_6R_6 and R = H or Me.[61] States of the molecular fragments $(L^{(2)}\text{–Cr}\ldots L^{(1)}$ and $L^{(2)}\ldots\text{Cr–}L^{(1)})$ correspond to points A and B and the sign ± denotes the minimum in the potential well.

The set of energy and steric factors reflecting the kinetic stability or instability of OMC in a gas-phase process is in its turn reflected in the multidimensional potential energy surface for the OMC molecule. Fig. 4 illustrates the PES for dibenzenechromium(0),[61] which is characteristic also of other molecules of the type L_2M (L = ligand). The minimum in the potential well corresponds to a thermodynamically and kinetically stable state. Acquisition of an activation energy $E_a \geq D_1$ (D_1 is the energy of the abstraction of the first group L from the Cr atom) by the dibenzenechromium molecules induces movement along the reaction coordinate $Cr\text{–}L^{(1)}$ corresponding to the stepwise dissociation: $L^{(2)}\text{–Cr–}L^{(1)} \rightarrow L^{(2)}\text{–Cr} + L^{(1)}$. The activation energy in the unimolecular process is then virtually close to the dissociation energy D_1 of the first bond. Movement along the reaction coordinate $Cr\text{–}L^{(2)}$ arises similarly. After this, thermal activation takes place and the L–Cr fragment decomposes. For high levels of thermal excitation, following the absorption of light quanta or electron impact, there is a possibility of the transfer to the molecule of the energy $E_a \geq D_1 + D_2 = 2\bar{D}$. In this case there is a possibility of a concerted decomposition with the simultaneous dissociation of two ligands (movement

along the PES diagonal). This kind of decomposition of OMC is almost always observed when $D_2 < D_1$ and when $E_a \geq D_1$. The abstraction of a second ligand is greatly accelerated and takes place almost simultaneously with the first abstraction step (because $E_a \gg D_2$). A decomposition of this type has been observed for R_2Hg [99] and certain other OMC.

As in the consideration of the thermodynamic stability of OMC, we shall estimate the role of intramolecular and intermolecular non-bonding interactions in ensuring the kinetic stability of the condensed state of OMC relative to the formation of M–M bonds in the latter. The magnitude and sign of $\Delta H^{\neq}$ and hence also the rate of the process are determined by the relative contributions of opposite tendencies: the endeavour by the OMC to realise a state with M–M bonds (because this is favoured by thermodynamic factors) and the obstacle to this attempt by the M–R bonds and the non-bonding R...R interactions in the molecule and in the packing of the OMC.

The contribution of the entropy term retards the formation of M–M bonds, because the entropy change corresponding to this is negative. On the other hand, any change in the structure of the OMC involving a weakening and rupture of the M–R bonds is reflected in a positive contribution to $\Delta S^{\neq}$ (because the entropy then increases), which accelearates the process. Such structural changes are linked directly to the "rigidity" or "looseness" of both the molecular structure and of the packing of the OMC molecules. The more "rigid" molecules and molecular packing are kinetically more stable in relation to the formation of M–M bonds in the condensed state. The obstacles offered to the formation of M–M bonds in the condensed state of the OMC by the non-bonding R...R interactions and the "rigidity" or "looseness" of the structure are directly linked to the degree of steric shielding of the metal atoms from one another by the substituents (ligands), determined both by the molecular structure and by the molecular packing.

The symmetry (or, in other words, the degree of order) in the structure of the condensed state of the OMC plays an important role in such shielding. Since the character of the molecular collisions in the liquid (partial ordering) is such that their number is sufficient for the realisation of mutual orientations of the molecules which promote the formation of M–M bonds in the activated complex, one may conclude that in this case the steric hindrance to the formation of these bonds is generated mainly due to the shielding of the metal atom in the OMC molecular structure. In the crystalline state (total order) the possibility of the formation of M–M bonds is influenced also by the crystal packing. For example, the compound $(Ph_3Ge)_2Hg$ decomposes with liberation of metallic mercury in solution, on fusion, and also in the amorphous solid state, but is stable in the crystalline state, because the crystal packing of the molecules ensures the complete shielding of the Hg atoms from one another.[100]

Thus one may reach the following conclusion: the greater the steric shielding of the metal atoms from one another in the structure of the condensed state of the OMC (owing to its molecular structure or molecular packing), the more stable is this OMC state in the thermodynamic and kinetic aspect in relation to the formation of polynuclear OMC, metal clusters, and the solid metal, i.e. products containing metal–metal bonds.

The characteristic feature of the relation between the structure of the condensed state of the OMC and its stability in relation to the formation of M–M bonds described above is valid not only for mononuclear OMC of the type of MR_n but also for polynuclear OMC, namely metal clusters having the composition M_nR_m, because their molecules have in principle a structure analogous to that of the mononuclear OMC with the sole difference that in them not one atom but a group of metal atoms is surrounded by substituents (ligands). It is valid also for the characterisation of the stability of the condensed state of the OMC relative to the formation in the latter of intermolecular M...R bonds, i.e. the formation of oligomeric and polymeric structures.

V. THE STABILITY OF ORGANOMETALLIC COMPOUNDS UNDER NON-EQUILIBRIUM CONDITIONS

In most cases organometallic compounds exist in their synthetic and decomposition processes under the conditions of uncompensated energy (heat, radiation) and mass (changes in the relative amounts of the OMC and organic compounds—products resulting from decomposition and the segregation of the solid metal) fluxes. The presence of such fluxes disturbs the adiabatic conditions and leads to a non-equilibrium state of the system and to irreversible processes. Typical examples of such irreversible processes under non-equilibrium conditions include (1) the cryosynthesis of OMC with atomic (gaseous) metals,[24,25] (2) the deposition of the metal from the OMC vapour phase during thermal decomposition,[20,21] (3) the photodecomposition of OMC in the condensed or gaseous phase,[16,18] (4) the decomposition and synthesis of OMC under the influence of electron impact *in vacuo* or in a gas,[28,29] and a number of others.

The cryosynthesis of OMC with gaseous metals is an irreversible process by virtue of the very formulation of the experiment, because the latter employs extremely high supersaturations of the vapour phase with respect to the metal. The metal vapour obtained at high temperatures (~2000 to 2500 K) in a form in equilibrium with the condensed phase, is transported *in vacuo* as a flux of atoms which react at low temperatures with the condensed phase of the organic compound. At low temperatures the metal vapour is then in a state remote from equilibrium and the cryosynthesis of the OMC is therefore significantly irreversible.

The deposition of the metal from the vapour phase of the OMC during thermal decomposition[20,21] is carried out under the conditions of an energy (heat) flux through the support to the OMC and mass fluxes [of the OMC to the support and of organic compounds (decomposition products) from the support, condensed phase of the metal being deposited on the support]. The optimum conditions for the deposition process are then believed to be a flux of OMC unlimited with respect to time and an energy flux from the side of the support "unlimited with respect to power" and time.[20] Such conditions render the deposition process irreversible.

In the OMC decomposition processes under the influence of electromagnetic radiation (photodecomposition) or electron impact the distribution of the molecules with respect to energy differs from the equilibrium distribution and the decomposition products are frequently formed in electronically excited states[16,23,29] as a result of which these processes are likewise irreversible.

The kinetics of the irreversible processes under non-equilibrium conditions depend on how far the state of the system deviates from equilibrium. Near equilibrium, the rate of the process is usually linearly related to the process parameters and the method of stationary concentrations can be used for its description. Under conditions remote from thermodynamic equilibrium, non-linear relations are observed and are responsible for the presence of many different stationary states of the system and the occurrence of autowave processes and decaying vibrations in homogeneous gas-phase and liquid-phase reactions and in heterogeneous gas–solid and liquid solution–solid reactions.[101–106]

Apart from chemical kinetic factors, the study of non-equilibrium kinetics of irreversible processes[107] includes the consideration of mass-transfer (diffusion, turbulence) and heat transfer (thermal conductivity, convection) factors, small and large fluctuations in the state of the system, and also non-equilibrium states and irreversible processes in the interaction of the molecules with the electromagnetic radiation. The stability or instability of the system, in particular, of the OMC + decomposition products system, under such conditions, which approach those which obtain in reality, is determined by methods based on the theory of non-linear vibrations,[108] the non-equilibrium thermodynamics of irreversible processes,[101-104] synergistic relations,[109] or catastrophe theory.[106,110]

The OMC synthesis-decomposition processes occurring under conditions close to equilibrium should, generally speaking, lead to the decomposition of the structure,[101] while under conditions remote from equilibrium there is a possibility that the formation of dissipative structures may be observed. It is known[101] that chemical instabilities, which disturb the symmetry of the system, lead to the spontaneous self-organisation of spatial order in the system with formation of dissipative structures.[101-105]

The instability which leads to the disturbance of the symmetry in the arrangement of atoms or electrons is observed both in isolated molecules of OMC and coordination compounds (the Jahn–Teller effect[30]) and in solids (the charge-orbital ordering in the structure of the solid,[111] Peierls instability of M_n chains,[112] etc.).

The formation of metastable and high-temperature phases of the metal in the thermal decomposition of OMC,[21] the appearance of electronically excited states of the metal atoms and singly-charged metal ions on decomposition under electron impact (on the basis of emission spectra[29]) and on photo-decomposition or decomposition induced by a laser (on the basis of absorption[16] and emission[23] spectra), and the segregation of the metal under the conditions of the low-temperature decomposition of the OMC, in particular bistriphenylgermylmercury, on cooling the solution to 77 K[113] are evidence for the thermodynamic non-equilibrium state of the OMC + decomposition product system.

If the state of the OMC is thermodynamically stable (or chemically stable according to Gray[114]) and stable with respect to diffusion,[114] one can assume that such a state is stable as regards all aspects of stability (quantum-chemical, thermodynamic, kinetic, and macrokinetic) and is an equilibrium state. Chemical instability can never be observed in an equilibrium system but it can play an indirect role under conditions remote from equilibrium. The region of the phase space in which chemical instabilities can be observed is then always located near a region where diffusion instabilities exist.[114] The diffusion stability of an atomic metal + organic complex-forming compound system gives rise to the possibility, in the course of matrix synthesis, of the transition of the system to a kinetically and thermodynamically stable state of the OMC as a result of fluctuations. On the other hand, the diffusion instability of such a system leads to the thermodynamic instability of the OMC as a consequence of its kinetic instability, because of the possibility that the metal atoms may aggregate and an equilibrium may be established between the OMC and the solid metal or metal clusters having a large effective surface area.[25,80] Rigid or highly viscous matrices are therefore used for the synthesis of OMC with atomic metals. The breakdown of conditions for the matrix isolation of the metal atoms from one another and the diffusion instability of the matrix[24,115] lead to a greater probability of the formation of polynuclear OMC and metal clusters as products of the condensation of the intermediate compounds, in which the number of ligands at the metal is insufficient for the kinetic stabilisation of the OMC: $M + L \rightarrow ML \xrightarrow{ML} M_2L_2$ and $M + ML_2 \rightarrow M_2L_2$, etc. Reactions of bistoluenechromium(0) and bistoluenevanadium(0) of a similar type with chromium and vanadium atoms have been recently discovered.[116]

A good example of the formation of dissipative structures is provided by the irreversible heterogeneous gas–solid reactions used for the deposition of inorganic coatings from the vapour phase in the thermal decomposition of OMC.[20,21] The growing surface of the solid phase can be regarded as an open thermodynamic system in deposition processes.[117] The characteristic features of the formation of dissipative structures in these processes have been investigated in fair detail in a number of studies.[20,21,117-123] It has been shown that processes involving the formation of a solid phase (the attainment of stationary surface areas of the growing solid phase, the multiphase nature of the deposit, the aggregation of particles and their dynamic characteristics, and the layer structure of the particles formed in the kinetic region of the reaction),[117] OMC adsorption processes and processes involving the desorption of the decomposition products,[21] the possible autocatalytic processes,[118] the finite rate of removal of the decomposition products,[120] the limited thermal conductivity of the support, and the inadequate power of the heat flux through the support[121] play an important role in their formation. Vibrational and monotonic processes involving the attainment of stationary states,[119] the limitation of the rate of the deposition process with respect to pressure and the occurrence of a peak in this rate,[119] temperature hysteresis and the excitation of auto-oscillations in the rate of deposition,[121] the fixation of time oscillations in concentration and temperature in the form of three-dimensional layer structures of the coatings,[119,122,123] and also the fixation of three-dimensional fluctuations of the rate of growth in the form of columnar structures[21,123,124] and filamental crystals[21,125] have been observed experimentally. Studies of theoretical models of the deposition process have demonstrated their satisfactory agreement with experiment.[21]

The formation of dissipative structures in a solution of an OMC has been observed for allylpalladium compounds[126] under the conditions of hindered diffusion in Liesegang rings and also for the ferrocene–ferrocenium system on irradiation with visible light of their solutions in alcohols.[127]

Under the conditions of non-linear kinetics, there is a possibility of a state of the system such that the OMC decomposition process is strongly retarded, despite the existence of conditions under which the OMC might have been unstable both thermodynamically (according to equilibrium thermodynamics) and kinetically. In such cases the non-equilibrium thermodynamic stability of the OMC in relation to the decomposition process arises, but this stability corresponds to the attainment by the system of a stationary state which in the general case may be unstable in time (in relation to local structural fluctuations). This state may be called a dynamically stable non-equilibrium state, which corresponds to a definite degree of the thermal decomposition process.

---o0o---

Thus one may conclude that a complex and varied problem such as that of the stability of OMC in their synthetic and decomposition processes must be solved only by a combined procedure on the basis of general concepts of the stability and structure of material systems taking into account all its aspects and the energy and steric factors. This approach makes it possible to investigate the stability of various types of OMC in relation to perturbations of any type, to reduce to

an integral unique system the results obtained in this field, and to discover various aspects of the problem and their interrelation. The approach can also help to abolish the existing confusion among investigators who mix up various aspects of the stability of OMC. On the other hand, the combined approach is very fruitful, because it allows one to use for the solution of the problem the advances in various sciences—chemistry, physics, and mathematics. It must be emphasised that the approach described permits the investigation of the OMC synthesis-decomposition processes, starting with idealised processes in an isolated OMC molecule and continuing up to real processes, which constitute the basis of a series of new promising technologies involving the industrial application of OMC.[20,21,24,25]

Thermal Decomposition and Stabilisation of Poly(vinyl Chloride)

V.B.Troitskii and L.S.Troitskaya

The kinetics and mechanism of the thermal dehydrochlorination of poly(vinyl chloride) and low-molecular-weight chlorohydrocarbons which model various fragments of the polymer molecule, are discussed. Studies designed to determine the qualitative and quantitative compositions of the unstable fragments in poly(vinyl chloride) macromolecules by ^{13}C NMR are examined. Attention is concentrated on the consideration of the mechanism of the action of the most effective thermostabilisers for the polymer-organotin compounds. The principal features of synergism in the stabilisation of poly(vinyl chloride) and the mechanism of the action of synergistic mixtures are analysed.
The bibliography includes 107 references.

I. INTRODUCTION

Poly(vinyl chloride) (PVC) occupies one of the leading places in the world manufacture of polymeric materials. An important disadvantage of PVC is its instability towards various kinds of thermal and chemical influences. The thermal ageing of the polymer begins above 373 K.

The main principles of the ageing and stabilisation of polymers have been examined in Emanuel' and Buchachenko's book.[1] Various aspects of the problem of the thermal decomposition and stabilisation of PVC have been the centre of attention of many investigators. Studies on the ageing and stabilisation of PVC in Gorky are being pursued under the supervision of G.A.Razuvaev.

The aim of the present review is to analyse the present state of research into the main problems of the thermal decomposition and stabilisation of PVC. PVC belongs to the class of polymers which decompose under the influence of heat with elimination of side fragments from the macromolecules with the preferential formation of one low-molecular-weight product (namely HCl—more than 90%) and polyenes:

$$\sim(CH_2—CHCl)_n\sim \rightarrow mHCl + \sim(CH_2—CHCl)_{n-m}—(CH=CH)_m\sim;\quad n > m.$$

Despite the apparent simplicity of this overall reaction, investigators of the thermal decomposition of PVC have encountered extremely complex processes, some of the details of which still remain obscure.

II. THERMAL DECOMPOSITION OF LOW-MOLECULAR-WEIGHT MODEL COMPOUNDS

The experimental data (Table 1) on the thermal decomposition of compounds modelling various fragments of PVC macromolecules permit the following conclusions. In gaseous and liquid phases all chlorohydrocarbons decompose under the influence of heat with formation of HCl and an olefin (other products have not been detected). The kinetic curves for the decomposition of chlorohydrocarbons are described by first-order equations. In terms of the rate of their decomposition (or in terms of the corresponding rate constants), alkyl chlorides can be arranged in the sequence tertiary ≫ secondary ≫ primary.

Table 1. Arrhenius parameters and the temperature ranges of the thermal decomposition reactions of low-molecular-weight models of fragments of PVC macromolecules.

Model compound	$\lg A$, s^{-1}	E, kJ mol^{-1}	ΔT*, K	Phase	Refs.

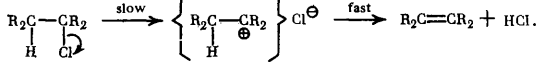
8-Chloro-6-tridecylene	8.14	105	438—469	»	[9]
7-Chlorononа-3,5-diene	7.99	81	343—369	»	[9]

*ΔT = temperature range of the decomposition reaction.

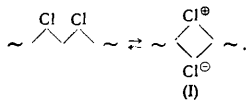
The activation energy for the thermal decomposition of secondary derivatives is lower by 21—33.5 kJ mol^{-1} and that of tertiary degrees is lower by 29—33.5 kJ mol^{-1} than the activation energy for the decomposition of primary derivatives. The reaction is greatly accelerated by the presence of a non-terminal double bond in the β-position relative to the chlorine atom. If the carbon—carbon bond is located at the end of the molecule (as in 3-chlorobut-1-ene), then the activation energy for the thermal decomposition of this compound is much higher than for a compound with an internal double bond (as in 4-chlorohex-2-ene) and is only slightly lower than the activation energy for the thermal decomposition of secondary-chlorohydrocarbons. An alkoxy-group

in the α-position relative to the chlorine has an appreciable accelerating effect on the thermal decomposition of the chlorohydrocarbon (Table 1).

There is no rigorous evidence in the literature concerning the elementary steps in the thermal dehydrochlorination of the chlorohydrocarbons presented in Table 1. The absence of compounds other than HCl and an olefin, the absence of an appreciable retarding effect by free radical inhibitors on the thermal decomposition of the chlorohydrocarbons listed in Table 1, a marked accelerating effect of nucleophilic substituents (groups with a carbon–carbon double bond and alkyl and alkoxy-groups in the α-position relative to the carbon–carbon bond), and the acceleration of the thermal decomposition of chlorohydrocarbons in the liquid phase with increase of the polarity and basicity of the solvent have been established experimentally.[2–10] All these factors suggested[2,8] that the thermal decomposition reactions of chlorohydrocarbons are two-stage processes of type E1 (unimolecular elimination reactions) and that the first and rate-determining stage is an intense polarisation (partial ionisation but not dissociation) of the C–Cl bond:



It has been recently suggested[11] that the primary elementary step in the thermal dehydrochlorination of chlorohydrocarbons which model the PVC molecule is the formation of cyclic chloronium ions:



(I)

It has been shown[11,12] that a large amount of olefin (~30%) and HCl is formed in the liquid phase during the thermal decomposition of a chlorohydrocarbon containing in its molecule one chlorine atom (7-chlorotridecane) in the presence of dodecane-1-thiol or 9,10-dihydroanthracene. The thermal decomposition of chlorohydrocarbons containing two or three chlorine atoms per molecule (4,6-dichloro-n-nonane, 2,4,6-trichloro-n-heptane) in the presence of the same chain transfer agents yields only the chlorohydrocarbon reduction product. Thus different products are formed from monochlorohydrocarbons, on the one hand, and from dichloro- and trichlorohydrocarbons, on the other.

It has been shown[11,12] that the thermal decomposition of polychlorohydrocarbons, modelling the fragments of PVC macromolecules, in the presence of thiols involves the reaction

$$\sim CH_2{-}CHCl\sim + 2RSH \rightarrow \sim CH_2{-}CH_2\sim + RSSR + HCl; \quad R = Alk, Ar. \qquad (1)$$

The composition of the reaction products, in particular the presence of a disulphide, indicates a free-radical process mechanism.

Depending on the reaction conditions, the cyclic chloronium ion (I) can decompose both via a free-radical mechanism (in the presence of an electron donor and an effective chain transfer agent) and via an ionic-molecular mechansim.[11] There is also a possibility of a radical-chain mechanism of the thermal decomposition of polychlorohydrocarbons in the presence of active chain transfer agents, which include thiols and 9,10-dihydroanthracene.

The effective activation energy for a radical chain reaction with quadratic chain termination is described by the expression[12]

$$E_{eff} = \tfrac{1}{2}E_i + E_p - \tfrac{1}{2}E_t,$$

where E_i is the activation energy for the initiation step (approximately equal to the energy of the C–Cl bond dissociated), E_p the activation energy for the most endothermic chain propagation stage, and E_t the activation energy for chain termination. E_i and E_p make the greatest contribution to E_{eff}.

The C–Cl bond energy ($\sim E_i$) in chlorohydrocarbons having the structure $\sim(CH_2 - CHCl)_n\sim$ is 326.6 kJ mol^{-1}, while in compounds of the type $\sim(CH{=}CH)_m{-}CHCl\sim$ it amounts to 234.5–251.2 kJ mol^{-1}.[13] The most endothermic chain propagation stages are as follows:[14]

$$\sim CHCl{-}\dot{C}H{-}CHCl\sim \rightarrow \sim CHCl - CH{=}CH\sim + Cl^{\cdot}; \qquad (2)$$

$$\sim CH_2{-}\dot{C}Cl{-}CH_2\sim \rightarrow \sim CH{=}CCl{-}CH_2\sim + H^{\cdot}. \qquad (3)$$

Stage (2) is 83.7 kJ mol^{-1} endothermic and stage (3) is 163.3 kJ mol^{-1} endothermic.[14] After adding together $1/2E_i$ and E_p, neglecting E_t, we obtain E_{eff} = 326.6 kJ mol^{-1} for compounds of the type $\sim(CH_2 - CHCl)_n\sim$ and E_{eff} = 280.5–283.9 kJ mol^{-1} for $\sim(CH{=}CH)_m{-}CHCl\sim$.

For the thermal decomposition of chlorohydrocarbons in the liquid phase in the presence of active chain transfer agents (for example, of thiols) the most endothermic stages (2) and (3) do not occur because the free radicals react with the thiol and the effective activation energy for the thermal decomposition of hydrocarbons becomes equal to approximately half the C–Cl bond energy. Consequently, owing to the decrease of E_{eff} in the presence of active chain transfer agents, there is an increased probability of the decomposition of the chlorohydrocarbons via a radical chain mechanism.

The difference between monochlorohydrocarbons and polychlorohydrocarbons consists in the fact that the thermal decomposition of the latter involves the formation of the polyenes $\sim(CH{=}CH)_m{-}CHCl\sim$, in which the C–Cl bond energy is lower by ~83.7 kJ mol^{-1} than the energy of the same bond in monochlorohydrocarbons. Consequently, they are also characterised by a lower value of E_{eff} for thermal decomposition via a radical chain mechanism.

Thus the radical mechanism for the thermal decomposition of polychlorohydrocarbons which model the fragments of PVC macromolecules can compete with the ionic-molecular mechanism only in the presence of electron donors and active chain transfer agents. In the absence of such additives, the ionic-molecular mechanism predominates.

III. KINETICS OF THE THERMAL DECOMPOSITION OF POLY(VINYL CHLORIDE)

The thermal decomposition of PVC in the presence of HCl is an autocatalytic process.[15–26] Conditions under which critical phenomena are observed have been formulated and equations for the kinetics of the thermal decomposition of the polymer in a closed volume with removal of HCl have been derived.[15,22] The critical size of the polymer specimen, i.e. the maximum thickness of the film for which autocatalysis does not yet develop, is very small:[22] 0.24 mm at 463 K, 0.18 mm at 473 K, and 0.15 mm at 483 K. Hence it follows that correct data for the kinetics of the thermal decomposition of PVC, uncomplicated by autocatalysis, can be obtained only by employing a polymer in the form of a thin layer of powder or a film in a high vacuum. In addition, autocatalysis can be excluded by decomposing PVC in solution, but the solvent must not then exert a significant influence on the dehydrochlorination process.[24]

Fig. 1 presents experimental data for the thermal decomposition of PVC in the form of a thin layer of powder under high vacuum[27] and Fig. 2 illustrates the kinetic curves for the dehydrochlorination of the polymer in solution in 1,2,4-trichlorobenzene.[24] The dehydrochlorination process consists of two stages: initially the rate of reaction falls and after a certain time becomes virtually constant. This shows that unstable fragments of the macromolecules are decomposed initially and, after the complete decomposition, the rate of dehydrochlorination is determined by the decomposition of only the normal units of the PVC macromolecules. An increase in the initial concentration of the unstable fragments leads to an increased initial rate of dehydrochlorination of PVC and hardly affects the steady-rate of the process (Fig. 2).[24]

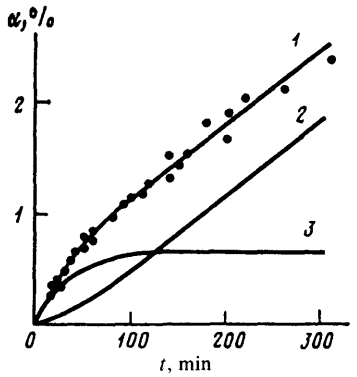


Figure 1. Kinetic curves for the dehydrochlorination of PVC *in vacuo* (~10–2 Pa) at 473 K and with constant freezing out of HCl: 1) experiment; 2) calculation by Eqn. (19); 3) result of the graphical subtraction of curve *2* from curve *1*;[27] α = degree of conversion.

Effective rate constants have been determined for the thermal decomposition of the unstable chloroallyl (k^1_{eff}) and ketochloroallyl ($k_п$) fragments:

$$k^1_{eff} = 10^{9.6\pm0.5} \times e^{-28000\pm1000/RT}\ s^{-1}\ (\text{Refs. 17, 27}),$$
$$k_п = 10^{14.9\pm0.8} \times e^{-36100\pm1700/RT}\ s^{-1}\ (\text{Ref. 26}),$$

as well as normal PVC units:

$$k^0_{eff} = 10^{11.8\pm0.5} \times e^{-38000\pm1000/RT}\ s^{-1}\ (\text{Refs. 17, 27}),$$
$$k_0 = 10^{9.4\pm0.7} \times e^{-21500\pm1500/RT}\ s^{-1}\ (\text{Ref. 26}),$$

where k_0 is the rate constant for the thermal decomposition of the normal units and k^0_{eff} the effective rate constant for their decomposition.

An important characteristic of the thermal decomposition of PVC is the length of the kinetic chain. The average length of the kinetic chain l_{av} can be determined from experimental data on the thermal decomposition of PVC containing unstable fragments at a known concentration by a simple division of the total amount of HCl evolved in the decomposition of all the unstable fragments by their initial concentration. It follows from the literature[24,28] that l_{av} = 4–10. This value of l_{av} is greater than the average number of conjugated double bonds in the polyenes formed, which is 3–5 according to ultraviolet spectroscopic determinations.[24,29] This is associated with the participation of the polyenes in the secondary intra- and inter-molecular cyclisation reactions,[11,20,24,29] which decreases the average number of conjugated double bonds.

The thermal decomposition of "ideal" PVC which contains no unstable fragments can be represented by the following equations[17,25,27]

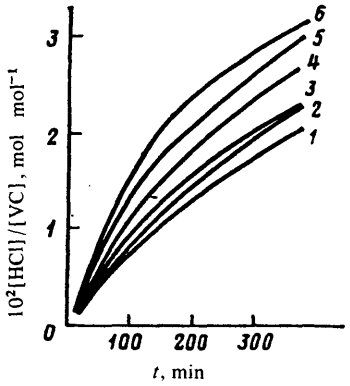

Figure 2. Kinetic curves for the thermal decomposition of PVC (1% solution in 1,2,4-trichlorobenzene) at 473 K for different initial contents of chloroallyl groups (mole %): 1) 0.006; 2) 0.012; 3) 0.017; 4) 0.036; 5) 0.069; 6) 0.107;[24] VC = vinyl chloride.

Initiation:

$$\sim(CH_2{-}CHCl)_n{\sim} \xrightarrow{k_0} HCl + \sim(CH_2{-}CHCl)_{n-1}{-}(CH{=}CH){\sim}. \quad (4)$$

Chain propagation:

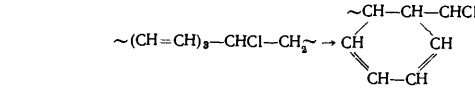
$$\sim(CH_2{-}CHCl)_{n-1}{-}(CH{=}CH){\sim} \xrightarrow{k_1} HCl + \sim(CH_2{-}CHCl)_{n-2}{-}(CH{=}CH)_2{\sim}; \quad (5)$$

$$\sim(CH_2{-}CHCl)_{n-2}{-}(CH{=}CH)_2{\sim} \xrightarrow{k_2} HCl + \sim(CH_2{-}CHCl)_{n-3}{-}(CH{=}CH)_3{\sim}; \quad (6)$$

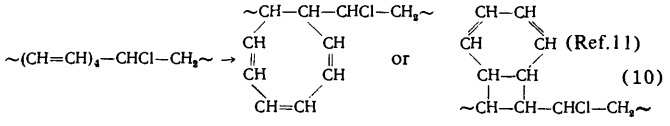
$$\sim(CH_2{-}CHCl)_{n-3}{-}(CH{=}CH)_3{\sim} \xrightarrow{k_3} HCl + \sim(CH_2{-}CHCl)_{n-4}{-}(CH{=}CH)_4{\sim}; \quad (7)$$

$$\sim(CH_2{-}CHCl){-}(CH{=}CH)_{n-1}{\sim} \xrightarrow{k_{n-1}} HCl + \sim(CH{=}CH)_n{\sim}. \quad (8)$$

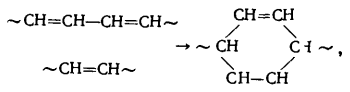
Chain termination:



; (9)



(10)

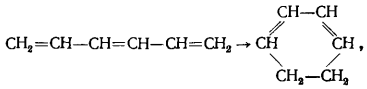


(11)

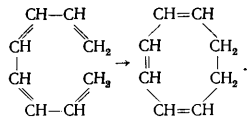
where $n = l_{av}$.

Reaction (4) represents the statistical initiation of the elimination of HCl from any unit of the macromolecules.

The occurrence of the termination reactions (9) and (10) has been confirmed by experiments with low-molecular-weight model compounds. The occurrence of the following cyclisation reactions of trienes and tetraenes has been demonstrated:[30,31]



(12)



(13)

Reactions (12) and (13) are described by first-order kinetic equations with the Arrhenius parameters $\lg A = 11.0$ and $E = 125$ kJ mol^{-1} for reaction (12)[30] and $\lg A = 11.0$ and $E = 71$ kJ mol^{-1} for reaction (13).[31]

The intermolecular polyene cyclisation reaction (11) leads to the formation of a cross-linked polymer.[19]

On the basis of the scheme presented above, the rate of evolution of HCl can be expressed by the equation[17,27]

$$\frac{d[HCl]}{dt} = k_0c_0 + k_1c_1 + k_2c_2 + \ldots + k_nc_n, \quad (14)$$

where k_0, k_1, ..., k_n are the rate constants for different stages, c_0, c_1, c_2, ..., c_n are the concentrations of the corresponding fragments, and $n = l_{av}$.

Using the theory of consecutive reactions,[32] we shall express c_0, c_1, c_2, ..., c_n at time t in terms of c_0^0 (the initial concentration of the ~CH_2–CHCl~ fragments in the polymer) and the rate constants k_0, k_1, ..., k_n:

$$c_0 = c_0^0 e^{-k_0t}, \quad (15)$$

$$c_1 = c_0^0\left[\frac{k_0}{k_1 - k_0}e^{-k_0t} + \frac{k_0}{k_0 - k_1}e^{-k_1t}\right], \quad (16)$$

$$c_2 = c_0^0\left[\frac{k_0k_1}{(k_1 - k_0)(k_2 - k_0)}e^{-k_0t} + \frac{k_0k_1}{(k_0 - k_1)(k_2 - k_1)}e^{-k_1t} + \right.$$
$$\left. + \frac{k_0k_1}{(k_0 - k_2)(k_1 - k_2)}e^{-k_2t}\right] \text{ etc.} \quad (17)$$

Having substituted the value of c_0, c_1, c_2, etc. [Eqns. (15)–(17)] in Eqn.(14), subject to the condition $k_0 \ll k_1 \ll k_2 \cong k_n$ (this has been demonstrated for model compounds[2–10]), we arrive at a greatly simplified formula:[17,27]

$$\frac{d[HCl]}{dt} = k_0c_0^0 l_{av}\left(e^{-k_0t} - \frac{l_{av} - 1}{l_{av}}e^{-k_1t}\right). \quad (18)$$

Integration of Eqn.(18) yields an expression for the concentration of HCl:

$$[HCl] = l_{av}c_0^0(1 - e^{-k_0t}) - (l_{av} - 1)c_0^0\frac{k_0}{k_1}(1 - e^{-k_1t}). \quad (19)$$

It can be shown that $k_{eff}^0 = k_0l_{av}$ and $k_{eff}^1 = k_1l_{av}$.[17,27] Knowing k_{eff}^0, k_{eff}^1, and l_{av}, it is possible to determine k_0 and k_1. The constants k_0, k_1, and l_{av} obtained by different workers[17,24,27,33,34] are listed in Table 2.

Comparison of Tables 1 and 2 shows that the rate constants for the decomposition of fragments of the PVC macromolecules are close to the rate constants for the thermal decomposition of the model compounds in the liquid phase.

Having substituted the values of k_0, k_1, and l_{av}[17,27] in Eqn.(19), it is possible to calculate the time variation of the HCl concentration in the decomposition of the "ideal" polymer which does not contain unstable fragments (Fig.1, curve *2*). The existence of a certain initial section of curve *2* where the rate of formation of HCl increases is striking. After that, the rate no longer changes. The increase in the rate of formation of HCl is associated with the accumulation and decomposition of fragments containing carbon–carbon double bonds: initially the rate of accumulation of such fragments is greater than the rate of decomposition but afterwards the two rates approach one another and equilibrium is attained at a constant concentration of the chloroallyl fragments. The equilibration time depends on the rate constant ratio k_0/k_1, which follows from Eqn.(19).

Table 2. Arrhenius parameters for the thermal decomposition reactions of fragments of PVC macromolecules.

Polymer fragment	$\lg A$, s^{-1}	E, kJ mol^{-1}	Phase	ΔT, K	l_{av}	Refs.
~CH_2–CHCl~	11.0	159	polymer melt	453—523	8	[17, 27]
~CH=CH–CHCl–CH_2~	9.8	113	ditto	453—483	8	[17, 27]
~CH_2–CHCl~	3.4	90	»	418—448	—	[34]
~CH=CH–CHCl–CH_2~	—	—	»	453	8	[33]
~CH=CH–CHCl–CH_2~	—	—	polymer solution	473	10—13	[24]

Fig.1 demonstrates the discrepancy between the experimental curve *1* and the theoretical curve *2* calculated by Eqn.(19). This means that the initial rate of thermal decomposition of PVC is determined not only by the statistical decomposition of the normal units of the macromolecule but also by the thermal decomposition of unstable fragments always present in the initial polymer. Graphical subtraction of curve *2* from curve *1* yields the kinetic curve for the thermal decomposition of the unstable fragments alone (curve *3*).

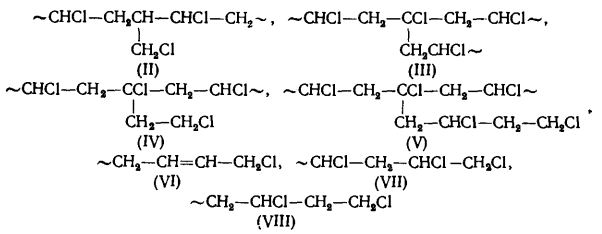
Fig.1 clearly illustrates the contribution of two thermal decomposition processes, initiated by the statistical decomposition of the normal units (curve *2*) and the unstable fragments (curve *3*), to the overall dehydrochlorination reaction of real PVC as a function of time. Knowing l_{av} and the amount of HCl evolved in the decomposition of all the unstable fragments (which can be readily determined from curve *3* in Fig.1), it is possible to estimate the concentration of the unstable fragments in PVC. For the PVC specimen whose thermal decomposition is illustrated in Fig.1, it amounts to ~0.08 mole %.

IV. THE NATURE OF THE UNSTABLE FRAGMENTS IN POLY(VINYL CHLORIDE) MACROMOLECULES

The controversy concerning the nature and concentration of the unstable fragments in PVC macromolecules and also the contribution of each of them to the initial rate of thermal decomposition of the polymer has continued for a long time.[7,9–11,15,24,28,29,33–50] The difficulty of the solution of this problem consists in the fact that the unstable fragments are present in the polymer at low concentrations.

The concentration of double bonds in PVC has been determined by the bromination[36,44] and ozonolysis[24,33,34,40] methods as 0.1–0.5 mol %. By combining the ozonolysis method with hydrolysis and subsequent determination of the molecular weight distribution (MWD) of the polymer[24,33,40] by ^{13}C NMR[44,47] and other procedures,[39] it was established that PVC contains 0.01–0.05 mole % of internal chloroallyl fragments. The bulk of the double bonds in PVC are located either at the ends or near the ends of the macrochains.

The question of the presence of a chlorine atom at a tertiary carbon atom in PVC has been the subject of controversy for many years. A convenient method has been developed[11,35] for the reduction of PVC to polyethylene using Bu_3SnH or Bu_3SnD as the reducing agent. Analysis of the ^{13}C NMR spectra of the reduced PVC demonstrated the presence of the following fragments in the polymer:[11,35,43,44]



The contents of the fragments (II)–(V) in different PVC specimens are presented in Table 3.

Table 3. Concentrations of branched structures in PVC macromolecules.[35]

Brand of PVC	T_p, K*	No. of fragments per 1000 monomer units			
		(II)	(III)	(IV)	(V)
A	373	4.0	0.6	1.6	1.8

*T_p = polymerisation temperature of vinyl chloride.

For different brands of PVC, obtained at temperatures ≤348 K, the overall concentration of the fragments containing a chlorine atom at a tertiary carbon atom is 0.1–0.28 mole %.[11,35,43,44]

PVC contains smaller amounts (0.01 mole %) of peroxy- and hydroperoxy-groups[33,36–38] and up to 0.02 mole % of internal fragments with a "head-to-head" structure.[48]

It has been demonstrated on model compounds that the peroxy- and hydroperoxy-groups as well as units of the polymer chain containing a chlorine atom in the allyl position (~CH=CH–CHCl–CH_2~) or at a tertiary carbon atom are unstable fragments of PVC macromolecules which readily decompose,[22–10,46] A group of investigators have carried out special experiments designed to synthesise PVC specimens containing low concentrations of the above unstable fragments.[24,28,33,45] It has been shown that an increase in the concentration of the internal chloroallyl fragments,[24,33,39,40,45] groups with chlorine atoms at a tertiary carbon atom,[28,43,44] and peroxy- and hydroperoxy-fragments[33,37,38] in the polymer appreciably increases the initial rate of thermal decomposition of the polymer.

The formation of all the unstable fragments in the initial PVC is determined by the characteristic features of the radical polymerisation of vinyl chloride and their quantitative content is directly related to the technological parameters of a specific process: the purity of the monomer, the concentration and nature of the initiator, the polymerisation temperature, the amount of oxygen present in the system, the type and concentration of the emulsifying agent, the suspension stabiliser and other additives, the degree of completion of the polymerisation process, the degree of purification of the water used, etc.

The presence of oxygen in the polymerisation of vinyl chloride leads to the formation of polymeric peroxides and hydroperoxides.[33,38,51] Their decomposition via the general mechanism[33,38,51]

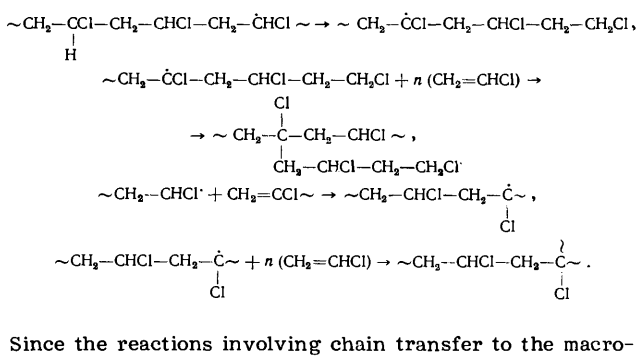
takes place simultaneously with the formation reaction. After polymerisation, up to 20–30% peroxy- and hydroperoxy-groups remain undecomposed in the polymer.[38]

In the decomposition of polymeric peroxides in the presence of an excess of the monomer, i.e. under the conditions of the polymerisation of vinyl chloride, there is a possibility that fragments of the polymeric peroxides are incorporated as end groups in the PVC macromolecule:

Judging from the parameters of the thermal decomposition of model compounds containing an alkoxy-group in the α-position relative to the C–Cl bond, the RCHCl–OR^1 fragments can also be classified as unstable groups in PVC macromolecules (Table 1).

It has been established[50] that the polymer formed on polymerisation of vinyl chloride under the conditions of a reduced pressure of the monomer contains a greater amount of unstable fragments, in particular branched structures with a chlorine atom at a tertiary carbon atom, and its thermal stability is lower.

The following mechanisms have been proposed for the formation reactions of the branched fragments with mobile chlorine atoms:[11,35]



Since the reactions involving chain transfer to the macromolecule in the polymerisation of vinyl chloride compete with the chain propagation reactions, whose rate is determined by the concentrations of the macroradicals and the monomer, it follows that the rate of the interaction of the macroradicals with the polymer molecule and the probability of the formation of unstable fragments increase with decrease in the monomer concentration.

Thus it has now been established that, in the usual brands of PVC, the highest concentration of unstable fragments is that of chlorine atoms at the branching sites (0.1–0.28 mole %). Consequently they should in fact exert a decisive influence on the initial rate of thermal decomposition of the polymer.[11,35,43,44] The quantitative contribution of other unstable groups (peroxy-, hydroperoxy-, and chloroallyl) and possibly also fragments of the type ~CH_2–CCl(OR)~ and ~O–CH=CH–CHCl~ to the initial rate of thermal decomposition of the polymer remains obscure. The influence of conditions in the polymerisation of vinyl chloride on the quantitative content of each unstable fragment in the polymer has not been adequately investigated.

The role of the ~C(O)–CH=CH–CHCl~ fragments in the thermal decomposition of PVC is not considered in this review, since this question has been discussed exhaustively in a recently published book[42] and review.[34]

V. THE MECHANISM OF THE THERMAL DECOMPOSITION OF POLY(VINYL CHLORIDE) IN THE ABSENCE OF HCl

There exist two theories of the thermal decomposition of PVC: the ionic-molecular[11,17,24,33,41] and radical[37,52,53] theories. According to the radical theory, the principal active species involved in the chain propagation reactions is atomic chlorine. Metals behave as effective acceptors of atomic chlorine. Mercury and silver (metals which do not interact with HCl) do not affect the rate of dehydrochlorination of PVC *in vacuo* after being added to the polymer even in large amounts (in 1 : 1 proportions by weight).[16] Mercury vapour does not retard the thermal decomposition of PVC in the absence of HCl either.[52] These findings show that the thermal decomposition of PVC proceeds mainly via an ionic-molecular mechanism. Data for the thermal decomposition of model compounds in the liquid phase (Section II) also serve as an argument in support of the ionic-molecular mechanism.

The occurrence of radical processes in the thermal decomposition of the polymer is indicated by the following experimental data. Apart from HCl, benzene is evolved in small amounts in the reaction (a factor of 100–1000 less then HCl), its yield diminishing in the presence of free radical inhibitors such as nitric oxide and α-naphthol.[22,52] The peroxides and hydroperoxides present at low concentrations in the polymer increase the initial rate of thermal decomposition of PVC.[33,37,53] However, it has been shown by the inhibitor method that the formation of HCl via the radical mechanism is a process involving very short chains (the chain length is ~2).[52] It follows from the experimental data for the thermal decomposition of PVC containing a specified amount of polymeric peroxides[33] that the average chain length of the radical dehydrochlorination reaction is ~2. This agrees with the above results.[52] The short chain length (~2) is apparently associated with the endothermic nature of the chain propagation stages (2) and (3), which hinders the radical chain process.

Thus the thermal decomposition of PVC in the absence of HCl proceeds mainly via the ionic-molecular mechanism complicated by radical reactions.

VI. THE MECHANISM OF THE AUTOCATALYTIC DECOMPOSITION OF THE POLYMER

The autocatalysis of the thermal decomposition of PVC is explained by the interaction of HCl with polyenes.[16,18,21,54] Definite information about the mechanism of this process is provided by experiments on its retardation by compounds which do not interact with HCl.[16,17,19–21,55–61] The stabilising effect of these compounds cannot be explained by the destruction of the catalyst.

Catalysis is not observed in the thermal decomposition of PVC powder in sealed evacuated bulbs in the presence of maleic anhydride, although HCl does accumulate in the bulbs.[21,55] The autocatalytic decomposition of PVC is suppressed by mercury, silver (in the form of a finely dispersed powder mixed with the polymer particles),[16,52,57] trialkylsilanes,[58,59] and the chlorides of coordination-unsaturated metals at microconcentrations.[17,56,60,61]

We shall now discuss the experimental data obtained from the standpoint of the radical and ionic theories of the autocatalytic decomposition of PVC. As shown in Section II, in the presence of active chain transfer agents, the probability of the radical thermal decomposition reactions of polychlorohydrocarbons should increase as a consequence of the suppression of the most endothermic chain propagation stages (2) and (3). Hydrogen chloride is a low-molecular-weight compound which readily diffuses in PVC and can play the role of a chain transfer agent and hence increase the rate of the radical chain thermal decomposition reaction of the polymer.

Mercury and silver can accept chlorine atoms; they should inhibit the radical thermal decomposition of PVC. However, from the standpoint of the radical chain dehydrochlorination of PVC in the presence of HCl, it is difficult to account for the suppression of the autocatalytic dehydrochlorination of PVC by maleic anhydride and metal chlorides at microconcentrations and also the fact that the usual inhibitors of free-radical reactions, namely toluene, diphenylmethane, and sterically hindered phenols, do not have an appreciable retarding effect on the autocatalytic decomposition of the polymer.[20,21,52,62] Maleic anhydride enters into the Diels–Alder reaction, but only with dienes having the cisoid structure. However, polyenes with the transoid configuration remain in the polymer and the radical chain process should therefore have developed. The chlorides of coordination-unsaturated metals react with polyenes to form paramagnetic charge-transfer complexes[63] whose involvement in the inhibition of radical reactions is difficult to explain.

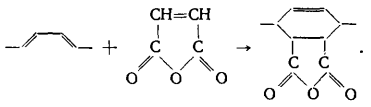
The radical chain theory of the autocatalytic decomposition of PVC also fails to explain the absence of a catalytic influence of HCl on the thermal decomposition of poly(vinylidene chloride) (PVDC),[17,20,23,64,65] a polymer whose chemical structure is close to that of PVC, and the accelerating effect of Cl_2 and Br_2 on the thermal decomposition of PVC, while no such effect is observed in the thermal decomposition of PVDC.[64]

The available experimental data can be accounted for by assuming that the interaction of HCl with polyenes results in the formation of charge-transfer complexes (CTC) in which the polyene behaves as the donor and HCl as the acceptor, the HCl reacting predominantly with polyenes having the cisoid structure:[17,27]

$[ClHCl]^{\ominus}$
(IX)

The complex $H^{\oplus}[ClHCl]^{\ominus}$ is a stronger electron acceptor than HCl, since the energy gain on formation of $[ClHCl]^-$ is 79.2 kJ mol^{-1}.[66] The ion pairs (IX) initiate the thermal decomposition of PVC via a heterolytic mechanism.

The inhibiting effect of maleic anhydride on the autocatalytic decomposition of PVC can be explained by the Diels–Alder reaction with *cis*-polyenes:



Trialkylsilanes reduce compound (IX) via the reaction[17]

The mercury and silver atoms interacting with polyenes can play the role of catalysts of the *cis–trans* isomerisation of the latter:

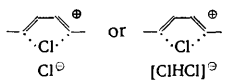
(20)

trans-Polyenes are thermodynamically more stable at 440–480 K than the *cis*-polyenes, since it is known[67] that, on heating above 373 K, *cis*-polyacetylene is converted into *trans*-polyacetylene.

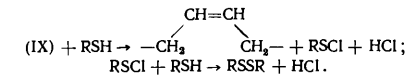
The paramagnetic CTC of the chlorides of coordination-unsaturated metals with polyenes can also play the role of catalysts of reaction (20).

The thermal decomposition of PVDC leads to the formation of polyenes with bulky electron-accepting substituents (chlorine atoms), which hinders their interaction not only with HCl but also with Cl_2 and Br_2. For this reason, these additives do not show an accelerating effect.[64]

The catalytic effect of Cl_2 and Br_2 on the thermal decomposition of PVC[64] can also be accounted for by the formation of an active intermediate species (ion pair) on interaction of the *cis*-polyene with the additive:



It may be that the reaction (1) of thiols with chlorohydrocarbons[11] also proceeds via the mechanism



In contrast to monochlorohydrocarbons, polychlorohydrocarbons give rise to polyenes on thermal decomposition, which interact with the acceptor (HCl) more readily than compounds with a single double bond.

Some workers believe that the autocatalysis is associated with the influence of HCl on the decomposition of the normal PVC units.[15,22,52]

Experimental data obtained recently lead to the conclusion that the autocatalytic decomposition of PVC in the presence of HCl has an ionic mechanism.[15,17,52,54]

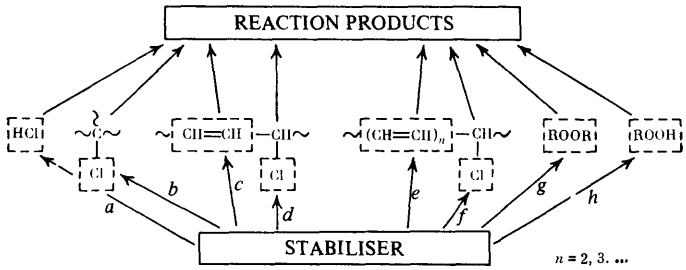
VII. THE MECHANISM OF THE ACTION OF EFFECTIVE STABILISERS OF POLY(VINYL CHLORIDE) IN ITS THERMAL DECOMPOSITION

The following procedures for reducing the rate of the autocatalytic decomposition of PVC follow from the ideas concerning the influence of HCl on the decomposition of the polymer: (1) by binding the HCl; (2) by interaction of the stabiliser with the double bonds (conjugated double bonds), and (3) by inhibition of the heterolytic chain reaction as a result of the deactivation of the ion pairs.

The initial rate of the non-catalytic decomposition can be reduced by reducing the concentration of the unstable fragments and the chain length l_{av} in the consecutive dehydrochlorination reaction.

It follows from Scheme 1 that the stabilisation of PVC is based on reactions of the stabiliser with HCl (*a*), reactions involving the nucleophilic substitution of the labile chlorine atoms by groups which are more strongly bound to the polymer (*b*, *d*, and *f*), reactions involving the addition to double (*c*) and conjugated double (*e*) bonds, and the decomposition of peroxides and hydroperoxides (*g* and *h*).

Scheme 1



The classification of stabilisers of PVC can be based on different features. It has been suggested that stabilisers be divided into two groups: (1) stabilisers acting on the non-catalytic HCl formation reaction and (2) stabilisers preventing the catalytic dehydrochlorination.[52] A method has been developed for determining the critical concentration of the HCl acceptors.[52,68] The classification based on the chemical structures of the stabilisers has been most widely adopted.

A classification of the PVC thermostabilisers based on their reactivities towards the units of the macrochains has also been proposed.[17]

The first group includes Group IA and IIA metal carboxylates,[20,68–70] compounds of the type R_4Sn (R = alkyl or aryl) and Ph_4Pb,[20] organic phosphites,[20,69,71,72] epoxy-compounds,[42,69] maleic anhydride (acid), maleate esters,[20,21,55,69,73,74] organosilicon and organogermanium hydrides,[58,59] oligosilanes,[75] and other compounds.[69] It has been shown[17,20,21,55,58,59,71,75] that the main stabilising function of the above compounds consists merely in reducing the rate of the autocatalytic decomposition of the polymer. The rate of the thermal decomposition of PVC in the presence of such stabilisers at best approaches the rate of its non-catalytic dehydrochlorination. These stabilisers are relatively inactive in nucleophilic substitution reactions (Scheme 1, reactions *b*, *d*, and *f*).

The second group includes the most effective PVC thermostabilisers: organotin derivatives of maleic and thioglycolic acids having the structures R_2SnX_2, $R_2Sn(OOCCH{=}CHCOO)$, and R_3SnX, where R = alkyl, X = OOCCH=CHCOOR, or SCH_2COOR,[20,69,76–83] as well as multicomponent synergistic mixtures based on Ca–Zn and Ba–Cd carboxylates.

Organic acid (except for maleic and thioglycolic acids) salts of dialkyltin, trialkyltin carboxylates,[20,69,83] triaryltin isocyanates,[84] cadmium carboxylates,[20,69,70,85] binary synergistic mixtures including zinc, cadmium, or dialkyltin carboxylates as well as an organic phosphite,[20,69,71,72] an organotin compound and an organic phosphite,[20,86] an organolead compound and an organic phosphite,[87] an organic phosphite and the chloride of a coordination-unsaturated metal,[20,71] an organosilicon or an organogermanium hydride and the chloride of a coordination-unsaturated metal,[88] the carboxylate of a coordination-unsaturated metal and a compound with OH, SH, and NH groups,[89–95] as well as ternary synergistic mixtures consisting of Ca–Zn carboxylates and a polyol, Ba–Cd

carboxylates and a polyol,[89,91,93-96] Group II metal carboxylates and epoxy-compounds,[42,69,97,98] and others[42,69] approach the second group in terms of the efficiency of their action.

In the presence of the above stabilisers the rate of dehydrochlorination of the polymer is several times lower [in the best case, in the presence of bis(alkyl maleate)dialkyltin derivatives, by a factor of 8[76]] than the rate of the non-autocatalytic decomposition of PVC. The efficiency of the action of the stabiliser is characterised by a period T from the start of decomposition in the presence of the stabiliser to the sharp increase in the rate of dehydrochlorination of PVC. In the thermal decomposition of PVC in the presence of stabilisers belonging to the second group, no colour change is observed during the period T and a cross-linked polymer is not formed. The stabilisers of this group participate in all the reactions indicated in Scheme 1.

The third group includes zinc carboxylates,[69,89-96] triphenyl-lead isocyanate,[87] organotin compounds having the structures $Ph_2Sn(OOCCH{=}CHCOO)$, Ph_2SnX_2, $RSnX_3$, and $R_2Sn(SCH_2COO)$, where R = alkyl and X = OOCCH=CHCOOR or SCH_2COOR,[69,76,83] and other compounds. They too are effective PVC stabilisers, but, in terms of the period T, they are appreciably inferior to compounds of the second group. Their characteristic feature is the formation, in the interaction with HCl and with fragments of the macrochains, of metal chlorides which are powerful catalysts of the dehydrochlorination of the polymer and of the reaction of the stabiliser with the normal units. This leads to the rapid consumption of the stabiliser and hence to the shortening of the period T.

In recent years much attention has been devoted to the study of the mechanism of the action of organotin compounds[11,17,34,42,69,76-83] and synergistic mixtures,[11,17,42,69,86-99] which effectively stabilise polymers and are widely used in practice.

1. Organotin Compounds

(a) Kinetics of the Thermal Decomposition of PVC in the Presence of Organotin Derivatives of Maleic and Thioglycolic Acids

We shall consider the kinetics of the thermal decomposition of PVC in the presence of the most effective stabilisers—organotin derivatives of maleic and thioglycolic acids. As an example, Fig. 3 presents the kinetic curve (curve *3*) for the accumulation of ionic chlorine in the thermal decomposition of the polymer in the presence of $Bu_2Sn(OOCCH{=}CHCOOC_6H_{11})_2$. Three sections can be distinguished in the curve: along the first section, the rate continually diminshes, along the second it is constant, and along the third it rises sharply.

The initial section of the kinetic curve corresponds to the interaction of the unstable fragments with the stabiliser. The presence of the stationary section shows that all the unstable units of the initial polymer have reacted with the stabiliser and a constant rate of thermal decomposition, initiated by the statistical disruption of the normal units of the macrochain, is established. The acceleration of the dehydrochlorination of PVC along the third section of curve *3* (Fig. 3) is caused by the development of the catalytic decomposition of PVC.

It has been demonstrated by γ-resonance spectroscopy [Mössbauer spectroscopy][79] that the organotin derivatives of maleic and thioglycolic acids Oct_2SnX_2, where X = OOCCH=CHCOOOct-iso or $SCH_2COOOct$-iso and Oct = octyl, mixed with PVC are converted into $Oct_2SnCl(X)$ at the end of the period T at 458 K and not into Oct_2SnCl_2, as suggested earlier by many investigators.

It is also seen from the kinetic data (Fig. 3, curve 3)[76] that at the end of the period T one acid residue in $Bu_2Sn(OOCCH{=}CHCOOC_6H_{11})_2$ is substituted by chlorine. During the first 70 min, 85% of dibutylbis(cyclohexyl maleate)tin is consumed and only 15% in the next 200 min (up to the end of the period T), i.e. almost the entire stabiliser is consumed in reactions with the active fragments present in the initial polymer.

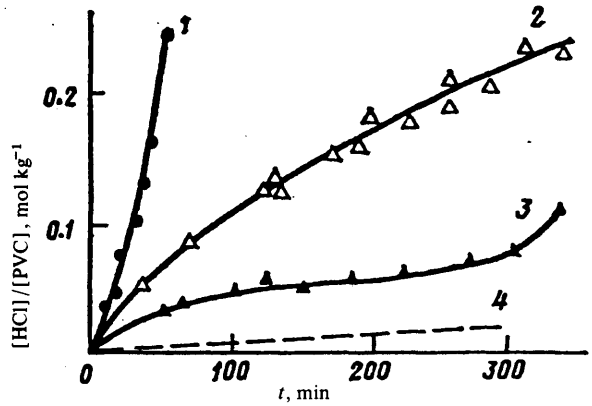


Figure 3. Kinetic curves for the dehydrochlorination of PVC at 463 K: 1) in evacuated (up to ~10^{-2} Pa) sealed tubes without the removal of volatile products; 2) *in vacuo* (~10^{-2} Pa) with constant removal of volatile products; 3) formation of ionic chlorine in the decomposition of PVC in evacuated sealed tubes containing added dibutylbis(cyclohexyl maleate)tin at a concentration of 7.0×10^{-2} mol/kg PVC; 4) theoretical curve for the dehydrochlorination of PVC in the presence of the "ideal" stabiliser.[17,76]

When the stationary section of curve *3* (Fig. 3) is extrapolated to the ordinate axis, an intercept is obtained, corresponding to the concentration of the stabiliser which has reacted with the active fragments and hence also to the concentration of the active fragments in the given PVC specimens (~2 per 1000 monomeric units).

The steady-state rate of thermal decomposition of the polymer in the presence of the stabiliser makes it possible to calculate l_{av} for the thermal decomposition of PVC *in vacuo*.[17,76] It has been established[100,101] that dialkyltin carboxylates readily undergo the exchange reaction with the chloroallyl fragments of PVC, substituting the labile chlorine atoms by groups which are more strongly bound to the polymer chains. It has been shown[11] that, after heating PVC with $Bu_2Sn(SC_{12}H_{25})_2$ or with a mixture of this compound and Bu_2SnCl_2 and the subsequent removal of the stabiliser from the polymer, the rate of thermal decomposition of PVC diminishes in proportion to the number of stabiliser fragments introduced into the PVC, which confirms the proposed[100] mechanism of the stabilisation of the polymer by organotin compounds.

Bis(alkyl maleate)dialkyltin derivatives react only slightly with the normal PVC units[76,102] and the slope of the steady-state section of curve *3* (Fig. 3) therefore corresponds to the rate of formation of dialkyltin chlorides when the stabiliser reacts with HCl and with the chloroallyl fragments arising on

decomposition of the normal units of the macrochains. Ultraviolet spectra show[17,76] that there is virtually no absorption at $\lambda > 280$ nm in the thermal decomposition of PVC in the presence of the given stabilisers, i.e. polyenes are virtually not formed and the average dehydrochlorination chain length is $l_{av}^{st} \cong 1$. Having divided the rate of formation of ionic chlorine along the steady-state section by two, it is possible to obtain the rate of dehydrochlorination of the normal PVC units for $l_{av}^{st} = 1$. Division of the steady-state rate of the thermal decomposition of PVC *in vacuo* without the stabiliser (curve *2*, steady-state section) by the rate of its decomposition in the presence of a stabiliser for $l_{av}^{st} = 1$ yields $l_{av}/l_{av}^{st} = 8$, whence $l_{av} = 8$.[17,76]

Fig. 3 also presents the theoretical curve (curve *4*) for the thermal decomposition of PVC in the presence of the "ideal" stabiliser, whereupon the dehydrochlorination of the unstable fragments is fully prevented and the decomposition of the normal unit proceeds with $l_{av}^{st} = 1$. Evidently the organotin derivatives of maleic acid approach the "ideal" polymer thermostabilisers as regards the efficiency of their action.

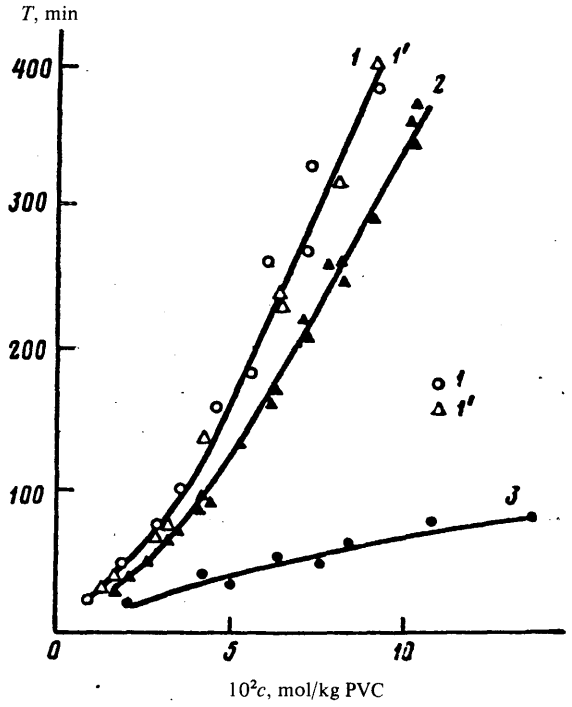

Figure 4. Dependence of the period T on the concentration of organotin maleates (c) in the thermal decomposition of PVC at 463 K: 1) dibutylbis(cyclohexyl maleate)tin; 1') bis(octyl maleate)dioctyltin; 2) dibutyltin maleate; 3) diphenyltin maleate.[76]

(b) Dependence of the Efficiency of the Stabilising Action of Organotin Compounds on Their Chemical Structure

The efficiency of the stabiliser over a wide range of concentrations can be estimated from the curves relating the period T to the concentration of the compound. It is seen from Fig. 4 that stabilisers of the type of bis(alkyl maleate)-dialkyltin derivatives are the most effective. At low stabiliser concentrations there is an inflection in the curve (curves *1* and *2*), after which the efficiency increases. The concentration of the stabiliser corresponding to the point of inflection can be called the second critical concentration. Its significance is that the rate of the bimolecular reaction of the stabiliser with unstable fragments becomes greater than the rate of decomposition of the unstable fragments from this point. The first critical concentration is that at which the rate of dehydrochlorination of the polymer diminishes in the presence of the stabiliser and the period T begins.[52,68,85]

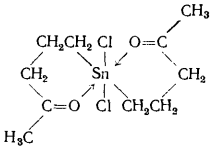
Bis(alkyl thioglycolate)dialkyltin derivatives are close in their efficiency to bis(alkyl maleate)dialkyltin derivatives, but they have one distinguishing feature, which has been noted by Troitskii et al.[76] It has been shown in model reactions[76,102] that compounds with the Sn–S bond are very reactive in nucleophilic substitution reactions with alkyl halides, which shortens the period T. The following series based on the efficiency of the stabilising effect of organotin stabilisers has been obtained from the dependence of the period T on the concentration:[17,76]

$Alk_3SnOOCCH{=}CHCOOSnAlk_3$, $Alk_2Sn(OOCCH{=}CHCOOR)_2 >$
$> Alk_2Sn(OOCCH{=}CHCOO)$, $Alk_2Sn(SCH_2COOR)_2 >$
$> Alk_3SnOOCCH{=}CHCOOR > Alk_3SnSCH_2COOR > Ph_2Sn(SCH_2COOR)_2 >$
$> AlkSn(OOCCH{=}CHCOOR)_3$, $AlkSn(SCH_2COOR)_3 > Alk_2Sn(SCH_2COO) >$
$> Ph_2Sn(OOCCH{=}CHCOO)$, $Ph_2Sn(OOCCH{=}CHCOOR)_2$ where Alk =
$=$Me, Bu, Oct; R=Et, Bu, Oct, C_6H_{11}, $-CH_2-CH_2-$,
$-CH_2-CH_2-OEt$, $-CH_2-CH_2-O-CH_2-CH_2-$.

The efficiency of the last member of the series is ten times smaller than that of the first.

In terms of the rate of interaction with s-BuCl (the low-molecular-weight model of the normal units of the PVC macrochain), organotin compounds can be arranged in a series which is the opposite of that based on the efficiency of the stabilising action.[76]

An increase in the stabilising effect is achieved when the carbonyl group is introduced into the substituent R in compounds of the type $R_2Sn(SCH_2COOR^1)_2$.[78] Thus $[CH_3C(O)CH_2CH_2CH_2]_2Sn(SCH_2COOOct)_2$ is twice as effective as the dibutyltin derivative.[78] The carbonyl group can form intramolecular complexes in dialkyltin dichlorides produced by the interaction of the stabiliser with HCl:



The catalytic activity of Alk_2SnCl_2 in such complexes is reduced.[78]

A sharp impairment of the stabilising activity of the compounds $R_2Sn(SCH_2COOR^1)_2$ is observed for R = CH_2Br or p-$CH_3OC_6H_4$, which is associated with the ease of cleavage of the Sn–C bond under the influence of HCl and the formation of a stronger catalyst of the thermal decomposition of the polymer, namely $SnCl_4$.[78]

Organotin derivatives of thioglycolic acid are more effective PVC thermal stabilisers than the derivatives of thioalcohols.[78] The authors[78] explained this by the fact that thioglycolic acid esters interact more readily with the double bonds than thioalcohols, since they give higher chain transfer rate constants. The introduction of a halogen atom (Cl, Br) into the acid residue of organotin derivatives of maleic acid diminishes the efficiency of their stabilising action.[103]

(c) The Interaction of Organotin Compounds with Low-Molecular-Weight Models of PVC

The reactions of the stabilisers of the type Bu_2SnX_2, where $X = SC_{12}H_{25}$, SCH_3, $O(O)CCH_3$, or $O(O)CC_{11}H_{23}$, with 2-chloro-2-methylbutane, 3-chlorobut-1-ene, and 1-chlorobut-2-ene have been investigated in detail.[77]

The following reactions take place in sealed tubes at 453 K;

$$RCl + Bu_2SnX_2 \rightarrow RX + Bu_2Sn(X)Cl,$$
$$2RCl + Bu_2SnX_2 \rightarrow 2RX + Bu_2SnCl_2,$$

where RCl is a chlorohydrocarbon.

Compounds with the Sn–S bond react more readily with model substances containing double bonds than with substances having a Cl atom at a tertiary carbon atom. The opposite behaviour has been observed for organotin carboxylates.[77]

It has been established[77] that the reaction of Bu_2SnX_2 with model compounds containing a double bond is accompanied by a rearrangement—a shift of the double bond. Bu_2SnCl_2 at low concentrations catalyses the rearrangement.

The interaction of the organotin compounds $RSnX_3$, R_2SnX_2, and R_3SnX, where $X = OOCCH{=}CHCOOR^1$ or SCH_2COOR^1, R = Me, Bu, Oct, or Ph, and R^1 = Et, Bu, Oct, or C_6H_{11}, with s-BuCl, which models the normal units of PVC macromolecules, at 453 K in evacuated sealed tubes has been studied.[76,102] As noted above, in terms of the rate of their interaction with s-BuCl, the compounds investigated can be arranged in a sequence which is the opposite of that based on the stabilising efficiency. In other words, the increased reactivity of the organotin compound leads to its rapid consumption in the nucleophilic substitution reaction with the normal units of the PVC macromolecules, which naturally diminishes the period T.

The reactions of organotin compounds with s-BuCl are accelerated by the products (alkyltin chlorides),[76,102] the catalytic effect diminishing in the following sequence:

$$SnCl_4 > AlkSnCl_3 > Alk_2SnCl_2 > Alk_3SnCl.$$

Thus an effective PVC stabiliser must possess the optimum reactivity towards the chlorine-containing units of the PVC macromolecules: on the one hand, it must interact vigorously with the unstable fragments of the macromolecules, and the rate of such bimolecular reaction must be higher than the rate of unimolecular thermal decomposition of the fragments, while, on the other hand, it should hardly react with the normal PVC units, since this decreases the duration of the stabilising action.

2. Synergistic Mixtures

Synergism is a phenomenon in which the stabilising action of a mixture of two or several substances exceeds the sum of the protective activities of the individual components. This phenomenon is very common in the stabilisation of polymers. The fundamental principles and mechanism of the synergistic action of binary mixtures of stabilisers in the thermo-oxidative and photo-oxidative ageing of polymers have been formulated in a book.[1]

A characteristic feature of PVC which distinguishes it from the majority of other polymers is that synergism is common in the stabilisation with respect to not only its thermo-oxidative or photo-oxidative ageing but also its thermal decomposition in the absence of oxygen. This is associated with the fact that the thermal decomposition of PVC is influenced by HCl and numerous unstable fragments of the macromolecules (Scheme 1) and that one compound cannot as a rule participate effectively in all the reactions simultaneously (certain organotin derivatives of maleic and thioglycolic acids, examined above, are an exception).

The possibilities for the combination of various compounds, each of which participates preferentially in a particular reaction (or group of reactions), are very great and numerous binary, ternary, etc. mixtures of this kind are therefore known.

Some of the products of reactions *a–h* in Scheme 1 (for example the chlorides of coordination-unsaturated metals) are, on the one hand, catalysts of reactions *b–g* (positive effects for stabilisation) and, on the other hand, they catalyse the interaction of the stabiliser with the normal units and accelerate the thermal decomposition of the polymer (negative effect). In order to attain the optimum stabilising effect, the reactivity of metal chlorides is therefore regulated by introducing complex-forming agents, which increases still further the number of synergistic mixtures.

Since reactions *a–h* take place in the polymer melt which is highly viscous, the stabiliser molecules must be capable of dissolving in PVC and diffusing in the melt. An effective stabiliser is a liquid or a readily fusible mixture of solid compounds. All additives to the stabiliser, which improve its spreading in the polymer or reduce the viscosity of the melt, increase the efficiency of the stabiliser, i.e. lead to a physical synergism.

This in fact explains the increased efficiency of the stabilising action of group IA and IIA metal carboxylates when they are introduced simultaneously with stearic acid[20] or certain polyols.[89]

(a) Mixtures Including the Chlorides of Coordination-Unsaturated Metals

The chlorides of coordination-unsaturated metals ($ZnCl_2$, $CdCl_2$, $PbCl_2$, $FeCl_2$, $FeCl_3$, $SnCl_2$, $SnCl_4$, and R_nMCl_{4-n}, where R = alkyl or aryl, M = Sn or Pb, and n = 1–3 as well as others), having low-lying unoccupied orbitals, greatly increase the stabilising activity of compounds in the first group of stabilisers (for example, organic phosphites,[20,71] epoxy-compounds,[98] organosilicon and organogermanium hydrides,[88] and oligosilanes[75]), forming synergistic mixtures with them.

The chlorides of coordination-unsaturated metals themselves exert a complex influence on the dehydrochlorination of PVC, which depends on the concentration of the additive and decomposition time. With increased concentration of the electrophilic catalyst, the initial rate of thermal decomposition of the polymer rises.[56,60,61]

The optimum concentrations of metal chlorides (which are as a rule low), at which the maximum synergistic effect is observed, have been found.[20,42,71,75,88,98]

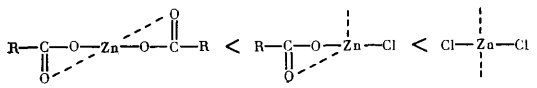
Analysis of the kinetics of the thermal decomposition of PVC in the presence of the synergistic mixtures considered, as well as the study of reactions with model compounds,[42,71,75,88,98,99,102,104] make it possible to conclude that the metal chlorides catalyse the interaction of the stabilisers in the first group with the unstable fragments of the macromolecules and with the double and conjugated double bonds (Scheme 1, reactions *b–f*).

Metal chlorides which do not behave as Lewis acids do not form synergistic mixtures of this kind.[42,71,75,88]

(b) Mixture of Other Compounds of Coordination-Unsaturated Metals with Organic Stabilisers

Synergistic mixtures with organic stabilisers (organic phosphites, epoxy-compounds, aminocrotonic acid esters, oligosilanes) are also formed by the carboxylates of coordination-unsaturated metals (zinc, cadmium, and dialkyltin),[20,34,42,69,71,75,99] organotin compounds (Ph_4Sn, trialkyl- and triaryltin isocyanates, and others),[20,86] and organolead compounds (Ph_4Pb and triphenyl-lead isocyanate).[87] The carboxylates of alkali and alkaline earth metals do not form synergistic mixtures with organic stabilisers.[20,34,42,69-71]

Mixtures of the above compounds of coordination-unsaturated metals with organic stabilisers are more effective than the mixtures with the corresponding metal chlorides[20,34,42,69,71,75] apparently because these compounds themselves stabilise PVC. Furthermore, as a result of the interaction of the metal compounds with HCl and with the unstable fragments, mixed chlorides are formed which are weaker catalysts of the thermal decomposition of the polymer than the metal chlorides. For example, the zinc salts can be arranged in the following sequence in terms of their catalytic activities:



Thus the reactivity of the zinc salt as a catalyst increases as the coordination sphere of the metal is opened.

(c) Mixtures of Zn–Ca and Cd–Ba Carboxylates

The mechanism of the synergistic action of a mixture of zinc and calcium carboxylates has been investigated.[89,99,105] As a consequence of the exchange reaction between the calcium carboxylate and $ZnCl_2$, a powerful catalyst of the dehydrochlorination of PVC is removed and zinc carboxylate, which readily enters into a nucleophilic substitution reaction with the unstable fragments of the macromolecules, is reformed.[99,105]

Calcium and zinc carboxylates form complexes with one another[99,105] and with zinc and calcium chlorides (mixed complexes).[99] The catalytic activity of $ZnCl_2$ in these complexes is reduced.[99]

Zinc carboxylates react also with the normal units of PVC, accelerating their decomposition, while calcium carboxylates diminish the rate of this reaction probably because the salts form complexes with one another.[89]

A study of the thermal decomposition of PVC in the presence of a synergistic mixture of cadmium and barium carboxylates established[70] that initially mainly $CdCl_2$ is formed (up to 90%), although the starting amounts of barium and cadmium carboxylates were identical. In the presence of barium stearate, cadmium chloride does not accelerate the decomposition of PVC, which suggests the formation of a complex between $CdCl_2$ and the barium salt.[70]

It was shown above that the synergistic effect is observed when individual stabilisers of the first and third groups are employed jointly. We shall consider synergistic mixtures in which the second component is not a stabiliser.

(d) Mixtures of Carboxylates of Coordination-Unsaturated Metals with Compounds Containing the OH, SH, and NH Groups

Mixtures of polyols with the carboxylates of coordination-unsaturated metals (Group IIB, III, and IV metals) exhibit an appreciable synergistic effect on the processes occurring in the thermal decomposition of PVC.[89-96] In their presence the rate of dehydrochlorination falls during the period T to the rate of decomposition of PVC *in vacuo*, an appreciably smaller insoluble fraction is produced, and the polymer does not become coloured.[89-91] As an example, Fig. 5 presents the dependence of the period T on the concentration of polyols in the presence of zinc and cadmium stearates.

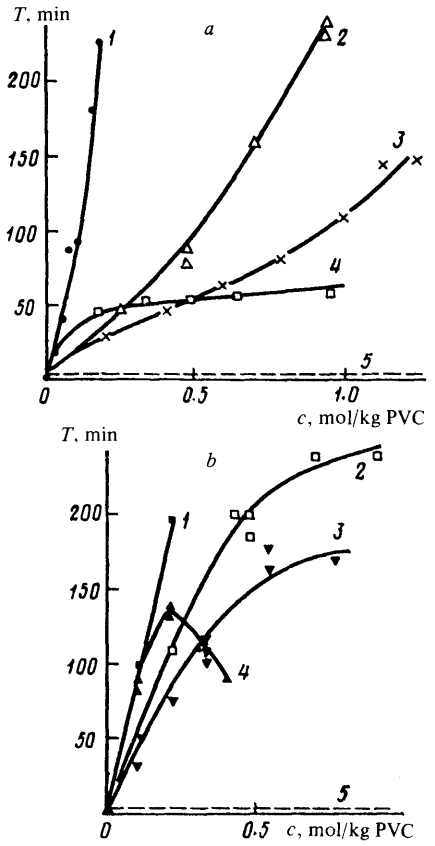


Figure 5. Dependence of the period T on the concentration of polyols in the thermal decomposition of PVC at 453 K in the presence of zinc stearate at a concentration of 0.1 mol/kg PVC (*a*) or cadmium stearate at a concentration of 0.05 mol/kg PVC (*b*).[89] *a*: 1) pentaerythritol; 2) ethylene glycol; 3) stearyl alcohol; 4) triethylene glycol; *b*: 1) glycerol; 2) ethylene glycol; 3) octyl alcohol; 4) triethylene glycol; the dashed lines represent the theoretical curves plotted assuming the additivity of the effects of the mixture components (curves 5).

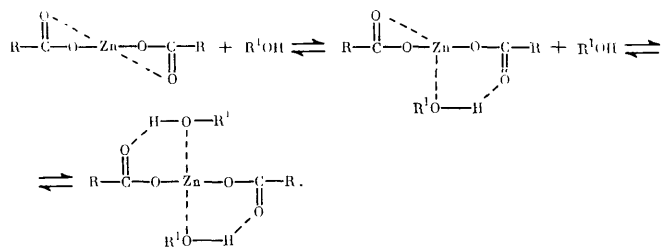
The efficiency of the synergistic action of the mixtures diminishes in the following sequence: polyols > triols > diols > aliphatic alcohols; zinc carboxylate > cadmium carboxylate > tin(II) carboxylates > aluminium carboxylate.

The following observations have been made as regards the effect of mixtures of polyols with zinc and cadmium carboxylates on the thermal decomposition of s-BuCl, a low-molecular-weight compound modelling the normal fragments of the polymer:[89-91] (1) the polyols greatly reduce the rate of reaction of the carboxylates of coordination-unsaturated metals with the normal PVC unit; (2) the thermal decomposition of PVC in the presence of a mixture of carboxylates of these metals with polyols involves the exchange of a chlorine atom in the chlorine-containing groups of the polymer not only for the carboxy-group of the salt but also for the alcoholic residue; (3) salts of coordination-unsaturated metals also catalyse the addition of polyols to the double (conjugated double) bonds; (4) the polyols inhibit the catalytic effect of the chlorides of coordination-unsaturated metals on the thermal decomposition of PVC and s-BuCl; (5) among the large number of oxygen-, sulphur-, and nitrogen-containing compounds capable of forming donor–acceptor complexes of the *nV* type with zinc salts, only those containing the OH, SH, and NH groups respectively give rise to effective synergistic mixtures with zinc carboxylates.

The results can be explained by the fact that the carboxylates of coordination-unsaturated metals and compounds with the OH, SH, and NH groups form complexes having a cyclic structure (resembling chelates):



It is known that chelate complexes have a higher thermal stability and are chemically more reactive than complexes with a non-chelate structure.[106]

The formation of six-membered cyclic complexes between the carboxylates of coordination-unsaturated metals and polyols results in a considerable decrease of the rates of reaction of metal carboxylates with the normal units of the macromolecules.[89-91] At the same time, the complexes retain a high reactivity towards the active unstable fragments of the macrochains (Scheme 1, reactions *b*–*f*).

A definite contribution to the synergism of the action of the coordination-unsaturated metal carboxylate–polyol mixtures comes also from the formation of complexes by the polyols with the chlorides of the same metals.[81,89-96]

Group I and IIA metal carboxylates do not form complexes with *n*-electron donors and do not give rise to mixtures with polyols exhibiting a synergistic activity like the mixtures of polyols with coordination-unsaturated metal carboxylates.[89-96]

Certain polyols, for example diethylene and triethylene glycols give rise to an antagonistic effect with the carboxylates of Group I and IIA metals (Li, Na, Mg, Ca, Sr, and Ba). These polyols can probably act like crown-ethers, shielding the cations and enhancing the nucleophilicity of the anion, which accelerates the decomposition of PVC via the anionic mechanism:[89]

$$CaSt_2 + n\text{TEG} \rightarrow St^-[Ca\cdots n\text{TEG}]^{2+}St^-,$$

where TEG = triethylene glycol and St = stearic acid residue.

Ternary mixtures, for example, zinc carboxylate–calcium carboxylate–polyol and cadmium carboxylate–barium carboxylate–polyol, exhibit a still greater synergistic effect than the binary mixtures of components (Fig.6).[89] In their presence the rate of accumulation of ionic chlorine is lower than in the decomposition of the polymer without additives *in vacuo*. In the ternary mixture the catalytic activity of zinc salts in relation to the normal units of PVC is reduced still further compared with the binary mixtures, which has been demonstrated by model reactions with s-BuCl.[89]

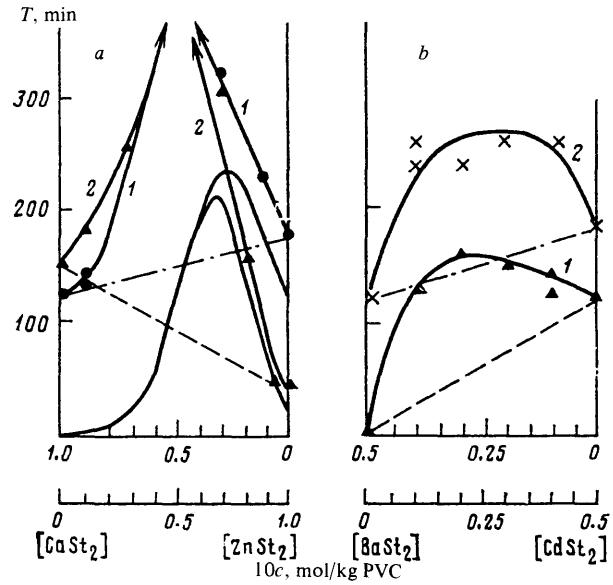


Figure 6. Dependence of the period *T* on the calcium stearate/zinc stearate (*a*) or barium stearate/cadmium stearate (*b*) molar ratio in the thermal decomposition of PVC at 453 K in the presence of polyols (mol/kg PVC):[89]
a: 1) 0.15 pentaerythritol; 2) 0.23 ethylene glycol;
b: 1) 0.1 stearyl alcohol; 2) 0.56 octyl alcohol; the dashed lines represent the theoretical curves plotted assuming the additivity of the effects of the mixture components; the thin continuous lines without symbols represent the limits of the region in which the white colour of PVC is retained.

3. Characteristic Features of the Reactions between the Stabiliser and PVC

We shall now consider the characteristics of the reactions between the stabiliser and the unstable fragments—the double (conjugated double) bonds in PVC.[107]

1. Compounds of coordination-unsaturated metals (Sn, Pb, Zn, Cd, Sb, etc.) participate in nucleophilic substitution reactions of the unstable fragments of PVC macromolecules. Compounds of these metals enter into the composition of the most effective PVC thermostabilisers.

2. The PVC melt (433–473 K) containing the added stabiliser is a dielectric with a low electrical conductivity and the formation of ions in such a system is unlikely. In terms of the classification of nucleophilic substitution reactions adopted in organic chemistry[8] the reactions of PVC with the stabiliser can be classified as belonging to the class of S_N2 bimolecular nuclophilic substitution reactions, subject to the stipulation that the reaction proceeds not between the anion and an alkyl chloride but apparently in a complex of the CTC

type, where the donor is the polymer fragment and the acceptor is the compound of the coordination-unsaturated metal.

3. It has been shown on model compounds that fragments containing chlorine in the allyl position and at the branching points are much more reactive in nuclophilic substitution reactions than the normal chain units. The large difference between the rates of these reactions makes it possible to select a compound of the coordination-unsaturated metal such that at 443–473 K it hardly interacts with the normal PVC units but reacts rapidly with the labile groups. All the effective PVC stabilisers satisfy this condition.

4. The nuclophilic substitution reaction is complicated by the elimination of HCl. The rate of the elimination reaction is determined by the electrophilic properties of both the initial components of the stabiliser and those of the products of their interaction with HCl and the chlorine-containing PVC fragments. Coordination-unsaturated metal chlorides accelerate the reaction of the stabiliser with the chlorine-containing fragments and the HCl elimination reaction.

5. Complex-forming agents containing O, S, N, and P atoms and forming complexes with compounds of coordination-unsaturated metals influence the rates of nucleophilic substitution and HCl elimination reactions. The best stabilising effects are attained when compounds having several OH, SH, and NH groups are used.

6. The rate of reaction between the stabiliser and PVC is lower than the rate of its reaction with the low-molecular-weight model compound, which apparently can be accounted for by the high viscosity of the polymer melt and the complication of the process by diffusion phenomena.

7. Whereas the nucleophilic substitution reactions are being vigorously investigated and they explain the mechanism of action of the majority of stabilisers, the reactions of the stabilisers with double and conjugated double bonds have been inadequately studied. At the same time, polyenes exhibit an increased reactivity at elevated temperatures (440–480 K): they participate in intramolecular and intermolecular reactions with liberation of benzene and the formation of a cross-linked polymer. The catalytic action of HCl is associated with its reversible addition to polyenes (reactive intermediate species, namely the ion pairs formed in this reaction, accelerate the thermal decomposition of PVC).

The steric structure of the polyenes should play a major role: dienophiles should interact only with *cis*-dienes, benzene can be formed only in the presence of triads of conjugated double bonds with a specific steric structure, etc.

The increased stabilising effect of many synergistic mixtures of compounds of coordination-unsaturated metals with substances containing the OH, SH, and NH groups as well as other organic compounds is associated with the increase in the rates of reactions involving electrophilic addition to double and conjugated double bonds.

The Deposition of Epitaxial Layers from the Vapour of Organometallic Compounds

B.V.Zhuk

Different methods of depositing epitaxial layers from the vapour of organometallic compounds have been compared. The stability of the deposition processes and new data on the preparation of epitaxial layers of $A^{III}B^{V}$, $A^{II}B^{VI}$, and $A^{IV}B^{VI}$ compounds have been examined.
The bibliography contains 206 references.

I. INTRODUCTION

In the nineteen-twenties, Razuvaev[1] studied the thermal decomposition of organometallic compounds (OMC) in a stream of hydrogen. Later, work by Paneth[2-6] drew attention to alkyl compounds of the transition metals as sources of free radicals in the gas phase at pressures of ~10^{-3} mmHg. Subsequently, Razuvaev and co-workers[7-9] showed that alkyl and aryl OMC act as sources of radicals in the liquid phase. Later, Razuvaev's school studied the mechanism of the decomposition of alkyl and aryl OMC of zinc,[10-12] cadmium,[13-15] mercury,[16-20] germanium,[21-23] tin and lead,[24-32] indium,[33] aluminium,[34-36] and antimony,[37] and a number of other compounds. These studies dealt with both the reactions of the radicals and the formation of metallic phases; by 1960 they had provided a theoretical basis for the study of the deposition of epitaxial layers of binary and multicomponent semiconductors using OMC, an intensively developing field of present-day materials science.

In 1959 it was found that the reaction of trimethylantimony with diborane gives a deposit with the composition BSb_x and gaseous methane.[38] It was subsequently shown[39] that the reaction of trimethylindium with phosphine takes place in three stages:

$$InMe_3 + PH_3 \xrightarrow{-100^\circ C} InMe_3 \cdot PH_3 \xrightarrow{-80^\circ C} (MeInPH)_n \xrightarrow{300^\circ C} InP$$

and that the reactions of trimethylgallium (TMG) with arsine and of trimethylindium with stibine take place according to the schemes:[40]

$$GaMe_3 + AsH_3 \xrightarrow{28^\circ C} \text{grey film} \xrightarrow{200^\circ C} \text{red film} + CH_4$$

$$InMe_3 + SbH_3 \xrightarrow{28^\circ C} (MeInSbH)_n \xrightarrow{160^\circ C} InSb + CH_4 .$$

The practical application of the alkyls of the elements of groups II and III of the periodic system began, however, after the development of the technology of the deposition of epitaxial layers in 1968, when the reaction of TMG with arsine was proposed for the preparation of epitaxial layers of gallium arsenide.[41] In subsequent years, the reactions of the alkyls of the group III elements with ammonia, the hydrides of phosphorus and arsenic, and antimony alkyls were proposed for the preparation of epitaxial layers of the compounds GaAs, GaP, $GaAs_xP_{1-x}$, and $GaAs_xSb_{1-x}$ and the ternary semiconducting compounds $Ga_{1-x}Al_xAs$,[42-45] aluminium phosphides,[46] aluminium and gallium nitrides,[47] indium arsenide and phosphide, and the ternary systems $Ga_xIn_{1-x}As$ and $InAs_xP_{1-x}$,[48] and epitaxial layers of $A^{II}B^{VI}$ compounds.[49,50] The hetero-epitaxial deposition of $A^{II}B^{VI}$ and $A^{III}B^{V}$ layers was reviewed in 1971.[51] Subsequently, the preparation of films by the reactions of alkyls of group IV elements with the hydrides and alkyls of group VI elements ($A^{IV}B^{VI}$ compounds) was described,[52] a number of patents on the preparation of epitaxial structures and hetero-structures by the reactions of OMC with hydrides appeared,[53-56] and the method began to be called the OMC–hydride process†.

Most work has been devoted to the deposition of epitaxial layers of $A^{III}B^{V}$ compounds, because of their widespread use in opto- and micro-electronics. Work on the development of epitaxial $A^{II}B^{VI}$ layers has begun to develop only since 1978, because of the difficulty of obtaining and alloying these compounds. At the same time, the theory of the deposition of epitaxial layers from OMC vapour has been developed, and this is reflected in a number of monographs[57,58] and reviews on the preparation of $A^{III}B^{V}$ [59-63] and $A^{II}B^{VI}$ [64,65] compounds. Except for Ref.65, where data on the thermal decomposition of various OMC in a stream of hydrogen were examined, most reviews have dealt with the preparation of hetero-structures for the production of electronic instruments, and the study of their properties. The present review examines the relationship between the mechanism and kinetics of the reaction and the stability of deposition processes, and discusses the latest data on the preparation of epitaxial layers from the vapour of OMC.

II. COMPARATIVE CHARACTERISTICS OF METHODS OF DEPOSITION FROM THE VAPOUR OF ORGANOMETALLIC COMPOUNDS

Methods of deposition from the vapour of OMC can be classified according to two main characteristics: the compounds used to transport the elements into the reactor, and the deposition conditions. In any method, the deposition from the vapour phase takes place via a number of

†In the foreign literature this method is called the MOCVD method—Metalorganic Chemical Vapour Deposition.

intermediate stages: I) volatilisation of the original compounds, II) mixing and transport of the starting materials, III) diffusion of the vapour of the starting materials to the support, IV) adsorption, V) reaction or thermal decomposition, VI) crystallisation of the epitaxial layer, and VII) removal of gaseous products from the reactor.

Three main methods of transport are used in deposition from the vapour of OMC. Thus binary compounds AB are obtained by the reaction:

$$AR_n(\text{gas}) + BR'_m(\text{gas}) \rightarrow AB(\text{crystalline}) + X(\text{gas}) \quad (1)$$

where n, m = 1, 2, 3, 4; A is an element from groups II, III, or IV, B an element from groups V or VI, R an alkyl group, R′ a hydrogen atom or an alkyl group, X the gaseous products of reaction (1), and (crystalline) and (gas) denote the condensate and the gas phase. In stages IV and V, reaction (1) can take place with the formation of intermediate polycondensed products with the formula $(-R-A-B-R')_n$, as observed for the reaction of TMG with arsine,[66] so that complexes of the type $AR_n.BR'_m$ are used for the deposition of binary semiconducting structures.[67]

A completely different method of transport involves the use of organobimetallic compounds containing an A–B bond.[68–72] Cadmium sulphide,[68] layers of titanium,[69] and epitaxial layers of $A^{IV}B^{VI}$,[70–72] $A^{II}B^{VI}$, and $A^{III}B^{V}$[73] compounds have been prepared. The use of molecular complexes and organobimetallic compounds makes it possible to reduce the synthesis of a complex semiconducting compound to the preparation of elementary semiconductors, but the stoichiometry and electrical properties of the layers can be controlled only by selecting the temperature and pressure, since the ratio of the reagents A and B is fixed in the original compound.

Depending on the conditions, deposition from the vapour of OMC is carried out by vacuum methods or by methods involving a carrier gas. Historically, methods of vapour-phase deposition based on the transport of the elements or chlorides using hydrogen[74] were transferred, by replacing the chlorides by OMC, to the deposition of epitaxial layers of binary compounds from the vapour of OMC. The process is carried out as follows: the carrier gas, usually hydrogen, is passed through bubblers in which it is saturated by the vapour of the OMC, and then through tubes into the reactor in which the epitaxial layer is deposited. Up to 12 material supply channels are used simultaneously. If a homogeneous reaction between the original compounds is impossible, they are mixed beforehand; if the reaction is possible, they are injected into the reaction zone. The carrier gas is used at atmospheric pressure or at a reduced pressure.[75]

The carrier gas is used as a reference defining the pressure in the deposition system, and makes it possible to transfer precise quantities of the original OMC and to control their supply automatically; this is particularly important in the production of multicomponent structures.

At the same time, the use of a carrier gas has a negative effect on the properties of the layers obtained, because of hydrogen etching of the growing layer, the concentration of impurities from the carrier gas in the epitaxial layer, the transfer of droplets and particles from the volatiliser to the reactor, and the increased difficulty of removing the reaction products. OMC displace light gases from an adsorption layer,[76,77] but since the relative concentration of the reagents does not exceed 1–2 vol.%, the carrier gas nevertheless blocks the adsorption centres, leading to energetic uniformity of the growth surface and hence to a corresponding decrease in the proportion of selective decomposition of the OMC.[78]

Vacuum methods of deposition from the vapour of OMC in the absence of a carrier gas have now been developed.[57,58] This method has been used to obtain epitaxial layers of $A^{IV}B^{VI}$,[72] $A^{III}B^{V}$,[79–82] and $A^{II}B^{VI}$[83–88] compounds. An attempt has been made[89] to obtain GaAs from arsine and TMG vapour under molecular-beam epitaxy conditions; arsine had previously been used as a source of arsenic in molecular-beam epitaxy.[90] In vacuum methods, the purity of the layers obtained is determined by the purity of the OMC and hydrides used, in which the concentrations of metal and non-metal impurities are 10^{-4}–10^{-5} vol.%. Hydrogen purified by diffusion through a palladium membrane contains up to 4×10^{-5} vol.% of oxygen-containing impurities.[91] The proportion δ of impurities in the layer can be determined from the relationship

$$\delta = \frac{j_i}{j_0}\frac{k_i}{k_0}$$

where j_i and j_0 are the fluxes of the molecules of the impurity and the OMC at the growth surface, and k_i and k_0 the coefficients of reactive adhesion of the impurity and the OMC.

The capture of oxygen-containing impurities in an epitaxial layer can be examined for the case of the deposition of $Ga_{1-x}Al_xAs$ from the vapour of TMG, trimethylaluminium (TMA), and arsine.[91,92] The hydrogen stream contained less than 1 vol.% OMC, and comparison of the rates of deposition given by the authors cited and estimation of the fluxes of the OMC into the adsorption layer indicate that for TMG and TMA, the value of k_0 is 1–0.01, whereas $k_i \cong 1$, since the OMC is a compound which is rapidly oxidised. Thus the concentration of aluminium and gallium oxides in the epitaxial layers can apparently reach several tenths of 1%. With decrease in the hydrogen pressure, therefore, layers of high quality are obtained at lower deposition temperatures than at atmospheric pressure.[75] Decrease in pressure facilitates the effective removal of the gallium oxide decomposition products from the reaction zone. This is confirmed by data[92] which show that at a concentration of oxygen-containing impurities in the hydrogen stream at the level of 10^{-6} vol.%, the $Ga_{1-x}Al_xAs$ layers with $x < 0.05$ were of high quality, whereas at $x > 0.05$ the conductivity and photoluminescence yield of the layers decreased sharply, since aluminium oxides are stable under the deposition conditions.

The thickness of the oxide on the $Ga_{1-x}Al_xAs$ surface is proportional to the value of x,[93] and layers of high quality are obtained only after the hydrogen has been specially purified from oxygen-containing impurities.[91] In deposition in a vacuum, the purity of the layers is determined by the purity of the OMC and the ratio of the flux corresponding to the leakage from the atmosphere into the reactor to the flux of the starting materials into the reactor. At a level of leakage into the reactor lower than the sensitivity of the helium leak detector, and fluxes of the original reagents into the reactor of ~10 litre mmHg s^{-1}, the concentration of oxygen-containing impurities due to leakage into the reactor is not more than 10^{-9} vol.% (without allowance for the absorption of oxygen and water vapour by the walls of the reactor and by the reaction mixture).[79]

In deposition under the conditions of molecular-beam epitaxy, the pressure of the residual gases in the reactor is 10^{-10} mmHg, and the fluxes of the atoms on to the growth surface corresponds to pressures of 10^{-5} mmHg, so that the purity of the layer with respect to the impurities present in the residual gases is 10^{-3} vol.%. The use of improved evacuation techniques will be unlikely to lower significantly the level of contamination of layers obtained in this way due

to residual gases, since at low pressures of the original reagents in the reactor, the atomically pure surface of the growing crystal actively captures impurities.

The mechanisms of the reactions taking place in the adsorption layer depend on its density and the quantity F, equal to the ratio of the energy of intermolecular interaction in the adsorption layer to the energy of the interaction of the adsorbed molecules with the surface. At a low density of molecules in the adsorption layer, $F \ll 1$, the original reagents react with the surface of the support, and a vapour–crystal (VC) growth mechanism is realised. At a medium density of the adsorption layer and a value of $F \cong 1$, the formation of surface compounds which can play the role of liquid is possible, and in addition to the VC growth mechanism, the vapour–liquid–solid (VLS) growth mechanism may be observed. At a high density of the adsorption layer, the value of $F \gg 1$; growth of the layer takes place by the VLS mechanism, drops of liquid are generated from the original elements on the surface, and metastable phases, polymer chains containing metal, carbon, and hydrogen, may be formed.

These relationships can be illustrated by the reaction of TMG with arsine. The reaction of TMG with arsine takes place via the formation at 203° of co-condensation products Me_2–Ga–As–H_2, which at 259° decompose with the liberation of condensation products $(Me–Ga–As–H)_n$, which subsequently decompose at 420 °C with the liberation of gallium arsenide.[66] A study of the deposition of gallium arsenide from arsine and TMG vapour at a hydrogen pressure of 75 mmHg[75] showed that an amorphous deposit with a thickness of up to 500 Å remains on the surface of the epitaxial layer; the photoluminescence spectrum of this deposit showed a weak broadened band at 1.37 eV, and the edge band appeared only after this surface amorphous layer had been etched; the layer was apparently formed by residues of the co-condensation products of TMG and arsine, involved in the growth of gallium arsenide. In the deposition of gallium arsenide in a vacuum,[80] at Knudsen numbers (Kn) in the flux of arsine and TMG vapour of 1–0.1, no residual products were observed on the surface of the films. At Kn ≅ 1 and a deposition temperature of 400°, block single-crystal layers were obtained; the epitaxy temperature was 430°, as in deposition by the method of molecular-beam epitaxy; at temperatures above 500°, highly perfect layers were obtained. At Kn ≅ 0.1, the epitaxy temperature increased to 500°, corresponding to the regular features observed in deposition in a stream of hydrogen at a reduced pressure.

A study of the defects in gallium arsenide layers obtained by deposition in a vacuum[82] showed that the films deposited at Kn ≅ 1 had a rough surface, on which drops with dimensions of up to 300 Å were observed; the principal defects were dislocations, twins, and subtractive packing defects. As Kn → 0, the size of the droplets increased to 1500 Å with an increase in the density of defects, followed by a sharp change to the growth of layers with an atomically smooth surface and minimum density of defects, in spite of the fact that the concentration of p-type carriers in the film reached 10^{19}–10^{20} cm^{-3}. This change in the properties of the layer with increase in the pressure at which the deposition was carried out can be attributed to a change in the growth mechanism from VC to VLS; the agent forming the liquid on the surface of the growing layer may be the intermediate compound considered above.

The characteristic features of the alloying of gallium arsenide with selenium are also related to the mechanism of the reaction in the adsorption layer. Thus when hydrogen selenide is introduced into the stream,[82] highly compensated specimens of n-type gallium arsenide are obtained, and the morphology of the surface and the concentration of defects correspond to the picture observed in the growth of layers with an excess of TMG, that is the introduction of a small quantity of selenium into the adsorption layer facilitates the "attraction" of TMG molecules, revealed in the apparent displacement of the conductivity conversion point. These data agree with the results of published work[94] where displacement of the conductivity conversion point was observed in the deposition of gallium arsenide from TMG and arsine with change in the concentration of impurities in the TMG.

The purity of binary semiconducting layers is determined to a large extent by the stoichiometry, since impurities are captured preferentially on the vacancies. This is illustrated by the deposition of layers of zinc selenide by the reaction of diethylzinc (DEZ) and hydrogen selenide.[85,88] Small quantities of ethyl iodide were introduced into the DEZ to a concentration of 0.01–1 vol.%. During the deposition, the temperature of the support was 350°, and the pressure in the reactor 0.2 mmHg. Zinc selenide was deposited by the reaction

$$ZnEt_2 + H_2Se \rightarrow ZnSe + 2EtH \qquad (2)$$

accompanied by the thermal decomposition of DEZ, which takes place vigorously at temperatures above 300°,[95,96] while zinc reacts with hydrogen sulphide according to the equation

$$Zn + H_2Se \rightarrow ZnSe + H_2 .$$

In the presence of an alkyl iodide, however, the zinc atoms can react with it to form the intermediate compound Et–Zn–I,[97] which undergoes symmetrisation to give DEZ and zinc iodide; the synthesis of DEZ from zinc and an alkyl iodide takes place up to 380°,[98] and the symmetrisation of the intermediate compound EtZnI is the limiting stage.[99]

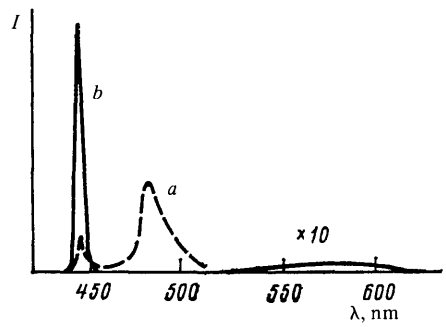

Figure 1. Photoluminescence spectra of zinc selenide layers; ratio of the fluxes of DEZ and hydrogen selenide 1 : 2 (*a*) or 1 : 5 (*b*).

Reaction (2) is rapid, so that the thermal decomposition of DEZ is possible only when there is an excess of it in the adsorption layer;[93] in this case, in the presence of an alkyl iodide, the compound EtZnI is formed and then decomposes to give Zn–I· radicals. The condensation of this radical leads to the capture of an iodine atom on a selenium vacancy in zinc selenide. Thus the photoluminescence spectrum of zinc selenide specimens obtained at a ratio of the DEZ flux to the hydrogen selenide flux into the reactor of 1 : 2 (Fig.1*a*), in addition to the edge band, shows a peak

at 480 nm, corresponding to an iodine donor level, and with change in the ratio of the fluxes of DEZ and hydrogen selenide to 1:5, the intensity of this peak decreases by a factor of 300[88] (Fig.1*b*). Thus the capture of the iodine impurity is due to the thermal decomposition of DEZ and the formation of EtZnI intermediate compounds, and the observed displacement of the iodine impurity by the growing crystal front is due to the suppression of the synthesis of the compound containing the Zn–I bond. The characteristics of the methods of molecular-beam epitaxy, deposition from OMC vapour in a vacuum, and the OMC–hydride process in a stream of hydrogen are compared in Table 1.

Table 1. Comparison of the characteristics of the methods of molecular-beam epitaxy and the OMC–hydride process in a stream of hydrogen and in the absence of a carrier gas.

Method	γ*	Desorption	LSC**	Growth mechanism	Deposition conditions
Molecular-beam epitaxy	10^{-5}	fast	attainable	VC	supersaturation rigidly related to the flux; removal of products not limited by diffusion
OMC-hydride process in hydrogen	10^{-7}–10^{-2}	blocked	not attainable	VLS	supersaturation depends on the reagent fluxes; removal of products limited by diffusion
OMC-hydride process without a carrier gas	up to 10^{-10}	fast	attainable	VC or VLS	supersaturation depends on the reagent fluxes and the pressure in the reactor; removal of products not limited by diffusion

*Ratio of the sum of the fluxes due to leakage into the reactor, residual gases, and impurities in the carrier gas to the flux of the original reagents reaching the support.
**Local stability of the concentrations.

The differences between the epitaxy processes in a vacuum and in a stream of carrier gas are considerable, particularly in stages III, IV, and VII. The carrier gas, which brings about the transport of the OMC from the volatilisers into the reactor, simultaneously acts as measurement reference for determining the pressures of the components in the stream. For deposition in a vacuum, this reference is not available, and this creates a number of difficulties in the control of the fluxes and the stabilisation of the deposition conditions, and requires examination of the dynamic process as a whole.[57,58]

The gas-dynamic conditions in the reactor when a carrier gas is used are traditionally studied by introducing an aerosol into the gas stream;[100] the aerosol particles, however, do not detect the fine swirling movements which are detected by interferometry. The gas dynamics of reactors of different design have been studied using a Mach–Zehnder interferometer.[101] The results of the study of the gas dynamics of horizontal reactors have been reviewed.[102] The relationship between the development of the growth surface and gas-dynamic factors has been studied.[103–105]

At pressures below 20 mmHg, schlieren and interferometric methods are not effective, so that indirect methods have to be used to study the flow of the vapour on to the support. The simplest method is to study the profile of the deposited layer, or to record the temperature and pressure profiles in the vapour stream. The reaction of DEZ with hydrogen selenide is used to make visible the flow picture at pressures of $10–10^{-3}$ mmHg.[106] The layer of zinc selenide deposited on a probing plate makes it possible to obtain a detailed picture of the flow on to the support from the tarnish iridescence colours, and the luminescence of the layer can be used to study the mixing of the streams when they are injected into the reactor and the separation into layers of components with different molecular weights.

The vacuum systems for epitaxy from OMC vapour consist of four main units: the volatiliser, the reactor, the traps, and the evacuation system; they operate in the pressure range 10^{-2}–5 mmHg, where viscous gas flow conditions are replaced by molecular flow conditions, and are characterised by a high degree of conversion of the original reagents. The diffusion of the OMC to the support takes place through a layer of reaction products diffusing in the opposite direction, and a complex relationship is established between the reaction rate, the pressure in the reactor, and the thickness of the "reduced" film. The rate of evacuation of the products from the reactor, the rate of the supply of the OMC vapour to the reactor, and the degree of transformation in the reactor are also related in complex fashion. Overall, however, the process of deposition from OMC vapour in a vacuum is autonomous.

The theory of dynamic vacuum systems for deposition from OMC vapour has developed comparatively recently, since 1967. Thus the fluctuations in the growth rate as a result of competition between stages III and VII have been examined.[107] According to the proposed model, binary diffusion of the OMC and the thermal decomposition products takes place in the "reduced" film, and the rate of removal of the reaction products from the reactor is of the same order of magnitude as the rate of binary diffusion. In this case, fluctuations in the concentrations of the OMC and the decomposition products can take place in the reactor, and the frequency of the fluctuations is related to the reaction rate constant, the rate of evacuation, and the geometric parameters of the reactor. Analysis of the model for stability of the stationary deposition conditions showed that the higher the rate of pumping and the smaller the mass-transfer constant in the reduced film, the higher the probability that fluctuational conditions will be established; the frequency of the fluctuations increases with increase in the rate of pumping, and decreases with increase in the mass-transfer coefficient to the surface of the support. The fluctuations in the concentrations of the OMC and the thermal decomposition products lead to non-uniformity of the composition of the film along its thickness and to the growth of layer structures.

A model of acoustic self-fluctuations in the density of the vapour in the reactor, brought about by the transfer process at the start of the deposition, has been examined.[108] In the approximation of a differential reactor, with simplifying assumptions about the pressure and temperature profiles, it was shown for the case of viscous flow in a long cylindrical reactor that the acoustic wave produced when the OMC vapour is introduced into the reactor is reflected, returns to the support, and induces a change in the OMC concentration at the support. At certain ratios of the reaction rates, the geometric parameters of the reactor, and the vapour pressure in the system, sustained fluctuations of the density are excited, and their energy is supplemented by the liberation of gas during the thermal decomposition.

The self-fluctuations in the rate of growth of a film due to thermal phenomena such as the finite nature of the rate of heat transfer from the heater to the surface of the support

and the absorption or liberation of heat in the reaction on the surface have been studied.[109] If the thermal decomposition of the OMC is endothermic and autocatalytic, the liberation of solid products leads to an increase in the reaction rate, an increase in the rate of removal of heat, and a decrease in the temperature of the support; as a result, the degree of coverage of the surface with thermal decomposition products increases, the reaction rate decreases, the temperature of the surface increases, and the cycle is repeated. If the decomposition of the OMC is kinetically restricted (at low temperatures), self-fluctuations in the temperature of the support will be excited if the power of the heater is insufficient or if the support has a low thermal conductivity. The change to diffusion deposition conditions suppresses the self-fluctuations. Exothermic reactions also lead to the excitation of fluctuations in the temperature of the support, since the liberation of heat in the reaction leads to an increase in its rate and to "depletion" of the starting materials, the reaction rate decreases, the temperature of the surface decreases, and the cycle is repeated. A low thermal conductivity of the support leads to an increase in the amplitude of the fluctuations; the heat liberated in the reaction supplements the energy of the fluctuations.[58]

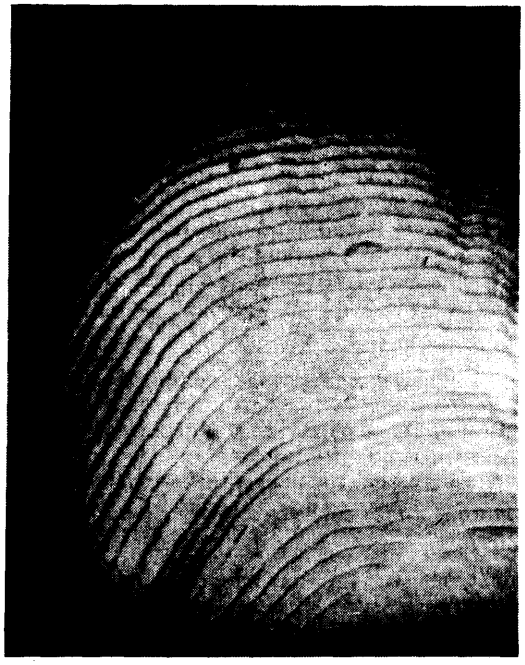

Figure 2. Transverse section of a layer of zinc selenide. Dark layers—with an excess of selenium; light layers—stoichiometric zinc selenide.[85]

The fluctuations in the pressure in the reactor and the corresponding changes in the composition of the layer being deposited have been observed experimentally; the experimental results agreed with the theory.[110,111] Essentially, all the above models relate to cases where competition between various types of mass transfer in the deposition system (stages II, III, and VII) moves the reaction from kinetic conditions to diffusion conditions or vice versa; this is a characteristic feature of deposition from OMC vapour in a vacuum, since at pressures of ~0.1 mmHg the concentrations of the OMC in the volume ($\sim 10^{15}$ cm^{-3}) and on the surface ($\sim 10^{15}$ cm^{-2}) are of the same order of magnitude. The fluctuations are suppressed when the deposition conditions move "deep" into the diffusion range, but this is not always possible, because of the influence of pressure and temperature on the quality of the deposited layer.

The fluctuations in pressure in the volatiliser–reactor–trap system, arising in the production of a binary compound AB by several parallel reactions, when the rate of the leading reaction is much greater than those of the other reactions, and when hydrogen, which is not frozen out in the trap, is liberated in the reaction products, have been examined.[112] The products of the main reaction are condensed in the trap. The highest rate of deposition corresponds to the growth of the stoichiometric layer AB, the graph giving the pressure dependence of the growth rate passes through a maximum, and fluctuations of pressure in the reactor should be excited at a certain critical pressure and are accompanied by fluctuations in the rate of liberation of hydrogen. Fluctuational conditions of this kind were observed in the preparation of zinc selenide by the reaction of DEZ with hydrogen selenide.[85] The fluctuations in pressures were accompanied by the growth of a structure consisting of periodically alternating layers of stoichiometric zinc selenide (light layers in Fig.2) and ZnSe with an excess of selenium (dark layers in Fig.2). The frequency of the fluctuations was related to the volume of the reactor, the working pressure, and the rate of removal of the volatile component.[112]

The fluctuations in the concentrations of the components of the reaction in the adsorption layer, due to the characteristic features of the desorption and adsorption of the OMC and the phenomena of heterogeneous catalysis and development of the growth surface, have been examined.[58,113] The fluctuating change in the surface concentrations in the adsorption layer is excited by autocatalytic phenomena, the activated chemisorption of the OMC and the decomposition products, the multistage nature of the surface reaction, and the two-dimensional condensation of intermediate phases, and can take place without a change in the pressure in the reactor.

Thus methods of deposition in a carrier-gas stream have been developed technically, and make it possible to produce multicomponent mixtures of OMC and hydrides under dynamic conditions, automatically, and with a high accuracy. A high carrier-gas pressure in the deposition system makes it possible to separate stages I and II, III and VII. The quality of the layers obtained by this method is decreased by contamination by impurities from the carrier gas, etching of the growing layer, blocking of the adsorption centres by molecules of the carrier gas, the consequent decrease in the fraction of the selective decomposition of the OMC, and local instability of the concentrations, due to convective and turbulent diffusion and small-scale rotational movements in the boundary layer.

The vacuum method of deposition from OMC vapour does not have the disadvantages associated with the use of a carrier gas, and this makes it possible to improve considerably the quality of the layers and to achieve automatic control of the deposition process, finer control of the supersaturation, and stabilisation of the fluxes of the reagents to the growth surface. This method is more complicated, however, in the generation of the fluxes of the original OMC, and requires detailed experimental and design studies to

find stable deposition conditions; this is related to the use of flow conditions close to the range corresponding to the change from viscous to molecular conditions.

III. DEPOSITION OF EPITAXIAL LAYERS OF $A^{III}B^{V}$ COMPOUNDS

Epitaxial layers of binary semiconducting compounds $A^{III}B^{V}$ are obtained by the reactions of OMC and hydrides and molecular complexes. There is comparatively little published information on the mechanism of the reactions accompanying deposition. A study of the reaction of TMG with arsine[66] (see above) showed that the polycondensed fragments containing the $\rangle$Ga–As$\langle$ bond undergo autocatalytic decomposition to gallium arsenide. The homogeneous nucleation of aggregates $(GaAs)_n$,[114–116] the formation of homogeneous polymeric species containing Ga, N, C, and H atoms in the reaction of TMG with ammonia, and the formation of polymeric layers containing In, P, C, and H in the reaction of trimethylindium with phosphine[117] have been proposed, but no direct proof of homogeneous nucleation has been give.

The conditions for the distillation of the molecular complexes $ClEt_2Ga.AsEt_3$, $ClEt_2Ga.AsMe_3$, $ClEt_2Ga.NEt_3$, and $ClEt_2Ga.PEt_3$,[118] which can be used to obtain layers of $A^{III}B^{V}$ compounds, have been studied. The complex $Me_3Al.NH_3$ has been used to obtain aluminium nitride.[47] The first methane molecule is removed at 60°, and the second at 160°; decomposition to form AlN is complete at 1200°.[47,119,120] The thermal decomposition of the complexes $Cl_3Al.NH_3$ and $Me_3Ga.NH_3$ [121,122] and the decomposition of the complexes $Et_3Ga.NH_3$, $R_3Ga.AsR_3$,[123] $Me_3In.PMe_3$,[124] and $ClEt_2Ga.AsEt_3$ [125] have been studied. A number of complexes containing the Ga–As bond have been studied to obtain layers in a horizontal flow reactor in a stream of helium.[126] It was reported that the type of conductivity depends on the method used to heat the support; the authors cited consider that this was proved by the fact that the Ga–As bond is not broken, although change in the type of conductivity is due rather to a change in the type of self-alloying impurities when working with a hot or cold reactor wall. The complex $(Et_2Ga.PEt_2)_3$ has been used to obtain layers of GaP.[127] The thermal decomposition of $ClEt_2Ga.AsEt_3$ has been studied.[128] The deposition of the ternary system $GaAs_{1-x}P_x$ with values of x in the range 0–0.6 from $ClEt_2Ga.AsEt_3$ and diethylphosphine vapour has been examined.[129]

The process of deposition from OMC vapour is analysed by the method of partial pressures,[130] which involves the numerical solution of systems of equations for the partial pressures and equilibrium constants, and the subsequent construction of equilibrium diagrams on coordinates temperature–pressure–composition. These diagrams have been constructed for the system Ga–As–Cl–H; a comparison[131] of the deposition of gallium arsenide from OMC vapour with the chloride–hydride process showed that the OMC–hydride process has a wider range of conditions for the existence of gallium arsenide, makes possible a smoother control of the supersaturation, and is less critical with respect to the degree of stabilisation of the conditions of the experiment. A study of GaAs layers deposited from a mixture of the vapours of arsine and the ether addition compound of TMG, labelled in the methyl group with the ^{14}C isotope, showed that the ^{14}C concentration did not exceed 6×10^{13} cm^{-3} and agreed with the thermodynamic analysis.[132,133] A thermodynamic analysis of the system TMA–trimethylantimony showed that at the deposition temperature of aluminium antimonide (623°) the product is aluminium carbide, and that the use of tri-isobutylaluminium instead of TMA makes it possible to decrease sharply the concentration range corresponding to the synthesis of aluminium carbide,[134] and this was confirmed experimentally.[135] Subsequent work was directed towards the preparation of the ternary and quaternary systems $Ga_{1-x}Al_xSb$ and $Ga_{1-x}Al_xAs_{1-y}Sb_y$ [136] and the study of the influence of the pressure of the OMC of group III elements relative to the vapour pressure of the compounds of group V elements on the composition of the $GaAs_{1-x}Sb_x$ layers obtained; the results of the thermodynamic calculations agreed with the experimental data.[137,138]

Published data on the kinetics of the growth of $A^{III}B^{V}$ epitaxial layers from OMC vapour are obtained by recording the dependence of the rate of deposition on the parameters of the process. The rate of deposition is independent of temperature in the range 600–800°. *..... semiconducting compounds and the development of instruments based on epitaxial layers, *..... group V, and is of first order with respect to the consumption of the OMC vapour. The process is generally carried out under conditions of diffusion control, so that the rate of deposition increases with increase in the flux rate.[41,75,139]

The mechanism of the deposition of gallium arsenide by the reaction of TMG with arsine has been studied by infrared spectroscopy. Thus TMG begins to decompose in a stream of hydrogen at a temperature above 400°, and the rate of the thermal decomposition is stabilised above 600°. Arsine begins to decompose at 650°; above 750°, the degree of conversion of AsH_3 is close to 1. When TMG, arsine, and hydrogen are introduced into the reactor, the infrared spectrum of the products shows a new peak at 2080 cm^{-1}, whose intensity increases with increase in the concentration of arsine in the stream and is a maximum in the temperature range 510–550°.[140]

Most work on the deposition of layers of $A^{III}B^{V}$ compounds from OMC vapour in recent years has been carried out in two main directions: the preparation and improvement of the properties of ternary and quaternary semiconducting compounds and the development of instruments based on epitaxial layers deposited from OMC vapour. Considerable progress has been made in these directions. Much work has been devoted to the production of lasers based on the hetero-structure $Ga_{1-x}Al_xAs$; lasers based on binary hetero-structures which operate for a long time at room temperatures, highly efficient solar batteries and batteries operating with the concentration of solar radiation,[141–144] field transistors,[145] photocathodes,[146] super-high-frequency transistors with record low noise values,[147] and a number of instruments for opto- and micro-electronics have been developed. The preparation of the quaternary system $Ga_{1-x}In_xAs_{1-y}P_y$ by the reaction of alkyl OMC with the hydrides of the group V elements with the preliminary decomposition of phosphine has been studied,[148] and this has led to the development of highly efficient semiconducting lasers in the near infrared range.[149] The ternary system $Ga_{1-x}In_xAs$ has been deposited,[150] and used to produce a number of opto-electronic instruments.[151] The systems $GaAs_{1-x}Sb_x$ [152] and $In_{1-x}Ga_xP$ with $x = 0.5$ [153] have also been prepared.

Work is continuing on the hetero-epitaxy of aluminium nitride from a mixture of the vapours of OMC, ammonia, and hydrazine on supports of silicon and sapphire for acoustic detectors.[154–156] Lasers based on $Ga_{1-x}Al_xAs$,

*Misprint in Russian text: two or more lines missing.

stable in proton fluxes,[157] layers of aluminium arsenide,[158] solid solutions $Ga_{1-x}Al_xN$,[159] and films of gallium arsenide on molybdenum[160] have also been obtained.

Intensive studies aimed at lowering the deposition temperature are being carried out[161-163] to produce epitaxial layers of high quality. The greatest success in this direction has been achieved by carrying out the reaction of TMG with arsine in a glow-discharge plasma. Thus the reaction of TMG with arsine at room temperature in the plasma of a helium discharge gave layers from which GaAs was isolated by treating with an electron beam.[164] A process has been developed for preparing a GaAs surface in the plasma of a helium discharge at 200° with the addition of HCl,[165] and layers of gallium arsenide suitable for use in instruments have been obtained.[166] The most perfect layers wer obtained at a support temperature of 400–450° and a pressure of helium vapour in the reactor of 1.5 mmHg.

Deposition from OMC vapour makes it possible to obtain sharp boundaries between layers with different compositions. Thus a superlattice has been produced[167] by alternating layers of n-$Ga_{1-x}Al_xAs$ (240 Å) with layers of unalloyed GaAs (225 Å). Study of the alloying profile in the layer showed that the lattice period (the distance between successive carrier concentration peaks) is ~250 Å, and that the mobility of the carriers is greater than the theoretical value; this opens up the possibility of producing improved devices.

Thus $A^{III}B^{V}$ epitaxial layers are obtained by deposition from OMC vapour using a wide range of compounds which ensure relatively low deposition temperatures and controlled alloy production. The use of OMC makes it possible to achieve precise control of the supersaturation, to obtain multicomponent systems, and to ensure that the parameters of the layer are constant over a wide area.

IV. DEPOSITION OF EPITAXIAL LAYERS OF $A^{II}B^{VI}$ AND $A^{IV}B^{VI}$ COMPOUNDS

Epitaxial layers of $A^{II}B^{VI}$ compounds show extensive promising possibilities for application in opto-electronic and electroluminescent instruments in the visible range of the spectrum.[168] Considerable effort has been put into the production of $A^{II}B^{VI}$ films, but success has been achieved only in recent years, when deposition from OMC vapour was used for this purpose. The ability of $A^{II}B^{VI}$ compounds to undergo self-compensation makes it possible to obtain conducting layers only with a low density of point defects, so that the deposition process presents more rigorous requirements regarding the level of purity from oxygen-containing impurities and the accuracy of the control of the supersaturation, compared with $A^{III}B^{V}$ compounds. Epitaxial layers of the chalcogenides of the group II elements are obtained from OMC vapour using reaction (1), and the reagents used are dimethylcadmium, dimethylzinc (DMZ), DEZ, sulphur and selenium hydrides, selenium and tellurium alkyls,[57,58] and heterocyclic derivatives of sulphur, selenium, and tellurium.[169] The thermal decomposition of the alkyls of the group II elements zinc[9-11] and cadmium[12-14] has been studied.

Table 2 gives published data[170-174] on the kinetics of the thermal decomposition of alkyls of the elements of groups II and VI. The thermal decomposition of DEZ and DMZ has been studied under static conditions,[170] in a stream of helium,[171] and in a high vacuum.[172] The decomposition of a mixture of DEZ and dimethylselenium has been studied.[173] In the decomposition of DEZ in a vacuum at a pressure of 10^{-5} mmHg, the following gaseous products were detected: CH_4, C_2H_6, C_2H_4, C_4H_8, and C_4H_{10}. Increase in temperature led to an increase in the yield of hydrogen, ethylene, and butene, and a decrease in the yield of ethane.[172] In the decomposition of DEZ under static conditions, the reaction was homogeneous. In addition to the gaseous products listed above, octane, octene, hexane, hexene, butane, and butene were detected. The data in Table 2 show that the activation energy increases with increase in the pressure and the proportion of the homogeneous reaction. Fig.3 gives published data[65] on the thermal decomposition of alkyls of cadmium, tellurium, and selenium in a stream of hydrogen. The temperature dependence of the deposition rate is determined entirely by the mass-transfer constants, as can be seen by comparing the curves for the decomposition of diethyltellurium (Fig.3). In the thermal decomposition of a mixture of DEZ and dimethylselenium, the limiting stage is the decomposition of dimethylselenium, and the ethyl radicals formed by the decomposition of DEZ induce the decomposition of $SeMe_2$.[173,174]

*Static conditions.

A method has been developed for obtaining dynamic P–T diagrams for heterogeneous OMC–support systems.[95,96] For a dynamic flow reactor a line is constructed on coordinates P, T, along which the rate of deposition of W according to the reactions

$$\text{OMC(gas)} \rightleftarrows \text{M(crystalline)} + \text{X(gas)} \qquad (3)$$

$$\text{M(crystalline)} \rightleftarrows \text{M(gas)} \qquad (4)$$

is equal to zero after allowance for the volatilisation of the metal. Here, M is the metal, and X the gaseous products. An expression has been obtained[175] for the rate of deposition for reaction (3), assuming that it takes place in three stages (III, IV, V), without allowance for volatilisation of the metal. Using the published data[175] and introducing the symbols P_{OMC} and P^0_{OMC} for the vapour pressures of the OMC close to the support and in the flow, and P_X and P_M for the pressures of the reaction products X and the metal vapour close to the support, it is possible to write the condition fulfilled on the line $W = 0$ as follows:

$$k_1 P_{OMC} - k_{-1} P_X + \alpha P_M = \alpha\gamma P^0_M \qquad (5)$$

where k_1 and k_{-1} are the rate constants of the forward and back reactions (3), α the coefficient of condensation of the metal, P_M^0 the equilibrium vapour pressure of the metal, $\gamma = P^{cr}/P_M^0$, and P^{cr} the critical supersaturation required for condensation of the metal on the support. For example, for the condensation of zinc on glass, $\gamma = 3$.[176] Condition (5) for $W = 0$ for a glass reactor, with allowance for the volatilisation of the metal, then has the form:

$$P_{OMC}^0 = \frac{3\alpha P_M^0 k_d}{\alpha + k_d}\left(\frac{1}{k_1} + \frac{1}{k_d} + \frac{1}{K \cdot k_d}\right)$$

where K is the equilibrium constant of reaction (3), and k_d the mass-transfer coefficient in the reduced film (for simplicity, it is assumed that the values of the transfer constants for OMC, M, and X are the same). At low pressures, the thickness of the reduced film is much greater than the dimensions of the reactor, and the following relationship is fulfilled on the line $W = 0$

$$\frac{R}{k_d} = \frac{\alpha\gamma k_d P_M^0}{\alpha + k_d}\left(\frac{1}{k_1} + \frac{1}{k_d} + \frac{1}{K \cdot k_d}\right) \qquad (6)$$

where R is the consumption of the OMC. It is possible to select the temperature and pressure in the reactor in such a way that the conditions $\alpha \gg k_d$ and $k_d \gg K$ are fulfilled. Eqn.(6) then takes the form:

$$\frac{R}{k_d^2} = \frac{\gamma P_M^0}{k_1} .$$

This relationship makes it possible to determine the activation energy of reaction (3). For the case of the volatilisation of the layer from the support, condition (5) takes the form:

$$k_1 P_{OMC} - k_{-1} P_X = \alpha P_M^0 . \qquad (7)$$

γ can be determined by comparing the temperatures of the volatilisation and condensation of the layer of metal and using Eqns.(5) and (7).

A detailed analysis of the influence of the conditions of the experiment on the observed activation energies of reaction (3) (without allowance for the volatilisation of the metal) has been carried out.[175]

The kinetics of the deposition of $A^{II}B^{VI}$ epitaxial layers have been studied.[177–182] The following method was used: the vapour of the alkyl of the group VI element was passed through a preliminary reactor (temperature 800°), in which the alkyl of the group VI element was converted into the corresponding hydride in a stream of hydrogen. The mixture of hydrogen, the hydride, and the decomposition products of the alkyl radicals was passed into a reactor in which the chalcogen hydride reacted with the OMC vapour. Cadmium and zinc sulphides and selenides were obtained in this way. The use of the preliminary reactor leads to the loss of the main advantage of the alkyls of the group VI elements over the hydrides, namely the possibility of mixing beforehand with OMC vapour.

Concentration of carbon in the specimens lay in the range $(4–8) \times 10^{20}$ cm^{-3} [177] or $(1–5) \times 10^{20}$ cm^{-3}.[178] The high concentration of carbon in the layers is apparently due to the capture by the growing layer of the cracking products of the alkyl radicals, and depends little on the deposition temperature. In fact, the concentration of carbon in the layers changes in the opposite sense to the rate of deposition.[178] The temperature dependence of the deposition rate shows two peaks: one at about 200°, and the second at about 550°.[177–179] Fig.4 gives the temperature dependence of the growth rate for the deposition of cadmium sulphide from a mixture of OMC vapour[177] and for condensation from a mixture of cadmium and sulphur vapour.[181] The regular features are similar; the curve obtained for condensation from the elements is displaced towards higher temperatures, because of the greater supersaturation, and in the deposition from the vapour of the OMC and the hydride, a decrease in the deposition rate is observed in the low-temperature range.

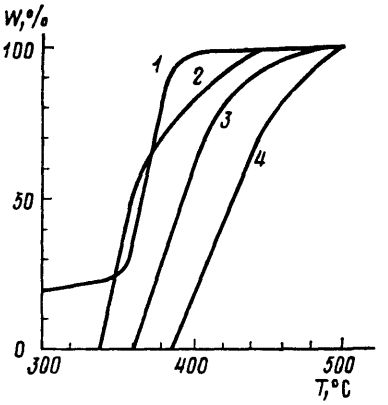

Figure 3. Thermal decomposition of cadmium and tellurium alkyls;[65] W is the ratio of the decomposition rate to the maximum decomposition rate. Compounds: $CdMe_2$ (*1*), $TeEt_2$ (*2*, *3*), $TeMe_2$ (*4*). Pressure of the OMC vapour in the stream of hydrogen: 9 mmHg (*1*), 2 mmHg (*2*, *3*), 10 mmHg (*4*); hydrogen flow velocity: 20 cm s^{-1} (*1*, *3*), 10 cm s^{-1} (*2*), 15.6 cm s^{-1} (*4*).

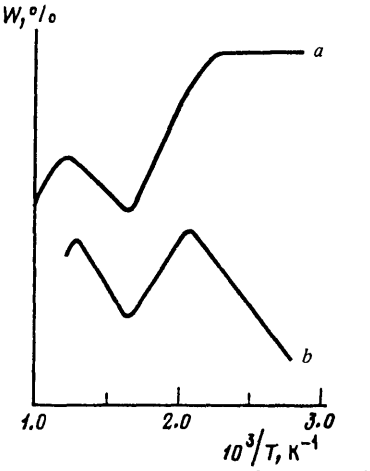

Figure 4. Temperature dependence of the relative rate of growth of cadmium sulphide: *a*) condensation from cadmium and sulphur vapour,[181] *b*) deposition from the vapour of $CdMe_2$ and the decomposition products of dimethyl sulphide.[177]

Up to 1 at.% gallium was detected in layers deposited on gallium arsenide supports; it was assumed[179] that this is transferred to the layer from the opposite side of the support. A mechanism has been proposed[179] for the growth of CdS layers from dimethylcadmium vapour and

hydrogen sulphide. It is suggested that growth takes place by a VLS mechanism with the formation of a two-dimensional liquid from cadmium atoms on the CdS surface. The most perfect layers were obtained with an excess of dimethylcadmium in the stream. Zinc selenide has been obtained by the reaction of DMZ with dimethylselenium in a stream of hydrogen.[180] The plot of the growth rate against the reciprocal of the temperature had a maximum at 560°, and at lower deposition temperatures, W decreased linearly with increase in $1/T$. H_2Se and methane were detected in the gaseous products. The cathodoluminescence spectra of the layers showed an intense band at 600 nm, a number of bands in the range 500–460 nm, and an edge band with phonon structure, indicating that the ZnSe layers obtained had a non-stoichiometric composition and a high density of defects.

The growth rate of a layer of a compound AB by reaction (1) is a function of the pressure in the reactor and the ratio of the fluxes of the OMC and the hydride in the reactor β.[87] Change in the deposition temperature as a result of a difference in the thermal stabilities of the OMC and the hydrides will lead to a change in the ratio β and the pressure in the reactor, and the recording of the temperature dependence of the growth rate may pass through different sections $W(\beta, P)$. For the deposition of ZnSe from the vapour of the OMC and the hydride, the reaction rate over a wide range of conditions is limited by stages II and VII. With increase in temperature and pressure in the reactor, the homogeneous synthesis of ZnSe begins (5 mmHg, 400°), and with decrease in the pressure to 0.5 mmHg, the homogeneous reaction is not observed up to 500°.

The processes of deposition of compounds AB by the reactions of OMC with hydrides have been classified[85] on the basis of the stability of the deposition process and the possibilities for the production of defect-free stoichiometric layers. The $P-T-X$ diagrams for $A^{II}B^{VI}$ compounds were used to construct a hierarchy of pressures: $P_A^{AB(B)}$—the pressure of the vapour of A over a composition with an excess of B, $P_A^{AB(A)}$—the pressure above a composition with an excess of A, and P_A^{cr}—the critical pressure for the formation of nuclei of the substance A on a layer AB with an excess of A. The pressures for the component B, $P_B^{AB(B)}$, P_B^{AB}, and $P_B^{AB(A)}$ are defined similarly. The effective pressures of the atoms P^e are defined in terms of the fluxes of the atoms into the adsorption layer as follows:

$$k_1 P_{OMC} - k_{-1} P_x = (2\pi MkT)^{-1/2} P^e$$

where M is the mass of the OMC molecule or the hydride, and the other quantities were defined above in the examination of the decomposition of the OMC. The pressure P^e and hence the composition of the layer determined by it is measured from the pressure above a layer AB with the stoichiometric composition.

The situations arising during deposition are shown in Table 3. At the temperature T_1 the hydride and the OMC are stable, and the compound AB is deposited by reaction (1); above the temperature T_1, the hydride or OMC decompose. If the sum $P_A^e + P_A^{AB}$ is less than $P_A^{AB(A)}$, the compound AB with a composition in its range of existence will be deposited, but the density of vacancies of the element B increases. If $P_A^e + P_A^{AB}$ is greater than $P_A^{AB(A)}$, a two-dimensional liquid of the element A may be produced on the surface, and if $P_A^e + P_A^{AB(A)} > P_A^{cr}$, condensation of the element A begins. With increase in temperature above T_2, the same regular features will also be observed for the element B, but with allowance for the reaction of the element B with the element A.

Table 3. Relationship between the effective pressures and the composition of AB and the stability of the process.[81]

Temperature	Effective pressures	Composition	Mechanism	Stability
$T<T_1$	$P^e=0$	AB	VC	stable
$T_2>T>T_1$	$P_A^e + P_A^{AB} < P_A^{AB(A)}$	AB, B vacancies	VC	stable
	$P_A^e + P_A^{AB} > P_A^{AB(A)}$	AB(A)	VLS	unstable
	$P_A^e + P_A^{AB} > P_A^{кр}$	*	VLS	stable
$T>T_2$	$P_A^e + P_A^{AB} < P_A^{AB(A)}$	AB	VC	stable
	$P_B^e + P_B^{AB} < P_B^{AB(B)}$	AB	VC	stable
	$P_A^e + P_B^{AB} < P_A^{AB(A)}$	AB(A)	VC + VLS**	unstable
$T>T_2$	$P_B^e + P_A^{AB} > P_B^{AB(B)}$	AB (B)	VC + VLS	unstable

*Formation of inclusions of the element A in the layer is possible.

**Reaction between the atoms of the elements A and B takes place on the surface of the layer.

It should be noted that the growth conditions are unstable when the pressures P_A^{cr} or $P_A^{AB(A)}$ reach the boundary of formation of the two-dimensional condensate.[58] The mechanism of the production of the instability is as follows: on two-dimensional condensation, a liquid phase is produced on the surface; on its surface there is a sharp increase in the coefficients of condensation and reactive adhesion, leading to exhaustion of the starting materials and a change from the VLS to the VC mechanism; subsequently, accumulation of atoms takes place again with a change to the VLS growth mechanism, and the process is repeated. The factor responsible is the hysteresis associated with the condensation–volatilisation process on going from adsorption to the formation of nuclei of the liquid phase or two-dimensional condensates. Fig.2 gives the transverse cross-section of a zinc selenide specimen deposited from the vapour of the OMC and the hydride. In spite of the fact that the growth rate changed by a factor of two along the plane of the specimen (concentration wedge), the frequency of the fluctuations in the composition was constant. This proves that the fluctuations in the selenium concentration in the layer are due to a collective process involving the entire surface. The fluctuations were suppressed by decreasing the pressure in the reactor or by increasing the hydrogen selenide pressure. With decrease in pressure, stoichiometric layers were obtained, and with increase in the hydrogen selenide pressure, layers with an excess of selenium were produced.[85]

In recent years, greatest progress has been made in the preparation of layers of zinc selenide. This is a broad-zone material with lattice parameter close to that of gallium arsenide. ZnSe layers are obtained by the reaction of DMZ or DEZ with hydrogen selenide or dimethylselenium vapour in a stream of a carrier gas or in a vacuum at pressures of 0.1–5 mmHg. Stutius[64,182–186] obtained ZnSe layers by the reaction of the OMC and the hydride at a temperature of 300–350 °C at a reduced pressure of H_2 in

a vertical reactor with a support at an angle of 45° to the axis of flow. He obtained highly perfect layers of zinc selenide on supports of gallium arsenide and germanium, which gave a clearly defined edge band in the photoluminescence spectrum and a ratio $I_e/I_i > 10^3$ (I_i and I_e are the intensities of the impurity and edge photoluminescence).[182] Later papers[64,182] gave the photoluminescence spectra recorded at a lower density of the exciting radiation; the ratio I_e/I_i for films with a thickness of 4 μm was greater than 50, and that for layers with a thickness of 0.1 μm was 0.5. Layers of ZnSe alloyed with aluminium, with a specific resistance reaching 0.05 Ω.cm, have been obtained. The alloys were produced by introducing TMA vapour into the reagent flux.[183,184]

To obtain better matching of the lattice parameters of gallium arsenide and zinc selenide, ZnS_xSe_{1-x} layers with $x = 0.05$ are obtained by adding H_2S to the stream of H_2Se. The decrease in the stresses at the ZnS_xSe_{1-x}–GaAs boundary leads to an increase in the photoluminescence yield of the layer.[183] The dependence of x on the mole fraction of hydrogen sulphide in the stream of hydrogen selenide y was obtained, and an equation relating these parameters was given:

$$x = \frac{0.0159y}{1 - y(1 - 0.0159)} .$$

With change in x in the range 0–0.1, the intensity of the edge band remains constant, and the intensity of the impurity band decreases and has a minimum at $x = 0.05$. This indicates that the intensity of the photoluminescence band at 600 nm is related to the density of defects at the ZnSe–GaAs boundary. To obtain ZnSe (p-type) layers, experiments were carried out to alloy zinc selenide with nitrogen, phosphorus, and arsenic from ammonia, phosphine, and arsine vapour. Nitrogen gives finer levels in ZnSe, but conducting specimens could not be obtained.[64,184]

The deposition of ZnSe from OMC vapour and the hydride at atmospheric pressure of hydrogen has been studied. The dependence of the growth rate on the consumption of the OMC and the hydride, and on temperature, was obtained in the range 450–700°.[187,188] Up to 560°, the value of W is independent of temperature, but above this value it decreases with increase in temperature. With increase in the hydrogen selenide flux, the rate of growth of the layer decreased, and with change in the DEZ flux a maximum in the deposition rate was observed; at a ratio of the DEZ flux to the H_2Se flux greater than 4, growth took place from an adsorption layer enriched in zinc. At a temperature of 520°, inclusions with the composition $Ga_2Se_3.9ZnSe$ were formed at the support boundary.

Zinc selenide has been obtained by the reaction of DEZ with dimethylselenium.[189] The growth rate in the temperature range 350–750° is limited by the transport of the OMC to the support, and the dependence of W on the consumption of the OMC is similar to that discussed above.[187] The preparation of epitaxial layers of ZnSe from a $ZnMe_2$–$SeEt_2$–H_2Se–H_2 mixture (molar ratio 0.45 : 9 : 2.9 : 675) has been reported. Mirror-smooth ZnSe layers with a low level of stresses were obtained.[190] Epitaxial layers of ZnS, ZnSe, and ZnO have been obtained by the reactions of DMZ with the corresponding heterocyclic derivatives of the group VI elements. Single-crystal layers of ZnS and ZnSe were obtained on supports of GaAs,[100] and ZnO layers were obtained on sapphire supports.[191] The chief advantage of the use of heterocyclic derivatives is that it is possible to mix them beforehand with the DMZ vapour.

The possibility of using deposition from OMC vapour to prepare a n-ZnSe–p-GaAs hetero-junction of high quality, suitable for producing electroluminescent and opto-electronic instruments, has been studied.[192–195] Epitaxial layers of ZnSe were obtained by the reaction of DEZ with hydrogen selenide, carried out in a vacuum at temperatures of 300–450° and pressures of 0.1–5 mmHg. Alloys were produced by introducing TMA vapour into the reagent flux. Plates of AGP-1 and AGChTs grade gallium arsenide with a concentration of p-type carriers of 10^{19} cm^{-3} were used as supports. This gave highly perfect ZnSe layers with a structureless edge photoluminescence band and a mirror-smooth surface, with a ratio $I_e/I_i > 10^3$ for a layer thickness of 0.5–5 μm.[188,196] Induced emission was observed on these layers.[197] The resonator was obtained by splitting along the cleavage planes GaAs plates with a deposited ZnSe layer with a thickness of 6 μm, without preliminary treatment of the surface. The threshold density of optical pumping was 50 W cm^{-2} at 77 K. Lasing was also achieved at room temperature.

The specific resistance of the ZnSe (n-type) layers varied in the range 3×10^{-3}–1 Ω.cm with change in the concentration of n-type carriers in the range 2×10^{18}–10^{16} cm^{-3}. For the production of devices, it is necessary to obtain a perfect n-ZnSe–p-GaAs hetero-junction with a low resistance. Examination of the reactions at the ZnSe–GaAs boundary showed that the interaction of gaseous hydrogen selenide with the p-GaAs surface can lead to displacement of the p–n transition in gallium arsenide, the formation of an insulating layer at the boundary, and the production of structures of the type n–p–n–p; this has been confirmed experimentally.[193]

The intermediate layer at the ZnSe–GaAs boundary has been studied by photoluminescence methods. The spectra recorded at right angles to the surface of the specimen contained an impurity photoluminescence peak at 600 nm. Observation of the photoluminescence from the splitting showed that the emission at 600 nm is localised in a range of 0.1–0.2 μm adjoining the gallium arsenide surface. Since the exciting radiation is completely absorbed in zinc selenide at a thickness of less than 0.1 μm, the observation of the band at 600 nm in the photoluminescence spectrum indicates that it is excited as a result of ambipolar diffusion of the carriers. Comparison of the intensity of the impurity photoluminescence band from sections of the ZnSe layer with different thicknesses made it possible to measure the diffusion length in zinc selenide specimens, which amounted to 2.5 μm at 300 K and more than 6 μm at 77 K.[192] The formation of the intermediate layer is related to the catalytic decomposition of hydrogen selenide on the gallium arsenide surface. Thus when gaseous H_2Se is supplied to the reactor, drops of selenium decorate the GaAs surface at 300°.[196] In the deposition of ZnSe on GaAs, two sets of conditions are realised in succession; the first corresponds to hetero-epitaxy, with the catalytic decomposition of hydrogen selenide and the growth of a ZnSe layer with an excess of selenium, and the second corresponds to auto-epitaxy, with the growth of stoichiometric zinc selenide.

In Ref.198, deposition from OMC vapour and the hydride in a vacuum gave zinc selenide layers with a thickness of 0.03–0.1 μm, whose photoluminescence spectrum, in contrast to Ref.64, gave a ratio $I_e/I_i \cong 10$, indicating the absence of an intermediate layer at the ZnSe–GaAs boundary. The photoelectric properties of hetero-junctions have been studied for ZnSe specimens alloyed with aluminium to a level of 10^{16}–3×10^{-18} cm^{-3}. The carrier collection coefficient increased with increase in the concentration of carriers; relative to the number of photons reaching the

p–n junction, it amounted to 0.92–1.00 in the range 460–890 nm, and at wavelengths less than 460 nm it varied in the range 0.2–0.3; this indicates the long length of ambipolar diffusion in the epitaxial layers (Fig.5).

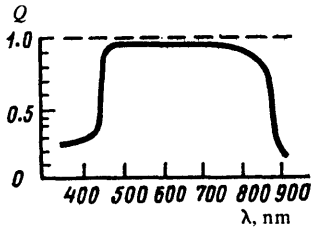

Figure 5. Dependence of the quantum efficiency Q of the hetero-junction p-GaAs–n-ZnSe on the wavelength of light.[198]

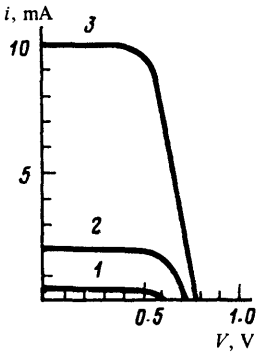

Figure 6. Load characteristics of a diode based on ZnSe–GaAs for different solar radiation powers: 0.4 MW cm^{-2} (*1*), 180 MW cm^{-2} (*2*), and 900 MW cm^{-2} (*3*).[198]

The forward and reverse branches of the voltage-current characteristic are approximated by the expressions:

$$i = i_0 \exp\left(\frac{V}{1.7\,kT}\right), \quad i = i_1 \exp\left[-C(V_0 - V)^{-\frac{1}{2}}\right]$$

where $i_0 = 10^{-8}$–10^{-9} A cm^{-2}, $C = 13$–14, and $V_0 = 1.30$–1.35 V. These forms of the forward and reverse branches of the voltage-current characteristic indicate that the predominant mechanism of current flow in the given diode is by tunneling.[199] The recording of the C–V characteristics of the hetero-junction showed that close to the ZnSe–GaAs interface there exists a layer of thickness 50 nm, which has a low concentration of carriers and which becomes narrower with increase in the concentration of carriers. The load characteristics of the diode were recorded using specimens with dimensions of 3 × 2 mm^2 without a brightening coating under direct solar radiation AM2 (Fig.6). The diode current was limited by the resistance of the contact, and not by the resistance of spreading; the efficiency of the diode varied in the range 15–18%, depending on the power of the incident radiation; the efficiency calculated with allowance for the production of a brightening coating was 18–22%.[198]

Experiments have been carried out to obtain zinc selenide from OMC vapour and the hydride at low carrier gas pressures. Conducting layers of zinc selenide were obtained without alloying at a deposition temperature of 250–300°; the conductivity decreased with increase in the deposition temperature to 370°, indicating uncontrolled alloying of the layers at low deposition temperatures.[200–202]

A number of studies have been devoted to the preparation of mercury telluride and the ternary system $Hg_xCd_{1-x}Te$.[203–206] The main difficulty in the production of this system is the high vapour pressure of mercury over compositions rich in mercury, which restricts the upper temperature of deposition to 400–420° and requires rapid cooling of the support with the epitaxial layer obtained when the deposition is complete. The deposition is carried out using a mixture of Hg–$CdMe_2$–$TeMe_2$–H_2 vapour, transported by a stream of hydrogen into the deposition zone. CdTe plates oriented with the (100), (110), or (111) faces are used as supports; the deposition temperature is 350–410°. An intermediate layer with a thickness of 0.4 μm, due to the diffusion of mercury in the support, was formed at the film–CdTe boundary. Increase in x was accompanied by a sharp change in the morphology of the surface of the layers; at $x < 0.2$, the surface was formed of irregular steps with cracks of a depth of up to 10 μm; at $x > 0.2$, the surface became mirror-smooth. Layers with an excess of tellurium showed n-type conductivity, and those with an excess of mercury showed p-type conductivity. The conductivity of the layers was determined by the consumption of mercury vapour in the reactor; the rate of deposition increased with increase in temperature.

A relatively small number of studies have been devoted to the preparation of epitaxial layers of $A^{IV}B^{VI}$ compounds. The deposition is carried out using the reaction of alkyls of group IV elements with hydrogen sulphide, hydrogen selenide, or tellurium alkyls in a stream of carrier gas (hydrogen). The temperature of deposition of the epitaxial layers was 550° for SnS, 500° for SnSe, 625° for SnTe, 550° for PbS and PbSe, 500° for PbTe, and 550–625° for $Pb_{1-x}Sn_xTe$.[52]

Table 4. Organobimetallic compounds used to prepare $A^{IV}B^{VI}$ compounds.[70–72]

Compound	T, °C	Solid products	Gaseous products
$(RS)_4Si$	500—600	SiS_2	SR_2
$(CH_3S)_2Cd$	400	CdS	SMe_2
$(R_3Ge)_2Hg$	400	Ge	C_1—C_4 (gas)
$Et_3SiTeGeEt_3$	450	GeTe	$TeEt_2$, *EtH*
$(Et_3Ge)_2Te$	450	GeTe	$GeEt_4$, $TeEt_2$
$(Et_3Ge)_2S$	450	GeS	$GeEt_4$
$Et_3GeTeEt$	450	GeTe	$GeEt_4$, $TeEt_2$
$(Et_3Sn)_2S$	350	SnS	$SnEt_4$
$(Et_3Sn)_2Te$	300	SnTe	$SnEt_4$, $SnEt_3H$
$Et_3SnTeEt$	400	SnTe	$TeEt_2$, $SnEt_4$

At lower temperatures, the compounds $A^{IV}B^{VI}$ can be obtained by the thermal decomposition of organobimetallic compounds containing a metal–chalcogen bond;[70–72] the deposition of the binary compound is identical to the deposition of the simple compound, for example of silicon or germanium. The process is simplified considerably, since the stage involving the mixing of the components is eliminated, making it possible to stabilise the stoichiometric

composition of the layer over the entire area of the support. Data on the preparation of epitaxial layers of compounds $A^{IV}B^{VI}$ from the vapour of organobimetallic compounds are given in Table 4. It can be seen from Table 4 that the deposition temperature of the layers is lower than that when a mixture of OMC vapour and the hydride is used.

---o0o---

Thus deposition from OMC vapour is widely used to produce micro- and opto-electronic devices with exceptional parameters. New methods for the deposition of epitaxial layers are being rapidly developed and introduced into practice, the range of OMC used in technology is being expanded, and the search for new compounds is being continued. In addition, the theory of the deposition of epitaxial layers of binary compounds is being slowly developed (for 150–200 technical papers there is fewer than one paper on the study of the mechanism of the process), and this is holding up the introduction of methods for the deposition of epitaxial layers from OMC vapour in industry.

Spectroscopic Study of the Steric Effects in Organic Compounds of Silicon Subgroup Elements

A.N.Egorochkin

The principal theoretical and experimental approaches to the study of the influence of the steric effects of substituents on the properties of organic and organoelemental compounds are examined. The role of these effects in complex formation with participation of organic compounds of silicon subgroup elements and the influence of steric effects on the conjugation in these compounds are analysed.
The bibliography includes 238 references.

III. Experimental studies of the steric effects in compounds of silicon subgroup elements 790

I. INTRODUCTION

The idea of a significant role of steric effects in chemistry, apparently put forward for the first time by Mayer,[1] has now undergone an extensive development not only in stereochemistry[2,3] but also in all other branches of chemistry.[4-10] Thus in the study of reactivity the possibility of the approach of the reacting molecules in space is considered to be an important factor determining the barrier to the reaction, i.e. the activation energy.[11,12]

The role of steric effects does not reduce solely to the alteration of the reactivity of the compound by regulating the degree of shielding of the reaction centre on varying the bulk of the substituents adjoining the centre. Another factor is the steric inhibition of resonance, i.e. partial or complete breakdown of the conjugation in the molecule (and hence also a change in its reactivity) after the introduction of bulky substituents into the molecule. Such substituents prevent the steric disposition of atomic fragments necessary for their conjugation with one another. Both the first[2,3,4,7,13,14] and second[15,16] factors have been examined in fair detail for organic compounds. For organoelemental compounds, the existing factual data are not so extensive and have been surveyed to a lesser extent, although there are reviews on the chemistry of phosphorus[17,18] and silicon[19-22] derivatives. At the same time, in organoelemental chemistry steric effects play a more varied role compared with carbon compounds. We shall differentiate three aspects of the influence of steric effects: on the reactivity, on the complex-forming capacity, and on conjugation in organoelemental compounds.

1. The Influence of Steric Effects on Reactivity

Organoelemental and particularly organopolyelemental compounds, containing chains of heteroatoms, possess polar and highly polarisable chemical bonds. Although such compounds are entirely stable thermodynamically, they are distinguished by an enhanced (compared with organic compounds) reactivity. The reactivity of organoelemental compounds varies within very wide limits not only under the influence of the inductive and resonance effects but also (sometimes predominantly) owing to the steric blocking of the reaction centres by bulky substituents. In the literature, including the review literature[6,8,10,19,20,22,23] there exist numerous clear examples of the inter-relation between the reactivity of organoelemental compounds and the steric effects of the substituents. The present review presents only isolated data concerning the influence of steric effects on reactivity and deals particularly with studies designed specifically to reduce the reactivity of organoelemental compounds.

For example, the thermal stability of the compounds $(R_3Sn)_2Hg$ increases significantly on passing from lower alkyl to phenyl substituents and to an even greater extent the trimethylsilylmethyl[24] substituent, which exhibits pronounced steric effects. Similarly, when CH_3 is replaced by C_6H_5 and C_6F_5 in the compounds $(R_3Ge)_2Hg$, which is accompanied by an increased shielding of the mercury atom, their reactivity diminishes and their thermal stability increases.[25] A sharp increase in thermal stability occurs on passing from $[(C_6H_5)_3.Ge]_2M$ (M = Hg or Cd) to $(C_6H_5)_3Ge-M[Ge(C_6H_5)_3]Ni(\eta^5-C_5H_5)-M-[Ge(C_6H_5)_3]Ni(\eta^5-C_5H_5)-M-Ge(C_6H_5)_3$, in which the atoms M are fully shielded by the ligands.[25,26] Yet another example of the influence of steric effects, this time not on the reactivity but on the very possibility of the existence of compounds, is provided by the synthesis of the derivatives $Mes_2Si=SiMes_2$, where Mes = mesityl,[27,28] and $[(CH_3)_3Si=C[OSi(CH_3)_3]R$, where R = $CAlk_3$ or 1-adamantyl,[29,30] with double bonds at the silicon atom. Despite the lack of theoretical prohibition of their existence, compounds of this type had not been isolated under normal conditions as stable species until the investigations of West and Fink[27,28] and Brook and co-workers,[29,30] and were merely detected in low-temperature matrices by means of physical methods or their formation was assumed as intermediates in reactions (see, for example, Gusel'nikov and Nametkin[31]). There is no doubt that, together with the electronic effects of substituents, the steric effects of bulky mesityl, adamantyl, t-butyl, and other substituents are important for the stabilisation of the double bond at the silicon atom.

2. The Influence of Steric Effects on the Complex-Forming Capacity

On passing from organic to organoelemental compounds, the possibilities for the formation of complexes of the donor-acceptor type (DA complexes) is greatly enhanced. Whereas the carbon derivatives R_3C-X (X is an unsaturated group of the type of aryl, alkenyl, naphthyl, etc.) are formed predominantly in complexes with electron acceptors by virtue of the electron-donating properties of the fragments X,[32,33]

two further types of DA complexes are extremely characteristic of organoelemental compounds.[34-37] These are complexes with an increased coordination number of the central element as well as DA complexes in which element–carbon bonds with low ionisation potentials play the role of carriers of the electron-donating properties.

Analysis of the characteristic features of the formation of these three types of DA complexes has shown that in many cases the steric effects play a major role in complex formation. In the general case the steric accessibility of the atom E in organoelemental compounds of the type R_nE (R is an alkyl group or a carbo-functional substituent and n is the oxidation state of the central element E) is determined not only by the size of R but also by the size of E and the length of the E–R bond, i.e. by the distance from the bulky group R to the reaction centre E. Similarly, when an organoelemental compound $R_{n-1}E-C\diagup\!\!\diagdown$ participates as an electron donor, by virtue of the fragment $E-C\diagup\!\!\diagdown$, in complex formation with an acceptor, then in this instance one must take into account both the dimensions of the given fragment and the steric effects of the substituents R and the atom E in the formation of the DA complex. Finally, in compounds of the silicon subgroup elements R_3C-X for $n = 4$, the steric effects of the R_3E and R_3C substituents apparently do not influence the formation of the DA complexes between the unsaturated groups X and the acceptor molecules (tetracyanoethylene, iodine, etc.).[38,39]

For compounds with several bulky organoelemental substituents at the unsaturated group X (for example, in the benzene ring or at the double bond), the influence of the steric effects of the substituents becomes comparable or even greater than their inductive and resonance influences.[40-42] A characteristic feature of DA complexes, which follows both from a theoretical study by quantum-chemical methods and from experimental data (see the relevant reviews[13,32-34]), is the mutual approach of the donor and acceptor centres of the interacting molecules in the complex to a distance optimal for the DA interaction, which depends on the nature of the given centres. The introduction of bulky substituents into the molecules constituting the DA complex can prevent such approach for purely steric reasons. This steric "inhibition" of the DA interaction is reflected in the spectroscopic and thermodynamic characteristics of the complex.[10,43]

It must be emphasised that the steric effect of substituents in the donor or acceptor molecules in complex formation are to some extent conventional in character. Indeed, with increase of the steric accessibility of the interacting centre in the donor (acceptor) molecule, the steric hindrance to the formation of a DA complex with the acceptor (donor) molecule diminishes even if the latter contains several bulky substituents.

As an example, one may quote the stannylacetylenes $(CH_3)_{3-n}R_nSnC\equiv CR$ with bulky substituents R (t-butyl, etc.), which can hinder the formation of DA complexes via the triple bond.[44] Steric effects are distinctly manifested in the formation of complexes with molecular iodine and become enhanced when the groups R accumulate in the molecule. In contrast to this, the substituents R do not in any way hinder the formation of a hydrogen bond with phenol, i.e. in DA complexes of this type stannylacetylenes do not exhibit the features of sterically hindered systems. The above example emphasises the difficulty of interpreting the experimental data in order to elucidate the characteristics of the influence of steric effects, since the latter are manifested in many instances as a property not of the donor acceptor separately but of the DA complex as a whole.

Generally speaking steric hindrance to the formation of complexes is pre-determined by the structure of the initial donor and acceptor molecules. For this reason, even if the donor (acceptor) centre is sterically blocked by bulky substituents and the acceptor (donor) centre is distinguished by a considerable steric accessibility, then the properties of the DA complex as a whole may be the same as in a system where there is no steric hindrance to complex formation.

Another factor closely related to the complication of the interpretation of steric effects already examined is the possibility of a change in the donor or acceptor properties of the initial components of the DA complexes owing to the steric effects of the variable substituents in their molecules. It is known, especially in organic chemistry,[2,4,7,13,15,45] that the introduction of bulky substituents can entail a weakening of the electronic intermolecular interactions in the molecules of the other species constituting the complex. If the donor or acceptor centre of a component of the DA complex is involved, then, together with the steric hindrance to the mutual approach of the centres, there is a possibility of secondary complications, which exert their influence via the steric effects in the initial components and the donor–acceptor properties of such interacting centres. From the above brief list of the complications introduced by steric effects into the complex-formation process, it already follows that the study of these effects in organoelemental compounds constitutes as a whole an extremely large and varied problem. It is useful to examine initially the influence of steric effects for a narrower range of model systems. There are organic compounds of silicon subgroup elements which have served for a long time as models for the solution of the most important problems in organoelemental chemistry.[42,46,47] The important role of steric effects and conjugation effects in organoelemental chemistry has been demonstrated in the literature in relation to these systems.

3. The Influence of Steric Effects in Conjugation

The problem of the inter-relation of the steric and resonance effects in organoelemental compounds is of independent importance. Indeed, conjugation effects in organoelemental chemistry are distinguished by a greater variety than in the chemistry of carbon. Together with the resonance effects characteristic of organic compounds, the role of hyperconjugation (σ,π-, σ,σ-, and σ,p-conjugation) is sharply enhanced in organoelemental compounds[42] and a conjugation effect arises which is in principle impossible for carbon compounds, namely the so-called $(p-d)\pi$ interaction which is traditionally attributed to the presence of unoccupied *nd* orbitals in the central elements E.[46,47]

It was shown a comparatively long time ago[48,49] and has been subsequently frequently confirmed by means of various methods, including spectroscopic methods (in particular for compounds of the silicon subgroup elements[42,46]), that there is a profound analogy between various conjugation effects. Therefore the magnitude of the effect both in the resonance interactions of the type of π,π- and p,π-conjugation, which are common in organic chemistry, and in the hyper-conjugation effects, which are more specific to organoelemental compounds, depends on the steric disposition of the interacting orbitals.[42] For example, the degree of the σ,π-conjugation (the variety of hyperconjugation which has been most thoroughly investigated) can be regulated within wide limits by varying the stereoelectronic state of the molecule.[23,42,50,51] The presence or absence of a strong resonance effect of the σ,π-conjugation, comparable in magnitude to that of the typical p,π-conjugation in organic compounds, in many instances alters radically the reactivity.[48,49,52]

Without analysing the role of steric effects, it is impossible to study the characteristics of another resonance effect specific to organoelemental compounds of Group IVB elements, namely that of the $(p-d)\pi$ interaction. The steric effects in such interactions are examined in greater detail below. Here we shall mention that the $(p-d)\pi$ interaction is less sensitive to steric effects, by virtue of the characteristic features of the geometry of the *d* orbitals,[47,53,54] than the σ,π-conjugation. Nevertheless, when there are several substituents X (with unshared *p*-electron pairs) at the central atom E (with unoccupied *nd* orbitals), the overall effect of the $(p-d)\pi$ interaction in the molecule due to pure steric effects, which specify the conditions governing the overlap of the interacting p_π and d_π orbitals, is significantly smaller than might have been expected on the assumption that the contributions by each E–X bond are additive.[47,53-55]

Thus there is a close inter-relation between the steric structure of organoelemental compounds, the steric effects of the substituents in their molecules, and the resonance intramolecular interactions. Determination of the characteristic features of this interaction for model compounds of silicon subgroup elements is the second aim of the present review.

Extensive data obtained in studies of the dependence of both the capacity for complex formation of organic compounds of silicon subgroup elements and the conjugation effects in these compounds on steric effects have accumulated in the literature. Despite this, both aims of the review are of current importance, since the available data have been subjected to an inadequate systematic treatment and conclusions reached in many studies are frequently ambiguous and their evidential value is low. The important question of the reliability of given studies devoted to the analysis of the extent to which the electron-donating properties of organic compounds of Group IVB elements are weakened owing to the steric effects of the substituents is fairly complex. Particular attention was therefore devoted in this review to the elucidation of the validity and soundness of the literature data.

II. GENERAL IDEAS CONCERNING STERIC EFFECTS

The aim of this Section of the review is to formulate the general ideas concerning the steric effects of substituents which follow from the existing reviews[3-5,7,8,13,15-17,43,56-59] and other publications of fundamental importance.

It has been emphasised[7] that one of the key postulates is that the set of phenomena combined by the term "steric effects of substituents" must be regarded as a special case of a more general problem, which is the object of conformational analysis.[60] A quantitative theoretical approach to the study of steric effects must therefore be based on the advances in the theory of conformational analysis, i.e. on quantum-chemical calculations of the total energy of the molecule as a function of the angles of rotation, which makes it possible to establish the most stable conformation.

Conformational analysis has led to the accumulation and systematic treatment of experimental data for the potential barriers to internal rotation and for the differences between the free energies of the conformers. Historical surveys of these studies have been published[16,56,58] and reviews of modern data for several thousands of compounds also exist.[3,16,58,59] In many cases the relations between the barriers to rotation and the electronic and steric effects are manifested extremely clearly. Thus the barriers to internal rotation in ethane derivatives (3–20 kcal mol^{-1}) are higher than for ethane itself (3 kcal mol^{-1}) and exhibit a tendency to increase with increase in the bulk of the substituents at the carbon atom.

The spatial removal to a greater distance of the groups involved in free rotation with increase in the length of the chemical bond connecting them lowers the barrier to internal rotation, which follows, for example, from a comparison of the barriers for Cl_3CCCl_3, Cl_3CSiCl_3, and $Cl_3SiSiCl_3$ (respectively ~11, 4.5, and ~1 kcal mol^{-1}); this is also indicated by the fact that the free energy of activation for internal rotation is significantly smaller in $[(CH_3)_3C]_2HSiSiH[C(CH_3)_3]_2$ (13.7 kcal mol^{-1} [61]) than in $[(CH_3)_3C]_2HCCH[C(CH_3)_3]_2$ (23 kcal mol^{-1} [62]) and also by the ratio of the molecular dipole moments of ethane and disilane derivatives.[63]

In compounds of Group IVB elements the type of $E(CH_3)_4$ an increase in the bulk of the atom E in the sequence C, Si, Ge, Sn lowers the barrier to internal rotation from ~4.5 to 2, 1.5, and <1 kcal mol^{-1} respectively.[61]

Important data have been obtained in the study of the barriers to internal rotation in benzene derivatives. The barrier to the internal rotation of the methyl group in toluene, which is almost zero, increases significantly on passing to $C_6H_5SiH_3$, which indicates an increase in the multiplicity of the silicon–phenyl bond due to the $(p-d)\pi$ interaction.[64] In the Ar–X–Ar (X = O, CO, etc.) systems and also in *ortho*-disubstituted biphenyls, structures with the "propeller" rotation of the aromatic rings are produced for steric reasons despite the fact that a planar molecule would have been most favourable for conjugation. It is striking that, with increase in the size of the *ortho*-substituents in halogeno-biphenyls, the dihedral angle steadily increases.

The review literature (see, for example, Refs.3, 16, 58, and 59) presents compilations of data for barriers to internal rotation also in other types of organic compounds. For example, it has been established for esters $R-C(=O)-OR'$ that the difference between the energies of the *cis*- and *trans*-isomers, arising as a result of rotation about the C–O bond, increases with increasing size of the substituents R and R'. At the same time, it follows from literature data that it is frequently impossible to observe a very clear and evident relation between the potential barriers to internal rotation and the conformer energy difference, on the one hand, and the characteristics of the molecular structure and especially the steric influence of the substituents, on the other. Together with experimental studies, computational empirical as well as semiempirical and non-empirical quantum-chemical methods are being developed in conformational analysis.

In the empirical methods the molecule is regarded as a system of interacting atoms.[58] Here five different contributions to the potential energy of the molecule, taking into account the energy of the non-bonding interactions between the atoms as well as the influence of the deformations of the angles and bonds and the electrostatic contribution to such interactions, are distinguished. Although the empirical methods do in fact make it possible to obtain practically important estimates of the potential barriers to internal rotation without resorting to extremely complex calculations, they do not provide a clear understanding of the nature of the barrier.[65]

An improved reliability of the calculations of the barriers to rotation and of the energy differences between the conformers can be achieved by employing semiempirical quantum-mechanical methods. The possibilities of the semi empirical methods have been assessed in two investigations.[58,65] It was found that, despite the importance of the information obtained (for example, for the estimation of the barriers to rotation in a series of compounds with related structures), these methods have limited applicability, because they include a series of empirically determined parameters. The dependence of the result on the suitability of the selected parameters lowers the

objectivity of the semiempirical methods. Non-empirical *ab initio* quantum-chemical methods have therefore been developed to an increasing extent recently for calculations of the potential barriers to internal rotation and of the total energy of the molecule as a function of the angles of rotation.[65] The theoretical principles of conformational analysis should apparently be developed in the course of systematic studies of the principle classes of compounds by non-empirical methods. However, so far this problem is extremely far from solution, in particular because of the high cost of such calculations even for molecules of medium size, the inadequate effectiveness of the computer programmes, and the necessity to employ faster computers for calculations on fairly complex molecules.[65] The application of *ab initio* methods has not so far led to a complete understanding of the nature of the barriers to internal rotation, but it has been shown in many instances that, for the most stable conformation of the molecule, the bond around which internal rotation takes place is characterised by the highest electron density, i.e. exhibits the maximum stability.[65–67]

We shall consider certain calculated quantum-chemical data for organosilicon molecules. Non-empirical calculations carried out in terms of different basis sets, established a significantly lower barrier to inversion at the nitrogen atom in the H_3SiNH_2 molecule than in the ammonia molecule and an increased multiplicity of the silicon–nitrogen bond due to the $(p-d)\pi$ interaction;[68] they confirmed the covalent character of the silicon–oxygen bond under conditions where the Si–O–Si angle in the disiloxane fragment is varied within wide limits;[69] they revealed a preference for a non-planar structure in 5-silylcyclopentadiene (apparently as a consequence of hyperconjugation), in contrast to its carbon analogue.[70]

Semi-empirical calculations have been used more widely for organosilicon compounds in conjunction with several variants of the zero differential overlap—the CNDO and INDO methods. As already mentioned above, the quality of the semiempirical calculations depends on the soundness (or success) of the selection of the computational parameters. A typical example is provided by the attempts to reproduce by the calculations the experimentally established planar structure of trisilylamine $(H_3Si)_3N$. According to Sadimenko et al.,[69] agreement between calculation and experiment has been achieved in only one[71] of the several variants of the calculation. The barrier to rotation in trisilylamine obtained from the calculated data of Rank et al.[72] is too high. The necessity for a critical approach to the results of semiempirical calculations follows, in particular, from the fact that one of the most important features of organosilicon compounds, namely the degree of their $(p-d)\pi$ interaction (for example, in the silicon–nitrogen bond) depends on the molecular geometry.[71,73] Inaccurate information about the geometry obtained from the calculations can therefore lead to incorrect conclusions about the importance of such interaction.

It follows from semiempirical calculations that a change in the conformation of the $H_3SiOSiH_3$ molecule, accompanied by the variation of the Si–O–Si angle, induces not only a change in the energy of the highest occupied molecular orbital but also the inversion of the sequence of orbitals.[74]

It has been established by the CNDO/2 method that the non-bonding Hal...Hal interactions are sharply weakened on passing from CF_4 to CCl_4 and their silicon analogues[75] and also to other fluoro- and chloro-silanes.[76,77] For the more complex molecules of methylsilanes and fluoromethylsilanes, semiempirical calculations[78–80] yield conformations which agree with experiment, but they are relatively unsuitable for the estimation of their barriers to rotation.

A wide variety of the conformations of the polysilanes Si_nH_{2n+2}, which has been confirmed indirectly by experiment, follows from calculations by the CNDO method.[81] The calculations also indicate an explicit preference for the geometry of benzyltrimethylsilane which is most favourable for hyperconjugation.[82] According to the calculated data of Drews et al.,[83] the minimum in the total energy of the trimethylsilylaniline molecule is attained for the geometry in which one methyl group is located in the plane of the aromatic ring.

Thus, while taking into account the above remarks about the applicability and accuracy of the quantum-chemical methods, one should note their important role in the establishment of the theory of conformational analysis, i.e. ultimately also in the solution of the problem of the influence of steric effects on chemical properties. At the same time, the limited amount of literature data precludes at present sufficiently unambiguous conclusions concerning the role of steric effects in organic chemistry; the data obtained for organoelemental compounds are clearly insufficient.

Together with the methods for the investigation of the role of steric effects examined above, a completely different approach proposed by Ingold and Taft,[7,9,14] has developed independently. It is based on the assumption (supported subsequently by theoretical considerations[7]) that it is possible to represent the Gibbs free energy ΔG of reaction or activation by the sum of independent components, i.e. $\Delta G = \Delta G_I + \Delta G_R + \Delta G_S$, which reflects the influence of the inductive (I), resonance (R), and steric (S) effects. This linear free energy principle holds for enormous numbers of chemical processes (and also in the correlation of many physical properties[84]) and among them it is possible to select those in which the influence of one of the effects on ΔG predominates. The process in which the steric effects exert a dominant influence ($\Delta G = \Delta G_S$) is in particular the acid hydrolysis of the esters XCH_2COOR. The logarithms of the hydrolysis rate constants, which are proportional to ΔG, depend on the steric constants E_S of the variable substituents X:[14]

$$\lg\left(\frac{k}{k_0}\right) = \delta E_S ,$$

where k and k_0 are respectively the rate constants for the acid hydrolysis of the substituted (XCH_2COOR) and unsubstituted (CH_3COOR) esters and δ is a constant which depends on the type of reaction series (the nature of R). Assuming that for hydrogen $E_S = 0$, the steric parameters E_S for a large number of substituents have been obtained.[14,84] Although theoretical evidence supporting the view that the constants E_S characterise only the steric effect has been presented in the literature,[85] the initial fundamental publication[14] was followed by a series of studies whose authors analysed, on the one hand, the possibility of the presence of a hyperconjugation component in E_S[7,45,86,87] and, on the other hand, examined the physical significance of E_S and estimated the validity of the experimental methods for each determination.[45,88,89] Ultimately no unambiguous conclusions were reached concerning the role of hyperconjugation, whose contribution to E_S depends on the type of compounds investigated[45] and in many instances is apparently extremely low.[87]

Analysis of the most thoroughly determined values of E_S (for 107 substituents) has shown[45] that the E_S for simple symmetrical

groups X are linearly related to the quantity $\nu_x = r_X - r_H$ [89] which represents the differences between the van der Waals radii of the atom X and the hydrogen atom. However, for bulky asymmetric groups and a complex steric configuration of the type of CR'R"R"' with different substituents, there is no simple correlation between the experimental E_S and the ν_x. The quantity ν_x for such groups may not have just one value but at least two, the minimum and maximum values,[88] and in neither case is a correspondence observed[45] between the calculated and experimental E_S. Even greater difficulties arise on passing from aliphatic to aromatic compounds, in which the *ortho*-effect of the substituents cannot be explained[90] solely by steric factors. Thus it has not been possible to use the parameter E_S to characterise the steric effects in cyclohexane derivatives.[91]

On passing to organoelemental compounds, the non-universality of the parameter E_S, which characterises in general (taking into account the above remarks concerning very complex substituents) the size of the substituent, becomes still more evident. Indeed, in these compounds it is necessary to take into account in the first place no longer simply the size of the substituent, i.e. the parameter ν_x or E_S (although even they are unknown for many organoelemental substituents), but the distance of the substituent from the reaction centre. Furthermore, the distance between a bulky substituent and the reaction centre can vary within wide limits both owing to the changes in the length of the chemical bond between them when the central element is varied and as a consequence of the possible mutual approach in space of the substituent and the reaction centre even when they are separated by several bonds. The size of the substituent alone does not then generally determine the steric situation and it can be characterised by the parameters of the type E_S and ν_x only in exceptional cases.

Two methods have been proposed for the estimation of steric effects in similar complex instances. In the method of cone angles,[17,92] developed in relation to compounds of the type of $Ni(PR_3)_4$, account is taken of the change in the size of the bulky ligand PR_3 as a function of the type of R. This change is characterised by the angle in the plane and the distance from PR_3 to the reaction centre (the nickel atom) is assumed to be unchanged. In the more sophisticated method of solid angles,[25,26,93] the steric shielding of the central element E in ER_n is estimated in terms of the sum of n solid angles (with the vertex at the atom E) occupied by the substituents R. The method of solid angles can also be used to estimate the shielding of atomic fragments, for example by an individual chemical bond or the remainder of the molecule.[25,26,93] This method has been used, in particular, to estimate the steric accessibility of a donor centre localised predominantly at a tungsten atom with formation of molecular complexes with derivatives of dicyclopentadienyltungsten dihalides.[94] A steric model, close in its physical significance to the method of solid angles, has been proposed by Galkin and Cherkasov.[95]

Thus it is impossible to propose a set of universal constants characterising steric effects. Among the methods for the estimation of the role of steric effects in the molecule and especially in a series of compounds with consistently varied substituents, that of solid angles appears to be the most promising. Its use, however, requires the application of computers and data (sometimes exact) for the molecular geometry.

As a problem in physical organoelemental chemistry, that of steric effects can be formulated by isolating from the overall Gibbs free energy the component due to the influence of steric factors. Despite the limitations and difficulties arising under these conditions, this approach is in fact used in most investigations.

III. EXPERIMENTAL STUDIES OF THE STERIC EFFECTS IN COMPOUNDS OF SILICON SUBGROUP ELEMENTS

1. Steric Effects in Complex Formation

The data presented in this Section are classified in terms of the fragments E–X (E is a silicon subgroup element and X is a substituent).

(a) Compounds with E–Group V Element Fragments

Steric effects have a marked influence on the properties of the carbon analogues of these compounds, namely amines.[2,5,13,58] For example, tertiary alkylamines have an anomalously low basicity due to the steric effects of the substituents at the nitrogen atom.[96] A linear relation between the inductive constants σ^* of the substituents and the basicity has been observed for primary, secondary, and tertiary amines.[96] The points corresponding to compounds with bulky substituents show consistent deviations from these straight lines. Another characteristic example is that of the sharp increase of the basicity of aromatic amines with increasing bulk of two alkyl groups at the nigrogen atom. The basicity of the nitrogen atom increases owing to the steric inhibition of the p,π conjugation between the aromatic π-system and the substituent NR_2, which does not occupy the position most favourable for conjugation, since this position is prohibited owing to the intimate steric contacts between R and the *ortho*-hydrogen atoms of the aromatic ring.[97]

Steric effects exert a significant influence also on the properties of compounds with a silicon–nitrogen bond. Its length (1.71–1.76 Å)[98] is less than the sum (1.80 Å) of the covalent radii of the silicon and nitrogen atoms corrected for the amount of ionic character of the bond.[99] The shortening of the Si–N bond can be attributed to the influence of the $(p-d)\pi$ interaction,[46] which increases the multiplicity of this bond. However, steric factors also make a definite contribution, which follows from the increase of the length of the silicon–nitrogen bond when the methyl group is replaced by the bulkier silyl group in the series (the Si–N bond lengths are given in brackets in Å) $N(CH_3)_2SiH_3$ (1.715), $N(CH_3).(SiH_3)_2$ (1.726), and $N(SiH_3)_3$ (1.734), on replacement of the silyl group by the trimethylsilyl group in the series $NH(SiH_3)_2$ (1.725), $NH[Si(CH_3)_3]_2$ (1.738), $N(SiH_3)_3$ (1.734), and $N[Si(CH_3)_3]_3$ (1.760), and on replacement of a hydrogen atom in the organoelemental substituent X on passing from $NH[Si(CH_3)_3]_2$ to $NX[Si(CH_3)_3]_2$.[98] At the same time the barrier to the internal rotation of the SiH_3 groups in $N(CH_3).(SiH_3)_2$ (3.3 kcal mol^{-1}) is higher than in $N(CH_3)_2SiH_3$ (1.5 kcal mol^{-1}), which is believed[100] to demonstrate (together with steric factors) a greater contribution of the $(p-d)\pi$ interaction to the Si–N bond in the first of these compounds. The steric effects of the bulky trimethylsilyl groups leads to the appearance of a fairly high barrier to the rotation about the N–N bond in the radical-cation $[(CH_3)_3Si]_2N \overset{+}{-} N[Si.(CH_3)_3]_2$.[101]

The possibility of the approach of the silicon and nitrogen atoms in space with formation of a donor–acceptor bond between them, as in silatranes, is regulated not only by the electronic but also by the steric effects of the substituents R and R' at these atoms in compounds of the type $R_2Si(OCH_2.CH_2)_2NR'$.[102–104] Bulky substituents increase the length (i.e. weaken) of the donor–acceptor bond. Thus, on passing from R' = H to CH_3 and $C(CH_3)_3$, the Si–N distance increases from 2.30 to 2.68 and 3.16 Å respectively.

Analysis of the factors determining the steric structure of the germatranes $RGe(OCH_2CH_2)_3N$ also led Tandura et al.[105] to the conclusion that the degree of transannular interaction between the nitrogen and germanium atoms depends not only on the electronic but also on the steric effects of the substituents R.

Ideas concerning the intramolecular coordination interactions between the E and X atoms (here X has an unshared electron pair), similar to those observed in silatranes and related derivatives, have been invoked also to account for the physical properties of compounds with a simpler structure, for example, those with fragments of the type $Si(CH_2)_nX$.[106] Together with the electronic effects of the substituents at the E and X atoms, the intramolecular coordination [which apparently takes place via a mechanism involving the $(p-d)\sigma$ interaction[106]] is also regulated by steric factors, as shown[107] for X = N (this will be discussed below for other X).

The influence of steric effects in the formation of intermolecular complexes involving compounds with E–N fragments is just as evident. Steric effects play a significant role both in the reactions of vinylsilanes with amines[108] and in the formation of complexes with $SnCl_4$ as acceptor.[109] The enthalpy of complex formation with $SnCl_4$ is determined not only by the electronic effects of the substituents in the Si–N fragments but also by steric factors, which is indicated by the decrease of ΔH in the presence of bulky substituents at the nitrogen atom. The absence of appreciable steric effects in the protonation of the same compounds, i.e. under conditions where there is a sharp decrease of the possible steric hindrance originating from the acceptor in the donor–acceptor complex, is striking.

Systematic investigations of the electron-donating capacity in the formation of hydrogen bonds involving compounds with the Si–N,[110–114] Ge–N,[110,112,114,115] and Sn–N[110,116,117] groups, starting with the first studies by Abel et al.[110] and Pacl et al.,[111] revealed the possible influence not only of electronic but also of steric effects of the substituents attached to these groups. In the study of a hydrogen bond of the type $\geq E-N\cdots H-N\leq$ or $\geq E-N\cdots D-C\leq$ with pyrrole or deuteriochloroform by infrared spectroscopy, the parameter $\Delta\nu$, namely the shift of the stretching vibration frequency of the unassociated pyrrole or deuteriochloroform on formation of a hydrogen bond, was used as a quantitative measure of the electron-donating capacity. This parameter is proportional to ΔH and ΔG for hydrogen bond formation at least in series of isotypical compounds.[118]

The steric shielding of the donor centre (the nitrogen atom) by three substituents should be accompanied by a decrease of $\Delta\nu$ and ΔH and hence of the electron-donating capacity of the compounds. In order to obtain information about the donor–acceptor properties of the substituents R_3E (E = C, Si, Ge, or Sn) in the compounds $(R_3E)_nNR'_{3-n}$ (this was one of the main tasks in the investigations quoted above[110–117]), it is therefore necessary to have information about the influence of the steric effects on $\Delta\nu$.

For certain compounds with E–N fragments, such information has been obtained by correlation analysis in a study,[117] where, together with organoelemental amines, a wide range of organic amines were also considered. Among the latter, there are compounds for which the parameters $\Delta\nu$ [the shift of the ν(C–D) frequency in the infrared spectrum of deuteriochloroform on formation of the $\geq N\cdots D-C\leq$ hydrogen bond] vary linearly with the sum of the inductive constant σ^* of the three substituents at the nitrogen atom, which indicates the virtual absence of steric effects in the formation of the hydrogen bonded complex. The steric effects are insignificant both for the compounds $AlkN(CH_3)_2$ and for $(CH_3)_3EN(CH_3)_2$ (E = Si, Ge, or Sn). However, on passing to compounds with the $N(C_2H_5)_2$ and $N[Sn(CH_3)_3]_2$ fragments, the steric hindrance generated by the substituents at the nitrogen atom prevents the formation of a hydrogen-bonded complex and is responsible for the decrease of $\Delta\nu$.[117] The increased role of steric effects following the accumulation of substituents of the type $(CH_3)_3E$ (E = C, Si, and Sn) at the Group V element is also indicated by NMR data for the compounds $(C_2H_5)_{3-n}\cdot P[E(CH_3)_3]_n$.[119] It follows from these data that the anomalies (from the standpoint of the donor–acceptor properties of the substituents) in the changes in the chemical shift increase with increasing n.

(b) Compounds with E–Group VI Element Fragments

The Si–O–C and Si–O–Si valence angles are known for many organosilicon compounds (see, for example, a number of reviews[120–122]). If it is assumed that these angles are determined by the influence of only the electronic factors of the substituents at the silicon and carbon atoms and that steric effects do not play an appreciable role, a number of contradictions arise. Thus, on passing from $(CH_3)_2O$ (the C–O–C angle is 111°43′ [123]) to Alk_3SiOCH_3 [120] (Alk = CH_3, C_2H_5, or n-C_3H_7) and H_3SiOCH_3,[124] the Si–O–C angle increases to 117–123°, while in the case of $Alk_3SiOC(CH_3)_3$ it amounts to 127° ± 3°.[120] Similarly the angle increases from 121° to 140° on passing from $CH_3OC_6H_5$ to $Alk_3SiOC_6H_5$.[120]

There is no doubt that the main cause of the larger changes in the Si–O–C angles compared with the C–O–C angles is the electronic effects of the silyl substituents, i.e. the electron-accepting properties of the $SiAlk_3$ group compared with the electron-donating properties of the substituents CH_3 or $CAlk_3$. However, steric effects are also significant,[120] which is manifested particularly clearly in the disiloxanes $R_3SiOSiR_3$. The successive transition from R = CH_3 to H, Cl, and F is accompanied by some shortening of the Si–O distance (1.63, 1.63, 1.59, and 1.58 Å respectively) and a significant increase of the Si–O–Si valence angle from 130° ± 10°[125] to 144°,[126] 146°,[127] and 156°,[128] in conformity with the enhancement of the electron-accepting properties of R in this series.

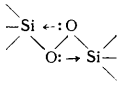
Contrary to the expectation based on the comparatively similar electronegativities of the hydrogen atom and the phenyl and vinyl groups, the Si–O–Si angles in hexaphenyldisiloxane,[129,130] hexavinyldisiloxane[131] and also in $(H_2C{=}CH)_3\cdot SiOSi(C_6H_5)_3$ [131] are 180°. Apparently the main cause of the linear structure of the disiloxane fragment is the large bulk of the substituents, while the packing effects do not exert a decisive influence,[130] although, according to Vlasenko,[131] they do contribute to an increase of the Si–O–Si angle.

A number of instances of the influence of steric effects on the structure of organocyclosiloxanes have been quoted in a review of X-ray diffraction data.[122] The steric effects of two bulky $(CH_3)_3SiO$ substituents in *ortho*-positions in the benzene ring hinder the free rotation about the $O-C_{ar}$ bond, revealed by a change in both the dipole moments[132] and the NMR spectra.[133] Intramolecular coordination interactions between the E and O atoms not linked by direct chemical bonds are well known for organoelemental compounds.

However, it follows from the review of early studies[106,134] that data for intramolecular coordination in silicon compounds are contradictory. It is known[46,55] that, with increase of the effective positive charge on E and also on passing from E = Si to E = Ge and Sn, the energy of the coordinate bonds increases. Therefore there is no doubt about the occurrence of intramolecular interactions in compounds with fragments of

the type SiF_3, $SiF_2(CH_3)$, and $SiF(CH_3)_2$ [135,136] and also for germanium and, even more so, tin[105,106,137] derivatives.

Analysis of the literature data has shown that the coordination interactions between the E and O atoms are influenced (like the intramolecular coordination between E and N) by the steric effects of the substituents linked to the donor and acceptor centres in the molecule. This is shown very clearly for organosilicon peroxides with the fragment



in which intramolecular coordination leads to a decrease of the electron-donating capacity of the oxygen atoms owing to their involvement not only in $(p-d)\pi$ interaction with the neighbouring silicon atom but also in an intramolecular interaction with the more remote silicon atom. With alkyl substitution at silicon, intramolecular coordination is disturbed and the electron-donating capacity of the oxygen atoms increases. This is manifested particularly by a sharp increase of $\Delta\nu$(O–H) on formation of the hydrogen-bonded complexes (>O...HO) with phenol.[138]

The length of the Ge–O intramolecular coordinate bond in compounds with the $O=C-C-C-GeCl_3$ fragments varies from ~2.1 to 3.2 Å.[105] Together with intermolecular interactions, whose influence on the length of the coordinate bond has been considered by Tandura et al.,[105] the energy of this bond is apparently determined also by the influence of the substituents on the geometry of the five-membered rings formed, i.e. by the steric factors. Study of the thermodynamic and kinetic parameters of an intramolecular metallotropic rearrangement (the 1,5-shift of the R_3Ge group between two oxygen atoms in $R_3GeOC(CH_3)=CHC(CH_3=O]$ has shown that formation of a coordinate bond between the germanium atom and the oxygen atom of the CO group is influenced by the steric effects of the substituent R.[139]

The steric effects of the substituents are shown very clearly in the formation of intermolecular complexes with a siloxane or disiloxane group.[121] Thus a decrease of the heat of complex formation with increasing length of the alkyl substituent R and with the degree of its branching was established a comparatively long time ago[140] in studies by the dipole moment, infrared spectroscopic, calorimetric, and cryoscopic methods of the complexes of $SnCl_4$ with the alkoxysilanes $Si(OR)_4$ and $R'Si(OR)_3$. The complex forming capacity also decreases with intensification of the steric effects of the substituents at the silicon atom, which follows from the data obtained in a study of the complexes of $SnCl_4$ with $(R_3SiO)_3PO$.[141]

Whereas compounds containing siloxane linkages show little tendency towards self-association,[121] the formation of intermolecular associated species is an extremely characteristic feature of the related tin and lead compounds and the influence of the steric effects of the substituents is then strikingly revealed. Thus, according to NMR data for tin nuclei, compounds of the type $(C_4H_9)_3SnOAlk$ are monomeric at room temperature and have a tetrahedral tin atom,[142] while the derivatives $(C_4H_9)_2Sn(OAlk)_2$ are monomeric only for Alk = s-C_4H_9 or t-C_4H_9, which prevent dimerisation by virtue of steric factors. The replacement of the butyl group in the OC_4H_9 fragment of the monomeric complex $C_4H_9Sn(OC_4H_9)_3$ by lower alkyl groups leads to a decrease of steric hindrance, the compounds undergo association, and the tin atom becomes hexacoordinate.[142] The bulky substituents R and R' prevent the association of the tin carboxylates $R_3SnOCOR'$ [143] and, when R = $C_6H_5C(CH_3)_2CH_2$, the compounds are monomeric also for R' = H or CH_3.[144,145] The lead derivatives R_3PbX (where X has unshared electron pairs) are highly associated, but in the presence of bulky substituents the compound [for example, $(C_6H_5)_3PbOSi(C_6H_5)_3$ [146]] exists in the monomeric form.

The most systematic information about the influence of electronic and steric effects of substituents at the E–O bond, referring mainly to silicon compounds, has been obtained in the study of the hydrogen bonds with various electron acceptors by infrared spectroscopy and ^1H NMR[121] (although the information about the steric effects has also been obtained by analysing the infrared spectra of individual siloxanes[147]).

Individual correlation lines of the type $\Delta\nu = \Delta\nu_0 + a\Sigma\sigma^*$, representing the correlation between $\Delta\nu$ [the shift of the ν(O–H) frequency of phenol in the formation of hydrogen bonds with the test compounds] and the sum of the inductive constants σ^* of the substituents at the silicon atom have been observed also for the compounds $R_3SiOC_2H_5$, $RSi(OC_2H_5)_3$, $RSi(OCH_3)_3$, and $(R_3Si)_2O$.[148,149] However, a more careful analysis of the parameters $\Delta\nu$ [150,151] as well as the data of Voss et al.[152] and the conclusions reached by Voronkov et al.[121] demonstrated the influence on the electron-donating properties of compounds with the Si–O bond not only by the inductive effect but also by the steric effect of the substituents linked to the silicon and oxygen atoms. For example, on passing from the compounds $X(CH_3)_2SiOC_2H_5$ to $X(CH_3)_2SiOC(CH_3)_3$ (X represents various organic substituents), the electron-donating capacity does not increase (as might have been expected on the basis of the inductive effect) but actually falls.[151,152]

The accumulation of bulky substituents at the atoms of the Si–O or Ge–O fragment results in a dependence of the steric accessibility of the silicon atom in these fragments, as an electron donor centre for the formation of the hydrogen bond, on the size and geometry of the other species involved in the hydrogen-bonded complex. By varying the hydrogen bond acceptor (phenol, pyrrole, deuteriochloroform), it is therefore possible to discover the electron donors which entail steric hindrance in complex formation with the acceptors. Such difficulties are observed, in particular, on formation of hydrogen-bonded complexes with pyrrole by compounds of the type $(CH_3)_3EOE(CH_3)_3$, where E = C or Si,[151] and also $Ge(OC_6H_5)_4$ and $CH_3Ge(OC_6H_5)_3$.[153]

When an even more pronounced steric hindrance is generated at the oxygen atom, for example, on passing to compounds of the type $(C_6H_5)_3SiOSi(C_6H_5)_3$, hydrogen-bonded complexes with the phenol coordinated to the oxygen atom of the Si–O–Si fragment cannot be detected from the infrared spectra,[154] despite the seemingly extremely favourable configuration of this fragment (the angle between the heavy atoms is 180°).[129,130]

Although the steric hindrance in the formation of hydrogen-bonded complexes between alkoxysilanes and deuteriochloroform is apparently weaker than in the case of pyrrole,[151,153] steric effects have also been detected by ^1H NMR in the complexes with chloroform.[121,155,156] The change in the chemical shift in the ^1H NMR spectrum of chloroform on formation of a hydrogen bond with $(CH_3)_3SiOAlk$ depends both on the inductive and steric (E_S) constants of the alkyl substituents and the steric hindrance increases with increasing n in $(CH_3)_{4-n}Si(OC_2H_5)_n$.[156] The comparatively high electron-donating capacity of the cyclotrisiloxanes $(R_2SiO)_3$ compared with compounds having a linear structure or containing larger rings can serve as yet another clear example of the manifestation of steric effects on formation of hydrogen-bonded complexes with phenol. In strained cyclic trisiloxanes, the electron-donating capacity at the oxygen atom increases both as a result of the

improved steric accessibility of these atoms for the formation of the hydrogen bond and the weaker $(p-d)\pi$ interaction in the silicon–oxygen bonds.[157] Bulky substituents at the silicon atom reduce the capacity of silanols with the Si–O–H fragments for the formation of intermolecular hydrogen bonds.[158]

The high efficiency of the NMR method in the study of steric effects [for example in compounds of the type $(CH_3)_3$. .SiOAlk [159]] was recently demonstrated yet again in the systematic investigation of alkoxysilanes by ^{13}C, ^{29}Si, and ^{17}O NMR.[160–162] It was established that the chemical shifts of the signals in the NMR spectra of mono-, di-, tri-, and tetraalkoxysilanes are determined by the joint influence of the inductive and steric effects of the substituents. The role of the steric effect increases with increasing number of alkoxy-groups at the silicon atom, in conformity with the results obtained by the other research techniques examined above. Steric effects can influence also the chemical shifts in the NMR spectra of alkoxygermanes.[161,163] According to NMR data,[164] in compounds with the $(CH_3)_3Si–O–C=C$ fragments, the conformations in which conjugation between the oxygen atom and the double bond is reduced are preferred owing to the steric effects of the trimethylsilyl group.

(c) Compounds with the E–Group VII Element Fragments

There is limited information in the literature about the influence of steric effects on the complex-forming capacity and physical properties of compounds with such fragments. An infrared spectroscopic study of hydrogen bonding with phenol in compounds of the type $R_3E–Cl...H–O–C_6H_5$ and $R_3ECH_2Cl...H–O–C_6H_5$ failed to reveal[165] anomalies which could not be accounted for by the electronic effects of the substituents at the chlorine atoms and would require allowance for steric effects. However, it does not follow from this that steric effects are completely absent from compounds of the type considered, since careful analysis of the ^1H NMR spectra of derivatives of the type $(n-C_3H_7)_3ECl$, where E = Si, Ge, or Sn, indicates the presence of steric hindrance to free rotation about the C–E bonds, which increases in the sequence Sn < Ge < Si.[166]

The free rotation about the Si–C bond is hindered also in $[(CH_3)_3C]_3SiX$, the barrier increasing from 6 to 8.5 kcal mol^{-1} with increase in the size of X in the sequence H < Cl < Br < I.[167] There are indications of a dependence of the complex-forming capacity of the compunds R_nSiCl_{4-n} (R = CH_3 or C_2H_5, n = 0–4) in relation to acetone on the bulk of the substituents at the silicon atom.[168]

Steric effects exert an appreciable influence on the intramolecular coordination between the silicon and chlorine atoms not linked by a direct chemical bond in compounds containing the $SiCH_2Cl$ fragments.[106] Such intramolecular interactions, which have already been partly examined above, are intensified with increase of the atomic number of the element E and with increase of its effective positive charge. Under conditions close to the most favourable ones, for example, in the case of $Cl_3SnCH_2CH_2CH_2Cl$,[169] the presence of a coordinate bond was therefore demonstrated by direct experiments. In silicon compounds this kind of bond is fairly strong only in the presence of three acceptors—the fluorine atoms at the silicon atom,[135] the enthalpy of formation of the coordinate bond diminishing after the replacement of the fluorine atoms by methyl groups,[135] and in $(CH_3)_2(ClCH_2)SiH$ it amounts to only ~1 kcal mol^{-1}.[170]

At the same time the weak coordination interactions in compounds with the $E–CH_2Cl$ fragments (E = Si or Ge)[171,172] exhibit a distinct dependence on both the electronic[170–172] and steric[171] effects of the substituents at the atom E. Thus, on passing from Alk_2HSiCH_2Cl to $AlkH_2SiCH_2Cl$, i.e. on replacement of the alkyl group by the smaller hydrogen atom, the number of molecules coordinated via an intramolecular  linkage increases approximately by a factor of 1.5.[171]

(d) Compounds with E–Ar Fragments

The results of X-ray diffraction studies indicate appreciable steric effects in tetra-aryl derivatives of silicon subgroup elements. Thus, apparently owing to the steric hindrance generated by the four substituents at the silicon atom, the Si–C bond length (1.872 Å[173]) in tetraphenylsilane is greater than in phenylsilane (1.843 Å).[174] Steric hindrance at the central atom increases after the introduction of methyl groups in the *ortho*-position in the benzene ring. Thus, on passing from tetraphenylgermane to tetra(o-tolyl)germane, the Ge–C bond length increases from 1.957 Å to 1.966 Å,[175,176] while in the corresponding tin derivatives the Sn–C bond length increases from 2.144 Å to 2.160 Å.[177]

Anomalous valence angles are also observed at the central atom. These anomalies are particularly marked for the mesityl derivatives in which the aromatic rings contain two *ortho*-methyl substituents. The angles between the Mes–E–Mes bonds in the compounds Mes_3EH with E = C, Si, or Ge (Mes = mesityl) are respectively 118.3°, 116.0°, and 115.5°, i.e. they increase with decrease of the atomic number of E and with increase of the steric hindrance of the atom of the latter.[30,178] The conformation in which the mesityl substituents are arranged around the silicon or germanium atom in a propeller fashion corresponds to the minimum steric strain.[179] The barriers to internal rotation about the E–Mes bonds in Mes_3EH, which amount to 8.3, 6.0, and 3.1 kcal mol^{-1} for E = Si, Ge, or Sn respectively, apparently agree with the hypothesis of a predominant contribution to these quantities by steric interactions of the *ortho*-substituents in the neighbouring aromatic rings[179] (see also Refs. 180 and 181).

The anomalies discussed above, observed for the mesityl derivatives, are clearly manifested in their infrared spectra. Thus the frequencies and intensities in the E–H (E = Si or Ge) stretching vibration bands in the infrared spectra of Mes_3EH are extremely unusual.[182] For the vast majority of the substituents R in R_3EH, the mode of the E–H bond vibrations remains unchanged, since the substituents R influence the frequency and intensity of this highly characteristic vibration only via their electronic effects. The pronounced steric hindrance in mesityl derivatives leads to the disturbance of the mode of the given vibration and to a change in the conditions for the $(p-d)\pi$ interaction of the atom E with the aromatic ring.[182] As a result, the frequency and intensity of the E–H bond vibration no longer depend solely on the electronic effects. These anomalies are more marked for silicon derivatives than for germanium derivatives.

It follows from the NMR data for the compounds Ar_3ER, where R are various organic substituents, and Ar_4E, where E = Si, Ge, or Sn, that the activation energy for the intramolecular rotation of the aryl groups is determined both by the presence of *ortho*-substituents in the aromatic rings and by the size of the atom E.[183] Steric effects in compounds of this type make a significant imprint also on their reactivity. Thus the substitution of bromine in the bromo-derivatives of triarylgermanes and triarylstannanes with methyl substituents in the *o*-position is inhibited by steric factors to a lesser extent in the organotin compounds as a consequence of the smaller size of the tin atom compared with the germanium atom.[184]

It was established comparatively long ago[43] that the accumulation of bulky organic substituents in the aromatic ring alters significantly the thermodynamic characteristics of the charge-transfer complexes of benzene derivatives even with comparatively smaller acceptor molecules such as those of iodine chloride. In particular, this is shown by a sharp decrease of the equilibrium constant of the complex-formation of 1,3,5-tri-t-butylbenzene and to an even greater extent hexaethylbenzene, compared with the less sterically hindered alkylbenzenes. The entropy of formation of the hexaethylbenzene–iodine complex as well as the equilibrium constant are low. The acceptor apparently does not overcome the steric barrier established by the bulky substituents and is located at a distance from the donor, which is greater than the optimum distance for the donor–acceptor interaction.[43]

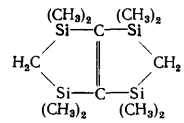
It is noteworthy that the equilibrium constant is more sensitive to steric effects than, for example, the frequency of the charge-transfer band ν_{CT} in the ultraviolet spectrum of the complex. For this reason, no anomalies associated with the steric factors are observed in the values of ν_{CT} for a series of compounds $C_6H_5CH_{3-n}[Si(CH_3)_3]_n$ (n = 1–3) and the equilibrium constant diminishes with increase of n (i.e. the size of the ring substituent).[185] However, with increase of the number of t-butyl or trimethylsilyl substituents in the ring, whereupon the role of the steric effects increases, anomalies do appear also in the values of ν_{CT}. This is manifested, in particular, by a decrease of the electron donating capacity of substituted phenols containing such groups in the formation of complexes with tetracyanoethylene.[186]

Like the decrease of the complex formation constants, the decrease of the electron-donating capacity is associated (for a molecule of a benzene derivative with bulky substituents) with the impossibility of realising the potential electron-donating properties because of the steric hindrance in the approach to the acceptor molecule to the optimum distance for electronic interactions of the complex. The fact that the distance actually attained exceeds (for steric reasons) the optimum distance can be formally regarded as a decrease of the electron-donating capacity. For this reason, the frequency ν_{CT} in the ultraviolet spectra of complexes of phenol derivatives having two or three bulky substituents [$C(CH_3)_3$, $Si(CH_3)_3$, $Ge(CH_3)_3$] with tetracyanoethylene ceases to be satisfactorily correlated with the σ^+ constants of the substituents.[186,187] This shows that both the electronic and steric effects are important in the formation of complexes by compounds of this kind. When bulky substituents are introduced into the phenol molecule (in the *ortho*-position relative to the hydroxy-group), the electron-accepting capacity of the compound in the formation of a hydrogen bond with tetrahydrofuran diminishes due to steric hindrance.[186]

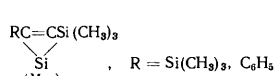
Extremely clear results have been obtained by yet another method for the estimation of the steric effects of substituents in benzene derivatives, which is based on analysis of the correlations between the ionisation potentials I_D, characterising the energy of the highest occupied molecular orbital (HOMO), and the charge-transfer band frequencies ν_{CT} in the ultraviolet spectra of the complexes of these derivatives with tetracyanoethylene.[188] It follows from the general theory[32] of charge-transfer complexes that there should be a linear relation between I_D and ν_{CT}; this has been frequently confirmed experimentally,[39] especially for compounds with related structures.[189] However, with increase of the number of organoelemental substituents in the benzene molecule, the linear relation between I_D and ν_{CT} ceases to hold. Thus, for the compounds $C_6H_{6-(m+n)}(CH_3)_m[CH_2Si(CH_3)_3]_n$ ($m+n$ = 1–6), the points on the plot corresponding to the hexasubstituted derivatives of the type $C_6[CH_2Si(CH_3)_3]_6$, $C_6(CH_3)_4[CH_2Si(CH_3)_3]_2$, $C_6(CH_3)_3[CH_2Si(CH_3)_3]_3$, and also $C_6H_2[CH_2Si(CH_3)_3]_4$ deviate from the linear relation between I_D and ν_{CT} towards higher values of ν_{CT}, i.e. the electron-donating capacity falls due to the steric hindrance to complex formation with tetracyanoethylene.

According to the ionisation potentials of sterically hindered benzene derivatives,[188] the steric hindrance influences also the effects of the conjugation of the substituents with the ring; these results will be examined in the next Section of the review.

A number of anomalies have also been observed in the properties of sterically hindered ethylene derivatives.[20,42] Thus the ring strain in the compound



leads to an increase in the length of the multiple bond and alters the valence angles.[190] The accumulation of bulky substituents at the C=C bond is accompanied not only by an increase in its length but also by the twisting of this bond. Thus the C=C bond lengths are respectively 1.368 and 1.370 Å and the tortional angles are ~30° and ~50° in $[(CH_3)_3Si]_2C{=}C[Si(CH_3)_3]_2$ [191] and in the sterically even more hindered $[(CH_3)_3Si]_2C{=}C[Si(CH_3)_2C(CH_3)_3]_2$.[192] The sharp decrease of the reactivity of the silacyclopropenes



is caused by the presence in the molecule of the two bulky mesityl substituents.[193,194] It is noteworthy that electronic factors also influence the stability of compounds of this type.[195–197]

(e) The Central Atom E as the Acceptor Centre and the E–C Bond as the Donor Centre in Complex Formation

In contrast to carbon compounds, complex formation via the central atom E is characteristic of derivatives of silicon subgroup elements.[6,8,34,46,55,106] In complex formation of this type, the atom E functions as a ν-acceptor, apparently by virtue of its unoccupied *nd* orbitals.[47,55] The possibility of the realisation of the potential ν-acceptor properties (determined by the nature of the atom E and the electronic effects of the substituents linked on it) depends also on the steric shielding of the atom E by these substituents and on the steric situation at the donor centre of the donor molecule. In the absence of the complicating influence of steric effects, the ν-acceptor capacity increases with increase of the atomic number of E (on passing from Si to Ge, Sn, and Pb) and with increase of the effective positive charge on E, which is ensured by the addition of electron-accepting substituents to E.[55,106] The influence of steric effects is manifested both by the breakdown of these characteristics of complex formation and by the anomalous thermodynamic characteristics of the complexes.

Although the complex-forming capacity of silicon compounds is the smallest among all the derivatives of the elements E, it has been established by infrared spectroscopy[198] that even triethylsilane is solvated specifically by electron-donating solvents and that steric effects are then manifested to an appreciable extent. These effects are smaller for oxygen-containing solvents than for nitrogen-containing solvents, in which the donor centre (the nitrogen atom) is more shielded by the substituents. On passing from triethylsilane to triethylgermane, the solvation intensifies, but the steric effects in the formation of donor–acceptor complexes hardly change.[198]

It is striking that, judging from the infrared spectra, a fairly profound analogy is observed between the formation of the solvate complexes $R_4E...L$, where L is an electron donating solvent,[198] and the intramolecular coordination of the type

examined above.[106,170-172] The analogy holds also from the standpoint of the steric effects of E and the substituents R linked to L in complex formation. In addition, competition between these two types of complexes is well known.[170-172,199] With increasing electron-donating capacity of L or with increase of the concentration of the latter in solutions, the intramolecular coordination probably breaks down and the concentration of the solvates $R_3(XCH_3)E...L$ rises; however, the role of the steric effects under these conditions has been inadequately studied.

Another form of simultaneous complex formation via two possible pathways is known for the phenyl derivatives of silicon and germanium.[200-202] These compounds can exhibit both π-donor (by virtue of their aromatic rings) and ν-acceptor [by virtue of the atoms E (Si, Ge)] properties in relation to molecular oxygen. It has been shown by the method of the low-temperature quenching of luminescence that in the phenyl derivatives of silicon only the π-donor capacity is realised and the steric effects are then insignificant. Phenyl derivatives of germanium behave as both π-donors and ν-acceptors in complexes with molecular oxygen. In the latter case the equilibrium constant of the complex formation reaction depends markedly on the steric effect of the substituents linked to the germanium atom. It increases, for example, on passing from $(C_6H_5)_4Ge$ to $C_6H_5GeH_3$ by a factor greater than 20,[200,202] although these compounds have similar π-donor capacities and apparently identical charges on the germanium atom.

Compared with silicon and germanium compounds, tin derivatives have more pronounced ν-acceptor properties; in addition, a higher sensitivity of these properties to the influence of substituents at the central atom is characteristic of these compounds. Therefore the study of the donor–acceptor complexes involving tin compounds yielded extremely clear information about the steric effects in the donor and acceptor molecules. Thus calorimetric investigations of the complexes $Alk_{4-n}SnCl_n$ with different N- and O-donors established an increasing enthalpy of complex formation (i.e. of the strength of the donor–acceptor bond) with increase of n.[203]

At the same time a significant dependence of ΔH and of the composition of the complex on the steric hindrance in the donor molecule has been observed.[203] For donors generating an intense steric hindrance, for example, $(C_4H_9)_3N$, even the strongest acceptor $SnCl_4$ forms complexes in which the donor: acceptor ratio is 1:1 (and not 2:1).[203] The influence of the steric effects of the alkyl groups in tetra-alkylstannanes is very strong in the formation of complexes with molecular oxygen,[204] iodine,[205-208] and tetracyanoethylene.[37] It has been established by the method of low-temperature quenching of luminescence, even in relation to the comparatively weak complexes with molecular oxygen, that the equilibrium constant of complex formation decreases with increase of the size of the alkyl group in the tetra-alkylstannanes in the sequence $CH_3 > n\text{-}C_4H_9 > n\text{-}C_5H_{11}$.[204]

For the stronger charge-transfer complexes with iodine and tetracyanoethylene (acceptors), in which the Sn–C bond having a comparatively low ionisation potential (8.2–9.7 eV[37]) functions as the donor, the influence of steric effects has been studied very thoroughly. It has been shown that comparison of the ionisation potentials of the compounds Alk_4Sn, obtained by photoelectron spectroscopy, and the ultraviolet spectra of the complexes of these compounds with iodine[205-207] and tetracyanoethylene[37] permits a quantitative estimation of the steric effects of the alkyl groups at the tin atom.

In these studies it has also been established that the steric effects influence not only the formation equilibrium constant of the charge-transfer complex[206] but also the rate constants for the subsequent process, for example the insertion of tetracyanoethylene in the tin–carbon bond in Alk_4Sn.[37] Under these conditions, both in the formation of the complex and in its subsequent reaction, the character of the influence of the steric effects does not change qualitatively. In both cases these effects intensify if the alkyl groups are replaced in the sequence $CH_3 \ll C_2H_5 < iso\text{-}C_3H_7 < iso\text{-}C_4H_9 < t\text{-}C_4H_9$; in contrast to other tetra-alkylstannanes, tetraneopentyltin, in which the central atom is most shielded by bulky substituents, does not react with tetracyanoethylene.[37] On the other hand, the increase of the size of the central atom on passing to lead compounds and the increase of the E–C interatomic distance should reduce steric hindrance, which is in fact observed for the complexes $(CH_3)_{4-n}(C_2H_5)_nPb$ with tetracyanoethylene.[37]

The equilibrium constants of the complex formation reactions of tetra-alkylstannanes with iodine, complicated by the steric effects of the bulky alkyl groups, are comparatively low.[207] The constants are very much greater for the formation of charge-transfer complexes between iodine (acceptor) and Alk_3SnX, where X = Br or I (donors).[209] In contrast to tetra-alkylstannanes, in this case the hydrogen atom X functions as the donor centre in complex formation and not the tin–carbon bond.[209,210]

It is to be expected that the role of the steric effects in complexes involving tetra-alkyl derivatives of silicon or germanium as well as compounds containing the silicon–silicon and germanium–germanium fragments as donors is greater than in tetra-alkylstannanes and distannanes. However, systematic studies of this kind have not been carried out and there exist only fragmentary factual data on the spectra of the complexes.[39,211] Appreciable steric effects are manifested in cyclic polysilanes.[212,213] Thus the polysilane $[(CH_3)_3C(CH_3)Si]_4$ whose electronic transition band occurs at an extremely high wavelength and which has a very low ionisation potential is nevertheless resistant to oxidation. The unusual properties of this compound are caused not only by electronic but also by steric effects of the four t-butyl substituents.[212,213]

Anomalously long Si–Si and Si–C bonds are observed in cyclotrisilanes $(R_2Si)_3$ with bulky substituents R: 2,6-dimethylphenyl,[214] neopentyl,[215] and t-butyl.[216]

Important information about steric interactions between the silyl substituents and saturated cyclic systems,[217] including highly strained silacyclopropane derivatives,[218] has been obtained by ^{29}Si NMR.

2. The Influence of Steric Effects on Conjugation in Compounds of Silicon Subgroup Elements

As shown above, the presence of bulky substituents in the donor and/or acceptor molecules exerts a significant influence on the spectroscopic and thermodynamic characteristics of DA complexes.

Steric factors can influence the donor and acceptor centres of the complex by regulating the degree to which these centres approach one another in complex formation, as a result of which the potential complex-forming capacity is not fully realised. Furthermore, steric effects can alter the electronic intermolecular interactions already in the initial

donor or acceptor molecules. As an example, one may quote the steric inhibition of conjugation[2,4,13] or, conversely, the establishment of favourable conditions for conjugation[42] in the molecule. These phenomena, which are well known for organic compounds,[2,4,7,13,15,45] are observed also in organoelemental chemistry.[42]

We shall consider the influence of steric factors on the extremely specific effects of the $(p-d)\pi$ interaction and hyperconjugation, especially for compounds of the silicon subgroup elements. The problem of the $(p-d)\pi$ interaction with participation of the unoccupied *nd* orbitals of the E atoms has been studied in detail.[46,47,53-55] It follows from these studies that the π-acceptor properties of the atoms E in relation to the substituents X (an atom with unshared electron pairs or an αβ-unsaturated hydrocarbon group), which have been thoroughly investigated experimentally, can be interpreted as $(p-d)\pi$ interaction in the E–X fragments via the partial transfer of electron density from the atom X to the unoccupied *nd* orbitals of the atom E. Under these conditions, the E–X bond acquires partial double bond character and the degree of the latter depends on the ratio of the electron-donating properties of the atom X and the electron-accepting properties of the atom E. The ratio of these properties in the atoms involved in the E–X bond depends in its turn on the other substituents attached to the bond.

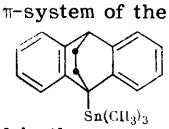
From the standpoint of the influence of stereoelectronic factors on $(p-d)\pi$ interaction, it is possible to consider two cases. The first case is that of compounds of the type R_3EX in which the substituents R are incapable of forming $(p-d)\pi$-bonds with E, i.e. the molecule has only one substituent X involved in the $(p-d)\pi$ interaction with E. In this case it has been shown for E = Si[219] and Ge [220] that the relative capacity of the substituent X for the formation of $(p-d)\pi$-bonds with E is determined exclusively by the resonance constants σ_R,[46] characterising the conjugation of these substituents with the benzene ring and a double or triple bond.[221] This confirms yet again the profound analogy, established a long time ago,[49] between the conjugation effects in organic and organoelemental systems and also the wide-scale applicability of the constant σ_R as a quantitative measure of these effects.

The second case is that of compounds of the type R_2EX_2, REX_3, and EX_4 with several substituents X involved in the $(p-d)\pi$ interaction with the atom E. In such compounds two additional factors (compared with the derivatives R_3EX) influence the $(p-d)\pi$ interaction in the molecule, namely the effective charge on E, which depends on the inductive and mesomeric effects of X, and the overlap integral of the interacting p_π and d_π orbitals of the atoms X and E. The complex situation arising in the $(p-d)\pi$ interaction of the atom E with several atoms X is associated, in particular, with the impossibility of the interaction of E with each of the several X just as strong as with a single X in the molecule. Indeed, as a result of the difference between the valence angles in the molecule (~109.5°) and the angles between the maximum intensity vectors of the d_π orbitals (90°), the interaction of E with several X takes place if the orientation of the d_π orbitals is such that it does not ensure the maximum overlap integrals of the p_π–d_π type in any of the E–X bonds.[53] This is one of the two causes (the second cause is the change in the effective charge on the atom E under the influence of X) of the non-additive dependence of the overall effect of the $(p-d)\pi$ interaction in the molecule on the number of substituents X linked to E. For example, the group overlap integrals of the EX_2 fragment are linked to the two-centre integrals (*s*) of the E–X bonds by the relation $S = (\frac{4}{3})^{1/2}s$.[53]

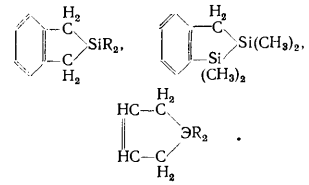
Analysis of the dependence of the frequencies of the highly characteristic stretching vibrations of the E–H bonds in the infrared spectra of the derivatives $AlkX_2EH$, where E = Si [222] or Ge,[220] on the electronic effects of the substituents has shown that, only when account is taken of the above relation between the group and two-centre integrals, is it possible to derive information from spectroscopic data about the influence of the purely electronic factors on the strength of the $(p-d)\pi$-bonds in the EX_2 fragment. In particular, the important conclusion has been reached that the degree of the $(p-d)\pi$ interaction increases with increase of the effective positive charge on the central atom E (Si, Ge).[220,222]

The resonance hyperconjugation effect and particularly its most thoroughly studied variety, namely σ,π-conjugation, are subject to an even more pronounced influence by stereoelectronic factors than $(p-d)\pi$ interaction.[42] By means of a specific alteration of the molecular geometry, it is possible to ensure virtually any spatial disposition of the orbitals interacting via the σ,π-conjugation mechanism and hence achieve both the maximum manifestation of these effects and any of its intermediate values up to its complete absence. Such extensive possibilities for the variation of the effect can be accounted for by the following characteristics of the σ,π-conjugation. The σ,π-conjugation is most pronounced for the maximum overlap of the π orbital of the E–C bond with the π orbital of the C–C or Ar group in compounds with the E–C–C–C or E–C–Ar fragments. Such overlap is attained when the E–C bond and the axis of the π orbital are arranged coplanarly, i.e. when the E–C–C angle is 90°. It has been demonstrated unambiguously for benzyl and allyl derivatives of mercury that the Hg–C–C angle is close to 90°.[223-225] Spectroscopic studies of similar derivatives of silicon subgroup elements have also supported unambiguously similar values of the E–C–C angle,[51,226,227] although direct X-ray diffraction measurements have not in fact been carried out.

Detailed analysis[42] of the factors determining the σ,π conjugation has shown that, in the compounds R_3E-CH_2-X, where X is an αβ-unsaturated substituent, the above conjugation intensities with increase of the electron-donating capacity of R and the electron-accepting capacity of X, with increase of the atomic number of E, and also in the presence of a positive charge on the orbital of the substituent X. The same factors regulate the degree of the σ,π conjugation also in compounds with a more complex structure, where the molecular geometry can ensure the approach of the angle E–C–C to 90°; for other molecular conformations, σ,π conjugation breaks down. Thus the rigid fixation of the Sn–C bond in the nodal plane of the π-system of the compound[51]



and the analogous bond in the corresponding organomercury compound[228] (see also Baidin et al.[229]) leads to the complete breakdown of the σ,π conjugation. For the same reasons, there is no σ,π conjugation in compounds containing planar rings:[230-233]



It is striking that an increase in the size of the rings, accompanied by their conformational non-rigidity, leads to the formation of conformations in which sterically favourable conditions arise for σ,π conjugation (for further details, see the earlier review[42] and in the case of organopolysilanes also Sakurai[234]). Extremely important information about the characteristic features of σ,π conjugation has been obtained for

"sterically overloaded"[40,188,235,236] benzene derivatives $C_6H_{6-n}[CH_2Si(CH_3)_3]_n$. With increase of the size (n) of bulky substituents, the requirement necessary to ensure conditions most favourable for the conjugation of these substituents with the ring break down, which is manifested in the photoelectron spectra and the EPR spectra of the radical-cations of these compounds.[40,188,235] The degree of σ,π conjugation then depends on the angle between the C–Si bond and the plane of the benzene ring or the axis of the C=C bond (for the corresponding ethylene derivatives[41,237,238]). In the latter case, when the sterically most favourable conditions for σ,π conjugation have been created, having fixed rigidly in space the fragments involved in the conjugation, it is possible to obtain ethylene derivatives with very low ionisation potentials (less than 7 eV[41]). Such high electron-donating capacity of compounds of this kind is caused by the maximum extent of σ,π conjugation; for this reason, one observes in this instance a kind of enhancement of conjugation as a result of the creation of the most favourable steric conditions.[41]

- - - o 0 o - - -

Thus, on the one hand, studies designed to create a general theory of steric effects in chemistry are being prosecuted at the present time. Fundamental advances on these lines will apparently become possible only after a set of specific quantum-chemical investigations have been carried out; so far this problem is far from being solved. On the other hand, a planned general interpretation of an increasing amount of experimental data is being carried out in organic and organoelemental chemistry, which has led, in particular, to the development of empirical methods for the estimation of steric effects and also to the understanding of the specific features of the more varied role of these effects in organoelemental compounds.

Compounds of the silicon subgroup elements are used (at least in the chemistry of non-transition elements) as important model systems for the investigation of the steric effects both in the ground electronic state and (judging from the extensive data on reactivities which have not been included in this review) in the transition state. Together with their independent importance, spectroscopic investigations of the steric effects in the ground electronic states of such model compounds can have a direct bearing on the study of reactivity, since it has been shown for a series of organoelemental systems, for example, for tetra-alkylstannanes,[37] that steric effects in the ground and transition states differ little. Improvement of the spectroscopic research techniques for the primary stages of not too fast reactions involving organoelemental compounds is therefore likely to be useful for the prediction of the influence of steric effects on reactivity.

Advances in the Chemistry of Organolanthanides

M.N.Bochkarev, G.S.Kalinina, and L.N.Bochkarev

The results of studies on the synthesis, structure, and reactivity of organometallic derivatives of the lanthanide elements are surveyed. Data concerning their practical applications are presented.
The bibliography includes 235 references.

I. INTRODUCTION

The chemistry of organometallic derivatives of the lanthanides began to develop vigorously after the characteristics of the formation of organic derivatives of d elements had been elucidated in broad outline. In the last decade an increasing number of investigators have turned their attention to this little studied field in the search for new highly effective stereospecific and regioselective catalysts. Since 1975, Soviet chemists have taken an active part in the development of methods of synthesis of new types of organometallic derivatives of the lanthanides[1,2] although physicochemical studies on the known cyclopentadienyl complexes had been made earlier in our country.[3,4]

The first organometallic lanthanide compounds isolated and reliably characterised were the cyclopentadienyl complexes obtained in the middle of the 1950's.[5,6] Compounds of this type remained for a long time the only ones known for the lanthanides. However, at the present time virtually all classes of organic derivatives of the lanthanides (Ln), also known for transition metals, have been synthesised, including the hydrides, the carbonyls, the σ-alkyl and σ-aryl compounds, the carbonyl derivatives, and the dienyl, allyl, indenyl, cyclo-octatetraenyl, and other complexes. Organometallic derivatives containing an Ln–E bond, where E = nitrogen, phosphorus, oxygen, sulphur, selenium, mercury, boron, germanium, or tin, as well as complexes in which the lanthanide is present in combination with molybdenum tungsten, cobalt, manganese, and rhenium have been synthesised. Carbon-containing clusters with an Ln–Ln bond have been obtained. Only the arene complexes of the lanthanides apparently remain unknown.

In the study of the properties of organometallic derivatives of the lanthanides, their high catalytic activity in the polymerisation of olefins and especially dienes was discovered. In recent years processes have been discovered in which organolanthanides play the role of activators of hydrogen and carbon monoxide and dioxide. All these facts indicate great potential possibilities of the derivatives of *f* elements in catalysis.

The main distinctive factor determining the catalytic activity and specific properties of the compounds considered is the presence of a completely or partly filled 4*f* sublevel in the lanthanide atoms. A detailed discussion of the characteristics of the electronic structure of the lanthanide complexes is found in another review[7] and the literature quoted therein. Here we shall only note the principal characteristics which determine the behaviour of the free lanthanides and their organic derivatives in chemical reactions.

All the 15 elements which follow barium in Mendeleev's Table are electropositive metals. Their normal electrode potentials (+2.522–2.255 V) are close to those of the alkali metals. Accordingly, the organic complexes of the lanthanides are as a rule ionic and exhibit clearly the properties of Lewis acids. The most characteristic oxidation state is Ln^{3+}. Only three elements, namely samarium, europium, and ytterbium, form stable bivalent derivatives, although the Ln^{2+} state is known for all the lanthanides.[7,8] Organometallic compounds with the quadrivalent metal (Ln^{4+}) are known only for cerium. The high ionic radius (0.848–1.061 Å) characteristic of the lanthanides is responsible for their high coordination numbers (up to 12). Compounds with an octacoordinate lanthanide atom are the most common.

A series of reviews,[7,9–17] a collection of articles,[8] and a chapter in one of the books of the "Methods of Organoelemental Chemistry" series[18] have been devoted to organometallic derivatives of the lanthanides. However, the available information in this field has been increasing so rapidly that at the present time it is already felt that a systematic survey of the accumulated data is necessary. In the present review we attempted to examine as fully as possible advances in the chemisty of the organic derivatives of the lanthanides in the field of synthesis and reactivity, including catalytic processes, during the last 5–7 years (up to 1984 together with a few later studies). In addition, data are presented on the synthesis and properties of the phthalocyanide complexes and alkoxides of the lanthanides. In order to create an integral picture of the modern organometallic chemisty of the lanthanides, the review includes a series of earlier studies as well as data for scandium and yttrium compounds.

II. HYDRIDES

The lanthanide hydrides LnH_2 and LnH_3 are readily formed when the free metals are saturated with hydrogen at room temperature.[19] They are usually isolated in the form of powders but, at an elevated temperature, it is possible to obtain crystalline specimens. Heating the hydrides decomposes them into the initial elements. The decomposition temperature depends strongly on the metal: CeH_3 is the least stable (decomposition temperature 157 °C) and LuH_3 is the most stable (decomposition temperature 416 °C). All the

hydrides, with the exception of ScH_2, are rapidly oxidised in air. Water decomposes the trihydrides, LnH_3, at an appreciable rate; the dihydrides LnH_2 are hydrolytically more stable.

Unstable variable-composition hydrides LnM_xH_y are formed when lanthanide melts containing various metals (Mg, Al, Mn, Fe, Co, Ni, etc.) are saturated with hydrogen.[19] The tetrahydroborates $Ln(BH_4)_3$ and the extremely unstable tetrahydroaluminates $Ln(AlH_4)_3$ are obtained in the reactions of the salts LnX_3 with $MM'H_4$ (M = Li or Na; M' = B or Al).[20,21]

The first communication about the synthesis of organometallic complexes containing an Ln–H bond appeared in 1974.[22] It stated that Cp_3CeCl and Cp_2CeCl_2 ($Cp = \eta^5$-C_5H_5) afford respectively Cp_3CeH and Cp_2CeH_2 on interaction with sodium hydride in boiling tetrahydrofuran (THF). The structure of these products was confirmed by elemental analysis and infrared spectroscopy (the bands in the region of 2040 cm^{-1} were assigned to the Ce–H bond vibrations).

The lutetium hydride $Cp_2LuH.THF$ was obtained in two ways:[23]

$$Cp_2Lu{-}R\cdot THF + H_2 \xrightarrow[50\ bar]{} Cp_2Lu{-}H\cdot THF + RH,$$
$$R = CH_2Ph,\ CH_2SiMe_3;$$
$$Cp_2LuCl\cdot THF + NaH \xrightarrow[20^\circ]{} Cp_2Lu{-}H\cdot THF + NaCl.$$

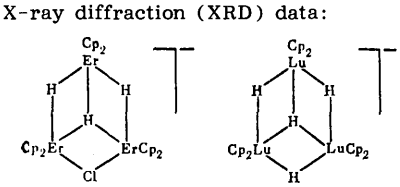
It has been stated[23] that the frequencies ν(Lu–H) and ν(Lu–D) in the infrared spectra of the product and its deuterio-analogue are 770 and 720 cm^{-1} and 540 and 510 cm^{-1} respectively. Apart from elemental analysis, the structure of the hydride has been confirmed by its reaction with Me_3SiCl, which gave rise to trimethylsilane and Cp_2LuCl.

The use of t-butyl derivatives in the synthesis of the hydrides by the hydrogenolysis of the Ln–R σ-bond made it possible to carry out the reaction at atmospheric pressure:[24,25]

$$2(RC_5H_4)_2Ln\text{-}Bu\text{-}t.\cdot THF + 2H_2 \rightarrow [(RC_5H_4)_2Ln{-}H\cdot THF]_2 + 2t\text{-}BuH;$$
$$Ln = Y,\ Er,\ Lu.$$

The deuterio-derivatives have been synthesised analogously. Bands in the ranges 1350–1240 and 975–900 cm^{-1} respectively have been assigned to the Ln–H and Ln–D vibrations in the compounds obtained. X-Ray diffraction analysis of the yttrium dimer $[(MeC_5H_4)_2YH.THF]_2$ and the samarium dimer $[(Me_5C_5)_2SmH]_2$ dimer confirmed the presence of bridging hydrogen atoms, although their coordinates were not accurately established. The differences between the properties (infrared and ^1H NMR spectra and solubility) of the lutetium complex synthesised by Evans and co-workers and the hydride described by Schumann and Genthe[23] led Evans and co-workers[24,25] to the conclusion that the hydride has a different structure.

The dimeric hydrides $(Cp_2LnH.THF)_2$ are also formed on thermal decomposition of the same t-butyl complexes at 20–75 °C via the mechanism of the β-hydride decomposition.[24] It is of interest that thermolysis in the presence of a small amount of LiCl leads to the formation of other products. The erbium complex afforded a product having the composition $\{[Cp_2ErH]_3Cl\}[Li.(THF)_4]$ containing the trinuclear anion (A) according to X-ray diffraction (XRD) data:



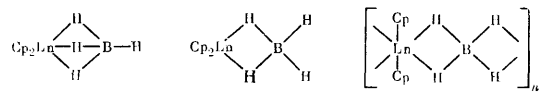
(A) (B)

The analogous anion (B), free of chlorine, has been obtained in the thermolysis of Cp_2Lu–Bu-t.THF.[24] The hydride band in the infrared spectra of the anions (A) and (B) is observed in the region of 1200 cm^{-1}.

The formation of the bivalent ytterbium hydride BuC ≡ CYbH is postulated in the initial stage of the reaction of atomic ytterbium cocondensed with hex-1-yne at 77 K.[26] This complex multistage process leads ultimately to the oligomer $[(BuC \equiv C)_3Yb_2H]_n$. Under the same conditions, samarium gives rise to a product for which the formula $[(C_6H_9)_2SmH]_n$ has been suggested.

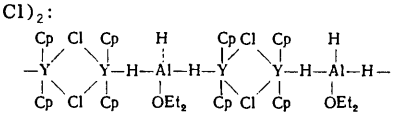
The chemical properties of the lanthanide hydrides are similar to those of the organohydrides of electropositive transition metals. They are hydrolysed by water and D_2O to H_2 or HD respectively and readily exchange hydrogen for a halogen on interaction with RX (R = CCl, Me, or Me_3Si). The yttrium hydrides $[(RC_5H_4)_2YH.THF]_2$ combine with two equivalents of t-butyl isocyanide, giving (according to XRD data) the dimers $\{(RC_5H_4)_2Y[C(H) = N\text{-}Bu\text{-}t]\}_2$ with bridging formimidoyl groups.[27]

The vibrational spectra methods of the complexes Cp_2LnBH_4. .THF (Ln = Sm, Er, or Yb), synthesised by the interaction of Cp_2LnCl with sodium tetrahydroborate, suggested[28] that, for Ln = Sm the anion is a tridentate ligand (C). When the Ln^{3+} cation is smaller (for example, when Ln = Yb) a complex with a bidentate tetrahydroborate group (D) is formed and the removal of coordinated THF by heating *in vacuo* gives polymeric structures, (E):



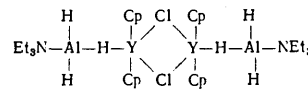
(C) (D) (E)

The complex $(Cp_2YCl)_2AlH_3.Et_2O$ has been obtained by the reaction of AlH_3 with dicyclopentadienylyttrium chloride.[29] Its investigation by X-ray diffraction showed that two of the three hydrogen atoms in the AlH_3 group are involved in the formation of the intermolecular Y–H–Al bridges, which leads to the formation of oligomeric chains containing the dimeric units $(Cp_2YCl)_2$:



The secondary Cl...Al bonds formed evidently make a significant contribution to the stability of the complex.

The same workers showed[30] that, when the ether in this complex is replaced by the more basic triethylamine, only one of the three hydrogen atoms in AlH_3 assumes the bridging position. As a result, the product of the reaction of $[Cp_2YCl]_2$ with $AlH_3.NEt_3$ is no longer a polymer but a dimer having the following structure:



The interaction of lithium tetrahydroaluminate with Cp_2YCl gives rise to the hydrides $(Cp_2YH)_2(AlH_3)_2$ containing bridging hydrogen atoms.[31]

III. COMPOUNDS WITH A LANTHANIDE–CARBON σ-BOND

The following main types of lanthanide compounds containing σ-linked organic ligands are known:

$$R_3Ln,\ R_2LnX,\ RLnX_2,\ Li_x[LnR_{3+x}],\ Cp_2LnR,$$
$$Cp_2Ln(\mu\text{-}R)_2AlR_2,\ Cp_2Ln\langle^{CH_2}_{CH_2}\rangle PR_2,\ Cp_2Ln\langle^{R}_{CH_2-PR'_2}$$

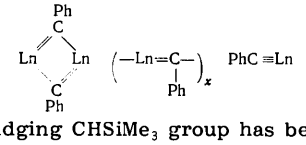
A general and most convenient method of synthesis of complexes of the R_3Ln series involves reactions of alkyl- or aryl-lithium with the lanthanide trichlorides:[32–39]

$$3RLi + LnCl_3 \xrightarrow{THF} R_3Ln + 3LiCl;$$

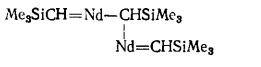
Ln = Sc, Y, La, Tb, Er, Tm, Yb, Lu; R = CH_2—Bu-t, CH_2SiMe_3, $CH_2(SiMe_3)_2$, $CH_2SiMe_2C_6H_4OMe$-*o*, $CH_2C_6H_4NMe_2$-*o*, Ph,

In most cases the products contain the coordinated solvent ($R_3Ln.2THF$). The formation of $Me_3La.THF$ has been noted,[32] but this compound has not been isolated in a pure state.

All the complexes R_3Ln decompose rapidly on contact with oxygen and moisture. Their thermal stability is determined by the nature of the substituent R. Alkyl derivatives decompose in the temperature range 50–100 °C. The compounds with R = CH_2SiMe are still less stable, decomposing slowly at room temperature.[37] Decomposition of the compound $(Me_3SiCH_2)_3Er.(THF)_2$ leads to the evolution of Me_4Si and the formation of the polymeric complex $[(Me_3SiCH)(Me_3SiCH_2)Er]_x$. Analogous results were obtained in a study of the reactions of YCl_3 and $NdCl_3$ with the alkyl-lithium reagents $LiCH_2Ph$, $LiCH_2C(Me)_2Ph$, and $LiCH_2SiMe_3$.[40–43] In the reaction with benzyl-lithium the formation of $(PhCH_2)_3Ln$ complexes in the initial stages has been postulated. These then decompose rapidly with evolution of toluene and the formation of compounds having the composition PhCLn. According to the authors of the above studies, the products can have the structures of carbene- or carbyne-metal complexes:



A dimer with a bridging $CHSiMe_3$ group has been proposed for the structure of the product of the reaction of $NdCl_3$ with $LiCH_2SiMe_3$.[42]



Derivatives of bivalent lanthanides of the type R_2Ln are known for europium and ytterbium. Most of them have been obtained by the oxidation reduction transmetallation reaction between R_2Hg and the metallic lanthanide:[44–49]

$$R_2Hg + Ln \rightarrow R_2Ln + Hg$$

Ln = Eu, Yb; R = C≡C—Bu-t, C≡CPh, C_6F_5, HC_6F_4-*p*,

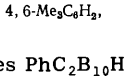
The acetylides $(RC \equiv C)_2Ln$ can be synthesised in addition by the direct interaction of the substituted acetylene RC ≡ CH with the metallic lanthanide in liquid ammonia[50] or by the reaction of phenylacetylene with R_2Yb (R = C_6F_5 or C ≡ C–Bu-t).[49]

The phenylethynyl and carbaboranyl complexes decompose on heating above 200 °C. The polyfluorophenyl derivatives are less stable and decompose at an appreciable rate even at room temperature. Judging from the conditions and products of the reactions of R_2Yb (R = C_6F_5, *p*-HC_6F_4, or C ≡ CPh) with aldehydes, ketones,[51] Ph_3SnCl, $HgCl_2$, I_2, C_6F_5COOH, and certain nickel, rhodium, and platinum complexes,[52] the reactivity of R_2Ln is similar to that of the organolithium and organomagnesium compounds.

The ease of their reactions with alkyl or aryl-iodides is extremely characteristic of the lanthanides. In most cases this results in the formation of a mixture of R_3Ln, R_2LnI, $RLnI_2$, and LnI_3, which are difficult to separate. However, under these conditions, samarium, europium, and ytterbium give rise to the compounds RLnI, whose properties are close to those of Grignard reagents:[53,54]

$$RI + Ln \xrightarrow{THF} RLnI$$

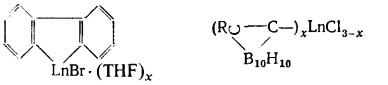
Ln = Sm, Eu, Yb; R = Me, Et, Ph, *o*-MeC_6H_4, 2.6-$Me_2C_6H_3$, 2, 4, 6-$Me_3C_6H_2$,



The carbaboranyl derivatives $PhC_2B_{10}H_{10}LnI$ (where Ln = Sm, Eu, or Yb) have been obtained in addition by the reaction of phenylcarbaboranyl-lithium with LnI_2.[54]

The compounds RLnI are in many respects similar to organomagnesium derivatives, but significant differences have been observed in their reactivities, particularly in the interaction with carbonyl compounds[55–58] and unsaturated hydrocarbons.[59,60]

It has been noted[57] that praeseodymium, neodymium, gadolinium, and dysprosium react with iodoethane to form coloured solutions containing EtLnI complexes but evidence for their structure is not quoted. On the other hand, a study of the reactions of Ph_3CCl, $PhCH_2Cl$, and PhBr with metallic praeseodymium, neodymium, gadolinium, and holmium established[61–63] that these reactions lead to the formation of compounds of tervalent lanthanides $RLnX_2$. The latter decompose slowly at room temperature, producing more complex organolanthanides and products of the reactions of the radicals R. The lanthanum complex $Ph_3CLaCl_2.N(CH_2CH_2OCH_2.CH_2OCH_2CH_2)_3N$ has been obtained by the reaction of triphenylmethyl-lithium with $LaCl_3.L$.[64] The interaction of 2,2′-dilithiobiphenyl and carbaboranyl-lithium with $Ln(Hal)_3$ also leads to the formation of the corresponding derivative of a mixed type:



Ln = Pr, Sm, Ho, Yb (Ref.65) Ln = La, Tm; R = Me, Ph
x = 1, 2 (Ref.39)

In those cases where the molar ratio of the reactants in the reactions of RLi with $Ln(Hal)_3$ described above exceeds 3, the products are bimetallic complexes of the *ate*-type:

$$LnCl_3 + (3 + x)\,RLi \rightarrow Li_x[LnR_{3+x}] + 3LiCl.$$

The phenyl derivatives $Li[LnPh_4]$ (Ln = La or Pr) have been isolated in a form free from the solvent.[32] All the remaining complexes contain electron-donating ligands [THF, tetramethylethylenediamine (TMED), and ether]: $[Li(THF)_4].[LnR_4]$ (Ln = Y, Sm, Er, Tb, Yb, or Lu; R = 2,6-$Me_2C_6H_3$, t-Bu, or CH_2SiMe_3,[38,66,67] $[Li(THF)_4][LnClR_3]$ [Ln = Er or Yb; R = $CH(SiMe_3)_2$,[38] $[Li(TMED)_2][LnR_4]$ (Ln = Y, Er, Yb, or Lu; R = t-Bu or CH_2SiMe_3),[36,68] $[Li(TMED)_3][LnMe_6]$ (Ln = Y or La–Lu).[68,69]

Bimetallic compounds with bulky carbaboranyl substituents $(MeC_2B_{10}H_{10})_3Yb.THF.MeC_2B_{10}H_{10}Li.(THF)_2$ and $Me_2C_2B_{10}H_{10}YbCl_2.MeC_2B_{10}H_{10}Li.2THF$[39] apparently also have the structure of *ate*-complexes.

The alkynyl complexes $[Li(THF)_4][Ln(C \equiv C\text{-Bu-t})_4]$ (Ln = Sm, Er, or Lu) are formed when isobutane is displaced from $[Li(THF)_4][Ln(t\text{-Bu})_4]$ by t-butylacetylene.[70] X-Ray diffraction study of $[Li(THF)_4][Lu(2,6\text{-}Me_2C_6H_3)_4]$ [66] and $[Li(THF)_4]\{Yb[CH(SiMe_3)_2]_3Cl\}$ [38] showed that the lanthanide atoms in these compounds are tetrahedrally coordinated, while those in $[Li(TMED)_3][LnMe_6]$ (Ln = Ho or Er)[68] are octahedrally coordinated.

All the bimetallic complexes rapidly decompose in air but are fairly stable, with the exception of the etherate $[Li(Et_2O)_4][Lu(CH_2SiMe_3)_4]$, in an inert atmosphere or *in vacuo*.

A large group of compounds containing a wide variety of σ-linked ligands is formed by cyclopentadienyl derivatives of the type Cp_2LnR. They are usually synthesised by the reaction of RLi with the corresponding chloride:

$$Cp_2LnCl + RLi \xrightarrow{THF} Cp_2LnR\cdot THF + LiCl\ ;$$

Ln = Y, Dy, Ho, Er, Yb; R = Me [71—73]; Ln = Gd, Er, Yb, Lu; R = Me, Et, iso-Pr, Bu, t-Bu, t-C_6H_{11}, CH_2SiMe_3, CH_2Ph, Ph_3C, 4-ClC_6H_4, 4-MeC_6H_4 (Refs.74, 75); Ln = Gd, Yb; R = (Ref.71); Ln = Sc, Gd, Ho, Er, Yb; R = C ≡ CPh (Refs.71, 76).

The ethynyl derivatives are also obtained by substituting the methyl group in Cp_2LnMe [70] or one Cp group in Cp_3Ln [77] by acetylenes:

$$Cp_2LnR + HC{\equiv}CR' \rightarrow Cp_2LnC{\equiv}CR' + RH\ ;$$

Ln = Nd, Er, Yb; R = Me, η⁵-Cp, R'=Bu, C_6H_{11}, Ph, ferrocenyl.

Using the same reactions, complexes with methylcyclopentadienyl rings have been synthesised:

$(Me_5C_5)_2LnMe\cdot Et_2O$ (Ln=Yb, Lu) (Ref.78),

$(Me_5C_5)_2YbMe\cdot THF$, $[(Me_5C_5)_2YbMe_2]Lu\times$

$\times(Et_2O)_2$, $[(Me_5C_5)_2YbClMe]Li\cdot(Et_2O)_2$ (Ref.79),

$(MeC_6H_4)_2SmC{\equiv}C-Bu\text{-}t$ (Ref.80),

[1, 1'—$(CH_2)_3(C_5H_4)_2$] $LnC{\equiv}CPh$ (Ln=La, Ce) (Ref.81).

Depending on the nature of R and the isolation method, the complexes can contain solvent or can be non-solvated. In the majority of the complexes the substituents R are of the bridging type, which is the reason for the dimeric form of these compounds. X-Ray diffraction of the complexes $Cp_2LnBu\text{-}t.THF$,[82] $Cp_2LuCH_2SiMe_3.THF$, and $Cp_2LuC_6H_4Me\text{-}4$ [74] has shown that in the presence of bulky substituents the compounds are monomeric.

The study of the reactivity of these complexes in relation to $(Me_5C_5)_2LnMe$ (Ln = Y or Lu) has shown recently[83,84] that a methyl group linked to the metal is readily displaced not only by acetylenes but also by hydrocarbons without activated C—H bonds:

$$(Me_5C_5)_2LnMe + RH \rightarrow (Me_5C_5)_2LnR + MeH\ ;$$

R = Me, Et, Pr, Ph, CH_2SiMe_3, C_5H_4N.

On interaction with diphenylacetylene, the bivalent lanthanide derivative $(Me_5C_5)_2Sm$ gives rise to the adduct $(Me_5C_5)_2Sm(Ph)C \equiv C(Ph)Sm(C_5Me_5)_2$.[25]

σ-Complexes with Ln^{4+} are known for cerium: Cp_3CeR, $(Ind)_2CeR_2$ (Ind = indenyl; R = Me, Et, Ph, CH_2Ph or COPh).[85]

The first cyclo-octetetraenyl complexes with σ-linked ligands, namely $(C_8H_8)Lu(CH_2SiMe_3).(THF)_2$ and $(C_8H_8)Lu.(C_6H_4CH_2NMe_2\text{-}o).THF$ have been obtained recently by the reaction of RLi with the chloride $(C_8H_8)LuCl.THF$.[86]

The bimetallic lanthanide derivatives $Cp_2Ln(R)_2AlR_2$ with bridging alkyl groups are formed in the reaction of cyclopentadienyl-lanthanide chlorides with lithium tetra-alkylaluminates:[72,87,88]

$$Cp_2LnCl + LiAlR_4 \rightarrow Cp_2Ln(R)_2AlR_2 + LiCl\ ;$$

R = Me, Et.

The presence of bridging alkyl groups has been confirmed by X-ray diffraction of the ytterbium compound $Cp_2Yb(\mu\text{-}Me_2).AlMe_2$.[88]

The zwitter-ionic lanthanide complexes $Ln[(CH_2)_2PR_2]_3$ (Ln = La, Pr, Nd, Sm, Gd, Ho, Er, or Lu; R = Me or t-Bu),[89,90] $Cp_2Lu(Cl)CH_2PPh_3$,[90] $Cp_2Lu(R)CH_2PPh_3$ (R = t-Bu or CH_2SiMe_3), and $Cp_2Lu(Bu\text{-}t)CH(SiMe_3)PMe_3$ [91] have been obtained by the reactions of the ylides CH_2PR_3 with the lanthanide chloride derivatives $LnCl_3$ and Cp_2LnCl.

IV. π-COMPLEXES OF ORGANOLANTHANIDES

1. Complexes with Alkenes and Alkynes

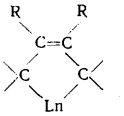
Like the compounds of *d*-metals, the lanthanide derivatives are capable of forming stable π-complexes with alkenes and alkynes. Allyl derivatives of samarium, holmium, and erbium have been obtained by the Girgnard reaction:[92]

$$Cp_2LnCl + C_3H_5MgBr \xrightarrow[-78^\circ]{} Cp_2LnC_3H_5 + MgBrCl\ .$$

The scandium complex $Cp_2ScC_3H_5$ had been synthesised earlier by the same method.[76]

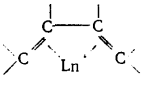
The allyl complexes are readily oxidisable and hydrolysable. Their infrared spectra contain an absorption band at 1533 cm^{-1}, which is characteristic of the delocalised C—C bonds in the allyl fragment.

The cocondensation of the lanthanide and buta-1,3-diene of 2,3-dimethylbuta-1,3-diene at −196 °C yielded the solids $Ln(C_4H_6)_3$ and $Ln(Me_2C_2H_4)_2$ (Ln = La, Sm, or Er),[93] which decompose in air. Their structure has not been accurately established. Judging from the hydrolysis products, among which the main one is but-2-ene, the compounds contain dialkyl groups:



R = H, Me.

However, in this case one can assume that the metal in the complexes is in the +4 oxidation state for LnR_2 and +6 for LnR_3, which appears unlikely. As an alternative, the authors propose a π-dienyl group with a formally zerovalent metal:



Apparently complexes of an analogous kind are formed in the cocondensation of the lanthanide metal vapours with disubstituted acetylenes RC ≡ CR.[94] The high molecular weights of the complexes indicate their oligomeric structure.

More definite structural data have been obtained for the 2,4-dimethylpentadienylneodymium complex $(C_7H_{11})_3Nd$, synthesised by the reaction of $NdCl_3$ with the 2,4-dimethylpentadienyl anion.[95] According to XRD data, the neodymium atom is surrounded by three dienyl groups. The atoms of the pentadienyl chain have a nearly planar disposition. The lengths of the Nd—C[1(5)] [2.801(9)Å] and Nd—C(3) [2.749(10) Å] bonds are reduced compared with those of the Nd—C[2(4)] [2.855(8) Å] bonds, which reflects the difference between the charge densities on the carbon atoms in the different positions and indicates a significantly ionic nature of the metal—carbon bond.

2. Cyclopentadienyl Derivatives

Compounds with cyclopentadienyl substituents are the most thoroughly investigated organic derivatives of the lanthanides. The following main groups of complexes are known at the present time: Cp_2Ln (Ln = Sm, Eu, or Yb); Cp_3Ln (Ln = La—Lu); Cp_4Ce, Cp_3CeX, and Cp_2CeX_2; Cp_2LnX, $CpLnX_2$,

$(Cp_2LnX_2)M$, Cp_2LnR, and $(Cp_2LnR_2)M$ (Ln = La–Lu; M = Li or Al). The last two groups contain an Ln–C σ-bond and were examined above in Section III.

The most general method of synthesis of the cyclopentadienyl compounds, including Cp_4Ce, involves the interaction of alkali metal or magnesium cyclopentadienides with the salts LnX_3:[96–98]

$$LnX_3 + 3CpM \rightarrow Cp_3Ln + 3MX;$$
$$(PyH)_2[CeCl_6] + 4CpNa \rightarrow Cp_4Ce + 4NaCl + 2(PyH)Cl.$$

However, one should note that the possibility of synthesising Cp_4Ce by the above reaction has been denied by Deacon et al.[99] and it has been shown that this pathway leads to Cp_3Ce. Doubt has also been cast on studies on the synthesis of Cp_3CeX and fluorenyl and cycloheptatrienyl derivatives of cerium(IV).[99]

Tricyclopentadienylpromethium has been obtained using Cp_2Be as the donor of Cp groups.[100]

The products contain as a rule molecules of the electron-donating solvent, in which these reactions are carried out, coordinated to the lanthanide atom. Complexes free from the solvents are obtained when the products are sublimed or heated cautiously *in vacuo* (Ln = Eu)[101] and also when the syntheses are carried out in benzene or ether.

Complexes with a bivalent Ln atom have been obtained in the case of europium and ytterbium by the reaction of cyclopentadiene with the corresponding metal in liquid ammonia[102] and by the reduction of Cp_2LnCl to Cp_2Ln with sodium or ytterbium in THF.[103]

A method has been proposed for the synthesis of the cyclopentadienyl complexes of the lanthanides based on the oxidation-reduction transmetallation reaction between Cp_2Hg and the lanthanides.[104–106] Depending on the reactant ratio and the nature of the lanthanide, Ln^{2+} and Ln^{3+} derivatives can be obtained in 30–60% yield:

$$Cp_2Hg + mLn \xrightarrow{THF} (m-1)\,Ln/Hg + Cp_2Ln\cdot(THF)_x;$$
$$Ln = Sm,\ Eu,\ Yb;\ m = 4,\ 5;\ x = 2–4;$$
$$3Cp_2Hg + 2Ln \rightarrow 3Hg + 2Cp_3Ln\cdot(THF)_x.$$

The reaction of metallic lanthanides with cyclopentadienylthallium is more convenient from the preparative standpoint:[107]

$$x\,CpTl + Ln \rightarrow Cp_xLn + xTl;$$
$$Ln = Nd,\ Sm\ (x = 3);\ Ln = Yb\ (x = 2,\ 3).$$

The authors of the same study showed that the synthesis of Cp_2Yb involved the initial formation of Cp_3Yb, but Yb^{3+} is rapidly reduced further to Yb^{2+}.

The first soluble bivalent samarium complex $(Me_5C_5)_2Sm.(THF)_2$ has been obtained by the cocondensation of the metal and ligand vapours at −120 °C.[108]

All the cyclopentadienyl derivatives of lanthanides, including halogenoderivatives and bimetallic complexes, are solids (m.p. 250–400 °C) and are extremely sensitive to moisture and oxygen (only the Ce^{4+} complexes are stable). On heating *in vacuo*, they sublime (with the exception of Cp_3Eu, which decomposes, and the involatile bimetallic compounds) in the temperature range 150–250 °C and at a pressure of 10^{-3} mmHg. The unsubstituted Cp_3Ln are sparingly soluble in alkanes and aromatic hydrocarbons but are readily soluble in THF, pyridine, and other electron-donating solvents. The introduction of alkyl groups into the Cp rings increases the volatility and solubility of the complexes. The structures of more than 20 compounds of this series have now been investigated: $(Cp_3Pr)_n$,[109] $(Cp_3Sm)_n$,[110] $(Cp_3Sc)_2$,[111] $[(MeC_5H_4)_3Nd]_4$,[112] $Cp_3Pr.CNC_6H_{11}$,[113] $Cp_3Gd.THF$,[96] $(Cp_3Yb)_2.NC_4H_4N$,[114] $(Me_3C_5)_2Sm.(THF)_2$,[108] $(Me_5C_5)_2Yb.(C_5H_5N)_2$,[115] $(MeC_5H_4)_2Yb.THF$,[116] $(Me_5C_5)_2Yb.THF.(PhMe)_{1/2}$,[117] $(Me_3SiC_5H_4)_2Yb.(THF)_2$,[118] and $Cp_2Yb.DME$ [119] [the complexes Cp_2LnCl and $(Cp_2LnCl_2)M$, whose structures have been investigated are considered below].

X-Ray diffraction, vibrational, electronic spectroscopic data, and measurements of magnetic susceptibility have shown that the bond between the cyclopentadienyl rings and the lanthanide atom is ionic.[7,120,121] The most characteristic chemical property of the compounds Cp_xLn (x = 2 or 3), apart from their hydrolytic and oxidative instability, is a very marked tendency towards the formation of complexes of the type $Cp_3Ln.L$ with Lewis acids, for example, with NH_3, THF, DME, R_3P, etc.[7,115,122,123] Less basic ligands are then displaced by more basic ones.

It is of interest that $Me_2PCH_2PMe_2$ is a monodentate ligand in the complex $(MeC_5H_4)_2YbCl.Me_2PCH_2PME_2$, in contrast to the bidentate ligand $Me_2PCH_2CH_2PMe_2$ in the coordination polymer $[(MeC_6H_4)_2Yb.Me_2PCH_2CH_2PMe_2]_n$.[124] The CO and NO groups of the nitrosyl carbonyl complexes of transition metal derivatives of the type $[(MeC_5H_4)Mn(CO)NO]_2$ and $Me_2Sn[Mn(CO)_5]_2$ can also play the role of electron donors.[125–127] The adducts formed under these conditions have been investigated by infrared spectroscopy and NMR.

The cyclopentadienyl rings in Cp_3Ln are readily split off in reactions with proton-containing reagents (HCl, HCN)[16,123] and metal salts ($FeCl_3$, $LnCl_3$),[7,16] which leads to derivatives of the type Cp_2LnX. Fragmentation of the Cp derivatives of the lanthanides under electron impact begins with the elimination of the Cp ring.[3,128] The energy of the bond between the Ln^{3+} cation and the cyclopentadienyl rings is in the range 45–78 kcal mol^{-1}.[128,129]

Complexes of the type Cp_2LnX are readily obtained also in the reactions of $LnCl_3$ with alkali metal[16] or thallium[28] cyclopentadienides (in proportions of 1 : 2). Among them lanthanum, cerium, and praseodymium derivatives were missing for a long time. However, the use of trimethylene-1,1-bis-cyclopentadienyl or Me_3Si-substituted Cp rings as ligands made it possible to obtain halogen-containing complexes of these metals as well.[81,97] The same methods, i.e. the reactions of Cp_3Ln with LnCl and HCl or $LnCl_3$ with CpNa, are used to synthesise the monocyclopentadienyl compounds $CpLnCl_2$.[130] Dicyclopentadienylmercury can also serve as a donor of Cp groups.[106]

In terms of their physical properties, the halogeno-derivatives are close to the compounds of the Cp_3Ln series. Their reactivity is determined by the presence of a mobile anion X, which can be readily replaced by another functional group by reaction with the corresponding alkali metal derivative:

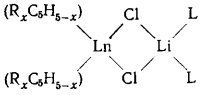
$$Cp_2LnX + M\text{-}Z \rightarrow Cp_2Ln\text{-}Z + MX;$$
$$M = Li,\ Na;\ Z = Alk,\ OR,\ OCOR,\ NH_2,\ PR_2.$$

These reactions are examined in detail in other Sections of this review. The complexes Cp_3CeCl and Cp_2CeCl_2 [synthesised by the reactions of $(PyH)_2CeCl_6$ with CpNa][7] and their derivatives Cp_3CeZ,[131,132] obtained like the complexes Cp_2LnZ, are known for cerium.

In recent years attention has been concentrated in the study of derivatives of Cp_2LnX series (as well as other cyclopentadienyl complexes of the lanthanides) on the determination of their structure by X-ray diffraction. It was found that the metal atoms in the $CpErCl_2.(THF)_2$,[133] $(Me_5C_5)_2.YbSCSNEt_2$,[134] $(MeC_5H_4)_2YbCl.Me_2PCH_2PMe_2$,[124] and $\{[(Me_3Si)_2C_5H_3]_2LnCl\}_2$ (Ln = Sc, Pr, or Yb)[97] have distorted tetrahedral coordination, as in the dimers $[(MeC_5H_4)_2YbCl]_2$ [135] and $(Cp_2ScCl)_2$ [136] investigated previously.

A distinctive feature of the cyclopentadienyl complexes of the lanthanides is their tendency to form bimetallic complexes of the type $[Cp_2LnCl_2]Li.(THF)_2$.[16,97,137–139] These compounds are apparently formed in the intermediate stages of all the reactions of $LnCl_3$ with alkali metal cyclopentadienides.

For the 1 : 2 reactant ratio, they become the final products and can be isolated in high yields. X-Ray diffraction studies of the complexes $\{[(Me_3Si)_2C_5H_3]_2NdCl_2\}Li.(THF)_2$,[122] $[(Me_5C_5)_2YbCl_2]Li.(Et_2O)_2$,[139] and $[(Ph_2MeSiC_5H_4)_2.YbCl_2]Li.(Et_2O)_2$ [139] showed that the Ln and Li atoms in them are linked by bridging Cl atoms:



The iodine analogue $[(Me_5C_5)_2YbI_2]Li.(Et_2O)_2$ and the aluminium-containing complex $[(Me_5C_5)_2YbCl_2]AlCl_2$ have the same structure.[139] The solvents L in these complexes are usually THF or Et_2O, in which the syntheses were carried out. These solvent molecules can also be readily substituted by other stronger bases, for example DME [dimethoxyethane (Editor of Translation)] and tetramethylethylenediamine.

A different structure, characterised by the presence of the anion $[(Me_3SiC_5H_4)_2NdCl_2]^-$, has been proposed for the complex $[(Me_3SiC_5H_4)_2NdCl_2][Li(THF)_4]$ formed when $[(Me_3SiC_5H_4)_2NdCl]_2$ reacts with $LiCl.(THF)_4$ or when $Me_3SiC_5H_4Li$ reacts with $NdCl_3$.[140] The authors found evidence supporting this structure, namely the fact that the Cl–Nd–Cl angle (99.3°), the Nd–Cl distance [2.668(4) Å], and the average Nd–C_{ring} distance (2.78 Å) in the complex $[(Me_3SiC_5H_4)_2][AsPh_4]$ differ appreciably from the corresponding values (81.1°, 2.744 Å, and 2.76 Å) in the bridged compound $[(Me_3Si)_2C_5H_3]_2Nd(\mu\text{-}Cl)_2Li.(THF)_2$.

The reaction of equimolar amounts of $YbCl_3$ and Me_5C_5Li yielded the monocyclopentadienyl complex $[Me_5C_5YbCl_3]Li.THF$.[139] The analogous iodine derivative $(Me_5C_5YbI_3)Li.(Et_2O)_2$ has been obtained by the reaction of metallic ytterbium with Me_5C_5I in the presence of LiI.[79]

3. Indenyl, Fluorenyl, and Cycloheptatrienyl Complexes

A study of the idenyl complexes of the lanthanides was first undertaken by Tsutsui and Gyfling in their search for evidence that *f* electrons are involved in the formation of chemical bonds.[141,142] The compounds $(C_9H_7)_3Ln.THF$ (Ln = La, Sm, Gd, Tb, Dy, or Yb) were obtained by the reaction of C_9H_7Na with $LnCl_3$ in THF. On the basis of NMR data, it was postulated that the samarium complex is covalent. However, subsequent X-ray diffraction study of a non-solvated $(C_9H_7)_3Sm$ specimen demonstrated the η^5-coordination of the indenyl ligands.[143]

The cerium derivatives $(C_9H_7)_xCeCl_{4-x}$ (x = 2, 4)[22,98] and the tetrahydroindenyl complexes $(C_9H_{11})_xLnCl_{3-x}$ (Ln = La, Nd, or Er; x = 1, 2)[144] were synthesised analogously.

The properties of the indenyl complexes are similar to those of the cyclopentadienyl compounds, but, in contrast to the latter, they do not sublime and are soluble in hydrocarbons.

Among the series of fluorenyl derivatives, tri- and tetrafluorenylcerium, synthesised by the reaction of fluorenylsodium with $(PyH)_2CeCl_6$,[145] and the bimetallic complexes $(C_{13}H_9)_2LnCl_2Li.(THF)_2$ (Ln = La, Nd, Sm, Ho, or Lu) are known.[146,147] The latter are formed by the reaction of $C_{13}H_9Li$ with the chlorides $LnCl_3$. Analysis of the infrared and ^1H NMR spectra of these complexes indicated that the fluorenyl residues are linked via σ-bonds to the Ln atom, while the chlorine atoms are bridging; the THF molecules are coordinated to the lithium atom.

It has been shown[148] that the addition of UCl_4 to lithium R-cycloheptadienide induces the rapid formation of an unstable organouranium compound containing the cycloheptatrienyl anion $C_7H_6R^-$ (R = H, Me, or Bu) as the ligand. Analogous complexes have been obtained with gadolinium and erbium chlorides. It has been suggested that the ions of the *f* elements attract to themselves the electron density of the cycloheptadienyl ligands, increasing thereby the polarisation of the C–H bonds of the methylene groups and hence facilitating the elimination of the proton and the formation of trienyl ligands.

The cerium complex $(C_7H_7)_2CeCl_2$ has been obtained in the form of brown crystals by the reaction[149]

$$(PyH)_2CeCl_6 + 2C_7H_8 \rightarrow (C_7H_7)_2CeCl_2 + 2C_5H_5N\cdot HCl + 2HCl\,.$$

Its structure has been confirmed by elemental analysis and infrared spectroscopic data.

4. Cyclo-octatetraenyl Complexes

During the last five years, these compounds have not been investigated; after the establishment of their similarity to the thoroughly investigated "uranocene", the interest in them decreased appreciably. The lanthanide compounds containing the $C_8H_8^{2-}$ dianion can be obtained by the reaction of the metal with cyclo-octatetraene in liquid ammonia:[150]

$$Ln + C_8H_8 \rightarrow LnC_8H_8\,;$$
$$Ln = Eu,\ Yb\,.$$

In a more universal method, $K_2C_8H_8$ is used:[151,152]

$$LnCl_3 + xK_2C_8H_8 \xrightarrow{THF} \begin{cases} \rightarrow [(C_8H_8)_2Ln]K + 3KCl\,; \\ \quad Ln = Sc,\ Y,\ La,\ Ce,\ Pr,\ Nd,\ Sm,\ Gd,\ Tb\,. \\ \rightarrow [C_8H_8LnCl\cdot(THF)_2]_2 + 2KCl\,; \\ \quad Ln = Sc,\ Ce,\ Pr,\ Nd,\ Sm\,. \end{cases}$$

In the latter case, bimetallic or chlorine-containing complexes are formed, depending on the ratio of the initial reactants. It has been shown by X-ray diffraction[153] that the cerium and bridging chlorine atoms in the cerium dimer $[C_8H_8CeCl.(THF)_2]_2$ form a planar four-membered ring with Ce–Cl distances of 2.855(2) and 2.935(2) Å. The cerium atom is located symmetrically relative to the C_8H_8 planar ring. The anion $(C_8H_8)_2Ce^-$ in the complex $[(C_8H_8)_2Ce][K(MeOCH_2CH_2)_2O]$ has the characteristic "metallocene" structure with an average Ce–C distance of 2.742(8) Å.[154]

The complex $(C_8H_8)_2Ce$ has been isolated in the form of a black crystalline substance on reduction of tetraisopropoxycerium with triethylaluminium in the presence of cyclo-octatetraene.[155] A decrease of the excess of C_8H_8 leads to the formation of the complex $(C_8H_8)_3Ce_2$, in which there are two different types of C_8H_8 ligands according to infrared spectroscopic data. Products with the same stoichiometry have been obtained by the cocondensation of the lanthanide (Ln = La, Ce, Nd, or Er) and cyclo-octatetraene vapours at −196 °C.[156,157] It has been shown by X-ray diffraction of the neodymium derivative $[(C_8H_8Nd.(THF)_2][(C_8H_8)_2Nd]$ [157] that the C_8H_8 rings in the anion $(C_8H_8)_2Nd^-$ are not parallel and are separated by different distances from the Nd atom. The cation $[C_8H_8Nd.(THF)_2]^+$ is located asymmetrically relative to the anionic group and two carbon atoms of one of the C_8H_8 rings of the anion are in the coordination sphere of the cationic Nd atom (see Figure). The corresponding lanthanum, cerium, and erbium complexes are isostructural with the neodymium complex.

Quantum-chemical calculation for the anion $(C_8H_8)_2Ce^-$ showed[158] that the interaction of the 5*d* orbitals of the metal with the ligands makes a decisive energy contribution, while the *f* electron is localised at the metal.

The cyclopentadienyl-cyclo-octatetraenyl complexes C_8H_8LnCp are known for Sc, Y, Nd, Sm, Ho, and Er.[151,159] A "sandwich" structure has been proposed for these compounds.

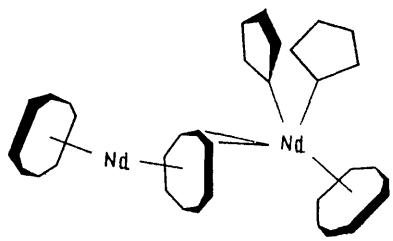
V. COMPOUNDS WITH AN Ln–E BOND

1. Compounds with an Ln–N Bond

The amido-derivatives $Ln(NR_2)_x$ (x = 2, 3), $Cl_2Ln\,NR_2$, and Cp_2LnNR_2, the phthalocyanines Pc_2Ln and PcLnH, and porphyrins are known among complexes of this class. In all cases R in the NR_2 fragment is the trimethylsilyl group. Only a mention has been made of the isopropylamides $Ln[N(Pr\text{-}iso)_2]_3$ (Ln = Y, Yb, or Nd)[160] without any description of the methods of synthesis and properties of these compounds. The amidolanthanides, obtained for the first time in 1972[161] by the reaction

$$LnCl_3 + 3LiN(SiMe_3)_2 \rightarrow Ln[N(SiMe_3)_2]_3 + 3LiCl$$

have been most thoroughly investigated.



The structure of the complex $[C_8H_8Nd(THF)_2][(C_8H_8)_2Nd]$.

Derivatives of bivalent ytterbium and europium are formed when EuI_2 and YbI_2 are used in this process[162] and also when the chloride $ClEu(NR_2)_2$ is reduced with sodionaphthalene.[163]

The disproportionation reaction[164]

$$2\,PrCl_3 + Pr[N(SiMe_3)_2]_3 \rightarrow 3Cl_2PrN(SiMe_3)_2$$

which is extremely characteristic of lanthanide compounds, has been used to synthesise mixed chloroamide complexes. The same product and its neodymium analogue have been obtained by the hydrochlorination of $Ln[N(SiMe_3)_2]_3$.[164]

An X-ray diffraction study has been made of the complexes $Ln[N(SiMe_3)_2]_3$ (Ln = Nd,[165] Sc, Eu, or Yb[166]), $Eu[N(SiMe_3)_2]_2(DME)_2$,[163] and $Yb[N(SiMe_3)_2]_2[Me_2PCH_2CH_2.PMe_2]$[162] and showed that, in the absence of a coordinating ligand, the group $Ln(N<)_3$ has a pyramidal configuration (the Ln atom is displaced from the N_3 plane by approximately 0.4 Å). The addition of the ligand (DME) increases the polarity of the $Ln(N<)_3$ fragment.

In the last of the complexes enumerated above interaction between the Yb atom and the carbon atoms of the $SiMe_3$ groups, which is unusual for a compound of this kind, was observed. (The Yb...C distance is 3.4 Å, which is less than the sum of the covalent radius of Yb^{2+} and the van der Waals radius of the methyl group.)

Compounds with the NH_2 group at the lanthanide atom, namely $CpLnNH_2$ (Ln = Er or Yb) have been synthesised in the course of a study of the reactivity of the cyclopentadienyl derivatives. They are formed when Cp_2LnCl interacts with sodium amide[167] and in the thermolysis of the ammine complexes Cp_3LnNH_3.[168] The last reaction has also been used to synthesise the cyclopentadienylbis(trimethylsily)amide complexes $(Me_5C_5)_2LnN(SiMe_3)_2$ and $Me_5C_5Ln[N(SiMe_3)_2]_2$ (Ln = Nd or Yb).[137]

The lanthanide amides $Ln(NR_2)_3$ are crystalline substances, which are extremely sensitive to moisture and which sublime *in vacuo* at 80–100 °C. The cyclopentadienyl derivatives Cp_2LnNR_2 are less volatile. Their high reactivity and relative availability makes these compounds convenient starting materials for the synthesis of organolanthanides of other classes. Thus it has been found that $Ln[N(SiMe_3)_2]_3$ (Ln = Pr or Nd) react exothermically with carbon dioxide in DME at 20 °C and 1 atm, forming the complexes $Ln[N(SiMe_3)_2]_3.2CO_2$.[169] Their structure has not been accurately established, but, on the basis of infrared spectroscopic data, one may conclude that it differs from that of the erbium and ytterbium carbamate complexes $Ln(OCONR_2)$, obtained by the reaction of LnX_3 with carbon dioxide and amines R_2NH.[170]

The phthalocyanine and porphyrin complexes of metals constitute a specific group of coordination compounds and are usually not dealt with in reviews and monographs devoted to the chemistry of organometallic compounds. We thought it useful to consider these compounds briefly, because they possess a number of interesting properties and information about them significantly completes our ideas about the possibilities of organolanthanides.

The complexes Pc_2LnH ($Pc = C_{32}H_{16}N_8^{2-}$), obtained by the reaction of lanthanide acetates with *o*-phthalonitrile at 280–290 °C, should probably be regarded as the first reliably characterised lanthanide-phthalocyanines.[171,172] This method is virtually the only convenient procedure for the synthesis of phthalocyanine compounds, which can have the compositions Pc_2LnX, Pc_2Ln, and Pc_3Ln_2. They are all intensely coloured crystalline substances which are stable in air. The interest in them has increased particularly after the discovery of the electrochemical properties of lanthanide-diphthalocyanines.[173] It has been established[174] that their colour is determined by the oxidation state of the lanthanide in the complex: violet for Pc_2Lu^{2-}, blue for $PcLu^-$, green for Pc_2Lu, and red-brown for Pc_2Lu^+.

An X-ray diffraction study of Pc_2NdH[175] showed that the neodymium atom in this complex occupies the central position between two parallel phthalocyanine ligands, one of which has the form of a saucer extended towards the Nd atom. One ligand has been rotated relative to the other by 45° around the normal to their planes. The Nd–N distance varies from 2.39 to 2.49 Å. The photoelectron spectrum of this complex[175] indicates the chemical equivalence of all eight central nitrogen atoms, whence it follows that the mobile hydrogen atom does not form a strong bond with any of them, although a weak interaction is not excluded.

A porphyrin complex, tetraphenylporphyrinacetylacetonato-europium, has been obtained (for use as a shift reagent) by heating $(C_5H_7O_2)_3Eu$ with tetraphenylporphyrin.[176] The compound is readily soluble in organic solvents and is stable in relation to oxygen and water. The samarium, gadolinium, erbium, and ytterbium complexes as well as the octaethylporphyrin complexes of europium, gadolinium, ytterbium, and lutetium have been obtained analogously.[177] The single band in the photoelectron spectra of the nitrogen atoms in these compounds indicates their equivalence. The relatively high energy of this band (398 eV) indicates a significantly covalent character of the Ln–N bond, according to the authors.[177]

2. Compounds with an Ln–P Bond

Apart from the complexes containing a P–Ln coordinate bond (which are considered among cyclopentadienyl derivatives), only a few compounds with the Ln–P group are known. They include the trisphosphine compounds

$Ln[P(Bu\text{-}t)_2]_3.(THF)_2$ (Ln = Y, Ho, Er, Tm, Yb, or Lu)[178] and derivatives of the Cp_2LnPR_2 series (Ln = Tb, Ho, or Er and R = t-Bu;[179] Ln = Yb and R = cyclo-C_6H_{11} [180]). Compounds of both types have been obtained by the reaction of $LiPR_2$ with the corresponding lanthanide chloride:

$$LnCl_3 + 3LiP(Bu\text{-}t)_2 \xrightarrow{THF} Ln[P(Bu\text{-}t)_2]_3.(THF)_2 + 3LiCl;$$
$$Cp_2LnCl + LiPR_2 \rightarrow Cp_2LnPR_2 + LiCl .$$

The exchange reaction between Cp_2ErCl and $Me_3SiP(Bu\text{-}t)_2$ has been used to obtain $Cp_2ErP(Bu\text{-}t)_2$.[175] When the tris-phosphine complexes are heated *in vacuo*, they lose the solvate THF and are converted into the coordination polymer $\{Ln[P(Bu\text{-}t)_2]_3\}_x$.

Bis(methylcyclopentadienyl)(diphenylphosphine)samarium was synthesised recently by the hydride method:[80]

$$[(MeC_5H_4)_2SmC{\equiv}CPh]_2 + 2HPPh_2 \rightarrow 2(MeC_5H_4)_2SmPPh_2 + 2PhCCH .$$

This reaction is particularly convenient for the formation of the metal–heteroelement bond.

All the phosphine derivatives of lanthanides are yellow or orange substances which are stable in an inert atmosphere, but, like the majority of the organolanthanides, hydrolyse extremely readily in moist air.

3. Compounds with Ln–O, Ln–S, and Ln–Se Bonds

The greatest number of publications on derivatives of the Ln–O group referred to β-diketonates and similar chelate complexes. They have been surveyed in a recent review[15] devoted to the Ln–O–C derivatives and will not be considered here. The compounds discussed below include the alkoxides $Ln(OR)_3$, $Cl_xLn(OR)_{3-x}$, and $R'_xLn(OR)_{3-x}$, complexes of the $Ln[M(OR)_4]_3$ series, the mercaptides $Ln(SR)_3$, and thier Se analogues.

The alkoxides $Ln(OR)_3$ are comparatively readily available, are appreciably volatile and soluble, and exhibit a high reactivity, as a result of which they are convenient starting materials for the synthesis of other derivatives. The lanthanide isopropoxides are used particularly frequently. The alkoxides can be obtained by the reaction of the alcohols with the metal, $LnCl_3$, or another alkoxide $Ln(OR')_3$:[181]

$$Ln + 3ROH \rightarrow Ln(OR)_3 + {}^3/_2H_2 ;$$
$$LnCl_3 + 3ROH \xrightarrow{NH_3} Ln(OR)_3 + 3NH_4Cl ;$$
$$Ln(OR')_3 + 3ROH \rightarrow Ln(OR)_3 + 3R'OH .$$

The OR/OR′ exchange is also observed in the reaction of $Ln(OR)_3$ with the esters CH_3COOR' (R′ = alkyl or $SiMe_3$).[182] The reaction of $LnCl_3$ with alkali metal (Li, Na) alkoxides is more convenient for the synthesis of trialkoxides:

$$LnCl_3 + 3MOR \rightarrow Ln(OR)_3 + 3MCl_3 .$$

It is preferable to use NaOR, since LiCl dissolves in the solvents employed more readily than NaCl, which hinders the isolation of the pure $Ln(OR)_3$.

In a recent study[183] it has been shown that scandium, yttrium, and lanthanum tri-isopropoxides can be fairly readily obtained by a direct electrochemical method. The anodic dissolution of the metal is achieved by means of diaphragm-free electrolysis in absolute alcohol with Bu_4NBr as the electrically conducting additive; best results have been obtained using an alternating current.

The alkoxides $Ln(OR)_3$ can exist in the form of monomers and associated coordination species,[183] the degree of association (and hence the volatility and solubility of the alkoxide) being determined by the nature of Ln, the bulk of R, the method of synthesis, and the technique used to isolate the product. With increase of the degree of branching of R, the degree of association diminishes sharply.

The monomeric phenoxides $Ln(OAr)_3$ [Ar = hindered 2,6-di(t-butyl)-4-methylphenyl, Ln = Sc, Y, La, Pr, Nd, Dy, Ho, or Yb] have been synthesised by the usual method, i.e. by the reaction of NaOAr with $LnCl_3$.[184] X-Ray diffraction of the scandium derivative of this series showed that the Sc and O atoms form a planar group; the average O–Sc–O angle is 119.5°.

The use of LiOAr in reactions with lanthanide chlorides with a specific stoichiometry leads to bimetallic complexes with bridging chlorine atoms, namely $[Ln(OAr)_2(\mu\text{-}Cl)_2Li.(THF)_2]$ and $[LnCl(OAr)(\mu\text{-}Cl)_2Li.(THF)_2]$.[122]

The asymmetric cerium(IV) complex $Cp_3CeOPr\text{-}iso$ has been obtained in a low yield by the reaction of cerium tetraisopropoxide with Cp_2Mg.[155]

A characteristic feature of lanthanide alkoxides is their ability to form bimetallic complexes of the type $Ln[M(OR)_4]_3$ (R = iso-Pr; M = Al, Ga, In, or Zr).[15,185] These products are readily soluble and are appreciably volatile (they distil or sublime at 180–200 °C and 0.1 mmHg). They are readily formed on interaction of $LnCl_3$ with $KM(OR)_4$ or with potassium alkoxide in the presence of the salt MCl_3 as well as on simple mixing of the alkoxides $Ln(OR)_3$ and $M(OR)_x$ in alcoholic or tetrahydrofuran solution. The latter reaction was subjected to a detailed investigation,[185] which showed that the complexes can contain solvating alcohol molecules and can have a variable composition with respect to the metals; their solubility changes significantly under these conditions.

The study of the interaction of PhLnI (Ln = Ce, Sm, Eu, or Yb) with the ketones RCOR′ showed[58] that under mild conditions the products are the alkoxides RR′PhCOLnI, which afford the corresponding alcohols after hydrolysis. In the presence of an excess of PhLnI the alkoxide formed is deoxygenated; the hydrolysis product is in this case an olefin. It is noteworthy that in the reaction with a chalcone the PhLnI adds exclusively in the 1,2-positions, while PhLi and PhMgI give rise to both 1,2- and 1,4-adducts.[58]

The first compounds containing an Ln–S bond (thioacetonate, thiocarbamate, and phosphinothioate complexes and thiophenoxides) were obtained at the end of the 1960's.[15,186] The methods of their synthesis do not differ fundamentally from those for the oxygen analogues.

A series of compounds with substituted thiophenyl groups, having the general formula $(iso\text{-}PrO)_{3-x}Ln(SAr)_x$ (Ln = Pr, Nd, or Sm; Ar = 4-ClC_6H_4, 4-t-BuC_6H_4, or 4-t-Bu-2-Me-C_6H_3; x = 1, 2, 3), have been obtained in the reactions of lanthanide tri-isopropoxides with the corresponding phenols for different reactant ratios.[187] The mercaptides derived from the cyclopentadienyl and indenyl complexes Cp_3CeSr and $(C_9H_7)_2Ce(SR)_2$ are known for cerium(IV).[132]

Lanthanide alkylmercaptides were obtained recently[188] via the amido-derivatives:

$$[(Me_3Si)_2N]_3Ln + x\,n\text{-}BuSH \rightarrow [(Me_3Si)_2N]_{3-x}Ln(SBu\text{-}n)_x;$$
$$Ln = Pr, Nd, Sm, Gd;\ x = 1{-}3 .$$

The asymmetric derivatives (x = 1, 2) are readily formed also in the disproportionation reaction between $(R_2N)_3Ln$ and $(n\text{-}BuS)_3Ln$.

The lanthanide organoselenides of the type $(n\text{-}BuSe)_3Ln$ (Ln = Pr, Nd, or Sm) have been synthesised very recently[189] by analogy with the thio-derivatives. Ytterbium(II) butylselenide has been obtained by the reaction of n-BuSeH with $[(Me_3Si)_2N]_2Yb$.

All the symmetrical mercaptides and selenoxides are very sensitive to the action of moisture, are almost insoluble in organic solvents, and, in contrast to the alkoxides, are involatile. On the other hand, the monomercaptides $[(Me_3Si)_2N]_2LnSBu\text{-}n$ sublime *in vacuo* at 140–160 °C and are readily soluble in toluene, THF, and hexane.

In the study of the reactivity of lanthanide compounds relative to small molecules, it was found that the tervalent lanthanide alkoxides, mercaptides, and selenides readily combine with three equivalents of carbon dioxide under normal conditions.[189,190] The addition is accompanied in all cases by the insertion of CO_2 in the Ln–X bond with formation of carbonate, thiocarbonate, and selenocarbonate structures, which is indicated by the appearance of intense absorption bands in the ranges 1530–1580 and 1330–1350 cm^{-1} in the infrared spectra of the products:

$$(t\text{-}BuO)_3Ln + 3CO_2 \rightarrow \quad (t\text{-}BuOCO_2)_3Ln \ ;$$
$$Ln = Pr, Nd, Sm \ .$$

A difference is observed in the reaction of CO_2 with the mercaptides $(n\text{-}BuS)_3Ln$. The addition of the third carbon dioxide molecule is accompanied in this case by the appearance of a band at 2380 cm^{-1} in the infrared spectrum. The high value of this frequency suggests that the third CO_2 molecule adds as a coordinated species. The thiocarbonates readily undergo decarboxylation:[190]

$$(RS)_3Pr \underset{-CO_2;\ 200°}{\overset{+CO_2;\ 20°}{\rightleftarrows}} RSCO_2Pr(SR)_2 \underset{-CO_2;\ 130°}{\overset{+CO_2;\ 20°}{\rightleftarrows}} (RSCO_2)_3PrSR \rightleftarrows$$
$$\underset{-CO_2;\ 90°}{\overset{+CO_2;\ 20°}{\rightleftarrows}} (RSCO_2)_2PrR\cdot CO_2 \ ;$$
$$R = n\text{-}Bu.$$

The decarboxylation of the carbonates $(t\text{-}BuOCO_2)_3Ln$ is accompanied by the side reactions, which render the process irreversible.[190]

4. Compounds with an Ln–M Bond

A report was published in 1971[191] stating that the reaction of metallic erbium with $Hg[Co(CO)_4]_2$ in THF leads to the formation of the product $Er[Co(CO)_4]_3.(THF)_4$. On the basis of infrared spectroscopic data, the authors suggested that the compound contains the Er–Co bond. The same method was used to synthesise the cobalt carbonyl complexes $Ln[Co(CO)_4]_x.(THF)_y$ (Ln = Sm, Eu, Tm, or Yb; $x = 2, 3$; $y = 3, 4$).[192,193] Analogous products containing a variable amount of THF are formed when the free lanthanides react with dinuclear carbonyls[194] or when lanthanide halides react with the anion $Co(CO)_4^-$:[195]

$$Co_2(CO)_8 + Ln \xrightarrow{THF} Ln[Co(CO)_4]_3\cdot(THF)_x;$$
$$M_2(CO)_{10} + Ln \xrightarrow{THF} Ln[M(CO)_5]_3\cdot(THF)_x;$$
$$Ln = Sm, Tm, Yb; \quad M = Mn, Re \ .$$
$$LnCl_3 + 3\,NaCo(CO)_4 \xrightarrow{THF} Ln[Co(CO)_4]_3\cdot(THF)_x;$$
$$Ln = Er, Yb; \ x = 1-4 \ .$$

In the presence of an equimolar reactant ratio, the last reaction gives rise to the formation of the unstable dinuclear compounds $Cl_2LnCo(CO)_4$ (Ln = La, Sm, Dy, Ho, or Yb)[196] and $Cl_2SmM(CO)_5$ (M = Mn or Re).[197]

The easy cleavage of the metal–metal and metal–halogen bonds by metallic lanthanides had also been noted earlier.[198] However, in characterising the lanthanide complexes formed in these reactions, the authors[198] confined themselves to indicating their similarity to Grignard reagents without specifying their structure.

The presence of a direct Ln–M bond has been postulated in all the lanthanide complexes with metal carbonyls indicated above on the basis of the method of their preparation, their reactivity, and their infrared spectra. The exact structure of one of these products, namely $[CpMo(CO)_3]_3La.(THF)_6$, has been recently established by X-ray diffraction.[199] It was found that the La atom is surrounded by three equivalent $CpMo(CO)_3$ fragments and that the bond between the La and Mo atoms is formed via the carbonyl group: Mo–C–O–La. It is natural to suppose that in the erbium analogue $[CpMo(CO)_3]_3Er.(H_2O)_7$ obtained earlier[124] and in the majority of other metal carbonyl complexes of the lanthanides, there is no direct bond between the metal and the lanthanide either. This has been confirmed by structural studies of the cyclopentadienylytterbium complexes $(Me_5C_5)_2YbCo(CO)_4.THF$ and $[(Me_5C_5)_2Yb]_2.[Fe_3(CO)_7(\mu\text{-}CO)_4]$[200,201]), where the presence of a carbonyl bridge has also been established.

One can speak with much confidence about the presence of an Ln–M bond in non-transition metal derivatives. Three main methods for the synthesis of such compounds are known:[2,44,164,202–205]

$$\text{(A)}\ Ln[N(SiMe_3)_2]_3 + 3R_3SnH \xrightarrow{DME} Ln(SnR_3)_3\cdot DME + 3(Me_3Si)_2NH \ ;$$
$$Cl_2LnN(SiMe_3)_2 + R_3SnH \xrightarrow{DME} Cl_2LnSnR_3\cdot DME + (Me_3Si)_2NH \ ;$$
$$Ln = Pr, Nd; \ R = CH_2SiMe_3 \ .$$
$$\text{(B)}\ LnCl_3 + 3LiMPh_3 \rightarrow Ln(MPh_3)_3 + 3LiCl \ ;$$

$$Cp_2LnCl + LiMPh_3 \rightarrow Cp_2LnMPh_3 + LiCl \ ;$$
$$Ln = Pr, Nd, Gd, Er, Yb; \quad M = Ge, Sn \ .$$
$$\text{(C)}\ 7[(C_6F_5)_3M]_2Hg + 2Ln \xrightarrow{DME} 2Ln\{Hg_2[M(C_6F_5)_3]_7\}\cdot(DME)_3 + 3Hg \ ;$$
$$Ln = Pr, Nd, Ho; \ M = Ge, Sn \ .$$

All three methods, (A), (B), and (C), are general and are widely used to synthesise polynuclear compounds, but there are many limitations as regards lanthanide derivatives. Thus, if the germanium hydride Ph_3GeH or triethyltin hydride is used in the Razuvaev–Vyazankin reaction [method (A)], the ether linkage in the solvent (DME) is cleaved and the alkoxides $(R_3M)_xPr(OCH_2CH_2OMe)_{3-x}.DME$ are formed.[202] Compounds obtained by method (B) contain admixtures of side products too difficult to separate (the dicyclopentadienyl complexes, which have been obtained in an analytically pure state, are an exception).[203] The transmetallation reaction [method (C)] requires the presence of electron-accepting substituents at the mercury atom. The complexes obtained by this method are ionic {they comprise the Ln^{3+} cation and anionic species of the type $[(C_6F_5)_3Ge]_3Hg^-$ and $[(C_6F_5)_3Ge]_4Hg^{2-}$} and do not contain, as suggested initially,[204] a direct Ln–Ge bond. Praseodymium does not interact (at 100°, 10 h) with compounds which do not contain electron-accepting substituents, namely $(Et_3Ge)_2Hg$, $(Ph_3Ge)_2Hg$, and $[(Me_3SiCH_2)_3Sn]_2Hg$.[205]

Analogous ionic complexes have been obtained by method (A).[206,207] This is the first example of the synthesis of ionic compounds by the hydride method. The reaction between the lanthanide alkoxide and the hydrogermane is carried out in the presence of acceptors of the germyl anions $(C_6F_4)_3Ge^-$ formed in the first stage of the process. Trinuclear compounds with pentafluorophenyl substituents are used as such acceptors:

$$3(C_6F_5)_3GeH + \quad (t\text{-}BuO)_3Pr + 2[(C_6F_5)_3M]_2M' \xrightarrow{DME}$$
$$\rightarrow\{[(C_6F_5)_3Ge]_3[(C_6F_5)_3M]_4M'_2\}Pr\cdot(DME)_3 + 3\ t\text{-}BuOH;$$
$$M = Si, Ge, Sn; \quad M' = Cd, Hg \ .$$

$(C_6F_5)_3SnH$ reacts analogously. The bifunctional hydrides $(C_6F_5)_2GeH_2$ and $(C_6F_5)_2Ge(H)Ge(C_6F_5)_2H$ produces, in such processes, more involved complexes with anions incorporating up to 10 germanium and mercury atoms.[208]

The disproportionation reaction, which is characteristic of lanthanide derivatives, makes it possible to convert the trisubstituted complexes into asymmetric products:[164]

$$2[(Me_3Si)_2N]_3Pr + [(Me_3SiCH_2)_3Sn]_3Pr\cdot DME \xrightarrow{DME}$$
$$\rightarrow 3[(Me_3Si)_2N]_3PrSn(CH_2SiMe_3)_3\cdot{}^1/_2\ DME \ .$$

All the compounds with the Ln–M group are solids, which are unstable in air and are sparingly soluble in aliphatic and aromatic hydrocarbons; they melt with decomposition on heating to temperatures above 150–200 °C. Their reactivity

has been investigated mainly in relation to $[(Me_3SiCH_2)_3Sn]_3Pr.DME$[202] and $\{[(C_6F_5)_3Ge]_7Hg_2\}Pr.(DME)_3$:[205]

$$(R_3Sn)_3Pr\cdot DME \begin{cases} \xrightarrow[50^\circ]{H_2O} R_3SnMe + (R_3Sn)_2O + Pr(OH)_3 ; \\ \xrightarrow[20^\circ]{HCl} R_3SnMe + R_3SnCl + PrCl_3 + H_2 ; \\ \xrightarrow[120^\circ]{BrCH_2CH_2Br} R_3SnSnR_3 + PrBr_3 + H_2C{=}CH_2 ; \\ \xrightarrow[50^\circ]{(PhCOO)_2} R_3SnOCOPh + R_3SnPr(OCOPh)_2 ; \\ \xrightarrow{CF_3COOAg} R_3SnOCOCF_3 + (CF_3COO)_3Pr + Ag . \end{cases}$$

When the hydrolysis is carried out under milder conditions (20 °C, 30 min), one Sn–Pr bond is retained. The complex $R_3SnPr(OH)_2$ formed is stable in air like the benzoyloxy-derivative $R_3SnPr(OCOPh)_2$, in contrast to the majority of organometallic lanthanide derivatives.

It has been found recently[169] that stannyl-lanthanide complexes combine with carbon dioxide at 20 °C under normal pressure:

$$(R_3Sn)_xPr[N(SiMe_3)_2]_{3-x}\cdot DME + 2CO_2 \rightarrow (R_3Sn)_xPr[N(SiMe_3)_2]_{3-x}\cdot 2CO_2\cdot DME$$
$$x = 1, 3;\ R = CH_2SiMe_3 .$$

The infrared spectra of the adducts contain absorption bands characteristic of coordinated CO_2 (at 2180, 1620, and 1520 cm^{-1}). It is of interest to note that, depending on the conditions, the hydrolysis of these complexes may be accompanied by carbon dioxide evolution or can give rise to a new CO_2-containing product: $R_3SnPr(OH)_2.2CO_2$.

Lanthanide germylmercurates do not combine with carbon dioxide under comparable conditions. Their reactions with hydrogen chloride have been used to determined their structures:[205]

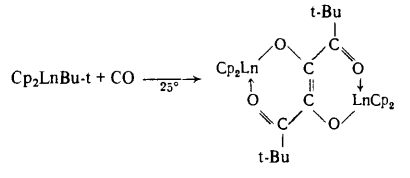
$$\left\{\begin{matrix}[(C_6F_5)_3Ge]_8Hg^- \\ [(C_6F_5)_3Ge]_4Hg^{2-}\end{matrix}\right\} Pr^{3+}\cdot(DME)_3 \begin{cases} \xrightarrow{1HCl} (C_6F_5)_3GeH + \{[(C_6F_5)_3Ge]_4Hg\}PrCl\times \\ \times(DME)_3 + [(C_6F_5)_3Ge]_2Hg \\ \xrightarrow{3HCl} 3(C_6F_5)_3GeH + PrCl_3 + \\ + 2[(C_6F_5)_3Ge]_2Hg ; \\ \xrightarrow{(excess)\ HCl} 5(C_6F_5)_3GeH + 2(C_6F_5)_3GeCl + \\ + 2Hg + PrCl_3 . \end{cases}$$

It is seen from the equations presented above that the ionic groups are the first to decompose.

VI. OTHER COMPOUNDS

The cocodensation of lanthanide vapour with CO in an argon matrix at 4 K leads to the formation of extremely unstable metal carbonyls of the type $Ln(CO)_x$ ($x = 1–6$).[209,210] Analysis of the infrared spectra of these complexes showed that they resemble transition metal carbonyls.

An interesting dionediolate complex has been obtained by the reaction of $Cp_2LnBu\text{-}t$ with an excess of carbon monoxide.[211] The structure of the product has been postulated on the basis of X-ray diffraction data:



Use of 1-pyrazolyl borate ligands frequently makes it possible to obtain unusually high coordination numbers of the metal atoms, for example, six in the case of tin.[212] The interaction of $KHB(C_3H_3N_2)_2$ with $LnCl_3(H_2O)_x$ in water leads to crystalline anhydrous complexes $Ln[HB(C_3H_3N_2)_3]_3$ (Ln = Y, La, Ce, Pr, Sm, Gd, or Er).[213] The asymmetric complexes $Cl_2Er[HB(C_3H_3N_2)_3]$ and $ClEr[HB(C_3H_3N_2)_3]_2$ have been synthesised from anhydrous erbium chloride in THF.

Until recently, only halide clusters of the type Er_7I_{10} were known in the series of lanthanides.[214] However, the first carbon-containing lanthanide clusters, namely $Gd_{10}C_4Cl_{18}$ and $Gd_{10}C_4Cl_{17}$, were obtained in 1982 and their structures were characterised.[215] They are formed in an overall yield of 90% on heating stoichiometric amounts of $GdCl_3$, Gd, and graphite to 800–850 °C. The metallic skeleton of these clusters is made up to two Gd_6 octahedra having a common edge. All the accessible faces of the octahedra are centred on binary carbon groups C_2 with a C–C distance of 1.47 Å and have bridging chlorine atoms. The Gd–Gd bond length is in the range 3.212–4.086 Å for $Gd_{10}C_4Cl_{18}$ and 3.121–4.014 Å for $Gd_{10}C_4Cl_{17}$ (the atomic radius of gadolinium is 1.79 Å).

VII. APPLICATIONS OF ORGANOLANTHANIDES

The principal field in which organic derivatives of the lanthanides are used is catalytic reactions. The catalytic properties of inorganic lanthanide compounds have been known for a long time and have been used in a wide variety of processes, such as the cracking of petroleum, the hydrogenation and dehydrogenation of hydrocarbons, the isomerisation of olefins, the dehydration of alcohols, the synthesis of ketones from alcohols and acids, the cracking of alkanes, the emulsion of polymerisation of acrylonitrile, the manufacture of nylon, etc.[8] The olefin and diolefin polymerisation processes in which catalysts based on the lanthanides as a rule exhibit a higher activity and stereospecificity than other catalytic systems, are the most important.

In the middle 1960's it was observed that a mixture of $LnCl_3$ (Ln = Y, La, Ce, Pr, Nd, Sm, Gd, Er, or Yb) and trialkylaluminium induces the polymerisation of butadiene under mild conditions with the preferenital (>95%) formation of 1,4-*cis*-polybutadiene.[216] Studies on these lines have developed greatly and have now reached the level of industrial application. It has been established that, apart from the mixture inidcated above, stereospecific polymerisation and copolymerisation of diolefins are catalysed by the $LnCl_3.xL/R_3Al$[217–219] and cerium octanoate/R_3Al/halogen[220] systems and by lanthanide phosphates, naphthenates, and carboxylates mixed with R_3Al and a halogen.[219]

Systems based on the "light" lanthanides (Ce, Pr, and Nd) show the highest activity. Catalysts with bivalent lanthanides are inactive. The addition of a small amount of alcohol to the $LnCl_3/R_3Al$ binary system appreciably increases its activity without altering its stereospecificity.[221] It has been found that a new effective catalyst, namely $LnCl_3.3ROH/R_3Al$, is formed under these conditions. Allyl complexes of the type $LiLn(C_3H_7)_4.$dioxan (Ln = Ce, Nd, Sn, Gd, or Dy) induce the rapid and far-reaching polymerisation of butadiene.[8] A stereoregular 1,4-polymer is also formed in this instance, but (in contrast to the catalyst quoted above) it has the *trans*-structure to the extent of 80–90%. The 1,4-*trans*-polymer is also obtained in the presence of tribenzylneodymium etherate $(PhCH_2)_3Nd.(Et_2O)_3$.[40] It has been suggested that all three Nd–C bonds participate in the polymerisation with formation of tricrotyl- (or tri-isopropenyl)-neodymium complexes in the intermediate stages.

The LnX_3/R_3Al, $LnX_3(LnO)/RLi(RMgX)$, $Ln/Mo_2O_3/Al_2O_3$, $Ln(acac)_3/R_3\text{-}_mAlX_mPPh_3$, LnO/MH,[8] $(Me_5C_5)_2Ln.L$, and $(Me_5C_5)_2LnMe$ (Ln = Sm, Eu, Yb, or Lu; L = Et_2O, THF, or R_3Al) systems are used for the polymerisation of ethylene and its derivatives.[222] Weak catalytic properties have been

observed also in catalysts of the Ziegler–Natta type containing the cyclo-octatetraenylcerium complexes $Ce(C_8H_8)_2$, $Ce_2(C_8H_8)_3$, and $C_8H_8Ce(O\text{-}Pr\text{-}iso)_2AlEt_2$. The dimeric complexes $[(RC_5H_4)_2LnMe]_2$ and $(RC_5H_4)_2LnMe_2AlMe_2$ (Ln = Y, Ho, Er, or Yb; R = H, Me, or $SiMe_3$) are effective homogeneous catalysts of the polymerisation of ethylene.[87] The processes take place at 75 °C and 5 atm in the presence of the lanthanide complex and at 95° and 33 atm in the presence of an aluminium-containing catalyst.

The stereospecific polymerisation of phenylacetylene with formation of the *cis*-polymer (80–100%) in the presence of systems comprising lanthanide naphthenate or phosphonate complexes and R_3Al, sometimes with the addition of a third component, has been mentioned.[223]

Thus, in all the catalytic lanthanide systems active in the polymerisation reactions of unsaturated hydrocarbons, an Ln–C bond is present or is formed in the initial stages of the process. A study of the mechanism of these processes in relation to the model reaction of $(Me_5C_5)_2LuMe.Et_2O$ with propene[78] and of the thermal decomposition of the butyl derivative $(Me_5C_5)_2LuBu$ [224] enabled the authors of these investigations to propose a general mechanism of polymerisation in the presence of organolanthanide catalysts. Three main reaction pathways involving the Ln–R groups have been suggested: (a) the insertion of the olefin with formation of Ln–C–C–R; (b) the β-hydride decomposition of Ln–R and the subsequent insertion of the olefin in the Ln–H bond with formation of Ln–C–C–H; (c) the β-alkyl decomposition of Ln–R and the subsequent insertion of the olefin in the Ln–R′ bond. One should note that, in the presence of coordinated ligands in the catalyst molecule, the above stages are preceded by the dissociation of the Ln ← L bond.[78,222] This mechanism of the polymerisation of olefins in the presence of organic derivatives of the lanthanides is consistent with other data, for example, the incorporation of CO_2 in the oligomeric complex $Ln–(CH_2)_x–Me$, which leads to the corresponding acids $Me–(CH_2)_x–COOH$ after hydrolysis.[219]

The complexes formed on cocodensation of the vapours of the lanthanide (Nd, Sm, Er, and Yb) and acetylene derivatives RC ≡ CR′ catalyse the hydrogenation of alkenes and alkynes by hydrogen under normal conditions.[26,95,108,225] The mechanism of these reactions, proposed by Evans et al,[26] involves the formation of the lanthanide hydride in the initial stage:

$$Ln–R + H_2 \rightarrow Ln–H + RH \quad ;$$

$$Ln–H + RC{\equiv}CR \rightarrow \underset{R}{\overset{Ln}{}}\!\!>C{=}C<\!\!\underset{R}{\overset{H}{}} \quad ;$$

$$\underset{R}{\overset{Ln}{}}\!\!>C{=}C<\!\!\underset{R}{\overset{H}{}} + H_2 \rightarrow \underset{R}{\overset{H}{}}\!\!>C{=}C<\!\!\underset{R}{\overset{H}{}} \quad .$$

The complexes formed when the SmMg alloy is treated with anthracene in THF[226] and the alloy $LaNi_5$ [227] are also capable of activating molecular hydrogen. Both compounds readily absorb hydrogen to form hydrides and the latter reduce olefins to alkanes under mild conditions.

The lanthanide salts have marked catalytic properties. For example, SmI_2 and YbI_2 catalyse the deoxygenation of epoxides and sulphoxides, the reduction of aldehydes, the conversion of alkyl halides into alkanes, and the synthesis of tertiary alcohols from ketones and RX.[228,229] The salts of tervalent lanthanides promote or catalyse the oxidation of benzoins to benzils,[230] the formation of pyrimidine,[231] and the selective 1,2-reduction of conjugated ketones by sodium tetrahydroborate.[232] It has been found that lanthanum, cerium, praseodymium, neodymium, and samarium β-nitroso-α-naphthoxides, deposited on alumina, catalyse the dehydrohalogenation of 3,4-dichlorobut-1-ene to give chloroprene.[233]

In the above processes the initial catalysts are inorganic derivatives, but organolanthanides are apparently formed in all cases as intermediates.

Cerium amalgam readily reacts with alkyl and benzyl iodides in a ketone to form the tertiary alcohol $H_2C = CHCH_2C(R).(R')OH$ or $PhCH_2C(R)(R')OH$.[234] These reactions demonstrate the preparative possibilities of the lanthanides.

The use of organic derivatives of lanthanides as antiknocking agents in motor fuels is promising.[8] Particularly satisfactory results have been obtained for cerium, praseodymium, neodymium, and ytterbium, 2,2,6,6-tetramethylhepta-3,5-dionates whose antiknocking properties are superior to those of tetraethyl-lead.

The β-diketonates and similar chelate complexes of the lanthanides have also found extensive applications as shift reagents in NMR spectroscopy.[235]

Russian Chemical Reviews

September 1985

This issue is devoted to the 70th anniversary of the birth of the outstanding Soviet scientist Academician Nikolai Markovich Emanuel' who directed the journal "Uspekhi Khimii" from 1972 until the last days of his life.

Emanuel"s scientific interests embraced many fields of science: the chemical physics of the liquid-phase oxidation of organic substances; elementary reactions and kinetics of processes in the condensed phase; the ageing and stabilisation of polymers; the kinetics of biological, mainly pathological, processes.

The issue includes articles by a number of the pupils of Academicain Emanuel'. They demonstrate the breadth of his thought and a surprising ability to foresee the scientific prospects for the development of particular branches of science.

Translated from *Uspekhi Khimii*, 54,1393-1419 (1985) U.D.C. 547.91.222

The Chemical Physics of the Ageing and Stabilisation of Elastomers

N.M.Emanuel' (deceased)

The ageing and stabilisation of elastomers are considered from the standpoint of chemical physics. A general method for the fitting to the kinetic curves of relations characterising the ageing of elastomers under the influence of oxygen, light, ozone, and mechanical stresses is discussed. Different principles and procedures for the stabilisation of elastomers are analysed. The bibliography includes 75 references.

INTRODUCTION

Modern chemistry is concerned primarily with new materials for various branches of technology, agriculture, and ordinary life. Elastomers occupy one of the leading positions among such materials and the range of articles based on them is extremely wide.[1] The world production of different types of rubber in 1984 amounted to 14 million tonnes.[2]

The principal deficiency of the majority of elastomers is rapid ageing under operating conditions. Thus, when anticorrosion measures are taken, metals last for 15 and more years. Elastomers and articles prepared from them have in most cases a much shorter useful life.

Ageing is known to be a process which develops with time, i.e. the study of its mechanism is the subject to chemical kinetics. The knowledge of the mechanism of ageing makes it possible to solve rationally the problem of increasing the life of the articles and to predict their likely usefulness under various conditions.

Research into the kinetics and mechanism of the ageing and stabilisation of polymeric materials has developed in recent years on a broad front. A new field in the chemistry of macromolecular compounds, namely the chemical physics of the ageing and stabilisation of polymers, was initiated on the basis of these investigations.[3-5] It includes the study not only of the elementary reactions and macroscopic stages

in the ageing and stabilisation but also the role in these processes of the physical organisation of the polymer, the dynamics of molecular movements, and other physical factors which determine the operating properties of polymeric materials.

In the course of the processing, storage, and use elastomers are acted upon by numerous external factors which cause the initiation and development of chemical and physical processes leading to the alteration of the operating properties (Fig.1). At the present time it is possible to indicate which particular ageing factors act on particular articles containing elastomers (Fig.2). The principal elementary stages in the ageing process, the types of stabilisers, and the mode of their action are also known (Fig.3).

The aim of the present review is to describe the state of the principal trends in the chemical physics of the ageing and stabilisation of elastomers.

II. A GENERAL METHOD FOR THE FITTING OF EQUATIONS TO KINETIC CURVES

In the study of the ageing of elastomers under both natural and artificial conditions, various kinetic relations describing the variation of the parameters of the operating properties of materials or parameters indirectly related to these properties (for example, the absorption of oxygen in

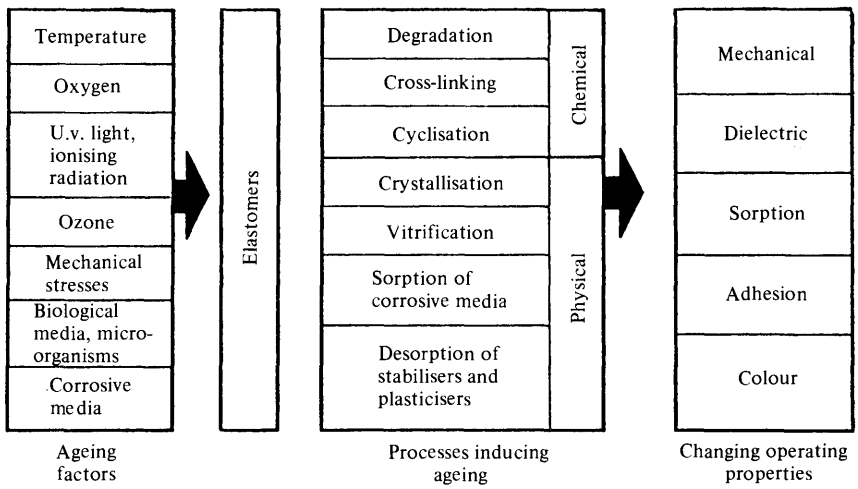

Figure 1. The effect of external factors and the changes in the operating properties of articles as a result of the ageing of elastomers.

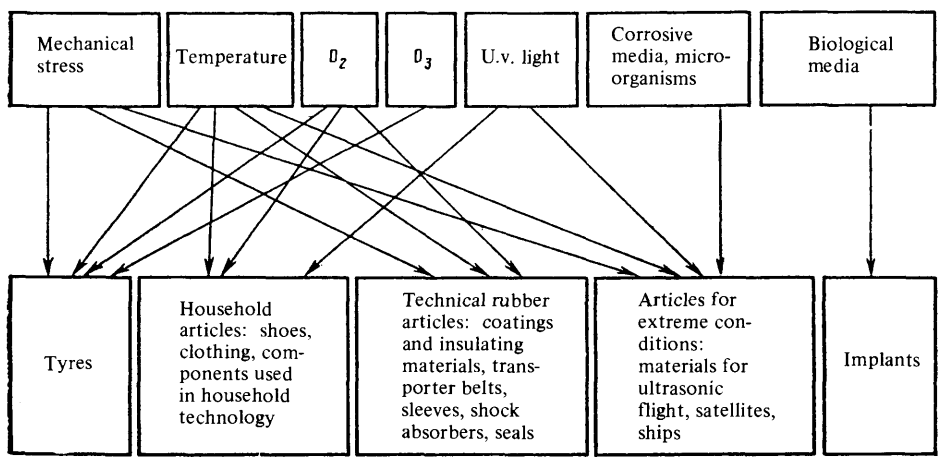

Figure 2. Principal types of articles based on elastomers and the external factors inducing their ageing.

thermo-oxidative ageing, the decrease of the mass of the specimen in thermal degradation, etc.) are obtained.

Extensive experimental data on the kinetics of the ageing of polymers, including elastomers, have now been accumulated. Various types of kinetic curves are known. As an illustration, Fig.4 presents several experimental curves for the ageing of various elastomers.[6-11] In a formal kinetic description of the ageing of polymers, it is of interest to obtain generalised kinetic curves which would make it possible, on the one hand, to classify a set of experimental data, and, on the other hand, would permit the solution of many problems of practical importance, for example the prediction of the behaviour of the operating properties during ageing.

Mathematical functions describing satisfactorily each of the above types of kinetic curves are known. A particular function can be chosen either on the basis of the known process mechanism or on the basis of analogies or an empirical selection by fitting equations to experimental data using the familiar methods of regression analysis.

A wide variety of chemical and physical processes take place in the polymeric material during ageing but under the real storage and operating conditions only some of them alter the operating properties. In many cases the changes in the operating properties can therefore be attributed to the occurrence of specific processes.

The decrease of the tensile strength σ in the high-temperature ageing of polymeric materials is mainly caused by degradation reactions and is described satisfactorily by the equation

$$\varphi = \exp(-\alpha t), \qquad (1)$$

where $\phi = (\sigma/\sigma_\infty - 1)(\sigma_0/\sigma_\infty - 1)^{-1}$, α is the transformation coefficient, and σ_0 and σ_∞ are the initial and limiting

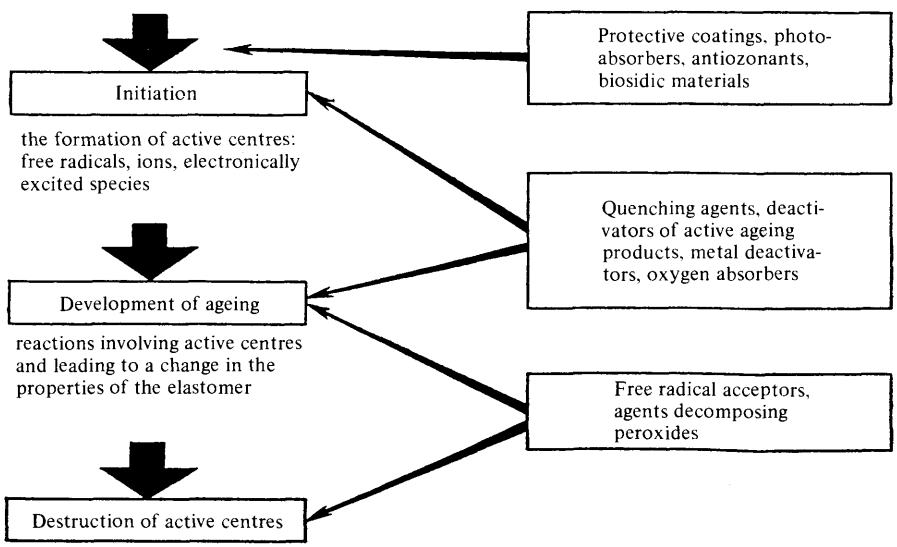

Figure 3. Principal elementary stages in the ageing of elastomers, the types of stabilisers, and the mode of their action.

stresses. Fig.5 presents a generalised kinetic curve for the decrease of ϕ in the ageing of various plastics and elastomers.[12] The deformation caused both by cross-linking and degradation reactions increases during the ageing of elastomers. The accumulation of the residual deformation ε is described by the equation

$$\psi = 1 - \exp(-\alpha t), \qquad (2)$$

where $\psi = (\varepsilon/\varepsilon_0 - 1)(\varepsilon_\infty/\varepsilon_0 - 1)^{-1}$. The generalised kinetic curve for a series of elastomers is illustrated in Fig.6.

III. THERMO-OXIDATIVE AGEING OF ELASTOMERS

A large set of data for the thermo-oxidative ageing of elastomers, some of which have been surveyed in monographs and reviews,[13-21] has now accumulated. The kinetics of the absorption of oxygen are most frequently studied in thermo-oxidative ageing.

1. Formal Kinetics of Thermo-oxidative Ageing

Analysis of the experimental data for the absorption of oxygen in the thermo-oxidative ageing of various polymers in both open and closed systems has shown that three main types of kinetic curves are encountered: curves of the autoaccelerating type, curves which decrease exponentially with time, and S-shaped kinetic curves.[22]

Kinetic curves of the first type are characteristic of the absorption of oxygen in the thermal oxidation of elastomers at temperatures below 200 °C; they are described by the equation

$$N_{O_2} = a(t - \tau)^2, \qquad (3)$$

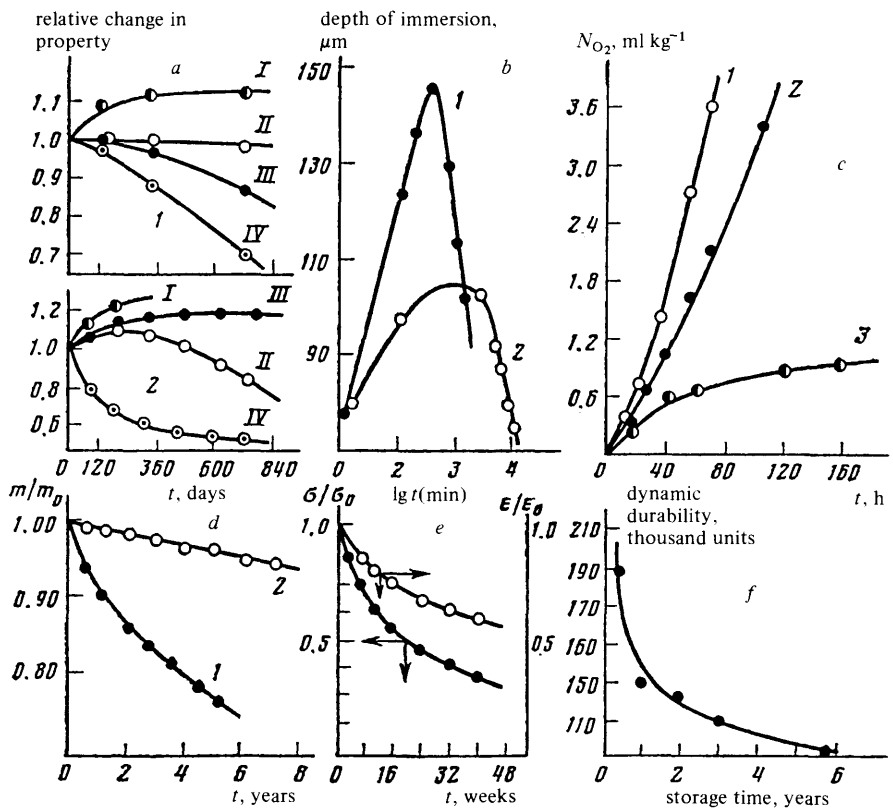

Figure 4. Kinetic relations obtained in the ageing of various elastomers: *a*) changes in the mechanical properties of raw rubber specimens during natural ageing in a climatic station: 1) butyl rubber; 2) butadiene-acrylonitrile rubber [I) Young's modulus; II) tensile strength; III) microhardness; IV) deformation on rupture]; *b*) changes in the microhardness of rubbers based on the raw butadiene-nitrile rubber in transformer oil during wear by rubbing: 1) 170 °C; 2) 120 °C; *c*) absorption of oxygen by the natural rubber latex containing 2% of 3,5-di-t-butyl-4-hydroxybenzyl acrylate at 70 °C: 1) without antioxidant; 2) antioxidant introduced mechanically; 3) antioxidant bound chemically to the raw rubber macromolecules; *d*) changes in the mass of polydimethylsiloxane (curve *1*) and segmented polyurethane (curve *2*) after implantation into a subcutaneous cell in rabbit; *e*) changes in the mechanical properties of specimens of a fluoro-silicone elastomer (Dow Corning, USA) at 200 °C; *f*) changes in the dynamic durability of protective rubber based on butadiene–styrene raw rubber during storage in an unheated space.

where N_{O_2} is the amount of oxygen absorbed by the polymer, a is a constant, and τ is the induction period. The parameters a and τ depend on the structure of the polymer, the oxygen pressure, and temperature. The equation is valid for low degrees of oxidation.

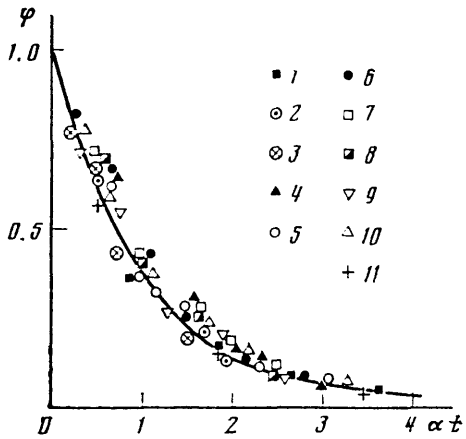

Figure 5. Generalised kinetic curve for the decrease of the tensile strength during the ageing of various plastics and elastomers: *1*) polyimide composite, 300 °C ($\alpha = 3.8 \times 10^{-3}$ h^{-1}); *2*) phenylon, 220–250 °C ($\alpha = 1.6 \times 10^{-3}$ h^{-1}); *3*) capton-H film, 300 °C ($\alpha = 2.6 \times 10^{-1}$ $week^{-1}$); aromatic polyamides, 300 °C;

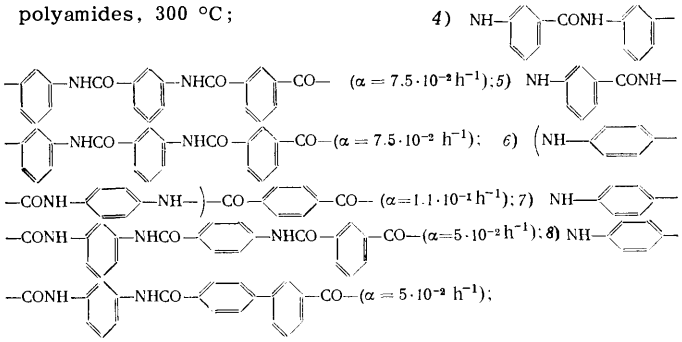

rubbers based on different raw rubbers; *9*) butadiene–sytrene, 90 °C ($\alpha = 3.5 \times 10^{-3}$ h^{-1}); *10*) butadiene–nitrile, 20 °C ($\alpha = 0.1$ $year^{-1}$); *11*) isoprene, 100 °C ($\alpha = 2.8 \times 10^{-2}$ h^{-1}).

Fig.7 presents the generalised kinetic curve for the absorption of O_2 in the oxidation of various polymers, including elastomers, at 90–200 °C. Kinetic curves of an analogous type can be obtained for the thermal oxidation of vulcanised elastomers with different contents of technical carbon[23] and vulcanised elastomers with different structures of the main chain in the network,[24] and also kinetic curves recorded at different partial pressures of oxygen[25] and for vulcanised elastomers with different amounts of bound sulphur.[26]

An equation relating the change in the mechanical properties (tensile strength and elongation on rupture) to the absorption of oxygen and the accumulation of oxygen-containing groups in the polymer has been obtained for polyolefins.[27] Fig.8 presents analogous experimental data obtained in the thermal oxidation of vulcanised butadiene–styrene rubber.[21]

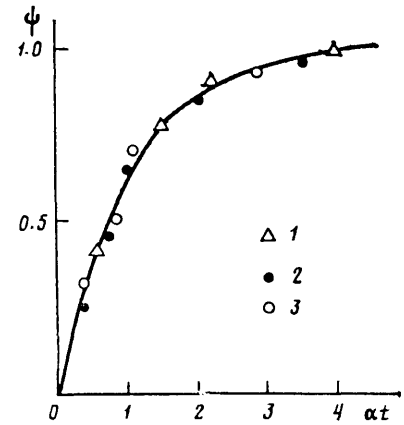

Figure 6. Generalised kinetic curve for the increase of the residual deformation during the ageing of various rubbers based on different polymers: *1*) butadiene–styrene, vacuum, 90 °C ($\alpha = 0.1$ day^{-1}); *2*) butadiene–styrene, 120 atm, 70 °C ($\alpha = 0.2$ day^{-1}); *3*) butadiene–acrylonitrile, SKI-18, ammonia, 20 °C ($\alpha = 3.5 \times 10^{-2}$ day^{-1}).

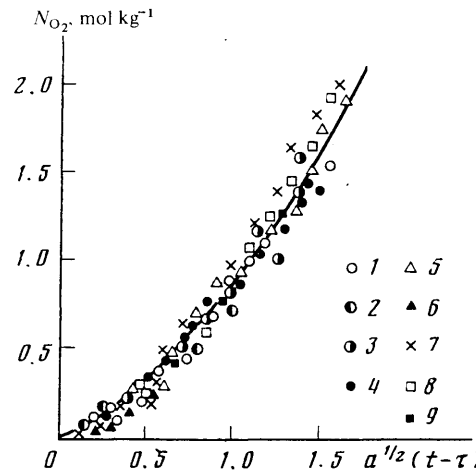

Figure 7. Generalised kinetic curve for the absorption of oxygen in the oxidation of various polymers: *1*) polyethylene (90 °C); *2*) polypropylene (130 °C); *3*) ethylene–propene copolymer (130 °C); *4*) poly-4-methylpent-1-ene (130 °C); *5*) vulcanised natural rubber (110 °C); *6*) polystyrene (160°); *7*) polyheptene (100 °C); *8*) polynon-1-ene (100 °C).

It has been suggested that the thermo-oxidative stability of polymers be characterised by the temperature at which 0.1 mol kg^{-1} of oxygen is absorbed in air in the course of 15 min[27] (Table 1). The values of 0.1 mol kg^{-1} was selected

because in the presence of this amount of absorbed oxygen the chemical and physical properties of polymers begin to change appreciably.

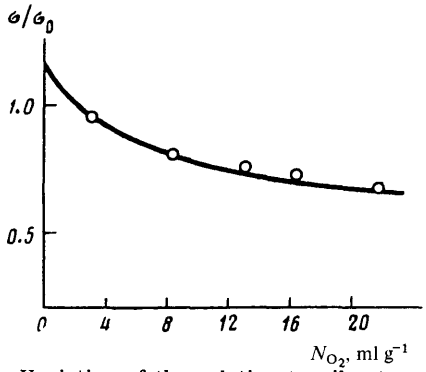

Figure 8. Variation of the relative tensile strength of vulcanised butadiene–styrene rubber as a function of the amount of oxygen absorbed at 110 °C and an oxygen pressure of 1 atm.

Table 1. The thermo-oxidative stability of carbochain polymers.

Polymer	$T_{1/2}$*, °C	Polymer	$T_{1/2}$*, °C
Polypropylene	135	Poly-4-methylpent-1-ene	165
Polyisoprene	135	Polyethylene	170
Polybutadiene	155	Polystyrene	205
Poly(methyl methacrylate)	160	Poly(vinyl chloride)	210

*The temperature corresponding to the absorption of 0.1 mol kg^{-1} of oxygen in 15 min.

2. Characteristic Features of the Solid-Phase Reactions in the Thermo-oxidative Ageing of Elastomers

Kinetic studies of the thermo-oxidative ageing of elastomers have always been based on the theoretical ideas concerning the liquid-phase oxidation reactions of hydrocarbons. Numerous investigations established that the liquid-phase oxidation of hydrocarbons is a degenerate-branched chain process.[4,28–30] However, the thermal oxidation of elastomers, like that of other polymers, shows many differences from the liquid-phase oxidation of hydrocarbons despite the similarity of the kinetics and the reaction products. Elastomers may contain domain structures—structurally similar groups segregated to form a microheterophase, while in filled elastomers there is a phase consisting of "hard" rubber adsorbed on the filler.[31,32] Such inhomogeneity of the physical structures of elastomers and the occurrence of solid-phase reactions give rise to the following characteristic features of the thermo-oxidative ageing of solid elastomers.

1. The inhomogeneity of the three-dimensional distribution of the active centres and reactants (oxygen, radicals, and stabilisers).

2. The structural-kinetic inhomogeneity, i.e. the distribution of regions differing in the frequencies and amplitudes of molecular movements, which influence the kinetics of radical processes.

3. Slow migration of segments of the macromolecules in polymers diminishes the rate of emergence of the radicals from the cage compared with a liquid and the probability of the radical recombination within the cage is greater in elastomers than in a liquid, i.e. the cage effect is more marked.

4. The slower diffusion of oxygen in polymers compared with liquid hydrocarbons is responsible for the specific features of the reactions of alkyl macroradicals which not only react with oxygen, as happens in hydrocarbons undergoing oxidation, but also enter into a whole series of other reactions: they isomerise, abstract hydrogen atoms from neighbouring C–H bonds, and react with hydroperoxides.[33]

5. In a liquid the R and RO_2 radicals migrate by diffusing; in solid polymers the diffusion of free-radical species is slow and other mechanisms of the migration of a free valence may operate—the relay migration and the transfer of the free valence by low-molecular-weight radicals and molecules.[1,34,35] The relative contributions of these mechanisms depend on the oxidation conditions and the structure of the elastomer.

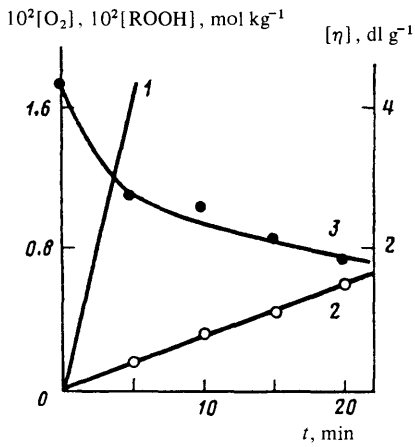

Figure 9. Kinetics of the absorption of oxygen (curve *1*), the accumulation of hydroperoxides (curve *2*), and the changes in the intrinsic viscosity of *cis*-1,4-polyisoprene (curve *3*) at 80 °C, $[DAC]_0 = 0.06$ M.

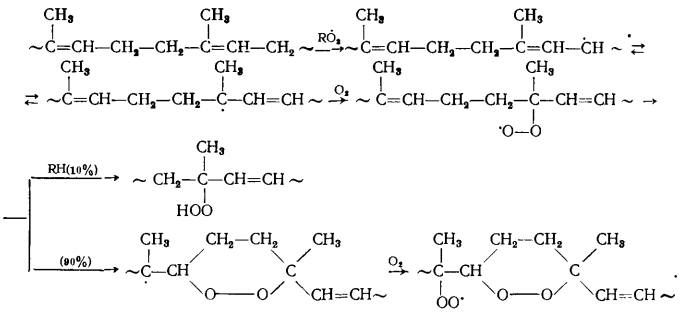
3. The Mechanism of the Thermo-oxidative Degradation of Polydienes

In the thermo-oxidative degradation of *cis*-1,4-polyisoprene only part of the absorbed oxygen is consumed in the formation of hydroperoxy-groups (Fig.9). This is associated with the propagation of the oxidation chain in two directions:[36,37] (a) via a reaction involving the intramolecular addition of the peroxy-radical to the double bond with formation of a cyclic peroxide with a rate constant k_p; (b) via the reaction involving the abstraction of a hydrogen atom from the α-methylene group with formation of a hydroperoxide (k_p'). The overall scheme includes the following

reactions:



The ratio $k'_p/k_p[RH] = 8.3$ for *cis*-1,4-polyisoprene.[37]

Oxidation results in the formation of peroxy-macroradicals in which peroxide bridges adjoin the free valence. Such structural fragments, which have been identified by NMR, are unstable and constitute centres for the degradation of polyisoprene via the scheme

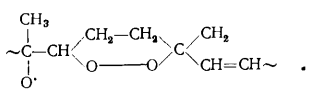
$$2R\dot{O}_2 \rightarrow 2R\dot{O},$$
$$R\dot{O} \rightarrow \text{degradation}.$$

According to this scheme, the rate of degradation is proportional to the rate of initiation;[37] the proportionality coefficient, measured in experiments on the initiated degradation of polyisoprene, is 15, i.e. the decomposition of the RO macroradicals formed is 15 times faster than the chain termination in the polyisoprene being oxidised.[37]

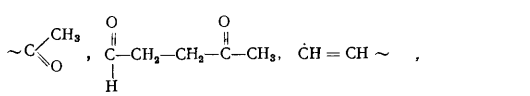
The kinetics of the oxidative degradation of polyisoprene in the presence of inhibitors have been investigated.[38] It was found that, in the presence of an inhibitor (phenol or aromatic amine), a new source of degradation appears, namely the reaction of the peroxy-macroradical with the inhibitor radical Iṅ:

$$R\dot{O}_2 + I\dot{n} \rightarrow ROOIn \rightarrow R\dot{O} + In\dot{O};$$
$$R\dot{O} \rightarrow \text{degradation}.$$

The radical ṘO has the structure



Its decomposition results in the formation of the groups



Together with the mechanism of the oxidative degradation described above, there is a possibility of another mechanism, according to which the polyisoprene degradation centres are the allyloxy-radicals formed on decomposition of the hydroperoxy-groups.[39]

4. Stabilisation of Elastomers

The stabilisation of elastomers has attracted continuous attention for many years and numerous studies have been devoted to the mechanism of the action of stabilisers. Two main types of antioxidants, which cause chain termination, are known: electron donors and proton donors. It has been shown by infrared spectroscopy that phenols and aromatic amines with bulky substituents are present in the matrices of polydiene elastomers as weak π-complexes with the double bonds.[40]

The mechanism of action of the antioxidant in the oxidation of elastomers depends on its concentration in the polymer. In the concentration range from 4.5×10^{-4} to 4.5×10^{-3} mol kg^{-1} the oxidation of *cis*-1,4-polyisoprene in the presence of sterically hindered phenols proceeds as a chain reaction with chain termination by the inhibitor molecules; the effectiveness of antioxidants in the polymer is close to that in hydrocarbon media (Table 2).[38]

Table 2. Kinetic parameters of the chain termination by phenolic antioxidants in the inhibited oxidation reactions of *cis*-1,4-polyisoprene (80 °C, $p_{O_2} = 10^5$ Pa).

Antioxidant	f	$k_2k_6^{-1/2}$, kg$^{1/2}$ mol$^{-1/2}$ s$^{1/2}$
2,6-Di-t-butyl-4-methylphenol	2.0	42.6±10.4
2,2-Methylenebis(6-t-butyl-4-methylphenol)	2.6	42.1±9.9
4,4-Methylenebis(2,6-di-t-butylphenol)	2.7	37.9±12.9
2,4,6-Tris(3,5-di-t-butyl-4-hydroxyphenyl)-1,3,5-trimethylbenzene	1.9	28.9±6.4
Ester of 3,5-di-t-butyl-4-hydroxyphenylpropionic acid and pentaerythritol	2.0	38.8±4 5

The rate of the inhibited chain oxidation is

$$W_{O_2} = \frac{k_2[RH]W_0}{fk_7[InH]_0}, \quad (4)$$

where W_0 is the rate of initiation and f the inhibition coefficient, i.e. the number of kinetic chains terminated by one antioxidant molecule.

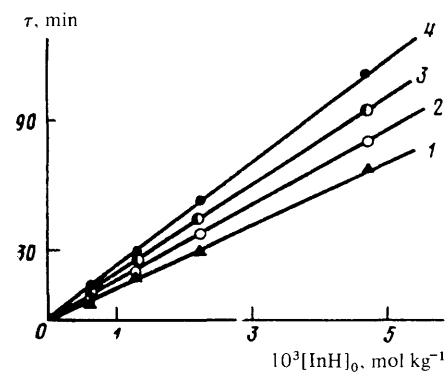


Figure 10. Dependence of the induction period in the oxidation of *cis*-1,4-polyisoprene on the initial concentration of antioxidants (80 °C, oxygen pressure 10^5 Pa): *1*) 1,3,5-trimethyl-2,4,6-tri(3,5-di-t-butyl-4-hydroxybenzyl)benzene; *2*) ester of 3,5-di-t-butyl-4-hydroxyphenylpropionic acid and pentaerythritol; *3*) 2,2-methylenebis(6-t-butyl-4-methylphenol); *4*) 4,4-methylenebis(2,6-di-t-butylphenol).

Figs.10 and 11 present the variation of the induction period of the oxidation reaction with the initial concentration of the antioxidants and of the inhibited oxidation chain length ν with the reciprocal of the concentration of the antioxidants.

In the concentration range from 4.5×10^{-3} to 4.5×10^{-2} mol kg^{-1} the rate of oxidation is[38]

$$W_{O_2} = \frac{aW_0}{[InH]_0} + bW_0, \quad (5)$$

where a and b are coefficients. The first term of Eqn.(5) reflects the occurrence of a chain oxidation process with chain propagation via the reaction of RO_2 and RH; the second term is associated with the involvement of the inhibitor radicals in chain propagation.

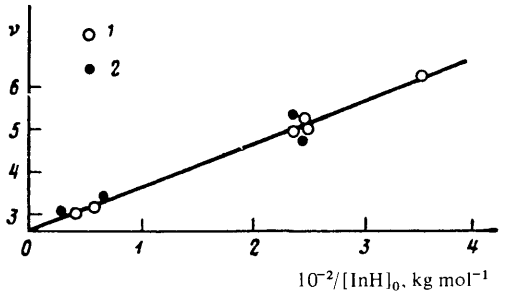

Figure 11. Dependence of the chain length ν of the inhibited oxidation of *cis*-1,4-polyisoprene on the reciprocal of the concentration of antioxidants (80 °C, oxygen pressure 10^5 Pa): *1*) 2,6-di-t-butyl-4-methylphenol; *2*) 2,2-methylenebis(6-t-butyl-4-methylphenol).

Table 3. Kinetic characteristics of the inhibitors of the oxidation and degradation of *cis*-1,4-polyisoprene (80 °C, $p_{O_2} = 10^5$ Pa).

Inhibitor	$k_7 k_6^{-1/2}$, kg$^{1/2}$ mol$^{-1/2}$ s$^{-1/2}$	$10^{-3} \frac{W_{degr}[InH]_0}{W_0^2}$, s
	43	5.5
	36	2.5
	52	2.1
	333	0.27
	3.9	1.4
	4.4	1.4

The rate of degradation of *cis*-1,4-polyisoprene depends on the rate of initiation and on the initial antioxidant concentration:

$$W_{degr} = k_{degr} \frac{cW_0^2}{fk_7[InH]_0}, \quad (6)$$

where k_{degr} is the degradation rate constant and c is a coefficient.

The coefficient of the proportionality between W_{degr} and $W_0^2/[InH]_0$ is a measure of the inhibition of the degradation process by the antioxidant. There is no parallel variation of $k_7(RO_2 + InH)$ and $W_{degr}[InH]_0/W_0^2$. Thus, in order to be able to select effective stabilisers it is important to know their ability to terminate kinetic chains and to suppress oxidative degradation.

Table 3 presents the kinetic characteristics of inhibitors of the phenolic and amine types in the oxidation and degradation of *cis*-1,4-polyisoprene.

Thermoanalytical methods [differential scanning calorimetry (DSC), differential thermal analysis (DTA), and thermogravimetric analysis (TCA)] have been used successfully in recent years for the determination of the efficiency of the action of stabilisers in elastomers.[41]

The thermo-oxidative stability of rubbers containing identical amounts of different antioxidants is estimated in terms of two parameters: the time corresponding to the appearance of the exothermic oxidation peak under isothermal conditions (the induction period τ) and the temperature at which this peak appears in the course of dynamic heating (T_0).

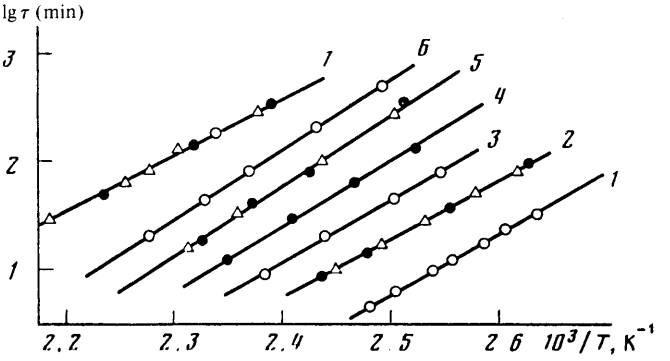

Figure 12. Relation between lg τ and $1/T$ for different compositions: *1*) polyisoprene; *2*) purified natural rubber (NR), NR + 2,6-di-t-butyl-*m*-cresol; *3*) NR + 1,7,10,16-tetrahydroxy-4,13-diazacyclo-octadecane; *4*) NR + *N*-phenyl-β-naphthylamine; *5*) NR + *N*-isopropyl-*N*-phenyl-*p*-phenylenediamine, NR + zinc diethyldithiocarbamate; *6*) raw NR; *7*) NR + *NN'*-diphenyl-*p*-phenylenediamine, NR + *p*-(*p*-toluenesulphanilamido)diphenylamine.

Fig.12 illustrates the linear relations between lg τ and the reciprocal of temperature, the straight lines obtained for different specimens being almost parallel. Analogous results have been obtained in another study.[42] A generalised lg τ – $1/(T + \Delta T)$ relation, where ΔT is a factor defined as the temperature difference $T_{st} - T_{sp}$, was derived from these data (Fig.13). The observed relations give rise to extensive possibilities not only for the estimation of the efficiency of the action of stabilisers but also for predicting the useful life of polymeric articles.

IV. PHOTO-OXIDATIVE AGEING OF ELASTOMERS

1. The Mechanism of Photo-oxidative Ageing

The photochemical oxidation of elastomers is a free-radical chain process with degenerate photobranching by hydroperoxides. This is confirmed by the form of the kinetic curve for the accumulation of the reaction products (ketones and alcohols), which are S-shaped, while the curve describing the variation of the concentration of the hydroperoxy-groups passes through an extremum, the maximum concentration of the hydroperoxides corresponding to the maximum rate of accumulation of the oxidation products (Fig.14).

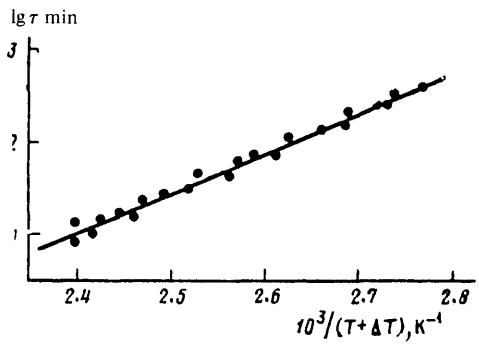

Figure 13. Generalised relation between lg τ and $1/(T + \Delta T)$, where $\Delta T = T_{st} - T_{sp}$ is the difference between the temperatures of the beginning of the exothermic peak for the standard and the specimen.

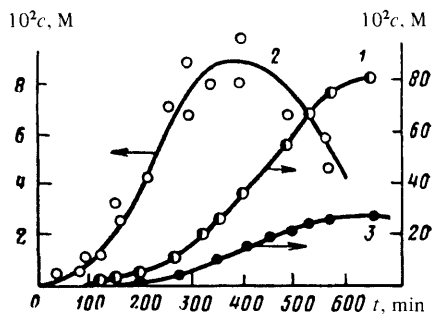

Figure 14. Kinetic curves for the accumulation of hydroxy-groups (curve *1*), carbonyl groups (curve *2*), and hydroperoxy-groups (curve *3*) on irradiation of 0.1 mm polyisoprene films with light having a wavelength $\lambda = 300$ nm.

The termination of the kinetic chain may be quadratic (for example, in polybutadiene) or linear (for example, in polyisoprene). This is manifested by the different character of the dependence of the rate of oxidation on the intensity of light (Fig.15). The chain length in the oxidation of polyisoprene is almost independent of the light intensity and amounts to ~100 units, whereas a decrease in the rate of initiation in polybutadiene, for example from 8×10^{-7} to 8×10^{-9} mol kg^{-1} s^{-1}, increases the chain length from 100 to 1000 units.[43]

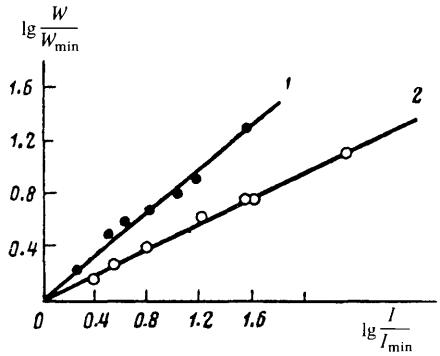

Figure 15. Dependence of the rate of oxidation on the light intensity I in the sensitised photochemical oxidation of polyisoprene (line *1*) and polybutadiene (line *2*); W_{min} and I_{min} are the minimum rate and intensity.

The linear chain termination in certain rubbers indicates that peroxy-radicals decompose with formation of low-molecular-weight radicals. In contrast to the widely familiar oxidation mechanism according to which chain termination takes place on direct interaction of macroradicals, in this case the mechanism is

$$\mathrm{RH} \xrightarrow{W_0/h\nu} \dot{\mathrm{R}},$$
$$\dot{\mathrm{R}} + \mathrm{O_2} \xrightarrow{k_1} \mathrm{R\dot{O}_2},$$
$$\mathrm{R\dot{O}_2} + \mathrm{RH} \xrightarrow{k_2} \mathrm{ROOH} + \dot{\mathrm{R}},$$
$$\mathrm{R\dot{O}_2} \xrightarrow{k_{3.1}} \dot{r},$$
$$\mathrm{R\dot{O}_2} + \dot{r} \xrightarrow{k_{3.2}} \text{products},$$

where $\dot{r}$ is a low-molecular-weight radical. The expression for the rate of oxidation is

$$W = -\frac{d[O_2]}{dt} = \frac{d[ROOH]}{dt} = \frac{k_2[RH]}{k_{3.1}} W_0. \qquad (7)$$

In the general case, the dependence of the rates of oxidation on the rate of initiation (i.e. on the intensity of light) is complex, since at higher rates of initiation direct reactions of the macroradicals, leading to the appearance of a relation of the type $W \sim W_0^{1/2}$, compete with the radical decomposition process leading to linear chain termination. A change in the dependence of the rate of oxidation on the rate of initiation is observed, for example, in the photochemical oxidation of block and statistical butadiene–styrene copolymers.[44]

At room temperature the free radicals formed in the photochemical oxidation of polydienes are relatively unstable and the kinetics of their reaction have therefore been investigated at low temperatures.[45] Irradiation of raw rubbers with ultraviolet light leads to the appearance of EPR signals with a weak resolution (Fig.16), which have been attributed to terminal allyl radicals. On heating, they can be converted into allyl radicals and, in the presence of oxygen, into peroxy-radicals.[46]

The direct study of the nature of the radicals and of the kinetics of their reaction under conditions of photochemical oxidation showed that allyl radicals are the main free-radical species detected by EPR (Fig.17). The free valence in polybutadiene is destroyed on recombination of allyl and not peroxy-radicals, as usually happens in the oxidation of saturated polymers.[47] This feature must be taken into account when the stabilisation of elastomers is considered.

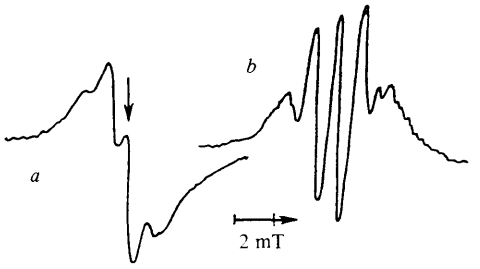

Figure 16. EPR spectra of *cis*-polybutadiene irradiated with ultraviolet light at 77 K: *a*) first derivative; *b*) second derivative; the arrow indicates the position of the DPPH signal.

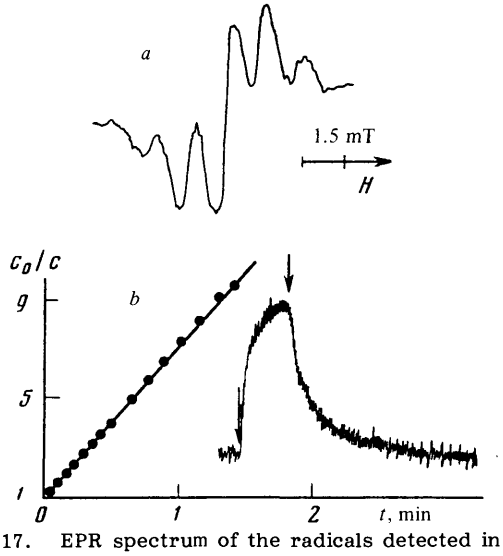

Figure 17. EPR spectrum of the radicals detected in the sensitised oxidation of polybutadiene (*a*) and the kinetics of their accumulation and destruction on switching on and switching off light (*b*); the instants when light is switched on and off are indicated by arrows.

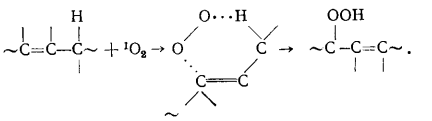
The sensitised oxidation mechanism involving singlet oxygen ($^1O_2$, state $^1\Delta_g$), which has been discussed by a number of investigators[48] and which is an alternative to the free-radical mechanism examined above, proved to be ineffective. The widely current hypothesis of the key role of singlet oxygen in polymer photochemical oxidation processes is based on the postulate of a high reactivity of the double bond towards singlet oxygen in solutions:[49]



However, in elastomers the reactivity of double bonds proved to be much lower (by a factor of 10^2–10^3).[50] This is the main reason why the pathway involving $^1O_2$ cannot compete with the radical chain mechanism for the oxidation of materials based on polydienes.

2. Stabilisation of Elastomers to the Action of Light

The following main mechanisms of the action of photostabilisers of polymeric materials have now been established: (a) shielding (ability to absorb ultraviolet light); (b) quenching of the excited state of the polymer or additives; (c) deactivation of impurities; (d) decomposition of hydroperoxides; (e) interaction with free radicals.

The experimental data concerning the action of stabilisers in polydienes show that the most effective photostabilisers are photoresistant antioxidants (Table 4). Shielding also plays an important role.

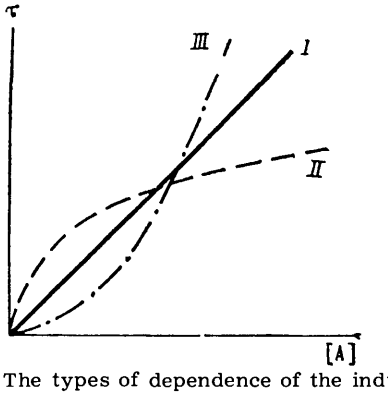


Figure 18. The types of dependence of the induction periods in the photochemical oxidation of elastomers on the concentration of photostabilisers [A].

As a result of the predominance of these two mechanisms, three types of concentration dependences of the induction periods in the photochemical oxidation of elastomers are characteristic of the majority of photostabilisers which are most effective for polydienes (Fig.18). In conformity with the theory of critical phenomena, in the inhibited oxidation[51] of the first type (Fig.18, curve *1*), a nearly linear variation of the induction period τ with the stabiliser concentration [A] is observed when the parameter k_{ROOH}/W_0, characterising the ratio of the rates of degenerate branching and initiation by impurities, does not exceed 10^7 litre mol^{-1}. Such variation is in fact characteristic of the relatively

photoresistant, weakly absorbing antioxidants of the class of stable nitroxy-radicals in polydienes (Fig.19) as a consequence of the high value of W_0.

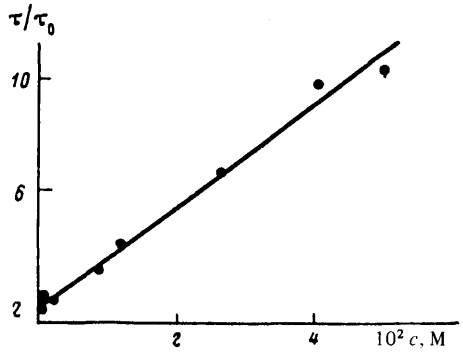

Figure 19. Dependence of the induction period in the photochemical oxidation of DSSK-30 butadiene–styrene rubber on the concentration of the 4-benzoyloxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radical.

A second type of dependence of τ on [A] (with saturation, curve II in Fig.18) is observed when the stabiliser is photochemically unstable and can initiate photochemical oxidation:

$$\mathrm{RH} \xrightarrow{h\nu;\ W_0} \dot{\mathrm{R}},$$
$$\dot{\mathrm{R}} + \mathrm{O_2} \xrightarrow{k_1} \mathrm{R\dot{O}_2},$$
$$\mathrm{R\dot{O}_2} + \mathrm{RH} \xrightarrow{k_2} \mathrm{ROOH} + \dot{\mathrm{R}},$$
$$\mathrm{A} + f\mathrm{R\dot{O}_2} \xrightarrow{k_4} \text{products},$$
$$\mathrm{A} + \mathrm{RH} \xrightarrow[\mathrm{O_2}]{h\nu;\ k_5} \mathrm{R\dot{O}_2}.$$

In this case

$$\tau = \frac{1}{k_5\,(1 + m/f)} \ln\left\{1 + \frac{k_5\,(1 + m/f)\,[\mathrm{A}]}{W_0}\right\}, \qquad (8)$$

where m is the number of radicals formed from the stabiliser A and f is the inhibition coefficient. An example of such a relation is presented in Fig.20.

A third type of such variation, to which curve III in Fig.18 corresponds, is characteristic of the case where the same substance behaves both as the antioxidant and as the absorber of ultraviolet light. The concentration variation of τ is described by the equation

$$\tau = \frac{2.3f\,[\mathrm{A}]^2\varepsilon l}{W_0}, \qquad (9)$$

Table 4. Mechanisms of the photoprotective action of stabilisers.

Type of stabiliser	Main fragment	Effectiveness in polydienes	Main mechanism	Additional mechanism	Factor limiting effectiveness
Benzotriazoles and benzophenones		Low	Quenching	Shielding (large thicknesses)	—
Phenyl benzoates and phenyl salicylates		Low	Rearrangement to benzoates	Shielding (large thicknesses)	—
Aromatic amines	Ar—NH—Ar	Low	Interaction	—	Photostability
Sterically hindered phenols		Moderate	Interaction with radicals	—	Photostability
Sterically hindered amines		High	Oxidation with formation of inhibitors	—	Photostability of nitroxy-radicals
Stable nitroxy-radicals		High	Interaction with radicals	—	Photostability
Metal complexes (with dialkyldithiocarbamates)	ML_n, where $L = R_2N—\overset{\overset{S}{\|}}{C}—S—$	Moderate	Decomposition of hydroperoxides	Interaction with radicals; shielding	Low photostability
Azophenols and azoamines	Ar—N=N—Ar—X, where X=OH, NH_2	High	Interaction with radicals	Shielding (large thicknesses)	Low photostability

where ε is the extinction coefficient and l the thickness of the polymer film. The experimental curve corresponding to this type is illustrated in Fig.21.

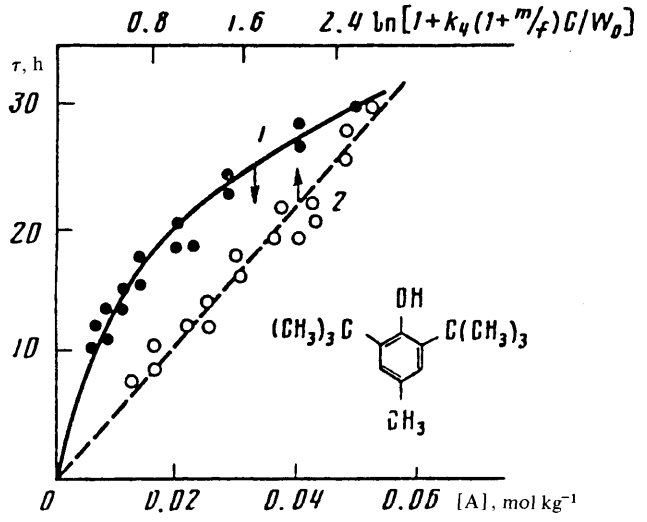

Figure 20. Dependence of the induction period in the photochemical oxidation of a film of IST-30 butadiene–styrene block copolymer on the concentration of 2,6-di-t-butyl-4-methylphenol (curve *1*) and its linear form in terms of the variables of Eqn.(8) (line *2*).

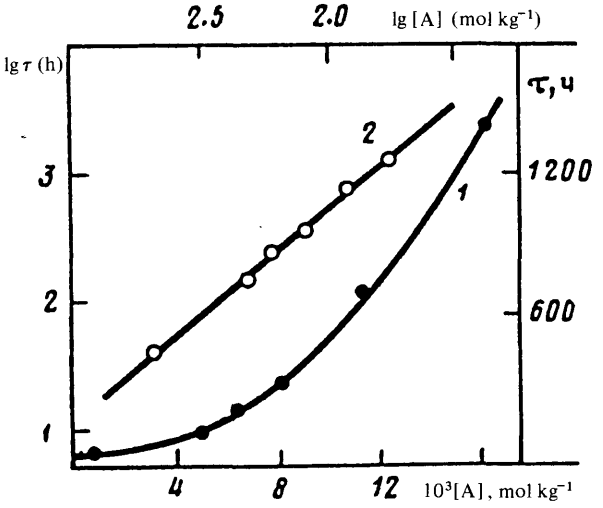

Figure 21. Dependence of the induction period in the photochemical oxidation of a film of the IST-30 butadiene–styrene block coploymer on the concentration of 4-hydroxy-3-methylphenylazo(azobenzene) (line *1*) and its logarithmic form (line *2*).

(a) *Synergism in the stabilisation of polymers towards the action of light.* Synergistic mixtures of stabilisers, whose classification as well as that of the mechanism of the synergism are given in Table 5, are widely used in practice for the stabilisation both of elastomers and of other polymeric materials.[52–57]

Table 5. The principal mechanism of the action of synergistic systems.

Mechanism	General mechanism of action of system	Example of system
	Thermal oxidation	
Regeneration of active inhibitor	$A^1 \rightleftharpoons \dot{R}$ (+A^2)	Decrease of critical inhibitor concentration	$RO_2 + RH \rightarrow ROOH + \dot{R}$ $ROOH \rightarrow \dot{R}O_2$ $\dot{R}O_2 + A^1 \rightarrow$ products $ROOH + A^2 \rightarrow$ products (Tbl)	Formation of new stabiliser	$A^1 + A^2 \rightarrow A^3$		Photochemical oxidation	
Quenching of excited states of antioxidant	$A \rightleftharpoons A^* \rightarrow$ products (Q)	Diffusion of antioxidant from the volume protected by the u.v. ligh absorber to the surface layer undergoing photochemical oxidation	$[A]_{eff} = [A]_{av} L/l$	
Notation: L = thickness of specimen, l = thickness of surface layer, A* = excited state of photostabiliser, Q = quenching agent, and R′ = $C(CH_3)_3$.

In the photochemical oxidation of polymers systems acting according to two fundamental principles are capable of exhibiting synergism: with and without the interaction of the components. Among the possible mechanisms, the principal ones are the physical mechanisms involving the quenching of excited states of the antioxidants, the diffusion of the antioxidant from the volume protected by the ultraviolet light absorber to the surface layer undergoing oxidation, and the influence of additives on the distribution of stabilisers in polymers.

The diffusion mechanism of the synergism was analysed quantitatively for an antioxidant which does not absorb light and a strongly absorbing ultraviolet light absorber, both uniformly distributed throughout the thickness of the specimen.[55] The light intensity in the polymer film decreases as one moves away from the irradiated surface in proportion to $\exp(-\varepsilon c x)$, where x is the distance from the surface and c the concentration. The rate of photochemical processes varies in accordance with the same law within the thickness of the specimen and one can assume

that photoprocesses proceed mainly in a narrow surface zone whose width is $1/\varepsilon c$. The antioxidant present in the polymer is consumed in this zone at a much higher rate than in the deeper layers. The concentration gradient thus generated leads to the appearance of a diffusional flux of the antioxidant from the bulk of the specimen to the surface layer, the flux decreasing the rate of the photoprocess in the reaction zone, while the deep layers of the specimen serve as a "reservoir" of the antioxidant.

For an oxidation process described by the general scheme

$$\mathrm{RH} \xrightarrow{O_2;\ W_0} \mathrm{R\dot{O}_2},$$
$$\mathrm{R\dot{O}_2} + \mathrm{RH} \xrightarrow{k_1} \mathrm{ROOH} + \dot{\mathrm{R}},$$
$$\mathrm{R\dot{O}_2} + \mathrm{R\dot{O}_2} \xrightarrow{k_2} \text{products},$$
$$\mathrm{R\dot{O}_2} + \mathrm{A} \xrightarrow{k_3} \text{products},$$
$$\mathrm{ROOH} + \mathrm{A} \xrightarrow{k_4} \text{products},$$

the following system of equations has been obtained taking into account the diffusion of the antioxidant into the zone where oxidation takes place:

$$\frac{\partial [\mathrm{R\dot{O}_2}]}{\partial t} = W_0 \exp(-\varepsilon c x) - f_b k_3 [\mathrm{R\dot{O}_2}][\mathrm{A}] - 2k_2 [\mathrm{R\dot{O}_2}], \qquad (10)$$

$$\frac{\partial [\mathrm{A}]}{\partial t} = -k_4 [\mathrm{ROOH}][\mathrm{A}] - f_b k_3 [\mathrm{R\dot{O}_2}][\mathrm{A}] - \frac{\partial^2 [\mathrm{A}]}{\partial x^2} D, \qquad (11)$$

$$\frac{\partial [\mathrm{ROOH}]}{\partial t} = k_1 [\mathrm{RH}][\mathrm{R\dot{O}_2}] - f_h k_4 [\mathrm{ROOH}][\mathrm{A}], \qquad (12)$$

subject to the initial conditions

$$[\mathrm{A}]_{t=0} = [\mathrm{A}]_0;\ [\mathrm{R\dot{O}_2}]_{t=0} = 0;\ [\mathrm{ROOH}]_{t=0} = 0$$

and the boundary conditions

$$\left.\frac{\partial [\mathrm{A}]}{\partial x}\right|_{\substack{x=0,\\ x=l}} = 0;\ \left.\frac{\partial [\mathrm{R\dot{O}_2}]}{\partial x}\right|_{\substack{x=0,\\ x=l}} = 0;\ \left.\frac{\partial [\mathrm{ROOH}]}{\partial x}\right|_{\substack{x=0,\\ x=l}} = 0,$$

where l is the thickness of the film, D the diffusion coefficient of the antioxidant, ε and c are the extinction coefficient and the concentration of the ultraviolet light absorber, and f_b and f_h are the branching and inhibition coefficients.

The system in a general form can be solved numerically and, subject to a number of physically justified simplifying assumptions, also analytically. Two typical cases are of the greatest interest from the practical point of view.

1. Rapid diffusion regime, where the concentration of A is almost constant throughout the thickness of the specimen. For strongly absorbing specimens and when substances A reacting with free radicals are employed, we have

$$\tau = \left\{\frac{([\mathrm{A}]_0 - [\mathrm{A}])}{W_0}\right\} f_b \varepsilon c l. \qquad (13)$$

In the case of compounds A which react with peroxides, we obtain

$$\tau = \left\{\frac{([\mathrm{A}]_0 - [\mathrm{A}])}{(k_2 [\mathrm{RH}])}\right\} f_h \varepsilon c l \left(\frac{2k_3}{W_0}\right)^{1/2}. \qquad (14)$$

2. Diffusion-controlled regime. Diffusion results in an additional supply of the antioxidant to the surface layer, but this does not equalise the concentration of A throughout the thickness of the specimen. The corresponding expressions for τ assume the following form:

$$\tau = \pi D \{f_b \varepsilon c ([\mathrm{A}]_0 - [\mathrm{A}])/2W_0\}^2; \qquad (15)$$

$$\tau = [2\pi D k_3/W_0]\{f_h \varepsilon c ([\mathrm{A}]_0 - [\mathrm{A}])/(2k_3[\mathrm{RH}])\}^2. \qquad (16)$$

It follows from theoretical relations that the photostability of the specimen depends on the overall concentration of stabilisers, the component ratio (the 1:1 ratio is optimum), the thickness of the specimen, and, in the diffusion-controlled regime, also the light intensity. These relations have been tested experimentally. The results presented in Fig.22 show that there is a satisfactory agreement between theory and experiment.

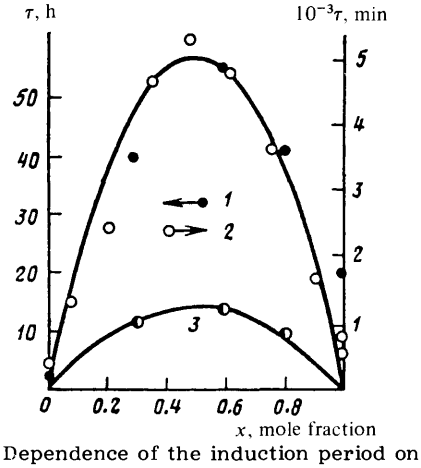

Figure 22. Dependence of the induction period on the mole fraction of the antioxidant in the photochemical oxidation of 60 μm (curve *1*) and 10 μm (curve *3*) polybutadiene films containing a mixture of 4-heptyloxy-2-hydroxybenzophenone and 2,6-di-t-butyl-4-methylphenol as well as films of polychloropropene containing a mixture of 2-hydroxy-4-octyloxybenzophenone and bis(3-t-butyl-2-hydroxy-5-methylphenyl)methane (curve *2*).

(b) *Synergism in the quenching of the excited states of the antioxidants by photostabilisers.* If the antioxidant is photochemically active, then synergism is possible when a photostabiliser capable of deactivating the excited states of the antioxidant is used as a second component. In the presence of a mixture of a quenching agent Q and an antioxidant A, the dependence of the induction period on the concentrations has the following form:

$$\frac{\tau}{\tau_0} = \ln(1 + \beta [\mathrm{A}]\eta)/\eta \ln(1 + \beta [\mathrm{A}]), \qquad (17)$$

where $\beta = k_5(1 + m/f)/W_0$, k_5 is the rate constant for the photochemical reaction of the antioxidant, and $\eta = [\mathrm{A}^*]_Q/[\mathrm{A}^*]$ a coefficient characterising the decrease of the rate constant for photochemical initiation involving A in the presence of Q. Fig.23 presents the dependence of the relative induction period in the photochemical oxidation of polybutadiene films on the relative concentration of the quenching agent, illustrating this mechanism of the synergism.

A new principle for the construction of synergistic systems involving the use of additives influencing the distribution of stabilisers in polymers has been proposed recently on the basis of a detailed study of the solubilities and distribution of additives in polymers. Such additives can be both chemically relatively inert substances (for example,

surfactants) and certain stabilisers. The highest efficiency of the synergistic mixture is then attained when photostabilisers are employed as the additional additives.[57]

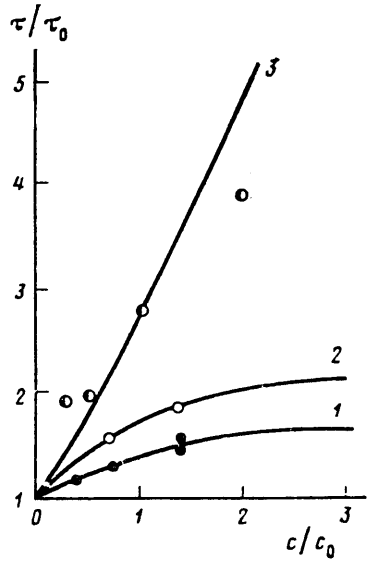

Figure 23. Dependence of the induction period on the concentration of the quenching agent. Curves—theoretical calculations for $\beta[A]_0 = 2$ (curve *1*), 4 (curve *2*), or 20 (curve *3*); circles—experimental data for mixtures of 2-(2-hydroxy-5-methylphenyl)benzotriazole and bis(3-t-butyl-2-hydroxy-5-methylphenyl)methane (curves *1* and *2*) or 2,6-di-t-butyl-4-phenylphenol (curve *3*).

(c) *The influence of the supermolecular structure on the efficiency of photostabilisers.* Thermoelastoplastics have now found extensive applications. These materials occupy an intermediate position, as regards their properties, between plastics and elastomers and consist of block copolymers. When the properties of the block differ appreciably, they form different phases with a fairly sharp interface.[58,59] Such materials include, for example, diene–styrene block copolymers. The kinetics of the photoprocesses are then influenced by the distribution of the stabilisers between the phases and their migration from one phase to another. For diene–styrene block copolymers, the difference between the reactivities of the additives to the "hard" and elastomeric phases is so significant that this property can be used to investigate the distribution and migration of additives.

For example, even after a brief irradiation with ultraviolet light of copolymer specimens containing stable nitroxy-radicals, the latter are almost fully consumed in the polydiene phase, whereas not more than 10% are consumed in the polystyrene phase (Fig.24, *a* and *b*). When the specimen is kept in the dark, the concentration of the nitroxy-radicals in the polystyrene phase falls, while that in the polydiene phase increases (Fig.24c), and after prolonged storage the initial distribution of the additive is restored. These data made it possible to estimate the distribution of the stabiliser between the phases and to determine the diffusion coefficient in the "hard" phase.

The photostability of the copolymer depends on the ratio of the volumes of the "hard" and elastomeric phases. Effective stabilisation requires the use of additives which are predominantly concentrated in the hard phase where they are more resistant to the action of light and hence can diffuse to the elastomeric phase being oxidised, ensuring its photostabilisation. The interfacial diffusion of the stabiliser must also be taken into account in selecting the conditions for accelerated tests of elastomers for photostability.

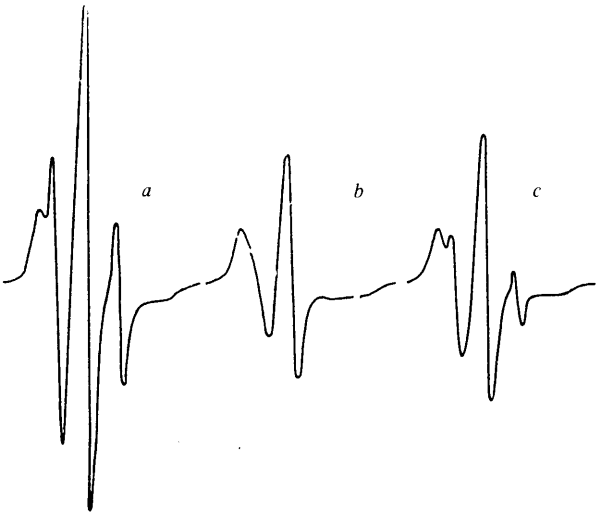

Figure 24. EPR spectra of the 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radical before (*a*) and after (*b*) irradiation with ultraviolet light for 2.5 min and also after maintaining the irradiated specimen in the dark for 100 min (*c*).

V. OZONE-INDUCED AGEING OF ELASTOMERS

Ozone is an active species in the ageing of elastomers containing double bonds in the main chains of the macromolecules. Ozone is formed at sites where electric motors operate, electric welding is carried on, and sources of ultraviolet light are employed. Considerable amounts of corrosive gases, ejected with the exhaust gases of automobiles and with factory smoke, are formed in the air of large cities and industrial undertakings. Photochemical smog, one component of which is ozone, is formed from these gases under special meteorological and geographical conditions. The concentration of ozone in photochemical smog (up to 5×10^{-1} mg m^{-3}) is sufficient for the ageing of the majority of technical rubber articles.[60]

As ozone adds to the macromolecules of the elastomer, the formation and growth of surface cracks and the accumulation of oxygen-containing groups in the surface layer are observed. The absorption of ozone by stretched elastomer specimens differs significantly from that by undeformed specimens.[61] The rate of absorption of ozone by the specimens in the absence of stretching stresses diminishes after several minutes of exposure. The layer formed on the surface, on which the double bonds have reacted,

inhibits further absorption of ozone. The rate of absorption of ozone by stretched specimens remains close to the initial value, since the cracks formed under the influence of mechanical stresses open up and continually regenerate a fresh surface.

1. Kinetics and Mechanism of the Degradation of Polymers by Ozone

When polymers are acted upon by ozone, a decrease of the molecular weight and the accumulation of oxygen-containing functional groups (acids, ketones, peroxides, etc.) are observed.[62] Table 6 presents the effective rate constants for the reactions of ozone with the functional groups and the numbers of breaks in the chain per reaction step (n) in solution in carbon tetrachloride. The following trend has been observed for polymers: with increase in the rate constant for the reaction of ozone with the polymer, the number of breaks per reaction step diminishes.

Table 6. The rate constants for the reactions of ozone with various polymers k_{eff} and the numbers of chain breaks n per reaction step in solution in CCl_4 at 20 °C.[62]

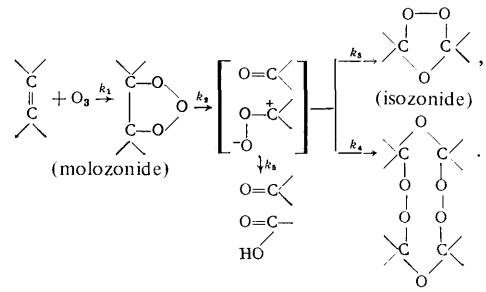
Polymer	k_{eff}, litre mol^{-1} s^{-1}	n
Polyphenyl	$5.0\cdot10^{-2}$	—
Polynaphthalene	$2.0\cdot10^{3}$	—
Polycarbonate	3,0	—
Polyisobutylene	$1.2\cdot10^{-2}$	0.05
Polyethylene	$4.6\cdot10^{-2}$	0.1
Ethylene-propylene copolymer	$6.0\cdot10^{-2}$	0.06
Polypropylene	$8.0\cdot10^{-2}$	0.1
Polystyrene	0,3	0.01
Polyvinylcyclohexane	0,8	—
Polyphenylacetylene	$1.4\cdot10^{3}$	—
Polybutadiene	$6.0\cdot10^{4}$	0.06
Polyisoprene	$4.4\cdot10^{5}$	0.002
Polychloroprene	$1.0\cdot10^{4}$	—

Table 7. The rate constants for the reactions of ozone with elastomers deposited on a fine-grained silica gel at 20 °C.

Elastomer	$10^{-4}\,k_{eff}$, kg mol^{-1} s^{-1}
Natural rubber	10.5
Polyisoprene	10.5
Polybutadiene	5.1
Butadiene-styrene copolymer (SKS-30 ARKP)	4.6
Polychloroprene	1.0
Butyl rubber	10.5

Table 7 presents the rate constants for the reactions of ozone with the elastomers deposited on a fine-grained silica gel in order to eliminate diffusion-dependent limitations. These rate constants are satisfactorily correlated with the rate constants for the corresponding polymers in solution (Fig.25). This makes it possible to predict the resistance of elastomeric materials to ozone with the aid of model experiments carried out in solution.

The degradation of elastomer fragments with unsaturated bonds proceeds via the formation of a molozonide and zwitter-ions in accordance with the scheme



The macromolecules are cleaved only as a result of the reaction with the rate constant k_5; the contribution of this reaction does not exceed 1–2%. The main reaction product is the isozonide.

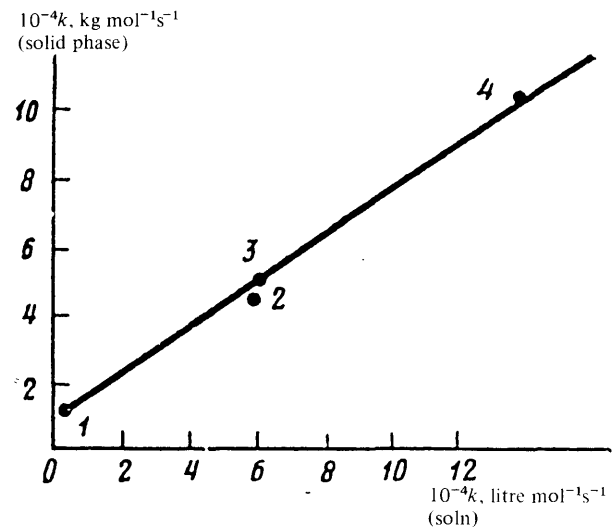


Figure 25. Correlation between the rate constants for the reactions of ozone with polydienes in solution and in the solid phase: *1*) polychloroprene; *2*) butadiene–styrene copolymer; *3*) *cis*-polybutadiene; *4*) *cis*-polyisoprene.

2. Protection of Polymeric Materials Against the Action of Ozone

Antiozonants and wax are used to protect elastomers against the action of ozone. Antiozonants include compounds of two classes: *p*-phenylenediamines and dihydroquinolines. There exist different explanations of the protective action of *p*-phenylenediamines in relation to ozone:

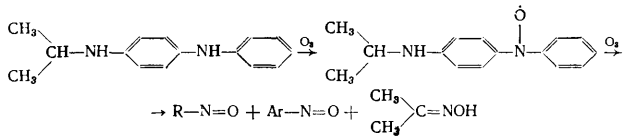
(a) The antiozonant reacts with ozone, diffusing to the surface of the article and forming a protective layer which constitutes a physical barrier.[63] This mechanism does not explain the effectiveness of antiozonants in elastomers subjected to a dynamic load, where the protective layer cannot remain continuous.

(b) The antiozonant reacts with the product of the addition of ozone to the polymer, preventing the decomposition of the resulting ozonides[64-66] or connecting the ends of the ruptured chains.[67,68] This hypothesis has not so far received convincing experimental confirmation.

(c) The antiozonant catalyses the decomposition of ozone on the surface of elastomers. This mechanism is inconsistent with the process kinetics.

(d) The antiozonant is a powerful competitor with the elastomer double bonds in the reaction with ozone. Despite its satisfactory agreement with many experimental data,[69] this mechanism cannot explain why other additives which actively react with ozone are ineffective.[70]

Ozone reacts with *p*-phenylenediamine to form nitroxyradicals, which are further converted into nitrosoalkyls, nitrosoallyls, and oximes:[71]



Dihydroquinones are less reactive than *p*-phenylenediamines but the antiozonants of these classes exhibit synergism in their influence on the resistance to ozone.[72]

Among the explanations of the protective action of antiozonants, the last has received the greatest amount of experimental confirmation: the antiozonant traps ozone on the surface of the elastomer. Fig.26 presents the logarithmic dependence of the relative time before the appearance of cracks on the relative rate constant for the interaction of ozone with the antiozonant in solution in carbon tetrachloride.[69]

The protective action of waxes is based on two effects:[73] the creation of a binary layer on the surface which diminishes the permeability of the polymer to ozone and interaction with ozone. For protective waxes, there is also a correlation between the time before the appearance of cracks and the rate constant for the reaction of ozone with the waxes (Table 8).

Table 8. The rate constants for the reactions of ozone with protective waxes in solution in CCl_4 at 23 °C on the time before the appearance of a crack on the SKI-3 elastomer during atmospheric ageing.[73]

Wax	$10^3 k$, litre $mol^{-1}s^{-1}$	τ, days	
		Batumi	Tashkent
Paraffin	4	30	32
MEV-1	42	54	60
MEV-2	60	180	90
MEV-4	70	100	65
Ceresite-80	6	119	59
MEVu-2	107	687	105

VI. THE INFLUENCE OF MECHANICAL STRESSES ON THE KINETICS OF THE REACTIONS OF ELASTOMERS

The influence of stress on the reactivity of elastomer macromolecules in reactions of various types has been observed and studied quantitatively. The stresses have accelerating, retarding, and neutral effects. The experimental data have been interpreted theoretically from the standpoint of transition state theory and conformational analysis.[74]

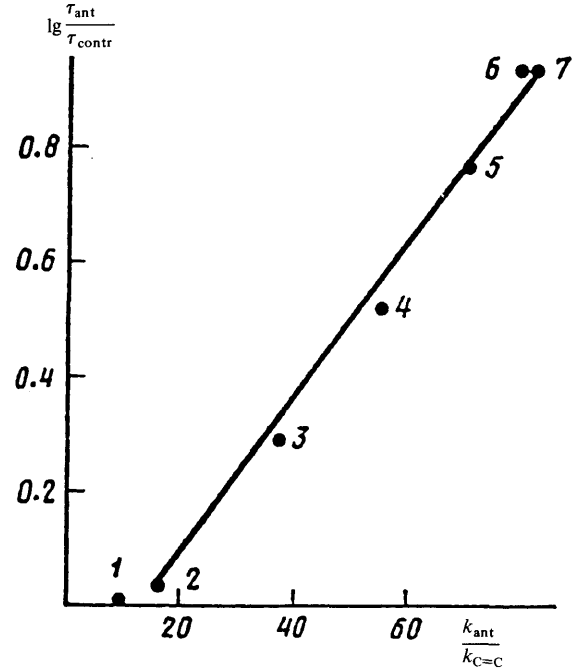


Figure 26. Logarithmic dependence of the optimum time τ_{ant} of the appearance of cracks on the relative rate constant for the interaction of ozone with antiozonants in solution in CCl_4; k_{ant} and $k_{C=C}$ are the rate constants for the reactions of ozone with the antiozonant and the double bond respectively: *1*) control;

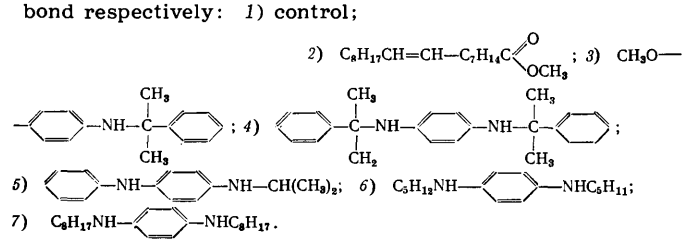

In real articles excessive stresses can arise in the region of defects (for example, at the mouth of the crack) and the effects described above are in fact to be expected there.

One of the most dangerous reagents is atmospheric ozone, whose action is accompanied by the formation of microcracks and macrocracks. Fig.27 presents data concerning the influence of stretching stresses and deformations on the rate of growth of cracks, the lifespan, the degree of oxidation, and the chemical relaxation time of the elastomers. With increased load, the above parameters are found to increase in the initial stage up to ~20% deformation. After that, the degradation process slows down—the resistance to ozone-induced ageing increases with increasing stretching stress. This constitutes the fundamental difference from the familiar

dependence of the life of polymers on the load—an exponential decrease of the lifespan with increasing σ (Zhurkov's equation).

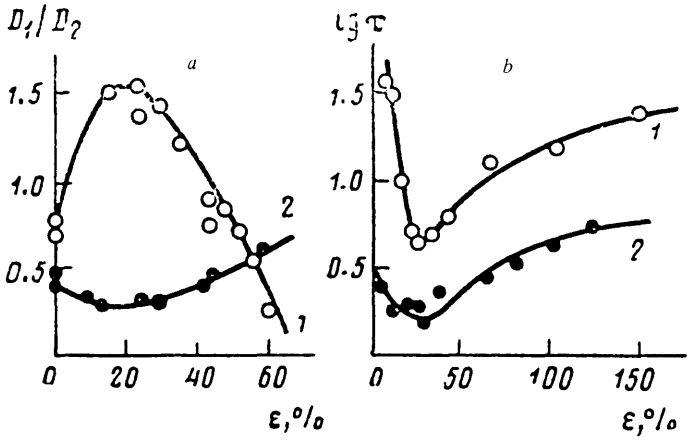

Figure 27. Variation of the optical density ratios D_{1720}/D_{1640} (curve *1*) and D_{1640}/D_{1375} (curve *2*) with the degree of deformation of *cis*-polyisoprene in its reaction with ozone; $[O_3] = 7 \times 10^{-8}$ M, 20 °C; *b*) variation of the chemical relaxation time of *cis*-polyisoprene with the degree of deformation in an atmosphere of ozone: *1*) $[O_3] = 2 \times 10^{-6}$ M; *2*) $[O_3] = 1 \times 10^{-5}$ M, 20 °C.

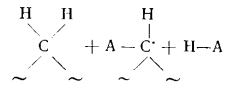
The phenomenon of "critical" deformation can be accounted for by a change of the reactivity of the double bond. This effect is caused by the competition of two opposed processes: the formation of cracks, which accelerate degradation, and a decreased reactivity of the double bond at the mouth of the crack. The first factor is manifested even for the smallest deformations. The contribution of the second is possible only when breaking stresses appear and therefore the first and second factors predominate respectively under the conditions of small and large deformations.[74]

The critical deformation is manifested most strikingly in elastomers with a *cis*-structure; in natural rubber and its synthetic analogue—polyisoprene as well as polybutadiene. In all these cases the stretching deformations do not increase the hardness of the elastomers and it is therefore impossible to account for the decreased rate of oxidative degradation with increasing deformation by a change in physical properties. The retarding influence of the physical factor can be shown only in systems where the molecular mobility diminishes with increasing stretch, as happens, for example, in the butadiene–styrene rubber with a *trans*-structure; however, the critical deformation in such systems is much less pronounced. This is apparently caused mainly by the fact that they have a *trans*-configuration of the monomer units, the reactivity of whose double bonds does not diminish under the influence of loads.

Many reactions of elastomers are accompanied by the rehybridisation of the carbon atoms in the main chain from the sp^2 to the sp^3 state. These can be both free-radical processes and reactions proceeding via S_N1 and S_N2 mechanisms. One of the commonest processes of this type is the abstraction of a hydrogen atom:



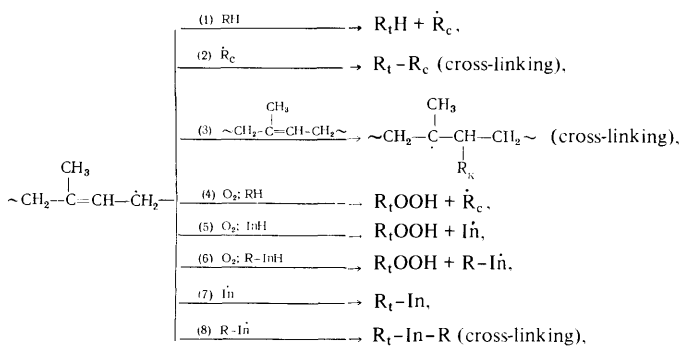
where A is a hydrogen acceptor (a molecule, a radical, or an atom, for example, O_3, O_2, RO_2, HO, CCl_3, Cl, Br, stable nitroxy-radicals, etc.). This reaction is extremely important in the thermo-oxidative degradation of elastomers (initiation, chain propagation, etc.). Recent studies have shown that the rates of reactions of the above class increase under the influence of external stretching stresses. A universal equation relating the rate of reaction to the load and temperature has been obtained:[74]

$$\ln\left(\frac{v_\sigma}{v_0}\right) = \frac{\alpha\sigma}{RT}, \qquad (18)$$

where v is the rate of reaction, the subscripts σ and 0 refer to a polymer specimen with a load and without a load respectively, σ is the stress, and α a proportionality coefficient, which depends on the nature of the acceptor and the supermolecular structure of the specimen.

VII. THE ROLE OF RADICAL REACTIONS IN THE WEAR OF VULCANISED ELASTOMERS

Antioxidants exert a significant influence on the rate of wear of vulcanised elastomers with polysulphide cross-links under "rolling-up" conditions, low-molecular-weight antioxidants increasing the rate of the process and those linked to the network decreasing it.[75] These data can be accounted for by the following reaction scheme for the terminal macroradicals arising as a result of mechanical breaks in the vulcanisation network in the region of the rupture centre, which is produced when a strip is torn off and twisted in the "net".



where R_t and R_c are the terminal and central radicals respectively.

Reactions (2), (3), and (8) lead to the formation of new cross-links and thereby heal the network defects, which is the cause of the retardation of wear in the absence of low-molecular-weight antioxidants.

In the presence of low-molecular-weight antioxidants the terminal macroradicals in the region of the growing decomposition centre are stabilised in the reactions with the antioxidants and thereby prevent the processes leading to the healing of the network defects.[75]

The problem of the ageing and stabilisation of elastomers constitutes a major branch of polymer materials science—the science concerned with the creation of polymeric materials

and the preservation or regulation of their physical properties. Chemical processes alter the structure and physical properties of polymers, while the structural–physical properties of the polymer strongly influence in their turn the direction and rate of its chemical reactions.

Thus the physicochemical approach to problems of polymer materials science is best adapted to the specific features of this field, being concerned with a combination of the problems of the physics and chemistry of elastomeric materials, and creating new ways and principles for the control of their properties and stability.

Reactive Derivatives of Nucleic Acids and Their Components as Affinity Reagents

D.G.Knorre and V.V.Vlasov

The review is devoted to derivatives of nucleic acids and their components—nuclectides, nucleoside triphosphates, and oligonucleotides carrying reactive groups. Such derivatives are important tools for the investigation of protein-nucleic acid interactions and the functional topography of complex protein and nucleoprotein structures and can give rise to the prospect of being able to influence in a highly selective manner living organisms, including the nucleic acids and the nucleoproteins of the genetic apparatus. The review considers the principal groups of such reagents, the methods of their synthesis, and their properties which determine the possibility of their use for the selective (affinity) modification of biopolymers. The general principles of the construction of affinity reagents and their applications are analysed in relation to nucleotide affinity reagents. The bibliography includes 121 references.

I. INTRODUCTION

Among the inexhaustible variety of proteins in living nature, a large group of proteins possess the ability to interact specifically with nucleotides and nucleic acids having a definite structure. The substrates or effectors for hundreds of enzymes with different specificities are nucleotides, nucleoside di- and tri-phosphates, and nucleotide coenzymes. Virtually all the proteins and the nucleoproteins ensuring the storage, replication, and application of hereditary information in cells and viruses participate in selective interaction with nucleic acids. These are the enzymes of the DNA replication system, enzymes for the transcription and subsequent processing of the RNA formed, the repair enzymes ensuring the removal of damaged sections of DNA and their regeneration, and all the macromolecular components involved in the biosynthesis of proteins, including aminoacyl-tRNA-synthetases, ribosomes, and numerous translation factors. The study of the mechanism and, in the first place, the structural principles of the selective interaction of nucleic acids and nucleotides with proteins, frequently referred to as the protein–nucleic acid recognition, is one of the essential tasks of molecular biology and bio-organic chemistry.

The selective interaction between nucleic acids is of no less cardinal importance, although perhaps not in terms of quite so many aspects, in ensuring the operation of the key processes involved in vital activity. It is sufficient to recall that the specific interaction of the complementary nucleotide sequences constitutes the basis of the double helix structure of DNA established by Watson and Crick.[1]

One of the most effective methods for the study of the specific interactions of biopolymers with low-molecular-weight or polymeric partners (ligands) is chemical modification of biopolymers by means of reagents which retain the principal structural features of a specific ligand and hence the affinity for the polymer and at the same time carry a reactive group capable of chemical interaction with the biopolymer under conditions close to those which really obtain in its functioning. Such reagents have been called affinity reagents and the method itself is usually referred to as affinity labelling or affinity modification.[2,3] In the complex of a biopolymer with an affinity reagent the chemical reaction with the biopolymer takes place in the vicinity of the region of specific interaction (recognition), the ligand being covalently fixed in this region. The fragment of the affinity reagent ensuring a specific affinity for the biopolymer directs the reagent to a specific section on the surface of the protein molecule or to a specific sequence of nucleotides in the nucleic acid and therefore constitutes a kind of address which helps the reacting group to find its target. Affinity reagents can therefore be referred to also as addressed reagents.

Reactive derivatives of nucleic acids and their components are therefore important instruments for the investigation of the protein–nucleic acid recognition and the interaction between nucleic acids. These derivatives also lead to the prospect of being able to act in a highly selective manner on many key biochemical and molecular-genetic processes in living organisms.

This review is devoted to the chemistry of addressed nucleotide reagents, containing as the address nucleotides, nucleoside triphosphates, oligonucleotides, and nucleic acids, the methods of their synthesis, and their properties important for their use in affinity modification. Its aim is not to give a systematic account of all the numerous applications of the reagents for the solution of problems in biochemistry, molecular and cell biology, and medicine. These applications constitute merely individual, most thoroughly demonstrated and important examples. To a large extent the review is based on the studies carried out in the Biochemical Division of the Novosibirsk Institute of Organic Chemistry, Siberian Division of the USSR Academy of Sciences, which has now been transformed into the Novosibirsk Institute of Bio-organic Chemistry.

Reactive derivatives of nucleic acids and their components constitute one of the most systematically investigated groups of affinity reagents. The main principles of their construction, the problems arising in the use of such derivatives, and the ways in which they can be solved have therefore been elucidated in a particularly clear-cut manner in the course of their investigation. A special Section of the review is therefore devoted to the general questions of affinity modification in relation to addressed nucleotide reagents.

II. CERTAIN PHYSICOCHEMICAL CHARACTERISTICS OF THE AFFINITY MODIFICATION PROCESS

According to the main idea of the method of affinity modification, the reaction of a biopolymer P proceeds in a complex with an affinity reagent attached via a system of non-covalent interactions in the region where the biopolymer recognises a certain natural ligand L. The formation of the complex PL can be detected either by a number of physicochemical methods or from the manifestation of the biological function due to the interaction of P with L. In most of the examples below we are dealing with enzyme activity, a quantitative characteristic of which is the rate of the enzyme-catalysed reaction. This rate is proportional to the concentration of the enzyme–substrate complex or, in the case of a reaction involving two substrates, the concentration of the complex of the enzyme with both substrates. The recognition region is in this case part of the active centre of the enzyme.

The concentration of the complex PL is given by

$$[PL]=K[L]P_t/(1+K[L]),$$

where K is the constant for the association of P with L and P_t the total concentration of the biopolymer.

The affinity reagent, constructed on the basis of a natural ligand L and containing a reactive group X, can be represented by L–X. This reagent competes with L for the recognition region. In the presence of both compounds, the concentrations of the complexes of P with L and L–X are given by

$$[PL]=K[L]P_t/(1+K[L]+K_x[L-X]),$$
$$[P\cdot L-X]=K_x[L-X]P_t/(1+K[L]+K_x[L-X]),$$

where K_x is the constant for the association of P with L–X.

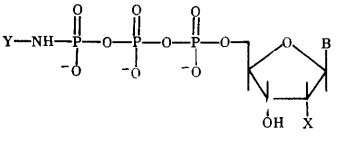
If a quantitative characteristic of a biological function F is proportional to the concentration of the complex, then, in the general case, where the complex P.L–X is also functionally active, we have

$$F=\alpha[PL]+\alpha_x[P\cdot L-X],$$

where α and α_x are proportionality coefficients. For an enzymic reaction, these characteristics are the rate constants for the conversion of the complexes PL and P.L–X into the enzyme–reaction product complex. If $\alpha_x = 0$, i.e. the complex with the reagent is functionally inactive, then L–X behaves as a competing inhibitor in relation to L.

For the systems in which reactive derivatives of nucleic acids and their components have been investigated, several instances of the functional activity of affinity reagents are known.

Derivatives of nucleoside 5′-triphosphates, in the first place compounds (I, a–f), have found extensive applications in the study of nucleic acid polymerases:



(Ia) B = adenine
(Ib) B = guanine
} X=OH, Y=

(Ic) B = thymine X=H, Y= 
(Id) B = adenine, X = H
(Ie) B = thymine, X = H
(If) B = adenine, X = OH
} Y = (henceforth ClRCH$_2$–)

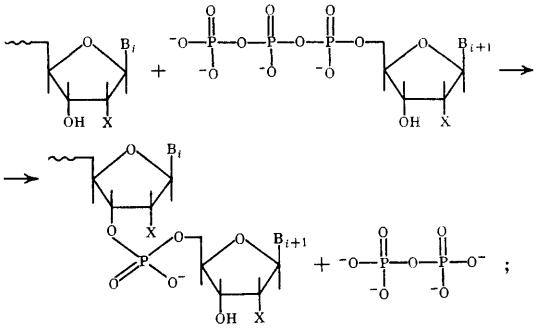
Nucleic acid polymerases catalyse the synthesis of DNA molecules (DNA polymerases) or RNA (RNA polymerases) by transferring the nucleotide residue from nucleoside 5′-triphosphate to the growing polynucleotide chain:



X = H for DNA polymerases;
X = OH for RNA polymerases.

Henceforth in the review we shall employ widely the nomenclature adopted in the nucleic acid chemistry and approved by the International Union of Pure and Applied Chemistry (IUPAC) and the International Union of Biochemistry (IUB).[4] According to this nomenclature, the orthophosphoric acid residue is designated by p and the nucleoside residue by the initial letter of its name. The symbol p to the left of that of the nucleoside means that the phosphate is linked to the 5′-hydroxy-group, while p on the right means that the phosphate is linked to the 3′-hydroxy-group of ribose or deoxyribose. In the case of deoxyribonucleosides, the letter d is placed before the nucleoside symbol. In this formulation the reaction catalysed by polymerases is represented as follows:

$$\sim pN^i + pppN^{i+1} \xrightarrow[\text{(RNA polymerase)}]{} \sim pN^ipN^{i+1} + pp \quad ; \qquad (1)$$
$$\sim pdN^i + pppdN^{i+1} \xrightarrow[\text{(DNA polymerase)}]{} \sim pdN^ipdN^{i+1} + pp \; .$$

The most important feature of nucleic acid polymerases is their dependence on the template nucleic acid, RNA or DNA. Accordingly, one distinguishes RNA-dependent and DNA-dependent polymerases. The template nucleic acid promotes, at each stage of chain propagation, the selection of a fragment for incorporation in the growing chain of one of four monomers, complementary to the template nucleotide located in the decoding section of the enzyme. Since after the addition of a new monomeric fragment, the template shifts by one unit relative to the decoding section and the selection is carried out by the next template nucleotide, the nucleic acid is synthesised with the nucleotide sequence complementary to the template nucleic acid.

Studies carried out with three nucleic acid polymerases from *Escherichia coli* showed that the γ-amides of nucleoside triphosphates, in particular the reactive derivatives (Ia) and (Ib), are substrates of the DNA-dependent RNA polymerase.[5,6] On the other hand compounds (Ic) and (Id) are effective affinity reagents for a DNA-dependent DNA polymerase (DNA polymerase I)[7] and the RNA-dependent DNA polymerase.[8] The γ-amide of dTTP (Ic) was not found to possess substrate properties in relation to the DNA polymerase I. It has been

shown in relation to the γ-anilide of adenosine 5′-triphosphates† that not the pyrophosphate but the pyrophosphate anilide [*N*-phenylpyrophosphorimidate?] is liberated in the synthesis of RNA from this analogue.

The key enzymes in the biosynthesis of proteins are aminoacyl-tRNA-synthetases. Each of them catalyses the addition of a specific aminoacid to the corresponding transport RNA by forming an ester linkage between the aminoacid carboxyl and the OH group at the 3′-end of RNA. The process is coupled with the hydrolysis of ATP to adenosine 5′-monophosphate (AMP) and pyrophosphate:

$$R\overset{+}{C}H(NH_3^+)COO^- + pppA + tRNA - OH \rightleftarrows tRNA{-}OCOCH(NH_3^+)R + pA + pp \quad (2)$$

The reagent (Ia) is a competitive inhibitor for a broad spectrum of aminoacyl-tRNA-synthetases and cannot replace ATP as the substrate.[9–11] However, in the case of leucyl-tRNA-synthetases isolated from the chloroplasts and cytoplasm of *Euglena gracilis*,[12] compound (Ia) proved to be a substrate capable of replacing ATP in reaction (2).

The biosynthesis of protein takes place on ribosomes and is programmed by the template (information) RNA (mRNA). The aminoacid sequence in the protein synthesised is programmed in the mRNA by a sequence of trinucleotides (codons) which select from a mixture of aminoacyl-tRNAs one possessing an anticodon specifically recognised by the corresponding codon. The corresponding aminoacid is thereby selected. For example, polyuridylic acid $(pU)_n$ promotes the selection of phenylalanyl-tRNA with the anticodon –pGpApA–.

Analogously polyadenylic acid $(pA)_n$ promotes the selection of the ribosomal lysyl-tRNA. The selected aminoacyl-tRNA reacts with the growing polypeptide chain, present on the ribosome in the form of peptidyl-tRNA, in the following manner:

$$\begin{aligned} &NH_3^+CH(R^1)CO - NHCH(R^2)CO - \ldots NHCH(R^i)CO - tRNA^i + \\ &+ NH_3^+CH(R^{i+1})CO - tRNA^{i+1} \rightarrow NH_3^+CH(R^1)CO - \ldots \\ &- NHCH(R^i)CO - NHCH(R^{i+1})CO - tRNA^{i+1} + tRNA^i. \end{aligned} \quad (3)$$

In the presence of polyuridylic acid and even of its short fragments down to $(pU)_3$, phenylalanyl-tRNA is therefore bound to the ribosome. In the presence of polyadenylic acid, Lys-tRNA is bound to the ribosome. It has been found that the alkylating derivatives of oligonucleotides $(pN)_n$, carrying the *N*-2-chloroethyl-*N*-methylaminophenyl fragment ClR either at the 5′- or the 3′-end also stimulate the binding to the ribosome of the aminoacyl-tRNA coded by them, i.e. the introduction of a reactive group in the 3′- or 5′-position does not disturb the functional activity of the oligonucleotide.[13–15]

Thus the affinity reagents L–X either function together with the ligand L or behave as competitive inhibitors of the function performed by the biopolymer. Naturally, reversible inhibition must be studied under conditions where the chemical activity of L–X, resulting in the covalent binding of L–X to the recognition region of the biopolymer, is not manifested. This can be readily achieved in the case of photoactive reagents, for example the reagents (Ia) and (Ib), which react under ultraviolet irradiation, which converts the azide, chemically inert under physiological conditions, into the highly reactive nitrene biradical. For this, it is sufficient to investigate the functional activity of P in the presence of L and L–X in the dark. Otherwise, it is necessary to employ fairly rapid tests for functional activity carried out over a period significantly shorter than the time of the chemical reaction of L–X in the complex with P. For certain reagents it is possible to convert the reactive derivative into an inactive derivative with a very similar structure. For example, having kept the reagents (Id) and (If) in water for a time sufficient to hydrolyse the C–Cl bond, it is possible to obtain from $ClRCH_2NHpppN$ the derivative $HORCH_2NHpppN$ similar in structure and hence in affinity to the biopolymer, to investigate its inhibiting activity as a function of the polymer being studied, and hence to estimate its affinity for the biopolymer.

The rate of the affinity modification is

$$v = k[P{\cdot}L - X] = \frac{kK_x[L - X]P_t}{1 + K[L] + K_x[L - X]},$$

where k is the rate constant for the reaction of L–X with P in the complex P.L–X.

When the affinity reagent (and the natural ligand when the latter has been introduced into the reaction mixture) are present in a sufficient excess relative to the polymer and do not undergo side reactions, we have

$$v = \frac{kK_x[L - X]_0 P_t}{1 + k[L]_0 + K_x[L - X]_0},$$

where $[L]_0$ and $[L–X]_0$ are the initial concentrations. Since the total concentration of the biopolymer decreases in affinity modification, we have

$$P_t = (P_t)_0 - [L - X - P],$$

where $(P_t)_0$ is the initial concentration of the biopolymer and L–X–P is the product of the affinity modification. In this case the process is a pseudofirst-order reaction:

$$v = \frac{d[L - X - P]}{dt} = \frac{kK_x[L - X]_0}{1 + K[L]_0 + K_x[L - X]_0}\{(P_t)_0 - [L - X - P]\}.$$

It follows from this expression that the dependence of the apparent rate constant on the concentration of the affinity reagent is hyperbolic and the natural ligand inhibits the affinity modification process (it is usually said that it protects the polymer against affinity modification). Both these findings are important criteria, whose fulfillment shows that the process investigated proceeds via the affinity modification mechanism.

If the addressed section of the reagent is fixed in the recognition region as a result of the affinity modification, the interaction of the natural ligand L with the biopolymer P is significantly hindered or becomes altogether impossible, i.e. the biopolymer becomes functionally inactive. Assuming that the functional activity of the biopolymer, retained at a specific instant, is proportional to the concentration of the unmodified biopolymer, it is possible to follow the course of the affinity modification from the inactivation of the biopolymer, which is described by a kinetic equation for a pseudo-first-order reaction in the presence of a sufficient excess of L–X in relation to the polymer:

$$-\frac{dF}{dt} = k_{app}F = \{kK_x[L - X]_0/(1 + K_x[L - X]_0\}F.$$

All the equations presented were derived on the assumption that L–X is consumed only in the reaction with the polymer in the complex P.L–X. If the reagent has been taken in excess relative to P, the reaction proceeds until the polymer has been completely consumed. However, in fact, sufficiently active groups X can as a rule react also with water, with the buffer components of the medium, and also with the biopolymer itself without preliminary complex formation, including its sections which have no direct bearing on the recognition region. The group X then reacts and loses its reactivity, while the address remains unaltered, i.e. the affinity for the

†Adenosine 5′-triphosphate (ATP) is the substrate or effector in hundreds of different enzymic reactions and its reactive derivatives and analogues are widely used in the study of the corresponding enzymes.

biopolymer is retained. The reaction product L–R becomes an inhibitor of the affinity modification with a constant K_r, which is the constant for the association of L–R with P. A kinetic analysis of this process has been carried out[16] on the assumption that the reagent has been taken in significant excess. The equation of the kinetic curve in the general case where $K_r = K_x$ is

$$[L-X-P]/(P_t)_0 = 1 - \left[\frac{1+K_x[L-X]_0}{1+K_r[L-X]_0-(K_r-K_x)[L-X]_0\exp(-k_0 t)}\right]^{\frac{\gamma K_x}{K_r-K_x}}.$$

In this case the reaction does not go to completion, i.e. the degree of conversion of P into L–X–P does not reach unity even in the limit:

$$\{[L-X-P]/(P_t)_0\}_{t=\infty} = 1 - \left(\frac{1+K_x[L-X]_0}{1+K_r[L-X]_0}\right)^{\frac{\gamma K_x}{K_r-K_x}}, \quad (4)$$

where k_0 is the pseudofirst-order rate constant for the reaction of L–X in solution with water and other components and $k_0\gamma$ is the rate constant for the conversion of the complex P.L–X into the affinity modification product. The degree of conversion at the end of the reaction can be measured with a sufficient accuracy even when the affinity modification is rapid and it is difficult to obtain the kinetic characteristics of the process. Evidently, in a suitable range of concentrations, it is possible to obtain from Eqn.(4) the association constants K_x and K_r as well as the quantity γ, which are present in Eqn.(4) as independent parameters.

The kinetics of the affinity modification become complicated still further when the interaction of P with L–X is a complex reaction proceeding via the formation of active intermediate species. This process has been considered by Knorre and co-workers,[17,18] such consideration being outside the framework of this review.

III. THE PRINCIPAL PROBLEMS SOLVED BY THE METHOD OF AFFINITY MODIFICATION AND THE GENERAL PRINCIPLES OF THE CONSTRUCTION AND USE OF AFFINITY REAGENTS

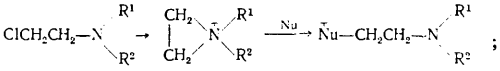
The nature of the reactive group of the affinity reagent, the method of introducing it into a natural ligand or its analogue, the carrier of affinity for the biopolymer (address), and the method used to carry out the affinity modification are to a large extent determined by the problem which has to be solved with the aid of the given reagent. Therefore, before proceeding to a systematic description of the different types of reactive derivatives of nucleic acids and their components, we shall consider the principal problems in the solution of which the method of affinity modification is used and the requirements arising from this which must be met by the affinity reagents and by the procedures employed for the affinity modification.

We shall begin with the question of the investigation of the region of the specific interaction of the biopolymer with the ligand with the aid of a reactive derivative of the ligand.

In its most simplified form, this approach presupposes that the addressing component of the reactant is fairly rigidly fixed in the recognition region via non-covalent interactions, after which the biopolymer is attacked by the reacting group and the reagent is covalently fixed in the same region. For a biopolymer with a known primary structure, it is then determined which particular aminoacid or nucleotide residue has been chemically modified. The monomeric fragment located in the recognition region or in its immediate vicinity is thereby found. If the three-dimensional structure of the biopolymer is known and data or fairly reliable ideas about the conformation of the reagent are available, it is possible to determine the entire region in which the biopolymer interacts with the address.

Clearly the rigid fixation of the address should sharply limit the region of contact between the biopolymer and the reacting group and hence the region in which chemical modification can occur. For it to actually occur, it is necessary that in this region there should be at least one group capable, in principle, of chemical interaction with the reagent employed. This is more probable the less selective the reacting group.

From this point of view, among heterolytic processes the most favourable are the reactions of strong and only weakly selective electrophiles with numerous nucleophilic centres of proteins and nucleic acids. The latter include the imidazole rings of the histidine residues, the ε-amino-groups of the lysine residues, the carboxy-groups of the aspartate and glutamate residues, the hydroxy-groups of the serine, threonine, and tyrosine residues, the SH groups of the cysteine residues, the carbonyl oxygen of the peptide bonds and glutamine and asparagine residues, the terminal amino- and carboxy-groups of the polypeptide chains, many positions in the heterocyclic bases of nucleic acids, and the phosphodiester internucleotide and terminal phosphomonoester groups of the polynucleotide chains. Among the reacting groups of this type in affinity reagents based on nucleic acids and their components, the moderately reactive CH_2ICO and CH_2BrCO groups and the aromatic and aliphatic 2-chloroethylamino-groups have found the greatest applications at the present time. The former react via a direct mechanism and the latter via the intermediate formation of highly electrophilic ethyleneimmonium cations:

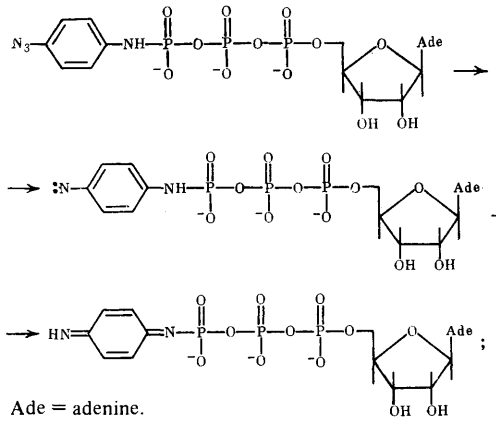


Nu = nucleophile.

For aromatic 2-chloroethylamines, the first stage is rate-limiting[19] and the intermediate cations are extremely reactive and do not accumulate in measurable concentrations, reacting almost instantaneously with nucleophiles, including water, which is invariably present when biopolymers undergo affinity modification. Their reactivity in relation to nucleophiles has come to be characterised by the competition factor, which is defined as the ratio of the rate of reaction with the nucleophile to the rate of reaction with water divided by the concentration of the nucleophile.[20]

Pt^{2+} derivatives have also been proposed recently as the reacting groups in affinity reagents for attack on nucleophilic centres.[21,22]

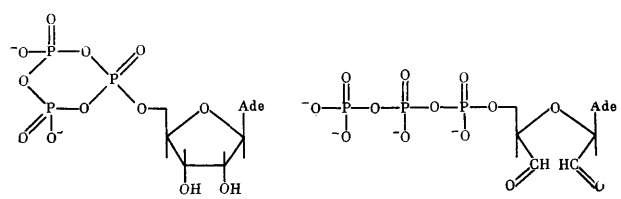
According to data obtained in anhydrous model systems, the singlet nitrene R–N:, capable of being inserted in X–H bonds, including C–H bonds, is even less selective. Derivatives of aryl azides, which generate nitrenes on irradiation with ultraviolet light, have therefore found extensive applications as affinity reagents. The potentially singlet nitrene can modify even the side groups in hydrophobic aminoacids–alanine, valine, leucine, isoleucine, phenylalanine, and proline. However, recent investigations of the behaviour of nitrenes in aqueous solution have shown that rapid secondary reactions, which depend significantly on the nature of other groups in the same benzene ring, are characteristic of these species.[23–24] Thus it has been established that compound (Ia) namely the γ-p-azidoanilide of ATP, is rapidly converted into a quinone imine imide on irradiation of its aqueous solution with ultraviolet light.[25]



Ade = adenine.

This compound is a powerful electrophile which reacts with imidazole, morpholine, and mercaptoethanol, but its selectivity is significantly higher than that of nitrenes.

For reagent (Ia) as an example, it is seen that, apart from the address, which in the given instance is the ATP residue, and the reacting group, it contains the connecting phenylamide fragment (spacer). For a rigid fixation of the address, the modification takes place in this instance outside the recognition region. Such reagents have come to be called exoreagents. For the reacting group to come into contact with the active centre, it is desirable that it be part of the composition of the address itself, i.e. that an endoreagent be employed. Naturally, this can be done only at the expense of some distortion of part of the address, having made sure that such distortion does not alter sharply the affinity for the biopolymer. Adenosine 5'-trimetaphosphate (II) (ATMP) or the product of the oxidation of ATP with periodatate at the *cis*-diol group (oATP) may serve as examples of endoreagents.



ATMP oATP

The former is a powerful phosphorylating reagent and, as a result of the modification, the ATP residue is directly bound to the nucleophilic centre of the biopolymer. The latter is capable of forming Schiff bases with the ε-amino-groups of lysine residues via the aldehyde groups.

A number of attempts at direct photochemical cross-linking of nucleic acids and their components in complexes with biopolymers have been described. By virtue of the short life of the excited state, one may expect that modification takes place directly in the region of the interaction of the chromophore with the biopolymer. However, the nature of the products formed and their stability, including their stability under conditions necessary for the subsequent identification and localisation of the modified fragment, have so far been little investigated and it is as yet impossible to assess the likely usefulness of this approach for the determination of the recognition region.

As already mentioned, the idea of the rigid fixation of the address is not itself non-controversial. Any recognition is ensured by a multipoint interaction. Less populated states with interaction via an incomplete set of points should therefore exist in the biopolymer–ligand complex together with the state in which all the contact points are employed. As a result of this, the reacting group can acquire a significant mobility. Biopolymers are also not rigid molecules and comprise different conformations in different proportions, as shown by the ability of many biopolymers to undergo specific conformational transitions. The biopolymer–ligand complex can therefore be represented by a multiplicity of states with different mutual orientations of the reacting group and the reactive sections of the biopolymer. The probability of affinity modification is determined not only by the population of a particular state but also by the extent to which this state is favourable for chemical reaction. Therefore, as a result of the modification of the biopolymer by the affinity reagent, the address may be fixed in a state which differs significantly from the functionally significant state and can actually be displaced from the recognition region, as shown schematically in Fig. 1.

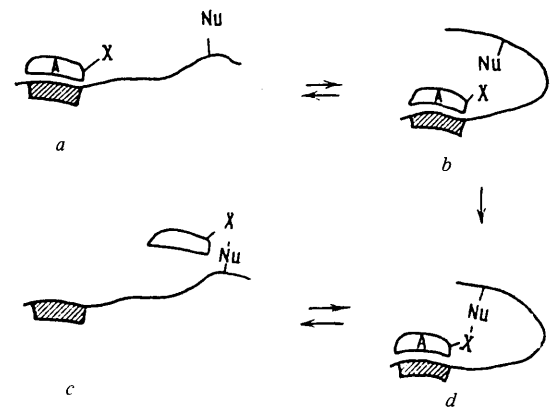


Figure 1. Schematic representation of the modification of a biopolymer at the nucleophilic centre by means of an Nu reagent consisting of the address A and the electrophile X, which leads to the fixation of the address outside the recognition region (shaded part): *a*) predominant conformation of the biopolymer–reagent complex; *b*) conformation present in a small proportion but having a favourable mutual disposition of the reacting groups; *c*) the same conformation after the reaction; *d*) predominant conformation of the modification product.

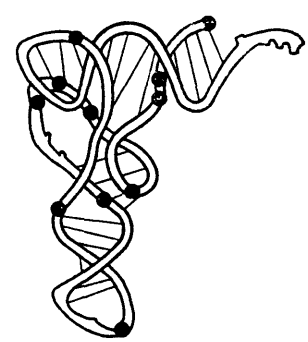

Figure 2. The positions in the structure of phenylalanine tRNA from *E. coli* of the guanosine residues (filled circles) through which groups capable of photoactivation are introduced statistically in the preparation of the azido-tRNA affinity reagent.[37]

It follows from all the foregoing features that even small changes both in the recognition region of the biopolymer and in its immediate environment as well as in the structure of the reagent can exert a drastic influence on the process and the result of the affinity modification. We shall present several examples.

As already stated, compound (Ia) is a competitive inhibitor of aminoacyl-tRNA synthetase from *E.coli*[9] and tryptophanyl-t-RNA synthetase from the ox pancreas.[10] In both cases ultraviolet irradiation of the complex of compound (Ia) with the enzyme entails the covalent addition of the reagent to the enzyme. However, whereas in the latter case it is accompanied by the inactivation of the enzyme, the addition of up to 20 residues of the reagent to phenylalanyl-tRNA synthetase does not lead to the loss of kinetic activity, i.e. the address remains fixed outside the ATP recognition region. The replacement of the *p*-azidoaniline residue in compound (Ia) by the *p*-azido-*N*-methylbenzylamine residue gives rise to a reagent which adds photochemically to phenylalanyl-tRNA synthetase and inactivates the enzyme.[26]

On irradiation with ultraviolet light, the reagents (Ie) and (Id) inactivate the RNA-dependent DNA polymerase and DNA polymerase(I) from *E.coli*. However, in order to obtain the same level of inactivation of the enzyme a concentration of the reagent lower by a factor of 50 is required in the first case compared with the second case.

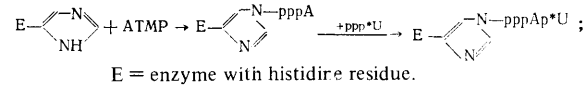
The reagent (If) has been investigated as an affinity reagent in relation to yeast hexokinase—the key enzyme in carbohydrate metabolism, catalysing the transfer of the orthophosphate residue from ATP to the 6-hydroxy-group of glucose. Depending on the pH of the medium, the enzyme exists in the monomeric or dimeric form. It has been found that compound (If) is not a competitive inhibitor of the monomeric hexokinase and accordingly does not inactivate the active centre of the enzyme. On the other hand, it has an affinity for the dimeric form of hexokinase comparable to that of ATP and inhibits this enzyme irreversibly.[27] It is of interest to note that an analogous derivative of AMP, namely $ClRCH_2NHpA$, inhibits irreversibly the monomeric form of hexokinase via the affinity modification mechanism, but does not act on its dimeric form.[28]

Thus the same reagent can behave very differently in relation to biopolymers fulfilling isotypical functions or in relation to different states of the same biopolymer. On the other hand, the examples presented have shown that, by introducing certain changes into the structure of the address of the spacer fragments, it is usually possible to find a suitable affinity reagent for the biopolymer investigated.

Together with a change in the structure, it is possible to influence the results of the affinity modification by altering the method by which it is carried out. A procedure has been proposed[29] which can find fairly wide-scale applications in the affinity modification of enzymes catalysing two- and three-substrate reactions. The initial stage of the reaction catalysed by the RNA polymerase from *E.coli* has been investigated and it was found that in the presence of the substrates pppA and pppU in conjunction with the template employed (a fragment of the T7 bacteriophage DNA) the enzyme catalysed the reaction

$$pppA + pppU \rightarrow pppApU + pp\ .$$

The use of ATMP as the affinity reagent can lead to its non-specific modification by virtue of its high reactivity. However, when ATMP was added to the enzyme, the subsequent addition of the second unit of the polynucleotide chain is possible only when the PPPA fragment is bound in the region of the active centre of the enzyme. When non-radioactive ATMP and UTP labelled with ^{32}P in the α-position in the triphosphate fragment are used, the radioactive label is found only in the section corresponding to the active centre of the enzyme. It has been shown that the addition is to a histidine residue:[29]



E = enzyme with histidine residue.

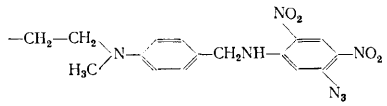
All that has been said above demonstrates that the synthesis and application of affinity reagents, suitable for the location of individual sections of monomers in the recognition region, is by no means the trivial task it might have appeared to be on the basis of a simplified model of affinity modification. It is therefore not surprising that only a limited number of reliably interpreted results have so far been obtained on these lines.

The problem of elucidating the functional significance of individual subunits in multisubunit structures with the aid of affinity modification appears much simpler. In this case it is sufficient that the reaction should have occurred within the limit of the subunit which interacts with the address. The greatest number of studies of this kind have been carried out with ribosomes and in particular with the ribosomes from *E.coli*, for which the primary structure of all the RNA molecules constituting the ribosome (ribosomal RNA or rRNA) and all the 53 proteins are now known. The identification of the regions corresponding to the binding of mRNA, namely two tRNA molecules carrying the peptide and aminoacyl residues (the P and A sites in ribosomes), as well as the region catalysing the transfer of the peptide residue to the aminoacyl-tRNA, the so-called peptidyltransferase centre, is of primary interest. Since the region where the codon–anticodon interaction takes place is of greatest importance for the mRNA recognition region, reactive derivatives of oligonucleotides containing one or several codons are widely used. Since the modifying proteins and rRNA fragments are identified by electrophoresis on the basis of the determination of electrophoretic mobilities, it is important that the large oligonucleotide or polynucleotide should be removed before identifying the modified component. For this purpose, it is convenient to employ reagents from which the address can be split off under fairly mild conditions. The oligoribonucleotide derivatives $ClRCH_2NH(pN)_n$ and $(pN)_n > CHRCl$, mentioned in the previous Section, in which the alkylating fragment is joined to the address via either a phosphoramide or an acetal linkage, satisfy this condition particularly well. Both types of linkage are fairly stable under the conditions of affinity modification but readily hydrolyse in a weakly acid medium.

In many cases the region of the interaction of the polymeric address with a complex subunit structure is fairly extensive. In particular, the regions of the interaction of mRNA and tRNA with a ribosome embrace a number of components of the ribosome, both rRNA and proteins. In order to identify this region by the traditional procedure based on the use of an individual compound as the affinity reagent, it is necessary to have a set of reagents with different positions of the reacting group relative to the address. Thus, in a study of the region in which mRNA is bound to ribosomes from *E.coli* and from rat liver[14,30–32] with the aid of alkylating derivatives of oligouridylates, it was found that both the distribution of the label between rRNA and the proteins and the sets of the modified proteins differ sharply depending on the end (3′ or 5′) of the oligonucleotide address to which the *N*-2-chloroethyl-*N*-methylaminophenyl fragment is linked.

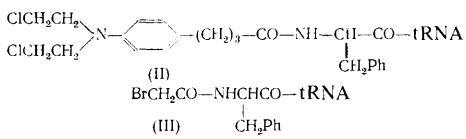
The synthesis of a large set of derivatives with different fixed positions of the reactive groups is fairly laborious for a polymeric address, for example, tRNA. It is therefore convenient to use as reagents for the first stage of the investigation derivatives in which the active groups are scattered statistically throughout the polymer molecule. The number

of such groups in each individual tRNA molecule should be small, not more than 2–3, in order not to disturb the ability of tRNA to interact specificially with the ribosome. tRNA derivatives containing fragments capable of being photoactivated have been synthesised for this purpose:



They are bound covalently to numerous tRNA guanine residues (Fig.2).[33] When 1–2 such residues are present on the molecules of the phenylalanine tRNA from *E.coli*, the latter retain the ability to bind phenylalanine enzymically and the resulting phenylalanyl-tRNA is bound selectively to the ribosome in the presence of poly-U. There derivatives (azido-tRNA) have found extensive applications in the study of the regions in which tRNA is bound to the ribosome in various functional states of the latter.[34,35]

The problem of the region corresponding to the interaction of phenylalanine tRNA with phenylalanyl-tRNA synthetase from *E.coli* has also been solved with the aid of azido-tRNA.[33] The above enzyme consists of two types of subunits—α and β. The problem was initially investigated with the aid of alkylating derivatives of tRNA carrying reactive groups on the aminoacyl fragment:



At first sight contradictory results were obtained: the first reagent alkylated predominantly the α-subunit[36] while the second alkylated mainly the β-subunit.[37] The use of azido-tRNA showed that, when the complex of the enzyme with the above derivatives is irradiated, tRNA adds predominantly to the β-subunit.[33] The fact that, for a substituent of small size at the α-amino group, the β-subunit is also alkylated and that after an increase in the size of the substituent mainly the α-subunit is alkylated permitted the additional conclusion that the acceptor end of tRNA in the complex with the enzyme is located near the region where the subunits come into contact.

Yet another problem in the solution of which affinity reagents can find extensive applications is that of the determination of the primary structure of large polymer molecules, for example, DNA. An important stage in the determination of the primary structure is the selective cleavage of the large polymer molecule into fragments of moderate length. In relation to DNA, this problem is solved with the aid of special restriction enzymes, which selectively cleave DNA in the vicinity of specific nucleotide sequences. At the same time, there are many chemical methods for the cleavage of DNA. For example, alkylation of the purine bases leads to their elimination, which makes it possible to cleave DNA under alkaline conditions in the depurinated sections. DNA is also cleaved in the presence of Fe^{2+} ions and O_2. For this purpose Fe^{2+} should be chelated, which is achieved either with the aid of special antibiotics, for example, bleomycin, or with the aid of model chelating agents, such as ethylenediaminetetra-acetic acid.[38] The cleavage of DNA with the aid of dyes on irradiation by a 337 nm laser having a high irradiation density has been described recently.[39] The cleavage takes place as a result of the absorption by the dye of two quanta and the subsequent radiationless excitation energy transfer to the σ-bonds of the ribose phosphate skeleton.

The addition of the corresponding reactive groups to oligonucleotides of specific structure leads to the prospect for the selective cleavage of DNA and RNA in the vicinity of sections complementary to the addressing oligonucleotides. Fig.3 presents the results obtained when a DNA fragment is treated by an addressed alkylating reagent complementary to the single-stranded section of this fragment.[40]

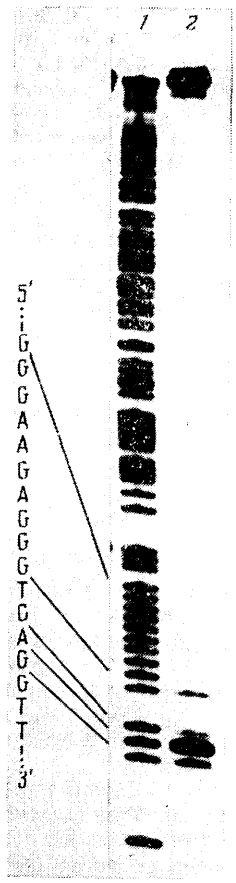


Figure 3. Results of the electrophoretic analysis in a polyacrylamide gel (autoradiograph) of the products of the cleavage of the 303-nucleotide single-stranded DNA fragment labelled at the 3'-end with the ^{32}P radioisotope after the complementarily addressed alkylation with the reagent $ClRCH_2$. .NHd(pTpGpApCpCpCpTpCpTpTpCpCpCpA) which is complemetary to the sequence of the fragment TpGpGpGpApApGp. ApGpGpGpTpCpA and after treatment with piperidine in order to achieve cleavage at the alkylated purines: *1*) products of the partial degradation of the fragment at the purine nucleotides (marker for the determination of the cleavage sites); *2*) products of the degradation of the fragment obtained with the aid of the complementarily addressed modification.[40]

In all the cases described above we were dealing with the use of affinity reagents as research instruments. However, another application of these reagents has begun to develop vigorously, namely the application involving specific action on biological processes. We shall consider this aspect in

relation to the approaches whereby nucleic acids, i.e. the genetic apparatus, can be specifically acted upon.

It is known that chemical influences on nucleic acids have found extensive applications for the preparation of modified forms of living organisms resulting from a change in the DNA structure (mutations). Such influences on nucleic acids are used in oncology for the suppression of the multiplication of malignant tumour cells, in certain special situations for the suppression of the immune response by the organism, for example, for the prevention of the rejection of surgically transplanted kidneys, and to regulate the multiplication of viruses in viral infections. In all the cases described one is dealing with relatively unselective reagents, which make an impact on all nucleic acids. Thus, in chemical mutagenesis the changes occur statistically in all the genes, generating numerous, as a rule unfavourable or even lethal, changes in the genetic apparatus. However, when one is dealing with micro-organisms or plants, the few mutations which impart to the organism a feature which is of interest from the practical point of view can be discovered by subsequent selection. Such selection can lead to the creation of new forms of plants and micro-organisms. When chemical reagents acting on nucleic acids, namely derivatives of 2-chloroethylamine, *cis*-dichlorodiammineplatinum, and others are used, in some cases it is possible to select doses which effectively arrest the growth of the tumour but are not yet lethal for the human organism as a whole. In those few cases where this can be achieved, chemotherapy makes it possible to prolong life and sometimes also to effect a radical cure of the patient.

The prospect of increasing the selectivity of such reagents and in the ideal case of creating reagents which would suppress the multiplication of viruses or cancer cells without harming healthy cells and would also suppress the multiplication of the immunocompetent cells (T-lymphocytes) which are designed to reject transplanted organs but would not act on cells fulfilling other numerous protective functions in the living organism is attractive. One of the imaginable pathways leading to the fulfillment of this aim involves the creation of complementarily addressed reagents on the basis of oligonucleotides or nucleic acids complementary to the affected target. This problem was formulated in a general form for the first time by Summerton.[41]

In order to realise fully this prospect, it is necessary to solve a number of new problems. In the first place, we are dealing with the creation of reagents acting on nucleic acids but at the same time possessing components having the same chemical composition and acting as the address. It is necessary to prevent to the maximum possible extent the action of the reacting group on the address itself, particularly in the numerous preliminary operations. One of the possible procedures involves the application of reacting groups whose reactivity is regulated in some way. It has been suggested[42] that the *N*-2-chloroethylalkylaminophenyl group, having the formyl residue in the *para*-position in the benzene ring, be used for this purpose. As a result of the strong electron-accepting effect of the formyl group, the alkylating properties of the 2-chloroethylamino-group are weak. This makes it possible to obtain nucleic acid derivatives of interest to the experimenter virtually without any risk of alkylating the address. Directly before using the reagent, it is possible to reduce the formyl group to the hydroxymethyl group, which increases by two orders of magnitude the reactivity of the *p*-*N*-2-chloroethyl-*N*-methylaminophenyl residue.

If we think of the future employment of complementarily addressed reagents as medical preparations or for the induction of mutations in living organisms but not in isolated DNA molecules, it is necessary to take into account, in the synthesis of the reagents, the possibility of the degradation of the address by nucleases and the necessity for the reagent to cross the outer and inner membranes of the target cells.

Studies on affinity modification involving living objects are in the very initial stage. In relation to the alkylation of derivatives of oligothymidylates with one uridine residue at the 3′-end, carrying at this end the alkylating groups $(dTp)_nUCHRCl$, it has been shown that they modify the complementary polyadenyl fragments in the cells of the Krebs ascites carcinoma, such fragments being usually located at the 3′-end of the mRNA of higher organisms.[43] At the same time it has been shown that the address is preserved and the high selectivity of the alkylation reaction has been demonstrated: the degree of modification of the fragments of poly-A exceeded by two orders of magnitude the degree of modification of the remaining nucleic acids in the cells. In order to increase their ability to permeate through the membrane, oligonucleotides with ethylated internucleotide phosphates $[dTp(C_2H_5)]_nUCHRCl$ were used.[44] The penetration into the cell was then significantly greater than in the case of the non-ethylated negatively charged address. The first successful data concerning the possibility of the effective modification of viral nucleic acids in cells and specific mRNA of the cells were obtained in experiments designed to suppress the development of the influenza virus in the cells of chicken fibroblasts[45] and to suppress the synthesis of immunoglobulins in the tumour cells of mouse myeloma.[46]

IV. REACTIVE DERIVATIVES OF NUCLEOSIDES AND NUCLEOSIDE MONO-, DI-, AND TRI-PHOSPHATES

Nucleosides and nucleoside mono, di-, and tri-phosphates are the simplest compounds containing chemical structures characteristic of nucleic acids: the heterocyclic bases, ribose or deoxyribose, and phosphoric acid residues. In order to obtain affinity reagents, it is possible to introduce reactive groups into each of these structures.

Reactive groups are frequently introduced into heterocyclic bases by their halogenation and subsequent substitution of the halogenated compounds. The widely employed derivatives of purine nucleoside polyphosphates having the azido-group in the 8-position as well as derivatives of purine nucleoside polyphosphates having SH or azido-groups in the 6-position may serve as examples of derivatives obtained in this way.

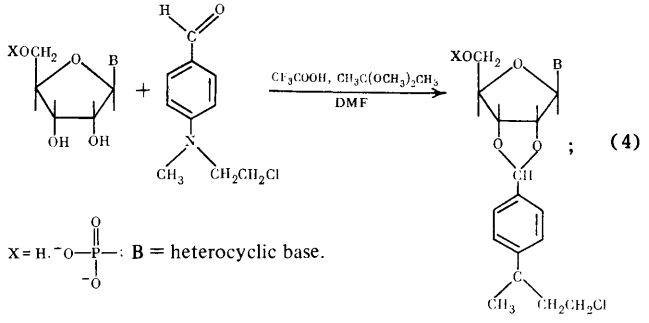
Such derivatives are affinity reagents of the endo-type, since the most specific fragments of the structure of nucleoside polyphosphates, recognised by enzymes, are their heterocyclic bases. A second approach to the introduction of reactive groups into heterocyclic bases leads to the formation of reagents of the exo-type and is based on the application of heterobifunctional reagents containing two groups with different chemical properties. One of the groups of the reagent ensures its addition to the heterocyclic base, while the other correspondingly becomes the reactive group of the affinity reagent obtained. Thus photoactivatable and arylating affinity reagents have been obtained by acylating the amino-groups of purine nucleoside polyphosphates by the halide of the corresponding substituted carboxylic acids.[47]

In the studies of the properties of derivatives of nucleoside polyphosphates having reactive groups in the heterocyclic bases it was observed that as a rule they differ sharply from the normal substrate in terms of their ability to interact with enzymes. For example, the analogue of guanosine triphosphate with the 4-azidobenzyl residue in the amino-group could not be used for the affinity modification of the enzyme adenylate cyclase, since its affinity for this enzyme was too low.[47] This is not surprising, because it is known that heterocyclic

bases play the main role in ensuring the specificity of such interactions. The introduction of substituents into heterocyclic bases should influence their interaction with enzymes and can influence their conformational state. Thus the 8-azido-derivatives of purine nucleoside polyphosphates mentioned above have the *anti*- and not the *syn*-conformation, in contrast to the normal substrates.[48] The synthesis and properties of derivatives of nucleoside polyphosphates having reactive groups in the heterocyclic bases have been recently considered in a number of reviews[48–50] and will not be discussed here.

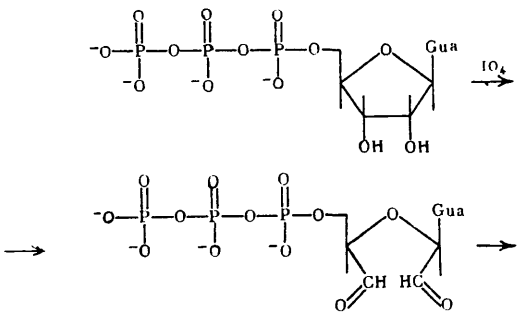
The principal method for the modification of ribose and deoxyribose involves the acylation of their hydroxy-groups. A number of derivatives with sulphonylating and aryl azide groups in the 2′(3′)-positions in ribose have been obtained by acylating adenosine polyphosphates.[49] Acylation of adenosine and subsequent separation of the product yielded derivatives with alkylating or sulphonylating groups in the 5′- or 2′(3′)-positions in ribose.[51,52]

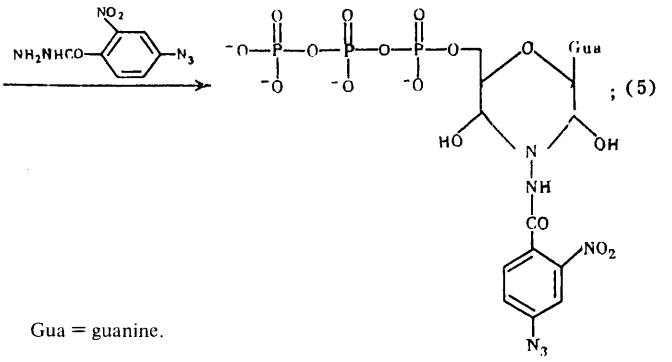
A method has been developed for the introduction of the alkylating fragment at the 2′,3′-cis-diol group. For this purpose, the nucleoside or nucleotide is treated in anhydrous dimethylformamide with 4-(*N*-2-chloroethyl-*N*-methylamino)-benzaldehyde in the presence of CF_3COOH and dimethoxypropane. Derivatives of uridine, adenosine, cytidine, and all four 5′-nucleotides have been obtained in this way.[53–56]



However, they have been tested as affinity reagents only at the level of oligo- and poly-nucleotides and will be discussed in the next Section.

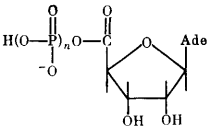
The oxidation of nucleosides and their polyphosphates by periodate leads to the cleavage of the furanose ring at the 2′,3′-diol group with formation of a reactive centre—the dialdehyde group. The latter can itself interact reversibly with the amino-groups of proteins via the formation of Schiff bases. The reduction of Schiff bases with tetrahydroborates leads to the irreversible binding of the reagents to the amino-derivatives. The nucleoside polyphosphates oxidised at the ribose residue have been used for the affinity modification of many enzymes.[49] The reaction of the ribose-oxidised guanosine triphosphate with a bifunctional hydrazide reagent yielded a derivative with an aryl azide group:[57]





Gua = guanine.

Derivatives of adenosine mono- and tri-phosphates, capable of reacting with the nucleophilic groups of proteins, have been obtained by phosphorylating adenosine oxidised at the 5′-carbon atom:[58,59]



$n = 1, 3$.

Reactive groups can be introduced into the structure of nucleoside polyphosphates by replacing the entire phosphate group or part of it. Many reagents of this type have been described in reviews[48–50] and many of them have been used as affinity reagents. However, numerous facts indicate that this method of introducing reactive groups into the structure of nucleoside polyphosphates is non-optimum, since the decrease of the overall negative charge of the molecule has a significant influence on its interaction with enzymes. Evidently the most rational procedure for the synthesis of affinity reagents derived from nucleoside polyphosphates involves the introduction of the reactive groups into their terminal phosphates. Derivatives of nucleoside triphosphates, which are the substrates of hundreds of enzymic reactions and which have reactive groups at the γ-phosphate residue, are of greatest interest. It is to be expected that the ability of the molecule as a whole to undergo specific interactions is least disturbed in such derivatives, because neither the base nor the carbohydrate component of the molecule have been affected and only the charge of the triphosphate group has been reduced by unity.[60] The vast majority of enzymic reactions with participation of nucleoside triphosphates represent either phosphate transfer or the transfer of the nucleotide residue to an acceptor, so that the triphosphate group should be located directly in the active centre of the enzyme near the acceptor binding centre. For this reason, reactive γ-derivatives of nucleoside triphosphates can be used also for the investigation of the acceptor binding sections.

In order to obtain derivatives of nucleoside 5′-triphosphates containing different substituents bound to the γ-phosphate, a simple general method, based on their conversion, with the aid of carbodiimides, into nucleoside 5′-trimetaphosphates, has been developed. The reaction can proceed both in an anhydrous medium using dicyclohexylcarbodiimide and in an aqueous solution using a water-soluble carbodiimide. The resulting nucleoside 5′-trimetaphosphate readily reacts with amines to form the corresponding γ-amides. Examples of compounds obtained in this way are compounds (I, a–f).[61–63]

In conformity with general considerations, it has been found that such γ-amides exhibit an affinity for the majority of the enzymes investigated in the class of hydrolases,

phosphotransferases, and synthetases and, as already mentioned, in some cases can serve as the substrates of these enzymes (see Section II). A systematic account of the data published up to 1980 has been given in the review of Grachev et al.[64] Since that time, the range of enzymes and protein factors investigated has expanded.

It has been shown that the derivative (If) is an affinity reagent in relation to the enzyme catalysing the reversible phosphorolysis of the terminal group in pCpCpA, which is a property characteristic of all transport RNA (ATP, CTP: tRNA nucleotidyl transferase):[65]

$$\text{tRNA-pXpCpCpA + pyrophosphate (pp)} \rightleftarrows \text{tRNA-pXpCpC + pppA,} \quad (5)$$

$$\begin{aligned}&\text{tRNA-pXpCpC + pp} \rightleftarrows \text{tRNA-pXpC + pppC,}\\ &\text{tRNA-pXpC + pp} \rightleftarrows \text{tRNA-pX + pppC;}\\ &\text{X = A, C, G, or T.}\end{aligned} \quad (6)$$

It is also an affinity reagent in relation to acetylcoenzyme A carboxylase, catalysing the conversion of acetyl-CoA into malonyl-CoA:[66]

$$\text{ATP} + HCO_3^- + CH_3CO\text{-CoA} \rightarrow \text{ADP} + p + {}^-OOC-CH_2-CO\text{-CoA},$$

and being of key importance for the biosynthesis of aliphatic acids and in relation to the Na^+, K^+-dependent ATPase, which plays the main role in the transmembrane transport of sodium and potassium ions.[67] It has been established that compound (Ib), a photoactive derivative of GTP, effects the affinity modification of the GTP-dependent protein initiation factor involved in the initial stage of the biosynthesis of proteins in eukaryotic organisms. Among the three subunits of the factor, the γ-subunit is modified exclusively.[68] It has been demonstrated in relation to creatine kinase, an important enzyme in bioenergetic processes in mice, catalysing the transfer of phosphate from creatine phosphate to ADP and supplementing thereby the store of mouse ATP, i.e.

$$^-OOC-CH_2-N(CH_3)-\underset{\underset{NH}{\|}}{C}-NH-\underset{\underset{^-O}{|}}{\overset{\overset{O}{\|}}{P}}-O^- + \text{ppA} \rightarrow {}^-OOC-CH_2-N(CH_3)-\underset{\underset{NH}{\|}}{C}-NH_2 + \text{pppA},$$

that not only the reactive derivatives with an aromatic spacer of the type (I, a–f) but also derivatives of aliphatic 2-chloroethylamines, for example

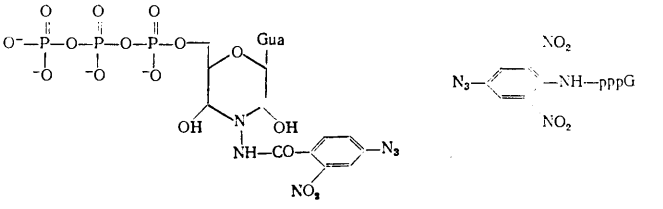
$$ClCH_2CH_2\diagdown\!\!\diagup N(H_3C)\text{—pppA}$$

are effective affinity reagents in relation to ATP-dependent enzymes.[69]

As already mentioned in Section III, the nucleoside 5′-trimetaphosphates are themselves affinity reagents. Apart from the RNA polymerase already mentioned, this has been demonstrated in relation to nucleotide-tRNA transferase[65] and phenylalanyl-tRNA synthetase from *E. coli*.[70]

The molecule of nucleotides are fairly large and the region of contact between the proteins "recognising" them can be fairly extensive. The data obtained with the aid of reagents without reactive groups in different parts of the molecule can therefore supplement significantly one another.

As an example, one may quote studies carried out with the protein elongation factor EF-G, which, combined in the complex with GTP, promotes the migration to the P site of the molecule of peptidyl-tRNA elongated by one aminoacid, formed on a ribosome via reaction (3) and present initially in the A site (such migration is necessary to make possible the start of the next peptide chain elongation cycle with selection of the next aminoacyl-tRNA molecule). In order that the EF-G factor should dissociate from the ribosome after such migration, it is necessary that the GTP molecule be hydrolysed to GDP and orthophosphate. Such activity is indeed characteristic of the complex of the ribosome and EF-G. However, in order to establish whether the corresponding catalytic centre is located on the ribosome or on the factor itself, it is important to determine where the GTP binding region is located. Experiments on affinity modification carried out with derivatives having reactive groups on the triphosphate fragment and on the ribosome residue have shown in both cases that the factor and not the ribosome is affinity labelled, i.e. that throughout most of its extent GTP is bound precisely to the factor:[57,71]



As a second example one may quote data obtained for ATP(CTP):tTNA-nucleotidyl-transferase. As can be seen from Schemes 5 and 6, this enzyme catalyses at least two reactions—the transfer of the CMP residue from CTP to the molecules of tRNA with an incomplete pCpC fragment and the transfer of AMP from ATP to tRNA with a complete pCpC fragment. It has not been established whether the enzyme has two different centres in order to effect these two reactions or whether all the events are played out at a single centre whose specificity changes depending on the nature of the tRNA end fragment. The use of periodate-oxidised ATP and CTP, namely oATP and oCTP, containing the dialdehyde groups in the modified ribose fragment, has shown that both compounds inactivate the enzyme. However, the employment of oATP leads predominantly to the inactivation of the enzyme in reaction (5), while oCTP inactivates reaction (6). These data show that CTP and ATP are located at least partially in different regions.[72]

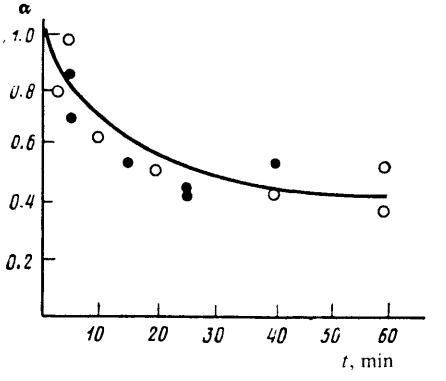


Figure 4. Kinetic curve for the inactivation of the tRNA-nucleotidyltransferase in the presence of 10^{-3} M reagent (If) at 37 °C: filled circles—residual activity determined from the incorporation of [^{3}H]AMP; open circles—ditto determined from the incorporation of [^{3}H]CMP in tRNA.[65]

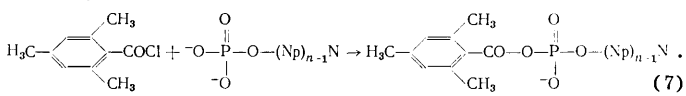
On the other hand, studies carried out with the aid of the derivative (If) having an alkylating group bound to the γ-phosphate, and also with the aid of ATMP and CTMP have shown that the modification of the enzyme suppresses both activities to the same extent. As an example, Fig. 4 presents

the results of a study of the kinetics of the enzyme inactivation by the derivative (If) measured on the basis of the incorporation in tRNA of labelled AMP and CMP from which the pCpCpA end has been partly removed. Evidently, within the limits of experimental error, the data obtained by means of both tests agree. This result shows that, when derivatives with a reactive group on the triphosphate fragment are used, the group which is equally important for reactions (5) and (6) is attacked.[65]

V. REACTIVE DERIVATIVES OF OLIGONUCLEOTIDES

The first reactive derivatives of oligonucleotides were obtained by Grineva and co-workers in connection with the method for the complementarily addressed modification of nucleic acids which they developed.[73,74] The alkylating derivatives of oligonucleotides with a reactive group at the 3′-end were synthesised by reaction (4) which in broad outline proved to be suitable in this case also. The only significant modification on passing from monomers to short oligomers and longer oligonucleotides was the employment of Cetavlon salts of oligonucleotides in order to improve their solubility in dimethylformamide.[75] The method has also been applied to the more readily available deoxyribo-oligonucleotides with a 3′-terminal ribonucleotide fragment.[76] The reaction of *p*-(*N*-2-chloroethyl-*N*-methylamino)benzylamine ($ClRCH_2NH_2$) with the 5′-terminal phosphate group of the oligonucleotide in the presence of condensing agents has been developed for the synthesis of derivatives with an alkylating group at the 5′-end. The condensing reagents used were initially diphenyl phosphorochloridate[77] and later mesitoyl chloride, which leads to the formation of a mixed anhydride between the 5′-terminal phosphate and mesitylenecarboxylic acid:[78]



(7)

Treatment of the resulting mixed anhydride with the amine $ClRCH_2NH_2$ leads to the formation of the required product. When ribo-oligonucleotides are employed, these condensing agents have been shown[79–81] to produce intramolecular cyclic phosphotriesters with participation of the 2′-hydroxy-group, which hydrolyse in water with the partial cleavage of the internucleotide bonds and the isomerisation of the natural internucleotide 3′ → 5′ bond to the 2′ → 5′ bond. Recently such derivatives have been obtained predominantly using as the condensing agent a mixture of triphenylphosphine and dipyridyl disulphide,[30] which does not attack the internucleotide bond in the presence of highly basic amines.[82]

Many important characteristics of the complementarily addressed modification have been established with the aid of these reagents. It has been shown in relation to the reaction of ribosomal RNA from *E.coli*[83] that alkylation of the latter by derivatives of the oligoadenilates $(pA)_nCHRCl$ proceeds as a typical intracomplex reaction—the degree of modification of the ribosomes as a function of the reagent concentration reaches a plateau and does not increase on further increase of the excess of the reagent. In the presence of a small excess of the reagent, about 90% of the latter is consumed in the alkylation of the ribosomes, although, according to the competition factor for the intermediate ethyleneimmonium cations, this quantity should have been a fraction per cent if the reaction proceeded without the preliminary complex formation.[83] The composition of the alkylated bases changes sharply. Whereas the alkylation of tRNA by the analogous derivatives of uridine of the methyl ester of UMP results in the predominant or even exclusive alkylation of the guanine residues,[84,85] the reaction in the complex, where the direction of attack is determined primarily not by the relative reactivities of the bases but by their accessibility to the attack by the alkylating group, fairly rigidly fixed by the address, results in the alkylation of adenine, guanine, and cytosine to comparable extents.[86] Analogous results have been obtained in the study of the alkylation of DNA.[87,88] It has been shown in relation to the reaction of yeast valine tRNA (Fig.5) with the reagent dCpdGprACHRCl, which interacts with the C–G fragments of tRNA, that the fourth, reckoning from the complex formation section, residues in the direction of the 5′-end of the target molecule are alkylated.[89] Later these data were confirmed on a synthetic model:

(5′) d(pXpXpCpCpTpGpTpTpTpGpGpC) (3′)
(3′) ClRHC < rAd(CpApApApCpCpGpT) (5′)

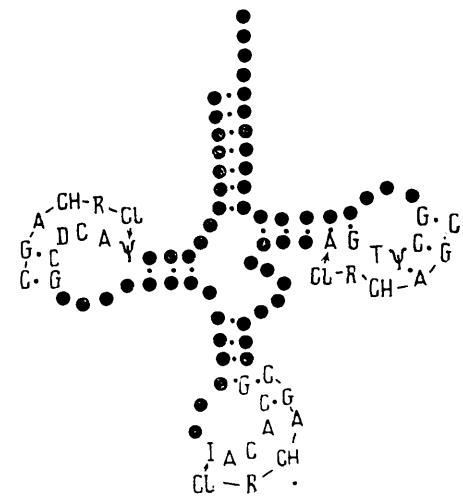


Figure 5. Specific alkylation by the complementarily addressed reagent dCpdGprACHRCl in the structure of the yeast valine tRNA;[89] the letters denote only the nucleotides in the reagent binding regions.

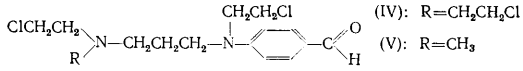
Here and in the next analogous scheme the symbol d is placed before the entire deoxyoligonucleotide sequence, rA denotes adenosine ribonucleoside, and the 5′- and 3′-ends of the two antiparallel complementary chains are indicated in brackets. In all the cases investigated only the d(pXpX) fragment was alkylated in the complex.[90]

Alkylation of DNA by oligonucleotide derivatives with subsequent cleavage at the alkylation points has been proposed as a general method for the selective cleavage of DNA at sections adjoining the nucleotide sequences complementary to the address.[91]

Several other methods for the introduction of reactive groups into the terminal fragments of oligonucleotides have been described. Thus, periodate oxidation followed by treatment with *N*-(4-azidobenzoyl)glycylhydrazide[92] and acylation of the *cis*-diol group with the imidazolide of *p*-azidobenzoic acid[93] have been used for the introduction of the photoactive arylazido-group at the 3′-terminal *cis*-diol.

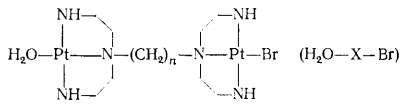
The introduction of an alkylating group into an oligonucleotide at the 5′-end via the alkylation with a trifunctional agent (IV),[42] in which the reactivity of one of the 2-chloroethylamino-groups is controllable, has been described:



(IV): R=CH_2CH_2Cl
(V): R=CH_3

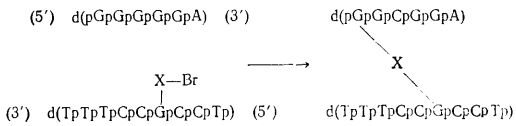
The phosphate is alkylated by the reactive aliphatic group (the second C—Cl bond is then hydrolysed) and the reactivity of the aromatic 2-chloroethylamino-group in the resulting derivative is then increased by reducing the formyl group to the hydroxymethyl group with sodium tetrahydroborate.[94]

The bifunctional platinum derivative[22]



(H_2O—X—Br)

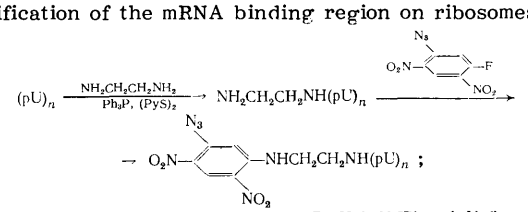
has been suggested for the introduction of reactive residues into the inner sections of an oligonucleotide. Water is readily substituted by the guanine residue in the oligonucleotide functioning as the address. The Pt—Br bond is significantly stronger and reacts with nucleic acid bases only under the conditions of a stable contact generated by a complementary complex. Complementarily addressed modification in a complex has been achieved in this way and, among the four guanine groups of the target oligonucleotide, only one, located in the position within the complex most favourable for the reaction, proved to have been modified:



Derivatives of oligonucleotides having the dimethylaminonaphthalenesulphonyl (dansyl, DNS) residue have been obtained. It has been shown in relation to the derivative DNS-$NHCH_2CH_2(pT)_9$ [95] that, in the two-quantum excitation by means of a laser having a wavelength of 337 nm, the polyadenylic acid complementary to the address is cleaved in the presence of this reagent, but polyuridylic and polycytidylic acids are not cleaved under these conditions.

The addition of a chelating fragment, namely ethylenediaminetetra-acetic acid, to an oligothymidylate has also been achieved. In the presence of Fe^{2+} and O_2 this derivative cleaves the complementary polyadenylate and, to a significantly lesser extent, non-complementary polynucleotides.[96]

In many cases a special group, by means of which it is possible to carry out a highly selective reaction with a heterobifunctional reagent containing the future reactive fragment of the addressed reagent, is introduced beforehand to reactive oligonucleotide derivatives in the course of their synthesis. Aliphatic or aromatic amino-groups, which can be introduced either at the terminal phosphate[97–99] or into the heterocyclic base, for example, in the synthesis of an oligonucleotide containing 5-aminouracil instead of one of the uracil residues,[100] are used for this purpose. As an example, one may quote derivatives employed for the affinity modification of the mRNA binding region on ribosomes:



NH_2Ph—pApUpG + $(BrCH_2CO)_2O$ → $BrCH_2CONHPh$—pApUpG ;
UpUpUp(5-NH_2)U + ICH_2COCl → UpUpUp (5-ICH_2CONH)U .

Derivatives in which the terminal phosphate has been replaced by the phosphorothioate residue have been proposed for the same purpose. In particular, derivatives of deoxyoligoribonucleotides have been obtained in this way by alkylating phosphorothioates with reagents (IV) or (V) with subsequent activation of the aromatic 2-chloroethylamino-group via its reduction with tetrahydroborate.[101,102]

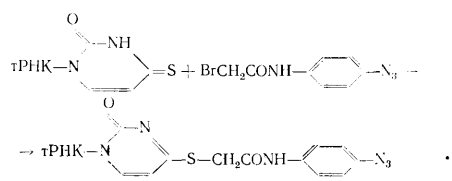
A novel method of synthesis of reactive derivatives of oligoribonucleotides has been proposed.[6,103] It is based on the substrate activity of γ-derivatives of nucleoside 5′-triphosphates in a reaction catalysed by RNA polymerase. In the synthesis of RNA on a DNA template using instead of the natural substrate its derivative with a reactive group, a product retaining this group at the 5′-end has been obtained:

$N_3PhNHpppA \xrightarrow{pppU} N_3PhNHpppApU \xrightarrow{pppC} N_3PhNHpppApUpC \rightarrow \ldots$

In certain cases reactive derivatives can be obtained by the appropriate treatment of the complex of the oligonucleotide or its derivative with the biopolymer. Thus the affinity modification of the mRNA binding region has been achieved[104] by treating the complex of the ribosomes of *E.coli* with the phenylalanine tRNA and $pp(pU)_7$ with water-soluble carbodiimide, which converts the terminal triphosphate group into a trimetaphosphate group.

VI. REACTIVE DERIVATIVES OF NUCLEIC ACIDS

The greatest number of reactive derivatives have now been described for transfer RNA in connection with the study of their interaction with ribosomes and aminoacyl-tRNA synthetases. A list of the derivatives synthesised can be found in other reviews.[105,106] Their greatest number has been obtained by the addition of the corresponding heterobifunctional reagents directly to the *cis*-diol group, for example, via reaction (4),[107] or with preliminary oxidation by periodate, and via the α-amino-group of aminoacyl tRNA. Compounds (II) and (III) are examples of such derivatives. The first affinity modification of ribosomes has been achieved with the aid of compound (II), first described by Grachev and Ryvkin,[108] and information has been obtained about the location of the peptidyl-transferase centre.[109] The selective addition of bifunctional reagents to certain so-called minor bases, which are present in large amounts in tRNA, has also been employed. Thus the presence of 4-thiouridine in the 8-position relative to the 5′-end is characteristic of the tRNA from *E.coli* and the 4-thiouridine group can be selectively alkylated by a reagent with an aryl azide group:[9]



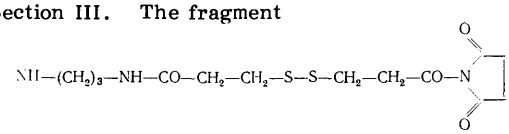
The method of direct photo cross-linking has also been used in the study of the interaction of tRNA with aminoacyl-tRNA synthetases.[110] A detailed analysis of the data obtained by this method can be found in the paper of Remy and co-workers in Knorre's monograph.[3] It must be emphasised that ultraviolet irradiation in the region of 260 nm damages significantly nucleic acids and proteins and the results obtained by the method of direct photo cross-linking must be treated with much caution. The method is undoubtedly attractive because of its simplicity and the absence of any perturbations to the ligand before the instant of elimination and the possibility of carrying out the process very rapidly using powerful light

pulses. However, as already stated, a detailed preliminary study of the reactions occurring and of the properties of the photo cross-linking products formed is required.

Methods based on the selective excitation of certain specific chromophores present in tRNA as minor components and absorbing in the long-wavelength ultraviolet part of the spectrum, sufficiently remote from the region corresponding to absorption by the remaining bases and proteins, are nowadays more attractive. An example of such a group is 4-thiouridine already mentioned. It has been shown[9] that irradiation of phenylalanine tRNA from *E.coli* in a complex with phenylalanyl-tRNA synthetase leads to the cross-linking of these two macromolecules. According to the data of Ofengand and Liou,[111] the tRNA containing in the 5'-position in the codon a uridine derivative (5-carboxymethoxyuridine), in a ternary complex with a ribosome and mRNA, is cross-linked on ultraviolet irradiation with the pRNA of the small subunit of the ribosome. The irradiation of ribosomes in a complex with yeast phenylalanine tRNA and polyuridilic acid leads to the cross-linking of the latter with the nucleoside wybutosine adjoining the anticodon from the 3'-end.[112]

As already stated in Section III, many problems of the protein–nucleic acid recognition and of the specific action on nucleic acids can be solved using derivatives of polynucleotides and nucleic acids in which reactive groups have been introduced statistically. Polynucleotides of this type can be obtained by copolymerisation with monomers containing chemically reactive groups. Thus the copolymerisation of ADP with 8-azido-ADP and of inosine 5'-diphosphate with 8-azidoinosine diphosphate has been described.[113] The copolymers obtained were used for the affinity modification of the RNA polymerase from *E.coli*.

Derivatives of phenylalanine tRNA from *E.coli* with statistically attached aryl azide groups have already been described in Section III. The fragment



with acylating activity has been introduced statistically[114] into accessible (not involved in the formation of the secondary structure) cytosine residues of the initiator methionine tRNA from *E.coli*. The derivative obtained was used for the affinity modification of methionyl-tRNA synthetase from the same source. The presence of the S–S bridge makes it possible to split off tRNA from the protein by treatment with thiols after the affinity modification. 4-Thiouracil residues, formed from cytosine residues on treatment of tRNA with hydrogen sulphide, have been introduced statistically into the same tRNA by treatment with hydrogen sulphide. The photoaffinity modification of ribosomes has been achieved with the aid of such tRNA.[115]

The use of the T7 phage mRNA, containing alkylating groups introduced by treating the mRNA with reagent (IV), for specific mutagenesis involving specific genes has been described.[116,117] Analogous derivatives have been obtained from the DNA fragment containing the gene imparting resistance to tetracycline.[118] These reagents have been used for the specific induction of mutations in the pBR 322 plasmid, widely used in gene engineering studies. Although all the experiments have been carried out with isolated phage and plasmid DNA, it is evident that this approach leads to prospects for mutagenesis in living organisms, directed to specific genes, as well as to the prospect for the blocking of the operation of specific genes. The statistical character of the distribution of the reactive groups in the solution of such problems is especially significant, since it is not known beforehand into which points within the gene it is necessary to introduce modifications in order to obtain interesting mutations or in order to switch off its operation.

The initial idea has been realised in a study[119] in which the cytosine residues in the T7 phage mRNA were modified by the reagent

After the introduction of the reagent at the cytosine groups of the address, it was activated by acid treatment, which converts the ketal into a ketone, enhancing thereby the electrophilic character of the C–Br bond. The statistical introduction of aldehyde groups into DNA forming part of the composition of chromatin was achieved by treatment with dimethyl sulphate and subsequent splitting off of 7-methylguanine groups. The aldehyde groups readily form Schiff bases with the amino-groups of the chromatin proteins in contact with them. Treatment with sodium tetrahydroborate leads to the formation of stable alkylamines, i.e. to the covalent binding of DNA to the proteins. Analysis of the reaction products make it possible to obtain important information about the structural organisation of nucleosomes—the nucleoprotein complexes in which the DNA in the cells of higher organisms is packed.[120]

---o0o---

The data presented in the review show that organic and bio-organic chemistry have armed investigators with a large arsenal of fine chemical instruments for the study of the problem of the protein–nucleic acid recognition and the development of fundamentally new approaches to influencing the genetic apparatus in living organisms. The number of reactive derivatives of nucleic acids and their components known at the present time is so large that the present authors have been unable to describe or even list all such derivatives and were forced to confine themselves to the description of the principal types. On the other hand, the methodology of the application of these instruments to the purpose of research still requires profound physicochemical and biochemical investigations. The authors believe that the most acute problems include the study of the mechanisms of the reactions used for the affinity modification of biopolymers and also the study by modern physical methods of the structures of the complexes of biopolymers with affinity reagents and the structures of the products formed. Such investigations have now become possible in relation to derivatives not only of nucleotides but also of those of oligonucleotides, which is a result of impressive advances in the field of their chemical synthesis.

Complexes of derivatives of oligonucleotides with complementary oligonucleotides and nucleic acids are unique models for the study of the general characteristics of their intracomplex reactions, modelling in their specificity natural enzymic reactions. In fact a new field of bio-organic chemistry, namely the organic chemistry of nucleic acid duplexes, has already begun to form.[121]

The possibility of obtaining oligonucleotides and their derivatives in amounts running into tens and hundreds of milligrams makes it possible to begin systematic studies on such derivatives of biologically active substances. The possibility of establishing the primary structure of virtually any nucleic acids ensures the specific synthesis of oligo- and poly-nucleotide addresses for the most varied sections of the genetic apparatus in living organisms and the development on this basis of methods whereby biological objects can be influenced, which are superior in their selectivity to other chemical methods and approach, in terms of the level of their selectivity, the most sophisticated antibiotics and

enzymes. The authors hope that this review will attract the attention of chemists involved in the most varied disciplines (organic and inorganic chemists, physical chemists, and analytical chemists) to this new vigorously developing field of science, which has extremely attractive prospects.

The Applications and Prospects for Further Applications of Biocatalysts in Electrochemical Systems

A.I.Yaropolov and I.V.Berezin

A new field involving the use of biologically active substances for the acceleration of electrode processes is examined. The coupling of enzymic and electrochemical reactions can be achieved in two ways: by mediated and direct electron exchange between the active centre of the enzyme and the electrode. The mechanism of the electrochemical oxidation of hydrogen with participation of immobilised hydrogenases is analysed in detail. Data indicating a tunnel mechanism of electron transport in the enzyme catalysis of electrode processes are presented. The principal applications of bioelectrochemical systems are indicated: as analytical sensors, as bioelectrochemical energy converters, and in bioelectrosynthesis.
The bibliography includes 129 references.

CONTENTS

I. Introduction 852
II. Methods for the coupling of enzymic and electrochemical reactions in bioelectrocatalysis 852
III. Principal applications of bioelectrocatalytic systems 858

I. INTRODUCTION

The field of bioelectrochemical research has two main components. The first involves the study of membrane phenomena, which are extremely common in living nature. Its main feature is the study of the properties of membranes, including membranes with incorporated enzyme systems. This is of considerable interest for the understanding of the energy conversion process and electron transport in living organisms. The second component in bioelectrochemistry is the use of biological systems as catalysts of electrode reactions. Its development is due to the high specificity and efficiency of enzymic reactions and also the possibility of their occurrence under mild conditions.

Biocatalysts can be employed to create electrochemical analytical devices, in the development of electrochemical energy converters, in the specific electrosynthesis of complex organic compounds, and also for the elucidation of the mechanisms of enzyme reactions by electrochemical methods.

At the present time one can speak of bioelectrocatalysis as a phenomenon involving the acceleration of electrode processes under the influence of biocatalysts.[1] The study of bioelectrocatalysis implies in the first place the study of the methods of coupling enzymic and electrochemical reactions and also of the mechanism of electron transport in the enzyme–electrode system.

The aim of the present study was to demonstrate the advances and prospects in this new branch of chemical research.

II. METHODS FOR THE COUPLING OF ENZYMIC AND ELECTROCHEMICAL REACTIONS IN BIOELECTROCATALYSIS

1. Electron Transport Using a Mediator

The coupling of enzymic and electrochemical reactions by means of a mediator can be achieved mainly in three ways, which differ in the mobility of the mediator and enzyme in relation to the electrode surface (Fig.1): (a) the enzyme and the mediator are in the bulk of the solution and the mediator diffuses to the electrode surface; (b) the enzyme is immobilised on the electrode surface and the mediator is in the bulk of the solution; (c) the enzyme and the mediator are immobilised on the electrode surface.

The mediator is as a rule either an electrochemically active product of the enzymic reaction or a transferring agent specially selected for the given system. The use of chemical compounds as mediators for the coupling of specific enzymic and electrochemical reactions imposes specific requirements which must be met by such transferring agents and which have been formulated.[2,3]

1. The stage involving the interaction of the mediator with the active centre of the enzyme must be rapid, i.e. the mediator must be a specific substrate of the enzyme.

2. The normal oxidation-reduction potential of the mediator must be close to that of the fuel of the oxidant. It is especially important that this condition be fulfilled in the development of electrochemical energy generators, since otherwise the efficiency of such systems diminishes. On the other hand, a transferring agent with a low oxidation-reduction potential is readily oxidised by oxygen, which is particularly undesirable when enzymes are used in electrochemical analytical devices.

3. The mediator must be electrochemically oxidised or reduced at the electrode of the given material under conditions close to reversibility.

4. The mediator system must be stable.

One of the first studies on bioelectrocatalysis was devoted to the catalytic properties of the enzyme hydrogenase in the electrochemical oxidation of hydrogen. The aim of these studies was to create the hydrogen anode of a fuel cell,[4-7] to determine the hydrogenase activity,[8,9] or to investigate the possibility of the electrochemical evolution of hydrogen in the presence of the enzyme.[10]

The possibility of creating a fuel cell anode on the basis of the *E.coli* hydrogenase has been examined.[4] The methylene blue–leuco-methylene blue system, which has an oxidation-reduction potential of +0.01 V relative to the hydrogen electrode (at pH 7.0), was used as the diffusionally mobile transferring agent. In this system methylene blue is enzymatically reduced by hydrogen to the leuco-form, which is then reoxidised at the platinum electrode. The maximum current density at the anode is 0.16 mA cm^{-2}.

The formation of hydrogen from the protons by the reduction of methylviologen in the presence of hydrogenase has been investigated by Yagi.[10] The reversibility of this system

with respect to hydrogen was demonstrated in this way.

It has been shown[1,2,3,11] that the optimum transferring agent for the hydrogen–hydrogenase–electrode system is methylviologen, whose oxidation-reduction potential is close to the reversible hydrogen electrode potential at a pH close to neutrality. It was established that, when the hydrogenases from *Thiocapsa roseopersicina* and *Pseudomonas aestuarii* are used for the anodic oxidation of hydrogen in the H_2–enzyme–methylviologen–carbon electrode system, it is possible to achieve this reaction under conditions close to reversibility.

The systems examined above contain the enzyme and the mediator in solution. From the practical point of view a system in which at least one of the components is on the electrode surface are more convenient.

The system for the oxidation of hydrogen based on hydrogenase and methylviologen as the mediator can serve as an example of the systems where the enzyme is immobilised on the electrode surface and the mediator is diffusionally mobile.[12] The authors developed a method for the adsorption immobilisation of hydrogenase on the surface of a carbon black electrode with a specific surface of ~100 $m^2\ g^{-1}$. The hydrogenase is adsorbed on the carbon black irreversibly and retains approximately 90% of the activity of the native enzyme. The enzymic reaction occurring in the immediate vicinity of the electrode surface in the presence of methylviologen and hydrogen results in the formation of the reduced form of the mediator, which can be reoxidised at the electrode or can diffuse into the bulk of the solution, the relative contributions of these processes depending on the electrode potential. The studies were carried out by the method involving the use of semi-immersed and rotating disc electrodes. The results obtained show that, in the presence of a sufficiently active enzyme, the reaction is controlled not only by the kinetics of the oxidation of hydrogen but also by the diffusion of the latter to the electrode surface. At a potential of −0.15 V and a methylviologen concentration of 8×10^{-3} M the current density at the electrodes was 1.1–1.2 mA cm^{-2}.

A number of studies have been devoted to the development of a biocathode for the fuel cell. The hydrogen electrochemical reduction reaction on carbonaceous materials in neutral solutions proceeds with a high overpotential. It has been suggested that a mediator enzyme system be used to activate this reaction.[13–16] The oxidation-reduction potential of the transferring agents in such systems is more positive than the range of potentials in which oxygen is electrochemically reduced on the carbon electrode. The cytochrome *c* oxidase–*NNN'N'*-tetramethyl-*p*-phenylenediamine (TMPD) system has been used,[18] TMPD being oxidised by the enzyme to a radical (Wurster's Blue) and the latter being reduced at the cathode. This mediator can be oxidised by oxygen also in the absence of a catalyst, but in the presence of cytochrome *c* oxidase the rate of this reaction greatly increases. It has been shown that TMPD–Wurster's Blue system is electrochemically reversible at the platinum and graphite electrodes and that its redox potential is 0.7 V.

The transferring system incorporating 4,4'-dihydroxybiphenyl and its oxidised form has also been used in the cathodic reduction of oxygen in the presence of laccase.[17] These mediators were resorted to in connection with the search for a system of transferring agents whose oxidation-reduction potential is close to the equilibrium potential of the oxygen electrode. Potato *o*-diphenol oxidase has been used to accelerate the oxygen electrochemical reduction reaction.[18] The mediators were catechol and caffeic and chlorogenic acids. The authors were able to shift the oxygen electrochemical reduction potential into the positive region by 300–350 mV.

NAD- and NADP-dependent enzymes play a major role in metabolic processes. Bioanodes employing dehydrogenases and the NAD–NADH redox transferring system have been described.[18–20] A disadvantage of these systems is the occurence of irreversible processes: frequent repetition of the electrochemical reaction lead, in particular, to the dimerisation of the transferring agent. In addition, the electrochemical NADH oxidation and NAD reduction processes proceed with a high overpotential. It has been shown[20] that the electrochemical oxidation of NADH on smooth and platinised platinum and also on pyrographite proceeds only at a potential above +1.3 V (relative to the normal hydrogen electrode). In the presence of phenazine metasulphate, the NADH oxidation potential at the pyrographite electrode falls to +0.4 V. The authors[20] describe the electrochemical oxidation of sodium formate at the pyrographite electrode in a system with the NAD-dependent formate dehydrogenase using phenazine methosulphate as the mediator and also using a two-enzyme system with an NAD-dependent formate dehydrogenase and an NADH-dependent dehydrogenase, where methylviologen is the electron transferring agent. The sodium formate oxidation currents in the given system at a potential above +0.2 V were 15 mA cm^{-2}. Systems in which the enzyme and the mediator are simultaneously immobilised

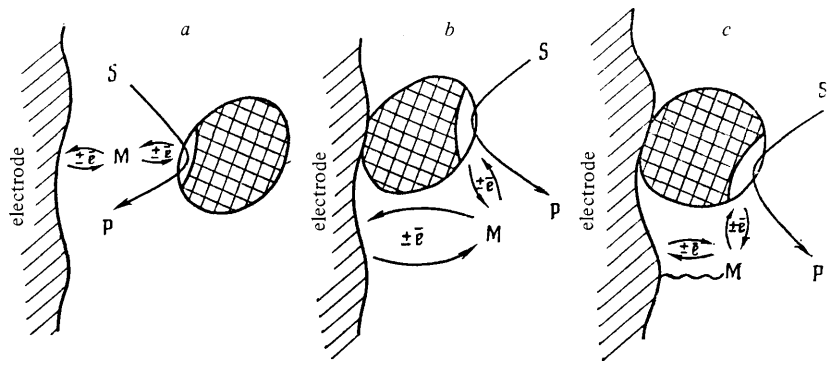

Figure 1. Schematic illustration of the possible ways of coupling enzymic and electrochemical reactions with the aid of a mediator; S = substrate, P = product of enzymic reaction; M = electron transferring agent (for the description of the schemes, see text).

on the electrode surface are superior to those described above. The possibility of creating a model of the enzyme fuel cell, using alcohol as the fuel, and also of devising an analytical electrochemical sensor for alcohol has been investigated.[21,22]. The alcohol oxidation catalyst was horse liver alcohol dehydrogenase and the mediator was nicotinamide-adenine dinucleotide. The enzyme and the cofactor were immobilised on the electrode surface in two ways: by adsorption via the hydrophobic and electrostatic interactions of the enzyme–cofactor system with the electrically conducting carrier and covalently by grafting NAD to the carrier and by sorbing the apoenzyme on the cofactor. It has been shown that the cofactor retains its physiological activity only when it is separated from the carrier by a distance of ~10 Å. When the enzyme and NAD were introduced into the cell, a stable current and e.m.f. were generated. The introduction of a small amount of potassium cyanide, which is an inhibitor of the enzyme activity of alcohol dehydrogenase (ADH), into the electrolyte reduced the current. The current was proportional to the substrate concentration and reached a maximum of 0.6 mA at a potential of 0.2 V.

Yastrebova et al.[23] also used the ADH–NAD enzyme–cofactor complex immobilised on the surface of a carbon black electrode as the mediator in the electrochemical oxidation of ethanol. The half-wave potential $E_{1/2}$ in the oxidation of NADH in the enzyme–cofactor complex is then lower by 0.22 V than $E_{1/2}$ for the oxidation of NADH adsorbed on the carbon black. The direct involvement of the enzyme in the electrochemical oxidation of NADH was confirmed by adding an ADH inhibitor (phenanthroline) to the adsorbed complex, which resulted in the disappearance of the catalytic effect. A mechanism for the oxidation of ethanol at the enzyme electrode has been proposed. The method suggested makes it possible not only to determine ethanol in the concentration range 3×10^{-5}–5×10^{-4} M but also to regenerate the NAD coenzyme using ADH. ADH and the following mediators have been employed[24] for the oxidation of ethanol: methylene blue and the *N*-methylphenazine ion, which oxidise NADH, are produced by the reduction of NAD due to the occurrence of the enzymic reaction and are themselves oxidised at the electrode. The anodic compartment of the electrochemical cell employed contained the enzyme methanol dehydrogenase, which oxidises methanol, according to the data of Varfolomeev et al.[2] in the presence of phenazine methosulphate and phenazine ethosulphate as mediators. The maximum current in the system reached 3.7 mA.

The FAD-dependent enzymes glucose oxidase and amino-acid oxidases belong to the group of enzymes which play a significant role in oxidation-reduction processes in living organisms. L-Aminoacid oxidase, bound covalently to the surface of a carbon black electrode modified with 2,4,6-trichlorotriazine, has been used[26] to determine L-aminoacids. The electrode potential varies linearly with the aminoacid concentration in the range 10^{-5}–10^{-2} M.

The study of the electrochemical oxidation of glucose in the presence of bio-organic catalysts is of great interest because this reaction takes place on platinum with a high overpotential. A carbon electrode modified with 2,4,6-trichlorotriazine with the covalently attached enzyme has been used[27] in the study of the reduction of glucose oxidase, which occurred at a potential of −0.51 V (relative to the Ag/AgCl electrode), which is more positive by 100 mV than in the reduction of the apoenzyme. The enzymic oxidation of glucose on a vitreous carbon electrode with adsorbed mediators has been investigated.[28] Glucose oxidase was deposited on the modified electrode and was separated from the bulk of the solution by a dialysis membrane. The transferring agents were tetracyano-*p*-quinodimethane and the potassium salt of its anion, pyocyanin, 9,10-phenanthrenequinone, dichlorophenol-indophenol, and dextran-dopamine. These compounds are substrates of glucose oxidase. The maximum current in the system depended on the concentrations of the components in the layer near the electrode and on the nature of the transferring agent, reaching 67 μA cm^{-2} under anaerobic conditions. The electrochemical oxidation of glucose has been investigated[29,30] in the presence of glucose oxidase immobilised on organic metals—the complexes of *N*-methylphenazinium (HMP^+) and *N*-methylacridinium (HMA^+) ions with the tetracyanoquinodimethane radical-ion. The biocatalytic effect occurred at potentials in excess of −0.05 V (Ag/AgCl). The dependence of the current on the glucose concentration was described by a curve with saturation, the limiting current depending on the electrode potential. The electrode with the immobilised enzyme retains its activity for more than 100 days.

Metalloenzymes, containing iron and copper ions in their molecule, play a major role in electron transport in biological systems. The cytochrome b_2–potassium hexacyanoferrate(III)/hexacyanoferrate(II) system has been used to activate the lactate oxidation reaction on the platinum electrode.[31,32] Studies were performed in a two-electrode cell whose anodic and cathodic compartments were separated by an electrically conducting bridge. A solution of the lactate, potassium hexacyanoferrate(III), and the enzyme was placed in the anodic compartment, while a solution of potassium hexacyanoferrate(III) was placed in the cathodic compartment. The enzymic reaction resulted in the formation of hexacyanoferrate(II), which was then electrochemically oxidised at the anode. The hexacyanoferrate(III) was electrochemically reduced at the cathode. The current in the external circuit when the cell was switched on varied linearly with the lactate concentration in the range from 5×10^{-6} to 4×10^{-3} M. 2,6-Dichlorophenol-indophenol, phenazine methosulphate, methylene blue, and indigocarmine have also been used as transferring agents. Johnson and co-workers[33,34] employed a mediator system to control the potential in the layer containing the enzyme galactose oxidase. In the course of the enzymic reaction, the active centre is reduced and then reversibly reoxidised by the mediator. The choice of the transferring agent is of decisive importance for the establishment of the appropriate potential in the system. Hexacyanoferrate(III), 2,6-dichlorophenol-indophenol, tetracyanomonophenanthroline ferrate, and tripyridinecobalt were used as the mediators.

As can be seen from the data presented, the mediator method of coupling the enzymic and electrochemical reactions using soluble mediators has been studied in fair detail. A new superior procedure for mediated transport, using transferring agents and enzymes in an immobilised state on electrodes as well as the direct electron exchange between the active centres of enzymes and the electrode, are of interest.

2. Electrochemical Reactions of Proteins on Electrodes

In connection with the possibility of using enzymes in electrocatalytic processes, the study of the electrochemical properties of proteins is of interest. The application of electrochemical research methods can yield important information about the mechanism of electron transfer in protein molecules and about the relation between the rate of electron transfer (or the rate of change of potential) and the conformational rearrangements of proteins.

The adsorption of proteins on the surfaces of electrodes plays a major role in the study of their electrochemical reactions. The adsorption of proteins on mercury electrodes and

the mechanism of electron transfer in such systems have been investigated by Kuznetsov and co-workers.[35-37] It has been shown that protein is rapidly adsorbed on the surface of mercury with formation of a monolayer of the denatured protein 8–10 Å thick. This protein layer is adsorbed irreversibly and covers approximately 80% of the mercury surface, forming a porous structure. The active centre of the denatured protein does not participate in electron exchange with the protein molecules in solution. The latter exchange electrons with the electrode through the pores in the irreversibly sorbed protein.

It is believed,[38] however, that, owing to the high surface pressure, the adsorbed molecules in the first monolayer on the mercury electrode are not denatured.

It has been shown that horse heart cytochrome *c* is reduced irreversibly on mercury.[39-42] The anodic potential scan does not show oxidation of the reduced protein. Cytochrome *c* is reduced with an overpotential[42] and the reduction process depends on the pH, the ionic strength of the solution, and the protein concentration.

Study of the behaviour of cytochrome *c* on a gold electrode modified with γγ-bipyridyl and 1,2-bis(4-pyridyl)ethylene showed that the prosthetic group of the protein undergoes reversible oxidation-reduction in the given system. It is of interest that modification of the lysine residues of cytochrome *c* causes cytochrome *c* to cease being a substrate of cytochrome *c* oxidases and at the same time the reversible electrochemical oxidation-reduction of the protein on the electrode stops.[43-48] The reversible oxidation-reduction of cytochrome *c* at the equilibrium potential has also been observed on a tin-doped indium oxide electrode[49] and a gold electrode modified with 1,2-bis(4-pyridyl)ethylene.[47] The oxidation-reduction rate constant on electrodes of this type is 0.014–0.019 cm s^{-1}.

Saponeva et al.[50] and Czochralska et al.[51] investigated the reduction of bacteriorhodopsin on mercury and platinum electrodes. The electrochemical behaviour of proteins has been examined in detail in a review.[52]

The proteins investigated[35-51] do not exhibit enzyme activity and behave solely as electron or oxygen transferring agents. The possibility of direct electron transfer to the active centres of enzymes in the absence of substrates has been investigated for xanthine oxidase,[53] lactate dehydrogenase,[54] catalase and superoxide dimutase,[55] peroxidase,[56] cholesterol oxidase,[57] and glucose oxidase.[58]

The haemin in the peroxidase molecule is electrochemically inactive on an amalgamated gold electrode and on gold and pyrographite electrodes. The reversible oxidation-reduction process observed on the gold amalgam corresponds to a reaction involving the S–S bonds.[56]

The electrochemical properties of cytochrome P-450 have been investigated[39] and it has been shown that cytochrome P-450 is reduced by mercury irreversibly at a potential of −1.4 V. Flavin-adenine dinucleotide (FAD), which forms part of the composition of the active centre of xanthine oxidase and D-aminoacid oxidase, is reduced on mercury in the range of potentials corresponding to free FAD.[36] The prosthetic group of another FAD-dependent enzyme, namely glucose oxidase, is reduced at the equilibrium oxidation-reduction potential of the enzyme.[58] The reversible oxidation-reduction on the mercury electrode of the prosthetic group of cholesterol oxidase, in which FAD is bound covalently to the apoenzyme has been observed, but it takes place with an overpotential.[57] One must note that the oxidation-reduction processes associated with the prosthetic groups of enzymes cannot indicate unambiguously the possibility of the effective electrocatalysis of the corresponding reactions by these enzymes, i.e. the redox reactions of the prosthetic groups in homogeneous enzyme catalysis differ from the corresponding redox reactions of the same groups in electrochemical systems. For example, peroxidase, in which the reduction of haemin has not been observed under anaerobic conditions,[56] is an effective catalyst of the electrochemical reduction of hydrogen peroxide. This effect will be discussed in detail below.

3. Direct Electron Transfer Between the Active Centre of the Enzyme and the Electrode

A fundamental problem in bioelectrocatalysis is that of the direct coupling of the enzymic and electrode reactions. The possibility of the direct electron transfer from the electrode to the active centre of the enzyme (or conversely) has been discussed.[11]

The preparation of effective catalysts of the electrochemical reduction of oxygen is of great practical importance. It is known that a steady-state potential established in an oxygen atmosphere for electrodes made of carbonaceous materials is far from the equilibrium oxygen potential and amounts to ~0.6–0.7 V. Cytochrome *c* has been used[59,60] as the catalyst of this reaction. It has been shown that the catalysis by cytochrome *c* occurs only in the adsorbed state over the entire experimental range of potentials (from −0.18 to +0.6 V). It has been established that in the presence of the biocatalyst not only does the rate of reduction of oxygen to hydrogen peroxide, i.e.

$$O_2 + 2\bar{e} + 2H^+ \rightarrow H_2O_2,$$

increase but also the parallel reaction involving its reduction to water occurs

$$O_2 + 4\bar{e} + 4H^+ \rightarrow 2H_2O.$$

The second reaction is associated with the rupture of the oxygen–oxygen bond and apparently proceeds via the adsorption of the oxygen molecules on the central iron atom in the active centre of cytochrome *c*.

A group of Japanese workers[61] established that cytochrome c_3 from *Desulfovibrio vulgaris* catalyses the reduction of molecular oxygen in the adsorbed state on the mercury electrode. In this case oxygen was fully reduced to water, i.e. via a four-electron mechanism without the formation of hydrogen peroxide. The maximum acceleration of the reaction was observed when the mercury electrode surface was 50% filled by the adsorbed cytochrome c_3.

The electrochemical reduction of oxygen and the direct electron transfer in the oxygen–*Polyporus versicolor* laccase–carbon electrode system has been studied in detail.[62,63] The enzyme was present on the surface of electrodes in the adsorbed state. The introduction of laccase into the system shifts the steady-state electrode potential towards positive values and accelerates the electrochemical reduction of O_2 in the potential range 1.2–0.6 V, the potentials and currents at the given potentials increasing with increase of the amount of enzyme adsorbed on the electrode. Gold, pyrographite, vitreous carbon, and carbon black were used as the electrode materials. The studies were performed under aerobic and anaerobic conditions. The maximum potential of +1.207 V was established in an oxygen atmosphere for electrodes which had been kept beforehand in a solution of laccase at a concentration of ~10^{-5} M for 24 h. The introduction of a laccase inhibitor into the system (F^- or N_3^- ions) virtually stopped the acceleration of the electrochemical reduction of oxygen (Fig.2). The stable and reproducible potential of +1.20 V permitted a detailed investigation of the mechanism of the electrochemical reduction of oxygen in the vicinity of the

equilibrium potential. The linear relation between the current and the overpotential is maintained in the potential range 1.20–1.15 V. In the potential range 1.18–1.15 V the slope of the polarisation curve increases up to $\partial E/\partial \lg i \cong 0.03$ V. At potentials more negative than 1.15 V, we have $\partial E/\partial \lg i \cong 0.06$ V. Along the 1.20–1.15 V section of the polarisation curve, $\partial E/\partial \lg i \cong \partial E/\partial \lg p_{O_2}$, i.e. the reaction is of first order with respect to oxygen and the dependence on pH is given by $\partial E/\partial \mathrm{pH} \cong 0.06$ V. The calculated stoichiometric number was found to range from 0.75 to 1.8 with an average of 1.2. Consequently, the slow stage in the electrochemical reduction of oxygen is repeated once. On the basis of the experimental data, the authors proposed a mechanism for the electrochemical reduction of oxygen in the presence of laccase:

$$\begin{gathered}
E + O_2 \rightleftharpoons EO_2, \\
EO_2 + \bar{e} \rightleftharpoons EO_2^-, \\
EO_2^- + H^+ \rightleftharpoons EO_2H, \\
EO_2H + 2\bar{e} + H^+ \rightarrow EO^- + H_2O \ (E = 1{,}2 \div 1.15\mathrm{V}), \\
EO^- + \bar{e} + H^+ \rightleftharpoons EOH^-, \\
EOH^- + H^+ \rightleftharpoons E + H_2O, \\
\hline
O_2 + 4\bar{e} + 4H \rightleftharpoons 2H_2O,
\end{gathered}$$

where E is the enzyme.

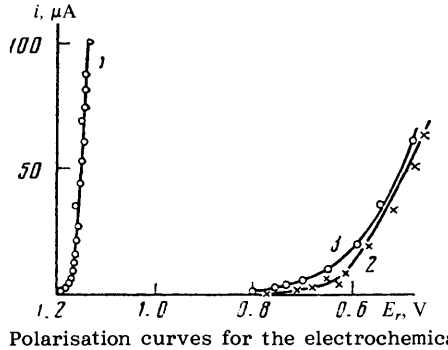

Figure 2. Polarisation curves for the electrochemical reduction of oxygen at an electrode with immobilised laccase: 1) in an oxygen atmosphere; 2) in the presence of the N_3^- inhibitor; 3) background curve in the absence of enzyme.

The synchronous transfer of two electrons in the slow stage is unusual for an electrochemical reaction. However, the authors postulate that the presence of a two-electron acceptor in the laccase molecule makes it possible to achieve this reaction.

The non-mediated catalysis of the electrochemical reduction of oxygen using potato *o*-diphenol : oxidoreductase has been investigated.[16] In the presence of the enzyme adsorbed on the carbon black electrode, a potential of +1.13–1.16 V is established in an oxygen atmosphere. It has been shown using a disc electrode with a ring that, as for the electrode with laccase, oxygen is reduced directly to water in the given system without the formation of H_2O_2.

The electrochemical oxidation of hydrogen in the presence of hydrogenase is of considerable interest in connection with the search for new non-metallic catalysts for the hydrogen electrode of the fuel cell. Results indicating the possibility of the direct oxidation of H_2 at carbon black electrodes by the hydrogenase from *Thiocapsa roseopersicina* immobilised by adsorption have been obtained.[64] The equilibrium hydrogen potential has been realised at these electrodes. Analysis of the kinetic parameters of the system led to the following mechanism of the electrochemical oxidation of hydrogen:

$$\begin{gathered}
E + H_2 \rightleftharpoons EH_2, \\
EH_2 \rightleftharpoons EH^- + H^+, \\
EH^- \rightleftharpoons EH + \bar{e}, \\
EH^- \rightarrow EH^+ + \bar{e} \ (E = 0.03 \div 0.05\mathrm{V}), \\
EH^+ \rightleftarrows E + H^+.
\end{gathered}$$

The rate-limiting stage is the transfer of the second electron on the assumption that all the remaining stages are reversible.

Study of the possibility of direct electron transfer in electrochemical systems containing the enzyme glucose oxidase and glucose is of interest for the creation of a reagent-free glucose sensor also in biochemical fuel cells. The electrochemical oxidation of glucose at a platinum electrode with immobilised glucose oxidase has been studied.[65–68] The enzyme was fixed with the aid of glutaraldehyde or polyacrylamide gel on the surface of the electrode which had been charged beforehand or with glutaraldehyde on the uncharged electrode. The method used to modify the platinum surface has been described.[69] Positive results have been obtained only for the first method of immobilising the enzyme on the charged electrode. The steady-state currents exceed in this instance by a factor of 2–3 the currents obtained using the platinum electrode without the enzyme and reach 10 μA cm^{-2}. In the remaining cases of enzyme immobilisation on platinum catalytic effects were not observed at all. The authors explained these overall negative results by the poor contact between the enzyme and the electrode.[65] The influence of the Ag^+ and Hg^{2+} ions, which inhibit glucose oxidase, on the electrocatalytic activity of the enzyme immobilised on the surface of platinum mesh has been investigated.[70] The electrode potential established in the presence of glucose and the enzyme decreased linearly with increasing inhibitor concentration. This can serve as one of the pieces of evidence showing that in this system there is direct electron transfer between the electrode and the active centre of glucose oxidase, although other data concerning this hypothesis are not quoted.

In all the investigations enumerated above the bioelectrocatalysts were present either in a dissolved form or in an immobilised state on the surfaces of metallic and carbon electrodes. However, direct electron transfer in the enzyme–electrode system cannot be achieved in all cases using the above procedures for the immobilisation of the enzyme on the electrode.

Studies involving the use of conducting complexes of tetracyanoquinodimethane and low-molecular-weight or polymeric organic compounds as carriers for the immobilisation of enzymes are of great interest for the development of a general approach to the creation of non-mediated bioelectrocatalytic systems.[71,72] A method has been developed[73–75] for the application of polymeric electrically conducting carriers in order to achieve non-mediated electron transport in the electrode–enzyme active centre system. The inclusion of the enzyme in a current conducting matrix improves contact between the active centre of the catalyst and the carrier. Immobilisation of enzymes and the formation of matrices with a high electrical conductivity (up to 10^{-2} Ω^{-1} cm^{-1} [76]) is achieved by the coprecipitation of polymeric polycations and enzymes by means of a half-reduced tetracyanoquinodimethane (TCQDM) salt. This immobilisation procedure is also distinguished by a high capacity of the carrier with respect to the protein. The radical-ion TCQDM salts and heat-treated

polyacrylonitriles (HTPAN) have been used[73–75] to immobilise hydrogenase. Data concerning the composition, capacity with respect to the protein, electrical conductivity, and the percentage retention of enzyme activity for the polymeric carriers of hydrogenase investigated are listed in the Table. Immobilisation activates hydrogenase with simultaneous increase of the stability of the enzyme with respect to denaturation in air. It is interesting to note that one of the polymers employed, namely poly-1-propargyl-1-methyl-4,4-bipyridylium (PPMB) is a substrate of hydrogenase. The electrocatalytic properties of the hydrogenase immobilised on polymer–TCQDM complexes were investigated in relation to the formation of H_2 on a polymeric enzyme electrode, which occurs only in the presence of hydrogenase in the system. It was shown that the electron transfer to the active centre of the enzyme in the course of the study of the hydrogen formation process up to the preliminary electrochemical reduction of the carrier with hydrogenase can be achieved from any section of the polymer matrix. The poly-1-propargylpyridinium (PPP)–TCQDM polymeric conductors with immobilised glucose oxidase have been used for the electrochemical oxidation of glucose.[72] A significant increase of the current was observed only in the presence of the enzyme on the electrode and of glucose in solution. The linear dependence of the currents at a specified potential on the glucose concentration in solution was maintained in the concentration range 0.15–2.0 mM. The experimental data were described by a parabolic function and were interpreted in terms of the Michaelis–Menten equation. A linear plot obtained employing the reciprocals of the variables yielded $i_{max} = 67$ μA cm^{-2} and a Michaelis constant of $4.0 \pm 0.5 \times 10^{-3}$ M at a potential of 140 mV (Ag/AgCl).

After immobilising cytochrome b_2 on the complex of TCQDM with *N*-methylphenazine (NMP), Kulis and Svirmickas[77] observed the acceleration of the electrochemical oxidation of lactate with electron transfer from the active centre of the enzyme to the electrode without the involvement of a low-molecular-weight mediator. On the basis of this system, the same workers[78] developed a reagent-free analytical sensor for lactate.

The reduction of hydrogen peroxide by peroxidase immobilised by adsorption on the NMP–TCQDM and NMA–TCQDM electrodes has been described.[79] Hydrogen peroxide was reduced at potentials of ~0.25 V relative to the saturated silver/silver chloride electrode. In the absence of peroxidase this reaction proceeds only at potentials below −0.2 V. The above studies confirm the possibility of the successful employment of radical-ion matrices ("organic metals") as electrode materials for the catalysis of electrochemical reactions by immobilised enzymes.

It is seen from the literature data quoted that there has been a growth of interest recently in the study of the direct electron transfer between the active centre of the enzyme and the electrode. However, all the studies listed above were designed to investigate the direct transfer in a specific system and were not concerned with problems of the characteristics of the electron transfer in bioelectrochemical systems as a whole

4. The Mechanism of Electron Transfer in the Enzyme Catalysis of Electrode Processes

The main problem in systems for the non-mediated oxidation or reduction of the active centre of the enzyme at the electrode involves the study of the mechanism of electron transfer from the enzyme to the electrode (or the converse process). The kinetic model of bioelectrocatalysis proposed by Varfolomeev and Berezin[80,81] cannot naturally provide an exhaustive answer. Probably the direct electron transfer requires a specific orientation of the enzyme active centre relative to the electrode and the shorter the distance from the active centre to the electrode the greater the probability of the transfer. However, the active centres of enzymes are apparently localised within the protein globule and after immobilisation can be located at an appreciable distance from the carrier surface.

Composition and characteristics of polymeric carriers.

Polymer	Probable composition of carrier	*A*, mg protein/g carrier	ρ, Ω cm	Retention of activity, %
PPMB 	$[(PPMB^{2+})(TCQDM)^{-}_{2} \cdot (TCQDM^{0}_{2})]_n$	200±20	$3.6 \cdot 10^4$	200
PPP 	$[(PPP^{+})(TCQDM)^{-}_{n}(TCQDM^{0})]_m$ $m/n = 0.25$	200±20	$1.2 \cdot 10^4$	400
PVBP 	$[(PVBP^{+})(TCQDM)^{-}(TCQDM^{0})]_n$	70±10	10^8–10^9	—
HTPAN 	HTPAN	25±5	$2.0 \cdot 10^3$	30

Notation: *A* = capacity of the carrier with respect to protein; ρ = resistivity of the carrier; PVBP = poly-1-vinyl-1-benzylpyridinium chloride.

The dependence of the efficiency of electron transfer on the distance between the active centre of laccase and the electrode has been studied[82] in relation to the electrochemical reduction of oxygen. Initially cholesterol was adsorbed on the surface of a carbon black electrode from alcoholic or heptane solutions or lecithin was adsorbed from a solution of benzene and the enzyme was then sorbed on top of the lipids. Thus the distance between the electrode and the laccase molecule increased to 6, 17, or 20 Å respectively (Fig.3). The oxygen electrochemical reduction currents at the appropriate potential were normalised with respect to the maximum rate of the enzymic reaction measured in independent experiments.

With increase of the distance from 6 to 17 Å, the authors observed a decrease of the rate of electron transfer through the cholesterol layer approximately by a factor of 4.5, while the decrease following the increase of the distance to 20 Å

(through the lecithin layer) was by a factor of ~200. The authors assume that the idea of the tunnel mechanism of electron transfer between the active centre of the enzyme and the electrode using the simple kinetic scheme

$$E + \bar{e} \rightleftharpoons E^{\neq} \xrightarrow[O_2]{} E + H_2O,$$

where E is laccase in the initial state and $E^{\neq}$ the enzyme in the reduced state, is sufficient to account for this phenomenon and also for the bioelectrocatalytic effect.

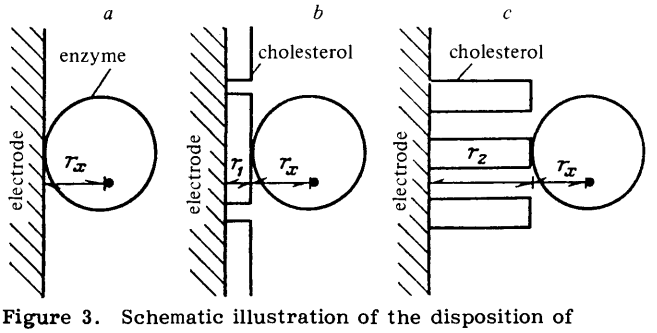

Figure 3. Schematic illustration of the disposition of the enzyme relative to the electrode surface: *a*) laccase adsorbed on the electrode surface; *b*) enzyme adsorbed on top of the liquid with a planar orientation relative to the electrode; *c*) enzyme adsorbed on top of the lipid with a vertical orientation relative to the electrode; r_1 = thickness of lipid layer with a planar orientation of cholesterol, r_2 = ditto with a vertical orientation, r_x = distance from the surface to the electron-accepting site in the enzyme.

The second stage is enzymic and limits the rate of the reaction. The first stage is electrochemical and proceeds reversibly and via the tunnel mechanism. These conclusions have been confirmed by potentiodynamic experiments under anaerobic conditions with laccase adsorbed on the electrode surface. Reversible maxima corresponding to the oxidation-reduction potential of copper of the first type, which is a primary electron acceptor in the active centre of laccase, are observed at potentials of ~+0.75 V. The tunnelling stage can be described by the equation:[83]

$$k_t(r) = A \exp(-2r/a),$$

where A is the frequency of the collisions of the electron with the potential barrier, U the height of the barrier, $a = \hbar[2m(U - E)]^{1/2}$, $\hbar$ the Planck constant, m the mass of the electron, and E the energy of the electron.

Thus in the system considered the probability of the tunnel electron transfer over a distance greater than 20 Å is sharply reduced, which has also been observed experimentally.

III. PRINCIPAL APPLICATIONS OF BIOELECTROCATALYTIC SYSTEMS

The enzymes which are effectively involved in the catalysis of electrochemical reactions can find applications in the conversion of chemical energy into electrical energy in the so-called biofuel cells.[84–86]

Using the high substrate specificity and efficiency of the catalytic action of immobilised enzymes, it appears possible to achieve the specific electrode synthesis of many organic compounds.

The application of enzymes in different kinds of electroanalytical sensors, which has been discussed by Bauman et al.[87] and by Updike and Hicks,[88] makes it possible to extend the range of compounds capable of being determined and to simplify the technique of the measurements.

1. Enzyme Electrodes

The procedure for the coupling of the enzymic and electrochemical reactions with mediation is most often used in electroanalytical enzyme sensors. The employment of these analytical devices significantly simplifies the analytical technique, makes it possible to extend the range of compounds which can be determined, and in many cases increases the sensitivity of the measurements.

The required compound, which may be electrochemically inactive, is determined from the change in the concentration of other components of the enzymic reaction (substrates or products). For example, the concentration of glucose, which is relatively inactive electrochemically, can be determined amperometrically by recording the electrochemical oxidation of the reaction product—hydrogen peroxide,[89] or the electrochemical reduction of the substrate—oxygen,[90] in reaction (1). It is also possible to follow the variation of the pH of the solution as a result of the formation of the product—gluconic acid.[91]

$$\text{Glucose} + O_2 \xrightarrow[\text{glucose oxidase}]{\text{immobilised}} \text{gluconic acid} + H_2O_2, \qquad (1)$$

$$H_2O_2 + 2I^- + 2H^+ \xrightarrow[\text{peroxidase}]{\text{immobilised}} I_2 + 2H_2O, \qquad (2)$$

$$H_2O_2 + 2\,Fe(CN)_6^{4-} + 2H^+ \xrightarrow{\text{peroxidase}} 2Fe(CN)_6^{3-} + 2H_2O. \qquad (3)$$

Another approach to the determination of glucose concentration involves the use of two-enzyme systems in which one of the products of the first enzymic reaction is the substrate of the second reaction. In this case the concentration of glucose is determined potentiometrically with the aid of an electrode sensitive to iodide ions[92] [reaction (2)] or amperometrically by recording the hexacyanoferrate(II) reduction currents [reaction (3)] at platinum or carbon electrodes.[93] A two-enzyme system employing glucose oxidase and cytochrome P-450, catalysing the conversion of aniline, by the hydrogen peroxide formed on oxidation of glucose, into *p*-aminophenol, which then undergoes anodic oxidation to the quinone, is also known. The limiting currents are then proportional to the glucose concentration.[94]

Instead of oxygen, artificial electron acceptors (AFA) may be used for the enzymic oxidation of glucose:[95]

$$\text{Glucose} + \text{oxidised AEA} \xrightarrow{\text{glucose oxidase}} \text{gluconic acid} + \text{reduced AEA}. \qquad (4)$$

Artificial electron acceptors are electrochemically active compounds and their reduced forms can be readily determined amperometrically. The possibility of determining glucose using polyviologens as AEA in the presence of oxygen has been described.[96] Measurements were made at pH 8.0, i.e. under conditions where glucose is not oxidised by oxygen in the presence of glucose oxidase. The AEA were separated from the bulk of the solution by a dialysis membrane.

Numerous methods for the determination of various organic and inorganic compounds with the aid of enzyme electrodes have now been described in the literature. These procedures as well as the construction of enzyme sensors have been discussed in detail in a number of reviews.[97-99]

Apart from being used in sensors, enzyme electrodes have been recently widely employed for medical purposes. The so-called implanted electrodes can serve as a source of energy and can transmit information about the changes in the organism. The applications and the principle of the operation of the implanted electrodes have been discussed in a review.[100]

A new type of biosensor, in which a particular effect of the enzyme reaction is converted into an electrical response by means of thermistors, transistors, or piezoelectric crystals, has appeared during the last decade.[101-103] Such analytical devices differ from those known previously by a rapid response, a high sensitivity, and universality. For example, the principle of the operation of the biothermistor is as follows. When heat is evolved as a result of an enzymic reaction, the temperature of the surrounding medium is altered and the thermistor responds to it. Over a certain range, the temperature change and hence the electrical response are proportional to the concentration of the component determined.

The new biosensors have found extensive applications in the critical analyses of a wide variety of metabolites, such as ascorbic acid, urea, glucose, creatine, cholesterol, ATP, lactate, etc., and also for the monitoring of enzymic processes. The combination of solid-phase immunoenzyme analysis with calorimetric monitoring made it possible to determine the concentrations of certain compounds below 10^{-13} M.

2. The Creation of Highly Effective Energy Converters Based on Biocatalysts

The characteristic features of enzyme catalysts make it possible to use biochemical reactions in electrochemical energy generators. There is a possibility of creating fuel cells which can use organic compounds as fuel—alcohol and carbohydrates. On the other hand, the high catalytic activity of biocatalysts makes it possible to devise fuel cells with an enhanced power, for example, in systems for the biophotolysis of water.[104]

As early as the beginning of the 1960s, the possibility of creating biochemical fuel cells was discussed.[84] Systems which can be divided into two classes exist at the present time. The first class comprises systems using biocatalysts (in the form of microorganisms, cells or enzymes) for the conversion of a particular material into an electrochemically active compound.[105-107] For example, phosphate esters and catechol and *p*-aminophenol ethers were hydrolysed[106,107] by hydrolases and the products of this reaction were then oxidised electrochemically at the electrode as the fuel. It has been shown that, when alkaline phosphatase is used, the oxidation reaction of the products of the enzymic reaction proceeds at potentials more negative by 0.3–0.4 V than the electrochemical oxidation of the initial substrates.

Methods for the conversion of complex organic substances into the simplest fuel as a result of the action of microorganisms have been described.[108-111] The primary substances employed were saccharides, urea, lactate, formic acid, and hexadecane. Ammonia, hydrogen, and methane were converted by the action of biocatalysts into a fuel capable of being oxidised at the electrode. A characteristic feature of such fuel cells is the presence of one or several stages which are not oxidation-reduction reactions and are used to convert the secondary fuel into the electrochemically active primary fuel.

The second class includes systems based on the direct utilisation of enzyme catalysts in bioelectrochemical reactions.[17] Evidently, such a function can be fulfilled only by oxidation-reduction enzymes. It is therefore promising to investigate the electrocatalytic properties of hydrogenases, glucose oxidase, acid dehydrogenases, methanol, and methane oxidases, as well as enzymes which activate the electrochemical reduction of oxygen. Fuel cells employing the enzyme glucose oxidase have been described.[66,112] The biofuel cell based on a hyaluronidase immobilised on Sepharose-CNBr reached a power output of 2.8 μW cm^{-2}.[113]

Electrodes for biofuel cells operating via a mechanism involving direct electron transfer and employing the enzymes laccase[62] and hydrogenase[114] have been described in the literature.

The so-called "cofactor-modified electrodes" can also find applications in fuel cells. The possibility of employing cofactors in electrochemical processes have been discussed in two investigations.[115,116]

A number of studies whose aim was to devise an anode for a fuel cell employing methanol as the fuel have been published in recent years.[117,118] The catalyst in this system was an NAD-independent methanol dehydrogenase and the electron acceptor was phenazine ethosulphate or phenazine methosulphate. The reduced mediator was oxidised at a platinum electrode. The cathodic reaction employed involved the reduction of oxygen on platinum. The maximum power output of the cell was 20 mW mg^{-1}.

3. Specific Electrosynthesis Under the Influence of Immobilised Enzymes

When biocatalysts are employed, it is possible to synthesise effectively compounds whose synthesis by other methods is difficult.[119,120] On the basis of the data of Wollenberger et al.,[121] it is possible to put forward a method of synthesis employing the oxidation reaction of ketosteroids catalysed by the enzyme steroid Δ^1-dehydrogenase. Wingard et al.[122] discussed the possibility of the electrosynthesis of ATP in the presence of ATP phosphatase from ADP and orthophosphate. Scheller et al.[123] proposed a method for the demethylation of benzphetamine, *p*-nitroanisole and aminopyridine in the cathodic reduction of oxygen to hydrogen peroxide in the presence of cytochrome P-450.

Methods whereby it is possible to regenerate enzyme cofactors have been recently discussed fairly frequently in the literature.[124-126] Torstensson and Johansson[127] proposed a method for the regeneration of nicotinamide-adenine dinucleotide (NAD) in a complex with alcohol dehydrogenase immobilised on the surface of a vitreous carbon electrode. The complex was obtained by employing an NAD analogue, namely $NH_2-(CH_2)_6-NHCOCH_2-NAD^+$. The electrode surface was modified with 2,4,6-trichlorotriazine. An enzymic reaction occurred in the presence of ethanol with formation of the NADH-analogue, which was then reoxidised electrochemically to the NAD-analogue. A deficiency of this method is

the occurrence of electrochemical side processes which lead to the degradation of the NAD-analogue and the formation of enzymically inactive dimeric compounds.

An NAD regenerating system employing PMS^+† as the mediator has been proposed.[128,129] The cofactor analogue NAD-dextran is reduced to NADH-dextran in the presence of substrates of the enzymes alcohol dehydrogenase and lactate dehydrogenase. NADH-dextran was oxidised chemically in the presence of PMS^+ to NAD-dextran. The PMSH formed is oxidised reversibly to PMS^+ at the electrode. The proposed method also makes it possible to regenerate NADP in the presence of glutamate dehydrogenase. The efficiency of the regeneration of the cofactor in such systems reaches 99.85%.

Reactions involving the electrosynthesis of a number of carbohydrate derivatives using methane monoxygenase have been described.[48,119]

It is to be expected that interest in the preparation of organic substances of this kind with the aid of the bioelectrosynthetic method will steadily grow. This is associated with the necessity for the large-scale manufacture of certain substances, for example, for the pharmaceutical industry, whose synthesis by the known organic synthetic methods is difficult.

The Reactivity of Polyfunctional Compounds in Radical Reactions

E.T.Denisov

Recent results of studies of the kinetics of the reactions of monohydric and polyhydric alcohols and polyfunctional esters with peroxy- and alkyl radicals, oxygen, and hydroperoxide are examined. By comparing the reactivities of mono- and polyfunctional compounds in relation to polar reagents, it is shown that the rule of the additivity of the partial rate constants breaks down in all cases. The data are analysed within the framework of the concept of the multidipolar interaction of the polar groups in the molecule and the transition state and the complete agreement between the published results and the conclusions based on this concept is demonstrated.
The bibliography includes 31 references.

I. INTRODUCTION

The reactivity of molecules in radical reactions depends both on their structure and on the structure of the attacking radical. The following factors influence the reactivity of molecules in radical abstraction and addition reactions. The first factor is the heat of reaction: the higher the heat, the faster the reaction; the dependence of the activation energy on the heat of reaction within the limits of a single reaction series can be fitted by the Polanyi–Semenov equation.[1] The second factor is the polarity (polar structure) of the transition state: the shift of electron density in the transition state from one atom to another lowers the activation energy.[2] The third is the steric factor associated with the presence of bulky substituents adjoining the reaction centre which hinder the attack by the radical.[2] All three factors depend on the nature of the atoms participating in the reaction and on the structure of the substituents. The molecule of an organic compound can therefore be subjected to an imaginary sub-division into a series of fragments and the reaction rate constant can be represented by the sum of the partial rate constants referred to the corresponding fragments. This additivity rule for radical reactions frequently holds satisfactorily and is fairly widely used.[3]

Comparison of the rate constants for the reactions of peroxy-radicals with monocarboxylic and dicarboxylic acid esters[4] and also for the reaction of the cumenylperoxy-radicals with diethylene glycol dicaprylate and pentaerythritol tetravalerate[5] revealed the failure of this rule. These facts served as the starting point for the development of the concept of the dipole–dipole interaction between the polar agent and the dipole moments of the polar groups in the polyfunctional molecule,[6] which has been referred to as multidipolar interaction, since several (more than two) dipolar groups are involved in it. Evidence concerning the validity of the above concepts has been obtained very recently for a wide variety of radical reactions. This review is devoted to the analysis and survey of these data.

II. THE STRUCTURAL FACTORS WHICH DETERMINE THE REACTIVITY OF MOLECULES

The rate constant for the elementary reaction of a radical with a molecule depends on the heat of reaction (the Polanyi–Semenov rule), the polarity of the transition state, the accessibility of the reaction centre, and the temperature and nature of the medium. The reactivity of the molecule is influenced by bond conjugation, by the inductive effect, and by the steric factor.

Each of the three factors indicated can influence the heat of reaction. The scale of this influence can be inferred by comparing the C–H bond strengths in the corresponding compounds. For example, the contribution of the conjugation effect can be estimated by comparing the C–H bond strengths in the methane (435 kJ mol^{-1}) and toluene (355 kJ mol^{-1}) molecules.[7] The difference of 80 kJ mol^{-1} is caused in this case by the fact that the free valence in the benzyl radical is conjugated with the π orbitals of the benzene ring. The decrease of the C–H bond dissociation energy from 435 kJ mol^{-1} in methane to 410 kJ mol^{-1} in methyl bromide is associated with the polar effect exerted by the bromine atom.[7] In ethanol the energy of the α-C–H bond is lower by 34 kJ mol^{-1} than in ethane, where D_{C-H} = 410 kJ mol^{-1} [7] owing to the combined influence of the inductive effect (the shift of the σ electrons along the C–O bond) and the effect of the conjugation of the free valence with the pair of p electrons of oxygen. Comparison of ethylbenzene and indan may serve as an example of the influence of the steric effect on the C–H bond strength. The methyl group in the α-phenylethyl radical prevents the most complete overlap of the p orbital of the unpaired electron with the π orbitals of the benzene ring. The α-C–H bond in ethylbenzene is therefore somewhat stronger than in indan and the phenyl radical attacks the indan α-C–H bond four times faster than that in ethylbenzene.[8]

The polar factor, which is manifested when the radical (atom) and the molecule have different electron affinities, is also very important.[8] An example may be provided by a

comparison of the reactions of chlorine and hydrogen with methane. Since the H–H and H–Cl bond strengths are equal (426 kJ mol^{-1}), it follows that the heats of these two reactions are also equal (−8 kJ mol^{-1}). Nevertheless the activation energies for these reactions differ by 38 kJ mol^{-1}: E = 54 kJ mol^{-1} for the reaction of hydrogen with methane and E = 16 kJ mol^{-1} for the reaction of chlorine with methane.[9] Such a marked decrease of activation energy on passing from H to Cl has been accounted for by the polar structure of the transition state Cl...H...CH_3 in which the Coulombic attraction in the fragments bearing unlike charges reduces the potential barrier. The polar structure of the transition state is determined in its turn by the high electron affinity of the chlorine atom (346 kJ mol^{-1}).

The inductive effect influences both the heat of reaction and the polar character of the transition state. For example, in the reactions of bromine atoms with the C–H bonds of cyclohexane and toluene the principal factor is the heat of reaction. The C–H bond in toluene (D_{R-H} = 355 kJ mol^{-1}) is much weaker than in cyclohexane (D_{R-H} = 393 kJ mol^{-1}) [7] and toluene is accordingly brominated 17 times faster than cyclohexane (at 353 K).[8] On the other hand, chlorine atoms attack cyclohexane molecules four times faster than toluene molecules (at 313 K).[8] This "inversion" of the reactivities of the molecules can be accounted for by the different contributions of the heat of reaction and the polar factor to the activation energy for the reaction. The reaction of bromine with toluene is thermally neutral, while that with cyclohexane is endothermic (q = 38 kJ mol^{-1}) and the relative reactivities of toluene and cyclohexane are therefore determined by the strengths of their C–H bonds. while the polar structure is of secondary importance.

The reaction of chlorine (D_{H-Cl} = 426 kJ mol^{-1}) is extremely exothermic with both toluene (q = 71 kJ mol^{-1}) and cyclohexane (q = 33 kJ mol^{-1}).[7] The polar effect, which is greater in the case of cyclohexane, therefore makes a decisive contribution to the decrease of activation energy.

Another example involves the attack by various species on the C–H bonds in the propionic acid molecule.[8] The methyl radical attacks predominantly the α-CH_2 group (at 373 K the α-C–H bond is attacked 8 times faster than the β–C–H bond). On the other hand, the chlorine atom attacks the stronger β–C–H bond 33 times faster than the weaker α–C–H bond (at 353 K). The ratio of the rate constants for the methyl radical is determined by the strengths of these bonds. On the other hand, the chlorine atom attacks faster in those cases where a more polar transition state is produced; this is hindered by the presence of the electron-accepting carboxy-group in the α-position. A relation between the rate constant, on the one hand, and the ionisation potential of the molecule I(RH) and the electron affinity of the peroxy-radical EA($RO_2^{\cdot}$), on the other, has been found empirically for the reactions of peroxy-radicals with aromatic alkyl-substituted hydrocarbons;[10] at 348 K the relation is of the form $\Delta \lg k = 31.48\ [I(RH) - EA(RO_2^{\cdot})]^{-1}$.

Finally, the third factor determining the reactivity is the accessibility of the reaction centre, which depends on the size and number of the bulky substituents near the reaction centre and on the conformation of the molecule. For example, the phenyl radical abstracts an H atom from hydrocarbons having the structure $(CH_3)_3C(CH_2)_nCH(CH_3)_2$ with relative rate constants of 0.71 (n = 0), 0.34 (n = 1), and 0.81 (n = 2),[8] i.e., instead of a smooth increase of the rate constant with increasing n, its decrease (by a factor of two) on passing from n = 0 to n = 1, i.e. after the appearance of one CH_2 group, is observed. An analogous relation (a periodic relation as a function of the number of CH_2 groups) has been observed for the reactions of the undecyl radical with the esters $CH_3OCO(CH_2)_nCOOCH_3$.[11]

All three effects (the inductive effect, the conjugation effect, and the steric effect) are local in character. The inductive effect is transmitted via the σ-bonds and rapidly decays: at the third carbon atom starting from the atom attached to a polar substituent it is no longer manifested. For the manifestation of an appreciable influence of the conjugation effect, a double bond or an aromatic ring must adjoin this atom (i.e. must be located in the 2-position). The steric effect is also manifested only in the vicinity (in the α-position and more weakly in the β-position) of the bulky substituent. The molecule whose C–H bonds are attacked by free radicals can therefore be subdivided into a series of structural groups, each of which enters into the reaction with its own partial rate constant. The rule of the additivity of the partial rate constants follows from this approach: the rate constant for the reaction of a free radical with a molecule is equal to the sum of the partial rate constants k_i for all the fragments constituting the molecule, i.e.

$$k = \sum_i^n k_i.$$

The rule of additivity holds fairly well in many cases. For example, it has been clearly established that, in the reactions of free radicals with hydrocarbons,[3] aliphatic acids, and esters, the reaction rate constant increases linearly with the number of methylene groups.[4] Table 1 presents the partial rate constants for the reactions involving the abstraction of a hydrogen atom by the $CH_3^{\cdot}$, $RO^{\cdot}$, and $RO_2^{\cdot}$ radicals.

Table 1. The partial rate constants (k, litre mol^{-1} s^{-1}) for the abstraction of H atoms from the C–H bonds in various groups.

Group	$CH_3^{\cdot}$ (338 K) [3]	$(CH_3)_3OO^{\cdot}$ (313 K) [3]	$(CH_3)_3COO^{\cdot}$ (303 K) [12]
$-CH_3$	5.0	$2.5\cdot10^4$	—
$>CH_2$	50	$1.4\cdot10^5$	$2.7\cdot10^{-4}$
$>CH$	500	$3.8\cdot10^5$	$4.8\cdot10^{-3}$
$>C{=}CHCH_3$	18	$4.8\cdot10^5$	—
$>C{=}CHCH_2{-}R$	120	$1.4\cdot10^4$	$8.4\cdot10^{-2}$
$C_6H_5{-}CH_3$	420	$2.4\cdot10^5$	$1.2\cdot10^{-2}$
$C_6H_5{-}CH_2R$	560	$1.6\cdot10^5$	0.10
$C_6H_5CH(CH_3)_2$	$1.8\cdot10^3$	$8.4\cdot10^4$	0.16
$>CHOH$	$3.4\cdot10^3$	—	$9\cdot10^{-3}$
$-CO-CH_2-$	850	$8.5\cdot10^4$	—

Note. The numerals in square brackets denote references (Ed. of Translation).

The rule of additivity is well known from experiments involving the reactions of atoms (H, Cl, Br) and free radicals ($HO^{\cdot}$, $RO_2^{\cdot}$, $CH_3^{\cdot}$, $CF_3^{\cdot}$) with hydrocarbons and monofunctional organic compounds.[3] The rule also holds for reactions of peroxy-radicals with hydrocarbons. Even in the oxidation of dicarboxylic acids and their esters, it holds in relation to the methylene groups in the molecule.[4] For example, the rate constants for the reaction of cumenylperoxy-radicals with the dimethyl esters of dicarboxylic acids increase linearly with increase in the number n of methylene groups in the acid residue: $\log k = 9.6 + 0.73n$ litre $mole^{-1}$ s^{-1} at

413 K. The situation is exactly the same for the dependence of k on the number of CH_2 groups in the alcoholic residue when the cumenylperoxy-radical attacks the molecule of a dibasic acid ester and the alcohol residue in the molecule is varied.[4] However, as shown below, in many reaction series the rule of the additivity of the partial rate constants does not hold, i.e. for a molecule consisting of n fragments we have

$$k \neq \sum_i^n k_i,$$

where k_i refers to the ith fragment. The deviation from the additivity rule can be characterised, for example, by the ratio

$$\sum k_i/k$$

or its logarithm. Using the theory of the absolute reaction rates, the deviation can be characterised in terms of the change in the Gibbs free energy of activation as

$$\Delta\Delta G_{ad}^{\neq} = \Delta G^{\neq} - \Delta G_{ad}^{\neq} = RT \ln \left(\sum_i k_i/k \right),$$

where $\Delta G_{ad}^{\neq}$ is the Gibbs activation energy for the molecule when the rule of additivity holds.

III. THE REACTIONS OF PEROXY-RADICALS WITH POLYHYDRIC ALCOHOLS AND POLYFUNCTIONAL ESTERS

Valuable experimental data on the reactivities of polyfunctional esters in reactions with cumenylperoxy-radicals have been obtained in the study of the oxidation of the esters in the presence of cumenyl hydroperoxide, which serves simultaneously also as the initiator of the reaction and as the source of cumenylperoxy-radicals.[11,13] The experimental conditions ensured in the system an intense exchange of the $RO_2^{\cdot}$ radicals for cumenylperoxy-radicals. The chain oxidation scheme in a system of this kind includes the following reactions:

$$\mathrm{ROOR} \xrightarrow{k_i} 2\mathrm{RO}^{\cdot} \xrightarrow{\mathrm{R'H}} \dot{\mathrm{R}}';$$

$$\mathrm{ROOH} \xrightarrow{k_{i,\mathrm{ROOH}}} \mathrm{RO}^{\cdot} + {}^{\cdot}\mathrm{OH} \xrightarrow{\mathrm{R'H}} \dot{\mathrm{R}}';$$

$$\dot{\mathrm{R}}' + \mathrm{O}_2 \rightarrow \mathrm{R'OO}^{\cdot};$$

$$\mathrm{R'OO}^{\cdot} + \mathrm{ROOH} \rightleftharpoons \mathrm{R'OOH} + \mathrm{RO}_2^{\cdot};$$

$$\mathrm{R'OO}^{\cdot} + \mathrm{R'H} \xrightarrow{k_p'} \mathrm{R'OOH} + \dot{\mathrm{R}}';$$

$$\mathrm{RO}_2^{\cdot} + \mathrm{R'H} \xrightarrow{k_p} \mathrm{ROOH} + \dot{\mathrm{R}}';$$

$$\mathrm{RO}_2^{\cdot} + \mathrm{RO}_2^{\cdot} \xrightarrow{k_t} \mathrm{ROOR} + \mathrm{O}_2;$$

$$\mathrm{R'O}_2^{\cdot} + \mathrm{RO}_2^{\cdot} \xrightarrow{k_t'} \mathrm{R''{=}O} + \mathrm{O}_2 + \mathrm{ROH};$$

$$\mathrm{R'O}_2^{\cdot} + \mathrm{R'O}_2^{\cdot} \xrightarrow{k_t''} \mathrm{R''{=}O} + \mathrm{O}_2 + \mathrm{R'OH}.$$

For sufficiently long chains and when the reaction of $\dot{\mathrm{R}}'$ with O_2 is very rapid, the rate of chain oxidation is described by the expression $v_{\mathrm{O}} = \{k_p[\mathrm{RO}_2^{\cdot}] + k_p'[\mathrm{R'O}_2^{\cdot}]\}[\mathrm{RH}] = a[\mathrm{RH}]v_i^{1/2}$; the variation of the ratio [ROOH]/[R'H] entails the variation of the coefficient a, which depends on the composition of the radicals, i.e. on the ratio $[\mathrm{RO}_2^{\cdot}]/[\mathrm{R'O}_2^{\cdot}]$. When [ROOH] = 0, the coefficient $a = k_p'(2k_t'')^{-1/2}$, and when [ROOH] $\rightarrow \infty$, we obtain $a \rightarrow k_p(2k_t)^{-1/2}$. The experiments were performed for [ROOH] $\geqslant$ 0.8 M,[13] whereupon the coefficient a reaches its maximum value of 6×10^{-3} litre$^{1/2}$ mol$^{-1/2}$ s$^{-1/2}$. The results of the measurement of $k_p(2k_t)^{-1/2}$ are presented in Table 2. The absolute values of k_p were calculated on the assumption that $2k_t = 4.05 \times 10^6$ litre mol^{-1} s^{-1} for cumenyl peroxide.[15]

With increase of the number of ester groups in the molecule, the partial rate constant k_{pi} also increases. If it is assumed, after Pozdeeva et al.,[14] that $\Delta \lg k_{pt} = \delta n$, where n is the number of ester groups, then we obtain $k_{pi} = 1.0$ litre mol^{-1} s^{-1} for the monoester ($n = 1$). This makes it possible to calculate $\Delta\Delta G_{ad}^{\neq}$, which varies in the series of propionate esters from 0 to −4 kJ mol^{-1}. In this series of compounds, the increase of the number of functional groups in the molecule increases the reactivity of the C−H bonds in each group. Another tendency has been observed for esters obtained from different aliphatic acids. Only the $-OCH_2-$ groups are apparently attacked in pentaerythritol tetraacetate, so that $k_{CH_2O} = 0.25\, k_p = 2.0$ litre mol^{-1} s^{-1}. For the attack by the cumenylperoxyradical on the α-CH_2 group of the acid residue in pentaerythritol tetrapropionate, we obtain $k_{\alpha\text{-}CH_2} = 0.25k_p - 2.0 = 1.5$ litre mol^{-1} s^{-1}. For pentaerythritol tetracaprate, the average value of k_{CH_2} for the methylene groups in the acid residue is significantly higher: $k_{CH_2} = (87.7 - 8.1)/32 = 2.5$ litre mol^{-1} s^{-1}. In the n-heptadecane molecule (see Table 3 below) the methylene group reacts with $RO_2^{\cdot}$, for which $k_{CH_2} = 2.8$ litre mol^{-1} s^{-1}.

Table 2. Kinetic parameters of the oxidation reaction of esters in the presence of cumenyl hydroperoxide (404 K, *o*-dichlorobenzene).[13,14]

Ester	$k_p'(2k_t'')^{-1/2} \times 10^3$, litre$^{1/2}mol^{-1/2}s^{-1/2}$	k_p, litre mol^{-1}s^{-1}	k_p^0, litre mol^{-1}s^{-1}*	$\Delta\Delta G_{ad}^{\neq}$, kJ mol^{-1}
$C(CH_2OCOCH_3)_4$	2.82	8.1	2.0	—
$C(CH_2OCOCH_2CH_3)_4$	3.69	13.9	3.5	−4.1

*Here k_p^0 represents the constant recalculated for one fragment.

Evidently the ester group lowers the reactivity of the nearest methylene groups of the acid residue and, on moving away from the OCO group, the reactivity of the methylene groups increases, tending to that in an n-paraffin molecule.

The coupled oxidation of a number of ethers and esters with n-decane has been studied.[16] The ratio of the rate constants for the reactions of decylperoxy-radical with the ester or ether and n-decane has been estimated from the dependence of the rate of the initiated oxidation on the concentration of the ester or ether added to the hydrocarbon. The relative partial rate constants (at 403 K) were obtained from a comparison of the relative rates with the structures of the monofunctional esters and ethers: 0.125 for the CH_2 group, 2.4 for the OCH_2 group, and 0.4 for the CH_2OCO. $.(CH_2)_6$ group. Calculation assuming additivity for diethylene glycol dicaprylate yielded $k_{rel} = 5.2$, while the experimental value is 2.8. $\Delta\Delta G_{ad}^{\neq} = 2.1$ kJ mol^{-1} corresponds to this deviation from additivity.

Apart from ethers and esters, the reactivity of polyhydric alcohols in reactions with peroxy-radicals has been investigated.[16,17] This reaction has been studied[17] by the method of coupled oxidation with a selective inhibitor,[18] in which the ability of peroxy-radicals derived from the alcohol to reduce certain compounds, particularly quinones, was used.[19] Under the conditions of the coupled chain oxidation, such a selective inhibitor lowers the rate of the process to an extent which depends on the rate of generation of the hydroxyperoxy-radicals from the alcohol: the faster the formation of these radicals, the more pronounced the inhibiting effect of the inhibitor. This makes it possible to determine the reactivity of the alcohol in relation to $RO_2^{\cdot}$ compared with the reactivity of RH. In the presence of a selective inhibitor Q (quinone) and an initiator I, the coupled oxidation of an alcohol HR'OH and the substance RH includes the following stages:[18]

$$I \xrightarrow{v_i} \dot{r} \xrightarrow{RH} \dot{R} \xrightarrow{O_2} RO_2^{\cdot};$$

$$RO_2^{\cdot} + RH \xrightarrow{k_p} ROOH + \dot{R};$$

$$RO_2^{\cdot} + HR'OH \xrightarrow{k_p'} ROOH + \dot{R}'OH;$$

$$O_2 + \dot{R}'OH \xrightarrow{fast} \dot{O}OR'OH;$$

$$\dot{O}OR'OH + Q \rightarrow \dot{Q}H + O_2 + R'{=}O;$$

$$RO_2^{\cdot} + \dot{Q}H \xrightarrow{fast} ROOH + Q;$$

$$RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_t} \text{products}.$$

At a sufficiently high concentration of Q in the system, the $RO_2^{\cdot} + RO_2^{\cdot}$ reaction does not play any role in chain termination and the peroxy-radicals derived from the alcohol react with Q so fast that the rate of reaction is limited by their formation via the reaction of $RO_2^{\cdot}$ with the alcohol.

Under these conditions, the rate of the inhibited oxidation is defined by the expression

$$v = k_p[RH][RO_2^{\cdot}] + v_i \cong k_p[RH][RO_2^{\cdot}],$$

where

$$v_i = 2k_p'[HR'OH][RO_2^{\cdot}],$$

and the rate constant ratio k_p'/k_p is found from the equation $k_p'/k_p = v_i[RH]/2v[HR'OH]$. Degtyareva et al.[16] carried out experiments under conditions such that the chains are short (the chain length was $\nu < 10$) and the degree of inhibition was low ($\nu/\nu_0 > 0.3$). Under these conditions, it is not permissible to neglect either v_i or the contribution by the $RO_2^{\cdot} + RO_2^{\cdot}$ reaction, i.e. it is necessary to take into account the fact that the following equalities hold in the quasi-stationary regime in the presence of Q: $k_p[RH][RO_2^{\cdot}] = v - v_i$ and $v_i = 2k_p'[HR'OH][RO_2^{\cdot}] + 2k_t[RO_2^{\cdot}]^2$. Bearing in mind that $v = v_0 = k_p(2k_t)^{-1/2}[RH]v_i^{1/2}$ when [Q] = 0, we arrive at the following formula after simple rearrangements:

$$\frac{k_p'}{k_p} = \frac{1}{2}\frac{[RH]}{[HR'OH]}\left\{\frac{1}{\nu - 1} - \frac{\nu - 1}{\nu_0^2}\right\},$$

where $\nu = v/v_i$ and $\nu_0 = v_0/v_i$. This formula is more accurate than that quoted in Ref.17 and was used to recalculate the k_p'/k_p ratios from the experimental data of the earlier study.[17] The results of the calculation are presented in Table 3.

$\Delta\Delta G_{ad}^{\neq}$ can be estimated more conveniently for the absolute values of k_p'. Following the procedure of Degtyareva et al.,[16] we assume that k_p is the same as for the reaction of cumenylperoxy-radicals with n-hexadecane. According to Denisov et al.,[4] $k_{pi} = 0.31$ litre mol^{-1} s^{-1} at 403 K for the reaction of the cumenylperoxy-radical with one methylene group of an n-paraffin, so that we obtain $k_p = 14 \times 0.31 = 4.3$ litre mol^{-1} s^{-1} for the reaction of $RO_2^{\cdot}$ with n-hexadecane (neglecting the attack by the peroxy-radicals on the methyl groups). On the basis of data for the coupled oxidation of n-hexadecane together with 1-decanol and 2-octanol[17] and assuming that the methylene groups in the alcohol molecules are attacked with the same partial rate constant as in the n-paraffin molecule, we obtain the following partial rate constants: $k_{CH_2OH} = 34.8 - 8 \times 0.31 = 32.3$ litre mol^{-1} s^{-1} and $k_{CHOH} = 43.4 - 5 \times 0.31 = 41.9$ litre mol^{-1} s^{-1}. Proceeding in exactly the same way as for the diethylene glycol dicaprylate–alcohol system and assuming that $k_p = 4.6$ litre mol^{-1} s^{-1},[5] we obtain $k_{CH_2OH} = 22.5 - 2.5 = 20$ litre mol^{-1} s^{-1} for 1-decanol and $k_{CH_2OH} = 23.0 - 2.2 = 20.8$ litre mol^{-1} s^{-1} for 1-nonanol; these values are very close and one can adopt the average $k_{CH_2OH} = 20.4$ litre mol^{-1} s^{-1}. On the basis of the data for 2-octanol (Table 3), we obtain $k_{CHOH} = 22.5 - 1.5 = 21$ litre mol^{-1} s^{-1}. Table 4 presents the values of k_p', the constants k_Σ obtained assuming additivity, and the values of $\Delta\Delta G_{ad}^{\neq}$ calculated on this basis. It is seen that polyhydric alcohols do not obey the rule of additivity in reactions with peroxy-radicals.

Table 3. The results of the measurement of k_p'/k_p for a number of alcohols by the method of coupled oxidation in the presence of a selective inhibitor {404 K, [Q] = 10^{-2} M, initiator—di-t-butyl peroxide}.[17]

Notation: 1) results obtained in experiments with hexadecane ($v_i = 1.3 \times 10^{-6}$, $v_0 = 7.6 \times 10^{-6}$ mol litre^{-1} s^{-1}); 2) results obtained in experiments with diethylene glycol dicaprylate ($v_i = 8.3 \times 10^{-7}$, $v_0 = 8.0 \times 10^{-6}$ mol litre^{-1} s^{-1}).

The coupled oxidation of a number of monohydric and polyhydric alcohols together with n-decane, n-hexadecane, and polyfunctional esters has been investigated.[16] Experimental measurements were made of the dependence of the rate of the initiated chain oxidation on the composition of the binary mixture (at 403 K using di-t-butyl peroxide as the initiator). The following scheme comprising reactions limiting the rate of chain propagation and termination is valid for the initiated chain oxidation (RH is a hydrocarbon or ester and HR'OH is an alcohol):

$$RO_2^{\cdot} + RH \xrightarrow{k_{p,11}} ROOH + R^{\cdot};$$

$$RO_2^{\cdot} + HR'OH \xrightarrow{k_{p,21}} ROOH + \dot{R}'OH;$$

$$HOR'O_2^{\cdot} + RH \xrightarrow{k_{p,12}} HOR'OOH + R^{\cdot};$$

$$HOR'O_2^{\cdot} + HR'OH \xrightarrow{k_{p,22}} HOR'OOH + \dot{R}'OH;$$

$$\left.\begin{aligned} RO_2^{\cdot} + RO_2^{\cdot} &\xrightarrow{k_{t,11}} \\ RO_2^{\cdot} + HOR'OO^{\cdot} &\xrightarrow{k_{t,12}} \\ HOR'O_2^{\cdot} + HOR'OO^{\cdot} &\xrightarrow{k_{t,22}} \end{aligned}\right\} \text{molecular products.}$$

The rate of the coupled chain oxidation with v_i = const is described by the expression

$$v = \frac{(k_{p,11} + k_{p,12}u)\cdot[RH] + (k_{p,21} + k_{p,22}u)\cdot[HR'OH]}{(2k_{t,11} + 2k_{t,12}u + 2k_{t,22}u^2)^{1/2}} \cdot v_i^{1/2},$$

where

$$u = k_{p,21}[HR'OH]/k_{p,12}[RH].$$

For low amounts of added alcohols, where the contribution of the $HOR'OO^{\cdot}$ + HR'OH reaction to chain propagation and the contribution of the $HOR'OO^{\cdot}$ + $HOR'OO^{\cdot}$ reaction to chain termination may be neglected, the expression for the rate of the coupled oxidation assumes a simpler form:

$$\frac{v}{v_0} = \left(1 + 2\frac{k_{p,21}[HR'OH]}{k_{p,11}[RH]}\right)\cdot\left(1 + \frac{k_{t,12}}{k_{t,11}}\cdot\frac{k_{p,21}}{k_{p,12}}\cdot\frac{[HR'OH]}{[RH]}\right)^{-1/2},$$

whence the following relation can be obtained:

$$\alpha = \frac{\Delta v}{v_0}\Big/\Delta\left(\frac{[HR'OH]}{[RH]}\right) = 2\frac{k_{p,21}}{k_{p,11}} - \frac{1}{2}\frac{k_{t,12}}{k_{t,11}}\cdot\frac{k_{p,21}}{k_{p,12}},$$

where $\Delta v = v - v_0$ and $v_0 = k_p(2k_{t,11})^{-1/2}[RH]v_i^{1/2}$ is the rate of oxidation of RH in the absence of HR'OH under the same conditions. The coefficient α is determined from the experimental dependence of v on [HR'OH]/[RH].

*The ratios k'_p/k_p were taken from Table 3.

The rate constant ratio $k_{p,21}/k_{p,11}$ in which we are interested can be obtained from α by estimating the second term in the above formula, which can be done in the following manner. It is known that the reactivity of the peroxy-radical depends only slightly on its structure and one can put $k_{p,12} = k_{p,11}$. In this case the expression for the parameter α becomes

$$\alpha = 2(k_{p,21}/k_{p,11})\cdot(1 - 0.25\ k_{t,12}/k_{t,11}).$$

The ratio $k_{t,12}/k_{t,11}$ may be estimated by comparing the values of α and $k_{p,21}/k_{p,11}$ measured by the method of coupled oxidation with the selective inhibitor described above. Table 5 presents such a comparison; it is seen that always the ratio $k_{t,12}/k_{t,11} > 1$ and the average value is 2.5 ± 0.6. We obtain the formula

$$k_{p,21}/k_{p,11} = 1.33\alpha.$$

for the calculation of $k_{p,21}/k_{p,11}$. We recalculated the values of $k_{p,21}/k_{p,11}$ from the data of Degtyareva et al.[16] in terms of this formula and the results are presented in Table 6.

In order to calculate the partial rate constants, we proceed in the following way. For the alcohol–hexadecane system, where all the methylene groups in RH are equivalent as regards their reactivity, we have $k_{p,11} = 14k_{CH_2}$ and $k_{p,21}/k_{p,11} = 14k_{p,21}/k_{CH_2}$. In the n-decane molecule the peroxy-radical attacks 8 methylene groups and the CH_2OH group; consequently

$$k_{p,21}/k_{CH_2} = 74.2 = k_{CH_2OH}/k_{CH_2} + 8,$$

whence

$$k_{CH_2OH}/k_{CH_2} = 66.2.$$

Analogously, on the basis of the ratio $k_{p,21}/k_{CH_2}$ for 2-octanol, we obtain $k_{CHOH}/k_{CH_2} = 156$. Using the rule of additivity, we obtain $k_{p,21}/k_{CH_2}$ for butane-1,3-diol and for 1,1,1-tri(hydroxymethyl)propane (Table 6).

Table 5. Comparison of the values of α and $k_{p,21}/k_{p,11}$ for coupled chain oxidation of alcohols together with n-hexadecane (403 K).

In the alcohol (hydrocarbon)–diethylene glycol dicaprylate binary system it is possible to employ as the reference value the ratio $k_{p,21}/k_{p,11}$ for n-decane, for which $k_{p,21} = 8k_{CH_2}$ and $k_{p,21}/k_{p,11} = 0.2$, whence $k_{CH_2}/k_{p,11} = 0.025$. The

partial rate constant k_{CH_2OH} can be found from the ratio $k_{p,21}/k_{p,11}$ for *n*-decanol; $k_{CH_2OH}/k_{CH_2} = 84 - 8 = 76$.

Proceeding analogously for the alcohol (hydrocarbon)–pentaerythritol tetravalerate system, we find

$$k_{p,21}/k_{CH_2} = 7.86 \quad (k_{p,21}/k_{p,11})$$

and for the CH_2OH group we have $k_{CH_2OH}/k_{CH_2} = 22.9 - 8 = 14.9$. The ratio k_{CHOH}/k_{CH_2} for the secondary alcohol group can be estimated assuming that the ratio k_{CHOH}/k_{CH_2OH} is the same as for the hexadecane peroxy-radicals, where it is 2.36; we obtain $k_{CHOH}/k_{CH_2} = 2.36 \times 14.9 = 35.2$. Evidently, the ratios k_{CH_2OH}/k_{CH_2} for hexadecane and diethylene glycol dicaprylate are similar (66 and 76), while that for pentaerythritol tetravalerate is significantly lower (15). Since the oxidation of the latter ester results in the preferential formation of peroxy-groups with a quaternary carbon atom in the α-position, the steric effect is apparently the cause of the reduced reactivity of the peroxy-radicals formed from this ester.

Comparison of the calculated ratios $k_{p,21}/k_{CH_2}$ with the value obtained assuming the additivity of the partial rate constants shows that the additivity rule does not hold for polyhydric alcohols; the values of $\Delta\Delta G^{\neq}_{ad}$ vary from −2 to +4 kJ mol^{-1}. Comparison of the estimates obtained by different methods on the whole indicates a satisfactory agreement: in hecadecane $\Delta\Delta G^{\neq}_{ad} > 0$ for the reaction of $RO_2^{\cdot}$ with butane-1,3-diol and $\Delta\Delta G^{\neq}_{ad} = -2.1$ kJ mol^{-1} (Table 4) and −1.7 kJ mol^{-1} (Table 6) for the reaction of $RO_2^{\cdot}$ with 1,1,1-tri(hydroxymethyl)propane. In diethylene glycol dicaprylate the sign and magnitude of $\Delta\Delta G^{\neq}_{ad}$ for the reaction of $RO_2^{\cdot}$ with 1,1,1-tri(hydroxymethyl)propane agree fairly well [−2.0 kJ mol^{-1} (Table 4) and −2.2 kJ mol^{-1} (Table 6)]. The tendency defined by the inequality $\Delta\Delta G^{\neq}_{ad} > 0$ is maintained for the reactions of $RO_2^{\cdot}$ with alcohols in which the hydroxy-groups are located at different carbon atoms of the carbon skeleton and $\Delta\Delta G^{\neq}_{ad} < 0$ for alcohols with the $-C(CH_2OH)_n$ group ($n = 3$).

In the oxidation of unsaturated compounds peroxy-radicals abstract hydrogen atoms from the olefin molecule and add to the double bond. In the oxidation of monomers such as acrylic acid, methacrylic acid, and their esters peroxy-radicals add preferentially to the double bond with formation of polyperoxides.[20] The addition of cumenylperoxy-radicals to the double bonds of a number of unsaturated monoesters and polyesters has been investigated.[21] Each ester (Table 7) was oxidised in the presence of cumenyl hydroperoxide, which was introduced in an amount ensuring the complete replacement of the ester peroxy-radicals by the cumenylperoxy-radicals. The oxidation was carried out at 323 K with azobisisobutyronitrile as the reaction initiator (the initiation rate constant was 2.2×10^{-6} s^{-1}). The process was carried out in a chain regime and the rate of oxidation was measured manometrically, corrections being applied for the evolution of N_2 on decomposition of the initiator and the evolution of O_2 on recombination of the cumenylperoxy-radicals. The reaction scheme (M = monomer) has the following form:

$$\begin{aligned}
&I \rightarrow \dot{r} \xrightarrow{O_2} rO_2^{\cdot} \xrightarrow{ROOH} RO_2^{\cdot} \xrightarrow{M} \dot{M}\ ; \\
&M^{\cdot} + O_2 \rightarrow MO_2^{\cdot}\ ; \\
&MO_2^{\cdot} + HOOR \rightarrow MOOH + RO_2^{\cdot}\ ; \\
&RO_2^{\cdot} + M \xrightarrow{k_p} \dot{M}\ ; \\
&RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_t} ROOR + O_2\ ; \\
&RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_t'} 2RO^{\cdot} + O_2\ ; \\
&RO^{\cdot} + HOOR \rightarrow ROH + RO_2^{\cdot}\ .
\end{aligned} \qquad (i)$$

The rate constants k_p, calculated from the experimental data assuming that the probability of the liberation of radicals into the bulk is 0.5 (Denisov[3]) and with the ratio $k_t'/k_t = 6.3$ (Howard[22]), are listed in Table 7. Comparison of the constants k_p and k_Σ (the latter were calculated assuming additivity) shows that the rule of additivity breaks down also in this group of reactions and to a greater extent the greater the number of ester groups in the molecule.

Table 7. The rate constants for the reaction of cumenyl-peroxy-radicals with the double bonds unsaturated esters (323 K).[21]

*The reaction rate constant calculated for one double bond.

IV. THE REACTIONS OF POLYFUNCTIONAL ESTERS WITH HYDROPEROXIDE AND OXYGEN

In the oxidation of organic compounds in the absence of initiators (including hydroperoxide), free radicals are generated via reactions involving molecular oxygen. Three chain initiation and oxidation reactions are known to have been investigated.[23] In the first, O_2 attacks the weakest C–H bond in the molecule with formation of alkyl and hydroperoxy-radicals:

$$RH + O_2 \rightarrow \dot{R} + HO_2^{\cdot}\ .$$

The reaction is endothermic and its heat is $q = -D_{R-H} + 221$ kJ mol^{-1}. In the second, compounds with weak C–H bonds, whose dissociation energy is less than 340 kJ mol^{-1}, enter into a faster termolecular reaction with oxygen:

$$RH + O_2 + HR \rightarrow \dot{R} + H_2O_2 + \dot{R}\ ,$$

whose heat is $q = -2D_{R-H} + 570$ kJ mol^{-1}. In the third, unsaturated compounds combine with oxygen at the double bond to form a biradical:

$$XHC{=}CH_2 + O_2 \rightarrow X\dot{C}HCH_2OO^{\cdot}\ .$$

In the reaction of RH with O_2 the initial species (oxygen, is non-polar, but the R...H...O_2 group, having a non-zero dipole moment, is formed in the transition state. The configuration of the transition state is close to that of the final products ($\dot{R}$ and $HO_2^{\cdot}$) and the dipole moment of $HO_2^{\cdot}$ is 2 D (according to Opeida's estimate[10]). In the reaction of O_2 with a double bond in the transition state a non-polar O_2 molecule is converted into a polar peroxy-radical. It is entirely possible that the formation of the radical is preceded by the formation of an intermediate of the type of the charge-transfer complex $\bar{O}_2...\overset{+}{C}H_2{-}\dot{C}HX$, which has a large dipole moment. In this case too the effect of the multidipolar interaction should be observed.

Studies have been made[24,25] of chain initiation in the oxidation of ethyl propionate (by the mixed initiation method) and diethyl sebacate (by the inhibitor method using the *NN*-di-β-naphthyl-*p*-phenylenediamine inhibitor). In both cases radicals are formed via the bimolecular reaction of oxygen with the ester C–H bonds:

$$v_{i0}=k_{i0}[RH][O_2].$$

The weakest C–H bonds are the α-C–H bonds in the alcohol residue, which in fact make a decisive contribution to initiation. This has been demonstrated by studying the chain initiation in diethyl sebacate deuteriated at the α-C–H bonds of the alcohol residue: deuteriated diethyl sebacate reacts with O_2 much more slowly, as can be seen from a comparison of the values of v_{i0}:[25]

	$10^8 v_{i0}$ (413 K)	$10^8 v_{i0}$ (433 K)
Diethyl sebacate	1.4	5.4
Diethyl [α-D_2] sebacate	0.26	0.7
Kinetic isotope effect	5.2	7.4

Table 8 presents the results of the study of the chain initiation in the aliphatic esters of a number of polyhydric alcohols. It is seen that k_{i0} for pentaerythritol tetrapropionate is approximately twice as high as for the tetraacetate. Consequently the C–H bonds in both the alcohol and acid residues participate in chain initiation. When calculated per ester fragment, the constant k_{i0} varies from ester to ester, i.e. additivity breaks down for this reaction also. A very large difference is observed between the constants k_{i0} for ethyl propionate and diethyl sebacate. An approximately tenfold difference between the k_i is also observed for the addition of oxygen to the double bond in acrylic esters ($\Delta\Delta G^{\neq}_{ad}$ = 7 kJ mol^{-1}).

Table 8. The rate constants for the reactions of oxygen with saturated and unsaturated esters.[24–26]

Ester*	T, K	k/n, litre mol^{-1}s^{-1}	$\Delta\Delta G^{\neq}_{ad}$, kJ mol^{-1}	E, kJ mol^{-1}	A, litre mol^{-1}s^{-1}
$(CH_3)_3CR_2$	423	$6\cdot10^{-7}$	—	—	—
$C_2H_5CR_3$	423	$4\cdot10^{-7}$	—	—	—
CR_4	423	$1.2\cdot10^{-6}$	—	—	—
$C(CH_2OCOCH_3)_4$	423	$6\cdot10^{-7}$	—	—	—
$C_2H_5OCOC_2H_5$	433	$4.7\cdot10^{-3}$	—	133.8	$6.5\cdot10^{13}$
$(C_2H_5)_2[OCO(CH_2)_4]_2$	433	$4.2\cdot10^{-6}$	25.3	141.7	$5.2\cdot10^{11}$
$H_2C{=}CHCOOC_4H_9$	473	$7.6\cdot10^{-7}$		91.6	$5.3\cdot10^{6}$
$(H_2C{=}CHCOOCH_2)_4C$	473	$7.2\cdot10^{-8}$	7.1	180.6	$1.0\cdot10^{18}$

Notation: n is the number of ester groups in the molecule, E the activation energy, and A the pre-exponential factor. *R = $CH_2OCOCH_2CH_3$.

The formation of radicals via this reaction of cumenyl hydroperoxide with the double bonds in polyacrylic esters has been recently studied.[27] The radicals are formed via the reaction

$$ROOH + XHC{=}CH_2 \rightarrow {}^{\cdot}CHXCH_2OH + RO^{\cdot}.$$

As can be seen from the data presented below, a marked deviation from additivity is observed in this reaction also (at 343 K):

Monomer	Methyl acrylate	Tri(hydroxymethyl)-propane triacrylate	Pentaerythritol tetra-acrylate
k, litre mol^{-1}s^{-1}	$1.75\cdot10^{-7}$	$6.1\cdot10^{-8}$	$2.4\cdot10^{-8}$
$\Delta\Delta G^{\neq}_{ad}$, kJ mol^{-1}	0	3.0	5.6

As can be seen from the examples quoted, the deviation from additivity of the partial rate constants is observed for a wide variety of reactions, namely for the reactions of $RO_2^{\cdot}$ with RH (RH = polyhydric alcohol or polyfunctional ester), of $RO_2^{\cdot}$ with $H_2C{\equiv}CHR$, of O_2 with RH, of O_2 with $H_2C{=}CHR$, and of ROOH with $H_2C{=}CHR$. The model which explains these findings is discussed in the next Section.

V. THE MULTIDIPOLAR MODEL OF THE TRANSITION STATE FOR THE REACTION OF A POLAR SPECIES WITH A POLYFUNCTIONAL MOLECULE

We shall consider the possible causes of the deviation from additivity of the partial rate constants for the reactions enumerated above. Substituents in unsaturated compounds are known to exert a mesomeric effect, which is manifested in those cases where the substituent is located in the α-position with respect to the double bond or when there is a system of conjugated double bonds in the molecule. In the examples quoted above (reactions involving pentaerythritol acrylate esters), the ester groups are separated by several C–C bonds, which completely rules out the mesomeric effect as a cause of the deviation from additivity. Furthermore, the same deviation is observed also in the reactions of aliphatic compounds, where there are no double bonds.

The inductive effect is transmitted via σ-bonds; we shall consider whether it can be the cause of the deviation from additivity. Analysis of the structures of molecules for which the above reactions have been investigated shows that the polar groups in the molecule are separated from the reacting bond (C–H or C=C) by four, six, eight, or more σ-bonds. The inductive effect is known to decay already in the second or third C–C σ-bond and for this reason cannot play any role in all the examples quoted above. It affects only the influence of the polar group nearest to the reaction centre and the appearance of additional groups in the molecule no longer involves their inductive effect.

The steric factor is manifested when a bulky group, in particular, a quaternary carbon atom, is present next to the reaction centre. In the pentaerythritol esters, where the peroxy-radical attacks a C–H bond in the alcohol group, this effect apparently occurs. However, it does not explain the change in the partial rate constant for the reaction involving peroxy-radicals (see the Section about the reactions of $RO_2^{\cdot}$ with esters), since, firstly, when the ester group is replaced by an alkyl group in such esters the steric effect is retained, secondly, on passing from a diester to a tetraester, the rate constant increases (Table 2), while the steric effect should reduce it, and, thirdly, in the reactions of $RO_2^{\cdot}$ with dicarboxylic acid esters and with polyhydric alcohols (Tables 3, 4, and 6) there is no steric hindrance to attack and yet the deviation from additivity does occur.

Thus the three effects examined above do not explain the deviations of the partial rate constants from additivity, which are frequently encountered experimentally. The most probable and possibly the only cause is the effect of the electrostatic interaction of the polar groups in the molecule and the influence of the field which they generate on the transition state. The point is that, in all the examples examined, the molecule containing functional groups is either attacked by polar species ($RO_2^{\cdot}$, ROOH) or forms a polar transition state, as in the reactions involving oxygen. Evidently the attack of a polar species on a polyfunctional molecule is accompanied by an electrostatic interaction, whose energy depends on the dipole moments and the disposition of these groups.

These simple considerations were used as the basis for the concept of the multidipolar interaction in the reactions of polyfunctional compounds.[6] From the standpoint of electrostatic interactions, a polyfunctional molecule constitutes a multidipole, i.e. a set of interacting dipoles. We shall consider such a molecule, containing n functional groups, as a set of interacting dipoles with dipole moments μ_1, μ_2, ..., μ_n. These dipoles rotate as a result of the rotation of the molecular fragments, but they cannot assume any arbitrary mutual orientation, because their rotation is limited by the condition that the valence angles and the internuclear distances in the molecule remain constant.

Thus a polyfunctional molecule considered in this way consists of a semirigid skeleton made up of atoms in which groups (dipoles) having a limited mobility are located at specific sites. If the polar groups are separated by several C–C bonds (two and more), then the distance between the centres of the dipoles will exceed the length of each group (dipole). The energy of the interaction of such dipoles can be described with an adequate approximation by the formula for the interaction of two point dipoles:[28]

$$U_{ij}\ (\text{kJ mol}^{-1}) = 60\,(\mu_i\mu_j N_A/\varepsilon r_{ij}^3)\,[\sin\theta_i \sin\theta_j \cos(\varphi_j - \varphi_i) - 2\cos\theta_i \cos\theta_j] \quad (1)$$

where N_A is the Avogadro number, ε the dielectric constant of the medium, θ_i and θ_j are the angles of inclination of the polar axes of the dipoles i and j relative to the line connecting their centres, and ϕ_i and ϕ_j are the angles between the polar axes of the dipoles and the perpendicular lines drawn through their centres; μ is expressed in Debyes (D) and r in Ångstroms (Å). The energy of the interaction at the dipoles is correspondingly equal to the sum of the energies of the pair interactions ($i \neq j$):

$$U_n = \frac{1}{2}\sum_i \sum_j U_{ij} \ . \quad (2)$$

In order to estimate the value which the energy of such an interaction can assume, we shall consider several examples. Suppose that $\varepsilon = 1$, that all the dipolar groups have a dipole moment of 2 D, and that all the r_{ij} are also equal.

(1) If $n = 2$ and $r = 3$ Å, then $U_{\min} = -18$ kJ mol^{-1} and $U_{\max} = 18$ kJ mol^{-1}.

(2) If $n = 2$ and $r = 4$ Å, then $U_{\max} = 7.5$ kJ mol^{-1}.

(3) If $n = 3$, $r = 4$ Å, and the dipoles are located at the vertices of a triangle, then $U_{\max} = 20$ kJ mol^{-1}.

(4) If $n = 4$, $r = 4$ Å, and the dipoles are located at the vertices of a square, then $U_{\max} = 28$ kJ mol^{-1}.

The activation energy for radical abstraction reactions varies in most cases in the range from 10 to 60 kJ mol^{-1}. Consequently the energy of the dipole–dipole interaction is comparable to the activation energy for radical reactions. When a molecule of this kind is attacked by a species having a dipole moment, a conglomerate consisting of $n + 1$ dipoles arises in the transition state, which also represents a set of point dipoles, the interaction energy of which is described by the expression

$$U_{n+1} = \frac{1}{2}\sum_i^{n+1} \sum_j^{n+1} U_{ij} \ . \quad (3)$$

The contribution of the multidipolar interaction to the Gibbs free energy of activation is

$$\Delta G_\mu^{\neq} = N_A\,(U_{n+1} - U_n) \ . \quad (4)$$

If the mutual orientations of the polar groups of the molecules and the distances between them are similar in the initial and transition states, we obtain

$$\Delta G_\mu^{\neq} = \frac{N_A \mu^*}{\varepsilon} \sum_i^n \frac{\mu_i}{r_i^3} f(\theta^*, \theta_i, \varphi^*, \varphi_i) \ , \quad (5)$$

where the asterisk refers to the polar group of the attacking species. The component of the Gibbs free energy of activation $\Delta G_\mu^{\neq}$, due solely to the dipole–dipole interaction, is defined by the simple relation[29]

$$\Delta G_\mu^{\neq} = RT \ln(k_0/k) \ . \quad (6)$$

The difference between the energies of the multidipolar interaction in the transition state and in the initial molecule may be both positive and negative. A monofunctional compound can be used as a reference. In this case k_0 already takes into account the dipole–dipole interaction and the formula $\Delta G_\mu^{\neq} = RT \ln(k_0/k)$ reflects the influence of the multidipolar interaction after the subtraction of the interaction of the attacking species with the field of the attacked reaction centre (the dipole–dipole pair interaction).

The relation between $\Delta G_\mu^{\neq}$ and the experimental activation energy E and the experimental pre-exponential factor A can be found in the following way. Since $E = RT^2 \mathrm{d}\ln k/\mathrm{d}T$ and $\ln k = \ln k_0 - \Delta G_\mu^{\neq}/RT$, we obtain

$$E = E_0 + \Delta G_\mu^{\neq} - T\mathrm{d}\Delta G_\mu^{\neq}/\mathrm{d}T \ . \quad (7)$$

The temperature dependence of E is due to two factors. Firstly, $\Delta G_\mu^{\neq} = \Delta G_{\mu 1}^{\neq}/\varepsilon$; the dielectric constant ε varies with temperature in accordance with the exponential function

$$\varepsilon = \varepsilon_0 e^{-L_\varepsilon T} \ .$$

Secondly, the extent of the rotation of the molecular fragments and the amplitude of the deformation vibrations of the bonds increase with increase of temperature. The mutual orientation of the dipoles is correspondingly averaged out and $\Delta G_{\mu 1}^{\neq}$ diminishes.

If the molecule is regarded as a microdielectric, one can assume that $\Delta G_{\mu 1}^{\neq}$ is related to temperature (like ε) in the following way:

$$\mathrm{d}\ln \Delta G_{\mu 1}^{\neq}/\mathrm{d}T = -L_G \ .$$

After substitution of the expressions for $\Delta G_\mu^{\neq}$ in Eqn.(7) and differentiation, we obtain

$$E = E_0 + \Delta G_\mu^{\neq} + T(L_G - L_\varepsilon)\Delta G_\mu^{\neq} \ .$$

Since the entropy is linked to the Gibbs free energy by the relation $\Delta S = -\mathrm{d}\Delta G/\mathrm{d}T$, we obtain for the change in the activation entropy as a result of the multidipolar interaction

$$\Delta S_\mu^{\neq} = -\mathrm{d}\Delta G_\mu^{\neq}/\mathrm{d}T = (L_G - L_\varepsilon)\Delta G_\mu^{\neq} \ . \quad (8)$$

On the other hand, $\Delta S_\mu^{\neq}$ can be estimated from the pre-exponential factor: since $\Delta S^{\neq} = R \ln A + \text{const.}$, we obtain

$$\Delta S_\mu^{\neq} = R \ln(A/A_0) \ . \quad (9)$$

Using Eqns.(7)–(9), we have

$$\Delta G_\mu^{\neq} = \frac{E - E_0}{1 + \ln(A/A_0)/\ln(k_0/k)} \ , \quad (10)$$

$$L_G = L_\varepsilon + T^{-1}[\ln(A/A_0)/\ln(k_0/k)] \ . \quad (11)$$

The conclusions which follow from the model of the multidipolar transition state examined above are compared with the experimental data in the next Section.

The influence of polar groups on the energy of the transition state partly resembles solvation, but there are two significant differences. Firstly, solvent molecules approach closely the polar transition state (reaction centre) and surround it, whereas the polar groups of the polyfunctional molecule exert their influence via a field over a certain distance. Secondly, the molecules solvating the polar group (including the reaction centre) are oriented in the energetically most favourable manner, whereas the orientation of the groups in a polyfunctional molecule is restricted by the specific disposition of the atoms and groups in it.

The dipole–dipole interaction can also exert a more profound influence on the transition state, apart from establishing a specific electrostatic potential. If readily polarisable bonds (π-bonds, atoms with p and d electrons), which are polarised in the transition state, participate in the reaction, then the polar groups in the molecule can influence the polarisation of the transition state, which can lead to an intensification of the effect of the multidipolar interaction and to a greater deviation from additivity. Finally, in those cases where the reaction proceeds with electron transfer and in the transition state a neutral species is converted into an ion (ion pair), the result should be a stronger and longer-range ($U \propto r^{-2}$ instead of $U \propto r^{-3}$) ion–dipole interaction and correspondingly a higher value of $|\Delta G_{\mu}^{\neq}|$.

VI. ANALYSIS OF EXPERIMENTAL DATA WITHIN THE FRAMEWORK OF THE CONCEPT OF THE MULTIDIPOLAR INTERACTION IN THE TRANSITION STATE

It follows from the model of a polyfunctional molecule as a system of interacting groups (dipoles) that, in those cases where such a molecule is attacked by a non-polar species, the ion–dipole interaction potentials in the molecule and in the activated complex are the same or very similar, so that the rule of the additivity of the partial rate constants should hold. As we have seen, the rule breaks down for the reactions of $RO_2^{\cdot}$ with a series of esters of pentaerythritol and its analogues (Table 2).

The rate constants for the reactions of trichloromethyl radicals with these esters have been measured.[30] The reactions were investigated in CCl_4 at 373 K using benzoyl peroxide as the initiator. It was continued until the consumption of the peroxide was complete. The amounts of chloroform and hexachloroethane formed were determined by gas–liquid chromatography. The reactions taking place in the initiator (I)–ester (RH)–CCl_4 system are described by the following scheme:

$$I \xrightarrow{k_d} \dot{r} + \dot{r} \xrightarrow{k_t} 2\dot{r}\,,$$
$$\dot{r} + CCl_4 \rightarrow rCl + \dot{C}Cl_3\,,$$
$$\dot{C}Cl_3 + RH \xrightarrow{k_p} CCl_3H + \dot{R}\,,$$
$$\dot{R} + CCl_4 \rightarrow RCl + \dot{C}Cl_3\,,$$
$$\dot{C}Cl_3 + \dot{C}Cl_3 \xrightarrow{k_t} C_2Cl_6\,.$$

According to this scheme, the amount of hexachloroethane formed at the end of the experiment corresponds to the amount of free radicals produced on decomposition of benzoyl peroxide. The reaction has a chain mechanism and the average chain length varies from 3 to 40 units. The rate constant ratio $k_p(2k_t)^{-1/2}$ was determined from the amount of $CHCl_3$ formed. The absolute value of k_p was calculated on the assumption that $2k_t = 3.1 \times 10^9$ litre mol^{-1} s^{-1}.[31] The experimental conditions and the values of $k_p(2k_t)^{-1/2}$ and k_p are listed in Table 9. The results make it possible to calculate and compare the partial rate constants for the reactions of dichloromethyl radicals with the $-CH_2OCOCH_2CH_3$ fragment for different numbers of ester groups in the molecule.

It is seen from the data in Table 9 that the k_p calculated per fragment are close for all three propionates regardless of the number of ester fragments in the molecule. Thus, to a first approximation, the rule of additivity holds for the reactions of trichloromethyl radicals with polyfunctional esters. The trichloromethyl radical is an electrophilic species, like the peroxy-radical. When the inductive effect is a possible cause of the deviation from additivity, such deviation would therefore have been observed also for the $\dot{C}Cl_3$ radicals, as happens for peroxy-radicals. The validity of the rule of additivity for radicals in the case of $\dot{C}Cl_3$ demonstrates that in this instance the inductive effect does not play a significant role. The transition state in the case where a C–H bond is attacked by $\dot{C}Cl_3$ apparently has a low dipole moment, which does not exceed 0.5 D. The energy of the interaction of the ester groups in such a dipole is low and its effect on k_p is within the limits of the accuracy of the measurement (for comparison, we may recall that the dipole moment of the peroxy-radical is ~2 D). An analogous result has been obtained for the reactions of non-polar undecyl radicals with monoesters and polyesters[11] (Table 10). The reactivity of the esters has been investigated by the method of competing reactions:

$$C_{11}H_{23}^{\cdot} + RH \xrightarrow{k_1} C_{11}H_{24} + R^{\cdot}\,,$$
$$C_{11}H_{23}^{\cdot} + O_2 \xrightarrow{k_2} C_{11}H_{23}OO^{\cdot}\,.$$

Table 9. The rate constants for the reactions of trichloromethyl radicals with esters (373 K, CCl_4).[30]

Ester	$10^3 k_p(2k_t)^{-1/2}$, litre$^{1/2}$mol$^{-1/2}$s$^{-1/2}$	k_p, litre mol^{-1}s^{-1}	k_p/n, litre mol^{-1}s^{-1}
$C(CH_2OCOCH_2CH_3)_4$	2.8±0.1	160	40
$C[CH_2OCO(CH_2)_8CH_3]_4$	22.3±0.4	1250	—
$(CH_3)_2C(CH_2OCOCH_3)_2$	1.8±0.1	100	50
$CH_3CH_2C(CH_2OCOCH_2CH_3)_3$	3.1±0.5	170	43

The source of undecyl radicals was dilauryl peroxide, which was decomposed in chlorobenzene in the presence of the ester RH in an atmosphere of oxygen. The intensity of the first reaction was inferred from the yield of undecane relative to the decomposed peroxide. Table 10 shows that the relative rate constants for the reactions of the alkyl radical with the esters calculated per group differ by not more than 15%.

Table 10. The rate constants for the reactions of undecyl radicals with esters (373 K, C_6H_5Cl).[11]

Ester	$10^4 (k_1/k_2)$	$10^4 (k_1/nk_2)$
$CH_3(CH_2)_4COOCH_3$	1.1	1.1
$CH_3OCO(CH_2)_8COOCH_3$	1.8	0.9
$CH_3(CH_2)_4COOCH(CH_3)_2$	1.2	1.2
$(CH_3)_2CHOCO(CH_2)_8COOCH(CH_3)_2$	2.2	1.1
$CH_3(CH_2)_3COOCH_2CH_3$	1.3	1.3
$[CH_3(CH_2)_3COOCH_2]_4C$	6.8	1.7

The deviation of the partial rate constants from additivity is thus observed only in those cases where the molecule is attacked by polar species ($RO_2^{\cdot}$, ROOH) or when a polar transition state is formed (in reactions with O_2). It follows from Eqn.(4) that the component $\Delta G_{\mu}^{\neq}$ due to the dipole–dipole interaction can be both positive when $U_{n+1} > U_n$ and negative when $U_{n+1} < U_n$, i.e. the deviations from additivity can be both towards a decrease and an increase of the reaction rate constant compared with the sum of the partial rate

constants. Indeed both cases have been observed experimentally (Table 11), but there are more examples with $\Delta G_{\mu}^{\neq} > 0$.

Table 11. The sign of the multidipolar effect ($\Delta G_{\mu}^{\neq}$) in various radical reactions.

Radical*	Molecule	Sign
$C_6H_5(CH_3)_2COO^{\cdot}$	$ROCO(CH_2)_nCOOR$	+
$C_6H_5(CH_3)_2COO^{\cdot}$	$ROCO(CH_2)_2COOR$	+
$C_6H_5(CH_3)_2COO^{\cdot}$	$ROCO(CH_2)_2O(CH_2)_2COOR$	+
$C_6H_5(CH_3)_2COO^{\cdot}$	$(CH_3)_{4-n}C(CH_2OCOCH_2CH_3)_{n-4}$	−
$C_{16}H_{35}OO^{\cdot}$	$HOCH_2(CH_2)_nCH_2OH$	+
$C_{16}H_{35}OO^{\cdot}$	$R_{4-n}C(CH_2OH)_n$	−
$RO_2^{\cdot}$	$HOCH_2(CH_2)_nCH_2OH$	+
$RO_2^{\cdot}$	$R_{4-n}C(CH_2OH)_n$	−
$C_6H_5(CH_3)_2COO^{\cdot}$	$R_{4-n}C[CH_2OCOC(CH_3)=CH_2]_n$	+
O_2	$C[CH_2OCOC(CH_3)=CH_2]_4$	+
$C_6H_5(CH_3)_2COOH$	$C[CH_2OCOHC=CH_2]_4$	+

*Here $RO_2^{\cdot}$ is the radical derived from diethylene glycol dicaprylate.

It follows from Eqns.(4) and (5) that $\Delta G_{\mu}^{\neq}$ is lower the further is the reaction centre from the polar groups. This conclusion has been tested in relation to the reactions of $RO_2^{\cdot}$ with pentaerythritol esters.[14] In the molecule of such an ester the radical $RO_2^{\cdot}$ attacks both the C–H bonds of the alcohol residue, located near the ester groups, and the C–H bonds of the acid residue. The greater the number of CH_2 groups in the acid residue, the greater the contribution of the CH_2 groups remote from the polar ester groups to the overall reaction rate constant. With increase of the number of methylene groups in the acid residue of the ester, the rate constant calculated per CH_2 group should therefore appraoch that of an n-paraffin, which has in fact been confirmed by experimental data:[14] $k_{CH_2} = 1.4$ litre mol^{-1} s^{-1} (407 K) for pentaerythritol tetrapropionate, 2.7 litre mol^{-1} s^{-1} for pentaerythritol tetracaprate, and 2.8 litre mol^{-1} s^{-1} for n-heptadecane. It is seen that, with increase in the number of CH_2 groups, the deviation from additivity diminishes as the distances of the attacked group from the dipolar groups are increased.

Table 12. The parameters* of the multidipolar interaction in the reactions of cumenylperoxy-radicals with the esters of mono- and di-carboxylic acids.[4]

Ester	k (413 K)	$\Sigma k_{pl}^{\prime\prime}$	$\Delta G_{\mu}^{\neq}$, from Eqn.(6)	E	lg A	$\Delta G_{\mu}^{\neq}$, from Eqn.(10)	$\Delta S_{\mu}^{\neq}$	L_G
$CH_3CH_2COOCH_3$	92	—	—	29	5.63	—	—	—
$CH_2(CH_2COOCH_3)_2$	7.2	185	11.1	69	9.58	11.8	76	9.3
$CH_3CH_2COOC_2H_5$	18	—	—	37	5.93	—	—	—
$CH_2(CH_2COOC_2H_5)_2$	7.0	37	5.6	69	9.57	6.0	70	14.4
$CH_3CH_2COOC(CH_3)_3$	8.9	—	—	53	7.65	—	—	—
$CH_2[CH_2COOC(CH_3)_3]_2$	2.6	185	6.6	73	9.65	5.7	38	9.6

*k and A are expressed in litre mol^{-1} s^{-1}, E and $\Delta G_{\mu}^{\neq}$ in kJ mol^{-1}, and $\Delta S_{\mu}^{\neq}$ in J mol^{-1} K^{-1}.

Table 12 presents the values of E and lg A for the reactions of peroxy-radicals with monoesters and polyfunctional esters. In all the cases quoted, the compensation effect is observed: with increase of the activation energy, the pre-exponential factor also increases. The concept of the multidipolar interaction explains this effect; within its framework, the effect is characterised by the coefficient L_G [see Eqns.(7)–(11)]. The physical significance of this compensation consists in the fact that, owing to the intensification of the torsional and deformation vibrations of the groups in the molecule as the temperature rises, the value of $|\Delta G_{\mu}^{\neq}|$ decreases.

Table 12 shows that the $\Delta G_{\mu}^{\neq}$ obtained by two different methods agree satisfactorily. Since the manifestation of the effect of the multidipolar interaction requires as an obligatory condition that one of the reactants should contain several polar groups, it follows that the effect should also appear when a radical containing several polar groups interacts with the polar molecule. Data of this kind have been obtained in the studh of the kinetics of the oxidation of mono- and tetra-functional unsaturated esters in the presence of ionol as the inhibitor. The rate constant for the reaction of peroxy-radicals with ionol was calculated from the experimental data (Table 13). They show that the peroxy-radical containing four ester groups attacks ionol ~4 times more slowly than one having a single ester group; $\Delta G_{\mu}^{\neq} \cong 4$ kJ mol^{-1}. The fact that in this instance the above difference is caused by the dipole–dipole interaction has been confirmed by experiments on the coupled oxidation of the same esters with cumene, from which the rate constants for the reactions of the same peroxy-radicals with the weakly polar cumene were obtained ($\mu = 0.4$ D for cumene and 1.6 D for ionol). The data in Table 13 show that the rate constants for the reactions of the above radicals with the non-polar cumene are very similar.

Table 13. The rate constants for the reactions of mono- and poly-functional peroxy-radicals of monomers with ionol (k_2, 323 K) and cumene (k_1, 343 K).

Monomer	k_1, litre $mol^{-1}s^{-1}$	k_2, litre $mol^{-1}s^{-1}$	$\Delta G_{\mu}^{\neq}$, kJ mol^{-1}
$CH_3OCOHC=CH_2$	1.2	$8.1\cdot10^3$	—
$(H_2C=CHCOOCH_2)_4C$	1.0	$1.9\cdot10^3$	4.1
$CH_3OCO(CH_3)C=CH_2$	0.7	$3.8\cdot10^3$	—
$[H_2C=C(CH_3)COOCH_2]_4C$	0.8	$1.1\cdot10^3$	3.5

The important factor is the heat of reaction, on which depends not only the activation energy but also the configuration of the activated complex. According to Hammond's postulate,[2] the configuration is closer to that of the reaction products the more endothermic the reaction. In its turn, the higher the heat of reaction, then, other conditions being equal, the weaker the reflection of the structural factors in the reaction rate constant. We shall consider how this tendency is manifested in the reactions of polyfunctional molecules. The comparison can be carried out for peroxy-radicals, hydroperoxide, and oxygen in their reactions with unsaturated compounds. The dipole moments of $RO_2^{\cdot}$ and ROOH are similar and oxygen, having added to the double bond, also produces a peroxy-radical. On the other hand, these reactants differ sharply in their reactivities, which can be seen from a comparison of the rate constants for the

above reactions. The reactions and the values of ΔH^0 calculated for them are presented below (on the basis of the data in Kondrat'ev's handbook[7]):

$$CH_3OO^{\cdot} + H_2C{=}CH_2 \rightarrow CH_3OOCH_2CH_2^{\cdot} \quad (\Delta H^0 = -46 \text{ kJ mol}^{-1});$$
$$CH_3OOH + H_2C{=}CH_2 \rightarrow CH_3O^{\cdot} + HOCH_2CH_2^{\cdot} \quad (\Delta H^0 = 30 \text{ kJ mol}^{-1});$$
$$O_2 + H_2C{=}CH_2 \rightarrow {}^{\cdot}OOCH_2CH_2^{\cdot} \quad (\Delta H^0 = 130 \text{ kJ mol}^{-1}).$$

The peroxy-radicals also differ in their reactivities in addition reactions: the $RO_2^{\cdot}$ derived from styrene is much more reactive than the $RO_2^{\cdot}$ derived from acrylates. The rate constants from the values of ΔH^0 and $\Delta G_{\mu}^{\neq}$ in reactions involving addition to the double bond in tetra-acrylate esters are compared below:

Reactant	$RO_2^{\cdot}$(styrene)	$RO_2^{\cdot}$(acrylate)	$C_6H_5(CH_3)_2COOH$	O_2
T, K	323	323	343	343
k, litre mol^{-1}s^{-1}	101	0.8	$2.4\cdot10^{-6}$	$4\cdot10^{-10}$
ΔH^0, kJ mol^{-1}	−46	—	30	130
$\Delta G_{\mu}^{\neq}$, kJ mol^{-1}	0.5	1.2	5.6	13.8

Evidently the effect of the multidipolar interaction is indeed manifested in the above series of reactions to a greater extent the more endothermic the reaction.

We have seen that the energy of the dipole–dipole interaction depends on the dipole moment of the species, their orientation, and the distance between them. For a distance of 4 Å and a dipole moment of 2 D, the absolute differences between the interaction potentials are $|U_{N+1} - U_n|_{max} =$ 12.5 kJ mol^{-1} ($n = 2$) and 8 kJ mol^{-1} ($n = 3$), as shown above. Thus the maximum energy of the multidipolar interaction is ~10 kJ mol^{-1} and $\Delta G_{\mu}^{\neq}$ can vary in the range from 0 to 10 kJ mol^{-1}. The data presented in Tables 4, 6, 7, 8, 12, and 13 show that the $\Delta\Delta G_{ad}^{\neq}$ do not as a rule exceed 10 kJ mol^{-1} and in most cases are in the range from 2 to 4 kJ mol^{-1}. There is only one exception: the data for the reactions of oxygen with esters of mono- and di-carboxylic acids (Table 8), where $\Delta\Delta G_{ad}^{\neq} = 25$ kJ mol^{-1}. This enormous difference between the rate constants is clearly outside the framework of the effect of the multidipolar interaction and its cause remains obscure.

For the reactions of unsaturated compounds with oxygen (Table 8) and a hydroperoxide, the $\Delta\Delta G_{ad}^{\neq}$ (7 and 5 kJ mol^{-1}) are apparently higher than the $\Delta G_{\mu}^{\neq}$ determined solely by the interaction of these groups as rigid dipoles (in these reactions the distance of the reaction centre from the ester groups is 5–6 Å and the energy of the dipole–dipole interaction is in this instance 2–3 kJ mol^{-1}). However, only a readily polarisable π-bond is involved in the above reaction; the polarisation of this bond contributes to $\Delta G^{\neq}$ and the observed $\Delta\Delta G_{ad}^{\neq}$ apparently includes both the energy of the electrostatic interaction of the dipolar groups and the difference between the polarisations of the reacting bond under the influence of the polar groups in mono- and poly-functional esters. One cannot rule out also a longer-range ion–dipole interaction when the reactions take place with electron transfer via the activated complexes $O_2^{\ddot{-}}...\dot{C}H_2{-}\overset{+}{C}OOR$ and $ROOH^{\ddot{-}}...\dot{C}H_2{-}\overset{+}{C}OOR$.

---o0o---

Thus the extensive experimental data for the reactions of $RO_2^{\cdot}$, ROOH, and O_2 with saturated and unsaturated polyesters as well as the reaction of the polyfunctional radical $RO_2^{\cdot}$ with ionol show convincingly that the deviations from additivity are in almost all cases a consequence of the electrostatic interaction of the polar groups as a set of dipoles. In the case of unsaturated compounds this effect is enhanced by the influence of the polar groups on the polarisation of the π-bonds in the transition state.

As shown above, the effect of the multidipolar interaction is characteristic of the reactions of polyfunctional compounds and apparently plays an important role in the reactions of polymers containing functional groups and biopolymers.

Activation of Molecular Oxygen by Metal Complexes and Its Role in the Mechanism of Liquid Phase Oxidation

I.P.Skibida

Problems of the involvement of molecular complexes of oxygen with variable-valence metal compounds in the liquid-phase oxidation of organic compounds, including the chain initiation reactions in radical chain oxidation, via the interaction of such complexes with the hydrocarbon are considered. The possibility of the operation of mechanisms resembling those of enzymic oxidation is analysed. Despite the lack in many instances of unambiguous evidence for the occurrence of the oxidation reaction via a mono- or di-oxygenase mechanism, one can assume that the reaction conditions and mechanisms in many chemical systems are close to those in biological systems.

I. INTRODUCTION

The catalytic oxidation reactions of organic substances in the liquid phase constitute one of the commonest types of chemical reactions. The study of their mechanisms is important both for the creation of new selective processes in chemical technology and for the understanding of many biochemical processes.

The liquid-phase catalytic oxidation reactions of organic substances in the presence of the majority of variable-valence metal compounds proceed via a radical chain mechanism.[1-3] The catalyst can then participate in all the elementary oxidation stages—chain branching, chain propagation, and chain termination. The acceleration of the catalytic reaction compared with the non-catalytic reaction is associated mainly with the increase of the rate of chain branching as a result of the radical decomposition of hydroperoxides by variable-valence metal compounds.[4]

When the oxidation reaction has a radical chain mechanism, the introduction of homogeneous or heterogeneous catalysts can influence the selectivity of the oxidation through interaction of the catalyst with free radicals, which in many instances alters both the rate and the composition of the chain propagation reaction products.

The ratio of the oxidation products can also vary owing to alteration of the chain length. Since an increase of free radical formation rate in the presence of the catalyst entails a decrease of the oxidation chain length, the free radical recombination products accumulate in large amounts in these oxidation reaction mixtures.[5]

The use of metal complexes as oxidation catalysts, which have a fairly pronounced peroxidase function, is usually complicated by the rapid oxidation of the ligand by peroxides or free peroxy-radicals,[6-8] which leads to the replacement of the ligand in the early stages of the oxidation process and hence can alter the oxidation reaction pathway in the course of the reaction.

Evidently the involvement of active free radicals in catalytic liquid-phase oxidation reactions cannot ensure a sufficiently high process selectivity because of the high reactivity, which leads to a large number of different reactions of the starting materials and the intermediates.

Nevertheless, in the words of Academician N.M.Emanuel', "the problem of the effective employment of natural raw materials is of prime importance in the chemistry of our time. The high selectivity and rate of a chemical reaction accompanied by small energy expenditures and in apparatus of minimal size have become the principal criteria of the likely usefulness of the chemical process from the practical point of view".[5]

From the standpoint of the increased selectivity of the oxidation reactions, the creation of conditions ensuring the direct insertion of oxygen in a C–H bond of the molecule of the organic substance with formation of alcohols, hydroperoxides, and other oxygen-containing compounds would be most promising.

In the absence of a catalyst, oxygen, which exists in a triplet ground state, is incapable of reacting with substrates in the singlet state because such a process infringes the spin conservation rule. The formation of molecular complexes of oxygen with variable-valence metal compounds removes the spin restriction and the direct reaction of oxygen with the substrate accompanied by the formation of hydroperoxides,

$$RH+O_2 \rightarrow ROOH$$

or alcohols,

$$RH_2+O_2+DH_2 \rightarrow HROH+H_2O+D \quad , \qquad (1)$$

where DH_2 is a cofactor (or cosubstrate), which serves as the reducing agent, becomes possible, in principle, in this system.

The problem of the activation of molecular oxygen by variable-valence metal complexes has been the subject during the last decade of numerous investigations devoted to various aspects of the structure of such complexes,[9,10] their reactivity, and the mechanism of their interaction with substrates undergoing oxidation.[11-15]

Variable-valence metal compounds readily interact in many instances with molecular oxygen, forming adducts in which oxygen is present in the form of the superoxide ion O_2^- or the peroxide ion O_2^{2-}. The peroxo-complexes can in their turn contain either one metal atom (when the metal can serve as a donor of two electrons, $M\begin{smallmatrix}O\\|\\O\end{smallmatrix}$) or two metal atoms (for metals which undergo a change in valence only by unity, the μ-peroxo-complexes M–O–O–M). Metal oxo-complexes (M=O) and μ-oxo-complexes (M–O–M), containing one oxygen atom, can also be formed. However, such complexes

are as a rule inactive in oxygen transfer processes. From the standpoint of their employment as oxidants, transition metal peroxo- and super-oxo-complexes of oxygen are the most promising.

II. INITIATION OF OXIDATION CHAINS BY VARIABLE-VALENCE METAL SUPEROXO-COMPLEXES

Despite the large number of studies which have been made on the mechanisms of the activation of molecular oxygen, it is at present fairly difficult to relate the mechanism of the oxidation of organic substances in the presence of complexes of molecular oxygen with the catalyst to the structure of such complexes. It has been suggested that paramagnetic mononuclear complexes of the type $M...O_2^-$ (superoxo-complexes) can serve as electron transfer agents:[16,17]

$$RH_2 + M \cdots O_2^- \rightarrow M \cdots O_2^{2-} + RH_2^+$$

or can participate in the radical substitution reaction[15]

$$RH_2 + M \cdots O_2^- \rightarrow M \cdots HO_2^- + RH^\cdot \qquad (2)$$

and can thus ensure the initiation of radical chain reactions.

The reactions of O_2^- coordinated in the titanium(IV) coordination sphere to various organic substrates have been investigated by EPR using a flow technique.[17] Although the authors did in fact observe that only compounds with comparatively weak C–H, N–H, or O–H bonds, such as *p*-toluidine, *p*-aminophenol, and 3,5-dihydroxybenzaldehyde, react with the complex $Ti(IV).O_2^-$, a direct relation between the rate of reaction and the bond dissociation energy apparently does not exist. Thus the dissociation energy of the C–H bond in toluene is approximately equal to the O–H bond energy in phenol, while the C–H bond energy in benzaldehyde is significantly lower. Nevertheless, only phenol is oxidised in the process of $Ti(IV).O_2^-$.

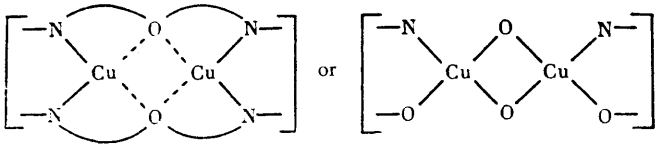
At the same time, a satisfactory quantitative correlation has been observed between the reaction rate constant and the ionisation potential of the substrate. The results obtained made it possible to suggest that at least in aqueous solutions at room temperature the rates of the radical substitution reactions (2) of the complexes $Ti(IV).O_2^-$ [17] and $Zr(IV).O_2^-$ [18] are negligibly low compared with the rate of electron transfer with formation of the coordinated dianion $Ti(IV).O^{2-}$ and the radical-cation of the substance being oxidised:

$$Ti(IV) \cdot O_2^- + RH_2 \rightarrow Ti(IV) \cdot O_2^{2-} + RH_2^+ .$$

The rate constants for the interaction of the complex $Zr(IV).O_2^-$ with amines and phenols are close to the corresponding constants for the complex $Ti(IV).O_2^-$.[18]

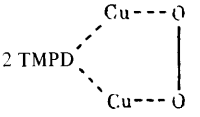
The oxidation of *NNN'N'*-tetramethyl-*p*-phenylenediamine (TMPD) by oxygen in the presence of square planar complexes of bivalent cobalt, such as the cobalt complexes of Schiff bases (CoL_2), leads to the formation of a coloured compound, whose electronic spectrum is the same as that of the complex $[Cl(L)_2TMPD^+]$.[16] Electron transfer takes place only in the joint presence in the solution of TMPD, O_2, and $Co(L)_2$, which suggests that the reaction proceeds in a ternary complex via a concerted mechanism.

Dinuclear copper complexes with chelate units



in which the distance between the copper atoms is not less than 3–3.5 Å, exhibit a high catalytic activity in the oxidation of TMPD by molecular oxygen.[19] The catalytic activity of these complexes is determined by their reduction potential: the more positive the reduction potential, the higher the activity of the catalyst.

Increasing the distance between the copper atoms above 3.5 Å causes the catalytic activity of the complex to fall rapidly. The maximum initial rate of oxidation is attained for the ratio [TMPD] : [catalyst] = 2 : 1. It has been suggested that the oxidation proceeds with two-electron reduction of oxygen to O_2^{2-} via an intermediate stage in which is produced the complex



The transfer of two electrons in such a complex can occur in one stage via a concerted mechanism.[19]

Despite the fact that at room temperature in aqueous solutions[17] the rate of electron transfer is probably significantly higher than the rate of the radical substitution reaction (2), chain initiation via reaction (2) can take place at least in the presence of certain copper, nickel, and coblat complexes.

The problem of demonstrating the involvement of complexes of molecular oxygen with variable-valence metal compounds in the oxidation chain initiation stage in many cases cannot be solved unambiguously primarily because almost all variable-valence metal compounds can decompose hydroperoxides into free radicals at rates greatly exceeding the rate of formation of radicals via reaction (2), which creates considerable difficulties for the identification of reaction (2) against the background of chain branching even in the presence of traces of hydroperoxides and imposes particularly stringent requirements on the degree of elimination of traces of hydroperoxides from hydrocarbons. In order to reach clear-cut conclusions about the role of reaction (2) in the oxidation process, it is necessary to carry out a quantitative comparison of the observed rates of oxidation with the rates which can be ensured by chain branching in the presence of the catalyst.

In addition, there are virtually no unambiguous methods whereby one could demonstrate a non-radical reaction pathway. The method of inhibitors widely employed in non-catalytic oxidation frequently fails to yield information in the presence of catalysts because, on the one hand, inhibitors (phenols or aromatic amines) can behave as promoting agents, or catalytic poisons, forming complexes with the catalyst, and, on the other hand, for sufficiently high rates of chain initiation, large concentrations of the inhibitor must be introduced into the reaction in order to obtain effects beyond experimental error, which can lead to its intense oxidation by oxygen. Thus, when the method of inhibitors is used to investigate the mechanism of catalytic oxidation, in each individual case it is necessary to have evidence that the inhibitor reacts in the given catalytic system only with the free radicals (i.e. that the introduction of the inhibitor does not alter the structure of the metal compound and that the rate of consumption of the inhibitor is independent of its initial concentration).

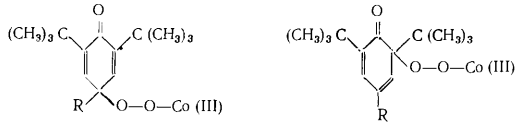
The occurrence of reaction (2) in the oxidation of α-methylstyrene in the presence of the copper complex of α-phthalocyanine has been postulated[20,21] on the grounds that the copper complex of α-phthalocyanine can be an active catalyst of the oxidation of α-methylstyrene, although it does not in

fact accelerate to any appreciable extent the degree of decomposition of the peroxide formed in this process.

Kinetic evidence for reaction (2) has been obtained in the study of the oxidation of styrene in the presence of cobalt stearate, which is also inactive in the decomposition of the polyperoxide formed.[22]

The complex of vitamin B_{12} and O_2 [a mononuclear paramagnetic cobalt(II) superoxo-complex[9]] can interact with hydroquinone and ascorbic acid to form free radicals from the substrate.[23]

Direct evidence for the occurrence of reaction (2) has been obtained by EPR in the oxidation of 2,6-di-t-butyl-4-R-phenols in the presence of bivalent cobalt complexes with Schiff bases (CoL_2).[24] It has been shown that the concentration of the superoxo-complexes, formed in the interaction of molecular oxygen with CoL_2 and detected by EPR, falls sharply when phenols are added to the solution. Under anaerobic conditions, one can then observe the formation of the corresponding free phenoxy-radicals. In an atmosphere of oxygen the reaction is not catalytic and leads to the formation of quinones:



with insertion of the Co(III)OO group in the *p*-position of the phenol for R = CH_3, C_2H_5, iso-C_3H_7, or t-C_4H_9 or in the *o*-position for R = $C_6H_{11}R'$. The phenoxy-radicals formed in the first stage of the process are apparently reduced by cobalt(II) ions with formation of the corresponding phenoxides, which react further with molecular oxygen at high rates.

The possibility of the involvement of the catalyst in the oxidation chain initiation stage, apparently owing to the preliminary formation of superoxo-complexes, has been demonstrated in relation to the oxidation of ethylbenzene in the presence of nickel bis(acetylacetonate).[25] The rate of chain initiation measured by the method of inhibitors proved to be 4×10^{-7} and 9×10^{-6} mol litre^{-1} s^{-1} in this process at 120 °C and catalyst concentrations of 3×10^{-3} and 2×10^{-2} M respectively. These rates are significantly higher than the rate of chain initiation in the absence of catalysts (1.5×10^{-9} mol litre^{-1} s^{-1}).[26]

Such high rates of formation of free radicals in the catalytic process could not be ensured by the decomposition of hydroperoxides, since nickel bis(acetylacetonate) exhibits only a weak activity in their decomposition reaction. In order to attain the above rates of formation of free radicals, the content of hydroperoxides in the system should have been not less than 0.01 M,[27] while the experimental concentration $[ROOH]_0$ in ethylbenzene at the beginning of the process did not exceed 1×10^{-4} M.

The addition of electron-donating ligands [alkali metal stearates,[28,29] dimethylformamide (DMF), hexamethylphosphoramide, or *N*-methyl-2-pyrrolidinone[30]], which form complexes with nickel bis(acetylacetonate), leads to an appreciable increase (by a factor up to 3) of the rate of formation of free radicals, although the rate of decomposition of hydroperoxides in the presence of electron-donating ligands diminishes.[28] As for the cobalt(II) complexes,[31,32] the coordination of electron-donating ligands apparently increases the equilibrium formation constant of the complex of molecular oxygen with the catalyst and lowers its oxidation-reduction potential, which creates in its turn more favourable conditions for reaction (2).

Free radicals are apparently formed in the interaction of RH_2 with metal superoxo-complexes in the oxidation of ethylbenzene in the presence of copper complexes of *o*-phenanthroline (*o*-phen).[33] The rate of absorption of oxygen (W_{O_2}) in this system depends greatly on the concentration of the dissolved oxygen and is described by the empirical equation

$$W_{O_2} = a(b + c[O_2])^{1/2},$$

where *a*, *b*, and *c* are constants.

The observed rate law agrees qualitatively with the following oxidation mechanism:

$$\mathrm{Cu(II)}(o\text{-phen})_n \xrightarrow{\mathrm{ROOH}} \mathrm{Cu(I)}\,(o\text{-phen})_n,$$

$$\mathrm{Cu(I)}\,(o\text{-phen})_n + O_2 \rightarrow \mathrm{Cu(II)}\,(o\text{ phen})_{n-1}O_2^{\cdot-} + (o\text{-phen}),$$

$$\mathrm{Cu(II)}\,(o\text{-phen})_{n-1}O_2^{\cdot-} + RH_2 \rightarrow HR^{\cdot} + HO_2^{\cdot} + \mathrm{Cu(I)}\,(o\text{ phen})_{n-1},$$

$$HR^{\cdot} + O_2 \rightarrow HRO_2^{\cdot},$$

$$HRO_2^{\cdot} + RH_2 \rightarrow HROOH + HR^{\cdot},$$

$$2HRO_2^{\cdot} \rightarrow \text{chain termination}.$$

The porphyrin complexes of nickel, iron, and manganese can also serve as initiators of the free-radical oxidation reaction.[34-36]

III. THE MONOXYGENASE OXIDATION MECHANISM

The monoxygenase oxidation mechanism is the term which has come to be given to the mechanisms of catalytic reactions with participation of molecular oxygen in which one oxygen atom is consumed in the oxidation of the substrate, while the other is reduced to water. The reaction takes place without the intermediate formation of free radicals in accordance with the overall equation

$$RH_2 + O_2 + DH_2 \rightarrow HROH + D + H_2O.$$

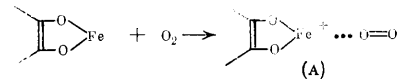
The enzymes catalysing such oxidation reactions have come to be called monoxygenases.

When a cofactor does not participate in the process, i.e. when the reaction proceeds in accordance with the overall equation

$$RH_2 + O_2 \rightarrow R{=}O + H_2O,$$

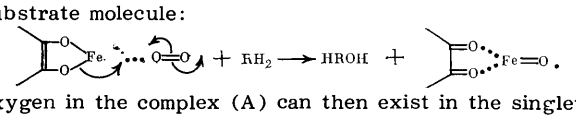
the monoxygenases of this type are referred to as internal monoxygenases.[37]

It has been suggested that in catalysis by monoxygenases oxygen is inserted in the substrate molecule via an intermediate stage involving the formation of oxenoid complexes (by analogy with carbenoid complexes), in which the oxygen atom has six electrons.[38] The hydroxylation of alkanes and aromatic compounds as well as the epoxidation of olefins can proceed via the oxenoid mechanism. For example, in the hydroxylation of substrates in the presence of iron compounds, electron transfer from iron to oxygen could give the intermediate complex (A)



(A)

resulting in the transfer of an oxygen atom with six electrons to a substrate molecule:



The oxygen in the complex (A) can then exist in the singlet form, which facilitates the reaction without the intermediate formation of radical products.

One of the chemical systems whereby it is possible to model the action of monoxygenases is apparently the hydroxylation of aromatic compounds by molecular oxygen in the presence of molybdenum hexacarbonyl $Mo(CO)_6$.[39,40] This reaction is accompanied by the formation in the first macrostage of the process of an arenemolybdenum tricarbonyl in accordance with the scheme

$$Mo(CO)_6 = Mo(CO)_5 + CO,$$
$$Mo(CO)_5 + ArH \rightarrow Mo(CO)_5(ArH),$$
$$(ArH)Mo(CO)_5 \rightleftarrows (ArH)Mo(CO)_4 + CO,$$
$$(ArH)Mo(CO)_4 \rightleftarrows (ArH)Mo(CO)_3 + CO.$$

The formation of the complex $(ArH(Mo(CO)_3$ can be detected by ultraviolet and infrared spectroscopy. The rate-limiting stage in this macrostage of the process is the dissociation of $Mo(CO)_6$ with elimination of one CO molecule, which has been confirmed by the weak dependence of the rate of oxidation on the substrate concentration.

The final reaction products (phenols or naphthols) are formed in the interaction of arenemolybdenum tricarbonyl with oxygen. The rate of this macrostage depends on the oxygen concentration. It has been suggested[39-41] that the rate-limiting stage in the oxidation of arenemolybdenum tricarbonyl is the formation of the intermediate complex $(ArH)Mo(O_2)(CO)_3$. The formation of a ternary complex, in which both reactants (O_2 and the substrate) are coordinated to a zerovalent molybdenum atom, facilitates the insertion of one oxygen atom in the molecule of the aromatic compound:

$$(ArH)Mo(O_2)(CO)_3 \rightarrow ArOH + Mo(O)(CO)_3 .$$

The molybdenum dioxo-complexes $O{=}\overset{\diagup\diagdown}{Mo}{=}O$ can also serve as effective catalysts of the oxidation of many organic substances via a non-radical mechanism.[42-46] Thus the complexes $MoO_2(S_2CNR_2)_2$ can catalyse the oxidation of trialkyl- and triphenyl-phosphines by molecular oxygen with formation of the corresponding oxides. In the absence of oxygen, the reaction is stoichiometric and leads to the formation of the inactive complex $Mo_2O_3(S_2CNR_2)_4$:

$$MoO_2(S_2CNR_2)_2 + PR_3 \rightarrow MoO(S_2CNR_2)_2 + R_3PO,$$
$$MoO_2(S_2CNR_2)_2 + MoO(S_2CNR_2)_2 \rightarrow Mo_2O_3(S_2CNR_2)_4 .$$

In the presence of oxygen, the oxidation of tertiary phosphines becomes catalytic owing to the regeneration of the dioxo-complex on interaction of oxygen with $Mo_2O_3 \cdot (S_2CNR_2)_4$:[47]

$$Mo_2O_3(S_2CNR_2)_4 + O_2 \rightarrow Mo_2O_3(O_2)(S_2CNR_2)_4,$$
$$Mo_2O_3(S_2CNR_2)_4 + Mo_2O_3(O_2)(S_2CNR_2)_4 \rightarrow 4MoO_2(S_2CNR_2)_2 .$$

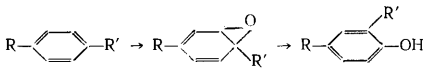
Reactions involving oxidation by molecular oxygen using cytochrome P-450 as the catalyst have attracted much attention because cytochrome P-450 forms part of the composition of microsomal oxidative systems.[37]

The cytochrome P-450 structure has been investigated by various methods and can now be regarded as fairly reliably established.[48-50] The iron atom in the complex is surrounded by four nitrogen atoms in equatorial positions; the axial ligands consist of cysteinyl sulphur and histidine.

It has been suggested that catalysis by porphyrins, metal complexes of azaporphyrins, and cytochrome P-450 ensures the development of the process via a non-radical pathway. In model systems cytochrome P-450 exhibits mainly a hydroxylating capacity, i.e. behaves similarly to monoxygenases, catalysing the incorporation of one oxygen atom in the substrate molecule.

Apart from the hydroxylation of aromatic and paraffinic hydrocarbons, the commonest reactions with participation of cytochrome P-450 as the catalyst involve the dealkylation of *S*-, *N*-, and *O*-substituted compounds.[37]

One of the most significant pieces of evidence showing that cytochrome P-450 catalyses the development of oxidative reactions via a non-radical mechanism is the high regioselectivity of such reactions, which is as a rule not characteristic of radical chain processes. As an example, one may point out that the hydroxylation of paraffinic hydrocarbons apparently proceeds with the preferential formation of 2-alkanols.[37] Examples of the oxygenation of substituted aromatic compounds, accompanied by a change in the position of the substituent in the aromatic ring, are known.[51] It has been suggested that the reaction proceeds via the intermediate formation of epoxides:



In the hydroxylation of aromatic compounds, the isomeric composition of the phenols formed is considered as one of the pieces of evidence for the molecular (monoxygenase) mechanism of the action of both cytochrome P-450 and other hydroxylating systems.

For many catalytic hydroxylating systems, incorporating iron(II), iron(III), copper(I), and titanium(III) ions as well as ligands with redox activity (the ascorbate ion, thiosalicylic acid, etc.), the proportions of the isomeric *ortho-para*-, and *meta*-phenols differ significantly from those of the corresponding isomers produced by the interaction of aromatic substrates with OH radicals.[52-56] This discrepancy can evidently be regarded as important evidence in support of the view that free hydroxy-radicals are not involved in the hydroxylation, but it cannot indicate unambiguously the interaction of the substrate with activated oxygen.

One of the important features of chemical hydroxylating systems is their ability to catalyse the epoxidation of olefins by molecular oxygen. Since this property is as a rule characteristic of enzymes (monoxygenases), it too can be regarded as evidence in support of a non-radical oxidation pathway.[57]

The hydroxylation of various substrates by molecular oxygen in the presence of cytochrome P-450 and NADPH(DH_2) is believed to proceed in several stages. A molecular complex of cytochrome P-450 with the substrate ($Fe^{3+}...RH_2$), which undergoes one-electron reduction on interaction with NADPH with formation of the $Fe^{2+}...RH_2$ species, combining with molecular oxygen, is formed in the first stage of the process. The ternary complex $RH_2...Fe^{2+}...O_2$ is reduced via a one-electron mechanism:

$$RH_2 \cdots Fe^{2+} \cdots O_2 \xrightarrow{\bar{e}} RH_2 \cdots Fe^{2+} \cdots O_2^- \rightleftarrows RH_2 \cdots Fe^{3+} \cdots O_2^{2-} .$$

The complex $RH_2...Fe^{3+}...O_2^{2-}$ contains iron in the formal +5 oxidation stage:[58]

$$Fe^{3+} \cdots O_2^{2-} \rightleftarrows Fe^{5+} \cdots O_2^{4-} .$$

This complex can be reduced via the oxenoid mechanism with the simultaneous transfer of two electrons to the oxygen molecule or via the peroxidase mechanism with the consecutive transfer of two electrons:[41]

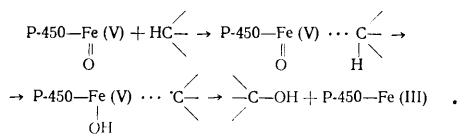
$$[Fe^{3+} \cdots O_2^{2-} \equiv Fe^{5+} \cdots O_2^{4-}] \xrightarrow{\bar{e}} [Fe^{3+} \cdots O_2^{3-} \equiv Fe^{4+} \cdots O_2^{4-}] \xrightarrow{\bar{e}} Fe^{3+}$$
$$\qquad\qquad\qquad

metal-O_2 complexes behave as hydroxylating agents only in aprotic media. In this case the transfer of an oxygen atom takes place via the oxenoid mechanism and the rate of the hydroxylation reaction is limited by the insertion of oxygen in the substrate molecule; in aqueous or other protic media, the hydroxylation takes place with participation of the free radicals OH or HO_2. An important element in the oxidation via the oxenoid mechanism in a ternary substrate–catalyst–oxygen complex is the activation of both reactants.[41]

The intermediate formation of radical species has been suggested also in the oxidation of norbornene in the presence of cytochrome P-450.[59] In this case oxidation by molecular oxygen leads to the formation of *exo*- and *endo*-2-norborneols in proportions of 3.4 : 1. The appreciable kinetic isotope effect (k_H/k_D = 11.5), found for this reaction, suggested[59] that the rate-limiting stage is the abstraction of a hydrogen atom from the norbornene molecule with the intermediate formation of an alkyl radical.

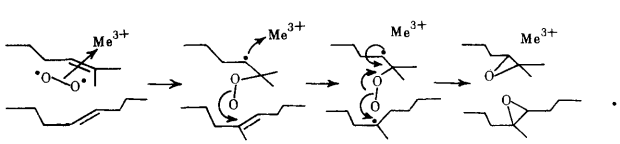
When oxygen interacts with cytochrome P-450, the oxo-complex P-450–Fe(V) of the formally quinquevalent iron is

formed in the first stage and then reacts with the hydrocarbon via the mechanism



In many investigations involving the use of metal-phthalocyanines as oxidation catalysts, the conclusion that oxygen can be activated by such complexes is based on the ability of metal-phthalocyanines to form complexes with oxygen.[60,61] However, the observed effects can be frequently attributed to the possibility of the formation of a catalyst–substrate complex and not the activation of oxygen. Thus the rates of oxidation of squalene and the composition of the products in the advanced process in the presence of cobalt-octaethylporphyrin, i.e. Co(OEP), and cobalt(III) and iron(III) tris(acetylacetonates), which cannot form complexes with molecular oxygen, are virtually identical.[62] Furthermore, it is known that there is an almost complete electron transfer in the molecular complexes of cobalt(II)-octaethylporphyrin with molecular oxygen to form a superoxide ion coordinated to a tervalent cobalt ion.[63] The interaction of this complex with an olefin should have led to the formation of the octaethylporphyrin complex of tervalent cobalt, which is incapable of coordinating oxygen, i.e. the oxidation in the presence of Co(OEP) should have been non-catalytic. Nevertheless, the number of substrate molecules reacting per catalyst molecule reaches 100.

The principal squalene oxidation products are epoxides; allyl alcohols and ketones, which are the main products of the oxidation of low-molecular-weight olefins, are virtually absent from the oxidation reaction mixture.[63] Since squalene is associated in solution[64] and a parallel arrangement of the chains is characteristic of the associated species, it has been suggested that the bimolecular interaction of the free-peroxy-radical with the double bond of a second squalene molecule plays an important role in the oxidation mechanism:



The dependence of the rate of oxidation W of pyridine solutions of ascorbic acid (H_2A) on the oxygen concentration in the presence of catalytic amounts of iron(III), copper(II),[65] UO_2^{2+},[66] VO_2^+,[67] and zinc(II)[68] complexes is described by the law

$$W = \frac{(k_1 + k_2[\mathrm{Py}])[\mathrm{HA}^-][\mathrm{O_2}][\mathrm{cat}]}{[\mathrm{H}^+](1 + K_a[\mathrm{HA}^-])},$$

This suggested[65–67] that the process proceeds via a non-radical mechanism as a result of the activation of molecular oxygen. It is evident, however, that an analogous dependence might have been obtained also for a radical non-chain mechanism[69] if it is assumed that the first stage of the process involves the formation of a molecular complex of the catalyst with the ascorbate anion HA^-, which dissociates in the coordination sphere of the catalyst with formation of the dianion A^{2-}. The oxidation of the coordinated dianion by molecular oxygen leads to the formation of the radical-anion $A^{\cdot-}$, which then disproportionates in the system. Indeed, it has been found that the $A^{\cdot-}$ concentration measured by EPR in the solution being oxidised is virtually identical with that calculated on the assumption of a radical non-chain oxidation mechanism.[69]

Among porphyrin complexes of both cobalt and iron, the highest activity in the oxidation reaction is shown by complexes having the composition M–P : O_2 = 1 : 1:

$$\mathrm{LCo{-}P} + \mathrm{O_2} \rightleftarrows \mathrm{LCo{-}P \cdots O_2}, \qquad (3)$$

where L is an axial ligand and P is a porphyrin.

The hydroxylating activity of the catalyst falls appreciably on dimerisation (disproportionation) of mononuclear complexes:

$$\mathrm{LCo{-}P \cdots O_2 + LCo{-}P \rightleftarrows LCo{-}P(O_2)P{-}CoL}. \qquad (4)$$

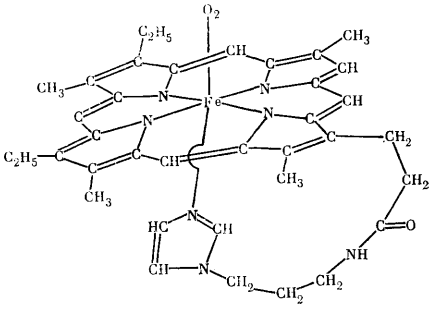
Depending on the reaction conditions, both mononuclear[70] and dinuclear,[71,72] complexes can be formed in solution. The formation of mononuclear 1 : 1 complexes with oxygen is characteristic of cobalt(II) complexes of protoporphyrin IX, while the irreversible reaction (4) takes place on raising the temperature.[73] It has been suggested that reaction (4) is preceded by a rearrangement of the complex LCo–P...O_2 in which the length of the O–O bond increases and its multiplicity diminishes.

The structure of the complex, in particular, the presence of a fairly strong base in the axial position, has a considerable influence on the complex-forming capacity of porphyrins in the reaction with molecular oxygen. In the complex formation reaction of Co(II)–P′ (where P′ is protoporphyrin IX) with oxygen, a satisfactory correlation is observed between the enthalpy of complex formation and the basicity of the axial ligand L[73] in the following sequence: benzimidazole < 4-t-butylpyridine < imidazole < 1-methylimidazole. The marked difference between the rate constants for reaction (4) with L = pyridine and imidazole suggested[73] that the stability of the oxygen complexes incorporating imidazole is ensured by the formation of hydrogen bonds between imidazole and O_2^- in the complex with the metal-porphyrin.

The presence of imidazole in the axial-position in haem-containing compounds has different effects on the rate constants for the complex formation reactions of haems with oxygen and carbon monoxide.[74,75] Thus the replacement of pyridine by imidazole hardly alters the rate constant for the formation of a complex of CO with mesohaem, while the corresponding rate constant for oxygen increases at least by a factor of 3.8×10^3.[76] In order to account for this effect, it has been suggested that the high π-basicity of imidazole plays a major role in the process. It strengthens the π-bond (compared with other bases) between iron ions and

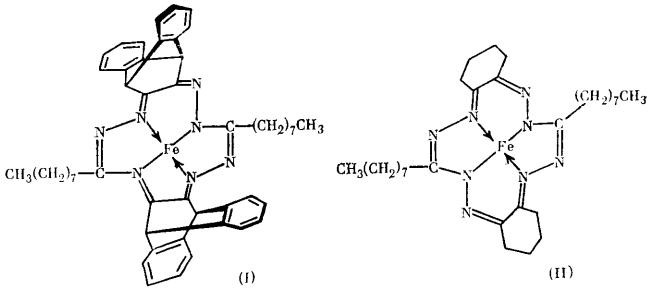
the unoccupied oxygen π* orbitals. The strength of the π-bond between iron and the A–B molecule (CO or O_2) should increase with increasing σ-basicity of the A–B molecule. Since the σ-basicity increases on passing from CO to O_2, the replacement of pyridine by imidazole should have a greater influence on the complex formation reaction of LCo–P with oxygen than with carbon monoxide.

The role of structural factors has been noted in a study of the stability of the complexes of O_2 with a synthetic section of the active centre of myoglobin:[77]



The possibility of the formation of this complex with molecular oxygen is also determined to a large extent by the presence of imidazole in the 5-position.

The influence of the structural factor on the complex formation reactions involving oxygen and also on the stability of oxygen complexes has been demonstrated.[78] The study of the interaction of O_2 with two complexes differing in the depth of the "cavity" formed by the ligand in which the iron atoms are located has shown that compound (I), in which the depth of the "cavity" is 5 Å, forms with oxygen reversible bright cherry-red 1:1 complexes. Compound (II), in which the depth of the "cavity" is 2.2 Å, combines irreversibly with oxygen in the stoichiometric proportions O_2:Fe = 0.5:1:



(I) (II)

The study of the mechanism of the oxidation of organic substances in the presence of rhodium(I) complexes has attracted much attention from the standpoint of the possibility of the activation of molecular oxygen. It has been suggested that the oxidation of olefins in the presence of chlorotris(triphenylphosphine)rhodium(I) takes place via the monoxygenase mechanism.[79–84] Triphenylphosphine, which is oxidised to the corresponding oxide under these conditions, functions as the reducing agent in the above process.

In one of the early studies of this cycle,[85] it was shown that chlorotris(triphenylphosphine)rhodium is an effective catalyst of the oxidation of aromatic compounds at temperatures above 100 °C.

An interesting feature of the process is the marked dependence of the rate of oxidation on the oxygen pressure,[85,86] which is not characteristic of catalytic oxidation via a radical chain degenerate branched mechanism. Such a dependence presupposes the involvement of oxygen in the rate-limiting stage of the reaction.

Although chlorotris(triphenylphosphine)rhodium and chlorocarbonylbis(triphenylphosphine)rhodium greatly accelerate the decomposition of hydroperoxides,[85,87] this does not rule out the possibility of the involvement of complexes of molecular oxygen with rhodium compounds both in the chain initiation stage [via reaction (2)] and in non-radical oxidation reactions of the substrates.

Lines due to the formation of species comprising rhodium(II) and O_2^-,[87,88] possibly the superoxo-complexes Rh(II).O_2^-, can be identified in the EPR spectra of solutions of $Rh(PPh_3)_2$. .COCl, saturated with oxygen, at 77 K. The concentration of these species increases greatly in the presence of cumenyl hydroperoxide,[87] apparently as the result of the facilitation of electron transfer from rhodium(I) to O_2 in the ternary complex:

$$ROOH \overset{\curvearrowright}{\cdots} Rh(I) \overset{\curvearrowright}{\cdots} O_2 .$$

The oxidation of cyclohexene by molecular oxygen in the presence of rhodium complexes activated by cumenyl hydroperoxide leads to the formation of cyclohexenyl hydroperoxide with a selectivity up to 95%.[86] Calculation of the rate of oxidation by the formula

$$W_{O_2} = (k_2/k_6^{1/2})[RH]W_i^{1/2} ,$$

where W_i is the rate of formation of free radicals in the decomposition of the hydroperoxide and k_2 and k_6 are respectively the rate constants for the oxidation chain propagation and termination, i.e. on the assumption of a radical chain oxidation mechanism, showed that the calculated W_{calc} is virtually identical with experimental W_{exp} only at the beginning of the process (at $t \to 0$); in later stages $W_{exp}/W_{calc} > 3$. This finding as well as the decrease of the reaction order with respect to the concentrations of cumenyl hydroperoxide (activator), the catalyst, the olefin, and oxygen from 1 to 0 as the concentration of the corresponding reactant increases suggested that the olefin is oxidised via a non-radical mechanism involving the formation of a ternary catalyst–substrate–oxygen complex after the preliminary modification of the catalyst in accordance with the scheme

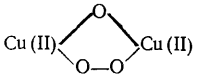
$$Rh(CO)Cl(PPh_3)_2 + ROOH \rightleftarrows Rh(CO)Cl(PPh_3)(ROOH) + PPh_3 ,$$
$$Rh(CO)Cl(PPh_3)(ROOH) + O_2 \rightleftarrows Rh(II)(CO)Cl(PPh_3)(ROOH)\cdot O_2^- ,$$
$$Rh(II)(CO)Cl(PPh_3)(ROOH)\cdot O_2^- + RH \rightarrow$$
$$\rightarrow Rh(II)(CO)Cl(PPh_3)(ROOH)\cdot O_2^-(RH) ,$$
$$Rh(II)(CO)Cl(PPh_3)(ROOH)\cdot O_2^-(RH) \rightarrow$$
$$\rightarrow ROOH + Rh(I)(CO)Cl(PPh_3)(ROOH) .$$

The catalyst in the initial form as well as rhodium(III) complexes and salts catalyse the radical chain oxidation pathway, which apparently explains the appearance of long induction periods after the introduction of different inhibitors at the beginning of the reaction in the presence of univalent rhodium compounds.[89] It is significant that the effectiveness of the modification of the catalyst by hydroperoxides depends greatly on the structure of the latter. For example, cyclohexenyl hydroperoxide hardly modifies the rhodium catalyst.[86]

The results of experiments using labelled oxygen must be regarded as the most reliable evidence in support of the mechanism involving the direct oxidation of substrates by molecular oxygen. With the aid of this method, combined with a series of kinetic methods, the possibility of the activation of molecular oxygen by high-spin complexes of bivalent nickel with a macrocyclic nitrogen-containing ligand has been demonstrated unambiguously.[90,91]

The hydroxylation of aromatic compounds, in particular cresols, in the presence of such complexes in an atmosphere of $^{17}O_2$ in solution in $H_2{}^{18}O$ showed that the phenol formed contains a ^{17}O atom, i.e. that oxygen is inserted in the direct interaction between ArH and O_2.

The possibility of the effective utilisation of a series of dimeric univalent copper complexes as models of monoxygenases has been demonstrated in recent years.[92–95] The formation of the dinuclear peroxo-complexes



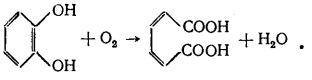
plays an important role in the mechanism of the activation of oxygen by such complexes.[96]

IV. MODELS OF THE ACTION OF DIOXYGENASES

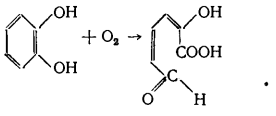
Enzyme systems catalysing the insertion of both atoms of molecular oxygen in the molecule of the substrate being oxidised (S) have come to be called dioxygenases. As a rule, such reactions do not require the participation of an extermal reductant in the process and are formally described by the equation

$$S + O_2 \rightarrow SO_2 .$$

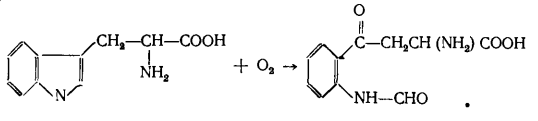
The most typical dioxygenases are catechol dioxygenases, protocatechuate dioxygenases, and tryptophan oxidases. The active centre in catechol 1,2-dioxygenase and protocatechuate 2,3-dioxygenase is a high-spin Fe^{3+} ion.[97–99] In the presence of these enzymes, the oxidation reaction proceeds with the dissociation of a C–C bond and, for example, in the oxidation of catechol leads to the formation of muconic acids:[100]



The metapyrocatechases—catechol 2,3-dioxygenases and protocatechuate 4,5-dioxygenases—contain iron in the form of Fe^{2+} and catalyse the *meta*-cleavage of catechols:[101]



Tryptophan 2,3-dioxygenase, whose composition includes the Cu^+ ion, catalyses the oxidative cleavage of the indole ring in tryptophan:[102]



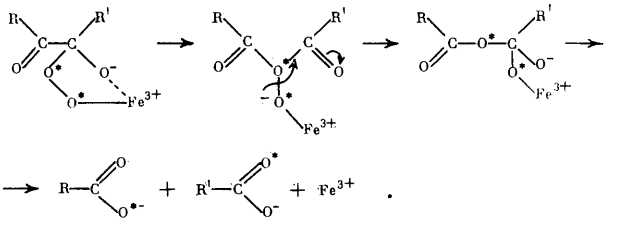
The mechanism of the action of all three enzyme systems involves many different intermediate stages, associated, in particular, with the rearrangement of the enzyme–substrate complexes formed initially.

The mechanism of the action of catechol 1,2-dioxygenases has been studied in greatest detail.[100,103,104] Experiments with $^{18}O_2$ have shown[100,103] that, in the course of the oxidation of catechols in the presence of catechol 1,2-dioxygenase, both atoms of molecular oxygen are incorporated in the oxidation product and no isotope exchange with the medium is observed. The reaction is accompanied by the formation in the first stage of an enzyme–substrate complex, which reacts further with molecular oxygen:[100,104]

$$E + S \rightleftarrows ES + O_2 \rightleftarrows ESO_2 \rightarrow ESO_2^* \rightarrow EP \rightleftarrows E + P,$$

where E is the enzyme, S the substrate, and P the reaction product.

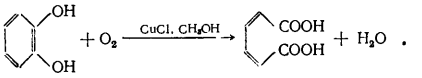
In certain cases, the formation of a "primary" complex with oxygen (ESO_2) may be detected in the system. However, in most systems the complex ESO_2 rapidly rearranges to form the "secondary" oxygen complex (ESO_2^*), and the rate of reaction is so high that the formation of the "primary" complex cannot be detected even by the stopped flow method and its formation can be inferred only indirectly on the basis of kinetic data.[100] The structures of the complexes ESO_2 and ESO_2^* have not been established. However, it is known that the formation of the intermediate complex ESO_2^* and its decomposition are accelerated when electron-donating substituents are introduced in the *para*-position in the benzene rings of catechols. This and also the finding that there is no change in the valence [oxidation state] of iron during the oxidation of catechols suggested that the reaction product is formed as a result of the insertion of oxygen in the C–C bond and is accompanied by the migration of an acyl group:



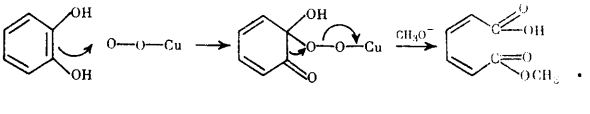
In the above formula the astericks denote the atoms of molecular oxygen.

Very few chemical models of the action of dioxygenases, in which the dioxygenase mechanism of the oxidation by molecular oxygen is demonstrated, have been described in the literature and as a rule the evidence presented cannot be regarded as unambiguous.

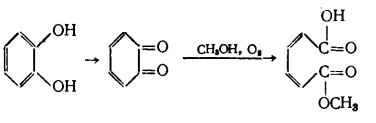
Copper(I) chloride catalyses the oxidation of catechol to muconic acid by oxygen in methanol in the presence of amines:[105]



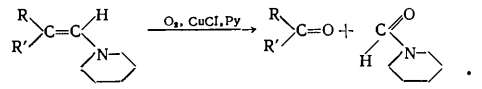
Although formally this reaction can be regarded as a model of the action of catechol 1,2-dioxygenase, in reality experiments with $^{18}O_2$ have shown that only one atom of the oxygen molecule enters into the composition of muconic acid.[105] The reaction can proceed via the intermediate formation of a peroxo-complex.[105] Its product is formed as a result of the interaction of the peroxo-complex with the anion CH_3O^-:



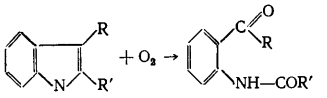
It has been suggested[106] that muconic acid is formed in the consecutive reaction



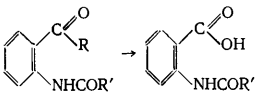
In pyridine solutions copper(I) chloride catalyses the oxidation of various substrates by molecular oxygen[107–109] at room temperature. For example, enamines are oxygenated with cleavage of the double bond and the formation of a ketone and *N*-formylpiperidine:[107]



The CuCl + amine system can serve as an effective catalyst of the oxidation of tryptophan and substituted indoles[108] at 25 °C. The reaction is accompanied by the dissociation of the double bond:



This system can be regarded as a model of tryptophan 2,3-dioxygenase which is capable, as pointed out above, of catalysing the oxidation of tryptophan [R = $CH_2CH(NH_2)$.COOH, R' = H]. However, formylkynurenine, which is a product of the enzymic oxidation of tryptophan, accumulates in the model chemical system in very small amounts (up to 1%) owing to its instability in relation to oxygen in the presence of pyridine complexes of univalent copper. The carbonyl compounds formed initially are oxidised at high rates and with a selectivity up to 60% to 2-acetamidobenzoic acid:[108]

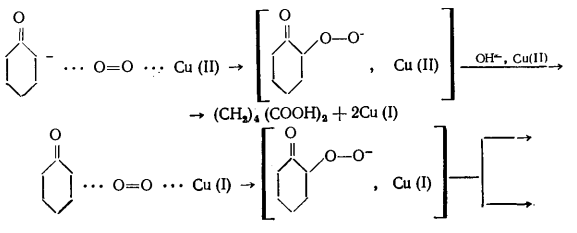


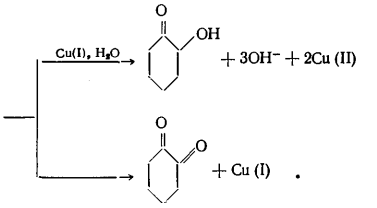
Thus the chemical system is less selective. The dinuclear μ-peroxo-complex Cu...O_2...Cu apparently serves as the oxygen transferring agent in the CuCl + O_2 + pyridine system.[110,111] The role of pyridine reduces to increasing the degree of dissociation of the dimeric form of copper(I) chloride $(CuCl)_2$, which is inactive in the reaction with molecular oxygen.

Certain cobalt complexes with Schiff bases[112] and with porphyrins[113] can also be regarded as models of tryptophan 2,3-dioxygenase.

The oxidation of alcohols and ketones in alkaline solutions in the presence of copper(II) complexes of *o*-phenanthroline can apparently also proceed via the dioxygenase mechanism.[33,114,115] The rate of oxidation of ketones in such a system increases linearly with increasing alkalinity of the medium,[116,117] i.e. as in the enzymic oxidation of catechols;[118] the deprotonation of the substrate plays a significant role in this process.

The reaction takes place via a non-radical mechanism, as shown, in particular, by the sequence in the formation of the reaction products, which is unusual for a radical-chain oxidation reaction: in the initial stages of the oxidation of cyclohexanone, the only oxidation products are adipic acid and cyclohexane-1,2-dione.[117] The latter is oxidised at rates much lower than the rate of accumulation of adipic acid, so that both products are formed via parallel (in relation to the substrate oxidised) pathways:





The rate of oxidation of ketones and the process selectivity (reaching 90–95% in the presence of *o*-phenanthroline) decrease greatly when 5-nitro-1,10-phenanthroline is used as the ligand,[116] which makes it possible to regard the reaction

$$RO^- + Cu(II)L_2 \rightarrow RO^{\cdot} + Cu(I)L_2 ,$$

whose rate should increase on passing from *o*-phenanthroline to 5-nitro-1,10-phenanthroline, as insignificant.

The increase of the rate of formation of free radicals when cyclohexane-1,2-dione is introduced at the beginning of the reaction also reduces the rate and selectivity of the oxidation of ketones.

The hypothesis of the involvement of superoxide ions in the process[114] is also inconsistent with experiment, since it is known that the complex $Cu(o\text{-phen})_2$ can play the role of superoxide dismutase[119] and the O_2 [O_2^-?] concentration in solution should therefore be negligible. Furthermore, the superoxide ion can react rapidly with *o*-phenanthroline,[120] which should have led to its consumption during the oxidation process. Nevertheless the concentration of *o*-phenanthroline hardly changes in the oxidation of ketones.

Thus the $CuCl_2$ + *o*-phenanthroline + base catalytic system can be regarded as one of the systems in which the simultaneous activation of both oxygen and the substrate by the catalyst leads to the operation of a non-radical oxidation mechanism, ensuring a high process selectivity close to room temperature.

The examples quoted above demonstrate the practical feasibility of liquid-phase oxidation processes at high rates and with high selectivities via a non-radical mechanism at comparatively low temperatures (close to room temperature) using as catalysts relatively simple catalytic systems modelling the action of biological enzymes.

Diffusion and Sorption of Aqueous Electrolyte Solutions in Polymers

G.E.Zaikov

The diffusion and solubility of electrolytes in polymers of different types (hydrophobic, hydrophilic, and moderately swelling) are examined. Diffusional transport in such systems is characterised by a number of features: dissociation, ion hydration, the formation of water clusters, and interaction with the functional groups of the polymer. The concentration dependence of the diffusion coefficients is analysed taking into account these effects and also the influence of the volume fraction of the polymer on the diffusion parameters. The mechanism of the distribution of the electrolyte in the hydrophobic and hydrophilic matrices is examined; it is shown that in the latter case account must be taken of the electrostatic factor, which influences the solubility of ions in polymers with ionogenic groups.
The bibliography includes 60 references.

I. INTRODUCTION

The investigations by Academician N.M.Emanuel' and his school on the degradation and stabilisation of polymers have led to the establishment of an independent and important field of chemical science dealing with such topics. It concerns the study of the structure and morphological changes in polymers as well as rational methods for controlling and regulating these changes.[1,2] When polymeric materials come into contact with liquid corrosive media, hydrolytic degradation takes place involving the diffusion of the components of the corrosive medium (acids, bases, salts, and water). In many cases of practical importance the rate of diffusional transport determines the limiting conditions under which polymers can be used. For example, the required properties of anticorrosion coatings in petroleum and gas mains include low diffusion coefficients in them of atmospheric and soil moisture as well as electrolytes; the polymer coating can then be used for a long time. On the other hand, self-degrading coatings of medicinal drugs or dialysis membranes should possess effective transport characteristics, which permit a productive and controllable liberation of medicinal drugs or separation of components.

The mechanism of diffusional transport in aqueous electrolyte solutions in a polymer is determined to a significant extent by the strength of the interaction between water molecules and macromolecules.[3] The subdivision of polymers into hydrophobic, hydrophilic, and moderately hydrophilic, proposed by Reitlinger,[4] therefore appears quite natural. Although the classification of hydrated polymer systems known at the present time as hydrophobic (in which the equilibrium water content under normal conditions and for 100% humidity is not more than 1%), hydrophilic (containing more than 10% water under the same conditions), and moderately hydrophilic (with an intermediate water content) simplifies the overall picture of the interaction of polymers with water, nevertheless it is also convenient from the practical point of view. In considering the diffusion of electrolytes, we shall adhere to this classification. We shall only note that the arbitrary nature of such subdivision arises from the dependence of the strength of the interaction of the macromolecules with water on temperature and from the variation of the degree of crystallinity of the polymer (recrystallisation, conversion into an amorphous form).[5]

The degree of hydrophilicity, i.e. the content of the water which has undergone equilibrium dissolution in the bulk of the polymer, can be estimated quantitatively with the aid of the solubility parameter δ ($J^{1/2}$ $m^{-3/2}$) [6] using the method of group contributions[7] and the Flory–Huggins theory of polymer solutions.[8]

Information about the overall content of water in the polymer is of limited value for measurements of the rate of diffusion, because the same amount of water can exist either in the bound state in the vicinity of polar groups of the macromolecules or can be distributed freely in the hydrophobic region. The mobilities of water molecules in the bound and free states are different.[9] The most reliable information about the transport mechanism is provided by the combined use of diffusion measurements and spectroscopic and relaxation methods. It is then possible to record not only the rate at which the electrolyte enters the polymer but also the structural changes accompanying diffusion.[10]

On the basis of extensive experimental data, one can assume that the first water molecules sorbed by the hydrophobic polymer are distributed between the units of the non-polar chain and that the energetic contribution of this process to the free energy of absorption is extremely low. A further increase in the moisture content in the system entails the preferential interaction between the water molecules and the consequent formation of clusters. This effect appreciably diminishes the mobility of water molecules, which is characterised by a decrease in the diffusion coefficients with increasing water concentration in the polymer.

Another situation arises in the diffusion of water in hydrophilic polymers. Here water molecules initially interact strongly with the highly polar groups of the polymer—the ionic and polar fragments are hydrated. The subsequent portions of water plasticise the polymer matrix, which leads, firstly, to an increase of the mobility of the segments (the polymer passes from the vitreous to the highly plastic state) and, secondly, to an increase in the fraction of "free" non-hydrating water in the polymer. Many hydrophilic polymers can undergo a transition under normal conditions into a viscous fluid state and they combine fully with water to form solutions provided that they are not cross-linked [poly(vinyl alcohol)(PVA), proteins]. Weakly cross-linked hydrophilic polymers can undergo limited swelling and their water content can reach several hundreds. The morphology

(porosity, crystallinity) of the hydrophilic polymers then changes significantly. A number of characteristic features of the diffusion of water in strongly swollen gels make it similar to the diffusion of water in solutions.

Moderately hydrophilic polymers combine with water to a limiting extent at room temperature even when they are in an amorphous state and are not cross-linked. They are also capable of the transition from the vitreous to the highly elastic state (for example, in the case of polyamides), of undergoing a change in the degree of crystallinity, and also of undergoing a change in the type of crystal lattice and pore deformation.[11] More refined effects, for example a transition from one crystalline modification to another (cellulose)[11] or the establishment of the liquid crystal state,[5] are also possible. When the transport of water is considered under conditions where the water content in polymers undergoing limited swelling is low, it is necessary to take into account the superposition of two transport mechanisms: one of them is analogous to diffusion in a hydrophilic polymer when the diffusing substance is in the vicinity of the polar group, while the other resembles diffusion in hydrophobic polymers when the water molecule overcomes hydrophobic regions whose dimensions significantly exceed the length of the diffusional jump. When the moisture content of the specimen is high, account must be taken of extensive hydrated regions where the macromolecules have been plasticised and the transport model should not differ greatly from the transport model in hydrophilic polymers.

II. DIFFUSION IN HYDROPHILIC POLYMERS

The multiplicity of phenomena accompanying the diffusion of electrolyte solutions in polymers can be characterised by the set of pair interactions presented in Table 1.[3] The predominance of a particular type of interaction depends on the nature of the polymer. For example, the diffusion in hydrophobic polyolefins and polysiloxanes is complicated by interactions of the water–water (cluster formation) and water–electrolyte type,[12] while in polar polymers the interaction of the polymer–electrolyte type becomes dominant.[13]

Electrolytes alter the physical structure of the polymer either by direct interaction with various polar and ionised groups or indirectly as a result of the influence of the ions on the structure and activity of the solvent. The direct interaction of ions with macromolecules can be both non-specific, i.e. can be determined by long-range Coulombic forces, and specific, being determined by the specific influence which the electrolyte exerts on the conformation of the macromolecules, for example, in its competition with water for the formation of hydrogen bonds with the functional groups of the polymer (guanidinium salts, hydrochloric and hydrofluoric acids) or in the course of the redistribution of hydrophobic contacts (tetra-alkylammonium ions) in the polymer.[14]

1. Relation between the Diffusion Coefficients and the Volume Content of the Polymer

It is useful to begin the examination of the diffusion of electrolytes in polymers in terms of the somewhat simplified but frequently employed Mecke-Meares and Yasuda theories (see, for example, Moiseev and Zaikov[15] p.119). The essential features of these theories consist in the attempt to relate the diffusional parameters of the solutes (the diffusion coefficient D and the permeability P) in hydrophobic polymers containing different amounts of water to the diffusion coefficient of the electrolyte in the pure solvent (D^0). On the basis of the above theories, it becomes possible to predict the diffusion coefficients of the electrolyte in the polymer D knowing only D^0 (tabulated data) and the volume concentration of water in the polymer ϕ_w (experimental data). Both theories treat the electrolytes as an individual substance; the effects of the ion–ion interaction, the deviations from ideality, and the possibility of partial dissociation are neglected.

Table 1. The types of interactions in electrolyte–water–polymer systems.[13]

Type of interaction	Nature of interaction	Manifestation at physicochemical level
Polymer–polymer	Electrical, polar, and dispersion interactions	Wide variety of ordered crystalline and supermolecular structures, the presence of three main physical states of the polymers (vitreous, highly elastic, and viscofluid)
Electrolyte–electrolyte	Electrical forces (ion–ion); ion–dipole interactions (for incompletely dissociated electrolyte molecules); hydrophobic interactions (for large organic ions)	The operation of Coulomb's law, the existence of an ionic atmosphere, dissociation, complex formation, etc.
Water–water	Dipole–dipole interactions	The existence of hydrogen bonds, the formation of ordered structures (clusters), cluster water–monomeric (free) water equilibrium
Electrolyte–water	Ion–dipole interactions	Hydration, formation of crystalline hydrates
Water–polymer	Polar and hydrophobic interactions	The hydration of polymer groups and segments, plasticisation, antiplasticisation, conformational transitions, crystallisation, transformations of crystal structures, conversion into an amorphous form, degradation, etc.
Electrolyte–polymer	Electrical and polar interactions, hydrophobic interactions (for large organic ions)	Conformational changes in macromolecules, change in crystal structure, complex formation, structure formation (by polyvalent ions), plasticisation

The Mecke-Meares theory of steric hindrance explains the decrease of the self-diffusion coefficients of electrolytes in hydrophilic polymers compared with aqueous solutions by the increase of the diffusional path, because the ions have to move round the macromolecules. In the absence of interaction between the functional polar groups of the polymer and the electrolyte, the polymer hindrance effect is taken into account by the factor

$$(1-\varphi_p)^2/(1+\varphi_p)^2,$$

where ϕ_p is the volume fraction of the polymer.

In contrast to the previous theory, Yasuda's theory uses the concept of the free volume instead of the mechanistic ideas about the polymer as a medium interfering with the movement of ions.[16] The hydrated polymer is regarded as a quasi-homogeneous matrix in which segmental movement of the macromolecules and the presence of the solvent result in the existence of an additive free volume

$$f_v = f_v^w \varphi_w + f_v^p \varphi_p, \qquad (1)$$

where ϕ_w and ϕ_p are the volume fractions and f_V^w and f_V^p are the free volumes of water and the polymer respectively. In formulating the expression for the diffusion coefficient of the electrolyte as a function of ϕ_w, the following assumptions

are made: (1) the effective free volume, in which the solute (electrolyte) is accommodated, corresponds to the free volume of water in the polymer, i.e. account is taken only of the first term of Eqn.(1); (2) the size of the fluctuating cavities, which determine the free volume, corresponds to the size of the diffusing species; (3) there is virtually no interaction between the polymer and the solute molecules.

The probability of the formation of a cavity whose dimensions correspond to the cross-sectional area of the diffusing species (S_S) is defined as $\exp(-BS_S/f_V)$, where B is a constant, for small electrolyte species. In this case the diffusion coefficient of the electrolyte in the polymer, where the volume fraction of water is ϕ_w, is defined by the equation

$$D = D^0 e^{-k_f(1-\Phi_w)\Phi_w^{-1}}, \qquad (2)$$

where $k_f = BS_S/f_V^w$.

It follows from Eqn.(2) that the diffusion coefficient D increases with increasing concentration of water in a hydrophobic polymer, approaching in the limit the diffusion coefficient of the electrolyte in pure water, which has been confirmed in a series of experiments. With decrease of the water content in the specimen, the diffusion coefficient of the electrolyte also falls. The shielding effect of water becomes weaker, so that the possibility of the direct interaction of the electrolyte ions with the macromolecules increases and Eqn.(2) ceases to hold for sufficiently low values of ϕ_w. It is therefore important to emphasise that, from the standpoint of the model considered, the polymer influences the diffusion of the electrolyte only indirectly by reducing the fraction of the free volume of water in the system.

Two important corollaries follow from Eqn.(2). Firstly, the dependence of $\lg D$ on ϕ_w^{-1} is more pronounced the greater the cross-sectional area of the diffusing species. Secondly, for a series of species of different cross-section and within a specific range of values of ϕ_w, the quantity $\lg(D/D^0)$ should decrease linearly with increasing S_S and the higher the water content in the polymer the more marked should be this dependence. To illustrate this conclusion, we shall resort to the results of a study[17] in which the above dependence was observed for a series of organic compounds diffusing in poly(hydroxyethyl methacrylate) hydrogels (Fig.1). The introduction of a cross-linking agent diminishes the water content in the polymer and, as follows from Eqn.(2), leads to a sharper decrease of the diffusion coefficient with increasing r^2, where r is the radius of the diffusing molecule.

Yasuda's model does not take into account the specific features of the electrolyte as a substance capable of dissociating into ions and it is therefore applicable mainly to natural solutes and does not describe the diffusion in polymers containing charged ionogenic groups (ion-exchange resins, polyelectrolytes).[18]

2. The Influence of the Ionogenic Groups of the Polymer on the Diffusion of Electrolytes

The question of the influence of the ionogenic groups of the polymer is important for understanding the mechanism of the processes involving the dyeing and hydrolytic degradation of synthetic and natural fibres, mainly polyamides; the influence of the charged groups on the transport of electrolytes in these polymers, which belong to an intermediate class, will be examined in greater detail in the next Section.

Nikolaev and co-workers[19,20] have made a considerable contribution to the development of ideas about the mechanism of the diffusion of electrolytes in ion-exchange resins. Ion-exchange resins as a rule contain large amounts of water and can be formally classified as hydrophilic polymers. In order to explain the diffusion in hydrophilic polymers containing ion-exchange groups, a loose quasi-crystal model has been proposed.[19] It is based on the following postulates: (1) owing to thermal movement, the counterions can move away from the functional group of the polymer and can give rise to defects resembling those in ionic crystals (vacancies and incorporated ions); (2) migration in the membrane takes place in two stages: during a period τ_0, the counterion is in a potential well, whose existence is due to the presence of the functional group, and oscillates about the equilibrium position. After that, during a period τ_1, it diffuses in a medium analogous to an electrolyte solution until it reaches the next functional group; (3) the functional groups are uniformly distributed in the polymer and in the swollen state the system is quasi-homogeneous.[20]

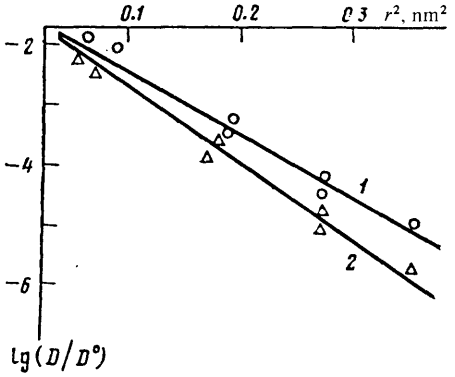

Figure 1. The influence of the size of the diffusing species on the diffusion coefficients in poly(hydroxyethyl methacrylate): 1) $\phi_w = 0.42$; 2) $\phi_w = 0.37$.[17]

The diffusion coefficient of the counterion in the polymer is determined by the two characteristic times τ_0 and τ_1:

$$D_i = \lambda^2/[6(\tau_0 + \tau_1)]^{-1}, \qquad (3)$$

where λ is the average distance between the nearest ionogenic groups, which is calculated on the basis of a scheme assuming the closest packing with the aid of the formula $6.6 \times 10^{-9} C_p^{-1/3}$ (C_p is the capacity of the swollen material, equiv.m^3). After the introduction of the tortuosity coefficient of the diffusion path (r_0) the final expression for the effective diffusion coefficient of an ion in the polymer is

$$D_i = D_i^0 r_0/[(\tau_0/\tau_1) + 1], \qquad (4)$$

where D_i^0 is the diffusion coefficient of the ion in solution.

Experimental measurements of the rate of diffusion in ion-exchange materials of different chemical nature indicate the possibility of the variation of D_i by 5–7 orders of magnitude, while the diffusion coefficients of ions in aqueous solutions vary only within the limits of one order of magnitude. Analysis of experimental results enabled the author to conclude that the main parameter determining the rate of diffusion in polymers is the residence time of the counterion in the vicinity of a given functional group. The stronger the bond between the counterion and the functional group, the longer the time τ_0 and hence the lower the diffusion coefficient.

A decrease in the water content of ion-exchange membranes, for example, as a result of the increase of the degree of cross-linking, strengthens the bond between the counterion and the functional group as a consequence of the diminution of the degree of their hydration. The decrease in the dielectric constant in the system when electrolytes diffuse from non-aqueous solvents also has a negative influence on the ionic mobility. For example, comparison of the diffusion coefficients of the Na^+ and Cs^+ ions in a Nafion membrane from aqueous solutions and acetonitrile ($\varepsilon = 37.5$) solutions showed that the diffusion parameters diminish in the less polar medium approximately by a factor of 120 for Na^+ and 550 for Cs^+.[21]

The presence of dissociating groups in the polymer complicates the electrolyte diffusion process as a result of the occurrence of ion-exchange reactions. The appearance of maxima on the kinetic curves for the sorption of electrolytes by polymers, which are absent in experiments with pure water, characterises the different capacities of the dissociating SO_3H and $SO_3^-M^+$ groups for the sorption of water (M^+ is a metal cation which can give rise to a neutral form).[22]

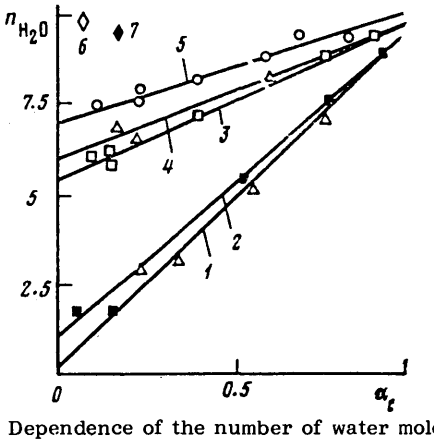

Figure 2. Dependence of the number of water molecules sorbed on the counterions of a "Nafion" membrane on the degree of substitution of the proton by the cation of the SO_3H group: 1) K^+; 2) Cs^+; 3) Ba^{2+}; 4) Sr^{2+}; 5) Ca^{2+}; 6) Al^{3+}; 7) Fe^{3+}.[22]

During the diffusion of a solution of alkali into a polymer specimen containing strongly acid groups, the latter are neutralised. At each instant, the following equation holds:

$$n_w = n_h(1-\alpha_c) + \alpha_c n_k = (n_h - n_k)(1-\alpha_c) + n_k, \qquad (5)$$

where n_h, n_k, and n_w are the numbers of moles of water sorbed by one mole of the acid and the neutral form of the sulpho-groups and the number of moles of water sorbed per mole of the counterion respectively and α_c is the degree of substitution of the proton in the SO_3H group by the cation.

In conformity with this equation, there is a linear relation between n_w for SO_3H and $1 - \alpha_c$. Fig.2 shows that the total amount of sorbed water per sulpho-group in the neutral form increases with increasing charge of the counterion in the sequence $K^+ < Cs^+ < Ba^{2+} < Sr^{2+} < Ca^{2+} < Fe^{3+} \cong Al^{3+}$, which can be explained by the polarising influence of the ion on the nearest water molecules. The diffusion kinetics of ion exchange are described in greater detail in a monograph.[23]

3. The Influence of the Chemical Structure of the Polymer on Diffusion

The term "chemical structure of the polymer" is understood as the chemical composition, the sequence of elementary units, and the degree of branching of the polymer chain. The principal characteristics of the chemical structure are the polarity of the macromolecule, steric factors (i.e. the stereoregularity of the macromolecule), and the ability of the molecules to form hydrogen, polar, and van der Waals linkages. There are important reasons to believe that the chemical structure determines the possibility of the existence of a structural hierarchy of polymers: the presence of α- and β-helices, crystallinity, supermolecular formations, porosity, etc. The possibility of obtaining a polymeric particle (membrane, coating, etc.) with the necessary degree of crystallinity or porosity depends on specific conditions in the preparation and previous history of the specimen: the choice of the solvent, the rate of its evaporation, the existence of temperature gradients, the character of the support, the storage conditions, and a number of others.[24,25]

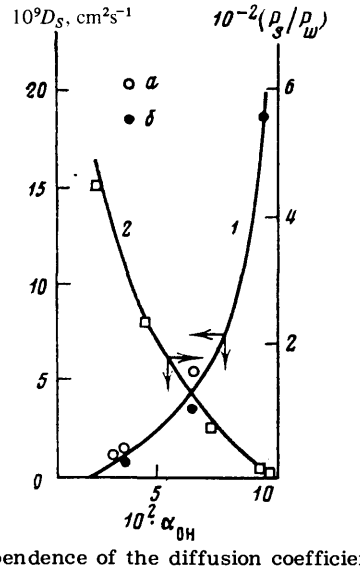

Figure 3. Dependence of the diffusion coefficients of NaCl (curve *1*) and of the relative permeability to the salt and water (curve *2*) on the weight fraction of the hydroxy-groups in cellulose acetate: *a*) stationary measurements; *b*) measurements of the delay time.[3]

As in the transport of water molecules, the permeability to and diffusion of electrolytes are regulated by the ratio of the hydrophilic and hydrophobic units of the macromolecules. Fig.3 presents the diffusion coefficients and the relative permeabilities for a salt and water (P_{NaCl}/P_W) in cellulose acetate films. Evidently, with increase of the weight fraction of hydroxy-groups, i.e. with decrease of the degree of acetylation, a sharp increase of the rate of diffusion of sodium chloride is observed. The principal cause of the increase of P_{NaCl} is the increased water content in the more hydrophilic matrix, which entails the plasticisation of the macromolecules and hence an increase in the free volume in the system.

The accompanying decrease of the relative permeability shows that, despite the overall tendency towards an increase of P_{NaCl}, the value of P_w under the conditions of an applied hydrostatic pressure increases faster, since the mechanism of water transport in strongly swelling membranes changes from diffusional to convective.[26]

A large difference between the mechanisms of the permeability of cellulose and nitrocellulose membranes has been demonstrated.[27] Since the conformations of the molecules of the modified and unmodified celluloses are virtually identical according to infrared spectrscopic data, the above differences can be caused only by the interaction of the OH and NO_2 groups with the solvent and solute and also by some increase in the size of the cavities accompanying the replacement of the nitro-groups in nitrocellulose by hydroxy-groups.

Interesting studies of the influence of the ratio of hydrophilic and hydrophobic units in the macromolecule have been made using membranes based on poly(ethylene terephthalate)-poly(hydroxyethylene glycol) (hydrophilic component) block-copolymers. Membranes of this type are used in medicine for the purification of blood plasma by removing low-molecular-weight impurities, salts, and urea. The linear dependence of the purification half-life on the content of the hydrophilic component in the matrix indicates the need to take into account the ratio of the hydrophilic and hydrophobic groups in the polymer in the solution of practically important problems in membrane separation. An increase of the content of poly(hydroxyethylene glycol) in the copolymer increases the degree of its swelling, which impairs, in its turn, the selectivity and mechanical properties of the film used for dialysis. In constructing separators, oxygenators, dialysis apparatus, etc., it is therefore necessary to select optimum conditions which ensure a high productivity of the membrane and reliable operating qualities of the given article. The hydrophobic blocks play an important role in the fulfillment of the latter requirement. By crystallising and forming domains, they protect the hydrophilic matrix from extensive swelling or dissolution, forming, as it were, effective cross-links.[25]

Membranes based on ethylene–potassium acrylate (25%) copolymers are used in silver-zinc accumulators. When styrene is grafted to the copolymer, the resistance of the polymer matrix to oxidative degradation in the electrolyte improves. It has been shown by an isotopic method that the permeability of membranes to OH^- ions passes through a maximum corresponding to a grafted styrene content of 2.5%, whereas a further increase of the hydrophobic component entails a decrease of P_{OH^-}, as was to be expected. The permeability to Ag^+ ions under the same conditions diminishes monotonically and, in the presence of 16.5% of styrene, the membrane becomes impermeable to Ag^+ ions.[28] These data as well as the results of a number of other studies show that specific conclusions about the influence of the hydrophilic-hydrophobic balance must be made to take into account the specific nature of the diffusing ion. In the example described above the hydroxide ion, as well as the H^+ ion, is characterised by an anomalous diffusional behaviour not only in solution but apparently also in many polymer systems capable of forming hydrogen bonds.

4. The State of the Electrolyte in the Polymer

(a) Ion hydration. The theory of the diffusion of electrolytes in polymers deals with hydrated species and ions as independent kinetic units and does not take into account quantitatively the exchange between the free water and the water of hydration, i.e. the dynamic character of hydration. The polymer matrix is regarded as an inert medium, usually quasi-homogeneous, in which there is sufficient water to ensure, firstly, the hydrolytic dissociation of the electrolyte and, secondly, that the ionic and functional groups of the macromolecules are in a hydrated state.

The commonest evidence for the presence of a hydration shell around the ions diffusing in a hydrophilic polymer is the observation that the sequence in which their diffusion coefficients vary is the same as for their diffusion coefficients in solution. The decrease of the diffusion coefficients of singly charged and multicharged ions in hydrophilic and weakly cross-linked polymer membranes corresponds to an increase of the radius of the hydrated ion and not to its crystallographic radius:[3]

$$D(Cs^+) > D(Rb^+) > D(K^+) > D(Na^+) > D(Li^+);$$
$$D(Na^+) > D(Ca^{2+}) > D(Y^{3+}) > D(Th^{4+})$$

However, for a low water content in moderately hydrophilic polymers, the sequence of the diffusion parameters can be inverted. For example, the decrease in the diffusion coefficients in polyamides (nylon-6) corresponds to the increase of the crystallographic radii of the singly charged cations Na^+, Rb^+, and Cs^+.[29] In exactly the same way, the activation energy for conduction by salts in nylon-6,6 and nylon-6 increased with increase in the crystallographic radius (Table 2). This result made it possible to conclude that there is no hydration, or the latter is extremely limited, in polyamides containing not more than 8% of water.[29]

Table 2. The activation energies for electrical conduction by various salts in nylons (electrolye concentration 0.1 M).

Polymer	Activation energy, kJ mol^{-1}			
	LiCl	NaCl	KCl	RbCl
Nylon 6	44.0	54.4	59.2	65.2
Nylon 6,6	49.4	54.5	—	57.0

With a high moisture content (ϕ_w = 0.7–0.9) in the same polymer, namely poly(vinyl alcohol), the mutual diffusion coefficients, determined interferometrically, increase in the sequence

$$D(K^+) > D(H_2O) > D(Na^+) > D(Mg^{2+}),$$

i.e. the same sequence as that corresponding to the increase of the radius of the hydrated ion (0.27, 0.30, 0.35, and 0.42 nm respectively), while in the presence of a low moisture content (ϕ_w = 0.1–0.2) the same diffusion parameters increase in conformity with the increase in the crystallographic radius[30] in the sequence

$$D(Mg^{2+}) > D(Na^+) > D(H_2O) > D(K^+).$$

Information about the state of the ion in a polymer matrix and about its diffusional mobility can be obtained directly by EPR spectroscopy. However, we may note that this method is applicable only to a limited number of paramagnetic ions such as Cu^{2+}, Mn^{2+}, Fe^{2+}, VO^{2+}, etc. Nevertheless, the extensive possibilities and high sensitivity of EPR spectroscopy made it one of the most promising methods for the investigation of the state of an electrolyte in a polymer, which has come to be widely used in physicochemical and biological research.[31,32]

The degree of interaction of water molecules with ions in a polymer matrix can be estimated quantitatively by analysing the dependence of the chemical shift of the proton signal, recorded by NMR, on temperature, moisture content, the nature of the ion, and certain other parameters. The position of the ^1H NMR signal of the water sorbed by the polymer depends on the capacity of the diffusing ion for hydration. The greater the polarising power of the cations, the greater the downfield shift of the signal. If electrostatic forces are mainly responsible for the polarisation of water molecules near the ion, the chemical shift should be proportional to the ratio of the ionic charge to the square of the crystallographic radius of the ion, i.e. the distance from the centre of the ion to the nearest molecule (z_i/r^2). Such a relation has been observed for a series of alkali and alkaline earth metal cations in the KU-2 cation-exchange resin.[33] The Rb^+ and Cs^+ ions, which have such large radii that electrostatic forces become weaker than those governing the interaction of the water molecules with one another and with the functional groups of the polymer, are an exception. An analogous linear relation has been observed also for anions.

In the course of the desorption of water from the polymer, the hydration shell of the ion is disrupted. The dielectric constant of the system falls and the dissociating cation–anion pair acts on water as a dipole and not as individual point charges. The position of the signal of the water protons undergoes a sharp upfield shift in this case. At a water concentration in the polymer approximately equal to two water molecules per ion and less, the NMR method does not make it possible to estimate the chemical shift as a consequence of the broadening of the resonance lines in the proton, which restricts the application of the method to moderately and weakly swelling polymers.[33]

(b) Dissociation of the electrolyte. The state of the electrolyte in a polymer is determined by the ratio of its ionised and unionised forms, i.e. by the degree of its ionisation. Other conditions being equal, the degree of ionisation depends on the electrolyte concentration. It is therefore useful to characterise the ionisation of an acid or base by the thermodynamic dissociation constant, which determines the strength of the given electrolyte in the diffusion medium and does not vary with concentration.

Depending on whether the electrolyte exists in the polymer in a dissociated form or as neutral molecules, the mechanism of the diffusional transport varies. For example, in the case of an acid, dissociation leads to the appearance in the system of the most mobile form of the protons. In addition, many degradative processes occurring in the polymer via an acid or base-catalysed mechanism are also determined by the concentration of hydroxide and hydronium ions.[15] Information about the state of the electrolyte in the polymer is therefore extremely important not only for the understanding of the diffusion mechanism but also for the prediction of changes in the system as a whole (decrease of the molecular weight and viscosity, a change in the ratio of the crystalline and amorphous phases, etc.).

The methods are known for the determination of the ionisation constant of an electrolyte in hydrophilic polymers: the ion-exchange method,[34] the spectrophotometric (indicator) method, and the conductimetric method.[35]

Table 3 presents the pK for certain electrolytes in hydrophilic polymers saturated with water. It is noteworthy that the dissociation constants of electrolytes hardly differ from the corresponding parameters in pure water in all the cases considered. This effect can apparently be accounted for by the shielding influence of water, which prevents the interaction of the electrolyte with the polymer molecule.[35]

5. Dependence of Diffusion Coefficients on the Electrolyte Concentration

The concentration dependence of diffusion coefficients characterises the features of electrolyte transport in hydrophilic polymers. In the general case its manifestation is due to the following factors: the differences between the mobilities of the dissociated and undissociated forms of the electrolyte; the non-ideal thermodynamic behaviour of the polymer–electrolyte solution system; the interaction of the ions with the functional groups of the polymer; the change in the structure of the polymer as a result of swelling.[36]

Table 3. The ionisation constants of electrolytes in hydrophilic polymers (pK) and in water (pK_w).

Electrolyte	Polymer matrix	c_w, wt.%	pK_w	pK	Method	Refs.

Notation. Methods: 1) ion exchange; 2) spectrophotometric; 3) conductimetric; c_w = water content in the polymer.

(a) The influence of dissociation on the diffusional transport of the electrolyte. In a hydrophilic polymer the electrolyte can exist in partly or fully dissociated states. If the diffusing species formed as a result of the dissociation of the electrolyte have different mobilities, then the overall mobility of the electrolyte should be determined by the degree of its dissociation α_c:

$$D=\alpha_c D_s+(1-\alpha_c)D^u, \tag{6}$$

where

$$D_s=\frac{2D_C D_A\,(z_C-z_A)}{z_C D_C-z_A D_A}, \tag{7}$$

where D_A and D_C are the diffusion coefficients, z_A and z_C are the charges of the anion and cation respectively, and D^u is the diffusion coefficient of the undissociated species.

In order to account for the concentration dependence of the diffusion coefficients in the polymer, we shall formulate Fick's equation as follows:[37]

$$J_{H_mA}=-\sum_{m=1}^{m}[D_{H^+(A^{m-})}\nabla c_{H^+(A^{m-})}-D^u_{H_mA}\nabla c^u_{H_mA}], \tag{8}$$

where $D_{H^+(A^{m-})}$ and $D^u_{H_mA}$ are the diffusion coefficients of the dissociated and undissociated forms of the acid H_mA respectively, $c_{H^+(A^{m-})}$ and $c^u_{H_mA}$ are the concentrations of the corresponding forms, and J_{H_mA} is the flux of the diffusing acid. In all subsequent examples, the diffusion coefficients will be assumed to be constant.

In solutions with centimolar concentrations, hydrochloric acid is almost fully dissociated and Eqn.(8) becomes

$$J_{HCl}=-D_{H^+(Cl^-)}\nabla c_{H^+}. \tag{9}$$

Here

$$D_{H^+(Cl^-)}=2\cdot D_{H^+}D_{Cl^-}/(D_{H^+}+D_{Cl^-}) \quad \text{and} \quad c_{H^+}=c_{Cl^-}=c_{HCl}.$$

Eqn.(9) demonstrates the constancy of the diffusion coefficients of any strong acid in strongly swelling hydrophilic polymers. The absence of a concentration dependence of $D_{H^+(A^-)}$ has been observed experimentally for hydrochloric and trichloracetic acids.[3]

In the experimental concentration range, the strong dibasic acid H_2SO_4 undergoes appreciable dissociation of the second proton and the hydrogen ions diffusing in a neutral polymer matrix are surrounded by SO_4^{2-} and HSO_4^- ions. In this case Eqn.(8) makes it possible to obtain an expression for the effective diffusion coefficient:

$$D_{eff}=D_{HSO_4^-}\left[1+\frac{(\beta-1)}{(1+c_{H^+}/2K_2)^2}\right], \qquad (10)$$

where $K_2 = 1.25 \times 10^{-2}$ is the second dissociation constant of sulphuric acid and $\beta = D_{SO_4^{2-}}/D_{HSO_4^-}$ is the ratio of the diffusion coefficients of the individual ions.[37]

Analysis of Eqn.(10) shows that, if $\beta = 1$, i.e. when $D_{SO_4^{2-}} = D_{HSO_4^-}$, a single diffusion coefficient would be sufficient for the description of diffusional transport. At low acid concentrations $c_{H^+} \ll K_2/2$ and $D_{eff} = D_{HSO_4^-}\beta = D_{SO_4^{2-}}$. Indeed, the fraction of SO_4^{2-} ions in the bulk phase increases with increasing dilution of H_2SO_4 and in the limit transport involves only bivalent ions. On the other hand, at high acid concentrations, where $c_{H^+} \gg K_2/2$, the SO_4^{2-} ions are almost absent. Graphical solution of Eqn.(10) in terms of the variables D_{eff} and $(1 + c_{H^+}/2K_2)^{-2}$ made it possible to determine β, $D_{HSO_4^-}$, and $D_{SO_4^{2-}}$, which are 0.15, 5.9×10^{-10} $m^2\ s^{-1}$, and 0.9×10^{-10} $m^2\ s^{-1}$ respectively.[37] The lower diffusion coefficient of the bivalent SO_4^{2-} ion compared with that of the HSO_4^- ion indicates an increase of the diffusional resistance of the medium as a consequence of the increased hydration of multicharged ions and also stronger electrostatic and specific interactions in the polymer matrix.

In the case of phosphoric acid, which is weaker than the acids examined above, Eqn.(8) assumes the following form:

$$D_{eff}=D_{H^+(H_2PO_4^-)}\left[1+\frac{2\beta_1}{K_1}c_{H^+}\right], \qquad (11)$$

where $K_1 = 7.51 \times 10^{-3}$ is the first dissociation constant of phosphoric acid and $\beta_1 = D_{H^+(H_2PO_4^-)}/D_u$. Eqn.(11) predicts a linear increase of the diffusion coefficients with increasing concentration, which has indeed been observed in the transport of H_3PO_4 in water-saturated PVA films.

A linear increase of D_{eff} with increasing concentration c_{H^+} is observed for H_3PO_4 in the range of moderate concentrations, but in highly dilute solutions ($c_{H^+} = 2.5 \times 10^{-3}$ equiv. dm^3) there is an appreciable deviation from linearity. This effect has been explained[37] by the specific binding of the diffusing acid species in the polymer matrix.

For the almost fully dissociated acids HCl and CCl_3COOH as well as for the undissociated acetic acid CH_3COOH, there is no concentration dependence of the diffusion coefficients over the entire experimental concentration range.

In conclusion of this Section, we present in Table 4 the diffusion parameters of a series of acids of different types, determined in PVA films containing 75–78% of water. For comparison, the corresponding diffusion coefficients of the same acids in pure water are also quoted. Comparison of the diffusion parameters of different organic acids indicates the important role of the size of the diffusing species. The molecular diameter increases on passing from acetic to toluene-*p*-sulphonic acid, while the diffusion coefficients diminish in the same sequence.

Table 4. Diffusion parameters of acids in PVA films containing 75–78% of water ($\bar{D}$) and in pure water (D^0).[3]

Acid	$10^{10}\bar{D}$, m^2s^{-1}	$10^{10}D^0$, m^2s^{-1}	$\bar{D}/D^0$
$H^+(Cl^-)$	14.0	30.0	0.47

H_3C–C$_6$H$_4$–SO_3H	0.75	—	—

III. DIFFUSION IN MODERATELY HYDROPHILIC POLYMERS

Moderately hydrophilic polymers contain a limited number of polar groups. Typical examples of polymers of this class are the polyamides, the amount of water which they absorb under normal conditions being 2–10%. Numerous studies of the sorption and diffusion of electrolytes have been carried out on polyamide specimens, which reflects the great interest of investigators in the problem of dyeing by acid and basic dyes.[38] Polyamide membranes are widely used in dialysis and reverse osmotic systems.[39] The purely technological problems involving the search for the optimum dyeing, purification, or separation conditions give rise to a problem of great theoretical importance, namely that of the study of the mechanism of the interaction of low-molecular-weight components in a polymer matrix.

The characteristic features of the diffusion of charged species into polar polymers which distinguish the latter from non-polar polymers are related to the strong interaction of such species with the functional groups characteristic of, for example, the polyamides ($-NH_2$, $-COOH$, $-CONH-$). Such interaction may entail the complete loss of mobility by some of the diffusing ions or an exchange interaction with the functional group R in accordance with the scheme

$$R + E \underset{}{\overset{K}{\rightleftharpoons}} RE.$$

When the number of binding groups exceeds the number of electrolyte molecules (E), for example those of HCl in polyamide 6, the diffusion is retarded in accordance with the equations

$$\frac{\partial c}{\partial t}=D_{eff}\frac{\partial^2 c}{\partial x^2}; \quad D_{eff}=D/(1+K[R]_0), \qquad (12)$$

where D is the true diffusion coefficient, $[R_0]$ the concentration of the reacting groups in the polymer, K the exchange equilibrium constant, and x the diffusion coordinate.

For a correct interpretation of the results of diffusion experiments, it is essential to know the composition and state of the electrolyte and the nature and distribution of the polar groups of the polymer.

1. The Influence of the Ionogenic Groups of the Polymer on the Concentration Dependence of the Diffusion Coefficients

In the initial state the polyamide macromolecules contain unequal numbers of terminal amino-groups B_0 and carboxy-groups A_0. Some of the amino- and carboxy-groups are linked to one another in a zwitter-ionic form. The sorption of acid under conditions where $B_0 > A_0$ therefore includes three consecutive stages:

$$\begin{gathered} R{-}NH_2 + HCl \xrightarrow{(a)} R{-}NH_3Cl, \\ R{-}NH_3^+{-}R{-}COO^- + HCl \xrightarrow{(b)} R{-}COOH + R{-}NH_3Cl, \\ R{-}CONH{-}R + HCl \xrightarrow{(c)} R{-}NH_3^+COO{-}R(Cl^-), \end{gathered} \qquad (13)$$

If $A_0 > B_0$ in the polymer, then only reactions (b) and (c) take place.

Despite a number of limitations, the proposed scheme (13) can explain certain experimental facts (see Zaikov et al.,[3] p.123). The role of a neutral electrolyte, for example KCl, present in the polymer has been examined by Crespo.[40]

As a result of the interaction of the diffusing ions with the ionogenic and polar groups of the polymer, a dependence of the mobility of the ions on the degree of binding of these groups (the degree of filling of the adsorption sites θ_f) is observed in the initial stages of the sorption process. With increased concentration of the acid in the polymer, the functional groups are deactivated in accordance with scheme (13) and their electrostatic and chemical influences on the diffusing ions and molecules diminish. When the acid concentration has passed through a critical region where the condition $c_{A_0} = c_{HA}$ holds, the diffusion coefficient of the electrolyte increases sharply. For example, the self-diffusion coefficient of sulphuric acid in the amine region of polyamide 6, measured by the radioactive isotope method, is described by the analytical expression[41]

$$D^*_{H_2SO_4} = \frac{K}{2K_2}\frac{\theta_f}{(1-\theta_f)}D^*_{HSO_4^-} + \left[1 - \frac{K}{2K_2}\left(\frac{\theta_f}{1-\theta_f}\right)\right]D^*_{SO_4^{2-}}, \qquad (14)$$

where θ_f is the degree of occupation of the terminal amino-groups and K/K_2 is the ratio of the equilibrium constant of reaction (a) in scheme (13) to the second dissociation constant of H_2SO_4. The agreement between the experimental and theoretical results can be seen from Fig.4. An analogous sharp increase in the effective diffusion coefficients in polyamides is observed predominantly for cations (protons) in the HBr–polyamide-6,6 and sulphuric acid–keratin systems.[3]

In diffusion systems where there is an equilibrium between the freely diffusing ions and ions bound to the functional groups of the polymer, the activity coefficient is determined by the ratio $\gamma = D_{eff}/D_i$, where D_i is the diffusion coefficient of the free ion, which is independent of the concentration.

As regards inorganic acid anions, the concentration dependence of their diffusion coefficients is less marked. For example, the self-diffusion coefficient of the Br^- ions in the amine region of polyamide 6,6 is almost independent of the acid concentration and increases slightly in the amine region (from 6×10^{-15} to 10^{-14} m^2 s^{-1}). The diffusion coefficient of the Cl^- ion in polyamide 6 at 70 °C also depends only slightly on the concentration over a wide range of degrees of saturation of the adsorption sites:[3]

θ_f	0.19	0.40	0.75	0.82
$10^{11}D_{Cl^-}$, m^{2}s^{-1}	0.40	0.45	0.49	0.52

The coefficients $D_{SO_4^{2-}}$ and $D_{HSO_4^-}$ depend more markedly on the concentration but even their concentration dependence is less pronounced than that of D_{H^+}.

The complex dependence of the diffusion coefficients of the anions of organic dyes on concentration reflects the interaction of the moving anions not only with the polymer matrix but also with one another.

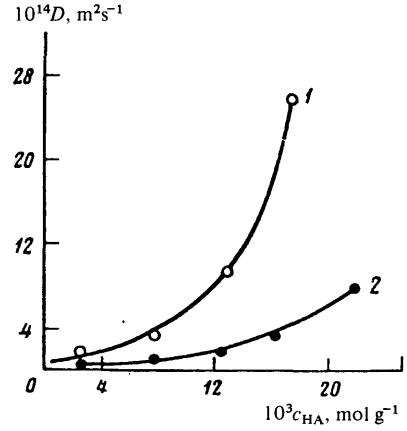

Figure 4. Dependence of the diffusion coefficients of sulphuric acid in polyamide 6,6 at 25 °C on its concentration;[41] 1) $D(H_2SO_4)$; 2) $D(SO_4^{2-})$; circles—experiment; continuous curves—calculated data.

The diffusion of organic acids has been studied in less detail than that of inorganic acids, but the relations obtained suggest that the mechanism of their sorption in the amine region is the same as that of inorganic acids. Table 5 presents the diffusion and thermodynamic parameters for the sorption of weak organic acids by polyamide 6,6.

The mobility of ions in water is determined by the size of the hydration shell which is greater for ions with a smaller crystallographic radius. However, the mobility of cations in moderately hydrophilic polymers diminishes with decrease of the crystallographic radius.[42] This fact shows that the cations present in the polymer lack a hydration shell.

2. The Equilibrium Sorption of Electrolytes

The "equipotential internal solution" model has been one of the first to be proposed for simple inorganic ions sorbed by moderately hydrophilic polymers. According to this model, an electrolyte solution, analogous to the external solution but having a potential $\Delta\phi$ relative to the latter, exists in the polymer:

$$K_p = \bar{c}_{Na}/c_{Na} = c_{Cl}/\bar{c}_{Cl} = \exp[\sinh^{-1}(c_f/2c_{NaCl})], \qquad (15)$$

This equation agrees quite well with experiment at moderate and high electrolyte concentrations in the polymer. At high dilutions, appreciable discrepancies are observed between the experimental and calculated K_p.[43]

In the Gilbert–Ridal theory (see Zaikov et al.,[3] p.189), it is assumed that ions are adsorbed on a limited number of statistically distributed ionogenic groups of the polymer in accordance with the equation

$$\lg\left(\frac{\theta_f}{1-\theta_f}\right) = \lg c_{CA} + \frac{W_p + W_v - e\Delta\varphi}{2.3kT}, \qquad (16)$$

where W_p and W_v are the polarisation and van der Waals interaction energies respectively, e is the electronic charge, and c_{CA} the concentration of the electrolyte.

The ion-exchange model has been proposed by Myagkov and Pakshver (see Zaikov et al., [3] Chapter 5) to account for the sorption of HCl, KCH, naphthalene-2-sulphonic acid, and certain dyes by polyamide 6. This model predicts that

$$\lg[x(x_0-x)^{-1}] = \lg k - 2\,\mathrm{pH},$$

where x_0 and x are the total number of functional groups and the number of such groups bound to the ion respectively and k is the sorption constant.

The models mentioned above make it possible to obtain only a limited agreement between the calculated and experimental data, which is the reason for the development of the Mathieson–Whewell polyelectrolyte model (quoted after Zaikov et al.[3]). The authors of this model postulate that the energy required to remove H^+ from the polymer to the solution depends on the electrostatic and osmotic interactions of the electrolyte in the polymer and on the chemical affinity (the difference between the standard chemical potentials of H^+ in the polymer and in the solution $\Delta\mu_H^0$). For a partly dissociating group in the polymer, the following equation is frequently used:

$$\mathrm{pH} = \mathrm{p}K_A - \lg[(1-\alpha_c)\alpha_c^{-1}] - \frac{0.434}{RT}(zF\Delta\varphi + \Delta\mu_H^0), \qquad (17)$$

where z is the charge on the group, K_A the dissociation constant, T the absolute temperature, F the Faraday, and R the gas constant.

Association of groups bearing unlike charges in the polymer distorts the potential and its distribution in the membrane. There exist two ways of taking into account association. According to the first procedure, a correction coefficient β, characteristing the fraction of charged groups incorporated in the ion pairs (associated species), is introduced in order to describe the potential. In this case the electrostatic factor is determined by the coefficient $-0.0434F\phi_m\beta/RT$, where ϕ_m is the average membrane potential. However, since β is difficult to calculate because it depends on the electrolyte concentration and hence on the coordinate of the diffusion process, it is more convenient to employ two kinds of carboxy-groups (in the general case acid groups)—free and paired, which dissociate with their own dissociation constants K_p and K_q respectively [see Eqn.(17)]. In this case the concept of a homogeneous membrane potential ϕ_m is retained.

The molecular weights of polymers dissociating only at the terminal groups influence the solubility of the electrolyte. If it is assumed that the accessibility of these groups, the pK, and $\Delta\mu_H^0$ are independent of the degree of polymerisation, then Eqns.(15) and (17) make it possible to relate the degree of polymerisation and the content of end groups c_f to the acid concentration:

$$\mathrm{pH} = \mathrm{const} - 0.434\,\sinh^{-1}(c_f/2c_s), \qquad (18)$$

When $c_f/2c_S > 200$, i.e. when the concentration of the added salt c_S is low, $\sinh^{-1}(c_f/2c_S)$ can be replaced by the corresponding logarithmic relation:

$$\mathrm{pH} = \mathrm{const} - \ln(c_f/c_s). \qquad (19)$$

Graphical solution of Eqn.(19) with a constant c_S, which is presented in Fig.5, indicates a satisfactory agreement between theory and experiment.

In the absence of specific interaction, titration curves make it possible to estimate the pK of the acid groups of the polymer. For example, for keratin twice the pH at the midpoint of the titration curve (i.e. on the plot of pH against $\bar{c}_{HA}$) is equal to the pK of glutamic acid, which can serve as a model of the elementary unit of this polymer. However, for adipic acid, the model of the elementary unit of polyamide 6,6, such an equaltity has not been observed even if a correction is made for the shift of the isoelectric point of this polymer as a consequence of the inequality of the numbers of its acid and basic groups. The most probable cause of this discrepancy is a lower dielectric constant ε in polyamide 6,6 compared with the keratin matrix, where ε does not differ markedly from its value in water.

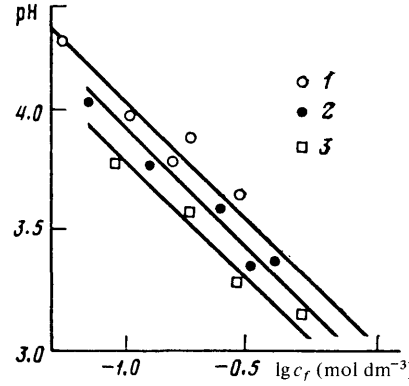

Figure 5. The influence of the degree of polymerisation (of the content of end groups) on the pH in the PA–HCl system for different degrees of ionisation: 1) 0.7; 2) 0.6; 3) 0.5.[3]

Table 5. Diffusion coefficients (D), activation energies for diffusion (E_D), changes in the chemical potential ($\Delta\mu$), and heats of sorption (ΔH) of organic acids in polyamides 6,6 at 60 °C (see Zaikov et al., [3] Chapter 5).

Acid	$10^{13}D$, m^{2}s^{-1}	E_D, kcal mol^{-1}	$\Delta\mu$, kcal mol^{-1}	ΔH, kcal mol^{-1}
Formic	13.2	2.8	0.18	0.4
Acetic	18.1	7.7	−0.41	−0.4
Propionic	14.4	7.2	−0.42	−0.24

Salicylic	2.7	21	−1.8	−1.9
Benzoic*	0.3	12.9	—	−3.2
Sorbic**	2.6	3.1	−1.9	−9.8

*Polyamide 610, temperature 45 °C.
**Temperature 55 °C.

Table 5 lists the chemical affinities $\Delta\mu$ of various acids for the polymer, calculated by Eqn.(17). Apart from their theoretical interest, these results are of practical value for the estimation of the stabilities of dyed articles.

IV. DIFFUSION IN HYDROPHOBIC POLYMERS

Polymers of this class are characterised by a high chemical stability in relation to electrolyte solutions. The low polarity of their macromolecules is responsible for the low solubility

of water and electrolytes in hydrophobic polymers, for example, in polyolefins, polyesters, and fluorinated plastics (PTFE). As a consequence of the low polarity of the polymer medium, the acids, bases, and salts contained in it are associated. In this connection, one may note that polymers resistant to acid hydrolysis are as a rule hydrophobic; however, the opposite claim is invalid, because not every hydrophobic polymer is resistant to acid hydrolysis. An example of this is provided by polysiloxanes (see Zaikov et al.,[3] p.147).

1. The Influence of the Nature of the Electrolyte

The most characteristic feature of the diffusional transport of electrolytes in hydrophobic polymers is its selectivity. For example, the permeation of nitric acid through a film of ftoroplast-42 (a type of PTFE) is recorded after ~10^3 s, while the permeation of sulphuric acid through a similar film can be observed only after a year.[44]

Almost all hydrophobic polymers are readily permeable to hydrochloric, hydrofluoric, nitric, acetic, and fluorosilicic acids and to ammonium hydroxide solutions. Sulphuric and phosphoric acids, inorganic bases, and salts diffuse much more slowly (see Reitlinger,[4] p.45). For a series of electrolytes, for example in the polypropylene–KCl system,[47] the permeability could not be measured at all apparently owing to the low solubility of the electrolyte and the inadequate sensitivity of the method of measurement.

The permeability of hydrophobic polymers and the vapour pressures of the electrolytes were first compared by Shterenzon and co-workers.[47,48] Electrolytes characterised by a high vapour pressure diffuse into polymers with coefficients close to the diffusion coefficients of water (D_{H_2O}). Another group of electrolytes, having low volatilities, is transported in polymers with diffusion coefficients much lower than those of water in the same polymer. An analogous classification of electrolytes into "strongly diffusing" and "weakly diffusing" has been proposed by Alt.[49] It is important to note the arbitrary nature of the subdivision of electrolytes into volatile and involatile. At high temperatures and concentrations a typical involatile electrolyte such as sulphuric acid behaves as a volatile electrolyte as regards transport.

The influence of the nature of the volatile electrolyte on its diffusion coefficient is non-specific and is expressed solely by the dependence of the diffusion coefficient on the size of the diffusing species (see Zaikov et al.,[3] p.155).

The concentration dependence of the diffusion coefficient of HCl in low-density polyethylene (LDPE) has been investigated with the latter in contact both with a dry gas at different partial pressures and with an aqueous solution.[50] It was noted that the integral diffusion coefficients of hydrogen chloride diffusing from aqueous solutions increase with increasing concentration of hydrochloric acid, tending to the constant value found for the dry gas. In order to account for this result, a comparative study was made of the equilibrium sorption of HCl from a dry gaseous phase and from aqueous solution. At identical vapour pressures, a greater amount of HCl is sorbed from the solution than from the gas phase. This difference has been explained by the fact that, in the presence of water, some of the electrolyte molecules permeating into the polymer are bound in the form of associated species and an additional amount of HCl passes from the solution to the polymer in order to establish an equilibrium. The overall amount of the sorbed acid (c_{HCl}) is in this case determined by the equation

$$c_{HCl} = c_F + MK_H c_F (p_w k_w)^n \qquad (20)$$

where c_F is the concentration of free HCl not bound in the hydrates, M the molecular weight of HCl, K_H the equilibrium constant of the hydrate formation process, k_w the constant for the sorption of water by the polymer, p_w the partial pressure of water vapour over the solution, and n the number of water molecules in the hydrate, which is 5.0 ± 1.3 for the given system.[50]

It is seen from Eqn.(20) that the ratio of the hydrated and unhydrated forms of the acid diminishes with decrease of the partial pressure of water vapour.

The proposed model makes it possible to obtain an expression for the effective diffusion coefficient of HCl in polyethylene and to describe quantitatively its concentration dependence:

$$\bar{D}_{HCl} = \frac{D^0_{HCl}}{1 + MK_H (k_w p_w)^n}, \qquad (21)$$

where D^0_{HCl} is the diffusion coefficient of dry gaseous HCl. The average number of water molecules in the HCl hydrate, calculated from the results of kinetic (diffusion) measurements, is 4.3 ± 1.7, which is fairly close to the values of n obtained from equilibrium sorption data.[50]

The possibility of the existence of hydrates of volatile electrolytes in hydrophobic polymers was pointed out by Dolezel,[51] who observed a sharp increase of D_{HNO_3} in poly(vinyl chloride) in the presence of a 50% concentration of the acid.

Murov et al.[52] proposed a model involving the parallel-consecutive binding of the electrolyte and water in hydrophobic polymers of the type of polyethylene and polypropylene (PP). According to this model, the non-stationary flux of water molecules from dilute solutions of the volatile electrolyte, subject to the condition $p_w \gg p_s$, can exceed the non-stationary flux of the electrolyte (consecutive binding scheme). In this case it is assumed that the electrolyte diffuses in the hydrated polymer matrix and the probability of the existence of free electrolyte molecules is lower the higher the concentration of water in the polymer. With increase of the concentration in the solution in the external phase, the water and the electrolyte vapour pressures become similar ($p_w \cong p_s$) and the components are bound in the polymer in accordance with the parallel kinetic scheme. The transport of unhydrated electrolyte species is in such cases facilitated.

A further development of ideas concerning the interaction of water and the electrolyte in the polymer was achieved by Shterenzon (see Zaikov et al.,[3] p.159). If it is assumed that the composition of the hydrated complex $HA \cdot xH_2O$ is analogous to that of the external solution, then

$$\lambda_D^2 = r_0 \left[\frac{p_s}{p_s^0} \left(\frac{p_w}{p_w^0} \right)^x \right]^a \qquad (22)$$

where λ_D is the non-stationary permeability coefficient,[3] reflecting the rate of movement of the diffusion front of the electrolyte in the polymer, p_w^0 and p_s^0 are the vapour pressures of the pure electrolyte and pure water respectively, r_0 and a are empirical constants, and x is the number of moles of water per mole of the acid.

The calculated and experimental values of λ_D agreed satisfactorily over a wide range of HCl, HF, HNO_3, and H_2SiF_6 concentrations. Here it is appropriate to emphasise that the concentration dependence of λ_D(HCl) has the same form in dilute (7%) and concentrated (29%) solutions, which makes it possible to put forward the hypothesis of a transition of the diffusion mechanism from consecutive to parallel binding.

2. The Influence of the Nature of the Polymer

The chemical structure of hydrophobic polymers influences only weakly the rate of diffusional transport. In most cases the difference between the diffusion parameters is determined by the difference between the morphologies of the polymers. For example, the extremum in the dependence of the sorption of nitric acid by vinylidene fluoride–chlorotrifluoroethylene and vinylidene chloride–hexafluoropropene copolymers on composition can be accounted for by the transformation of the structure into an amorphous form[53] (the permeability constants of the membranes have been published,[15] p.141).

The polar groups present in a polymer as a result of oxidation alter significantly the diffusion characteristics of hydrophobic polymers. It has been shown,[54] that, with increase of the concentration of the carbonyl groups in polyethylene on oxidation, its electrical conductivity and sorption capacity with respect to salt solutions also increase. Polyethylene films oxidised by sulphur trioxide absorb up to 20% of water and behave like polycarboxylic acid, manifesting, in particular, ion-exchange properties.

The introduction of a filler into the polymer matrix can decrease the mobility of the macromolecules and can lead to the appearance of defects in the polymeric diffusion medium and to the direct interaction of the diffusing species with the additives. Polyethylene containing 16% of graphite, which is inert with respect to the polymer and the electrolyte, is 10% less permeable than unfilled polyethylene. The introduction of a filler without a high adhesion capacity towards the polymer, namely chromium oxide, does not decrease but actually increases the rate of diffusion of HCl and especially HF. Dyeing of a chlororubber coating with TiO_2 also entails an increase of its permeability to Cl^- ions.[55] Zaikov et al.[3] (Chapter 6) have reviewed investigations of the interaction of electrolyte components with the additives introduced into a hydrophobic polymer (hydrophilic fillers of the type of talc and CaO, various surfactants, and plasticisers).

Table 6. The activation energies for the diffusion of electrolytes (Zaikov et al.,[3] Chapter 6).

Polymer	Electrolyte	c, wt.%	E_D, kJ mol^{-1}
Poly(ethylene terephthalate)	H_2SO_4	53	50
PTFE	HNO_3	98	18.8 (>323 K) 50.6 (<323 K)
PE	HNO_3	98	41.8
PE	H_2SO_4	10	55
PP	H_2SO_4	10	31

3. The Influence of Temperature

For many of the systems investigated, a linear relation has been observed between $\lg D_S$ and $1/T$, which makes it possible to calculate the activation energy for diffusion E_D (Table 6). A characteristic feature of the diffusion of electrolytes in polymers is manifested by the fact that the diffusion parameters are determined simultaneously by the electrolyte concentration in the polymer and the experimental temperature. It has been reported[56] that, for a non-steady state process involving the permeation of HCl into high-density polyethylene, E_D varies from 49.3 to 39 kJ mol^{-1} with increase in the concentration of the acid from 15 to 30 wt.%. An empirical equation for the dependence of the non-stationary permeation coefficient λ_D on temperature and concentration (pressure) of the electrolyte has the following form:

$$\lambda_D = A_0 e^{(U/RT)}, \quad (23)$$

where A_0 is an empirical parameter which depends on the concentration or vapour pressure of the electrolyte and U is the energy parameter. Here it is important to note that the pre-exponential factor depends on concentration and temperature (see Zaikov et al.,[3] p.161), which has been confirmed by a series of experiments.[57]

4. The Interaction of Diffusion Fluxes. Countercurrent Diffusion

The interaction of the diffusion fluxes of water and the electrolyte is manifested by the desorption of the latter into water from hydrophobic specimens. Thus a polyethylene specimen subjected to preliminary saturation with hydrochloric acid desorbs HCl into an aqueous environment extremely slowly, while the desorption in a stream of dry air is significantly faster. A detailed study[58] has been made of the phenomenon of the temporary cessation of the release of acid from the film under the conditions of the countercurrent diffusion of water. The interaction of water and the acid in the polymer increases the delay time θ and hence leads to unjustifiably low diffusion coefficients $D = l^2/6\theta$, where l is the thickness of the polymer film. Extrapolation of $\lg \theta$ to zero water vapour pressure p_W is therefore of considerable interest, since it makes it possible to estimate θ for the electrolyte without taking into account the binding to water.[12]

When hydrophobic polymers are used as protective coatings, the specimens become turbid in the presence of many electrolytes. The appearance of turbidity is initially very rapid and then slows down, taking place over a period of several tens and hundreds of hours. The intensity of the turbidity depends on the nature of the polymer and the electrolyte and also on the concentration of the latter. Sulphuric, phosphoric, and acetic acids and ammonia do not cause turbidity, while the countercurrent diffusion of hydrochloric, nitric, and hydrofluoric acids in the region of an ~30% concentration leads to the formation of the electrolyte solution phase in the case of LPPE.[47]

Just as a mist is formed in the gas phase, in hydrophobic polymers there is a possibility of the appearance of tiny droplets resulting from the association of the volatile electrolyte with water. However, the formation of a new phase within the polymer requires the expenditure of energy on the deformation of its structure. In polymers with different physicomechanical characteristics, identical expenditures of the energy liberated as a result of the interaction of water and electrolyte lead to the formation of drops of different size. In certain cases the resistance of the polymer to deformation is so great that the new phase cannot be formed.[47] The enthalpy ΔH^0 of the process $(CA)_{gas} \rightleftarrows (CA)_{soln}$ has been suggested as a quantitative criterion of the possibility of forming clusters in hydrophobic polymers.[47] The ΔH^0 for the electrolytes investigated can be arranged in the sequence

$$\Delta H^0_{NH_3} > \Delta H^0_{HNO_3} > \Delta H^0_{HCl} > \Delta H^0_{NH_4Cl}.$$

In the countercurrent diffusion of water and ammonia, the liberated energy (10 kJ mol^{-1}) is insufficient for the formation of drops, while the energy evolved as a result of the interaction of the HCl and ammonia fluxes is so great that a

continuous layer of ammonium chloride is formed within the polyethylene film, disrupting the polymer matrix. In practice the above effects are used to obtain X-ray contrast materials and for the layer-by-layer cleavage of polymer membranes in microscopic studies.

5. The Sorption of the Electrolyte

For an approximate estimate of the concentration of the sorbed electrolyte in the amorphous phase of the polymer, it has been suggested[47] that a simplified version of the Flory equation be employed:

$$-\ln \varphi_s = 1 + \frac{\bar{v}_s (\delta_s - \delta_p)^2}{RT}, \qquad (24)$$

where δ is the solubility parameter, ϕ and $\bar{v}$ are respectively the volume fraction and the molar volume of the ith component, and s and p are subscripts referring to the electrolyte and the polymer respectively. Eqn.(24) shows that the degree of equilibrium sorption of the electrolyte is greater the lower the modulus of the difference between the solubility parameters of the polymer and the electrolyte. For polyolefins $\delta_p = 16$, for pentaplast $\delta_p = 10$, and for sulphuric acid $\delta_s = 35$ $J^{1/2}cm^{-3/2}$. It follows from Eqn.(24) that the concentration of H_2SO_4 in pentaplast should exceed the concentration of acid in polyolefins by a factor of 40. The different permeabilities of pentaplast and polyethylene to H_2SO_4 indirectly support this.[3]

---o0o---

A quantitative description of the diffusion and solubility of electrolytes in polymers is an essential condition for the prediction of the chemical stability of the material and of the operating parameters of anticorrosion coatings (hydrophobic polymers). For the successful employment of medical polymers as implants and elements of artificial organs, information is also required about the equilibrium and kinetic parameters for the sorption of the components of the biological medium (on hydrophilic and moderately hydrophilic polymers). The optimisation of the dyeing and printing processes is impossible without a description of the diffusion in fabric materials.[59] The theory of membrane purification, separation, and concentration methods is also based on the diffusion mechanism in hydrophilic and moderately hydrophilic membranes.[60] One can claim with confidence that in the future our ideas about the diffusion of electrolytes in polymers will expand significantly in connection with the vigorous development of chemotronic systems and photochemical and mechanochemical energy converters.

Modification of DNA by Alkylating Compounds

K.E.Kruglyakova

The results of studies of the physicochemical properties of alkylating compounds—alkylnitrosoureas (ANU)—with a broad spectrum of biological activities (mutagenic, carcinogenic, and antitumour) as a result of the alkylation and carbamoylation of DNA as well as other cell components are presented. The identified chemical products of the interaction of ANU with DNA and its components are listed. The structural transformations of the DNA macromolecules as a consequence of their chemical modification are examined and the possible biological consequences of the modification of DNA by ANU are discussed. The bibliography includes 148 references.

I. INTRODUCTION

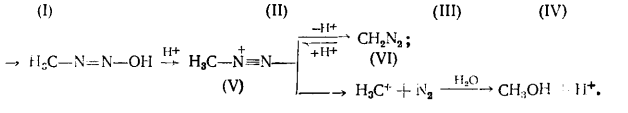
Alkylating compounds with a broad spectrum of biological activities have long attracted the attention of investigators. The knowledge of the mechanisms of the action of these compounds on the most important cell biopolymers will make possible their specific employment to achieve the desired effect. Among alkylating compounds, alkylnitrosoureas (ANU), which have been investigaged vigorously in recent years as chemical mutagens,[1-10] carcinogens,[11-17] and antitumour agents,[18-21] are of great interest.

Academician N.M.Emanuel' and his students have widely used for many years physicochemical and chemical kinetic methods in the study of many most important biological systems,[22-26] biochemical reactions,[27-29] and various pathological processes.[30-33] Their discovery of the antitumour properties of ANU and the introduction into clinical practice of *N*-methyl-*N*-nitrosourea (MNU) as a drug for the treatment of the undifferentiated cancer of the lung and lymphogranulomatosis[18] stimulated in recent years the wide-scale synthesis of new ANU derivatives and the study of the physicochemical properties and the molecular mechanism of the action of these compounds in order to discover ANU most effective in practical use.

One of the main (and perhaps most important) causes of the biological action of ANU may be reactions involving the interference with the functioning of the cell genome as a result of the modification of DNA due to the alkylation and carbamoylation of its macromolecule.

II. CHEMICAL AND PHYSICOCHEMICAL PROPERTIES OF ALKYLNITROSOUREAS

Certain reactions of ANU can be analysed in relation to one of the representatives of compounds of this class which have been investigated, namely MNU. It has been established that the ANU are readily hydrolysed in aqueous solutions and that the rate of hydrolysis changes significantly as a function of the composition of the medium, pH, temperature, and other factors. A general scheme for the actions of MNU in aqueous solution can be represented in the following manner:[34-41]



Under the influence of hydroxide ions, the proton is abstracted from the nitrogen atom of the MNU molecule (I) with formation of a urea anion (II), which is converted into the diazotate anion (III) and isocyanic acid (IV).

The first stage of the decomposition of MNU is in this instance rate-limiting and is of pseudofirst order. This serves as the basis for the method involving the titration of MNU with alkali,[37] which is used together with other chemical methods for the investigation of the kinetics of this reaction.[38,39] The anion (III) formed is converted into the methanediazonium cation (V) under the influence of protons. In a highly alkaline medium, diazomethane (VI), which is an alkylating agent, is formed.[40]

In a neutral medium, diazoalkanes are usually not formed and the methylating properties are in this instance due to the methanediazonium cation,[41] whose addition to nucleophiles is accompanied by the evolution of nitrogen. In an aqueous medium hydrolysis takes place with formation of methanol:

The rate of reaction of MNU in aqueous solution depends particularly on the pH of the solution and it has been established that in a Britton–Robinson buffer the half-life of MNU diminishes with increasing pH. The composition of the medium influences the reactions of MNU in aqueous solutions. In the presence of buffer mixtures (phosphate and phosphate-citrate buffers) an increase in the rate of reaction of MNU owing to the action of nucleophiles is observed.[42]

In an acid medium one of the products of the reaction of MNU is nitrous acid,[38,39] which is known to be capable of functioning

as a deaminating agent:[43]

$$\underset{\mathrm{CH_3}}{\mathrm{H_2NCONNO}} + \mathrm{H_2O} \xrightarrow{\mathrm{H^+}} \mathrm{HNO_2} + \underset{\mathrm{CH_3}}{\mathrm{H_2NCONH}}.$$

Thus, depending on the conditions, the reactions of MNU in various media can give rise to products of several types: diazomethane (pH > 7), and methanediazonium cation and isocyanic acid (pH ~ 7), and nitrous acid (pH < 7). In the reactions with nucleic acids and their components, these products can exhibit their characteristic properties and can modify the biomacromolecules.

Analysis of the chemical nature and electronic structure of MNU established that this compound possesses donor–acceptor properties, which may be responsible for the varied manifestations of the biological activity of MNU.

It has been demonstrated by quantum-chemical and EPR methods that the NO group in the MNU molecule can behave as an electron acceptor or donor.[44–46] When an electron is captured by the NO group, the following reactions can take place:

$$\mathrm{H_2NCON(CH_3)NO} + \bar{e} \rightarrow \mathrm{H_2NCON(CH_3)N\dot{O}} \rightarrow$$
$$\rightarrow \mathrm{H_2NCONH\dot{C}H_2} + \bar{N}O \rightarrow \mathrm{CH_2NH} + \dot{C}ONH_2 + \bar{N}O.$$

The radical $\dot{C}ONH_2$ can behave as a carbamoylating agent.

The electron-donating properties of MNU are due to the abstraction of an electron from the nitrogen atom of the NO group with formation of a radical-cation whose decomposition can apparently give rise to the following products:

$$\mathrm{H_2NCON(CH_3)NO} \xrightarrow{-\bar{e}} \mathrm{CH_3{-}N{=}N{-}O^{\cdot}} + [\mathrm{CONH_2}]^+ \rightarrow$$
$$\rightarrow \mathrm{CH_3{-}N{=}N{-}O^{\cdot}} + \mathrm{H^+} + \mathrm{HNCO} \rightarrow \mathrm{CH_3^+} + \mathrm{N_2} + {}^{\cdot}\mathrm{OH} + \mathrm{HNCO}.$$

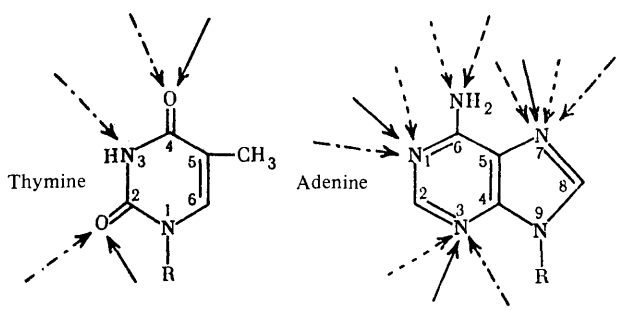
In this case the chemical reactivity of MNU is determined mainly by the radical $CH_3N = NO^{\cdot}$, whose interaction with biomacromolecules can lead to methylation. Carbamoylation takes place due to HNCO.

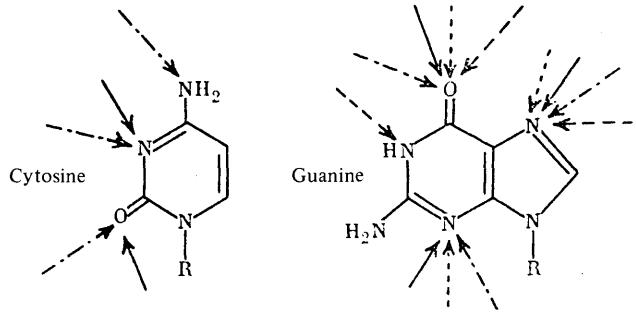
The radicals $\dot{C}ONH_2$, $CH_3{-}N = N\dot{O}$ and $H_2NCON(H)\dot{C}H_2$ have been detected by EPR in a frozen NMU solution under the conditions of the photosensitised electron transfer in the presence of an electron acceptor (donor).[45]

III. CHEMICAL PRODUCTS OF THE REACTIONS OF ALKYLNITROSOUREAS WITH DNA AND ITS COMPONENTS

In order to elucidate the molecular mechanism of the biological action of ANU, it is important to determine the principal sections of the biomacromolecules which may be modified by treatment with ANU. The first studies of the mechanism of the action of ANU derivatives were undertaken to investigate their alkylating properties.

The objects of study were nucleosides,[40,47] nucleotides,[48,49] polynucleotides,[50] and nucleic acids.[7] The observed sites where nucleic acid bases are alkylated can be represented schematically in the following manner (R represents the ribose or doxyribose residue):





The positions in which the bases are alkylated are indicated by arrows:
In nucleosides – – →
In nucleotides (polynucleotides) - - - →
In single-stranded DNA ——→
In double-stranded DNA –·–·→

The alkylation of triphosphate groups with formation of the monoethyl ATP ester (11% of the total amount of alkyl groups) has been demonstrated in model experiments with ATP and ethylnitrosourea (ENU).[49]

The possibility of alkylating DNA was first established in relation to the formation of 7-methylguanine in the reaction of DNA with MNU.[51] Later nine methylated derivatives were identified in an *in vitro* reaction of DNA with MNU: 1-methyladenosine, 3-methyladenine, 7-methyladenine, 3-methylguanine, 6-*O*-methyldeoxyguanosine, 7-methylguanine, 3-methyldeoxycytidine, 3-methylthymidine, and 4-*O*-methylthymidine. 3-Methyladenine (11.2% ^{14}C) and 7-methylguanine (75.7% ^{14}C) are formed in highest yields, while 4-*O*-methylthymidine (0.1% ^{14}C) is formed in the lowest yield. The amount of alkylated phosphate groups was 18% of the total radioactivity corresponding to DNA.[52,53]

It is noteworthy that, in those cases where MNU reacts with polynucleotides without a guanine residue, the contribution of the pathway involving the alkylation of phosphate groups increases sharply. For example, according to Shooter and Venitt,[54] the corresponding yield for the MNU-modified DNA is 18%, while according to other data, on treatment of polyadenylic acid with [$^{14}CH_3$]MNU, 23% of the yield is due to the alkylation of the bases and the remaining 77% is associated with the formation of phosphotriesters. The difference between the yields of the alkylated phosphate groups is frequently explained by the different experimental conditions and also by the instability of the products in alkaline media.[56]

The methyl and ethyl phosphotriesters are formed in DNA on treatment with the majority of alkylating carcinogens and are retained in it for a long time.[54,57] A dinucleotide containing alkylated phosphate groups has been isolated in the hydrolysis of DNA modified with MNU.[57]

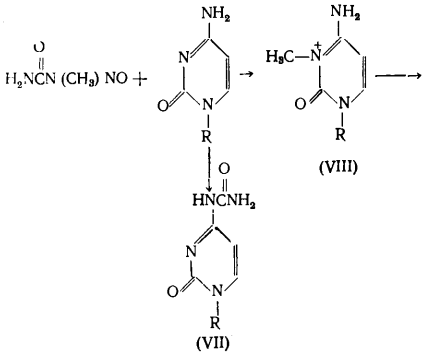
Comparative study of the reactivities of different alkylating compounds, namely dimethyl sulphate, diethyl sulphate, ENU, and MNU, in relation to the phosphodiester linkage in DNA established that the efficiency of the interaction was lowest for dimethyl sulphate and highest for MNU. This can apparently be explained by the fact that in the case of MNU and ENU the reaction intermediate is the alkanediazonium cation, which interacts electrostatically with DNA.[58]

The possibility of the carbamoylation of the DNA molecule in the reaction with MNU was first demonstrated[59] with the aid of tracer atoms. A DNA solution was treated for 72 h with MNU labelled at the carbonyl carbon atom with subsequent removal of the excess MNU (the ratio of the MNU and DNA phosphorus concentrations was 100 : 1).

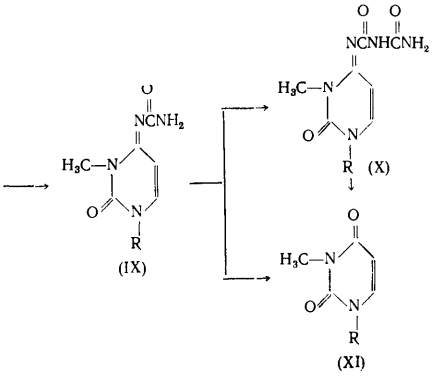
The hydrolysis of the modified [^{14}C]DNA to a depurinated acid with subsequent separation of the reaction products on ECTEOLA-cellulose demonstrated the presence of the label

in the depurinated fragment. It was suggested that the label is located in the phosphate fragment of DNA and (or) in cytosine.

Parallel experiments with nucleosides, polynucleotides, RNA, and DNA [60-67] confirmed the possibility of the carbamoylation of the NH_2 group of cytosine. The overall scheme for the reaction of MNU with cytidine[60,61] can be represented as follows:



(VII)



(IX) (X) (XI)

where R = ribose residue, (VII) = 4-*N*-carbamoylcytidine, (VIII) = 3-methylcytidine, (IX) = 3-methyl-4-*N*-carbamoylcytidine, (X) = 3-methyl-4-*N*-dicarbamoylcytidine, and (XI) = 3-methyluridine. Evidently the reaction of cytidine with MNU proceeds via two pathways—either via only carbamoylation to form compound (VII) or via alkylation with subsequent carbamoylation to form compounds (VIII), (IX), and (X). The carbamoylation products are readily hydrolysed with formation of compound (XI). On reaction with MNU, adenosine and guanosine give rise to carbamoylation products: 6-*N*-carbamoyladenosine, 1-methyl-6-*N*-carbamoyladenosine, and 2-*N*-carbamoylguanosine.[62]

The chloroalkyl derivatives of nitrosoureas have also been widely investigated.[68-71] Like MNU, these compounds decompose with formation of diazohydroxides, which alkylate the bases and phosphate groups of nucleic acid, and also isocyanates, which carbamoylate proteins, enzymes, and lipids.[72] Products of the interaction of ANU with nucleosides and DNA bases such as 7-chloroethylguanine (XII), 7-hydroxyethylguanine (XIII), 1,2-diguanylethane (XIV), 3-chloroethylcytosine (XV), and others have been identified.[73-76]

It has been established that the formation of DNA–protein and DNA–DNA cross-links, which have a significant influence on the cell metabolism, is possible in the reactions of chromatin with halogenoethylnitrosoureas:[71,76]

IV. STRUCTURAL CHANGES IN DNA MODIFIED WITH ALKYLNITROSOUREAS

The chemical modification of DNA (alkylation, carbamoylation, etc.) can lead to significant changes in the DNA structure. Some of the damage can be made good by the operation of enzymes in the repair system. The irreparable structural defects alter the normal functioning of the cell genome.

The structural changes in the DNA molecule (single- and double-strand breaks, etc.) have been observed *in vitro* and *in vivo* by many investigators when DNA was treated with the usual alkylating compounds.[77-79] Alkylation of the bases can lead to the degradation of the DNA chains as a result of the removal of the purine, which leads to the rupture of the sugar–phosphate linkages in the molecule as a result of consecutive transformations in the DNA chain.[80-82] The alkylated phosphate groups of DNA (phosphotriesters) are formed on treatment with the majority of alkylating compounds. They are unstable in an alkaline medium, but their thermal stability is fairly high.[83]

In order to detect the chemical modification of DNA, one may use infrared (IR) spectroscopy, the application of which to nucleic acids and their components has been widely discussed in reviews and monographs.[84-87] It has been established that the IR spectra of films of DNA modified with MNU reveal a change in the intensities of a number of bands, although, overall, the form of the spectrum is altered only slightly.[30,88] Fig.1 illustrates the change in the intensities of a number of IR bands of DNA as a function of the time of its interaction with MNU. Evidently, the light absorption by a number of groups and bonds in DNA (with amino-groups and conjugated double bonds of the bases as well as the sugar–phosphate linkages) diminishes during the reaction, which shows that, in the course of the first 3 h of the reaction of MNU with DNA, there is a possibility of deamination, and the rupture of the double bonds of the bases and of the DNA chains, most probably as a consequence of the methylation and carbamoylation of the bases.

Combination of various methods of physicochemical and biochemical analysis[88-95] made it possible to identify and estimate quantitatively the principal types of the structural defects in DNA occurring under the influence of MNU. The numerical parameters defining the overall damage to the macromolecular structure [determined by the viscometric method after the thermal denaturation of DNA (10.4 ± 1.0) and by the kinetic formaldehyde method (the KF method)[88] (11.0 ± 1.0)] agree well with one another. The application of the methods involving neutral and alkaline electrophoresis in agarose gels and the enzymic treatment of the modified DNA with endonuclease S_1,[92,96] which is specific to the single-stranded sections of DNA,[93,94] made it possible to determine the ratios of the numbers of double-strand breaks (DB), single-strand breaks (SB), the alkali-labile sections (ALS), and the thermolabile sections (TLS).[89]

Data obtained by pulse polarography are consistent with the above finding.[91] It has been shown that a much greater number of SB are formed in DNA treated with MNU after thermal denaturation than after brief treatment with alkali.

The thermolabile sections apparently contain alkylated nucleotides, whose glycosidic and phosphoester linkages are weakened on raising the temperature.[97]

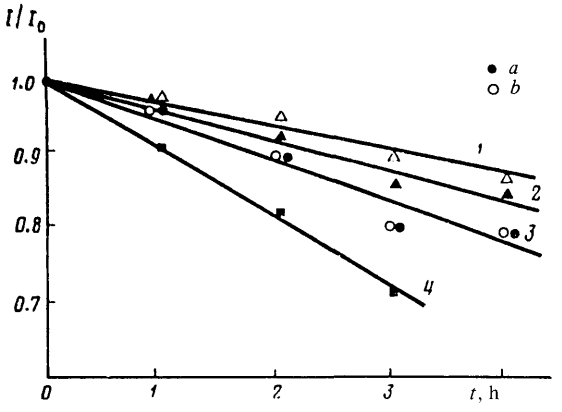

Figure 1. Dependence of the ratios of the intensities of a number of infrared bands of the modified DNA to the intensities of the infrared bands of native DNA on the duration of the interaction between DNA and MNU: 1) 960 cm^{-1} (vibrations of the sugar–phosphate linkages); 2) 1605 cm^{-1} (vibrations of the amino-groups of the bases); 3) 3350 cm^{-1} (*a*) and 3200 cm^{-1} (*b*) (vibrations of the amino-groups of the bases); 4) 1580 cm^{-1} (vibrations of the conjugated double bonds of the bases).[30]

The overall damage to the hydrogen bonds in the modified DNA can be estimated by two independent methods: from the decrease of the "melting" point on DNA T_m (the temperature of the transition of DNA from the helical to the disordered structure corresponding to the point of inflection on the curve relating the optical densities of the DNA solutions to temperature) and from the amount of the acid-soluble fragments (ASF) leached by nuclease S_1 from the modified DNA.[90]

Fig. 2*a* presents curves relating the optical densities of the DNA solutions to temperature for the control DNA (curve *1*) and after treatment with MNU for 4 h (curve *2*) and 16 h (curve *3*). Evidently T_m decreases during the reaction of DNA with MNU, which indicates an increase of the number of damaged hydrogen bonds in the modified DNA. This is also indicated by the increase of the amount ASF (Fig. 2*b*, curve *1*) in the reaction of DNA with MNU. The parallel increase of the relative amount of ASF with increasing difference between the T_m for DNA before and after its interaction with MNU (δT_m) (Fig. 2*b*, curve *2*) indicates a correspondence between the overall amount of sections with damaged pairing of the bases (which are converted by nuclease S_1 into the acid-soluble fraction) and the decrease of T_m, the quantitative relation (a decrease of T_m by 1° corresponds on average to 1% of damaged hydrogen bonds) being consistent with the data of Pritchard and Eichinger.[98]

It is noteworthy that the number of damaged hydrogen bonds is always greater than the number of alkylated bases and breaks produced. Thus, after 1 h of the reaction between MNU and DNA, the total damage to hydrogen bonds amounts to 2.5%,[90] while according to other data[53,99] the amount of alkylated DNA bases produced during the same period under identical conditions is 0.2–0.5%. Taking into account these data, the occurrence of the observed damage can be represented as follows.[100] Alkylation of different bases in the DNA molecule leads to the rupture of hydrogen bonds. The subsequent formation of depurinated sections also damages the hydrogen bonds. This leads to the formation of SB, which, as a result of statistical accumulation, can give rise to DB when they are close to one another. This pathway to the formation of SB can be accelerated by treating the modified DNA with alkali or by heating. According to Verly at al.,[95] 90 min heating at 100 °C is sufficient for the virtually complete removal of alkylated purines.

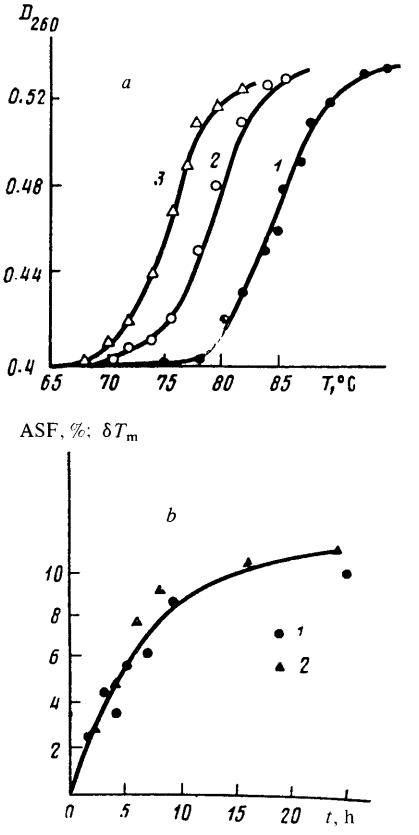

Figure 2. Melting curves relating the optical densities of the DNA solutions to temperature: 1) for native DNA; 2) after reaction with MNU for 4 h; 3) after reaction with MNU for 16 h; b) kinetic curves for the increase of the percentage content of the acid soluble fragments (ASF, curve *1*) and of the difference between the T_m of DNA before and after interaction with MNU (δT_m, curve *2*) in the reaction of DNA with MNU.[90]

The amount of sections where DNA has lost its helical structure as a result of alkylation (and other modifications) can be determined by the KF method,[101,102] which is based on the interaction of formaldehyde with the amino- and imino-groups of the DNA bases (not involved in the formation of hydrogen bonds) at temperatures below the "melting" point of DNA. This method has been used successfully to

observe the defects in the secondary DNA structure caused by the action of nucleases,[103] ionising radiation,[104] and thermal denaturation[105] and also to discover defects in the secondary structure of DNA in tumour cells.[106–108] The employment of the KF method for the analysis of the defects in the secondary structure of DNA produced in the reaction with MNU established that sections in which the DNA locally loses its helical structure are formed in the modified DNA and that their number agrees well with the number of SB determined by other methods.[89]

It has been established that the reaction of MNU with the tumour cell DNA is rapid[88,89] owing to the presence of sections in which the tumour cell DNA has locally lost its helical structure.[106–108]

V. BIOLOGICAL CONSEQUENCES OF THE CHEMICAL MODIFICATION OF DNA

The majority of the alkylated products detected in the reaction of DNA with MNU under *in vitro* conditions are also found under *in vivo* conditions.[109–111] As shown above, the main bulk of the alkylated products (up to 80% of the total amount) consists of 7-alkylguanine; adenine, guanine, cytosine, and thymine derivatives have also been detected. However, from the standpoint of mutagenesis and carcinogenesis, the greatest interest attaches to 6-*O*-alkylguanine and other oxygen-alkylated products.[110,112–114] In the course of the reactions of the alkylated products *in vitro* and *in vivo*, various intermediates can be produced, which alters significantly the mutagenic and carcinogenic activities of ANU and this must be taken into account when ANU are employed in experiments on living systems.[115,116] Mutations due to the alkylation of the DNA bases can arise as a result of erroneous base pairing. For example, when 6-*O*-alkylguanine is formed, the latter can pair with thymine (whereas under normal conditions thymine forms an A–T pair with adenine).[7,9,117–119]

As a result of the development of new methods for the identification of alkylated products, in recent years it has become possible to analyse the relation between the formation of these products and various manifestations of their biological properties.[120,121] A relation between the ability to alkylate guanine at the oxygen atom attached to the C(6) atom and the carcinogenic activity of the compounds has been established for many alkylating compounds;[122] however, the relation between the overall degree of alkylation and the carcinogenic activity was weak or almost altogether absent.[123] Alkylating agents [*N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (NG) and methyl methanesulphonate (MMS)] produce similar types of damage in DNA. When a combination of NG and MMS was used to investigate the different types of damage leading to mutations, transformation, and toxicity, it was shown that the frequency of mutations is correlated with the number of methylated adducts of 6-*O*-alkylguanines, but the cytotoxicity is not correlated either with the number of individual adducts or with the total level of alkylation of DNA (NG is more than 100 times more toxic than MMS).[124]

Comparison of the carcinogenic activities of the alkylating compounds (*N*-methyl-*N*-nitrosourethane, MNU, ENU, NG, MMS, etc.) in experiments on rodents with the mutagenic effects of these substances on bacteria established that the alkylating activity is fully correlated with the mutagenic effect but there is no correlation between each of these effects and the carcinogenic activity. A relation has been observed between the initial ratio of the 7-*N*- and 6-*O*-alkylguanines formed as a result of the reaction of the alkylating compound with DNA *in vitro* and its carcinogenic activity *in vivo*. This is evidence that the alkylation of guanine in the 6-*O*-position plays a key role in damaging DNA and is responsible for the experimentally observed carcinogenic activity of the alkylating compounds.[4,114]

The malignant transformation of cells depends on the duration of the existence of the modified base in DNA, which in the case of 6-*O*-methylguanine proved to be longest for brain cells, which are the most sensitive to MNU. On the other hand, its removal from the liver DNA is much faster and liver proved to be resistant to the malignancy-inducing activity of MNU.[125–127] Thus alkylation of DNA may be one of the principal reactions in carcinogenesis and in the mutagenic action of chemical compounds, which themselves (or their reaction products) can add to the nucleophilic centres of DNA.[128,129]

The carbamoylation reaction, which is characteristic of ANU, makes it possible in many instances to account for the high mutagenic and antitumour effects of such compounds by the formation of carbamoyl derivatives. Thus, mutations can occur due to the products of the carbamoylation of the bases by isocyanic acid, since it has been shown that when many plants are treated with its salt (potassium isocyanate), mutant forms are obtained.[130] However, one should note that a clear-cut correlation has not been observed between the degree of carbamoylation of nucleic acids and the antitumour activity of ANU, although such correlation has been traced between the alkylating activity (for the same degree of carbamoylation) and the antitumour activity.[131]

It has been shown that the carbamoylation reactions can significantly inhibit the cell repair processes. The enzymes involved in the repair and replication of DNA can be inactivated as a result of carbamoylation by the isocyanates arising during the reaction with ANU.[70,71,132]

The protein carbamoylation reaction has assumed a definite importance as one of the possible explanations of the antitumour properties of ANU.[133,134]

The manifestation of the biological activity of ANU can be influenced significantly by the reactions of the alkylated products involving damage to the structural integrity of DNA (SB, DB, ALS, and TLS) and of the carbamoylated products (modification of proteins) and also by the formation of DNA–protein and DNA–DNA cross-links which have been detected with mammalian cells were treated with chloro-derivatives of ANU.[135,136] Experiments with bacterial cells established a correlation between the number of DB induced in DNA by MNU and the survival rate of the cells.[137] The destruction of cells under the influence of ANU may be also caused by the formation of a considerable amount of ALS, as happens when cells are exposed to ionising radiation.[138]

In many instances a definite relation has been discovered *in vivo* between the induction of breaks in DNA and the carcinogenic activity for a specific class of substances. However, one should bear in mind that single-strand breaks in cell DNA can arise additionally owing to the action of excision reparation enzymes, which are capable, for example, of excising 3-alkyladenine and 6-*O*-methylguanine with formation of a depurinated section, which subsequently gives rise to SB.[131,139]

The alkylation and carbamoylation reactions, accompanied by a significant damage to the DNA structure, can alter the template properties of the latter which are responsible for the replication and transcription process.[140]

A very sensitive test of the template properties of the modified DNA may be provided by RNA polymerase systems of purified nuclei and with a soluble RNA polymerase.[141–143] The interference with the synthesis of RNA using as a template DNA modified with MNU has been investigated.[144,145] The template activity was determined from the amount of

[^{14}C]CMP in the RNA produced relative to the control (Fig.3, curve *1*). The control consisted of a system with untreated DNA. Evidently, even during the first hours of the reaction, the template activity diminishes exponentially. The extent of the disturbance of the template activity was greater the longer was the reaction between MNU and DNA. After 10 h, there is virtually no synthesis of RNA. Comparison of these results with the appearance of SB and DB in the DNA molecule under the influence of MNU (Fig.3, curves *2* and *3*) demonstrates a greater sensitivity of the RNA polymerase system to the damage sustained by the DNA structure than is shown by other methods. The cessation of template synthesis after 10 h indicates a significant damage to the DNA template, leading to the inhibition of transcription.

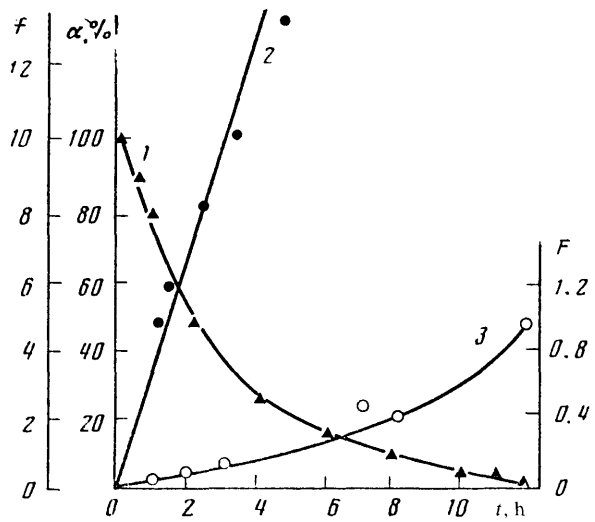

Figure 3. Variation of the template activity of DNA in the RNA polymerase system (curve *1*) {determined from the degree of incorporation α of [^{14}C]CMP in the RNA produced} and of the numbers of SB (*f*, curve *2*) and DB (*F*, curve *3*) as a function of the duration of the interaction of DNA with MNU.[143]

The change in the template properties of chromatin under the influence of MNU and the chloroethyl derivatives of nitrosoureas has been established[146] and in many instances the degree of inhibition of the template activity was found to be correlated with the antitumour effect of the ANU.

It has been established that ANU exhibit an antitumour activity with respect to malignant neoplasts of different origin and those induced by carcinogens in animals. However, the question of which of the DNA modification reactions is decisive in the manifestation of the antitumour activity of ANU is at present still obscure. It is assumed that the greater degree of inhibition of the DNA synthesis in tumour cells plays a significant role in this process owing to the decrease of the template activity of chromatin (as a result of alkylation and carbamoylation) and also the inhibition of the tumour cell reparation processes (resulting from the carbamoylation of the enzymes).[70] One cannot rule out the possibility that the selectivity of the action of ANU on tumour cells is based on their reactions with DNA whose structure differs from the DNA of the normal cells by the presence of sections in which the molecules have locally lost their helical structure,[106-108], which is responsible for the greater sensitivity of the tumour DNA to the action of chemical[100,147] and physical[148] agents.

Thus analysis of the possible ways of modifying DNA by alkylating compounds, particularly by ANU, makes it possible to relate the observed biological effects to different types of damage to the primary and secondary DNA structures and also to estimate the possibility of the specific synthesis and application of new biologically active preparations.

The Peroxide Oxidation of Membrane Lipids and Natural Antioxidants

E.B.Burlakova and N.G.Khrapova

The ways in which membrane lipids are oxidised are considered and the initiating and protective systems influencing the rate of this process are classified. The regulatory role of the interrelation between the composition of the membrane lipids and the degree of their oxidation, which makes it possible to regard this process as a procedure for the rapid renewal of the composition of the lipids and the alteration of the functional activity of membranes, is discussed. The kinetic characteristics of natural antioxidants as radical process inhibitors are presented and the characteristic features of their activity are deduced. They are discussed in terms of their involvement in the regulation of the peroxide oxidation of lipids.
The bibliography includes 119 references.

IV. Natural antioxidants 911

I. INTRODUCTION

The research into the peroxide oxidation of lipids (POL) in the USSR was initiated by studies carried out in 1954–1956 in Moscow State University and at the Institute of Chemical Physics at the USSR Academy of Sciences, which have been recognised as giving priority in this field to the Soviet Union.[1,2]

At the present time this field has been developing successfully not only in the USSR but also abroad. It is not fortuitous that so much attention has been devoted to the question of the biological significance of the oxidative processes occurring in membrane lipids. It has been established that the accumulation of the lipid oxidation products in membranes alters the structure of the latter and their functional activity. Lipid peroxides, which are the primary and labile lipid oxidation products, have attracted most attention by investigators.

The peroxide oxidation of lipids has been regarded for a fairly long time by many investigators as an undesirable process, which is actually harmful for the organism. This was promoted by the establishment of the following facts: (1) peroxides have been detected most frequently in the organs of animals following the development of various pathological conditions; (2) it has been shown in many studies that the administration of oxidised lipids to animals is toxic for the organism;[3,4] (3) the appearance of peroxy-groups in the aliphatic acid residues of membrane phospholipids alters the properties of the latter such as permeability and the stability of the lipid–protein complexes and induces the inactivation of enzymes.[5-11]

Questions associated with the role of natural antioxidants in the regulation of the peroxide oxidation of lipids are examined in this review.

II. SYSTEMS REGULATING THE RATE OF THE PEROXIDE OXIDATION OF MEMBRANE LIPIDS

The discovery in 1963[12] of two pathways leading to the peroxide oxidation of lipids, namely enzymic and non-enzymic, and the vigorous investigation of these processes in recent years have altered somewhat the assessment of the biological role of peroxides.

Many factors proved to be important for the establishment of the hypothesis of a significant role of peroxide oxidation for normal metabolism.

1. The improvement and increase of the sensitivity of methods for the determination of peroxides made it possible to detect them in many organs and tissues of intact animals.

2. Enzyme systems regulating both the rate of formation of peroxides and the rate of their utilisation have been discovered and investigated.[13-18] This means that peroxide formation and utilisation processes are characteristic of norma metabolising cells and the amount of peroxide in the membrane must be maintained at a specific stationary level.

3. Careful investigation of the toxicity of oxidised lipids showed that not so much the peroxides as the products of the more far-reaching oxidation of lipids, namely aldehydes, ketones, and acids, are toxic for the organism.[19]

4. It has been shown that lipid peroxides are intermediates employed by the organism for the synthesis of biologically active substances: prostaglandins, thromboxanes, steroid hormones, etc.[20-23] and they cannot therefore be regarded as undesirable side products of the oxidation process.

The synthesis of these substances in the organism from unsaturated aliphatic acids is achieved in several stages via the formation of short-lived labile endoperoxides under the influence of specific enzymes. For example, the cyclisation of arachidonic acid entails the formation of endoperoxides (the prostaglandins G_2 and H_2), which are transformed into the prostaglandins E_2, D_2, and $F_{2\alpha}$. When the thromboxane synthetase, localised in the membranes of thrombocyte microsomes, acts on the endoperoxides in this case, the thromboxanes A_2 and B_2—substances with pronounced adhesive properties, are formed. When the endoperoxides are acted upon by the enzymes of the microsomal fraction of the arteria vessels, the biosynthesis is switched towards the formation of prostacyclin—a substance which possesses antiadhesive and deaggregating activity, several tens of times superior to the antithrombic activity of prostaglandins.[20] Consequently, depending on which enzyme system is involved in biosynthesis, biologically active substances with different,

sometimes directly opposed, properties are formed from the same precursor—the endoperoxide of arachidonic acid. Peroxides are a universal raw material which is employed by the organism for a wide variety of purposes.

5. The peroxide oxidation of lipids is interrelated with the processes involving the renewal of the composition of the membrane phospholipids. It has been shown that an increase in the peroxide oxidation of lipids accelerates the metabolism of phospholipids, alters their relative composition, alters the lipid–protein ratios, and hence alters the structure of the membrane.[24–27]

The interrelation between the rate of the peroxide oxidation of lipids and the change in the composition of lipids is based on the acceleration of the release of phospholipids from membranes with increase of the rate of peroxide oxidation. In model experiments with isolated membranes a decrease of the phospholipid/protein ratio was observed after the induction of peroxide oxidation and a decrease of the relative amount of the readily oxidisable phospholipids such as phosphatidylethanolamine, phosphatidylserine, cardiolipin, and phosphatidylinositol. Acceleration of the "flip-flop" and the passive transfer of lipids has been demonstrated.[28,29] On the other hand, the data concerning active transport with the aid of lipid-transferring proteins are extremely contradictory. Thus it has been observed[29] that the induction of peroxide oxidation does not influence or even suppresses the transfer of phosphatidylcholine between membranes by the lipid-transferring protein.

Data concerning the role of the fluidity of lipid membranes in the activity of lipid-transferring proteins have been published.[30,31] It has been shown that a rigid state of the lipid-donor membrane is the most favourable for the operation of the lipid-transferring proteins. Since lipid peroxides increase the microviscosity of the lipid double layer in membranes,[32] they can thus increase the activity of the lipid-transferring proteins and the rate of release of lipids from the membrane.

One should bear in mind also the acceleration of the cleavage of the oxidised phospholipids with the aid of phospholipases compared with the unoxidised phospholipids.[33] Experiments *in vivo* showed in all the cases investigated that an increase in the peroxide oxidation enriches the lipid membranes in fractions more resistant to oxidation (phosphatidylcholine, sphinogomyelin, and cholesterol).[34–36] The results, which are treated from the standpoint of the alteration of the rate of catabolism of the phospholipids, have been confirmed by the alteration of the turnover times of the membrane lipids. This has been effectively demonstrated for irradiated plant cells.[36,37]

Calculations have shown that the turnover times for readily oxidisable phospholipids are satisfactorily consistent with the rate of their peroxide oxidation, which makes it possible to regard the peroxide oxidation of lipids as one of the important factors responsible for the renewal of the membrane lipids.

Numerous studies demonstrating the lipid-dependence of the membrane proteins, namely enzymes, receptors, channel-forming agents, translocators, etc., have been published recently. The change in the composition of lipids induced by the change in the rate of peroxide oxidation therefore alters also the activity of these membrane proteins.

6. It has been shown that the lipid peroxides themselves can both activate and inhibit the activity of enzymes[38–40] and can also play the role of allosteric effectors. The interactions of lipid peroxides with the catalytic and allosteric centres of proteins justify the differentiation from the lipid-dependent enzymes of a separate group of peroxylipid-dependent enzymes.[38,41,42]

An important factor in the action of lipid peroxides on enzymes is the possibility that they may transform the enzyme activity.[41]

Thus all these data support the view that the peroxide oxidation of lipids should be regarded as a physiological process and the lipid peroxides as the products of the metabolism of the normal metabolising cells. The low level of lipid peroxides characteristic of normal tissues by no means implies that peroxide oxidation does not occur in such tissues and can be explained by the fact that the processes involving the formation and consumption of peroxides are well balanced and that lipids are oxidised at a specific stationary level.[43]

On development of pathological states, such balance can be disturbed, the peroxides formed accumulate in the tissues and lead to serious damage to the bio-membranes.

We shall consider how a stationary lipid oxidation level is maintained in membranes. The oxidation of membrane lipids is a complex multistage process with its own characteristic features determined primarily by the involvement in the oxidation reaction of a number of enzymes, the structural organisation of the lipid double layer in the membranes, the high degree of unsaturation of the aliphatic acids forming part of the composition of the phospholipids, the multicomponent composition of the lipids, and the presence in the latter of substances capable of intensifying or weakening the effect of natural antioxidants and initiating oxidation.

It is noteworthy that only the enzymic pathway to the peroxide oxidation of lipids is at present recognised as a normal physiological process. The non-enzymic pathway to the autoxidation of lipids is still regarded by many investigators as an uncontrolled process, which is therefore abnormal. We believe that this view is incorrect.

The autoxidation of lipids is a special case of the liquid-phase oxidation of hydrocarbons whose theoretical principles have been examined in detail by Emanuel's school[44–49] and which constitutes a typical chain process with degenerate branching. A distinctive feature of such processes is an extremely high sensitivity to very slight changes in the composition and proportions of the components of the oxidation reaction and in the concentrations of various additives which can play the role of oxidation inhibitors or activators. These properties are in fact important for processes involved in the regulation of the functional activity of membranes. In contrast to oxidation *in vitro*, the rate of which can be varied appreciably within wide limits by altering the temperature, composition, and the component ratios, in membranes such changes are possible only within very restricted limits. Only processes whose rate depend significantly on slight changes in the composition of the components can therefore fulfill a regulatory function. Such requirements are met most fully by degenerate-branched chain oxidation processes. The non-enzymic oxidation of lipids can therefore hardly be regarded as an avalanche-like uncontrollable process. The question whether non-enzymic oxidation can take place in the lipid double layer in membranes in which the aliphatic acid residues of the phospholipids have a structural organisation is still controversial. However, the recognition of a mosaic structure of membranes with "lipid seas" permits the assumption that all the conditions necessary for the homogeneous liquid-phase oxidation are fulfilled in the oxidation of lipids.

The properties of lipids as oxidation substrates to some extent resemble those of polymers by virtue of the high degree of structural organisation in the lipid double layer in membranes. It has been shown that the characteristics deduced for the liquid-phase oxidation of organic substances can be legitimately applied to the low-temperature oxidation of polymers.[50] On this basis, one can assume that all the

features of the oxidation of lipids established in model systems will be manifested also in the oxidation of membrane lipids, although undoubtedly the structure of biological membranes should exert a significant influence on the intensity of this process.

Thus one may postulate that the oxidation of lipids in membranes can also take place via a non-enzymic mechanism. The question arises whether it is necessary to draw a sharp boundary between these two lipid oxidation pathways. It is noteworthy that the two lipid oxidation pathways have much in common, although they differ as regards the mode of initiation and the set of intermediate and final oxidation products.

In both cases the oxidation of lipids proceeds via a stage involving the formation of lipid free radicals which are fairly active and long-lived. The rate of oxidation depends significantly on the composition of the membrane phospholipids, especially on the number of double bonds in the unsaturated aliphatic acids (UAA), on the degree of structure formation in the lipid phase of the membrane, and on the presence of inhibitors, activators, and other substances which are highly effective even at low concentrations. In all probability the oxidation pathways at different stages can merge. Thus the active forms of oxygen produced enzymically can initiate the non-enzymic oxidation.[51-53] On the other hand, glutathione peroxidase decomposes lipid peroxides regardless of the pathway (enzymic or otherwise) which led to their formation.[54-57]

Regardless of whether the lipids are oxidised non-enzymically or with participation of enzymes, the following principal elementary stages in the development of this process must be considered: initiation, propagation, branching, and termination of the oxidation chains (Scheme 1):[44-49]

Scheme 1

$$\left.\begin{array}{l} RH \xrightarrow{k_1} R^{\cdot} \\ R^{\cdot} + O_2 \xrightarrow{k_2} RO_2^{\cdot} \end{array}\right\} \text{chain initiation;} \quad (0), (1)$$

$$RO_2^{\cdot} + RH \xrightarrow{k_3} ROOH + R^{\cdot} \quad \text{chain propagation;} \quad (2)$$

$$ROOH \xrightarrow{k_4} RO^{\cdot} + HO^{\cdot} \quad \text{chain branching} \quad (3)$$

$$\left.\begin{array}{l} R^{\cdot} + R \xrightarrow{k_5} \text{molecular products} \\ RO_2^{\cdot} + R^{\cdot} \xrightarrow{k_6} \text{molecular products} \\ RO_2^{\cdot} + RO_2^{\cdot} \xrightarrow{k_7} \text{molecular products} \end{array}\right\} \text{chain termination;} \quad (4), (5), (6)$$

RH = oxidation substrate.

The overall rate of oxidation of membrane lipids is determined by the ratios of the rates of each of these stages. A change in the rate of any oxidation stage leads to the breakdown of the steady-state nature of the process, to a change in the overall rate of oxidation, and to the accumulation of lipid peroxides in membranes, which can in its turn entail the appearance of states which are not characteristic of the normal cell. We believe that there exist several initiating and protective systems in the cell which alter the rate of oxidation of lipids and which can be regarded as regulatory. These systems can be divided into four groups.[43]

System I is responsible for a rigorously defined structural organisation of lipids and thus influences the rate of the chain initiation, propagation, and termination reactions.

System II comprises enzymes responsible for the formation and destruction of the active forms of oxygen and free radicals initiating the oxidation process and the enzymes participating in the decomposition of peroxides without the formation of free radicals from the latter.

System III regulates the metabolism of the membrane phospholipids and influences the rate of oxidation by altering the composition of the phospholipid UAA, the ratios lipid/protein, phospholipids/cholesterol, etc.

System IV comprises low-molecular-weight substances which fulfill the role of initiators, catalysts, inhibitors, quenching agents, synergistic agents, etc. and which influence the chain branching and termination stages.

It is already possible to state that the operations of these systems are inter-related and that the principal role cannot be attributed to any of them: each system operates within rigorously specified limits and in different cases the dominant and rate-limiting reactions change. It is therefore undesirable to speak of the first or second line of defence, as has been done in Fridovich's studies.[14,17,18]

We shall consider briefly the operation of these systems in different stages of the oxidation process.

The Chain Initiation and Propagation Stage. The steady-state concentration of lipid peroxy-radicals is determined by the composition of the lipid UAA (the strength of the double bonds), the concentrations of substances capable of rupturing the double bonds, and the rate of destruction of lipid peroxy-radicals. It is now known that several types of free radicals, differing both in the way they are formed and in their activity, exist in the cell. We shall not consider the primary mechanism of the generation of free radicals in membranes, because a whole series of reviews have been devoted to these questions.[18,51,57,58] We shall only note that, regardless of the nature of the free radicals formed, on the basis of the principle of the indestructibility of the free valence, they are exchanged for the lipid peroxy-radicals and the rate of this exchange is fairly high. An increase in the concentration of the lipid peroxy-radicals in membranes leads to an increase of the overall rate of oxidation, which is proportional to their concentration. It must be specially emphasised that we are considering only short-lived lipid peroxy-radicals. A change in the concentration of lipid peroxy-radicals, their additional formation or destruction caused by a change in the rate of operation of particular systems, leads to a change in the steady-state nature of the process.

Systems influencing the conditions governing the formation of active radicals in membrane lipids will therefore alter also the overall rate of oxidation. In all probability, the structural organisation of membrane lipids (system I), which influences the accessibility of the membrane phospholipid UAA to the action of oxygen, plays a decisive role in this instance. The closer the packing of the UAA in the membrane phospholipids, the smaller their accessibility to O_2 or singlet oxygen (O_2^*), and the lower the rate of initiation of free radicals. Any agents which interfere with the packing of the UAA (for example, chaotropic agents) accelerate the oxidation of lipids. Factors which maintain the membrane lipid structure inhibit oxidation.

Substances capable of deactivating O_2^* (singlet oxygen quenching agents) also alter the rate of initiation and inhibit the overall rate of oxidation (System IV).

A change in the activity of the enzymes involved in the formation or destruction of free radicals and the active forms of oxygen (system II) also exerts a major influence on the overall rate of oxidation of lipids. The activity of such enzymes depends on the degree of structural organisation in the lipid double layer in the membranes.

Indeed, it has been shown, for example, that the activity of the enzymes responsible for the formation of peroxy-radicals requires the lipids be in a liquid state, an increase in viscosity resulting in the inhibition of these enzymes.[56,59]

At the same time, in the non-enzymic generation of free radicals, the rate of initiation is also greatly influenced by a change in the viscosity of the lipid component. The liberation of radicals from the cage is significantly inhibited with increase of the viscosity.[60,61]

Attention should be drawn to the fact that in a normal metabolising cell, whose membranes have not been significantly changed, the degree of structural organisation in the lipids in all probability changes within restricted limits. When the peroxide oxidation of lipids in membranes is modelled by *in vitro* experiments, the structural organisation in the lipid double layer is disturbed. Therefore, the quantitative characteristics obtained in such model systems can be transferred, but with some caution, to the *in vivo* oxidation of lipids, the degree of structural organisation of which has a decisive influence on the rate of their oxidation.

Certain vitamins with long-chain side groups (system IV) are able to stabilise membrane lipids by improving the structural organisation of the lipid double layer. Recently the hypothesis of a structural interaction of tocopherols with components of biological membranes has gained wide currency.[62-64] According to the concept of these authors, the tocopherol molecule stabilises the membrane as a result of the specific interaction between its phytyl side group and the aliphatic acid chains of the membrane phospholipids. This model presupposes the interaction between the methyl groups of the side chains in tocopherols and the *cis*-double bonds of the UAA in such a way that the CH_3 group at the C(4) and C(8) atoms of the tocopherol side chain enters the "pockets" formed by the double bonds of the UAA residues of the phospholipids. The interaction takes place via van der Waals forces and increases the packing density of the membrane phospholipids, which hinders the penetration of oxygen to the UAA double bonds and the formation of lipid peroxy-radicals and entails a decrease of the overall rate of oxidation.

Vitamins with a different structure, which give rise to intermediate radical species in the oxidation reactions (vitamins A, C, D, and F) at certain concentrations, can play the role of initiators and can accelerate the oxidation of lipids by increasing the rate of formation of free radicals.[13,65-68] Variable valence metal ions, particularly the Fe^{2+} and Cu^{2+} ions[7,9,69] (system IV) can play a similar role of initiators. The rate of propagation of the oxidation chain depends significantly on the composition of the UAA of the phospholipids and on the degree of their saturation. For this reason, the changes in the metabolic rate of phospholipids and in the rate of their emergence from the membranes alter also the overall rate of oxidation (system III).

Thus the overall rate of oxidation of lipids at the chain initiation and propagation stages depends on all four systems: on the change in the structural organisation of the membrane lipids (system I and IV); on the activity of the enzyme system involved in the formation and destruction of free radicals and active forms of oxygen (system II); on the presence of singlet oxygen quenching agents (system IV); on the composition of the phospholipid UAA (system III); on the presence in the lipid of substances playing the role of oxidation initiators (system IV).

The Chain Branching Stage. The primary products of the oxidation of lipids are hydroperoxides, which are fairly labile and are capable of spontaneous decomposition into free radicals, which makes it possible to regard the oxidation of lipids as a degenerate-branched chain process. The rate of the chain branching reaction is determined both by the stability of the hydroperoxides formed and their amount. The stability of the hydroperoxides depends in its turn primarily on the structure of the UAA. The factors which alter the aliphatic acid composition of the membrane phospholipids (system III) therefore alter not only the susceptibility of these lipids to oxidation but also the stability of the hydroperoxides formed. The steady-state amount of peroxides in the lipid double layer depends both on the rate of their formation and on the rate of their release from the membranes.

Enzymes utilising ROOH (system II) therefore diminish their amount and hence the rate of the chain branching reaction and the overall rate of oxidation (for example, glutathione peroxidase, catalase, peroxidase).[14-17,69,70] Mercapto-compounds, which decompose peroxides via a molecular pathway without the formation of free radicals, have the same effect on the overall rate of oxidation (system IV).[71] Variable-valence metal ions, especially Fe^{2+} ions at low concentrations, catalyse the decomposition of peroxides into free radicals and thereby increase the overall rate of oxidation.[69]

Thus the overall rate of oxidation in the chain branching stage depends directly on the operation of three systems: on the activity of the enzyme system regulating the metabolism of membrane phospholipids (system III); on the activity of the enzyme system utilising hydroperoxides without the formation of free radicals (system II); on the presence in lipids of phosphorus- and sulphur-containing substances, which decompose peroxides without the formation of free radicals, and on the concentration of variable valence metal ions (system IV).

As regards the involvement of system I in the regulation of the rate of chain branching, its influence operates via other systems (systems II and III). As already stated, the effective lipid transfer between membranes, the catabolism of the oxidised forms of the lipids, and the operation of a number of enzymes of system II depend on the viscosity of the lipid. Nor is it possible to eliminate the influence of the viscosity of the medium on the [rate?] constant for the decomposition of peroxides into radicals. However, we were unable to find in the literature any special studies devoted to these questions.

The Chain Termination Stage. This stage consists of reactions involving the quadratic termination of peroxy- or alkyl-radicals derived from lipids (their recombination or disproportionation) and linear termination reactions at the interface or in the bulk phase, for example, linear termination by the molecules of natural antioxidants.

The change in the composition of peroxy-radicals resulting from the change in the composition of phospholipids (system III) can alter the rate of their recombination, the steady-state concentration of peroxy-radicals, and ultimately also the overall rate of oxidation of lipids. A change in the concentration of substances whose molecules are responsible for linear chain termination (system IV) alters markedly the overall rate of oxidation of lipids.

It must be specially emphasised that only natural antioxidants (AO) possess the ability to react directly with lipid peroxy-radicals. If an additional amount of free radicals are formed as a result of some kind influence on membrane lipids, whose generation could not be prevented either by the structural (system I) or enzymic (system II) protective systems, then the exchange reaction of these radicals with the lipid substrate can result in their exchange with the lipid peroxy-radicals. The excess concentration of lipid peroxy-radicals can be abolished only by natural antioxidants and their influence on the overall rate of oxidation greatly exceeds the effectiveness of the action of other systems. This is the reason for the special role of natural antioxidants in the regulation of lipid peroxide oxidation processes.[5]

Thus the overall rate of oxidation of lipids in the chain termination stage depends on the change in the UAA composition in the phospholipid metabolism (system III) and on the activity of the system of natural antioxidants and their synergists (system IV).

The principal features of the operation of systems III and IV have been analysed within the framework of this review. The characteristics of the operation of systems I and II are not considered in detail because the literature contains a number of detailed reviews on this topic.[15,18,57,72,73]

III. THE COMPOSITION OF LIPIDS AND THE INTENSITY OF THEIR OXIDATION

The present stage of the investigation of the characteristic features of the peroxide oxidation of lipids is characterised by an increased interest in kinetic studies in terms of the comparative aspects of the oxidation of individual phospholipids as well as phospholipids forming part of the composition of membranes by means of a series of models of increasing complexity. The models employed permit the elucidation of the role of fluidity, change, hydrophobic properties, and other physicochemical characteristics of the lipid double layer in the kinetics of peroxide oxidation.

Table 1. The influence of the medium on the kinetic characteristics of the initiated oxidation of lipid substrates of different composition.

Oxidation substrate	Yield of radicals	$10^3 k_2/\sqrt{k_6}$, litre$^{1/2}$ mol$^{-1/2}$ s$^{1/2}$	Refs.
Methyl oleate*	0.7	4.4	[76]
Methyl linoleate*	1.2	13	[76]
Methyl linolenate*	0.83	32	[76]
Cholesterol*	—	3.2	[77]
Phosphatidylcholine*	0.66	610	[78]
Phosphatidylcholine**	0.04	17.0	[78]

*Solution in chlorobenzene.
**Aqueous suspension.

Previously it was known that phospholipids whose composition includes unsaturated aliphatic acids are most readily oxidised. Studies in recent years have shown that the oxidation of phospholipids is influenced by the structure not only of the aliphatic acid residues but also by that of other components. Thus in a study of the oxidation of phosphatidylcholine (PC) and phosphatidylethanolamine (PEA), which have identical aliphatic acid compositions, it was found that the latter lipid is oxidised faster.[75] One of the important questions concerning the kinetics of the oxidation of phospholipids involves the study of the problem of the way in which the kinetic characteristics of the oxidation process vary in liposomes or micelles, compared with the oxidation of phospholipids in a homogeneous solution in an inert solvent. Table 1 presents the kinetic characteristics of the initiated oxidation reactions of the methyl esters of oleic, linoleic, and linolenic acids as well as cholesterol in benzene and of phosphatidylcholine in chlorobenzene and in the form of micelles.[76-78] Table 1 shows that the phosopholipid is oxidised significantly faster in a homogeneous medium (by a factor of 20) than the methyl esters of aliphatic acids and cholesterol. On passing to oxidation in the form of micelles, the yield of radicals diminishes sharply and the rate constant ratio $k_2/\sqrt{k_6}$ decreases by a factor of 35. According to Ingold,[78] changes in the viscosity and polarity of the medium exert the main influence on the rate of the chain propagation reaction [reaction (2)] in Scheme 1.

The high polarity of the peroxy-radical increases the possibility of its migration to the surface of the micelle, as a result of which the probability of recombination increases and the rate of the chain propagation reaction falls.

A further increase in the complexity of the model and its closer approach to the real conditions in the peroxide oxidation of lipids in cell membranes involves the study of the characteristic features of the oxidation reaction and of its inhibition in systems for the oxidation of mixtures of hydrocarbons. In the oxidation of two or several substrates, it is essential to take into account the occurrence of the so-called chain termination and propagation cross-reactions. Data for the kinetics of the co-oxidation of the methyl esters of aliphatic acids have been published.[79]

As a result of the co-oxidation, the same substrate can intensify the oxidation of slowly oxidised substrates and can inhibit that of rapidly oxidised substrates. Studies by the authors of this review revealed that the addition of PC to the rapidly oxidised microsomal lipids inhibits their oxidation, while its addition to slowly oxidised lipids intensifies it. Analogous data have been obtained for cholesterol and PEA.[80,81]

The next stage in the increase of complexity involves the study of the characteristics of reactions during which products functioning as inhibitors or initiators of the oxidation process are formed. Such substances include, in particular, cholesterol and PC.[80] The antioxidant activity of the products of the oxidation of such lipids has been demonstrated.[80,81]

The study of peroxide oxidation processes in a mixture of lipids made it necessary for investigators to take into account not only the change in the rate of initiation and the occurrence of chain propagation and termination cross-reactions, but also the changes in the charge, viscosity, and hydrophobic properties of the mixture. A change in the latter leads in its turn to an alteration of the elementary reaction constants and also of the activity of the enzyme initiating or inhibiting the peroxide oxidation of lipids. Thus complex changes in the inter-relations of the components of the regulatory systems III and IV take place during the oxidation process. In order to understand the characteristic features of the regulation of the peroxide oxidation of lipids by antioxidants, it is necessary to consider in greater detail their kinetic characteristics.

IV. NATURAL ANTIOXIDANTS

The natural antioxidants or bioantioxidants are substances of plant or animal origin which inhibit the development of oxidation processes in model reactions. It has been demonstrated for model oxidation reactions that the lipids isolated from various organs of intact animals (liver, spleen, brain, and blood) do indeed inhibit the development of oxidation processes.[5] The overall antiradical activity of the natural antioxidants contained in the lipids of the livers of intact animals, which has the high constant $k_7 = 2.0 \times 10^6$ litre mol^{-1} s^{-1}, has been determined by chemiluminescence[5] and the effective active fraction of the natural antioxidants, which amount to 0.3% of the total mass of lipids, has been calculated.

Cell bioantioxidants consist of exogenic antioxidants supplied with food and endogenic antioxidants which enter the cell by the humoral pathway or are synthesised in it.

Many experimental data show that the deficiency of particular natural antioxidants in the organism leads to the intensification of the oxidative processes in lipids and to the appearance in the latter of oxidation products in greater than normal amounts.

Various biologically active substances, namely tocopherols, ubiquinones, steroid hormones, etc., exhibit antioxidant activity in model experiments. It has been suggested that these substances fulfill the antioxidant function in the organism together with other functions specific to them.

The question of the contributions of various components of lipids to their antioxidant activity (AOA) has been widely discussed in the literature. However, there is no single point of view on this question. Some investigators attribute the antioxidant activity of lipids to the presence in them of an individual substance (for example, tocopherol or ubiquinone) others believe that the activity of lipids is determined by the set of properties of various components, a change in the composition of which is expressed by a change in the properties of lipids as a whole.[5] We believe that the AOA of lipids depends on the antioxidant properties of natural antioxidants, their amount, their possible mutual influence, and their interaction with substances which are not themselves antioxidants but increase or decrease the activity of the latter. In order to demonstrate the validity of a particular point of view, it is necessary to investigate the kinetic characteristics of natural antioxidants.

The structures of natural antioxidants have many features in common. Three groups of substances have the closest chemical structures: tocopherols, ubiquinones, and vitamins of group K.[82-87] On the basis of the similarity of the structures of these compounds and the interrelation of their metabolisms, it has been suggested that they can be interconverted in the organism. However, experiments involving the administration of 14C-labelled α-tocopheryl acetate showed that this hypothesis is incorrect.[110,119]

Each of these groups includes structurally related compounds: quinones, quinols, chromenols, and chromanols.[87] Quinols (hydroquinones) and cyclic chromenols and chromanols are reduced forms, while quinones are oxidised forms. In the course of many reactions occurring in lipids, intermediate forms such as epoxy-compounds, phenoxy-radicals, and semiquinone radical-anions can also be produced. In the organism, in the lipid double layer of the membrane, these forms can be interconverted and there exist enzymes which catalyse such interconversion. Each group of natural antioxidants is present in the lipids preferentially in one of the most stable forms for the given compound.

Thus vitamins of group K exist in blood in the form of quinones. Under the influence of dehydrogenase, the quinone gives rise to the hydroquinone form of vitamin K_1, which participates in the formation of prothrombin in the γ-glutamic acid carboxylation stage. Hydroquinone is then converted with the aid of epoxygenase into the epoxide of vitamin K_1, which is then converted by reductase into the oxidised quinone form.[88,89] The vitamin K isolated from lipids and converted into the hydroquinone form is extremely unstable, is readily oxidised in air, and loses its ability to react with peroxy-radicals.

The quinone form of ubiquinones is also the most stable. In the electron transport along the respiratory chain in the presence of reductants of the type of NAD, the quinone forms of ubiquinones are readily converted into the hydroquinone forms and conversely, with formation of semiquinone radicals. The hydroquinone form is fairly unstable and is oxidised to the quinone form by atmospheric oxygen. The cyclic forms of ubiquinones (ubichromenols) are the most stable. They are not involved in electron transfer along the respiratory chain. It has been suggested that these substances behave as antioxidants in lipids.[82,83,86]

Tocopherols are present in lipids mainly in the cyclic form as 6-hydroxychromans and this applies to both free tocopherol and its esters. In the organism the ester forms are readily hydrolysed to free tocopherol by enzymes.[90] In oxidative reactions, tocopherols, which function as antioxidants, react with peroxy-radicals to form phenoxy-radicals and these are then converted into quinones, dimers, and trimers.[91]

All the natural antioxidants belonging to the group considered have aliphatic substituents in the 2-position, which consist of several isopentane units. For ubiquinones, the number of isopentane units varies from 0 to 10 (from 0 to 50 carbon atoms), for vitamin K from 0 to 4 (up to 20 carbon atoms), and for the tocopherol homologues encountered in nature the number of units is always 3 and the phytyl side chain has 16 carbon atoms.

The side chains of natural antioxidants differ in the degree of unsaturation: there are no double bonds in the side substituents in tocopherols, in vitamins K the first isopentane unit is unsaturated, and each chain of ubiquinones contains one double bond in each isopentane unit.

The presence of long side substituents is a common property of the given group of natural antioxidants. The study of different forms of these substances has shown that they can react directly with hydrocarbon peroxy-radicals, i.e. they exhibit an antiradical activity.

Table 2. The rate constants for the interaction of peroxy-radicals with different forms of antioxidants.[6,94,98,103]

Antioxidant	k_7, litre mol^{-1} s^{-1}		
	quinone	hydroquinone	cyclic form
Tocopherols*			
α-Tocopherol	$(2.5\pm0.2)\cdot10^3$	$(4.7\pm0.5)\cdot10^6$	$(3.1\pm0.3)\cdot10^6$
β-Tocopherol	—	—	$(1.9\pm0.2)\cdot10^6$
γ-Tocopherol	—	—	$(1.4\pm0.1)\cdot10^6$
δ-Tocopherol	—	—	$(0.85\pm0.1)\cdot10^6$
Chroman-C11	—	—	$(3.2\pm0.3)\cdot10^6$
Chroman-C_6	—	—	$(2.9\pm0.1)\cdot10^6$
Chroman-C_1	—	—	$(3.2\pm0.3)\cdot10^6$
Ubiquinones**

***Measurement at 37 °C.
****The numeral in brackets indicates the number of carbon atoms in the side chain of the vitamin K_1 molecule.

Table 2 lists the constants for the reactions of natural antioxidants with peroxy-radicals. It is seen that only the reduced forms of the natural antioxidants, which have rate constants for their interaction with peroxy-radicals of the order of 10^5–10^6 litre mol^{-1} s^{-1}, exhibit an appreciable antiradical activity. The reduced form of vitamin K_1 has the highest constant $k_7 = (5.8 \pm 0.4) \times 10^6$ litre mol^{-1} s^{-1}. The antiradical activity of the phenolic forms of tocopherols

(homologues and analogues) is of the same order of magnitude (10^6 litre mol^{-1} s^{-1}). Ubiquinones and ubichromenols have constants k_7 amounting to 10^5 litre mol^{-1} s^{-1} and for the cyclic form, which has only one hydroxy-group, k_7 is smaller by a factor of 2 than for the hydroquinone form.[92-94]

For the quinone forms of tocopherols, ubiquinones, and vitamin K, the rate constants for this reaction are lower by two orders of magnitude. The esters (tocopheryl acetate) hardly react with free radicals.[92]

Thus the ability to inhibit the peroxide oxidation reaction of lipids is characteristic only of the reduced forms of natural antioxidants and is associated with the presence of the hydroxy-group in the molecule.

Since among all the reduced forms of the natural antioxidants tocopherols are the most stable, the antiradical activity of substances of different structures, differing in the number of substituents in the benzene ring of the chroman nucleus (homologues) and in the length of the aliphatic substituent in the 2-position (analogues), containing between 16 and 1 carbon atoms (chromans), has been investigated in relation to tocopherols. It has been established that the rate constants for the interaction of all the tocopherols investigated with peroxy-radicals are of the order of 10^6 litre mol^{-1} s^{-1} and the activation energies for this reaction are in the range 12.5–15 kJ mol^{-1}.[92]

The tocopherol homologues encountered in nature in different plants differ in the number and positions of the CH_3 groups in the benzene ring of the chroman nucleus but always have the same side substituents in the 2-position. It has been established[92] that the successive introduction of methyl groups in the 5-, 7-, and 8-positions in the tocopherol molecule increases the constant k_7. All these data agree well with experiments on the photolysis of tocopherols and with their oxidation-reduction potentials.[96,97]

Comparison of the antiradical activities of synthetic analogues of α-tocopherol, which are not encountered in nature, has shown[92,98] that the length of the phytyl side chains does not influence significantly such activity: the shortening of the side chain by each isopentane unit (5 carbon atoms) decreases the constant k_7 by 10–15% (Table 1). The introduction of one double bond into the side chain has approximately the same effect.

Analogous data have been obtained by Ingold and coworkers[99] for α-tocopherol and chroman C_1, which has a methyl group in the 2-position. The constants k_7 for the ubiquinones Q-2 and Q-10, differing by eight isopentane units, are hardly different (Table 2).[94] The values of k_7 for the synthetic analogues of vitamin K_1 change when the chain is shortened by two isopentane units by not more than 30% (Table 2). Consequently, the length and the degree of unsaturation of the side chain in the molecules of natural antioxidants do not exert an appreciable influence on the rate of their reaction with peroxy-radicals. Bearing this in mind, one may conclude, on the basis of a comparison of the constants k_7 for tocopherol and the cyclic form of ubiquinone (ubichromenol), that the replacement of the CH_3 group by the methoxy-group lowers the antiradical activity by a factor greater than 10.[93,94]

An analogous dependence has been observed also for the hydroquinone forms of vitamin K and the ubiquinol QH_2-6, whose constants differ by an order of magnitude.

Thus natural antioxidants have a labile hydroxy-group and react comparatively readily with hydrocarbon peroxy-radicals. The substituent in the *o*-position with respect to the hydroxy-group has a significant influence on the antiradical activity of natural antioxidants. Aliphatic side substituents have only a weak influence on the antiradical activity of such antioxidants.

Comparison of the overall antiradical activities of the natural antioxidants present in the lipids of the livers of intact animals and of individual antioxidants showed that they are comparable to the activities of the reduced form of vitamin K_1 and α-tocopherol.

However, the reduced form of vitamin K_1 is unstable and in the lipids which have been isolated vitamin K_1 can exist only in the form of a quinone and the activity of the total natural antioxidants can be usefully compared only with that of α-tocopherol. For lipids, this quantity proved to be 1.5 times lower than the activity of α-tocopherol, which we believe to be associated with the presence in lipids of antioxidants having a lower antiradical activity than that of tocopherol.

It is of interest to note that natural antioxidants have constants k_7 higher by 1–2 orders of magnitude than the majority of the phenols most widely used as antioxidants.[100] The activation energies for the interaction of peroxy-radicals derived from ethylbenzene with tocopherols of different structure (12–15 kJ mol^{-1})[92] and with ubiquinone QH_2-9 (17.4 ± 3.3 kJ mol^{-1} [94]) are lower than the corresponding value for the reaction with ionol (E = 20.5 kJ mol^{-1}).[101,102] On the basis of the low activation energies for the reactions involving the termination of peroxy-radicals by the molecules of natural antioxidants and the high rate constants for these reactions, it might have been expected that the above substances would inhibit the oxidation of model systems more effectively than synthetic phenols. However, in model low-temperature autoxidation systems (the most varied systems including both simple and complex systems) natural antioxidants proved to be much less active in inhibiting oxidation than synthetic antioxidants such as ionol, butoxyanisole, propyl gallate, and nordihydroguaiaretic acid, which has the constant $k_7 = 10^4$–10^5 litre mol^{-1} s^{-1}. Tests carried out by different investigators on tocopherols established that the efficiency of their antioxidant action varies in a complex manner with their concentration, the degree of unsaturation of the substrate, and the oxidation temperature.

Our analysis of the kinetic curves for the oxidation in the presence of tocopherols obtained in our own experiments and taken from the investigations of other workers,[92,103-106] showed that in all cases the dependence of the induction period of the oxidation reaction on the tocopherol concentration is unusual. Whereas for the majority of synthetic inhibitors the dependence of the efficiency of the inhibition on concentration is hyperbolic, for tocopherols the corresponding dependence passes through an extremum with the maximum inhibition effect at a specific concentration.[103] This maximum efficiency of the action of tocopherols is shown most markedly at low oxidation temperatures (at 20° and 40 °C). Comparison of the antioxidant activities of different tocopherol homologues showed that this type of relation with an extremum is characteristic of all the homologues, is independent of the oxidation substrate, and is most marked for α-tocopherol.[103] For the α-tocopherol analogues with short side substituents, the deviation from linearity and a decrease of the inhibiting effect with increase of their concentration have also been established,[92] i.e. the length of the side chain did not exert a significant influence on this feature of tocopherols. In all probability this unusual feature of the antioxidant activity of tocopherols is characteristic of the 6-hydroxychroman molecules themselves and is associated with the activity and stability of the radicals formed from them.

The elementary oxidation reactions involving the antioxidants and their radicals are examined in Scheme 2. The weakening of the antioxidant activity of tocopherols can be accounted for by the occurrence in the oxidation system of side reactions with participation of tocopherol or its radicals. Such reactions may be those of the inhibitor radical with a

hydrocarbon molecule [reaction (10)] and with a hydroperoxide molecule [reaction (7)] and the reaction of the inhibitor with the hydroperoxide [reaction (11)] or with oxygen [reaction (12)]. The rates of these reactions depend significantly on the structure of the antioxidant and the oxidation condition. We were interested in the properties of tocopherols under conditions close to physiological conditions: a low oxidation temperature (20–40 °C), a low degree of oxidation, and a high degree of unsaturation of the substrate.

Scheme 2

$$InH + RO_2^{\cdot} \underset{k_{-7}}{\overset{k_7}{\rightleftarrows}} ROOH + In^{\cdot} \qquad (7), (-7)$$

$$\left.\begin{array}{l} RO_2^{\cdot} + In^{\cdot} \xrightarrow{k_8} \text{molecular products} \\ In^{\cdot} + In^{\cdot} \xrightarrow{k_9} \text{molecular products} \end{array}\right\} \text{chain termination;} \qquad \begin{array}{l}(8)\\(9)\end{array}$$

$$In^{\cdot} + RH \xrightarrow[+O_2]{k_{10}} RO_2^{\cdot} + \text{molecular products} \quad \text{chain propagation,} \qquad (10)$$

$$InH + ROOH \xrightarrow{k_{11}} \text{molecular products} + \text{free radicals;} \qquad (11)$$

$$InH + O_2 \xrightarrow{k_{12}} In^{\cdot} + HO_2^{\cdot} \qquad (12)$$

HIn = inhibitor.

Under these conditions, the oxidation reaction of tocopherol itself [reaction (12)] may be neglected, since tocopherols are stable even on heating to 100 °C.[107]

Under the conditions of a low degree of oxidation, where the concentration of hydroperoxides in the substrate is low, it is possible to neglect reactions (−7) and (11). It remains to consider the possibility of the occurrence of reaction (10).

Reaction (10) was introduced into the scheme for the inhibited oxidation of hydrocarbons in order to calculate the rate constants from chemiluminescence data.[95,108] Depending on the constants k_6, k_8, and k_9, whose ratios make it possible to estimate the limits within which the constant k_{10} varies for α-tocopherol in the initiated ethylbenzene oxidation model, k_{10} is in the range $(0.5–1.2) \times 10^{-1}$ litre mol^{-1} s^{-1}, i.e. cannot be neglected in estimating the antioxidant activity.[92]

The ratio of the rates of the reactions which decrease the efficiency of the action of antioxidants can vary with the concentration of free radicals, since an increase of the rate of initiation W_i entails a quadratic increase of the rates of reactions (8) and (9) and a linear increase of the rate of reaction (10). Thus, with increase of W_i in the system, the contribution of the chain propagation by the antioxidant radical to the overall rate of oxidation diminishes, i.e. the efficiency of the antioxidant increases. An extended kinetic scheme for the oxidation of hydrocarbons has been examined[95] and relations confirming the increase of the efficiency of the antioxidants with increasing concentration of free radicals in the system have been obtained. This explains the finding that natural antioxidants exhibit the greatest efficiency in models involving the oxidation of highly unsaturated aliphatic acids.

If this oxidation system contains substances capable of removing from the reaction sphere the radicals of natural antioxidants or substances which regenerate their oxidised forms, a synergistic effect should be observed under these conditions. The role of synergists is usually assumed by substances having a low-oxidation-reduction potential and which readily pass from the oxidised to the reduced form (for example, ascorbic and citric acids).[45,109] For tocopherols, synergism with dibasic organic acids was established as early as 1942.[111]

It has been shown recently by direct experiments[112] that ascorbic acid reacts directly with tocopherol radicals, which is accompanied by an increase of the concentration of ascorbic acid radicals, while that of the tocopherol radicals falls.

We shall consider which properties of membrane lipids and natural antioxidants ensure a high efficiency of the regulation of the peroxide oxidation of lipids. As already stated, the oxidative processes occurring in membranes have their characteristic features: a structured lipid double layer, the multicomponent composition of the lipids, a high degree of unsaturation of the aliphatic acids forming part of the composition of the membrane phospholipids, and the presence in the latter of substances capable of intensifying or weakening the action of natural antioxidants.

It has been shown in a recently published study[113] that the activity of tocopherols in structured substrates is higher by 1–2 orders of magnitude compared with oxidation in the liquid phase. The authors believe that such increase of activity is associated with the fact that the OH groups of the tocopherols in the structured substrate are directed towards the hydrophilic medium. If radical species of the type of OH^- and O_2^- approach the membrane from this medium, then their termination by the tocopherol molecules is more effective the greater the number of hydroxy-groups of the antioxidants are present on the outer surface of the membrane.

The maximum inhibition of the oxidation reaction by natural antioxidants in model systems can be achieved in the oxidation of highly unsaturated substrates with a low content of peroxides and at low temperatures. Such conditions are in fact characteristic of the oxidation of lipids in biomembranes, i.e. the physiological conditions are optimal for the manifestation of the antioxidant activity of natural antioxidants. The high antiradical activities of natural antioxidants constitute the basis of the sharp change in the rate of the peroxide oxidation of lipids, which ensures a high effectiveness of regulation even when their concentration is altered only slightly.[106]

Since the reduced phenolic forms of natural antioxidants have constants k_7 higher by a factor of 100–1000 than those for quinones, the transition of natural antioxidants from one form to another, involving an appreciable decrease or increase of the antiradical activity, can also be regarded as a means for a rapid change in the intensity of the oxidative reactions occurring in lipids.[106,114]

The question arises whether ubiquinones and vitamins K_1, having unstable reduced forms which are readily converted into inactive quinones, can be regarded as natural antioxidants. In all probability they can be so regarded, because lipids always contain different reducing agents and enzymes capable of converting the quinones into the phenolic form.

Furthermore, one should bear in mind that in a lipid environment the stability of the phenolic forms of these compounds is higher. The question also arises whether the radicals formed from the antioxidant molecules can be active within the membrane. It has been established in experiments on animals that the relation between the antioxidant activity of lipids and the amount of natural antioxidants present in them passes through an extremum, as in model systems.[92] This permits the conclusion that the properties of weak antioxidants, established for them in model experiments, are characteristic of the natural antioxidants also in systems *in vivo*. This feature of the antioxidant activity of natural antioxidants can also be regarded as regulatory; in the presence of an excess of such substances in lipids, their inhibiting activity falls. We believe that the radicals formed from natural antioxidants fulfill, as it were, the role of a buffer which maintains the rate of oxidation of lipids at a specific level.[43,114]

Phenomena of this kind, namely a sharp change in efficiency following a slight increase in the concentration of the given substance up to the reversal of the effect, were first discovered and investigated in detail by Academician N.M.Emanuel' and were called the "critical phenomena" in inhibited liquid-phase oxidation reactions.[44]

In model hydrocarbon oxidation reactions, it was found that variable-valence metal ions at low concentrations activate the oxidation reaction, catalysing the decomposition of hydroperoxides, while at high concentrations they inhibit such reactions. The same type of relation has been established for Fe^{2+} ions in a study of the oxidation of lipids in membranes.[69] Retinol activates the oxidation of liposomes when present in small doses and stabilises them when present in large doses.[9,68] Such dual activity apparently constitutes a means for a rapid alteration of the rate of oxidation (regulation by the concentration).

A change in the composition of the membrane lipids, leading to a change in the rate of peroxide oxidation by altering the rate of initiation, has a significant influence on the rate of the reactions involving chain propagation by the radicals formed from natural antioxidants [reaction (10)]. Thus it has been established[95] that the contribution of the rate of reaction (10) to the antioxidant activity of natural antioxidants is less significant for higher rates of initiation and for a high degree of unsaturation of the oxidation substrate (regulation by the substrate).

Natural antioxidants participate in the regulation of the peroxide oxidation of lipids not as independent substances but as interacting components of a single system. The possibility of changing the concentration and activity of one set of natural antioxidants by administering others to animals constitutes proof of the validity of this postulate. For example, after a single administration of α-tocopheryl acetate (200 mg kg^{-1}) to intact animals, an increase of the concentration of the total antioxidants is observed in the liver lipids (by a factor of 37), while the amount of free α-tocopherol increases by a factor of only 10 during the same period.[5] An increase of the amount of a particular natural antioxidant is possible only when the product of the antiradical activity of the administered antioxidant and its concentration (k_7c) is comparable to the same product for the antioxidants present in the cell.[5]

At the same time one should bear in mind that the transformation of the relatively inactive forms of antioxidants into highly reactive forms is possible in the cell, so that, after the introduction of, for example, quinones, which can be reduced to phenols, an increase of the total amount of natural antioxidants is also observed.[115] Although ubiquinone and vitamin K_1 in the form of quinones cannot compete with tocopherols, in the reduced forms, as hydroquinones or ubichromenol, they can replace tocopherol in free-radical oxidation reactions.

After the introduction of vitamin K_1, not only an increase of the amount of natural antioxidants in lipids but also an increase of the activity of the lipids of the experimental animals compared with that of the control lipids was established, i.e. substances whose antiradical activity is greater than the total activity of the natural antioxidants and even greater than the activity of pure α-tocopherol accumulate in the lipids. Only the reduced form of vitamin K_1 exhibits such a high activity.[6]

The data presented confirm our hypothesis that tocopherols, ubiquinones, and vitamins of the K group are interrelated in the organism via their antioxidant functions. The question whether the system of natural antioxidants is linked with other systems regulating the peroxide oxidation of lipids remains open. In the first place one should note that it is difficult to draw a clear-cut boundary between these systems. Indeed, the phenolic forms of natural antioxidants are typical antioxidants, but at the same time they play the role of structural factors and on this basis can be assigned to the protective system I. On the other hand, quinones, which are potential antioxidants, can interact with $O_2^{\cdot-}$ (system II) to form semi-quinone radicals.[46,116,117] This results not only in the destruction of the possible oxidation initiation centres ($O_2^{\cdot-}$) but also in the formation of semiquinone radicals capable of terminating the oxidation chain on recombination with the lipid peroxy-radicals or on interaction with the OH group of the semiquinone. This leads to the simultaneous destruction of the oxidation initiation centres and the appearance of active free radical acceptors, which makes it possible to regard this reaction as a means for the inclusion of the oxidised forms of antioxidants in the regulation of the intensity of the peroxide oxidation of lipids in response to the increase of the rate of initiation of the oxidation process.

In all the cases considered, the interrelation of different systems for the regulation of the peroxide oxidation of lipids is based on physicochemical characteristics.

However, one must not forget also the biochemical mechanisms of such inter-actions. Thus it has been shown[24,26,35] that there exists a system for the maintenance of the steady-state in the peroxide oxidation of lipids, based on the relation between the rate of the peroxide oxidation of lipids and the rate of change of their composition. In response to the intensification of the peroxide oxidation of lipids, the composition of the lipids changes in such a way that they become more resistant to oxidation.[24] The presence of such a relation complicates the consideration of the characteristic features of the regulation of the peroxide oxidation of lipids but it enables the cell to switch the rate of the peroxide oxidation and the associated metabolism to a new level in response to the action of endogenic and exogenic factors. This has the consequence of a change in the structure and ultimately in the functional activity of the membrane.

The steady state nature of the lipid oxidation process constitutes the basis for the maintenance of a specific composition, structure, and function of membranes as highly specific, complex, and multicomponent systems. The membrane lipids fulfill a dual function: on the one hand, they maintain a rigorously specified structural organisation of the membranes, responsible for the effective fulfillment of their biological functions, and, on the other hand, they ensure the lability of their composition and the rapid response of the cell to changes in the organism.

Kinetics of the Radiation-induced and Photochemical Oxidation of Biomacromolecules in Aqueous Solutions

I.I.Sapezhinskii

The sequence of radiation-induced photochemical reactions of proteins, nucleic acids, and other biological species has been investigated: the primary stages in the formation of free macroradicals and other active products and their reactions leading to the modification of the primary structure of the biopolymers. Simplified versions of kinetic schemes which describe satisfactorily the experimental data are discussed. The redistribution of the initial damage-induced defects in protein-DNA-other cell components systems has been subjected to a formal kinetic analysis.
The bibliography includes 129 references.

I. INTRODUCTION

The question of the primary mechanisms of the action of light and ionising radiation on the principal biochemical components of the cell is one of the essential questions in radiobiology and destructive photobiology. As early as the middle 1950's, Academician N.M.Emanuel', who was engaged in the study of the kinetics of liquid-phase oxidation reactions, put forward a broad programme for the study of radiation-induced and photochemical reactions of proteins, nucleic acids, and lipids. Extremely simplified and fairly naive ideas about these processes were current at that time. This programme involved the study of the degradation of biomacromolecules by methods which were new at the time: EPR, pulse radiolysis, and flash photolysis. This review includes certain results obtained in the course of the execution of this programme.

The sequence of the effects of optical and ionising radiation on living organisms can be subdivided very arbitrarily and with much simplification into three stages. The first stage includes the entire set of the physicochemical primary processes from the instant of irradiation up to the formation of relatively stable products of the radiation-induced and photochemical modifications of the primary structure of the biopolymer. The second stage is molecular-biological and in it numerous enzymes systems for the repair of DNA molecules begin to operate, which leads to both the elimination of the modified sections of the nucleic acids and to the appearance of additional DNA structural defects. Finally, the third stage includes further processes which entail damage of the genetic material in the cells, organs, and tissues and this leads to the distortion of metabolism, the breakdown of the regulatory systems, and finally to biological effects. This review has a bearing only on the first, physicochemical stage—the action of radiation on proteins, DNA, and other components of the cell.

Proteins perform catalytic, transport, protective, immune, supporting and other functions in the living cell, forming part of the composition of all the cell organelles and their content amounts of 50% and above of the dry weight of living organisms. This is why, on exposure to light and ionising radiation, proteins bear the brunt of the radiation-induced stress and constitute in this sense the principal "chemical target" of the action of radiation. At the same time DNA macromolecules are the main "biological target", because damage to such molecules entails in most cases biological effects.

Radiation-induced and photochemical reactions of macromolecules involve numerous and varied reactions of free radicals, electronically excited states of the macromolecules, peroxy-radicals, peroxides, and other active species. Protein molecules are the most complex macromolecules with numerous groups which are modified by radiation. The discovery of all such changes is a task for the future and this applies, albeit to a lesser extent, to DNA.

During the last 20 years, there has been a qualitative leap forward in the understanding of the mechanisms of the radiation-induced and photochemical degradation of biopolymers. The use of EPR, pulse radiolysis, and flash photolysis makes it possible to discover tens of different intermediates participating in the degradation of proteins and nucleic acids: these are the active products of the radiolysis of water, numerous types of free macromolecules and peroxy-radicals, electronically excited states of aromatic groups of proteins and DNA bases, the radical-ions derived from the macromolecules, photoinitiators and radiosensitisers, singlet oxygen, and various peroxides. Naturally, the contribution of a particular species to the overall degradation process is determined by its yield and the kinetic characteristics of the possible competing reactions. The first aim of the present review was therefore a kinetic examination of the most probable processes and the simplest of the possible kinetic schemes which describe satisfactorily the experimental data.

In the living cell proteins compete with other molecules, including DNA, for the active species produced by photolysis and radiolysis and the second aim of the review was therefore a formal-kinetic examination of the redistribution of the initial damage-induced defects in multicomponent systems at concentrations comparable to those within the cell.

The inclusion in a single article of results concerning different influences on the macromolecules by ionising radiation, ultraviolet (u.v.) light, as well as light in the presence of photosensitisers is not surprising because many products of these reactions are the same and the kinetics of their behaviour are also similar. An exception is apparently the effect of u.v. light on DNA, in which the main photoproducts (pyrimidine dimers) are formed directly from the singlet and triplet electronically excited state without the participation of other intermediates.

II. THE YIELDS OF RADIATION-INDUCED AND PHOTOCHEMICAL REACTIONS OF PROTEINS AND NUCLEIC ACIDS

The study of radiation-induced or photochemical reactions of biomacromolecules has a history of almost 100 years. The total number of studies exceeded 10 000 long ago. Conferences are being held regularly and reviews devoted to the primary photochemical and radiation-induced reactions of proteins and DNA both in solutions and at the level of living cells are being published.[1-34]

Among the many thousands of applications, only a few contain quantitative data suitable for the construction of the possible reaction mechanisms—these are data concerning the yields of the modified groups, the disappearance of the initial groups, and the dependence of the observed effects on a broad spectrum of experimental conditions: the irradiation dose rate, the concentrations of the macromolecules, oxygen, and various additives, and temperature. Very few studies have been devoted specifically to the radiation-induced and photochemical oxidation of macromolecules, which is apparently associated with the rapidly increasing set of intermediates and final oxidation products. The lack of interest in the photochemical oxidation of biopolymers has been promoted also by the fact that certain photobiological effects of u.v. light are independent on the oxygen concentration, although photochemical oxidation reactions do naturally occur under these conditions.

Table 1. The radiation-chemical yields in the absorption of oxygen by solutions of nucleic acids (molecules/100 eV) at different temperatures and irradiation dose rates.[36]

Substance	c, M	0.4 Gr s^{-1}; 20 °C	0.04 Gr s^{-1}		
			5° C	20° C	50° C
Single-stranded DNA	$7\cdot10^{-4}$	6.8	—	6.6	—
	$4\cdot10^{-3}$	7.5	8.3	8.6	9.2
Double-stranded DNA	$7\cdot10^{-4}$	4.6	—	4.4	—
	$4\cdot10^{-3}$	—	4.7	—	—
RNA	$7\cdot10^{-4}$	4.0	5.0	5.4	6.6
Poly(U)	$2\cdot10^{-4}$	14.6*	17	—	—
	10^{-3}	21	—	—	—

*At 5 °C.

The principal overall characteristic of the oxidation processes is the rate of absorption of oxygen on irradiation—the radiation-chemical or quantum yield in the consumption of oxygen. Unfortunately there are few quantitative data for these quantities, although the methods for the determination of the rate of oxidation are extremely simple and the first studies on the absorption of oxygen using the Warburg apparatus were published about 60 years ago.[35]

Table 1 presents the radiation-chemical yields in the absorption of oxygen by solutions of natural nucleic acids and synthetic polyuridylic acid [poly(U)].[36] Evidently the yields for single-stranded DNA vary from 6.8 to 9.2 O_2 molecules per 100 eV depending on the experimental conditions. For double-stranded DNA, the yields are somewhat smaller (4.4–4.7). The yields in the case of RNA are 4–6.6 O_2 molecules per 100 eV. The maximum yields have been obtained for poly(U) (up to 21). Some increase of the yield with decrease of the dose rate and with increase of the temperature of single-stranded DNA, RNA, and poly(U) is striking. These results have been explained[36] by the occurrence of chain reactions with short chains and a scheme has been published for the reactions of free radicals derived from nucleic acids, the confirmation of which requires additional data. The radiation-chemical yields for the absorption of oxygen by proteins are in the range 2–4 O_2 molecules per 100 eV.[37]

Table 2 presents the possible participants in the radiation-induced and photochemical reactions of proteins (B) and nucleic acids (D). The yield in the absorption of oxygen in the radiation-induced oxidation of proteins and nucleic acids are comparable. The quantum yields of the sensitised and unsensitised photochemical oxidation of proteins are fairly high owing to the presence in the proteins of the readily oxidisable tryptophan, tyrosine, cysteine, cystine, methionine, and histidine residues. The quantum yields in the photochemical oxidation of DNA are extremely low. If it is assumed that the breaks in DNA arise in reactions involving free radicals, then the yield of the photochemical oxidation of DNA is of the order of 10^{-4}% according to Zavilgelsky et al.[32]

The active products of the radiolysis of water (Table 2, Nos. 3–7) are obligatory participants of the radiation-induced oxidation reactions. The contribution of each can be discovered with the aid of relatively selective acceptors. For hydrated electrons, this is nitric oxide, while for hydroxy-radicals the acceptors are alcohols and sugars. The superoxide radical-ion (O_2^-) or the hydroperoxy-radical are apparently involved in all types of oxidation of macromolecules. Singlet oxygen is almost always formed in sensitised photochemical oxidation, but its formation under influences of other types is problematical.[36]

Other inorganic and organic radicals may be formed in the photolysis and radiolysis of the additives introduced and they can interact fairly effectively with macromolecules. Low-molecular-weight peroxy-radicals react effectively with proteins and less so with DNA.[39-51]

Photosensitisers in singlet and triplet electronically excited states participate in the sensitised photochemical oxidation of biopolymers and the reaction mechanisms can be extremely varied.[38]

The free radicals derived from proteins and nucleic acids are formed under all types of influences. It is noteworthy that the very concept of "free macro-radicals" is fairly arbitrary, because irradiation results in the formation of a large set of radical species of different types. For proteins, these are the radical-anion and the free radical obtained from the peptide unit and the lysine, arginine, phenylalanine, tyrosine, cysteine, cystine, methionine, aspartic acid, glutamic acid, and proline free radicals.[52-60] Other types of radicals have also been suggested. For DNA, these are the thymine free radical and radical-anion, the guanine radical-cations, and free peroxy-radicals.[61-64] The study of the reactions of single-stranded DNA by pulse radiolysis led to the detection of cytosine, guanine, and adenine radicals.[65] Apparently the overall yield of protein and DNA free radicals, when these are present at high concentrations, can reach six radicals/100 eV under the conditions of complete trapping of the water radiolysis product. The quantum yields in the

formation of radicals when DNA and proteins are acted upon by ultraviolet light have not yet been measured; at a low temperature radicals are formed as a result of two-quantum reactions[66,67] and the concept of quantum yield is extremely relative. Protein and DNA peroxy-radicals are formed under all types of influences, but their yields are unknown. The electronically excited states of the protein and DNA groups naturally arise on exposure to u.v. light and the yields of the triplet states apparently reach several per cent. On sensitisation, there is a possibility of the population of the triplet levels by energy transfer from suitable sensitiser levels. In radiolysis the yields of the excited states in solutions of biopolymers are low[68] and it has been suggested that they are formed as a result of the Vavilov–Cherenkov radiation.[69–71]

Table 2. The radiation-chemical (molecules/100 eV) and quantum (%) yields in the oxidation or formation of particular products of the reactions of proteins (B) or DNA (D).[1–71]

No.	Initial, intermediate, or final products of the reactions of proteins and DNA	RIR	PSR	PCR

32	Inactivation of enzymes	0.01—3	0.1—10%	0.1—10%

Notation: RIR = radiation-induced reactions, PSR = photosensitised reactions, and PCR = photochemical reactions of protein and DNA macromolecules; the "+" sign refers to reactions with species whose participation in the processes has been reliably established, the "+-" sign refers to their possible participation, the "-" sign shows that they are not involved, and the "?" indicates their tentative involvement; $\dot{R}_{inorg}$ and $\dot{R}_{org}$ are the free radicals arising in photolysis or in radiolysis in the presence of inorganic or organic additives, ^1S and ^3S are the singlet and triplet electronically excited states of the photosensitisers, $^1O_2$ is singlet oxygen, $\dot{R}_B$ are protein free radicals of various types, $\dot{R}_D$ are DNA radicals, $R\dot{O}_{2B}$ and $R\dot{O}_{2D}$ are protein and DNA peroxy-radicals, ^1B and ^3B are the singlet and triplet electronically excited states of the aromatic groups of the protein, ^1D and ^3D are the corresponding states of the DNA bases, and π are stable and unstable peroxides derived from the macromolecules.

Unstable and stable peroxides (Table 2, No.22) are formed under all types of influences on the macromolecules in the presence of oxygen; the radiation-chemical yield in their formation, amounting to about one molecule/100 eV, is apparently significantly too low because of the occurrence of subsequent rapid reactions.

Table 2 (Nos.23–30) presents certain recorded changes in the macromolecule on exposure to light and ionising radiation. They are numerous and apart from these there are apparently also others hitherto undiscovered because the overall yield in the absorption of oxygen is greater than the sum of the yields of the known damage-induced defects.

Single and double breaks on γ-irradiation, the formation of cyclobutane dimers on u.v. irradiation, and the formation of "protein–DNA" cross-links under all types of influences can be included in the biologically significant damage to DNA. It is believed that the last type of damage is least well repaired by the numerous enzyme cell repair systems.

Table 2 shows that there are numerous data concerning the radiation-induced oxidation and other reactions of proteins and DNA. It is also seen that in many cases there are no quantitative data. This so far precludes the determination of a relatively complete picture of the reactions.

III. THE RATE CONSTANTS FOR THE POSSIBLE FREE-RADICAL REACTIONS INVOLVING BIOPOLYMERS

The rate constants for the free-radical reactions are obtained by pulse methods or are calculated from the dependence of the rate of the process on the concentration of the substrate, oxygen, or various added acceptors. It is noteworthy that the very concept of the rate constants for reactions involving protein and DNA macromolecules is fairly arbitrary. The effective rate constant for the reaction of a macromolecule with any species includes the sum of the partial rate constants for the reactions through individual groups of the polymer with these species. For DNA molecutes the rate constants were calculated either in relation to the concentration of the monomeric units or in relation to some fragment of the macromolecule or the entire polymer molecule—all these possibilities are used in the literature and the data must be recalculated.

The presence of large errors in the constants calculated using fairly complex kinetic schemes and with incomplete allowance for competing reactions is significant. In the general case many rate constants are correct within the limits of an order of magnitude. The Tables below present the averaged rate constants for proteins, DNA, lipids, and other substances, taken and recalculated from reviews quoted in previous Sections. Preference has been given to data obtained from the concentration variations. In the case of proteins data are quoted for the "average" protein with a molecular weight of $(2–4) \times 10^4$ and for DNA data are presented for molecules with a molecular weight of 4×10^4. It is noteworthy that the rate constants are similar to the diffusion constants and vary little with molecular weight. The situation is more complex for lipid membranes which can incorporate hundreds of a wide variety of chemical compounds; phosphoglycerides, glycolipids, and cholesterol. Data referring to the most reactive unsaturated lipids are quoted for such membranes.

Table 3 presents estimates of the rate constants for bimolecular reactions of the active water radiolysis products and singlet oxygen with proteins, DNA, lipids, cysteamine (one of the best known radioprotectors), phenolic inhibitors of free-radical processes, typical nitro-compounds (radiosensitisers), and oxygen. The constants have been adjusted

to 25 °C. Evidently the hydrated electron and the hydroxy-radical interact effectively with all the substances enumerated above and the rate constants are highest for proteins and lowest for lipids. The radical-anion O_2^- is significantly less reactive, reacting sluggishly with proteins containing no metal atoms; in the use of the iron- and copper-containing proteins the rate constants reach 10^7 litre mol^{-1} s^{-1}. Cystamine, phenols, and nitro-compounds react effectively with superoxide. Singlet oxygen reacts fastest with proteins and phenols, while its reactions with DNA and lipids are relatively ineffective.

Table 3. The estimated rate constants for the reaction of active radiolysis and photolysis products with proteins, DNA, lipids, cysteamine, phenolic inhibitors of free radical processes, nitro-compound radiosensitisers, and oxygen (litre mol^{-1} s^{-1}). [11,12,25,26,31,32,37]

Substance	e^-	OH	O_2^-	$^1O_2$
Proteins	$5\cdot10^{10}$	$(1—6)\cdot10^{10}$	$<10^3$	$10^8—10^{10}$
DNA	$2\cdot10^{10}$	$(1—6)\cdot10^{10}$	$<10^3$	$<10^4$
Lipids	10^6	10^7	$<10^3$	$10^3—10^5$
Cysteamine	$2\cdot10^{10}$	$2\cdot10^{10}$	10^6	—
Phenols	10^9	10^{10}	$10^6—10^7$	$10^5—10^7$
Nitro-compounds	$2\cdot10^{10}$	10^9	$10^7—10^9$	—
Oxygen	$2\cdot10^{10}$	$4\cdot10^{9}$*	—	—

*At pH 11.

Table 4. The estimated rate constants for reactions of various free radicals and peroxides with certain substances (litre mol^{-1} s^{-1}). [11,14,22,25,37,38]

Substance	$\dot{R}_B$	$\dot{R}_D$	$\dot{R}$	$R\dot{O}_2$	$\dot{R}_H$	Π_1	Π_2
Proteins	$10^6—10^8$	$10^6—10^8$	$10^8—10^{10}$	$10^{-1}—10^3$	10^9	$10^{-3}—10^{-2}$	—
DNA	$10^3—10^4$	$10^3—10^4$	$10^3—10^4$	$10^{-2}—10^1$	10^{10}	—	—
Lipids	$<10^3$	$<10^3$	$10^6—10^7$	$10^{-2}—10^1$	—	—	—
Protectors	$10^7—10^8$	$10^7—10^8$	$10^7—10^8$	—	—	1—10	—
Phenols	$10^4—10^6$	$10^4—10^6$	$10^5—10^7$	$10^4—10^6$	—	0.1—5	—
Nitro-compounds	10^9	10^{10}	$10^7—10^8$	—	—	—	—
Oxygen	$10^8—10^9$	$10^8—10^9$	$10^6—10^9$	—	—	—	—
k	$10^1—10^4$	$10^3—10^6$	$10^6—10^8$	$10^4—10^8$	$10^6—10^8$	$10^{-1}—10^{-5}$	$10^{-1}—10^{-5}$

Notation: $\dot{R}$ are low-molecular-weight organic radicals, $R\dot{O}_2$ are peroxy-radicals, $\dot{R}_H$ are sensitiser free radicals, Π_1 are protein peroxodes, Π_2 are DNA peroxides, k are the rate constants for the destruction of the corresponding radicals in first- or second-order reactions (s^{-1}).

In a complex multicomponent system the primary damage induced both by water radiolysis products and by the direct action of radiation quanta and charged particles leads to secondary reactions, both intramolecular and intermolecular. Numerous reactions of free radicals and a redistribution of the initial defects among different components take place. In order to represent the entire picture of the redistribution of damage-induced defects, it is necessary to have data for the interaction of the majority of different types of free radicals with one another and also for their reactions with cell components.

Table 4 presents the rate constants for the reactions of protein, DNA, and lipid free radicals, peroxy-radicals, and protein and DNA peroxides with various substances. The estimated rate constants, obtained as a rule by competitive methods, are presented. The wide range of these values is due to the different chemical natures of the radicals. Proteins, cysteamine, inhibitors, aromatic nitro-compounds, and oxygen exhibit a high reactivity in relation to all the active species. The interaction of lipids and DNA with various radicals is characterised by lower rate constants. It is also seen that there are virtually no data for the reactions of protein and DNA peroxides. The rate constants will be used below in Section VIII in the examination of the formal kinetics of the distribution of damaged-induced defects in "protein–DNA" and "protein–lipids" systems.

IV. KINETICS OF THE REACTIONS OF FREE MACRORADICALS IN SOLUTION

There exists an extensive literature on the reactions and transformations of free radicals analogous to those formed in proteins and nucleic acids. [55,60,63,67] These are primarily reactions involving the abstraction of a hydrogen atom, which may result in the migration of the free valence "within" the protein globule or the double helix of DNA. Reactions of this type probably lead to the protection of macromolecules by protectors of the type of cysteine and cysteamine. Free radicals can subsequently add to molecules with double bonds and to aromatic groups. In addition the free radicals can undergo decomposition, isomerisation, recombination, and disproportionation reactions. Finally one may also mention oxidation-reduction reactions, for example, with variable-valence metal ions.

Protein and nucleic acid macromolecules can be regarded as miniature chemical reactors with a complex geometry and internal dynamics, in which rapid free radical processes take place. The rates of these reactions are limited, on the one hand, by the reactivity of particular radicals in relation to groups in close proximity and, on the other hand, by the rapid and slow movements "within" the macromolecules.

The main bulk of data for the reactions and transformations of protein and nucleic acid free radicals have been obtained in experiments by the EPR method on dry specimens and frozen solutions at low temperatures. The kinetic characteristics of the behaviour of radicals in solutions cannot be estimated from data for the radiolysis and photolysis in the solid phase. This is because of the unusual nature of the processes involving the accumulation and destruction of macroradicals in solid specimens for which the kinetic curves cannot be described within the framework of the usual ideas concerning reactions in the liquid and gaseous phases and it is necessary to introduce the concept of the polychromaticity of the rate constants, the rate constant distribution functions, and activation energies; a non-uniform distribution of radicals and the occurrence of reactions at the temperatures of the structural transitions in the matrices are characteristic of the solid phase. [55,60,63,67,72–76]

Certain data for the kinetics of the accumulation and destruction of protein free radicals have been obtained for aqueous protein solutions by EPR, pulse radiolysis, and flash photolysis. The main difficulty in comparing data obtained by different methods consists in the fact that apparently all the radicals except those which give rise to broad lines are recorded by EPR, while flash photolysis and pulse radiolysis record only the radicals which give rise to absorption bands

outside the region of absorption by the macromolecules, i.e. above 300 nm. In the main these are the cystinyl and tryptophanyl free radicals.

Kinetic curves have been obtained[77-80] for the accumulation and destruction of protein free radicals on u.v. irradiation of their solutions. It was found that there are two stages in the destruction of free radicals: one rapid stage with times of the order of 10^{-2}–10^{-1} s and another, slow stage with times in the range 1–20 s. The disappearance of free radicals formally follows a kinetic first-order reaction equation and bimolecular components have not been found. It has been shown for serum albumin that the rate constant for the slow stage depends only slightly on temperature when the latter is varied from 10° to 40 °C. The characteristics of the destruction of free radicals do not differ greatly for different proteins. It has been found that the contribution of the slow component is proportional to the content of the alpha-helix in the proteins, which made it possible to employ this correlation for the determination of the content of the helix in a series of protein-containing species.[80] It also follows from the data quoted above[77-80] that the rate of accumulation of free radicals is higher than the rate of their destruction; the slow component is hardly manifested. This constitutes direct indication that the radicals are effectively destroyed by the radiation.

The kinetics of the destruction of free radicals in solutions of egg albumin have been studied by pulse radiolysis.[81] The kinetic curves for the destruction of the free radicals can be described by a set of exponential components with effective rate constants of 440, 8 and 0.4 s^{-1} when the experiments were carried out with the solution saturated by N_2O (the hydroxy-radicals react) and with approximately the same values on irradiation in an atmosphere of nitrogen. Analogous results have been obtained also for other proteins.[82-91]

The time scale of the reactions of the DNA free radicals in solutions at room temperature is extremely wide, ranging from microseconds to seconds.[65,92] A study[92] demonstrating the liberation of the K^+ and H^+ ions on irradiation of the potassium salt of polyuridylic acid in solution is of interest. This effect is treated as one involving the rupture of the poly(U) chain, entailing an increase in the degree of dissociation. It has been shown by pulse radiolysis with conductimetric measurements that the kinetics of the liberation of the ions are described by an equation for a first-order reaction with a rate constant of 0.8 s^{-1}. It has been suggested that the breaks in poly(U) are produced as a result of the decomposition of the poly(U) radicals formed when the polymer is attacked by hydroxy-radicals. The destruction of the macroradicals in first- and not second-order reactions is not very surprising, since analogous effects have been observed also in other systems. The free valence probably "moves" along the macromolecule, leaving behind a trail of transformations and the duration of this movement is rate-limiting. Next there are two possibilities: either there is a reaction between two macroradicals or a low-molecular-weight radical is initially split off from the macroradical and reacts with a polymeric radical. It is easy to show that the required disproportionation rate constant should not be less than 10^7–10^{10} litre $mole^{-1}$ s^{-1} and only then is it possible to account for the exponential character of the destruction of the free radicals. Data for the formation of lysozyme dimers on irradiation have been obtained[91] by pulse radiolysis (with recording of light scattering), the dimerisation rate constant amounting to 10^6 litre $mole^{-1}$ s^{-1}. If it is assumed that the formation of the dimers is the result of the recombination of the lysozyme macroradicals, then the above quantity must be regarded as the lower limit to the rate constants for the recombination of the macroradicals. This quantity is sufficient to explain the presence of slow components, but is too low to account for the rapid exponential components. The macroradicals most probably decompose with elimination of low-molecular-weight radicals and a cross-disproportionation. In the case of peroxy-macroradicals there is a possibility that the latter decompose with formation of O_2^-.

There exists yet another explanation of the exponential kinetic curves for the destruction of radicals—it involves the immediate formation of a pair of radicals on one macromolecule separated by a fairly short distance. This situation may obtain on irradiation of proteins with u.v.light.

In the presence of oxygen in the system, peroxy-macroradicals are formed. It is difficult to investigate them by direct methods, but there exists an extensive literature on the reactions and transformations of low-molecular-weight peroxy-radicals whose structures are similar to those of the radicals derived from the protein and DNA groups (see, for example, Timofeev-Resovskii et al.[25] and Kayushin et al.[60]).

The construction of a possible mechanism of the oxidation processes is the aim of a quantitative or at least a semi-quantitative description of the experimental data within the framework of a simplified kinetic scheme. The proposed schemes must explain the yields of the oxidation and product formation reactions and the kinetics of the decomposition of the groups of the macromolecules and of the accumulation of the modified products. The formulae obtained must be consistent with the dependence of the rate of oxidation on the dose rate, temperature, the concentrations of the substrate oxidised, oxygen, and various additives, pH, ionic strength, viscosity, etc.

A simplified kinetic scheme for the secondary free-radical reactions involving biomacromolecules is presented below.[78-98]

Scheme 1

$$B \xrightarrow{h\nu,\ O} \dot{R}\,(\dot{R},\ \dot{R}^+,\ R^-),\ O_2^-\,(H\dot{O}_2)\,, \qquad (I)$$

$$\dot{R} \xrightarrow{k_1} \ldots P_i\,, \qquad (II)$$

$$\dot{R} + O_2 \xrightarrow{k_2} R\dot{O}_2\,, \qquad (III)$$

$$R\dot{O}_2 + O_2^- \rightarrow \Pi + O_2\,, \qquad (IV)$$

$$R\dot{O}_2 \rightarrow P_i + O_2^- + H^+\,, \qquad (V)$$

$$2R\dot{O}_2 \rightarrow P_i + O_2\,, \qquad (VI)$$

$$2O_2^- \xrightarrow{2H^+} H_2O_2 + O_2\,, \qquad (VII)$$

$$R\dot{O}_2 + B \rightarrow \Pi + \dot{R}\,(R\dot{O}_2 \cdots HR \rightarrow \Pi + \dot{R})\,, \qquad (VIII)$$

$$\dot{R} + O_2^- \rightarrow \Pi\,, \qquad (IX)$$

$$R^- + O_2 \rightarrow \dot{P}_i + O_2^-\,, \qquad (X)$$

$$\Pi \rightarrow P_i\,, \qquad (XI)$$

where B is a biomacromolecule, $\dot{R}$ is a generalised representation of many types of macroradicals, RO_2 are peroxy-macroradicals, Π are stable or labile peroxides, and P_i is a generalised representation of the reaction products.

In the kinetic scheme considered, reaction (I) represents the primary processes involving the formation of free radicals of different types and the O_2^- radical-anion in the system. Reactions (II) and (III) are competing reactions of free macroradicals, while peroxy-macroradicals are formed in reaction (III). Reaction (IV) represents the cross-disproportionation of peroxy-radicals and superoxide radical-anions. It is noteworthy that the participation of O_2^- in the radiation-induced and photochemical oxidation of peptides and proteins has been discovered by the addition of superoxide dismutase, $O_2^- + O_2^- \xrightarrow{2H^+} H_2O_2 + O_2$.[93,94] The rate constant for reaction (IV) is about 10^9 litre $mole^{-1}$ s^{-1}. A process involving the additional formation of superoxides, namely reaction (V), has been proposed to account for data for the radiation-induced oxidation of proteins and DNA.[36,37] Reactions (VI) and (VII) are the usual radical disproportionation reactions.

Reaction (VIII) has been introduced to explain the relatively high yields in the absorption of oxygen, which exceed the yields in the formation of radicals when proteins and DNA interact with hydroxy-radicals. It has been suggested that this reaction proceeds via an intramolecular mechanism. Reactions (IX) and (X) are possible. It is noteworthy that reaction (IX) can proceed also in the presence of a deficiency of oxygen. Finally, the peroxides formed in reaction (IV) can decompose with formation of a wide variety of products.

The rates of the radiation-induced oxidation of proteins and DNA depend only slightly on temperature, which is consistent with Scheme 1, and only reaction (VIII) can have an activation energy greater than 10 kcal mole^{-1}, while the remaining reactions are characterised by lower activation energies. Within the framework of Scheme 1, the yield of peroxides and the absorption of oxygen should depend only insignificantly on the irradiation dose rate and should be determined by the competition between reactions (IV) and (VII), which has in fact been observed experimentally.[14,38,76,83,93-98]

For many compounds (serum albumins, trypsin, glycyltryptophan), the dependence of the rate of photochemical and radiation-induced oxidation on the oxygen concentration is described by the formula[95-98]

$$y = \frac{\omega}{\omega_{p=1}} = \frac{p(a_1 + 1)}{a_1 + p} , \qquad (1)$$

where ω is the rate of oxidation at a given oxygen concentration, $\omega_{p=1}$ the rate of oxidation in air, p the relative concentration of oxygen, and a_1 a parameter whose value is in the range 0.01–0.1. Within the framework of Scheme 1, the parameter a_1 is given by

$$a_1 = \frac{k_1}{k_2 O_2^{air}} ,$$

If it is assumed that $k_1 = 10^3$ s^{-1} and $k_2 = 10^8$ litre mole^{-1} s^{-1} (Table 4) and that the concentration of oxygen in water exposed to air at 25 °C is 2.6×10^{-4} M, then the calculated parameter a_1 is 0.04, a value which is comparable to that found experimentally.[95,98]

V. THE PRIMARY PROCESSES IN THE RADIATION-INDUCED OXIDATION

The formation of the hydroxy-radical, the hydrated electron, and the hydrogen atom when water is exposed to ionised radiation is the result of a series of physical and chemical processes which we shall not consider here. Free radicals are formed initially in tracks, spurs, and blobs and their distribution in space is extremely non-uniform. This non-uniformity and the inhomogeneity of the initiation should be taken into account in some way, but we do not possess the relevant experimental data. We shall therefore assume that the formation of the active water radiolysis products is fairly uniform.

The rate constants for the reactions of macromolecules with $\dot{H}$, $\dot{O}H$, and $\bar{e}$, presented in Section III, are close to the diffusion-dependent values. This actually implies that at protein and DNA concentrations of the order of 10^{-4} M the active radiolysis products are captured by these substrates; at concentrations of the order of 10^{-5} M there is no point in taking into account the cross reactions of the radiolysis products, since the rates of their reactions with biopolymers are much higher. In the presence of oxygen, the hydrated electron and the hydrogen atom do not participate in the oxidation process, but superoxides and hydroxy-radicals remain active:

$$2\dot{O}H \rightarrow H_2O_2 ,$$
$$2O_2^{\bar{}} \xrightarrow{2H^+} H_2O_2 + O_2 ,$$
$$O_2^{\bar{}} + \dot{O}H \xrightarrow{H^+} H_2O + O_2 .$$

It is easy to show that the third reaction makes the greatest contribution to the destruction of hydroxy-radicals. In order to simplify the kinetic calculations, it was useful to introduce formally a linear destruction reaction [reaction (XIII)] of hydroxy-radicals which are destroyed both in the reactions described above and in the interactions with impurities.

Taking into account these considerations, a simplified scheme for the primary processes involving the formation of macroradicals when biopolymers (B) are exposed to radiation is presented below:[92-103]

Scheme 2

$$H_2O \xrightarrow{h\nu} \dot{O}H, \bar{e} , \qquad (XII)$$

$$\dot{O}H \xrightarrow{k_3} H_2O_2, H_2O , \qquad (XIII)$$

$$\dot{O}H + B \xrightarrow{k_4} \dot{R} , \qquad (XIV)$$

$$\bar{e} + B \rightarrow R^{\bar{}} , \qquad (XV)$$

$$\bar{e} + O_2 \rightarrow O_2^{\bar{}} . \qquad (XVI)$$

At a fairly high oxygen concentration reaction (XV) may be disregarded and we obtain the following expression for the dependence of the relative rate of oxidation z on the concentration of the substance oxidised c:

$$z = \frac{\omega}{\omega_\infty} = \frac{c}{a_2 + c} , \qquad (2)$$

where $a_2 = k_3/k_4$, ω is the rate of oxidation, and ω_∞ the rate of oxidation at $c \rightarrow \infty$. Relations of this type have been known for a long time.[99] They describe satisfactorily the concentration variation for many low-molecular-weight substances and synthetic and natural polymers, including proteins and DNA. Since the rate constant k_3 is not elementary, relations of type (2) do not carry significant information about the oxidation process, but deviations from them in the radiolysis of aminoacids, sugars, and other substances are of interest.[100,101]

The unusual dependence of the gamma-chemiluminescence of solutions of glycyltryptophan on the peptide and oxygen concentrations made it necessary to consider the hypothetical $H\dot{O}_3$ species[96]—the acid analogue of the ozonide radial-ion $O_3^{\bar{}}$.

The influence of hundreds of substances on the radiation-induced reactions of proteins and nucleic acids have been investigated. Such studies had in the main two aims—the elucidation of the mechanisms of the radiation-induced reactions of macromolecules and the establishment of rapid tests for the preliminary testing and selection of potential protectors and sensitisers. The introduction of a fourth initial component into a system containing water, the polymer, and oxygen greatly complicates the system and makes it difficult to describe the experimental data within the framework of simple kinetic schemes. In many cases, it is possible to take the fourth substance into account. The acceptor introduced can interact with all types of active species involved in the radiation-induced oxidation: the active products of the radiolysis of water, the free radicals of the biopolymer, the peroxy-radicals, and the peroxides; the reactions of the acceptor entail the appearance in the system of new radicals

derived from the acceptor, which can also react with macromolecules. The introduction of the acceptor (A) leads to a whole set of reactions:

$$\dot{O}H + A \rightarrow \dot{R}_A , \qquad (a)$$

$$\bar{e} + A \rightarrow R_A^{\cdot -} , \qquad (b)$$

$$O_2^{\cdot -} + A \rightarrow R_A^{\cdot -} + O_2 , \qquad (c)$$

$$\dot{R} + A \rightarrow \dot{R}_A + P_i , \qquad (d)$$

$$R\dot{O}_2 + A \rightarrow \dot{R}_A + \Pi , \qquad (e)$$

$$\Pi + A \rightarrow P_i . \qquad (f)$$

All these reactions inhibit to some extent the radiation-induced oxidation of proteins and nucleic acids. Naturally reactions (a) and (d) make the greatest contribution to the protection. A series of protectors of the type of cysteamine and cysteine act in accordance with this mechanism. The rate constants for their reactions with all types of active species are fairly large and these substances give rise to free radicals which are relatively inactive.[102]

The acceptor free radicals $\dot{R}_A$ react with biopolymers at sufficient concentrations of the latter to form macroradials:

$$\dot{R}_A + B \rightarrow P_A + \dot{R} , \qquad (g)$$

where P_A are the acceptor reaction products. There is a possibility of the competing reaction

$$\dot{R}_A + O_2 \rightarrow R_A\dot{O}_2 . \qquad (h)$$

Judging from the available data,[97,102,103] such protective effects with latent sensitisation have been observed for solutions of biopolymers and even for living cells when alcohols and other substances, which react effectively with hydroxy-radicals to form fairly active acceptor free radicals, are introduced. The rate constants for the reactions of alcohol radicals with proteins are close to the diffusion-dependent values,[103] the oxy-radicals being the most reactive; effects unusual for free radical reactions are observed: the more hydrophobic the alcohol radical, the more readily it penetrates the hydrophobic "gaps" in the protein macromolecules.

Effects of explicit radiosensitisation have been observed for proteins, nucleic acids, and whole cells.[5,6,11,12] As a rule substances, the rate constants for the reactions of which with hydrated electrons are high, exhibit a sensitising activity. Several sensitisation pathways have been proposed, the simplest of which involves the formation of an acceptor radical-anion via reaction (b) and the formation of a macroradical in the reactions with biopolymers:

$$R_A^{\cdot -} + B \rightarrow \dot{R} + P_A . \qquad (i)$$

There are many competing pathways leading to the destruction of acceptor radical-anions, namely the reactions with oxygen, disproportionation, etc.

VI. KINETIC SCHEME FOR SENSITISED PHOTOCHEMICAL OXIDATION

Studies on the degrative effect of "near" u.v.light and visible light on living organisms have recently become more vigorous and the problem of protection against such damage and its prophylaxis has arisen.[14,104] When light acts on solutions of sensitisers, numerous reactions of their electronically excited states and free radicals, radical-ions, and peroxides take place in the presence of oxygen and lead to the degradation of the sensitiser molecules. Naturally there are many sensitisation mechanisms. A triplet–triplet energy transfer from acetone, acetophenone, and benzophenone to the DNA bases has been observed.[105,106] It involved the formation of cyclobutane dimers and breaks in the DNA chain were also observed. In the presence of oxygen the amount of dimer diminished, but the number of breaks increased. In photochemical oxidation this sensitisation pathway is probably fairly rare. Here we shall consider a possible but extremely simplified mechanism of the photochemical oxidation of macromolecules. The probable kinetic scheme for the primary processes is indicated below:

Scheme 3

$$S \xrightarrow{h\nu} {}^3S \qquad (XVII)$$

$${}^3S + S \xrightarrow{k_5} S + S, \qquad (XVIII)$$

$${}^3S + O_2 \xrightarrow{k_6} S + O_2, \qquad (XIX)$$

$${}^3S + O_2 \xrightarrow{k_7} S + {}^1O_2, \qquad (XX)$$

$${}^3S + B \xrightarrow{k_8} S + B, \qquad (XXI)$$

$${}^3S + B \xrightarrow{k_9} R + CH, \qquad (XXII)$$

$$\dot{C}H + O_2 \rightarrow S + O_2^{\cdot -} + H^+, \qquad (XXIII)$$

$${}^1O_2 \xrightarrow{k_{10}} O_2 , \qquad (XXIV)$$

$${}^1O_2 + B \xrightarrow{k_{11}} \Pi , \qquad (XXV)$$

where S is a sensitiser molecule in the ground state and ^3S the triplet electronically excited state of the sensitiser. The triplet state of the sensitiser can be quenched physically in reactions (XVIII)–(XXI), reaction (XXII), involving the formation of singlet oxygen, being the most important. Reaction (XXII) involves formation of free radicals from the macromolecules via a dehydrogenation or charge transfer mechanism and reaction (XXIII) represents the regeneration of the sensitiser. Reaction (XXIV) is the deactivation of singlet oxygen and reaction (XXV) involves the addition of singlet oxygen to the macromolecule. On the basis of the kinetic Scheme 3, subject to the condition that the concentrations of all types of active species are quasi-stationary, an expression has been obtained for the rate of oxidation ω:

$$\omega = \frac{a_0\omega_T cp\,(a_3 + a_4 p + c + a_7)}{(a_1 + p)\,(a_3 + c)\,(a_5 p + c + a_6)} ,$$

where ω_T is the rate of formation of triplet excited states of sensitiser:

$$a_0 = \frac{k_9}{k_8 + k_9}, \quad a_3 = \frac{k_{10}}{k_{11}}, \quad a_4 = \frac{k_7 O_2^{air}}{k_9},$$

$$a_5 = \frac{(k_6 + k_7)\,O_2^{air}}{k_8 + k_9}, \quad a_6 = \frac{k_5}{k_8 + k_9}, \text{ and } \quad a_7 = \frac{k_1 k_7}{k_2 k_9}$$

In the presence of a fairly high oxygen content ($p > 0.1$), the term a_1 may be neglected and apparently so can the parameter a_7, which simplifies the formulae. We shall consider special cases. At a high oxygen concentration, the dependence of the relative rate of the concentration of macromolecules is given by:

$$z = \frac{c}{a_3 + c} \quad (3)$$

Relations of this type have been observed for many systems: glycyltryptophan, in the presence of xanthene dyes, psoralen, and other sensitisers, and trypsin with sensitisation by eosin and retinal.[107-112]

When there is no generation of singlet oxygen, the concentration dependence simplifies:

$$z = \frac{c}{a_5 p + a_6 + c} \quad (4)$$

It may be assumed that this type of relation obtains in the systems glycyltryptophan–ketones, human serum albumin–riboflavin, and bovine serum albumin–anilinonaphthalenesulphonate (ANS).[107,111]

The dependence of the relative rate of oxidation on the relative oxygen concentration has a by no means simple form:

$$y = \frac{a_6 + a_5 + c}{a_3 + a_5 p + c} \cdot \frac{a_3 + a_4 p + c}{a_3 + a_4 + c} \quad (5)$$

For an experimental confirmation of a relation of this type, it is necessary to have numerous data with wide-scale variation of the concentrations of the substrate oxidised and of oxygen. Such studies have been performed in two systems: glycyltryptophan–eosin and trypsin–eosin.[108,110] So far as we are aware, studies of this kind on DNA have not been performed. Finally, when the contribution of singlet oxygen to the photochemical oxidation is low, the dependence on the oxygen concentration assumes the following form:

$$y = \frac{a_6 + a_5 + c}{a_6 + a_5 p + c} \quad (6)$$

It is seen from Eqn.(6) that the relative rate of photochemical oxidation falls with increasing oxygen concentration. This type of dependence has been observed for the human serum albumin–riboflavin system.[107] The parameters a_3, a_4, and a_5 have been determined from the experimental data presented above, which made it possible to estimate certain rate constants and their ratios (Table 5). The rate constants for the reactions of singlet oxygen with a series of peptides and proteins are close to the diffusion-dependent values. The quenching of triplet electronically excited states by proteins is also extremely effective. The quanitity $(k_6 + k_7)/(k_8 + k_9)$ characterises the efficiency of the quenching of triplet excited states of sensitisers by oxygen relative to the quenching by proteins and peptides; for proteins, the above quantity is of the order of unity. The ratio k_7/k_9 characterises the relative efficiency of the formation of singlet oxygen and of its involvement in the oxidation in relation to the formation of protein free radicals; Table 5 shows that the pathway involving singlet oxygen predominates.

VII. PHOTOPHYSICAL AND PHOTOCHEMICAL REACTIONS OCCURRING WHEN MACROMOLECULES ARE ACTED UPON BY ULTRAVIOLET RADIATION

The photophysical processes in proteins have been studied in much greater detail than in DNA. This is associated with the high luminescence yields in proteins and the insignificant luminescence yield in DNA molecules. The photochemical reactions in these systems are also different. Whereas approximately the same products are formed in the case of proteins as on exposure to ionising radiation and the photochemical oxidation proceeds with formation of free radicals, the main product of the photochemical reactions of DNA is cyclobutane dimers, while the yields of the remaining products are low. The dimers are fairly readily destroyed by enzymic repair systems, which ultimately lead to a very high photostability of the DNA molecule in living cells. The appearance of photobiological effects requires u.v. radiation doses, in terms of the energy absorbed by the cell nuclei, higher by 2–3 orders of magnitude than on exposure to ionising radiation.[14,17,100] A simplified scheme for the photochemical oxidation of proteins is given below:

Scheme 4

$$B \xrightarrow{h\nu} {}^1B, \quad (XXVI)$$

$${}^1B \rightarrow B, \quad (XXVII)$$

$${}^1B \rightarrow {}^3B, \quad (XXVIII)$$

$${}^3B \rightarrow B, \quad (XXIX)$$

$${}^3B + O_2 \rightarrow B + O_2, \quad (XXX)$$

$${}^3B + O_2 \rightarrow B + {}^1O_2, \quad XXXI)$$

$${}^1B \rightarrow P_i, \quad (XXXII)$$

$${}^3B \rightarrow P_i, \quad (XXXIII)$$

$${}^1B \rightarrow [{}^1B^{\cdot} \ldots \bar{e}] \rightarrow \dot{R}^{\cdot} + \bar{e}, \quad (XXXIV)$$

$${}^3B + B \rightarrow \dot{R}H + \dot{R}, \quad (XXXV)$$

$${}^3B \rightarrow \dot{R} + \dot{H}(\bar{e} + H^+), \quad (XXXVI)$$

$${}^3B + O_2 \rightarrow \dot{R}^+ + O_2^{\bar{}}, \quad (XXXVII)$$

$$[{}^1B^+ \ldots \bar{e}] + O_2 \rightarrow \Pi, \quad (XXXVIII)$$

$$\Pi \xrightarrow{h\nu} P_i, \quad (XXXIX)$$

where reactions (XXVI)–(XXXI) are the usual photophysical reactions.

Table 5. The rate constants and their ratios for the sensitised photochemical oxidation reactions of a number of substances and the constants calculated within the framework of thekinetic Schemes 1 and 3 from the literature.[98,107-112]

Substance	Sensitiser	$10^{-9} k_1$, litre mol^{-1} s^{-1}	$10^{-9}(k_8 + k_9)$, litre mol^{-1} s^{-1}	$\frac{k_6 + k_7}{k_8 + k_9}$	k_7/k_9
Glycyltryptophan	Eosin	1.1	1	27	6.2
Ditto	Uranin	1.2	—	—	—
»	Psoralen	1.1	—	—	—
»	Nicotinic acid	1	—	—	—
»	Acetone	—	1	8.6	—

Ditto	Uranin	8	—	—	—
»	Retinal	6.4	—	—	—
Human serum albumin	Eosin	21	—	—	—
Ditto	Riboflavin	—	4.8	0.54	—
Bovine serum albumin	ANS	—	4	0.75	—

The principal chromophores in proteins are tryptophan, tyrosine, and phenylalanine; the fluorescence yields of these molecules in neutral aqueous solutions are 23, 21, and 3.8% and the lifetimes of the singlet electronically excited states are 3.1, 3.3, and 5.3 ns respectively.[113-115] The

fluorescence yields for tryptophan-containing proteins are 1–30%, the lifetime of the singlet electronically excited state is 1–6 ns, and the yield of the triplet electronically excited states is up to 10%.[113,114,116–118] In photochemical oxidation oxygen is absorbed with a quantum yield of 0.5–2%, the tryptophan residues decompose with a yield of 1–2%, and enzymes are inactivated with yields of 0.1–3%.[113–120]

The fluorescence quantum yield in DNA is extremely low (10^{-3}–10^{-4}%) and the lifetimes of the singlet electronically excited states are 1–5 ps.[121] The yield of the dimers reaches 4% and on exposure to irradiation by a laser the number of single breaks and other defects increases.[32,122,123] It has been suggested that dimers may be formed with participation of both singlet and triplet electronically excited states—reactions (XXXII) and (XXXIII). The main bulk of these defects are probably formed with participation of singlet excited states, because oxygen does not interfere with dimerisation. There are insufficient experimental data to examine the possible DNA photochemical oxidation processes.

It has come to be assumed that the main reaction occurring in the irradiation of proteins with light at wavelengths in the range 260–300 nm is photoionisation with participation of singlet electronically excited states in the aromatic groups of the protein—reaction (XXXIV), which includes the formation of a complex with partial charge transfer. This reaction proceeds via a one-quantum mechanism in liquid aqueous solutions and via a two-quantum mechanism in frozen solutions.[34,113,116–119,124,125]

Reaction (XXXIV) results in the formation of a radical-cation and a hydrated electron. Other possible reactions leading to the formation of free radicals are also considered in the literature quoted.

Reaction (XXXV) represents the abstraction of hydrogen atoms in the reactions of triplet excited states of the aromatic groups of the protein with neighbouring groups in the macromolecule to form a pair of free radicals and, finally, reaction (XXXVI), which represents the formation of hydrogen atoms or photoionisation with participation of triplet electronically excited states of aromatic groups, is relatively unlikely, being energetically unfavourable.

It has usually been assumed that reaction (XXXI), involving the formation of singlet oxygen, is relatively ineffective in the case of proteins, although there is no evidence for this. We believe that this contribution to photochemical oxidation may prove to be significant.

In constructing a photochemical oxidation mechanism, account is taken of reaction (XXXVII)—the formation of the radical-cation derived from the aromatic groups and of the superoxide radical-anion. This reaction probably occurs in the photochemical oxidation of free tryptophan and peptides containing tryptophan. In order to determine the contribution of the superoxide, experiments have been performed[93,94] in which superoxide dismutase was added during the photochemical oxidation of glycyltryptophan. The enzyme inhibits sharply the formation of unstable peroxides, which indicates a significant contribution of the superoxide to the oxidation. In the case of proteins the addition of the enzyme reduces the yield of peroxide by only 20–30%, i.e. O_2^- is only partly released into space and a "latent radical" mechanism involving the formation of radicals, possibly via reaction (XXXVIII), operates. Oxygen reacts either with the complex in the excited state or with groups in the protein in the triplet excited state, forming peroxides directly. In dilute solutions, at a low optical density, unstable peroxides undergo photochemical decomposition [reaction (XXXIX)].

Thus examination of questions associated with the action of u.v. light on proteins and DNA leads to the conclusion that their reactions follow different pathways: in the case of proteins a free-radical mechanism of the formation of damage-induced defects operates, while in the case of DNA the reactions of free radicals are not important.

VIII. THE POSSIBLE REDISTRIBUTION PROCESSES INVOLVING THE INITIAL DAMAGE-INDUCED DEFECTS IN MULTICOMPONENT SYSTEMS CONTAINING DNA, PROTEINS, AND OTHER SUBSTANCES

The main target when living cells are acted upon by ionising radiation is the cell nuclei or more precisely the DNA molecules. The biochemical composition of the cell nuclei is extremely varied and the principal component consists of a wide variety of proteins. The protein : DNA ratio in different cells varies within broad limits,[126–128] such data being presented in Table 6. Proteins can perform a wide variety of biochemical functions and are effective acceptors of all types of active species. Tables 3 and 4 present the estimated rate constants for different reactions. Proteins and DNA interact effectively with the active water radiolysis products and the free radicals derived from DNA can react with proteins. In qualitative terms, it is understandable that the higher the protein concentration, the smaller the damage to DNA. Here we shall make an attempt to estimate the contribution of proteins to the radiation stability of DNA.

We shall consider a simplified kinetic scheme for the processes occurring in the protein–DNA system on irradiation in aqueous solution. We shall take into account only the reactions of hydroxy-radicals with the macromolecules and DNA:

$$H_2O \xrightarrow{h\nu} \dot{O}H,\ \bar{e},\ \dot{H}\ ,$$

$$\dot{O}H + B \xrightarrow{k_1'} \dot{R}_1\ ,$$

$$\dot{O}H + D \xrightarrow{k_2'} \dot{R}_2\ ,$$

where $\dot{R}_1$ and $\dot{R}_2$ are protein and DNA free radicals respectively. The macroradicals could enter into numerous reactions, including the following:

$$\dot{R}_1 + D \xrightarrow{k_3'} B + \dot{R}_2,$$

$$\dot{R}_2 + B \xrightarrow{k_4'} D + \dot{R}_1.$$

Finally we have the destruction of radicals leading to chemical modification:

$$\dot{R}_1 \xrightarrow{k_5'} P_1\ ,$$

$$\dot{R}_2 \xrightarrow{k_6'} P_2\ ,$$

where P_1 and P_2 are the modification products.

The contribution of the reaction with k_3' to the degradation of DNA can be hardly large, because the protein free radicals are not very active and the absolute DNA concentration in the nucleus is low. Subject to the condition that the concentrations of all the active species are quasi-stationary, the rate of degradation of DNA ω_D is given by

$$\omega_D = \frac{k_2'k_6'[D]\omega}{(k_6' + k_4'[B])(k_1'[B] + k_2'[D])},$$

where ω is the rate of formation of hydroxy-radicals. We introduce the variable $x' = [B]/[D]$ and obtain the following equation for the relative radiation stability of DNA (y'):

$$y' = \frac{\omega}{\omega_D} = (a_1'x' + 1)(a_2'x' + 1)\ , \qquad (7)$$

where

$$a_1' = \frac{k_1'}{k_2'} \quad a_2' = \frac{k_4'[D]}{k_6'}\ .$$

The parameters were estimated from the rate constants (Tables 3 and 4) and the DNA concentration (approximately 4×10^{-4} M). The quantity a'_1 varies in the range 0.1–1 and $a'_2 = 0.05$–0.2. If it is assumed that $a'_1 = 0.5$ and $a'_2 = 0.1$, we obtain from Eqn.(7)

$$y' = (0.5\,x' + 1)\,(0.1\,x' + 1) \qquad (8)$$

Table 6 presents the results of the calculation by Eqn.(8) and it is seen that the stability of DNA increases sharply with increase of the protein : DNA ratio. According to radiobiological data, the stability of cells increases in the same sequence.[4,18,21,25]

Table 6. The radiation stability (y') of DNA as a function of the "protein : DNA" ratio in the cell nuclei of a number of organs and tissues.[126–128]

Object	Protein : DNA	y'
Lymphocytes	2.8	3.1
Thymus	3	3.3
Bone marrow	3.3	3.5
Spleen	6.3	7
Small intestine	8.7	10
Lungs	11.2	14
Kidney	16.7	24.8
Liver	23.4	42.5
Brain	24.6	46
Heart	55.6	188

Remarks: The quantity y' was calculated by Eqn.(8) for a homogeneous solution of the protein and DNA at concentrations comparable to those within the cell nuclei, the stability of DNA in the absence of protein being adopted as unity.

Table 7. The average concentrations (c) and the effective first-order rate constants (k) for the reaction of the components of cell nuclei and membranes with singlet oxygen.

Substance	c, M	k, s^{-1}
Nuclear proteins	$3 \cdot 10^{-3}$	$3 \cdot 10^{6}$—$3 \cdot 10^{7}$
Nuclear DNA	$4 \cdot 10^{-4}$	4
Membrane proteins	10^{-2}	10^{7}—10^{9}
Membrane lipids	1	10^{3}—10^{5}
Inhibitors of the type of tocopherol	10^{-3}	10^{2}—10^{4}

Remarks: k is the product of the rate constant for the reaction of a given substance with singlet oxygen and the concentration of the latter (Table 3).

When the known protector cysteamine is introduced into the system (Tables 3 and 4), its competing reactions with hydroxy-radicals and the DNA free radicals are included in the system. Fairly effective protection can be achieved at protector concentrations of the order of 10^{-3} M, which is comparable to the concentrations giving rise to an effect in a radiobiological experiment.[129] Naturally, the formal kinetic results make it possible to estimate the degree of primary protection of DNA by the protein in solution and cannot claim to be able to account for the complex final biological results of the action of radiation.

Table 3 presents certain data for the reactions of singlet oxygen, which permits a rough estimation of the redistribution of damage-induced defects in multicomponent systems in sensitised photochemical oxidation involving such oxygen. Table 7 also presents estimates for the components of cell nuclei and membranes. It shows that the effective rate constants for the first-order reactions of cell components with $^1O_2$ are higher by several orders of magnitude for proteins than for the remaining components, i.e. proteins are the main target.

---o0o---

Data concerning the mechanisms of the action of radiation on proteins and nucleic acids are of significant interest from the standpoint of the control of the biological consequences of such influences in the primary physicochemical stages of the initial damage. It is seen from the results presented that numerous intermediates participate in the photochemical reactions of biopolymers—electronically excited states, radical-ions, free radicals, peroxy-radicals, and peroxides, as suggested by N.M.Emanuel' in the 1950's. In a number of cases the experimental data can be described within the framework of simplified kinetic mechanisms with participation of a small number of active species. Kinetic equations have also shown that the damage to the "main" DNA molecule can be greatly reduced in the presence of protein—the principal component of cell nuclei.

The complexity of the composition and structure of proteins and nucleic acids preclude the detection of all the reactions leading to the chemical modification of the primary structure of the biomacromolecules and the majority of the mechanisms proposed are tentative. All this indicates the necessity of further studies of these systems using modern methods for the determination of intermediate and final reaction products.

New Aspects of the Application of Nuclear Magnetic Resonance to the Study of Chemical Exchange Processes

A.V.Aganov, V.V.Klochkov, and Yu.Yu.Samitov

The application of the analysis of the total line shape (ATLS) in dynamic NMR to the investigation of complex chemical exchange is examined. Theoretical aspects of this problem, illustrated in relation to the available experimental data, are described. The methodological problems of dynamic NMR are discussed: the sources of error and the role of the medium, the interpretation of the activation parameters $\Delta H^{\neq}$, $\Delta G^{\neq}$, and $\Delta S^{\neq}$, and also the new varieties of the method and their applications.
The bibliography includes 171 references.

I. INTRODUCTION

Since the publication of the first fundamental studies,[1-6] numerous reviews and monographs surveying the results of kinetic studies by the NMR method have appeared. General information can be found in a series of publications.[7-17] A more detailed description of the principles of the theory, method, and applications can be found in reviews.[18-24] The bibliography of the publications in 1970–1974 can be found in a periodical publication.[25] The appearance in 1975 of a fundamental collected volume[26] of review articles on all the most important problems of dynamic NMR (DNMR) heralded the completion of the first stage of its development and establishment. The review articles in the following period were devoted to special problems: dynamic ^{13}C NMR spectroscopy[27] and its application to the study of the dynamics of metal carbonyl[28] and cyclic organic[29] compounds, the application of the methods for the analysis of the total line shape to the examination of the chemical exchange mechanism,[30] and the physical aspects of the theory based on the influence of chemical exchange on relaxation processes[31] and the study of "rapid kinetics".[32] Special mention should be made of the publication of the first book on the general theory of the NMR of chemically exchanging systems[33] and the first monograph devoted to the methodological aspects of DNMR.[34]

Several varieties of the DNMR method are known. The non-selective pulse NMR is an independent method both as regards theory and the procedure used to obtain spectroscopic and kinetic data and as regards experimental technique. The principles of its application to kinetic studies have been described.[35]

Modern NMR Fourier spectrometers make possible experiments under both stationary and selective pulsed conditions. The use of the relaxation times T_1 and T_2, corresponding to the nuclear transitions between individual energy sublevels,

together with the chemical shift δ and the spin–spin coupling constant J, has therefore become a common feature of combined studies of chemical systems. The same universality is to be expected in kinetic investigations in the immediate future.

The DNMR method in the stationary regime is used in the range of reaction rate constants 10^{-1}–10^5 s^{-1} (^1H NMR). Selective pulse methods not only significantly expand the above range (in certain cases from 10^{-3} to 10^6 s^{-1}) but sometimes can yield unique information about the mechanisms of complex chemical exchange processes. It has now become possible to carry out kinetic studies at an extremely low concentration of magnetic nuclei (in gases, in solutions at infinite dilution but with a high natural abundance of magnetic nuclei in the specimen, by ^{13}C and ^{15}N NMR without enrichment in the usual solutions, etc.).

The applications of NMR to kinetic studies are extremely varied and numerous. A fairly completely survey of the research carried out in recent years can be given only within the framework of a collected volume analogous to that of Jackman.[26]

In the present review we shall consider new aspects of the application of NMR to the study of systems with a complex chemical exchange as well as the scope and applications of the new special methods. The most important publications of recent years will be mostly quoted. Brief information about the studies published in 1979–1983 can be found in the periodical reference publication.[36]

II. NMR IN SYSTEMS WITH CHEMICAL EXCHANGE. PROBLEMS OF THE ANALYSIS OF THE TOTAL LINE SHAPE

1. Principal Postulates of the Theory. Multiparameter Exchange. Difficulties and Limits of Applicability

The most interest and most important field in which analysis of the total NMR line shape is used in systems with chemical exchange (ATLS DNMR)† involves the study of the mechanisms of intramolecular and intermolecular exchange in chemical systems where the number of exchanging sites is greater than two and the transitions between them are characterised by different rate constants. Although the theory describing the effect of chemical exchange on NMR spectra has been established in a general form, in the interpretation of the temperature variation of the spectra and in the analysis of kinetic and activation parameters for the chemical exchange serious difficulties are encountered, which are probably not always surmountable. The study of such problems has not been reflected in the review articles quoted above.

The general postulates of the theory for many-sided exchange in systems where there is no direct spin–spin coupling of the nuclear spins have been formulated within the framework of a stochastic theory.[3,4] In another approach[5] modified Bloch equations are used. In a general form the theory has been described by Reeves and Shaw.[37] A detailed discussion of this question can be found in Johnson's[18] and Swift's[31] books and we shall confine ourselves only to brief remarks.

We shall consider a set of magnetic nuclei which can execute random jumps between n different magnetic environments (equilibrium positions). We shall characterise these magnetic environments by a set of Larmor precession frequencies ω_r and spin–spin relaxation times $^*T_{2r}$ (which do not take into account the effects of chemical exchange). The subscript r denotes the equilibrium position ($r = 1, \ldots, n$). In terms of a rotating coordinate system, the equation describing the movement of the xy component of the macroscopic magnetisation $M_{xy} = M_x + iM_y$ in these equilibrium positions under slow pass conditions can be represented in the following general form:[34]

$$\{-{}^*T_{2r}^{-1} + i(\omega_r - \omega)\} M_{xy}^r + \sum_s K_{sr} M_{xy}^r + i\omega_1 M_0 P_r = 0 , \qquad (1)$$

where ω_1 is the angular frequency of the microwave frequency field, M_0 the equilibrium magnetisation, P_r the probability of finding the nuclei in the position r with $\sum_{r=1}^{n} P_r = 1$, $K_{rr} = -\tau_r^{-1}$, and $K_{rs} = k_{rs}$, τ_r being the resonance time of the nucleus in the position r and k_{rs} the rate constant for the transition of the nuclei from the position r to the position s; $-\sum_s k_{rs} = \tau_r^{-1}$.

On solving a system of n linear equations (1) for M_{xy} and bearing in mind that $M_{xy} = \sum_{r=1}^{n} M_{xy}^r$, it is possible to find the required function of the line form. The results of the solution of this system of equations be be conveniently represented in a matrix form. The line form function Y (for the absorption component) can then be formulated thus

$$Y \simeq \mathrm{Re}\{P \cdot [-T_2^{-1} + i(\Omega - \omega) + K^{-1} \cdot 1\} , \qquad (2)$$

where Re is the real component, K the nth order exchange matrix whose elements are the same as in Eqn.(1), T_2^{-1} and Ω are diagonal matrices with the elements $^*T_{*r}$ and ω_r, 1 is a unit column matrix, and P a row matrix with the elements P_r. This equation can be easily solved on a computer provided with a translator enabling it to operate with complex numbers.

The quantum-mechanical theory describing the influence of chemical exchange on NMR spectra was first proposed by Kaplan[6] and is based on the examination of the evolution of the density matrix for the spin systems in the Gilbertian representation (a detailed description of NMR spectra with the aid of the density matrix can be found in Lynden-Bell[20] and Slichter[38]). We shall consider briefly the main postulates of this theory.

Suppose that ψ is the wave function of a "pure" state which can be expanded in a series in terms of the basis functions Φ_n: $\psi = \sum_n C_n \Phi_n$, $p_{ij} = C_i C_j^*$. The coefficients C_i and their complex conjugates C_j^* incorporates the entire time variation of the state of the system. The average value of the physical quantity Q, to which corresponds the quantum-mechanical operator $\hat{Q}$, is defined in the form

$$\langle Q \rangle = \langle \psi | \hat{Q} | \psi \rangle = \sum_{m,k} C_m^* C_k \langle \Phi_m | \hat{Q} | \Phi_k \rangle = \sum_{m,k} p_{mk} \langle \Phi_m | \hat{Q} | \Phi_k \rangle ,$$

where the elements of the density matrix p_{mk} can be represented as a result of the action of the density matrix operator $\hat{P}$:

$$p_{km} = C_k C_m^* = \langle \Phi_k | \hat{P} | \Phi_m \rangle .$$

Then

$$\langle Q \rangle = \sum_{m,k} \langle \Phi_k | \hat{P} | \Phi_m \rangle \langle \Phi_m | \hat{Q} | \Phi_k \rangle = \sum_k \langle \Phi_k | \hat{P}\hat{Q} | \Phi_k \rangle = \mathrm{Tr}\, \hat{P}\hat{Q} = \mathrm{Tr}\, \hat{Q}\hat{P} .$$

Thus $\langle Q \rangle$ is independent of the choice of the basis functions Φ_n. The spin state of a macroscopic system such as the substance in the cavity of the NMR spectrometer consists

† The terminology is discussed in Ref.25 (1973, p.218), in Jackman's book,[26] and by Sandstrom.[34]

of a mixture of states with the corresponding wave functions and cannot be described by a single wave function. However, such a system can be described with the aid of the general system of basis functions Φ_n and the density matrix ρ with the coefficient ρ_{km} averaged with respect to the total assembly:[34]

$$\rho_{km} = \overline{C_k C_m^*} = \langle \overline{\Phi_k | \hat{P} | \Phi_m} \rangle = \langle \Phi_k | \hat{\rho} | \Phi_m \rangle .$$

Then the expected physical quantity Q averaged with respect to the assembly of systems is defined by the relation

$$\langle \bar{Q} \rangle = \mathrm{Tr}\, \hat{Q}\hat{\rho} .$$

Assuming that the Hamiltonian is the same for all the members of the assembly, the Schrödinger time equation can be written in the form

$$d\hat{\rho}/dt = \frac{i}{\hbar} [\hat{\rho}, \hat{\mathscr{H}}] . \qquad (3)$$

The wave function ψ can be represented by the product of the spatial and spin wave functions. In describing NMR, only the spin functions are considered. The basis functions for nuclei with a spin of 1/2 are the eigenfunctions α and β of the operator $\hat{I}_z$ (the z components of the spin momentum operator $\hat{I}$).

The spin-Hamiltonian for a group of identical nuclear spins can be represented in the following form in terms of a rotating coordinate system:

$$\hat{\mathscr{H}} = \hat{\mathscr{H}}_0 + \hat{\mathscr{H}}_1 = \sum_i (\nu_i - \nu) \hat{I}_{zi} + \sum_{j<k} J_{jk} \hat{I}_j \hat{I}_i + \sum_i \nu_1 \hat{I}_{xi} , \qquad (4)$$

where the subscripts i and j refer to individual spins, J_{ij} is the spin–spin coupling constant, $\nu_i = \omega_i/2\pi$, $\nu_1 \hat{I}_{xi}$ describes the interaction with the microwave frequency field H_1 having a frequency ν_1, and $\hat{I}_x$ is the x component of the spin operator $\hat{I}$.

For a description of the resonance absorption under slow pass conditions ($d\rho/dt = 0$) and in the absence of saturation and chemical exchange, it is sufficient to introduce the relaxation term $\hat{\rho}^* T_2^{-1}$ in the right-hand side of Eqn.(3):

$$i [\hat{\rho}, \hat{\mathscr{H}}] - \hat{\rho}^* T_2^{-1} = 0 . \qquad (5)$$

The resonance absorption line form is described by the function

$$Y(\nu) = \mathrm{Im} \left(\mathrm{Tr}\, \hat{\rho} \sum_i \hat{I}_i^+ \right) ,$$

where Im denotes the imaginary component of the expression in brackets, $\hat{I}^+ = \hat{I}_x + i\hat{I}_y$, and the components of the operator $\hat{\rho}$ are found from the solution of Eqn.(5).

The effects of chemical exchange are taken into account by including in Eqn.(5) the term $(\hat{\rho}^{a.e.} - \hat{\rho})\tau^{-1}$, where $\tau(k^{-1})$ is the average residence time in the equilibrium states and $\hat{\rho}^{a.e.} = \chi\hat{\rho}\chi^{-1}$. The elements of the exchange operator χ are defined in the following manner in the simplest case of mutual exchange in a system of spins of one kind:

$$\chi_{kl} = \langle \Phi_l | \hat{\chi} | \Phi_k \rangle . \qquad (6)$$

Consequently the elements of the density matrix after exchange $\rho^{a.e.}$ are given by

$$\rho_{kl}^{a.e.} = \sum_{nm} \chi_{kn} \rho_{nm} \chi_{ml} .$$

In the presence of exchange, Eqn.(5) can then be rewritten as follows:[39,40]

$$k \left(\sum_{nm} \chi_{kn} \rho_{nm} \chi_{ml} - \rho_{kl} \right) - \frac{\rho_{kl}}{{}^*T_2} + i [\hat{\rho}, \hat{\mathscr{H}}]_{kl} = 0 , \qquad (7)$$

where

$$i [\hat{\rho}, \hat{\mathscr{H}}]_{kl} = i\rho_{kl} \left\{ \sum_i (\nu_i - \nu) [(\hat{I}_z^i)_{kk} - (\hat{I}_z^i)_{ll}] + \sum_{i<j} [(\hat{I}_z^i \hat{I}_z^j)_{kk} - (\hat{I}_z^i \hat{I}_z^j)_{ll}] \right\} +$$
$$+ \frac{i}{2} \sum_{i<j} J_{ij} [\rho, \hat{I}_+^i \hat{I}_-^j + \hat{I}_-^i \hat{I}_+^j]_{kl} + i\nu_1 (\rho_{kk} - \rho_{ll}) \sum_i (\hat{I}_x^i)_{kl} .$$

Bearing in mind that $H_1 \ll H_0$, the last term in Eqn.(7) can be replaced by the constant iC.

For a description of more complex cases of chemical exchange, such as non-mutual exchange, intermolecular exchange, exchange in a system of nuclear spins of different kinds or systems with multiparameter exchange, etc., the theory based on the use of exchange operators of the type found by Eqn.(6) is inapplicable; a different definition of the elements of the density and exchange matrices is necessary. Subsequently the approach based on the use of Eqn. (3) in the Gilbertian representation was developed and applied to the analysis of the exchange effects in a wide variety of spin systems.[33,41,42]

Calculations of the line form based on Binsch's unified density matrix method,[21,43–46] in which the formulation of Eqn.(3) in terms of the Liouville representation

$$d\vec{\rho}/dt = -i\hat{\mathscr{L}}\vec{\rho}$$

proposed by Johnson[18] is used, are much more common and probably more convenient in the study of multiparameter exchange, the elements of the Liouville operator matrix are made up of the matrix elements of the spin-Hamiltonian operator for the system (in s^{-1}) in the following manner

$$L_{\mu\nu,k\lambda} = 2\pi [\mathscr{H}_{\mu k}\delta_{\nu\lambda} - \mathscr{H}_{\lambda\nu}\delta_{k\mu}] ,$$

where δ is the Kronecker delta.

Using this representation of the density matrix ρ, Binsch[43] successfully combined the possible versions of the exchange process, including intermolecular exchange.

If the system is subdivided into r non-interacting and independent subsystems, it is possible to formulate the general vector for the system $\vec{\rho}_l$ in a space l, which is the sum of the subspaces $\vec{\rho}_r$. The elements of this vector are ρ_r with the multiplier $f_r = n m_r P_r \left(\sum_r^n m_r \right)^{-1}$, where m_r is the number of nuclei (with a spin of 1/2), P_r the relative population of the subsystem r, and n the number of types of the subsystem. It is postulated that the relaxation processes and the effects of the chemical exchange can be taken into account in describing the time variation of $\vec{\rho}_l$ by including the corresponding operators $\hat{R}_l$ and $\hat{\chi}_l$ defined in the $\vec{\rho}_l$ space:

$$d\vec{\rho}_l/dt = (-i\mathscr{L}_l + R_l + \chi_l)\vec{\rho}_l \equiv M\vec{\rho}_l . \qquad (8)$$

The relaxation operator matrix R_l contains only the diagonal element ${}^*T_2$. In describing the intramolecular exchange, the exchange operator matrix χ_l can be made up of the following elements according to Alexander:[40]

$$\chi_{\mu_r \nu_r k_s \lambda_s} = \delta_{\mu k}\delta_{\nu\lambda} \left[-\delta_{\mu s} \sum_{t(\neq r)} k_{rt} + (1 - \delta_{rs}) k_{sr} \right] ,$$

where k_{sr} is the rate constant for the transition of the spin from the state s to the state r, which has the same significance as in Eqn.(1).

Under the conditions of stationary NMR, Eqn.(8) assumes the form

$$(-i\mathscr{L}_l + R_l + \chi_l)\vec{\rho}_l = 0 . \qquad (9)$$

It is more convenient to represent the operator $\hat{\mathscr{L}}$ as the sum of the operators $\hat{\mathscr{L}}_0 + \hat{\mathscr{L}}_1$; the elements of the operator $\hat{\mathscr{L}}_0$ are

made up of the elements of the Hamiltonian $\hat{\mathscr{H}}_0$ (4), describing the interaction of the spin system with the field H_0, while $\hat{\mathscr{P}}_1$ is made up of the elements of the Hamiltonian $\hat{\mathscr{H}}_1$. Eqn.(9) then becomes

$$(-i\mathscr{P}_{0l} + R_l + \chi_l)\vec{\rho}_l = i\mathscr{P}_1\vec{\rho}_l = i\vec{\sigma} \quad \text{or} \quad M_0\vec{\rho} = i\vec{\sigma} .$$

The complex magnetisation is described by the expression

$$G = (\vec{I} + \vec{\rho}_l) = i(\vec{I}^+ M_0^{-1}\vec{\sigma}) ,$$

where $\vec{I} = \sum_i I_i^+$, and $\vec{\sigma}$ for the intramolecular exchange is determined by the elements $\sigma_{\mu\nu} = CP_r\beta_{\mu\nu}$, where $\beta_{\mu\nu} = 1$ when μ and ν refer to the eigenvalues I_z differing by unity, and $\beta_{\mu\nu} = 0$ in the remaining cases. The NMR absorption function is defined as follows:

$$Y = \mathrm{Im}(G) = \mathrm{Re}(-C(\vec{I}^+[-i\mathscr{P}_{0l} + R_l + \chi_l]^{-1}\vec{\sigma})) . \qquad (10)$$

The dimension of the matrix M_0 is defined in the general case by the relation $\sum_{r=1}^{n}(2^{2m_r})$ (n is the number of equilibrium positions). However, since many elements of the vectors $\vec{I}$ and $\vec{\sigma}$ are 0, the dimension of the matrices employed diminishes to $\sum_r W_r$, where W_r is the maximum number of the possible transitions for individual systems in the position r.

In those cases where the computer is not provided with a translator for operation with complex numbers, Eqn.(10) can be solved by the method proposed by Szymanski and Gyff-Keller.[45]

Thus the solution of Eqn.(2) or (10) can yield a function describing the NMR absorption line form, which in the general case depends on several variables:

$$Y = Y(C_0, \nu_{ri}, T_{2ri}, J_{ij}^{(r)}, P_r, k_{rs}) . \qquad (11)$$

It has been suggested that the constants k_{rs} in Eqns.(2) and (11) are interdependent, which means that under this condition, with the values of k_{rs} obtained from the analysis of the line form described by Eqn.(11), is it possible to compare the true values of the corresponding activation parameters $\Delta H_{rs}^{\neq}$, $\Delta S_{rs}^{\neq}$, and $\Delta G_{rs}^{\neq}$. It is evident, as will be illustrated below, that this condition by no means always holds. The interpretation of the temperature variation of the NMR spectra of such molecules is an extremely difficult problem whose solution has not been found in a general form.

There is no doublt that a more or less successful solution of the problem is possible provided that the parameters of the NMR spectra of the partners of the exchange, which enter into the function Y, are known, i.e. when the slow exchange limit had been attained, the complete line assignment was carried out and account was taken (where possible) of the different effects influencing these parameters. The next stage involves the setting up of exchange matrices corresponding to different versions of the exchange (among the number of the possible versions, naturally excluding those which are indistinguishable spectroscopically[47]). At first sight, this problem has been exhausted and we are dealing only with computational procedures whose success is wholly determined by the complexity of the exchanging spin system and the capacity of the computer (including the adequacy of the programmes). In fact the problem is much more complicated. Eqns.(2) and (10) do not yield an unambiguous solution—even if only one version of the exchange is possible, identical line form functions can correspond to different sets of variables k_{rs}. For example, this type of ambiguity can be observed in the simplest case of the two-sided non-mutual exchange with an appreciable temperature dependence of the relative populations P_r.[48]

A rigorous solution of Eqns.(2) and (10) for many-sided exchange can be obtained when the exchange is described by a single rate constant $k_{rs} = k$ (many-sided one-parameter exchange). For such systems, the selection of a unique exchange scheme, corresponding to a real process, can be achieved by comparing the calculated and observed line forms over the entire experimental temperature range.[30] Here success depends on the extent to which the spectrum is characteristic. In the general case of multiparameter exchange the ambiguity may be either not self-evident (and in this case can probably lead to considerable errors in the determination of the activation parameters) or can be explicit and gives rise as a consequence to the problem of the interpretation of the kinetic and activation parameters.

There is no doubt that the latter problem arises only when the NMR line form is determined by several constants k_{rs}. If the spectrum can be subdivided into subspectra in which the temperature measurements correspond to any one of the processes occurring in the system, the problem reduces to the analysis of two-sided exchange, because the kinetic matrices specified by Eqns.(2) and (10) are subdivided into a series of matrices, each of which includes only one constant k. This approach has been used, for example, in the study of the simultaneous hindered rotation about four bonds in polarised ethylenes.[49] In this review we shall not discuss studies of this kind.

2. Sources of Errors. The Medium Factor. Problems of the Interpretation of the Activation Parameters $\Delta H^{\neq}$, $\Delta G^{\neq}$, and $\Delta S^{\neq}$

The problems concerning the accuracy of kinetic measurements by the NMR method have always been the subject of special attention but their importance was only fully recognised after the activation data for the main types of chemical exchange had been arranged systematically. The essential feature of this situation is strikingly illustrated by the analysis of data for the inversion of six-membered rings (cyclohexane, its *gem*-substituted derivatives, 1,3-dioxans, etc.)—one of the intermolecular exchange processes which have been investigated in greatest detail and in which "anomalies" due to the effects of the medium are least to be expected. The first most striking fact is that the error in the determination of the enthalpy of activation $\Delta H^{\neq}$ quoted in different communications varies within wide limits (from 2–3% to 20–25%). Furthermore, even for the classical cyclohexane molecule, the differences between the $\Delta H^{\neq}$ reported by different workers but obtained under similar experimental conditions (from 38.0 to 48.1 kJ mol^{-1}) greatly exceed the experimental errors quoted in the relevant communications (±0.4–1.0 kJ mol^{-1}). A selection of data can be found in a number of communications.[14,15,50,51] These factors in essence ruled out a comparative analysis, because the real effects were in most cases concealed in the actual errors of the method. There existed also the no less important problem of explaining the anomalously large negative and positive activation entropies $\Delta S^{\neq}$ (~25 e.u. for a reported accuracy to within 3–4 e.u.)[34] for a wide variety of compounds. The anomalies enumerated above are observed more strikingly in the analysis of data characterising the rotation about the partially double C–N bond in amides and related systems.[10,34,52] These anomalies, which were not explained at the time, to some extent discredited the DNMR method.

We shall briefly consider the problems relating to the mutual exchange processes for which a general analysis of the sources of experimental and computational errors has

been carried out.[34] With small stipulations, the conclusions reached can be wholly applied also to the case of non-mutual two-sided exchange.

Intramolecular exchange processes are known to be described by the Eyring and Wynn-Jones equations:[53,54]

$$\ln(k/T) = -\Delta H^{\neq}/RT + \Delta S^{\neq}/R \qquad (12)$$

$$-\Delta G^{\neq} = RT \ln \frac{kh\varkappa}{k_b T} \qquad (13)$$

Since the free energy of activation $\Delta G^{\neq}$ is determined "at a point", its values depend only slightly on the systematic errors and can be determined with a high degree of accuracy.[34,46,55,56] In precision experiments, where the temperature is determined to within not more than 0.5 K and the rate constant k is found by the ATLS method, the error of the estimate of $\Delta G^{\neq}$ may not exceed ±0.15 kJ mol^{-1}. In the standard kinetic studies, an accuracy to within a quantity of the order of 0.8 kJ mol^{-1} can be readily attained. It is of interest to note that a relative 100% error in the determination of k for a hypothetical exchange model ($T = 300$ K, $k = 100$ s^{-1}), with an error of ±6 K in the determination of temperature, leads to a relative error in the estimate of $\Delta G^{\neq}$ at the level of only 4.5%.

The enthaly $\Delta H^{\neq}$ and entropy $\Delta S^{\neq}$ of activation are found as the coefficients of the linear relation between $\ln(k/T)$ and T^{-1} based on Eqn.(12). The use of the Arrhenius equation $k = A_0 \exp(-E_a/RT)$ is less preferable because the condition that the frequency factor A_0 and the activation energy E_a are independent of temperature holds less vigorously. Calculation of $\Delta G^{\neq}$ by the equation

$$\Delta G^{\neq} = \Delta H^{\neq} - T\Delta S^{\neq} \qquad (14)$$

is unjustified, because the advantage of accuracy, which is guaranteed by the direct calculation using Eqn.(13), is thereby lost.

The accuracy of the estimation of the constant k depends mainly on the extent to which the optimum experimental conditions can be fulfilled, because there are no fundamental difficulties in the mathematical treatment of the spectra. The constant k can be estimated in two ways: by the one-parameter procedure or by the ATLS method. In the one-parameter method simple analytical relations between the constant k and some spectroscopic parameter, which can be obtained in the simplest cases, are used. The methods involving these relations have been discussed in detail.[18,19,31,34,50] An exhaustive analysis of the limits of applicability of the approximate formulae and the errors in the determination of k has been carried out.[34,57] The principal difficulty consists in the fact that the use of approximate relations yields a number of experimental points which is inadequate for a statistical treatment and as a result gives rise to a large random error. The size of the deviations depends on how rigorously the conditions of the approximation hold and in certain cases can exceed the random errors to such an extent that the value of the activation data obtained becomes doubtful. These systematic errors, which are difficult to take into account and which lead to large negative values of the entropy factor $\Delta S^{\neq}$, are also largely responsible for the "anomalous" values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$.

It has been shown[58,59] by means of special comparative analysis of the temperature variations of the spectrum that under favourable conditions the relative error in the estimation of $\Delta H^{\neq}$ with the aid of approximate formulae is not less than 2–3 kJ mol^{-1}, while ATLS yields an error of the order of 0.6–0.8 kJ mol^{-1}. Under these conditions, the differences between the average values of $\Delta H^{\neq}$ reached 20% (the approximate methods yield unduly low $\Delta H^{\neq}$). The attempts to improve the approximate formulae,[60] including the procedure involving the subdivision of the kinetic range into five intervals instead of the usual three,[61] do not in essence alter the situation. The systematic error factor can be to some extent weakened when the experimental conditions permit the employment of the approximate formulae over the entire kinetic range.[62] The use of these formulae is at present justified only in the region of slow exchange and for the determination of k at the collapse temperature T_c from the ^{13}C NMR spectra, because in the simplest exchange systems, where the one-parameter method is applicable, the line form can be readily calculated on a minicomputer under laboratory conditions.

In the ATLS method the rate constant k is found either by a visual comparison of the calculated spectra and spectra observed at a certain temperature or by resorting to iterative procedures (the method of "digitalisation of the spectra").[63,64]

According to Sandstrom's data,[34] the relative error of the constant k estimated by the spectrum digitalisation method is 5%, i.e. is of the same order of magnitude as in the visual comparison method; in other words, the accuracy of the determination of k by both methods approaches the limit set by the experimental error. However, in the analysis of the exchange in complex spin systems the visual comparison method is sometimes preferable.[65,66] We may note that, when the number of experimental points is sufficient, the method of least squares yields a random error in the estimation of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ comparable to the limit of accuracy under the conditions of a precision experiment.

The optimum conditions of the DNMR experiment are well known.[15,34,46] The importance of conditions such as a slow pass, the absence of phase and amplitude distortions, the monitoring of the resolution over the entire temperature range, etc. is self-evident. Numerous procedures for the measurement of the temperature of the specimen with a high accuracy are known[34] (±0.2–±0.5 K), so that the important problem of the measurement of the specimen temperature can also be excluded from consideration. We may note that in standard DNMR experiments the temperature of the specimen is determined indirectly from the readings of the instruments in the circuit for the electronic stabilisation of the temperature of the heat exchanger stream. Since the temperature calibration is extremely sensitive to the [heat exchanger] flow rate in the region of low temperatures, the readings of the instruments at temperatures below 203 K are as a rule too low, which leads to considerable systematic errors in the determination of $\Delta H^{\neq}$. If an internal NMR thermometer cannot be used for some reason, it is necessary to measure the temperature directly before and after recording each spectrum. The size of the temperature range is undoubtedly important, but, since it is determined solely by the characteristics of the specimen itself, it is necessary to take into account only that the greatest accuracy is achieved for a uniform distribution of experimental points over the temperature range.[34]

The principal source of systematic errors, which is not always subjected to a realistic assessment, is the errors in the determination of the parameters of the spectrum of the exchange partners and the difficulties in the establishment of their temperature variations, which is particularly important in systems involving a complex exchange. This problem is closely intertwined with the general problem of the role of the medium in kinetic experiments and assumes exceptional importance in experiments starting "with the specimen" (mainly in low-temperature studies), because the substance determines both the kinetic range (and hence also the temperature range of the measurements) and the conditions in the medium (these problems have not been reflected in the review literature concerning the solvent effect in NMR spectroscopy[67,68]).

Special difficulties do not arise when it is possible to record a series of spectra in the regions of slow and rapid exchange, since in this case it is possible to obtain not only sufficiently accurate values of δ, J, and $^*T_2$ but also their temperature variations in an analytical form, which are then taken into account in the ATLS. In such cases it is possible to obtain a high accuracy in the determination of the activation parameters: ±0.4–0.08 kJ mol^{-1} for $\Delta H^{\neq}$ and ±0.5–1.0 e.u. for $\Delta S^{\neq}$ [65,66,69] Since it is as a rule difficult to take into account all the sources of systematic errors, it is more reasonable to quote the overall error, which is of the order of ±2 kJ mol^{-1} for $\Delta H^{\neq}$ and ±2.5 e.u. for $\Delta S^{\neq}$ according to the data of Allerhand et al. [57] We may note that it is frequently necessary to introduce the spectroscopic parameters to some extent arbitrarily and one has to postulate just as arbitrarily that their intrinsic (non-exchange) temperature dependence has been maintained over the entire range of the measurements.

The error can therefore prove to be even greater, for example in the solution of dynamic problems in the low-temperature region where experimenters are forced to employ mixtures of solvent which behave differently in different combinations and at a different temperature. [70] The medium effect may become more difficult to take into account when the molecule is non-polar overall but its individual fragments are highly polar. This situation has been observed using specific solvents such as acetone, dimethyl sulphoxide, benzene, and chloroform, which tend to form complexes, hydrogen bonds, etc. (cases where the solvent, for example, chloroform, induces the same reversible changes as the usual intramolecular exchange [71] are not considered here). Such characteristics of the behaviour are to a large extent responsible for the "apparent effects" of the solvent on the activation parameters. It is in fact precisely this factor and not the use of approximate formulae, as believed by Sergeev[15] and Sandstrom, [34] and the simplifcation of the spectrum, as claimed by Ionin et al., [8] that is responsible for the frequently quoted anomalous values of E_a in dimethylformamide and other amides. [34,52,59,72] Thus use of approximate formulae merely increases the error. [73,74]

From the standpoint of the correctness of the comparative analysis of the activation data obtained in different solvents, particularly for systems with intramolecular non-mutual exchange, the actual dependence of these data on the type of solvent and on the concentration of the test substance in solution is of special interest.

We shall now turn to the results of precision experiments designed to investigate the influence of the solvent on $\Delta H^{\neq}$. The enthalpy of activation for cyclohexane ring inversion is almost independent of the type of solvent (methylcyclohexane, CS_2, hexadeuterioacetone) [75] and varies within the limits ±4 kJ mol^{-1} for acetone (in CCl_4, CH_2Cl_2, and $CDCl_3$ as solvents). [76] In amides and related systems the solvent effects on the enthalpy of activation for rotation about the C–N bond are expressed by a quantity of the order of ±4 kJ mol^{-1}; [71,77–80] an appreciable concentration dependence has also not been observed.

For systems with non-mutual exchange, such reliable results are not available. However, one can use data for the influence of the type of solvent on the enthalpy of the conformational equilibrium ΔH_0. [70] For example, the energy difference between the rotational isomers of 1-chloro-2-fluoroethane changes by 1 kcal mol^{-1} on dissolution in cyclohexane, while the corresponding change for *trans*-1,2-dichlorocyclohexane is by 0.89 kcal mol^{-1} [the correction for the temperature dependence of the dielectric constant $\varepsilon(T)$ was not taken into account]. It has been shown [81] that, within the framework of the theory of reactive fields, the correction for the temperature dependence of $\varepsilon(T)$ may be neglected in estimating the influence of the solvent on the conformational equilibrium with the aid of NMR: in substituted 1,3,2-dioxaphosphorinanes ΔH_0 varies within the limits 3.5–1 kJ mol^{-1} in a series of solvents—acetonitrile, acetone, methylene chloride, and carbon tetrachloride. Thus the medium factor can be taken into account in the comparative analysis of $\Delta H^{\neq}$, provided that the differences ($\Delta\Delta$) between the different media exceed 4 kJ mol^{-1}. For the free energy of activation, this range of $\Delta\Delta$ values is ±0.3–0.4 kJ mol^{-1} and for $\Delta S^{\neq}$ the $\Delta\Delta$ vary from ±4 to ±5 e.u. The quantities $\pm\Delta\Delta$ lie within a comparison region which can be easily established by analysing the activation data obtained for the same compounds under similar experimental conditions and using similar methods for the interpretation of the spectra (for example, on the basis of the data for cyclohexane quoted above). The same range of $\pm\Delta\Delta$ values has been obtained for the activation parameters determined in standard kinetic NMR experiments.

The discussion of the questions related to the effect of the solvent on activation parameters is outside the framework of the present review. There are numerous publications devoted to this problem. [82–85] It is very likely that in the immediate future, when it will be possible to survey the results of kinetic studies in highly diluted solutions and in the gas phase, the approach to this problem and the existing ideas will undergo radical changes. We may note that the temperature variation of the chemical shifts for reference compounds (tetramethylsiloxane, hexamethyldisiloxane, and benzene) [86–88] does not affect significantly the accuracy of the estimation of the activation data.

The questions concerning the experimental error become particularly important in the study of complex exchange, because here the accuracy is much more significant than in a standard kinetic experiment: insufficiently correct determination of the limits of the probable values of the activation parameters can cause an incorrect treatment of the exchange situation or can lead to the formulation of erroneous ideas about the molecular dynamics of the chemical system investigated.

The intepretation of the activation parameters for chemical exchange is to some extent an independent field of study, but, since these parameters are determined mainly by DNMR, the questions concerning their interpretation are deal with in virtually every serious DNMR study.

Since most of the chemical exchange processes involving polyatomic molecules take place without the participation of the excited levels of the molecule, the transmission coefficient κ in Eqn.(13) is assumed to be 1 or 0.5. The contribution of tunnelling to κ is neglected. This contribution becomes effective for low barriers to interconversions for molecules with few and light atoms. [89]

The constant k is related to the difference between the zero-point energy vibrations in the transition and ground states E_0 by the expression

$$k = \varkappa \frac{k_b T Q^{\neq}}{\hbar Q} \exp(-E_0/RT) , \qquad (15)$$

where $Q^{\neq}$ and Q are the partition functions for the transition and ground states and the relation between E_0 and V (see Figure), which is found with the aid of quantum-chemical calculations of the potential energy surface, is defined by the formula

$$E_0 = V + \sum_i^{\text{trans}} h\nu_i/2 - \sum_j^{\text{gr}} h\nu_j/2 ,$$

where the summation is carried out over the vibrational degrees of freedom for the transition and ground states.

It is assumed that all the vibration frequencies ν_i and ν_j are approximately the same with the exception of the single frequency ν, corresponding to movement along the reaction coordination. The difference between E_0 and V is $6\bar{\nu}$ kJ mol^{-1} ($\bar{\nu}$ is the wavenumber in cm^{-1}) and must be taken into account in the most accurate calculation; when the process is described in terms of torsional vibrations, whose frequencies are much lower, the above difference can be neglected. It follows from Eqn.(15) that

$$\Delta H^{\neq} = E_0 + RT^2 \, \mathrm{d} \ln \frac{Q^{\neq}}{Q} / \mathrm{d}T \,, \tag{16}$$

$$\Delta G^{\neq} = E_0 - RT \ln \frac{Q^{\neq}}{Q} \,, \tag{17}$$

$$\Delta S^{\neq} = R \ln \frac{Q^{\neq}}{Q} + RT \frac{\mathrm{d}}{\mathrm{d}T} \left(\ln \frac{Q^{\neq}}{Q} \right) \,. \tag{18}$$

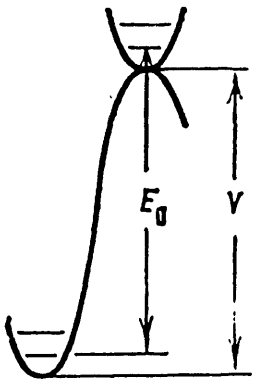

Diagram of the relative vibrational energy levels of the molecule: V = calculated theoretical energy; E_0 = zero-point vibration energy.

It has been suggested that the energy levels of the translational, rotational, and vibrational movements are mutually independent, i.e. $Q = Q_{\text{trans}} Q_{\text{rot}} Q_{\text{vibr}}$. For intramolecular exchange processes, evidently $Q_{\text{trans}} = Q_{\text{trans}}$ [sic].

(a) The activation enthalpy $\Delta H^{\neq}$. Since, as will be shown below, the ratio $Q^{\neq}_{\text{rot}}/Q_{\text{rot}}$ is independent of temperature, only the contribution of the vibrational partition functions Q_{vibr} must be taken into account in Eqn.(16). These partition functions differ only by the contribution q_r, which is determined by the degree of freedom of the vibrational movement at a frequency ν_r, which is absent in the transition state. Then

$$\frac{\mathrm{d}}{\mathrm{d}T} \left(\ln \frac{Q^{\neq}}{Q} \right) \simeq \frac{\mathrm{d}}{\mathrm{d}T} \ln \left(\frac{1}{q_r} \right) = \frac{\mathrm{d}}{\mathrm{d}T} \left\{ \ln \left[1 - \exp \left(- \frac{h\nu_r}{k_b T} \right) \right] \right\} \,,$$

whence

$$\Delta H^{\neq} = E_0 - R \frac{h\nu_r/k_b}{\exp (h\nu_r/k_b T) - 1} \,. \tag{19}$$

Thus $\Delta H^{\neq}$ depends on the temperature, but this dependence is not very pronounced and may be neglected. The difference $\Delta H^{\neq} - E_0$ approaches RT in the limit (at high values of T or at low frequencies ν_r) and can be calculated in principle.

The exceptional value of acurate experimental $\Delta H^{\neq}$ with correctly applied corrections is evident, since only by comparison with the latter is it possible to achieve a reasonable compromise in quantum-chemical calculations on the barriers. This applies both to *ab initio* calculations and to quantum-chemical calculations in terms of semiempirical approximations.[89-91]

The results of calculations have been discussed in the literature.[34,51] Strictly speaking, for comparison with such calculations, it is necessary to have the results of experiments in the gas phase, which, as will be shown below, lead to different values of $\Delta H^{\neq}$.

(b) The activation entropy $\Delta S^{\neq}$. This is a more "dynamic" activation parameter than $\Delta H^{\neq}$, but at the same time it is more difficult to use it for predicting the transition state. However, the view concerning this parameter has become optimistic in recent years. The initial scepticism was caused both by the large errors in the experimental estimates and by the problematic nature of the theoretical calculations of the entropy of the transition state. As a palliative measure, it was suggested that only the statistical contribution to $\Delta S^{\neq}$ be used on the basis of the symmetry properties of the molecule in the ground and transition states. This approach appears entirely convincing, because, subject to the assumptions underlying the estimation of the contribution of vibrational degrees of freedom to $\Delta H^{\neq}$, the contribution of the latter to $\Delta S^{\neq}$ is negligible[34] ($-0.20R - 0.03R$). Since the principal moments of inertia of the molecule I_A, I_B, and I_C in the ground and transition states can be assumed to be equal, it follows that the contribution

$$Q_{\text{rot}} = \frac{\pi^{1/2}}{\sigma} \left(\frac{8\pi k_b T}{h^2} \right) (I_A I_B I_C)^{1/2}$$

is determined only by the term $\sigma/\sigma^{\neq}$, where σ and $\sigma^{\neq}$ are the group orders of the pure rotations in the ground and transition states. Eqn.(18) can then be written in the form

$$\Delta S^{\neq} = R \ln \sigma/\sigma^{\neq} \,. \tag{20}$$

An additional term, namely the entropy of mixing $\Delta S^{\neq}_{\text{mix}}$, which takes into account the multiplicity of the degeneracy of the states, must be introduced into this equation:

$$\Delta S^{\neq}_{\text{mix}} = -R \sum_i P_i \ln P_i \,,$$

where P_i is the fraction of molecules passing through each transition state.

An alternative approach to the estimation of the statistical contribution to ΔS, consisting in the direct estimation of the number of independent ways in which the barrier can be crossed, is available. A discussion about these questions can be found in the literature.[34,92] However, analysis of a large amount of experimental data leads to the conclusion that this approach does not solve the general problem and furthermore is unjustified even in the simplest case—the description of the inversion of the ring in cyclohexane derivatives,[66] and it is essential to take into account all the contributions to $\Delta S^{\neq}$. However, although the difficulties expected in this procedure are evident, the conclusions reached by Hoffner et al.[66] give rise to a definite optimism. In certain cases it may be useful to discuss the problems in terms of the contributions to the partition functions by the rotational degrees of freedom of the internal rotors; however, this contribution is also insignificant.[34]

The above remarks concerning the corrections to $\Delta H^{\neq}$ and $\Delta S^{\neq}$ and the prospects for the employment of these quantities for the prediction of the transition state apply primarily to systems with the simplest form of the barrier profile under conditions where there are no medium effects. Here the

expected contributions to $\Delta S^{\neq}$ are small, of the order of magnitude of ±2 e.u., and comparable to the contribution of the statistical factor, while the accuracy of the experimental estimate can be raised to ±0.5 e.u. However, this problem has other aspects associated with the interpretation of the $\Delta S^{\neq}$ for a wide variety of compounds which are not merely of theoretical interest. These include the interpretation of the anomalously large positive and negative activation entropies, greatly exceeding their standard experimental error. Qualitatively, these effects have been explained as "entropy effects" of the highly polar interactions: they are caused by the considerable difference between the types of solvation of the molecules in the ground and transition states.[34,82] The sign of $\Delta S^{\neq}$ is determined by the relative polarity of these compounds: the large negative values correspond to molecules with a more polar form of the ground state (of the entire molecule or its individual fragments). It has been suggested that these effects can be used to predict the structure of the transition state.[83]

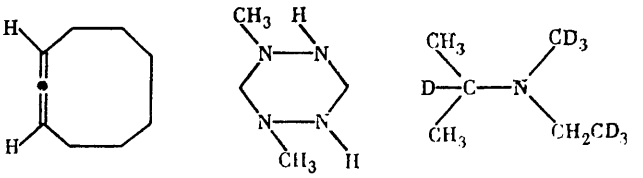
Another manifestation of the effects of this kind is large negative values of $\Delta S^{\neq}$ (up to −20– −30 e.u.), which are typical for tautomeric transformations in cyclic phosphoranes,[93] intramolecular phosphorotropic 1,3-migrations in a series of phosphorylated amidines,[94] and 1,3-sulphenyl migrations in amidine systems.[95] The negative entropies in the first two cases probably reflect the multistage mechanism of the processes described. Clearly, for such systems, theoretical calculations of the $\Delta S^{\neq}$ are hardly feasible in the immediate future. Nevertheless, the prospects for the employment of $\Delta S^{\neq}$ for the prediction of the transition state or at least for the explanation of the experimental results are entirely optimistic, particularly in the case where it is possible to develop reliable semiempirical rules in conjunction with the employment of a correct comparison of data for model compounds.

(c) The free energy of activation $\Delta G^{\neq}$. The high accuracy, the simplicity of the experimental estimation, and the principle of linearity[96,97] have been responsible for the employment of the most varied correlations of this parameter with the properties of the substituents, the medium, etc. in describing intramolecular exchange processes. Certain examples of such correlations have been given by Spaargaren et al.[58] However, we do not consider it necessary to discuss them within the framework of this review. We shall only mention the lack of validity of numerous discussions concerning the activation barriers ($\Delta H^{\neq}$) using free energy of activation data. Such identification is strictly speaking possible when the assumptions underlying the derivation of Eqns. (16)–(20) are valid. Furthermore, when the ATLS has not been carried out with a subsequent estimation of $\Delta H^{\neq}$ and $\Delta S^{\neq}$, the insensitivity of $\Delta G^{\neq}$ to errors in the determination of k and even to the values of k themselves can lead to an incorrect assessment of the exchange situation and hence to errors in the interpretation of different effects influencing the exchange processes. Evidently, in systems with a complex chemical exchange, the use of only the one parameter $\Delta G^{\neq}$ is impermissible.

3. Experimental Studies of Multiparameter Chemical Exchange

We shall consider more fully the studies by the ATLS DNMR method of systems in which a multiparameter exchange is observed and the constant k is determined from the temperature evolution of one group of lines in the spectrum.

In those cases where the processes are separated by a wide temperature range, it is in most cases possible to achieve a separate description of these processes, for example, in terms of the changes in the ^{13}C NMR spectra of cyclonona-1,2-diene (I) in the temperature range 96–263 K.[98]



(I) (II) (III)

The resonance line of the carbon atom in the C–H group, which is a singlet at room temperature, splits into two lines at 123 K with an integral intensity ratio of 2 : 1, of which one, the low-field line, is greatly broadened; on further decrease of temperature, it divides into two lines of equal intensity (at 103 K). These spectral changes correspond to two intramolecular processes: (a) the pseudorotation of the dominant (asymmetric) conformation, which averages out two non-equivalent signals; (b) the interconversion of the type "dominant" form ⇌ minor "symmetrical" conformation, which is responsible for the merging of all the signals into a singlet. Anet and Yavari[98] were able to determine the kinetic parameters of these processes with adequate accuracy.

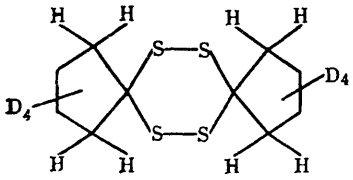
The rates of intramolecular topomerisation have been determined with the aid of the ATLS of the signal of the methylene protons in the ^1H NMR spectra of 1,4-dimethylhexahydro-1,2,4,5-tetrazine (II):[99] the rates of ring inversion and of the inversion of the bond pyramid at the nitrogen atom. Here the changes in the spectrum of the CH_2NH fragment in the temperature range 233–273 K are entirely due to the change in the rate of inversion of the nitrogen atom associated with the intermolecular hydrogen exchange involving the NH groups: the rate constants k were obtained on the assumption that the rate of ring topomerisation is low and does not influence the observed line form. The temperature range of the observed changes in the spectrum as a consequence of the topomerisation of the ring was 253–310 K.

Two intramolecular processes in deuteriated *N*-ethyl-*N*-methylisopropylamine (III) have been investigated:[100] (a) the inversion of the bond pyramid at the nitrogen atom, which is manifested by the exchange broadening of the ^1H NMR signals in the temperature range ~133–152 K, and (b) the rotation about the C–N bond, which contributes to the change in the ^1H NMR line form at 101–124 K. The kinetic parameters of both processes have been estimated on the assumption that the rotation takes place under the conditions of hindered inversion.

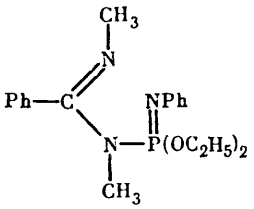
In this case, when the exchange processes responsible for the broadening of the NMR lines are separated by a short temperature range (20–30 K), the task of finding the kinetic parameters may be greatly complicated as a consequence of the uncertainty, noted above, in the determination of the constant k not only in the region of fast exchange but also in the region of slow exchange. If the signals of the "frozen out" forms are characteristic and fairly well separated in terms of the chemical shift scale, then in some cases, for example, when the region of the slow exchange covers a wide temperature range, it is possible to determine the kinetic and activation parameters for exchange processes on the basis of the ATLS of the low-temperature NMR spectrum.

The temperature dependence of the ^1H NMR spectrum of 3,3,6,6-bis(tetradeuteriotetramethylene)-*S*-tetrathiane (IV) has been described in this way[101] within the framework of the chair–twist–chair*–twist*# equilibrium, because the temperature range corresponding to the slow (in terms of the NMR scale) exchange is ~50 K:

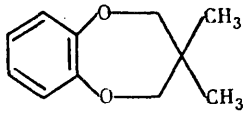
The asterisk denotes inverted structures.



(IV)



(V)

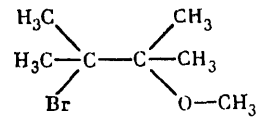


(VI)

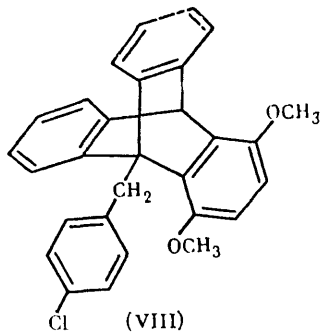
The authors showed that the introduction of a rate constant for the direct chair ⇌ chair* or twist ⇌ twist* transitions leads to a deviation of the calculated line form from the experimental form, whence it followed that the energy barriers in these transitions should indeed be higher than for the chair ⇌ twist exchange.

The kinetics of *Z*–*E* isomerisation and phosphorotropic tautomeric processes have been investigated on the same lines[94] for N^1N^2-diethoxy-N^1N^2-dimethyl-*N*-phenyliminophosphonylbenzamidine (V) (in this case the line form is calculated mainly in the region of slow exchange at 418–445 K). In those instances where the NMR spectra of the "frozen out" forms are only slightly separated in terms of the chemical shift scale, the uncertainty in the determination of the constant *k* may prove to be significant over the entire temperature range of the spectroscopic changes and can lead to errors in the determination of the activation parameters. Thus, in a study[102] of 3,3-dimethyl-1,5-benzodioxepan (VI) the ^{1}H NMR spectra of the "frozen out" chair and twist forms were observed at 133 K. The rate constants for the chair–chair and chair–twist transitions in the inversion of compound (VI) were determined by the ATLS method, but the authors[102] do not consider it possible to discuss the energy relations of the processes on the ground of the unreliability of the determination of temperature, the inaccuracy in the determination of the quantities $1/^*T_2$, and also the use over the entire temperature range of postulated relative proportions of the conformers; in the authors view, the anomalously large negative $\Delta S^{\neq}$ (−15 ± 5 e.u.) are a consequence of these errors. We believe that this is caused to a large extent by the erroneous nature of the estimation of the kinetic parameters of the exchange as a result of the uncertainty in the derivation of these parameters, because the changes in the spectrum corresponding to the above processes are manifested in virtually the same temperature range and the authors[102] do not quote alternative calculations of the rate constant which are essential in such cases.

A ^{1}H NMR study of the hindered rotation about the C–C bond in a series of 2-alkoxy-3-halogeno-2,3-dimethylbutenes has been reported.[103] The singlet due to the methyl groups (CH_3^*), observed in the spectrum of compound (VII)



(VII)



(VIII)

at room temperature splits into three lines at 162.5 K: an intense singlet and two lines with equal integral intensities, the ratio of the integral intensity of the first line to the sum of the other two being 43 : 57. This change in the signal of the methyl groups is caused by the decrease of the rate of rotation about the C–C bond when the rotational process can be regarded as exchange between the *trans*- and *gauche*-forms (a) and between two *gauche*-forms (b). Using the ATLS, the authors point out that it is impossible to differentiate the temperature dependence of the rate of the second process, because the theoretical line forms obtained with and without allowance for k_b do not reveal a significant difference (the spectra for $k_b = 0$ and $k_a = k_b$ were calculated) and are close to the observed line forms.

A study[104] of the hindered rotation about the C–C bond in 9-(*p*-chlorobenzyl)-1,4-dimethoxytriptycene (VIII) is instructive in this connection. At a low temperature (~246 K) the ^{1}H NMR signals of the methylene protons consist of an AB quartet and a singlet, due to the *d*-, *l*-, and *meso*-forms respectively. An increase of temperature leads to the merging of these signals into a singlet. It has been shown that, for different selections of the rate constant k_1 and k_2 for the *meso* ⇌ *d*(*l*) and *d* ⇌ *l* exchange processes respectively, the calculated line form agrees with the observed line form and the ranges of the constants k_1 or k_2 in which this occurs are comparable to the true values of k_1 or k_2. The authors[104] formulated the problem of the estimation of the kinetic parameters of exchange processes having similar rates and responsible for the exchange-induced broadening of a single group of NMR lines, but do not propose a solution. The solution of a similar problem for mutually independent processes has been described.[105] The uncertainty in the estimates of k_1 and k_2 (for two independent processes) can be expressed graphically by a family of $\ln k_1 - \ln k_2$ "iso-F" curves, along which the theoretical line form agrees with the experimental line form at a specific temperature when different sets of k_1 and k_2 are used. In order to find the solution, a series of straight lines intersecting the "iso-F" curves are drawn and the points of intersection are transferred to $\ln k_1 - T^{-1}$ and $\ln k_2 - T^1$ plots. A unique solution, corresponding to a real process, is found from the minimum standard deviation of the linear relations found in this way between $\ln k_1$ and $\ln k_2$ and temperature.

The examples examined are distinguished by the simplicity of the exchange situation, because the exchange mechanism is known. However, there are many systems in which there is a possibility of different versions of the exchange process and the choice of an unambiguous solution is an extremely complex problem, which probable cannot always be solved by the ATLS DNMR method. It can be solved fairly rigorously for the simplest case where the intramolecular exchange is characterised by a single rate constant and it remains only to find an alternative exchange mechanism. This problem has

been discussed in detail in a review,[30] where it is shown that in such cases agreement between the calculated and experimental line forms over the entire temperature range is a criterion of the reliability of the selected model. However, it is not always possible to predict the ways in which the exchange mechanisms can increase in complexity or to describe quantitatively this kind of chemical exchange in cases where an increase in its complexity has been established experimentally.

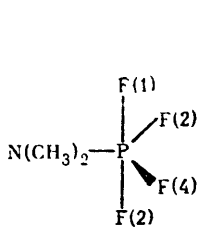
On the basis of the analysis of numerous experimental data and our own studies, we propose three criteria for the reliability of the description of complex chemical exchange, whose employment makes it possible to avoid errors in the interpretation of DNMR data:[106]

1. agreement between the calculated and observed NMR line forms over the entire temperature range;
2. the linearity of the temperature variation of the rate constants for the processes;
3. agreement between the activation parameters obtained as a result of the analysis of multiparameter exchange with the analogous values for systems where the particular process is unique.

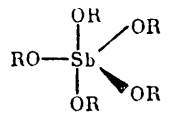
Examples which logically reflect the application of these criteria with increasing complexity of the exchange situation are presented below. One of the first studies of this kind was that of Saunders (see Steigel[30]), who investigated the degenerate shift of the methyl group in the heptamethylbenzenium ion. Two possible versions of the exchange were considered: in one case the methyl group passes to a neighbouring position (the 1,2-shift), whereas in the other the shift is random. Depending on the pathway followed in the shift, two versions of the transitional structure are also possible. Analysis of the ^{1}H NMR line form made it possible to give preference to the first exchange mechanism. The problem of the intramolecular exchange of the $CuP(C_2H_5)_3$ group in the $C_5H_5CuP(C_2H_5)_3$ molecule, in which the group either shifts to a neighbouring position or there is exchange between the 1- and 3-positions, has been solved analogously.[30,107] The calculated line forms for these exchange mechanisms differ appreciably; comparison with experiment has shown that the exchange proceeds via the 1,2-shift mechanism.

Processes leading to the averaging of the ^{1}H NMR spectra of *O*-acyl-3,7-dibenzyltropolones have been identified.[108] The ATLS method enabled the authors[108] to identify, together with the acyltropic tautomerism, two conformational transitions, namely the rotation of the acyloxy-group about the troponyl–O bond and the rotation of the acyl group in the acyloxy-fragment.

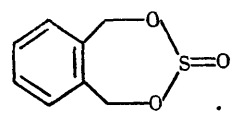
In the study of intramolecular dynamic processes in the phosphorane $PF_4N(CH_3)_2$ (IX),[30,109] it proved possible to distinguish two mechanisms of the rearrangement: the one-pair and two-pair ligand exchange processes in the pseudorotation of the bonds, i.e. the 1–4, 1–3, 2–3, and 2–4 or (1–3)(2–4) and (1–4)(2–3) ligand exchange processes. Analysis of the ^{31}P NMR line form permitted the unambiguous selection of the second type of rearrangement:



(IX)



(X): a) $R = CH_3$; b) $R = CH(CH_3)_2$

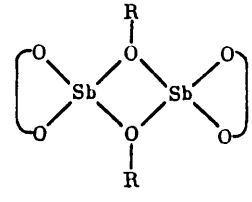


(XI)

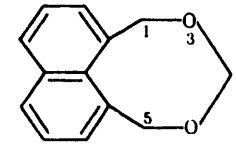
The possible mechanisms of the exchange in the dimeric structure of pentamethoxyantimony (Xa) have been examined.[110] It has been established that the mechanism according to which there is exchange between the dimeric structures (dissociation and formation of bridge bonds) operates and that, simultaneously with the rupture of the bridge bonds, the configuration of the bonds at the Sb atom changes, both processes being characterised by different rate constants.

The determination of the components of the conformational equilibrium using DNMR can be illustrated in relation to the analysis of the line form in the spectrum of the methylene protons of phthalyl sulphite (XI). The form of the low-temperature spectra indicates the appearance in solution of two forms[111,112] (two AB quartets). The "chair-a" conformation (with the axial position of the S=O bond) predominates. Additional arguments in favour of the second, "twist" conformation were obtained on the basis of the ATLS, because the exchange mechanism in which the low-field and high-field lines of the two AB quartets are averaged out corresponds to the real process. If the alternative "chair-e" conformation were realised, the mechanism would have corresponded to the averaging out of the high-field signal of the dominant form with the low-field form and conversely.

The use of the ATLS made it possible to establish for the first time that, as a result of the dynamic processes manifested in the ^{1}H NMR spectra, in the cyclic compounds of tricoordinate antimony the bond pyramid undergoes a change in its configuration.[113,114] It has been established that the monomeric form in the "chair-a" conformation and the dimeric form (XII) exist in solution and that exchange between them in fact reflects the evolution of the line form in the NMR spectra.



(XII)



(XIII)

In the examples quoted the first of the proposed criteria for the description of intramolecular chemical exchange processes in terms of DNMR was applied. Fundamental information about the validity of the description can be extracted from the analysis of the temperature dependence of the rate constant for the process described. When a suitable mathematical model of the real exchange mechanism is used, this dependence should be linear in terms of a plot of $\ln(k/T)$ against $1/T$ and, since changes in line form are observed over a narrow temperature range (~50 K), it should also be linear in terms of a plot of $\ln k$ against $1/T$. This approach is based on the high accuracy of the estimation of the activation parameters reached in the ATLS method.

A study of the molecular dynamics of 2,4-dioxa-3,5-dihydro-1*H*-cyclo-octa[*de*]naphthalene (XIII) showed[115] that calculation of the ^{1}H NMR line form for the methylene groups in the 1(5)- and 3-positions on the assumption of mutual conformational exchange led to its agreement with the experimental line form over the entire temperature range for both groups of protons. However, the differences between the values of k at the same temperature for the above groups of protons greatly exceeded the experimental error and the dependence of $\ln k$ on $1/T$ could not be fitted by a straight line. Analysis of the variation of the non-equivalence of the chemical shifts of the methylene protons at C(1) [C(5)]

in 3-*t*-butyl-2,4-dioxa-3,5-dihydro-1*H*-cyclo-octa[*de*]naphthalene (XIV) made it possible to establish that the change in the line form for compound (XIII) is caused by the chair–chair exchange in the presence of rapid chair–boat exchange. Calculation of the line form corresponding to this exchange mechanism, using the spectroscopic parameters of the "chair" and "boat" forms of compound (XIV) yielded a satisfactory linear temperature variation of the rate of the chair–chair transition for compound (XIII).

This principle was also used in the solution of the previously discussed problem of the separation of the contributions of the exchange processes occurring at similar rates and responsible for the exchange-induced broadening of one group of NMR lines.[105]

Using the same procedures, the "synchronous" nature of the rotation of a pair of rings in the collective internal rotation of the three aromatic rings in the triaryl derivatives of arsenic and phosphorus has been demonstrated[116] on the basis of the ATLS of the ^{19}F DNMR spectrum.

Finally there is a possibility of the situation where the changes in the NMR spectra are caused by processes whose spectroscopic assignment gives rise to no doubts and the $\ln(k/T)-1/T$ relation is linear. In this case it is necessary to employ a third criterion.

Thus, in the study quoted above,[99] identical activation energies were obtained for both processes and, on the basis of a comparison of this quantity with the literature data for similar processes, the authors concluded that their rates are limited by the inversion of the bond pyramid at the nitrogen atom. Olekhnovich et al.,[108] who noted the auxiliary role of the conformational transformations in acylotropic tautomerism, were guided by the same principle.

In the study quoted above,[110] approximately equal values of $\Delta H^{\neq}$ were obtained for the exchange of the dimer–dimer type involving compound (Xa) and for the pseudorotation of its bonds (~76 kJ mol^{-1}); the latter cannot be accounted for in terms of the ideas concerning the energy relations of the pseudorotation of the bonds of the pentacoordinate P, As, and Sb atoms, although the spectral changes in the case under consideration are consistent with the pseudorotation process. The study of the NMR for the monomeric compound (Xb) showed[110] that the barrier to the pseudorotation of the Sb^{V} bonds does not exceed 20 kJ mol^{-1}. The activation parameters for compound (Xa) were interpreted within the framework of ideas concerning the rate-limiting stages in the processes.

By virtue of the improvement in the computational procedures and in the apparatus, one can probably expect in the immediate years ahead a considerable progress in the study of systems with complex chemical exchange.

III. SPECIAL METHODS

1. The ATLS of Nuclei Other than ^1H

The exchange-induced broadening effects in the resonance absorption spectra of various nuclei with a spin of 1/2 (^{19}F, ^{13}C, ^{31}P, and ^{15}N) are described by the same equations as in the ^1H spectroscopy (the presence of a quadrupole moment in nuclei with a spin greater than 1/2 and their greater spin multiplicity make relaxation methods preferable to ATLS). The ^{19}F and ^1H NMR spectroscopic methods have similar sensitivities and the methods of the kinetic investigations using these nuclei differ little. The employment of the ATLS of the NMR spectra of the remaining nuclei has many features in common, which involve the sensitivity and the time scale of the method as well as the procedure used to record the spectra, which, considered together, distinguish the DNMR spectroscopy involving these nuclei from ^1H DNMR.

In the course of its rapid development, ^{13}C DNMR spectroscopy has already passed the inevitable period involving comparison with the scope of ^1H DNMR. Its advantages and, equally, its limitations and experimental difficulties have been demonstrated in relation to extensive experimental data,[27,29,34,117–119] which cannot be discussed within the framework of this review. We shall only touch upon some of the most important methodological aspects.

It is known that the range of the ^{13}C chemical shift (in p.p.m.) is ~20 times greater than that of the ^1H NMR shifts (or ~5 times greater in terms of frequency units). The range of the measurable rate constants therefore increases by a factor of 25 towards higher rates and collapse is reached at higher temperatures. However, one should note that, within the limits of a single structural fragment, an increase in the shift scale may not in fact occur.[113,120] In other cases the difference between the ^{13}C chemical shifts for the exchanging positions is so great that the advantage of a more extended time scale is transformed into a disadvantage of the method;[121] the region of the collapse and of the intermediate exchange occupies such a wide spectral range that the broadened spectral line merges with the base line. For "moderate" barriers (~40–60 kJ mol^{-1}), this region covers a wide temperature range and none of the regions of the rapid or slow exchange can be reached, which can lead to an erroneous interpretation of the spectrum.

In dynamic ^{13}C NMR with broad-band ^1H decoupling the exchange situation is relatively simple—it involves as a rule a two-sided exchange in a system of uncoupled spins, which has in fact led to numerous kinetic studies using ^{13}C NMR spectroscopy. However, serious experimental problems have been encountered, which must be taken into account in selecting the research methods. In the main they are associated with the low sensitivity of ^{13}C NMR spectroscopy and relaxation processes.

Special difficulties do not arise in studies with liquid specimens or with highly concentrated solutions. Here it is comparatively simple to attain a satisfactory signal-to-noise ratio in the region of the intermediate exchange in order to be able to employ the ATLS (naturally for moderate degrees of nonequivalence of the chemical shifts, amounting to ~200 Hz). However, it is usually necessary to work with dilute solutions, which requires a large number of accumulations. The time taken to record a single spectrum is so prolonged that the recording of a high quality spectrum in the region of intermediate exchange rates and collapse becomes extremely problematical, since it becomes essential to ensure a long-term stability of temperature and of its measurement.

This time factor becomes especially important in low-temperature measurements in solutions of sparingly soluble crystalline substances: after prolonged exposure to low temperatures, the substance crystallises. The measurement of temperature in the ^{13}C NMR method becomes very important in the recording of spectra with broad-band suppression of the ^1H signal, because the interaction of the microwave frequency radiation with a polar solvent leads to additional heating of the specimen (the degree of heating is proportional to the polarity of the solvent). For this reason, in those cases where a quantitative treatment of the temperature dependence of the ^{13}C NMR spectra is necessary, it is desirable to employ a ^{13}C NMR thermometer. The use of wide bulbs in order to increase the sensitivity creates certain difficulties in the measurement of temperature as a consequence of the high temperature gradient in the specimen (2 K cm^{-1}).

The relaxation processes are directly reflected in the accuracy of the determination of k from the exchange-induced broadening of the spectra. The point is that even in a single

exchange pair the relaxation times T_1 and the nuclear Overhauser effect (NOE) differ. This is clearly manifested in the region of a slow exchange, where the integral line intensities are inconsistent with the number of exchanging spins. An accurate analysis of the line form presupposes the knowledge of the temperature variation of T_1, which is not feasible owing to the chemical exchange effects.

Since the line width in the ^{13}C NMR spectra is just as small as in the ^{1}H NMR spectra, in kinetic studies it is very important to ensure the highest possible resolution determined by the capacity of the minicomputer. Such resolution is specified by the condition[34,122] $\Delta\nu = 2w/N$, where w is the width of the spectrum in the given frequency range and N the number of selected points on the descending component of the induction signal(DIS) (their uniform distribution on the DIS curve is assumed), i.e. $\Delta\nu$ is the distance between two points in the frequency range. Consequently the uncertainty in the determination of the line width is $2\Delta\nu$. Since the number N is limited by the capacity of the minicomputer, an improvement of the potential resolution is achieved by reducing w (in order to avoid the convolution of the spectrum, it is necessary to adjust the frequency range). For example, a resolution of 1.2 Hz is attained in the presence of 8192 points on the DIS curve for a width of the spectrum of 5000 Hz.[27] Since the error in the determination of the width of the exchange and non-exchange lines is ±1.2 Hz, for an exchange-induced broadening less than 10 Hz the constants k will be found with large errors. Another limiting factor and source of errors is the line broadening as a consequence of the residual splitting arising as the power of the microwave frequency field of the broad-band decoupling diminishes (the power is reduced in order to diminish the heating of the specimen).

It is easily seen that the ATLS method appplied to ^{13}C DNMR encounters serious difficulties and is justified only in those cases where the exchange problem cannot be solved by ^{1}H DNMR either due to the complexity of the spectra (for example, in the case of exchange in a five-spin or even more complex systems) or because the chemical exchange process itself cannot be observed.

We shall not dwell on well-known examples illustrating the inapplicability of ^{13}C DNMR spectroscopy to the study of certain types of chemical exchange, which can readily be identified by ^{1}H DNMR methods. We shall merely draw attention to the fact that the combined employment of both methods can be exceptionally useful in the analysis of systems with complex chemical exchange. The point is that in ^{13}C NMR spectroscopy one observes fairly frequently several exchange pairs simultaneously and the exchange processes can be manifested in different pairs. On the other hand, the same process can be reflected in different ways in the ^{1}H and ^{13}C NMR spectra, which makes it possible to avoid the uncertainty discussed previously. This approach has been illustrated by Sandstrom and Sjostrand.[123]

The ^{15}N NMR time scale is of the same order of magnitude (in terms of frequency units) as the ^{13}C NMR spectroscopic scale, but the sensitivity of ^{15}N spectroscopy is lower by two orders of magnitude than that of ^{13}C NMR. Kinetic studies on specimens with the natural abundance of the ^{15}N isotope therefore involve even greater difficulties. There has been only one investigation[124] of the hindered rotation about the C–N bond in L-arginine using ATLS. There have been more investigations using relaxation methods.[125] A number of studies have been carried out with the aid of the ATLS of the ^{15}N NMR spectra of enriched specimens, but these studies have been mainly devoted to intramolecular and intermolecular hydrogen exchange processes.[126–130].

The ^{31}P NMR time scale in frequency units is somewhat narrower than in carbon spectroscopy (by a factor of ~1.5), but, since the sensitivity of the ^{31}P NMR method is somewhat lower than that of ^{1}H NMR (by a factor of ~20), the difficulties are associated mainly with the relaxation processes when broad-band $^{31}P-\{^{1}H\}$ decoupling is used. There have been few studies carried out using ATLS. The intramolecular rearrangements in which the chemical shift of the signal due to the phosphorus nucleus remains unchanged but the line form is altered by virtue of the transposition of the spins linked to the ^{31}P nucleus are perhaps of greatest methodological interest.[109] Kinetic experiments under the conditions of selective $^{31}P-\{^{1}H\}$ decoupling will probably yield much information.

2. Kinetic Studies under Extreme Conditions. Gases. Liquids at High Pressures

Theoretical calculations of the activation and equilibrium parameters of chemical exchange are usually carried out for isolated molecules and until recently the calculated data have been compared with the results of studies in solutions. However, even the early ^{1}H DNMR data for the gas phase showed how incorrect is such a comparison.[131,132] There is no doubt that these experiments cannot be performed for every substance, but the exceptional value of experimental data of this kind has stimulated studies on these lines and their number has appreciably increased in recent years.

The main requirements which must be met by the given substance is a fairly high barrier to intramolecular transformations and volatility. A low concentration of the test substance is a very serious but not insurmountable obstacle in the experiments. Another cause of the reduced sensitivity is the broadening of the lines in the spectra for the gas phase owing to the low times T_1, because the mechanism of the spin–rotational relaxation in gases is more effective than in liquids.

The experimental technique has already been discussed.[132, 136] The Table presents the results of kinetic studies for the ATLS of the ^{1}H DNMR spectra for classical types of chemical exchange. On the basis of the very few data available, one can merely make general remarks. The temperature of the collapse with transition to the gas phase as well as the values of $\Delta H^{\neq}$ and k for different compounds vary in different ways. The times T_2 depend markedly on the pressure (the temperature and pressure dependences of the static parameters δ and J had been determined earlier and have been the subject of other investigations—see, for example, Raynes and Chadburn[138] and Bernstein[139]).

Interesting data have been obtained for the phase dependence of the rate constant and activation parameters for ring inversion in cyclohexane.[135,136] Assuming that the internal pressures in gaseous and liquid CS_2 at 298 K are respectively 0 and 3714 atm, while the difference between the values of $\Delta G^{\neq}$ in the gas phase and in the CS_2 solution is 370 cal mol^{-1}, then the activation volume is $\Delta V^{\neq} = -4$ cm^3 mol^{-1} [$\Delta V^{\neq} = (\partial G^{\neq}/\partial p)_T$]. This result is correlated with data obtained recently in the kinetic studies on cyclohexane ring inversion in various solvents at a variable pressure.[74] When the pressure is varied from 1 to 5000 atm, the $\Delta V^{\neq}$ vary from −5.0 cm^3 mol^{-1} (in acetone) to −1.5 cm^3 mol^{-1} (in $C_6D_{11}CD_3$), which is also consistent with the results of a study in which data for *NN*-dimethylacetamide were discussed.[140]

These experiments showed that, in the absence of strong electrostatic interactions, the activation parameters depend greatly on the state of aggregation. Few studies of this kind have been made. Experiments at a high pressure using shift reagents have been reported.[141] Data obtained in NMR studies of the influence of pressure on chemical kinetics[142] and molecular conformations[143,144] are available. The experimental technique is specific and has been discussed in the original communications.

Activation data for chemical exchange in liquid and gas phases.

Compound	Type of process	Conditions	T_c, K	$\Delta G^{\neq}$, kJ mol^{-1}	$\Delta H^{\neq}$, kJ mol^{-1}	$\Delta S^{\neq}$, e.u.	Refs.

*Here and below in the Table the determinations were made at 298 K.

3. Special Methods

Fairly numerous methods, supplementing or modifying the classical ATLS method, are known. Many of these have been used since the beginning of intensive investigations of DNMR and are well known. They include the isotope tracer method,[15,34,145] the employment of lanthanide shift reagents,[34,146,147] and the direct stereomutation method (the equilibration method) proposed by Mannschreck[148] and developed in subsequent studies[149,150] (for a discussion, see Sergeev[15] and Sandstrom[34]). Studies of the internal movements of molecules dissolved in nematic media are of special interest. They are based on the high sensitivity of the spectra of partly oriented molecules to chemical exchange processes, which average out certain direct dipole–dipole interaction constants. Their energy barriers can be estimated quantitatively, provided that the intramolecular movement and the rotation of the molecules as a whole in the liquid crystal mesophase matrix are independent. The method involves also other assumptions and limitations, but it is nevertheless extremely attractive because it makes it possible to obtain activation parameters which cannot be determined by other procedures (low barriers, barriers in systems where there are no suitable NMR labels for investigation by standard methods).

A detailed discussion of this method, which is in essence a component of NMR investigations in the mesophase, may be found in the article of Emsley and Lindon.[151] We may note certain publications in recent years devoted to the study of ring inversion in S-trioxan,[152] the pseudorotation in cyclopentane,[153] and internal rotation in alkylamides in a polystyrene matrix.[154]

When spectrometers operating at markedly different frequencies ν_0 are available, it appears very attractive to make use of the simplicity and relatively high accuracy of the determination of k at T_c from a relation of the type $k = \pi\Delta\nu/2^{1/2}$ for mutual exchange, where $\Delta\nu$ is the limiting line separation. Since $\Delta\nu$ depends on ν_0, it follows that T_c also depends on ν_0 (in amides T_c changes by 3 K when the frequency is altered from 60 to 220 MHz). This method is believed[155] to guarantee a high accuracy of the estimation of $\Delta H^{\neq}$ and $\Delta S^{\neq}$. In individual instances this is probably valid, but one should note that the accuracy of the recording of collapse is low and is in fact lower the greater the rigour with which the condition governing the applicability of this formula is fulfilled. The collapse temperature T_c is determined to within 2 K and the presence of 3–4 points over a narrow range cannot ensure a high accuracy of the interpretation of an equation of type (12). However, the main deficiency of the method is the unjustifiably large consumption of apparatus time: in essence, it is necessary to carry out the entire kinetic experiment, from slow exchange to collapse, on several spectrometers, because, the occurrence of collapse must be determined very accurately. There is no doubt that in many cases it is essential to use the same NMR thermometer.

Major difficulties arise in the use of formulae for mutual exchange which relate k in the vicinity of collapse to the spectroscopic parameters and which include the working frequency ν_0 as the variable parameter.[156] The above methods have not found extensive application probably for this very reason. The use of the effect of the "concertina chemical shifts", arising when a train of four pulses with phase rotation by 90° is employed, appears more attractive.[122] In media of low viscosity, where there is no dipole–dipole broadening, the duration of the pulses can be regulated in such a way that the chemical shift scale varies from 0 to 1, while the indirect spin–spine coupling constants remain unaltered. This technique, which has become available in recent years, can prove extremely useful in the analysis of exchange in complex spin systems and in systems with multiparameter exchange (and naturally when the above methods with variation of ν_0 are employed).

The method involving a rapid change of the medium[157] has been proposed for the investigation of hindered rotation in molecules which cannot be heated owing to their thermal instability. It is applicable in the presence of fairly high energy barriers when the equilibrium depends markedly on the solvent polarity and the equilibration time is long enough to record the NMR spectra. The experimental technique is fairly simple: the test substance is rapidly mixed with the solvent with a markedly different polarity and the attainment of a new equilibrium at a certain temperature is then observed. The scope of the method has been illustrated in relation to the study of the hindered rotation about the C–C bond in 9-(2-methoxy-1-naphthyl)-9-fluorol.

A high accuracy of the estimation of $\Delta H^{\neq}$, to within 3 kJ mol^{-1}, was attained. The limitations of the method are self-evident: the usual problems involving the employment of mixed solvents and the inconsistency of the observed heights of the barriers with the quantities obtained in non-polar solvents remain. It is easily seen that the method is similar to the direct stereomutation method already mentioned.

4. Relaxation Methods

Standard selective relaxation methods make it possible to obtain the same information about chemical exchange processes as DNMR is a stationary regime, but their application in the region of intermediate rates of exchange is less preferable, mainly due to the high errors in the determination of the rate constant k. In the regions of slow and rapid exchange, which are limiting as regards the ATLS, the relaxation methods yield more accurate values of k.

Methods involving the use of relaxation processes, which can yield data inaccessible by the ATLS method, are known. One of these involves the measurement of the relaxation time T_1 in a rotating coordinate system.[34,158] The nuclear spin system is acted upon by a 90° microwave pulse with an amplitude B_1 along the x axis. At the instant when the precessing (with a frequency $\nu_1 = \gamma B_1/2\pi$) vector with a magnetisation M is aligned rigorously along the y axis, the phase of the pulse is altered by 90° and it is applied along the y axis. Since the vectors B_1 and M are now parallel, the vector M is maintained along the y axis. This entails an exponential decrease of the length of the vector M with a characteristic time T_1. In the simplest case of a two-sided exchange we have

$$(T_{1\rho}^{-1})_{exch} = T_{1\rho}^{-1} - T_1^{-1} = \frac{\pi^2 k \cdot \Delta\nu^2}{k^2 + 4\pi^2 \nu_1^2} .$$

This relation is valid subject to the conditions $\Delta\nu^2/k \ll 1$ and $\Delta\nu \ll \nu_1 \ll \nu_0$. The method makes it possible to measure rates in the range 10^3–10^6 s^{-1} and to determine $\Delta\nu$, which is impossible in direct experiments in this range of rates.

In another method, proposed by Hoffman and Forsen[24] and known as the "saturation transfer method", the direct NOE is used in systems with slow chemical exchange. A procedure based on the cross-relaxation NOE has also been developed.[160,161] The idea of the saturation transfer method is simple and has been described in a number of communications;[15,24,162] when nuclei in a position r are acted upon by an additional saturating microwave frequency field, the line intensity corresponding to the nuclear transitions in the position s changes provided that the nuclei are interchanged between these positions. The method is useful in studies of complex chemical exchange, but its application is restricted; the spectral lines corresponding to these positions must be sufficiently remote from one another to avoid the occurrence of beats associated with the two microwave frequencies employed. This difficulty can be readily overcome in ^{13}C NMR spectroscopy (an additional pulse generator is required for this purpose). The method permits the measurement of rate constants smaller by 2–3 orders of magnitude than in ATLS. Questions concerning its use with allowance for the possibilities of modern experimental techniques have been discussed in a number of communications.[163–165]

Kinetic studies employed 2-D spectroscopy, which in many cases constitute an alternative to the saturation transfer method, have been developed in recent years.[166–171] They will probably prove effective in the study of multiparameter exchange but hitherto they have mainly aroused much publicity and have been of a comparative character.

---o0o---

DNMR, which is at present based on a highly sophisticated experimental technique, is undoubtedly a powerful method for the investigation of stereodynamics, tautomeric transformations, and other chemical exchange processes. In many cases its extensive possibilities make it possible to overcome difficulties in the study of systems with complex exchange. However, this does not resolve the general problem of the uncertainty arising in the use of ATLS and much effort is essential in this field to search for effective methods of analysis of the temperature variations of the NMR spectra.

Kinetics of the Formation of Adsorption Layers at a Solution–Air Interface

V.B.Fainerman

Studies of the kinetics of the adsorption of surface-active substances (SAS) from solutions have been reviewed. The influence of the chemical structure of the SAS (the length and degree of branching of the hydrocarbon chains and the nature of the polar group) on the mechanism of the adsorption process and the adsorption-kinetic characteristics of the SAS has been analysed. The correlation between the values of the adsorption and desorption rate coefficients and the adsorption equilibrium coefficient has been discussed.
The bibliography contains 119 references.

I. INTRODUCTION

There has recently been a significant increase in the number of papers dealing with the study of the kinetics of the adsorption of surface-active substances (SAS) at the interfaces between solutions and air or a liquid. The interest in this problem is due to the fact that many processes associated with the adsorption of SAS at these interfaces (the surface separation of substnaces, dispersion, including emulsification, and also foaming, wetting, spreading, etc.) and many surface phenomena in biological systems take place under conditions in which equilibrium between the surface layer and the bulk of the solution is not established. The study of the kinetics of adsorption gives important information on the nature of surface phenomena. It is needed, in particular, for an understanding of the mechanism of the action of SAS in technological processes and the control of their action.

It is known that a considerable time is required to establish the equilibrium surface tension at the freshly formed surface of SAS solutions. Three main mechanisms are considered to be responsible for the delay in establishing equilibrium. Milner[1] suggested that the delay is due to the diffusion of the solute from the volume of the solution to the surface layer (in present-day terms diffusion to the pre-surface layer directly adjoining the surface layer). The concept of a surface barrier decreasing the rate of the transfer of a substance from the pre-surface layer to the surface layer was proposed by Doss.[2] It is considered that another possible factor decreasing the rate of establishment of the equilibrium surface tension is related to processes of reorientation of the adsorbed SAS molecules in the surface layer. Hansen,[3] who first pointed out this possibility on the basis of published data,[4] however concluded that reorientation processes have only a slight influence on the surface tension of solutions of SAS with low molecular weight. A recent review[5] gave bulk diffusion and processes of rearrangement in the surface layer as the main factors determining the rate of decrease of the surface tension.

There are very few monographs or reviews on the kinetics of adsorption at liquid phase interfaces. In addition to the review[5] already mentioned, which deals chiefly with processes of adsorption on a surface undergoing periodic deformation, the only published summaries are in an out-of-date review[6] and a section in a monograph.[7] These reviews make practically no reference to the results of studied published in the Soviet literature.

The aim of the present work is to examine briefly the results of theoretical studies of the kinetics of adsorption from solutions containing one SAS in non-micellar form (mainly at freshly formed non-deformed liquid phase interfaces), to summarise experimental data on the kinetics of the adsorption of SAS at a solution–air interface, and to analyse the principal regular features of this process. Most attention has been paid to the adsorption of SAS of low molecular weight.

II. THE THEORETICAL STUDY OF THE KINETICS OF ADSORPTION FROM SOLUTIONS

A most important stage in the development of the theory of the kinetics of adsorption at liquid phase interfaces was a study[8] which solved in general form the problem of the diffusion of SAS from the bulk of a solution with adsorption at a phase boundary, first formulated in Ref. 9.

The physical picture of the adsorption process can be represented as follows. The initial moment of time corresponds to the formation of a fresh surface (flow of liquid from a nozzle, bubbling, etc.) or the instantaneous removal of SAS from the surface of a solution (for example by means of a moving barrier). At this moment, the concentration of the SAS in the surface layer is equal to its concentration in the bulk. Estimates show[10] that only 10^{-9} s after the moment of formation of the phase boundary, the concentration of SAS in the pre-surface layer decreases practically to zero (with the condition that there is no barrier to adsorption). This produces a concentration gradient, leading to the directed diffusion of the SAS from the bulk to the surface layer. When a surface barrier is present, and also as equilibrium is approached, the difference between the concentrations of the SAS in the pre-surface layer and in the bulk decreases, with a corresponding decrease in the diffusion flux and the rate of adsorption. Thus the kinetics of adsorption at any

moment of time can be determined by solving the diffusion equation if the concentration in the pre-surface layer is known.

For a planer surface, the problem can be written as follows:[8,9,11,12]

$$\frac{\partial c}{\partial t} = D\frac{\partial^2 c}{\partial x^2}; \quad x > 0, \; t > 0 \; , \tag{1}$$

$$c = c_0; \quad x > 0, \quad t = 0 \; , \tag{2}$$

$$c = c_0; \quad x \to \infty, \quad t > 0 \; , \tag{3}$$

$$AD\frac{\partial c}{\partial x} = \frac{\mathrm{d}(\Gamma A)}{\mathrm{d}t}; \quad x = 0, \; t > 0 \; . \tag{4}$$

Here, c is the concentration of the SAS; c_0 the concentration of the SAS in the bulk of the solution at the initial moment and under equilibrium conditions; t the time elapsed from the moment of formation of the surface; x the coordinate ($x = 0$ corresponds to the solution–air interface); D the diffusion coefficinet; Γ the dynamic adsorption; and A the area of the surface. Eqn.(4) is the condition for preservation of the quantity of SAS.

A more general formulation of the problem contains instead of Eqn.(1) a convective diffusion equation, and instead of Eqn.(4) equations for the balance of the SAS in the surface layer with allowance for the diffusion and convective fluxes.[11,13]

For a non-deformed surface (A = conts), the boundary condition (4) reduces to the form[8,9]

$$D\frac{\partial c}{\partial x} = \frac{d\Gamma}{\mathrm{d}t}; \quad x = 0, \; t > 0 \tag{5}$$

and for a deformed surface it can be written in the form[11,12]

$$D\frac{\partial c}{\partial x} = \frac{\mathrm{d}\Gamma}{\mathrm{d}t} + \Gamma\nu(t); \; x = 0, \; t > 0 \tag{6}$$

where $\nu(t) = d\ln A/dt$ is the rate of deformation of the surface.

The solution of the problem (1)–(3) and (5) is written in the form[8,14,15]

$$\Gamma = 2c_0\left(\frac{Dt}{\pi}\right)^{1/2} - \left(\frac{D}{\pi}\right)^{1/2}\int_0^t \frac{c(0,\tau)}{(t-\tau)^{1/2}}\,\mathrm{d}\tau \tag{7}$$

where τ is the integration variable.

It can be seen that the most general formulation of the boundary condition for $x = 0$ (Eqns.(4)–(6)) leads to an integral equation relating the values of the adsorption and the concentration of the SAS in the pre-surface layer. The subsequent course of the solution of the problem involves the introduction of additional equations which make it possible to eliminate $c(0, t)$ from Eqn.(7).

Two different approaches have been used. In the first, it is assumed that equilibrium between the pre-surface layer and the surface layer is established very rapidly, and that the rate of the adsorption process is determined exclusively by the rate of diffusion (diffusion mechanism of adsorption). In this case the relationship between the quantities Γ and $c(0, t)$ is given by the adsorption isotherm equation. The second, more general approach takes account of both the rate of diffusion and the rate of establishment of equilibrium between the surface layer and the pre-surface layer (mixed adsorption mechanism). This approach uses adsorption kinetic equations relating Γ and $c(0, t)$ under non-equilibrium conditions. Finally, there is a particular case when the rate of diffusion is high compared with the rate of establishment of equilibrium between the surface layer and the pre-surface layer (kinetic or adsorption mechanism of adsorption). In this case the concentration of the SAS in all parts of the solution (including the pre-surface layer) at any moment of time is equal to c_0. In this case the rate of adsorption is described by adsorption kinetic equations containing c_0 instead of $c(0, t)$.

An expression for the dynamic adsorption Γ for the diffusion mechanism of adsorption can be obtained using, for example, the Frumkin adsorption isotherm[16]

$$bc_0 = \frac{\theta_0}{1-\theta_0}\exp(-2a\theta_0) \tag{8}$$

which effectively describes the equilibrium adsorption of SAS at liquid phase interfaces.[17,18] When it is used for dynamic conditions (that is when $c(0, t)$ and θ are used instead of c_0 and θ_0 respectively), Eqn.(7) gives:[19,20]

$$\theta = \frac{2c_0}{\Gamma_\infty}\left(\frac{Dt}{\pi}\right)^{1/2} - \frac{1}{\Gamma_\infty b}\left(\frac{D}{\pi}\right)^{1/2}\int_0^t \frac{\theta\exp(-2a\theta)}{(1-\theta)(t-\tau)^{1/2}}\,\mathrm{d}\tau \; . \tag{9}$$

In Eqns.(8) and (9), b is the adsorption equilibrium constant; a the interaction coefficient of the SAS molecules in the surface layer; $\theta_0 = \Gamma_0/\Gamma_\infty$ the equilibrium degree of covering of the surface layer; Γ_0 the equilibrium value of the adsorption corresponding to the concentration c_0; Γ_∞ the maximum value of the adsorption (saturated monolayer); and $\theta = \Gamma/\Gamma_\infty$ the degree of covering of the surface layer under dynamic conditions.

Eqn.(9) does not have an analytical solution. It has been obtained only for a linear isotherm.[21] Numerical solutions of Eqn.(9) were obtained in Refs. 22–24 for the Langmuir isotherm ($a = 0$), and in Refs. 19 and 20 for the Frumkin isotherm. In these cases, dimensionless parameters are used, decreasing the number of solutions to be calculated. The problem of the kinetics of adsorption at a growing spherical surface was examined in Refs. 12, 13, 22, 23, 25–27.

The process of the exchange of SAS molecules between the pre-surface layer and the surface layer is described by the Langmuir equation,[28] which gives the total flux of SAS to the surface as the difference between the forward (adsorption) and back (desorption) fluxes. The magnitude of the forward flux is assumed to be proportional to the concentration of the SAS in the pre-surface layer and the fraction of unoccupied surface, and the magnitude of the back flux is assumed to be proportional to the adsorption:

$$I = \beta c(0, t)(1-\theta) - \alpha\Gamma \tag{10}$$

where I is the resultant flux, and β and α the rate constants of adsorption and desorption respectively.

Eqn.(10) provides an additional boundary condition to Eqn.(4) in the solution of Eqn.(1). When there is no deformation of the surface, the magnitude of the flux I is obviously equal to the rate of adsorption:

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}t} = \beta c(0, t)(1-\theta) - \alpha\Gamma \; . \tag{11}$$

For a deformed surface, the rate of adsorption is given by the expression:[11]

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}t} = \beta c(0,t)(1-\theta) - \alpha\Gamma - \Gamma\nu(t) \; . \tag{12}$$

The kinetic equation (11) is applicable only for an ideal surface layer, since for $d\Gamma/dt = 0$ it becomes the Langmuir isotherm. The kinetic equation for the surface layer described by the Frumkin isotherm (8) has the form:[29]

$$\frac{\mathrm{d}\Gamma}{\mathrm{d}t} = \beta c(0, t)(1-\theta) - \alpha\Gamma\exp(-2a\theta) \; . \tag{13}$$

A different form of kinetic equation of this type is given in Ref. 30; other versions of the kinetic treatment of Eqn. (8) are also possible.[31] Eqn. (13) with allowance for isotherm (8) can be rewritten as follows:

$$\frac{d\theta}{dt} = \frac{\beta}{\Gamma_\infty}\left[c(0,t)(1-\theta) - \frac{\theta}{b}\exp(-2a\theta)\right] \qquad (14)$$

where $b = \beta/\alpha\Gamma_\infty$.

Substitution of the magnitude of the concentration in the pre-surface layer, obtained from the solution of the diffusion-kinetic problem (1)–(3) and (5) in Eqn. (11) gives the expression:[14,15,32]

$$\frac{d\Gamma}{dt} = \beta\left[c_0 - \frac{1}{(\pi D)^{1/2}}\int_0^t \frac{d\Gamma/d\tau}{(t-\tau)^{1/2}}\,d\tau\right](1-\theta) - \alpha\Gamma \ . \qquad (15)$$

The same problem can be solved by another method, by the simultaneous solution of Eqn. (7) and the corresponding kinetic equation. Use of Eqn. (14) gives[29]

$$\theta = \frac{2c_0}{\Gamma_\infty}\left(\frac{D}{\pi}\right)^{1/2}\left\{t^{1/2} - \frac{1}{2}\int_0^t \left[\frac{d\theta/d\tau}{L(1-\theta)} + \frac{\theta\exp(-2a\theta)}{bc_0(1-\theta)}\right]\frac{d\tau}{(t-\tau)^{1/2}}\right\} \qquad (16)$$

where $L = \beta c_0/\Gamma_\infty$.

Eqns. (15) and (16) give exact solutions of the diffusion-kinetic problem for the mixed adsorption mechanism. Some results of calculations using Eqn. (16) are given in Refs. 29 and 33.

The adsorption and desorption rate constants appearing in Eqns. (10)–(16) can be specified using the molecular-kinetic approach[14,34] or expressed in terms of transition state theory.[35,36] The constants β and α cannot yet be calculated theoretically, so that the expressions given in the works cited are used only to interpret experimental data.

If the surface barrier is sufficiently high, the rate of adsorption will be determined by the rate at which this barrier is overcome, that is by the actual kinetics of adsorption. In this case, instead of Eqn. (14), it is possible to write:

$$\frac{d\theta}{dt} = \frac{\beta c_0}{\Gamma_\infty}\left[(1-\theta) - \frac{\theta}{bc_0}\exp(-2a\theta)\right] . \qquad (17)$$

From Eqn. (17), for $a = 0$, $\beta = \text{const}$, $\alpha = \text{const}$, and $\Gamma|_{t=0} = 0$ it follows that[37,38]

$$\theta = \frac{bc_0}{1+bc_0}\left[1 - \exp(-t/\tau_0)\right] \qquad (18)$$

where $\tau_a = [\alpha + \beta c_0/\Gamma_\infty]^{-1}$ is the purely adsorption relaxation time. The kinetics of adsorption for the kinetic mechanism on a deformed surface were examined in Ref. 11.

The results of studies of the non-equilibrium properties of freshly formed surface layers are most frequently represented in the form of the dependence of the dynamic surface tension of the SAS solutions on the lifetime of the surface layer. In the case of the diffusion mechanism of adsorption, it is fairly simple to go from the dynamic adsorption to the dynamic surface tension. In this case, it is usually assumed that the relationship between the surface tension and the adsorption under dynamic conditions is described by the same expression as under equilibrium conditions.[3,39] For example, for non-ideal surface layers of SAS, described by the Frumkin isotherm (8), the relationship between the equilibrium decrease in the surface tension π_0 and the adsorption is given by the Frumkin equation of state:[16–18]

$$\Pi_0 = -\Gamma_\infty RT\left[\ln(1-\theta_0) + a\theta_0^2\right] . \qquad (19)$$

Similarly, for dynamic conditions, it is possible to write:

$$\Pi = -\Gamma_\infty RT\left[\ln(1-\theta) + a\theta^2\right] . \qquad (20)$$

The applicability of this assumption is based on the observation of the principle of local equilibrium, which is used in the theory of the diffusion-controlled kinetics of adsorption.[40] The simplest equation for Π for the diffusion mechanism of adsorption is obtained for $\theta \ll 1$:

$$\Pi = 2RTc_0\left(\frac{Dt}{\pi}\right)^{1/2} . \qquad (21)$$

For the kinetic mechanism of the adsorption process, the surface tension is usually also assumed to depend only on the magnitude of the adsorption. In contrast to the case of the diffusion mechanism, however, this approach is approximate, since the secondary chemical potentials are not introduced into the calculation.[40] A difference in the relationships between Π and Γ under equilibrium conditions and under dynamic conditions may be due, for example, to processes of orientation and structure formation in the surface layer, where for identical adsorption the non-oriented layer may have higher values of the surface tension. For solutions of SAS with low molecular weights, this difference apparently does not exceed the uncertainty of the measurements. This can be seen not only from the works already cited[3,4] but also from a comparison of the results of studies[41,42] in which the kinetics of adsorption of sodium dodecyl sulphate were measured using radioactive tracers, and studies[43–45] of the same SAS using the methods of Wilhelmy and the maximum pressure in a bubble. As shown in Ref. 46, the values of the adsorption rate constants calculated form the data in Refs. 41–45, in spite of the introduction of Eqn. (20) for the treatment of the results from Refs. 43–45.

Where the kinetics of adsorption are described by Eqn. (18), Eqn. (20) gives:[38]

$$\Pi = \Gamma_\infty RT\ln\frac{1+bc_0}{1+bc_0\exp(-t/\tau_a)} . \qquad (22)$$

The possibility of calculating dynamic adsorption from the known diffusion and adsorption-kinetic characteristics of SAS (Eqns. (15) and (16)) is a significant achievement of the theory of the kinetics of adsorption. The fact that methods for the theoretical calculation of the constants β and α are imperfect, however, restricts the applicability of the theory described, and raises to prominance the problem of the experimental study of the adsorption-kinetic characteristics of SAS and their dependence on the nature of the substance, the composition of the solution and the surface layer, etc. The use of Eqns. (15) and (16) to calculate the values of the constants β and α from experimental data on the dynamic surface tension of solutions encounters difficulties which are practically impossible to overcome, because of the complex dependence of the constant β on θ and t.

The present author proposed and justified[29,33,47] an approximate model of the mixed adsorption process. According to this model, the rate of adsorption for a fixed degree of covering of the surface layer can be represented as the sum:

$$\frac{1}{d\theta/dt} = \frac{1}{(d\theta/dt)_k} + \frac{1}{(d\theta/dt)_d} . \qquad (23)$$

The subscripts "d" and "k" refer to the diffusion and kinetic mechanisms respectively, and $(d\theta/dt)_d$ and $(d\theta/dt)_k$ are determined from Eqns. (9) and (17).

If the values of the back rates of adsorption appearing in Eqn. (23) are interpreted as the corresponding resistances, the complete resistance to the motion of the molecules of the SAS from the bulk of the solution into the surface layer can be represented as the sum of the diffusion and kinetic resistances. The mixed kinetics of a first-order chemical reaction at a phase boundary are treated similarly.[48]

An advantage of Eqn.(23) is that it can be used to calculate the adsorption-kinetic characteristics of SAS. It makes it possible to use the experimental values of $d\theta/dt$ and the values of $(d\theta/dt)_d$ calculated from Eqn.(9) to determine the rate of adsorption for the kinetic mechanism

$$\left(\frac{d\theta}{dt}\right)_k = \frac{(d\theta/dt)\cdot(d\theta/dt)_d}{(d\theta/dt)_d - d\theta/dt} \qquad (24)$$

and hence the constant β (using Eqn.(17)). The experimental values of the constants β and α obtained by this method are discussed below.

In addition to the two-stage model of the adsorption process (diffusion–adsorption) described above, approaches not involving the introduction of a kinetic equation are also being developed: the surface potential method,[41] equalisation of the chemical potential,[31] and a diffusion method similar to that proposed in Ref.31, in which the surface layer is assigned a lower diffusion coefficient (compared with the bulk).[49]

On the other hand, in an approach proposed by Rebinder,[50] diffusion is ignored, and the decrease in the surface tension is described as a first-order reaction. The resulting expression has the form

$$\sigma = \sigma_0 + B_0 \exp(-kt) \qquad (25)$$

where σ_0 and σ represent respectively the equilibrium and dynamic surface tension of the solution, and k the rate constant. Eqn.(25) is widely used for the treatment of experimental results, and, as shown in Ref.51, is a particular case of Eqn.(22), describing purely adsorption kinetics.

The above discussion cannot claim to cover completely all the problems of the theory of the kinetics of adsorption at liquid phase interfaces. Without departing from the main theme of the review, reference can be made to studies of such important problems as the kinetics of adsorption from multicomponent solutions,[52–55] the kinetics of adsorption accompanied by mass transfer through the phase boundary,[56–58] the kinetics of adsorption and the dynamic surface elasticity for a surface undergoing periodic deformation,[5,59–64] and the kinetics of adsorption from micellar solutions with allowance for the breakdown of the micelles.[65–68]

III. EXPERIMENTAL METHODS

The dynamic surface tension of SAS solutions is studied by methods using oscillating and tapering jets, the shape and weight of a drop, the maximum bubble pressure, propagation of a capillary wave, by Wilhelmy's method, etc. The jet method is also used to measure the dynamic surface electric potential. Direct measurements of dynamic adsorption are made using radioactive tracers. The methods most frequently used can be examined briefly from the viewpoint of their correspondence to the theoretical models described in the previous section.

The theory of the oscillations of a liquid jet, developed by Rayleigh and Bohr,[69] formed the basis of one of the most widely encountered methods, namely the oscillating liquid jet method. The theory developed in Ref.69 took no account of the non-uniformity of the initial rate profile along the cross-section of the jet, or the surface elasticity. Approximate account was taken of these factors comparatively recently.[70–72] Direct experimental studies of the surface velocity of jets of water and SAS solutions,[73,74] and other published data,[71,72] indicate that the calculated values of the surface tension and the lifetime of the surface are insufficiently reliable in direct proximity to the nozzle (the first few oscillations). This explains the large discrepancies in the results obtained for the same systems by different authors.

The method based on the surface electric potential of a liquid jet[4,75] is free from a number of disadvantages of the oscillating jet method; in the determination of the lifetime of the surface and its rate of deformation by this method, however, difficulties arise as a result of the uncertainty of the calculation of the velocity of the surface of the jet, and also because of the Marangoni effect.[73,74] One modification of the jet method is the trough method with measurement of either the surface tension of a flowing film of liquid[76] or its surface electric potential.[4]

In the drop volume method, the correct interpretation of the results of the measurements requires allowance on the one hand for the existence of convective currents in the volume of the drop and on the other hand for the deformation (expansion) of the surface of the drop during its growth. The models of radial[12,23,25–27] and circulating[77] flow of liquid in a growing drop give significantly different expressions for the dynamic adsorption. Since the actual picture of the flow of liquid in a drop is fairly complex, the determination of the mechanism of adsorption and the calculation of the kinetic parameters of adsorption from the experimental values of the dynamic surface tension, obtained by the drop volume method, are associated with appreciable uncertainty, particularly for the diffusion mechanism of adsorption or mechanisms close to it.

The maximum bubble pressure method provides unique possibilities with respect to the time range of the measurements—from 1 ms to 1000 ms and more, which is much greater than for all other methods. The determination of the lifetime of the surface in the range of high frequencies of bubble formation and the nned to take account of the deformation of the surface of the bubble during the measurements are the main problems associated with this method; they were successfully resolved in Refs.78–82. For low values of the time, the uncertainty of the determination σ is ~1 mN m^{-1}, and the uncertainty of the determination of the lifetime is 1 ms.[81] With a comparatively simple method for taking account of the deformation of the surface,[83] it is possible to calculate the adsorption-kinetic characteristics of SAS from the results of measurements of the dynamic surface tension of their solutions.

Slow changes in surface tension are studied by Wilhelmy's method. A fresh surface is created by removing the surface layer of the solution by suction.[84]

A method involving the measurement of the surface tension of a surface expanding at a given rate has been proposed.[85]

The capillary wave method[86,87] and the method of small periodic deformations[63,64] raise the question of whether the mechanisms of adsorption are the same and whether the values of the rate constants of adsorption and desorption, calculated from the results of measurements of the dynamic surface tension by the usual methods, are equal to the values obtained from data on the propagation of a capillary wave or with periodic deformations of the surface. The answer apparently is that they are not. Thus the rate constant for the adsorption of a given SAS in the general case (see section IV) depends on different parameters, including the lifetime of the surface layer with a definite degree of covering. The periodic deformations involving elongation and contraction during the passage of capillary waves or the movement of a barrier influence the structure of the surface layer and hence the values of the constants β and α.

The radioactive tracer method[41,42] gives reliable values of the dynamic adsorption if the correction for the radioactivity of the bulk of the solution is small. This condition is

satisfied to the greatest extent by tritium, which has recently been used to study equilibrium adsorption. In Refs. 41, and 42, however, the range of reliable values of Γ was restricted to $t > 100$ s.

IV. THE KINETICS OF THE ADSORPTION OF SAS WITH DIFFERENT STRUCTURES

Experimental studies of the kinetics of the adsorption of SAS are carried out to investigate the mechanism of the process (diffusion, kinetic, or mixed) and the conditions under which a given mechanism is realised, and also to determine the rate constants of adsorption and desorption (for the kinetic or mixed mechanisms) and their dependence on the chemical structure of the SAS, its concentration, the presence of added substances in the solution, the degree of covering of the adsorption layer, and its lifetime.

In Refs. 46, and 47 an attempt was made to analyse some of these relationships on the basis of an approximate theory of the mixed adsorption process using a comparatively small amount of experimental data published by different authors on the dynamic surface tension of SAS solutions. Recent detailed studies of the kinetics of the adsorption of normal alcohols[81] and sodium alkyl sulphates[88] from aqueous solutions at their interface with air, and other recently published data, not only make it possible to analyse in much more detail the problem of the relationship between the properties of an SAS and its adsorption-kinetic characteristics but also to obtain a number of important results not discussed earlier.

To analyse the adsorption-kinetic characteristics of SAS, only those experimental studies which satisfy the following requirements have been selected from the large number studied: careful preparation and purification of the specimens; detailed information on the equilibrium surface tension of the solutions; and the use of reliable methods to study the dynamic surface tension. The preceding section shows that the last requirement is not satisfied, in particular, by the oscillating jet method, and some of the data obtained by this method were used only for qualitative estimates.

The results of studies of the kinetics of adsorption from solutions of non-ionogenic SAS can be examined first. A large number of papers (see Ref. 81) have been devoted to the study of the dynamic surface tension of aqueous solutions of normal alcohols. The results of studies by the present author using the maximum bubble pressure method,[81] covering a wide range of surface lifetimes (from 0.001 s to 100 s) for aqueous solutions of alcohols with different hydrocarbon chain lengths (from propanol to decanol), can be summarised as follows: in the homologous series of alcohols, with increase in the length of the molecule by one methylene group, the adsorption rate constant increases by a factor of 3–3.5†, that is to the same extent as the adsorption equilibrium constant. The increase in the adsorption rate constant (for 6 or 7 carbon atoms in the alcohol molecule) leads to a change in the adsorption mechanism: the low-molecular-weight alcohols are adsorbed by a kinetic mechanism, and the high-molecular-weight alcohols by a diffusion mechanism. These results for high-molecular-weight alcohols (heptanol and above) for the most part agree with the data in Ref. 89, where the surface electric potential of a liquid jet was used.

The authors of Ref. 90 (maximum bubble pressure method) and Ref. 91 (breaking meniscus method) studied comparatively dilute decanol solutions. Under these conditions, a slower (compared with Ref. 81) decrease in the surface tension with time was observed. Analysis of these results indicates that decanol is adsorbed by a diffusion mechanism at $t < 10$ s, and by a mixed mechanism, with approximately equal diffusion and kinetic resistances, for longer times. The values of the constants β for $t > 10$ s, calculated from the data in Refs. 90 and 91, were found to be much lower than those obtained by extrapolating the values of β for low-molecular-weight alcohols into the range of low values of t.[81] The decrease in the constant β with increase in t, previously observed in Refs. 46 and 47, is a common property of most SAS, and indicates appreciable structural changes in the adsorption layer, as a result of which the disordered orientation of the molecules for short lifetimes of the surface layer is gradually replaced by a more organised structure, which exerts appreciable resistance to the movement of the SAS molecules into the surface layer.

Another explanation for the dependence of the constant β on the lifetime of the surface layer is possible. It is known (see section III) that in all the methods used to study the dynamic surface tension of solutions in the range of short times (jet, drop, and bubble methods), the surface of the solution increases during the measurements, the increase being revealed to a greater extent at low values of t and to a smaller extent at large values of t. Thus the dependence of β on t can also be represented as the dependence of β on the rate of deformation of the surface $\nu(t)$. Since it is known from rheology that the structure of an object depends on the rate of its deformation, the decrease in the constant β with increase in t (decrease in $\nu(t)$) can apparently be attributed not only to a delay in the production of the equilibrium structure of the surface layer but also to a difference in the extent of its breakdown with increase in the surface area.

A mixed mechanism was also detected in a study of the kinetics of desorption from decanol monolayers at a constant surface pressure.[92]

The position of the polar group in the alcohol molecule has some influence on the rate of adsorption. Thus the rate of the decrease in the surface tension is slightly lower in s-octyl and t-hexyl alcohol solutions than in solutions of the corresponding normal alcohols.[93–95]

The kinetics of adsorption of normal acids are similar to those of the corresponding alcohols.[90,96] In particular, for decanoic acid (as for decanol), the published data[90,91,97] indicate a diffusion mechanism of adsorption at $t < 10$ s. The kinetics of the adsorption of undecanoic acid, calculated from the data of Ref. 98 (Wilhelmy's method), are close to purely diffusion kinetics throughout the entire range of lifetimes of the surface layer (from 200 s to 3000 s).

The results of measurements of the modulus of the dynamic surface elasticity of solutions of decanoic acid in the range of angular frequencies 10^{-2}–10^{2} s^{-1} also indicate a diffusion mechanism of adsorption.[64]

The maximum bubble pressure method ($t = 1$–100 s) has been used[99] to measure the dynamic surface tension of aqueous solutions of decyldimethylphosphine oxide ($C_{10}H_{21}PO(CH_3)_2$), dodecyldimethylphosphine oxide ($C_{12}H_{25}PO(CH_3)_2$), and dodecyldimethylamine oxide ($C_{12}H_{25}NO(CH_3)_2$). Comparison of the experimental data with the results of calculations using the diffusion equations showed that in the region of the lowest values of t studied (less than 1–2 s), these substances are adsorbed by a diffusion mechanism, but mixed adsorption kinetics are observed at longer times. This agrees with the results of a study[26] in which the initial slope of the curves on coordinates σ–t, given in Ref. 99, were used to determine the diffusion coefficients; the results showed good agreement with the

†For C_3–C_7 alcohols.

actual values. A detailed treatment of the data of Ref. 99 with a determination of the values of the constants β was carried out in Ref. 46. All the SAS indicated show a decrease in the constant β with increase in the degree of covering by the adsorption layer and increase in its lifetime. As in the case of the normal alcohols, the adsorption rate constants for the alkyldimethylphosphine oxides icnrease with increased length of the hydrocarbon chain.

The kinetics of the adsorption of non-ionogenic SAS with polyethylene oxide hydrophilic groups have been studied.[38,99,100–105] The results of measurements of the dynamic surface tension of aqueous solutions of the dodecyl ethers of heptaethylene glycol and nonaethylene glycol, and the hexadecyl ether of decaethylene glycol, by Wilhelmy's method at $t > 50$ s indicate that these SAS are adsorbed by a diffusion mechanism.[103,104] The same adsorption mechanism is observed for the hexadecyl ether of octaethylene glycol (ring separation method, $t > 600$ s).[105]

In Ref. 100, the kinetics of the adsorption of the dodecyl ethers of hexa-, hepta-, and octaethylene glycols in the range of surface lifetimes 0.05–0.9 s were studied using the dynamic surface electric potential at the surface of a flowing film of solution (the trough method). Assuming that the relationship between the surface electric potential of the solution and the magnitude of the adsorption is the same under dynamic and under equilibrium conditions, the authors cited used the results obtained for the dodecyl ether of hexaethylene glycol to calculate the magnitude of the adsorption.[100] The values of θ which they obtained were found to be lower than those calculated using diffusion theory.

The dynamic surface tension of aqueous solutions of the dodecyl ether of hexaethylene glycol was also measured in Ref. 99 (maximum bubble pressure method, $t = 1–100$ s). Treatment of the results[99] showed that the diffusion mechanism of adsorption is observed at low concentrations of the SAS (less than 0.02 mole m^{-3}) throughout the entire range of lifetimes t. With increase in the SAS concentration, the range corresponding to the diffusion mechanism of adsorption decreases to 5–10 s, and at longer times a mixed adsorption mechanism is observed. To reconcile the results of Refs. 100 and 99, it must be assumed that the slow change in the surface electric potential is related not to the kinetics of adsorption but to the slow relaxation of the structure of the surface layer, which does not influence the surface tension. This relaxation process may be determined by the orientation of the polyethylene glycol fragment of the SAS molecule.

Measurements of the modulus of dynamic elasticity of the surface of aqueous solutions of the dodecyl ethers of hexaethylene glycol and triethylene glycol in the range of angular frequencies $10^{-2}–10^{-1}$ s^{-1} also indicate a diffusion mechanism for the adsorption of these SAS, as in the case of the dodecyl ether of pentaethylene glycol at a very low angular frequency ($10^{-3}–10^{-2}$ s^{-1}).[63]

The degree of branching of the hydrocarbon chain of the molecule of a non-ionogenic SAS has a considerable influence on the adsorption mechanism and on the magnitude of the adsorption rate constant. The results of studies of the dynamic surface tension of aqueous solutions of di-isobutylphenoxyheptaethylene glycol ($[(CH_3)_3C]_2C_6H_3O(C_2H_4O)_7H$) by the maximum bubble pressure method ($t = 2–30$ s)[38] and by the drop weight method ($t = 0.05–2$ s)[101] indicate a kinetic adsorption mechanism. Thus molecules with highly branched hydrocarbon chains are adsorbed much more slowly than those with linear chains. Their adsorption rate constants also decrease more rapidly with increase in the degree of covering of the adsorption layer (in addition to the above SAS, this is also observed for alkyldimethylphosphine oxides and dodecyldimethylamine oxide[99]).

Among anionic SAS, the kinetics of adsorption from solutions have been studied in most detail for sodium alkyl sulphate solutions (see Ref. 88). Detailed studies of the dynamic surface tension of aqueous solutions have been carried out for sodium decyl, dodecyl, and tetradecyl sulphates in the range of surface lifetime 0.001–500 s (maximum bubble pressure method).[88] The mechanism of the adsorption of sodium decyl sulphate is kinetic throughout the entire range of values of t studied, that of sodium dodecyl sulphate is kinetic at $t > 0.005$ s, and that of sodium tetradecyl sulphate is diffusion at $t < 0.005$ s and kinetic at $t > 0.02$ s.

The magnitude of the rate constant of the adsorption of sodium alkyl sulphates decreases as equilibrium is approached, but the dependence of b on t for different SAS concentrations and degrees of covering of the surface layer is given by a single curve. For a more detailed study of the nature of the surface barrier to adsorption, the kinetics of the decrease in the surface tension when various electrolytes and non-electrolytes were added to the solution were studied.[88] The addition of inorganic electrolytes generally leads to an increase in the range of surface lifetimes in which the diffusion mechanism of adsorption is observed, and to an increase in the adsorption rate constant β. Exceptions are also observed, however. Thus the addition of multiply-charged counter-ions at low lifetimes (low degrees of covering of the surface layer) decreases the rate of adsorption, probably because of their structure-forming action on the surface layer of water.

The results of measurements of the constant β in aqueous solutions of sodium alkyl sulphates with and without the addition of inorganic electrolytes are summarised in Fig. 1 in the form of the dependence of β on the adsorption equilibrium constant b. This dependence was given for the first time for a comparatively small number of SAS in Refs. 46 and 47. The adsorption rate constant for a given lifetime of the surface layer in the range $b < 10$ m^3 $mole^{-1}$ increases rapidly with increase in the adsorption equilibrium constant. Further increase in the constant b as a result of an increase in the quantity of added inorganic electrolytes does not lead to an increase in β, because of the specific action of these electrolytes on the structure and properties of the surface layer of water.[88]

The relationship between the kinetics of the decrease in the surface tension of SAS solutions and the structure of the surface layer of water was observed particularly clearly in a study of aqueous solutions of sodium alkyl sulphates containing added normal alcohols with different chain lengths.[88] It was established that for approximately equal (low) concentrations of the added alcohols in the surface layer, low-molecular-weight alcohols (methanol, ethanol, and propanol), which apparently stabilise the water structure, decrease the rate of adsorption, whereas high-molecular-weight alcohols (pentanol, hexanol, heptanol, and octanol), which apparently break down the water structure, increase the rate of adsorption of the sodium alkyl sulphates.

Thus the results of Ref. 88 indicate that the surface barrier to the adsorption of the sodium alkyl sulphates at the solution–air interface is due both to electrostatic repulsion between the adsorbed and adsorbing ions (since it is suppressed by the addition of inorganic electrolytes) and by effects which are probably related to the need to break hydrogen bonds between the water molecules in the surface layer (suppressed by the addition of electrolytes and non-electrolytes which break down the water structure).

In Refs. 53 and 76, Wilhelmy's method on a flowing film of solution (the trough method) was used to study the kinetics of the adsorption of sodium decanoate, dodecanoate, the tetradecanoate in the presence of 0.1 M NaOH in the surface lifetime range 0.01–1.0 s. The use of more accurate values of

the diffusion coefficients of these substances (5.0×10^{-10}, 4.7×10^{-10}, and 4.4×10^{-10} $m^2 s^{-1}$ respectively)[106] instead of the value 2.8×10^{-10} $m^2 s^{-1}$ used in Ref. 53 indicates that sodium tetradecanoate is adsorbed by a diffusion mechanism, and sodium dodecanoate by a mixed mechanism. It is impossible to say anything definite about the mechanism of the adsorption of sodium decanoate, since its adsorption is close to equilibrium in the surface lifetime range studied.

The dynamic surface tension of aqueous solutions of sodium hexadecanoate was studied by the maximum bubble pressure method in Ref. 107. The pH of the medium and the addition of an inorganic electrolyte (0.2 M KNO_3) had a significant influence on the rate of decrease in σ. At pH 8.2, at which the rate of the decrease is a maximum, the kinetics of adsorption in the presence of the inorganic electrolyte are purely diffusion. At other pH values, and also in solutions without an added inorganic electrolyte, adsorption takes place by a mixed mechanism.

The kinetics of the adsorption of sodium di-iso-octyl succinate-1-sulphonate ($C_{20}H_{37}O_4SO_3Na$) were studied in Refs. 78 and 108. In Ref. 78, the maximum bubble pressure method was used (t = 0.01–0.2 s). Analysis of the experimental results shows that sodium di-iso-octyl succinate-1-sulphonate is adsorbed from aqueous solutions by a mixed mechanism throughout practically the entire range of surface layer lifetimes studied. The adsorption rate constant decreases with increase in t and increases when small quantities of sodium chloride are added.

The kinetics of the adsorption of cationic SAS were studied in Refs. 86, 87, 109–112. Analysis of the observed dependence of σ on t for dodecyltrimethylammonium chloride (fluctuating jet method, t = 0.005–0.05 s)[109] leads to the following conclusions: for $t < 0.01$ s, the mechanism of the adsorption of this SAS is diffusion, but at $t > 0.01$ s a mixed mechanism is observed, and the adsorption rate constant decreases with increase in t.

The maximum bubble pressure has been used[110] to study the influence of change in pH (from 7 to 12.5) on the dynamic and equilibrium surrace tension of an aqueous solution of dodecylammonium acetate ($C_{12}H_{25}NH_3COOCH_3$) and of dodecylammonium chloride with and without the addition of sodium acetate. The lowest value of the equilibrium surface tension and the highest rate of decrease in σ were observed at pH 9.85, at which dodecylammonium acetate is hydrolysed (to dodecylamine). In this case, a diffusion mechanism of adsorption is observed at t < 2–3 s, and a mixed mechanism with increase in the lifetime (to t = 100–200 s). The constant β decreases with increase in t. As expected, the addition of small quantities of sodium acetate has no influence on the kinetics of the adsorption of dodecylammonium acetate at pH 9.85, since there is no electrostatic surface barrier in this case.

The dynamic surface tension of aqueous solutions of hexadecyltrimethylammonium bromide has been measured (maximum bubble pressure method, t = 200–3000 s) in the range of values of σ close to equilibrium.[111] Treatment of these

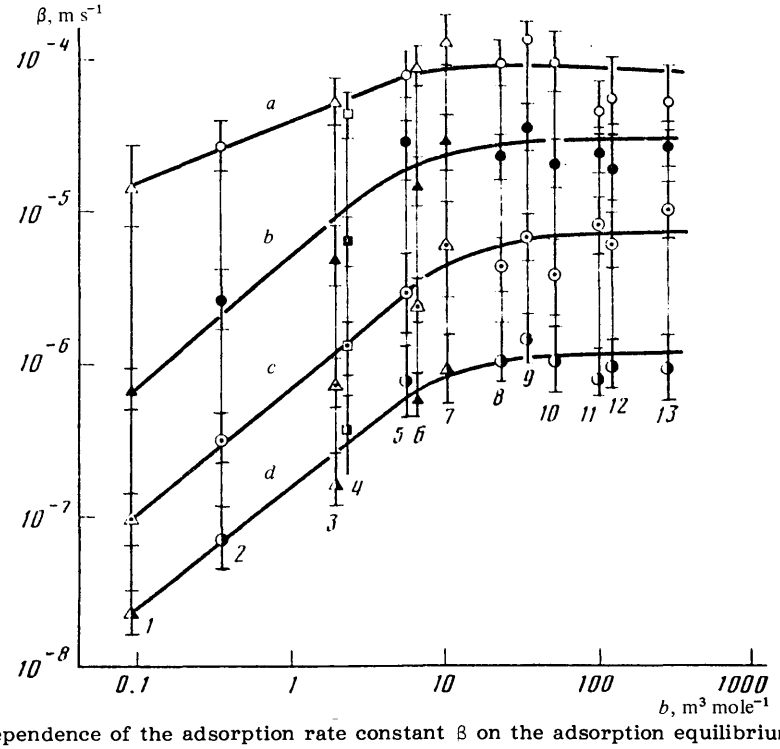

Figure 1. Dependence of the adsorption rate constant β on the adsorption equilibrium constant b for surface lifetimes of 0.01 s (*a*), 0.1 s (*b*), 1 s (*c*), and 10 s (*d*) for sodium alkyl sulphates: *1*) NaDeS in water; *2*) NaDS in water; *3*) NaDeS in 0.1 M NaCl; *4*) NaTS in water; *5*) NaDS in 0.1 M $LiNO_3$; *6*) NaDeS in 0.5 M NaCl; *7*) NaDeS in 0.1 M NaCl; *8*) NaDS in 0.1 M $NaNO_3$; *9*) NaDS in 0.01 M $MgCl_2$; *10*) NaDS in 0.1 M NaCl; *11*) NaDS in 0.3 M NaCl; *12*) NaDS in 0.05 M $MgCl_2$; *13*) NaDS in 0.5 M NaCl; temperature 25°; NaDeS = $C_{10}H_{21}OSO_3Na$, NaDS = $C_{12}H_{25}OSO_3Na$, NaTS = $C_{14}H_{29}OSO_3Na$.[88]

results showed[112] that the mechanism of the adsorption of this SAS is close to kinetic. The adsorption rate constant of hexadecyltrimethylammonium bromide decreases with increase in the lifetime and degree of covering of the surface layer, and is almost independent of the temperature of the solution; this feature, and the decrease in β with increase in temperature for sodium alkyl sulphate solutions,[36,88] indicates that the surface barrier to adsorption has an appreciable entropy component.

The rate constants for the adsorption and desorption of octyl-, decyl-, and dodecylammonium chlorides have also been determined by the capillary wave method.[86,87] The values of β for the cationic SAS, like the value obtained in these studies for the constant β for sodium dodecyl sulphate, are probably too high, because of the destructive action of the capillary waves on the structure of the surface layer, which is thus as it were continuously renewed. The material examined above, however, shows that the values of the constant β are higher for surfaces with a short lifetime than for long-lived surfaces.

Finally, brief mention may be made of the principal results of studies of the kinetics of formation of adsorption layers of polymers. Published data[113–118] indicate that the mechanism of this process is complex and depends on many factors. As a rule, at low concentrations of the polymers in solution at low degrees of covering of the surface layer, the adsorption mechanism is close to diffusion, but with increase in the concentration the role of the surface barrier increases. This last feature is associated with an increasing contribution from electrostatic repulsion forces[113,117] and with structural changes in the surface layer.[116–118] The rate of adsorption of polymers is influenced considerably by the pH of the solution, the presence of inorganic electrolytes, the sign and number of electric charges on the molecule, the hydrophobic character of the SAS, etc. The dependence of the surface tension of polymer solutions on the lifetime of the surface is described satisfactorily by Eqn.(25).

V. GENERAL REGULAR FEATURES AND CORRELATIONS

Comparison of the values of the adsorption rate constants obtained experimentally for different SAS reveals a number of regular features. If the values of β are compared for low or medium degrees of covering of the surface layer and fixed values of t for SAS with alkyl chains R of equal length, it is possible to write the following order of increase in the constant β: $R{-}OSO_3Na < R{-}N(CH_3)_3Cl < R{-}NO(CH_3)_2 < R{-}NH_2 < R{-}COOH < R{-}OH < R{-}PO(CH_3)_2 < R{-}O(C_2H_4O)_6H$.

It should be noted that the surface activity of the substances increases in this order, that is in this case, as in the case of sodium alkyl sulphates (see Fig.1), a correlation is observed between the adsorption rate constant and the adsorption equilibrium constant. It may therefore be expected that the relationship between β and b will not be sensitive to the characteristic features of the chemical structure of the SAS, and for fixed values of θ and t the same relationship will describe all the results obtained. This

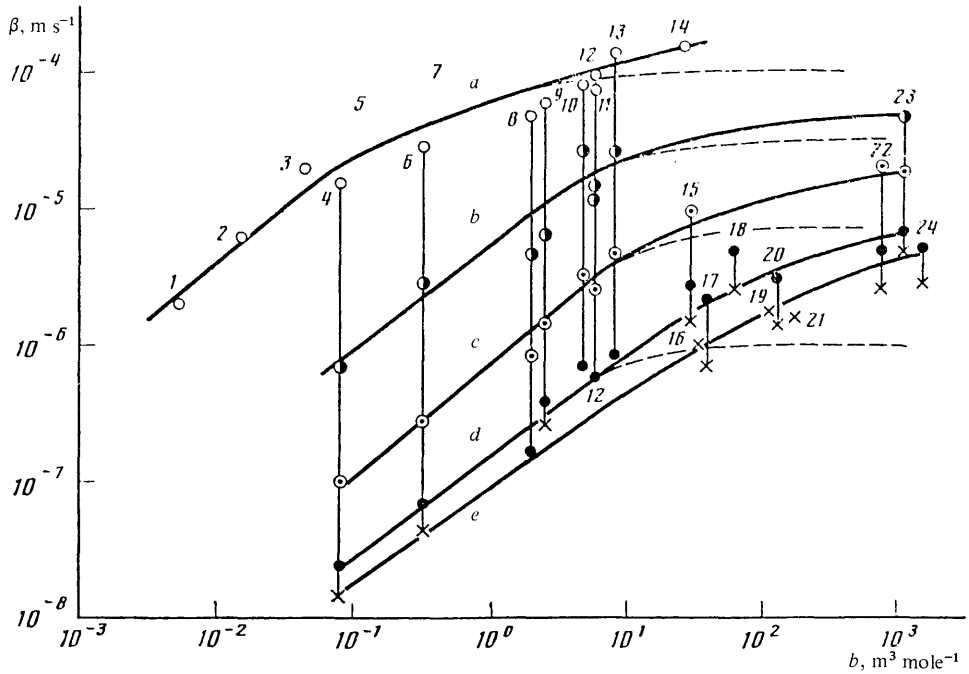

Figure 2. Dependence of the adsorption rate constant β on the adsorption equilibrium constant for surface lifetimes of 0.01 s (*a*), 0.1 s (*b*), 1 s (*c*), 10 s (*d*) and 50 s (*e*) and solution temperatures of 20–25 °C for the following surface-active substances: *1*) C_3H_7OH; *2*) C_4H_9OH; *3*) $C_5H_{11}OH$; *4*) $C_{10}H_{21}OSO_3Na$; *5*) $C_6H_{13}OH$; *6*) $C_{12}H_{25}OSO_3Na$; *7*) $C_7H_{15}OH$; *8*) $C_{10}H_{21}OSO_3Na$ in 0.1 M NaCl; *9*) $C_{14}H_{29}OSO_3Na$; *10*) $C_{12}H_{25}OSO_3Na$ in 0.1 M $LiNO_3$; *11*) $C_{20}H_{37}O_4SO_3Na$; *12*) $C_{10}H_{21}OSO_3Na$ in 0.5 M NaCl; *13*) $C_{10}H_{21}OSO_3Na$ in 1.0 M NaCl; *14*) $C_{12}H_{25}N(CH_3)_3Cl$ in 0.1 M NaCl; *15*) $C_{10}H_{21}PO(CH_3)_2$; *16*) $C_9H_{19}COOH$; *17*) $C_{12}H_{25}NO(CH_3)_2$; *18*) $C_{10}H_{21}OH$; *19*) $C_{10}H_{21}COOH$; *20*) $C_{12}H_{25}NH_2$; *21*) $C_{16}H_{33}OSO_3Na$; *22*) $C_{12}H_{25}PO(CH_3)_2$; *23*) $[(CH_3)_3C]_2C_6H_3O(C_2H_4O)_7H$; *24*) $C_{12}H_{25}O(C_2H_4O)_6H$ (from data in Refs.38, 78, 81, 88, 90, 91, 97–99, 101, 107–110).

relationship for $\beta < 0.5-0.8$ is shown in Fig. 2, which also gives the results obtained for sodium alkyl sulphates with the addition of inorganic electrolytes at $b < 10$ m^3 mole^{-1}; the graphs for $b > 10$ m^3 mole^{-1} in these systems are given by broken lines.

The results given in Fig. 2 show that there is a correlation between the dynamic and equilibrium adsorption characteristics of SAS. For high values of t, the dependence of $\lg\beta$ on $\lg b$ is practically linear throughout the entire range of values of b, whereas for short lifetimes the slope of the curve decreases with increase in b. This is apparently related to the fact that β has a limiting value of $\sim 10^{-2}-10^{-3}$ m s^{-1} (in the complete absence of a surface barrier).[36] In the range in which $\lg\beta$ is linearly dependent on $\lg b$, the following equation is applicable[46,47]

$$\lg\beta = k_1 + k_2 \lg b \qquad (26)$$

where k_1 depends on t, and $k_2 \cong 0.7$.

An interesting feature is that, as noted earlier,[46,47] a similar relationship between the rate constant and the equilibrium constant is observed for a number of chemical reactions, for example reactions involving radicals.[119] There is thus a definite analogy between the kinetics of the adsorption of SAS at a solution–air interface and the kinetics of certain chemical reactions. This analogy provides an additional basis for a chemical approach to the process of adsorption at this boundary, leading, in particular, to the possibility of treating adsorption as an exchange reaction with the formation of an intermediate complex from SAS and water molecules.[81]

It also follows from Fig. 2 that the addition of appreciable quantities of inorganic electrolytes leads to a decrease in the constant β, related to the influence of inorganic electrolytes on the exchange processes in the surface layer.

The results obtained up to the present show that there is a definite relationship between the surface activity of an SAS and the mechanism of its adsorption. Fig. 3 shows the relationship between the adsorption equilibrium constant and the lifetime ranges of the surface layers of different SAS during which these substances are adsorbed by a diffusion mechanism or by a kinetic mechanism. For substances with a low surface activity ($b < 0.1$ m^3 mole^{-1}), the adsorption takes place by a kinetic mechanism throughout the entire range of values of t accessible for measurement. With increase in the surface activity, a certain range of lifetimes appears in which adsorption takes place by a diffusion mechanism, and for substances with a very high surface activity ($b > 1000$ m^3 mole^{-1}), adsorption takes place by a diffusion mechanism throughout the entire range of values of t. For di-isobutylphenoxyheptaethylene glycol (point No. 23 in Fig. 3), the range of the kinetic mechanism of adsorption is anomalously large, and this, as discussed above, is related to the branched nature of its molecule.

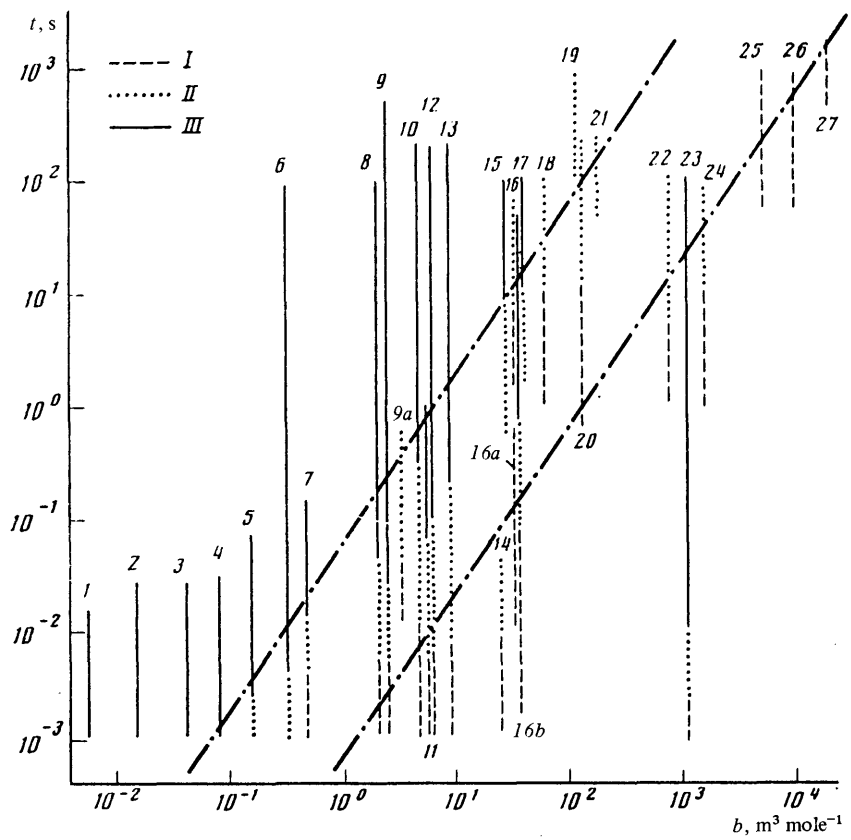

Figure 3. Ranges of different surface-active substance surface layer lifetimes in which diffusion (*I*), mixed (*II*), and kinetic (*III*) adsorption mechanisms are observed. Numbering: *1–24*) same as in Fig. 2; *9a*) $C_{11}H_{23}COONa$ in 0.1 M NaOH; *16a*) $C_{13}H_{25}COONa$ in 0.1 M NaOH; *16b*) $C_{12}H_{25}OSO_3Na$ in 0.01 M $MgCl_2$; *25*) $C_{12}H_{25}O(C_2H_4O)_7H$; *26*) $C_{16}H_{33}O(C_2H_4O)_{10}H$; *27*) $C_{16}H_{33}O(C_2H_4O)_8H$ (from data in Refs. 38, 53, 76, 78, 81, 88, 90, 91, 97–99, 101, 103–105, 107–110).

Fig. 3 contains straight lines which divide the entire field of values of $b-t$ into three regions. To the left of the straight line a the kinetics of adsorption are generally controlled by the surface barrier. The field of values of $b-t$ lying to the right of the straight line b corresponds chiefly to the diffusion mechanism of adsorption, whereas for values of b and t lying between these straight lines, the mixed mechanism predominates. This result is very important, since it makes it possible to predict the mechanism of an adsorption process on the basis of data on the equilibrium adsorption characteristics of SAS.

Since the lifetime of the surface layer determines its degree of covering by SAS molecules, a correlation between the value of the adsorption equilibrium constant and the degree of covering of the surface layer at which a given mechanism of adsorption is realised can be expected. Thus for substances with a low surface activity ($b < 0.1\ m^3\ mole^{-1}$), at least for $\theta > 0.1$, adsorption takes place by a kinetic mechanism, whereas for substances with a high surface activity ($b > 1000\ m^3\ mole^{-1}$), at least for $\theta < 0.9$, adsorption takes place by a diffusion mechanism.

Finally, the correlation between the desorption rate constant α and the adsorption equilibrium constant can be considered. The dependence of α on b can readily be obtained using the data in Fig. 2 and the relationship $b = \beta/\alpha\Gamma_\infty$. The results are given in Fig. 4, and show that the nature of the dependence of α on b is the opposite of the corresponding dependence of β on b. For comparatively weakly surface-active substances ($b < 0.1\ m^3\ mole^{-1}$), the constant α is independent of b. The constant α decreases with increase in b. The decrease in the desorption rate constant is particularly marked for sodium dodecyl sulphate solutions containing large quantities of added inorganic electrolytes (shown by the broken line in Fig. 4), since for these systems, for $b > 10\ m^3\ mole^{-1}$, the constant β does not increase with increase in the surface activity.

The physical significance of the constant α is that it is the probability that the SAS molecule penetrates the surface layer in unit time. Thus the quantity α^{-1} is the time for which the molecule is in the adsorbed state (adsorption time). According to Fig. 4, the adsorption time increases with increase in t, and for a given lifetime and high values of b it increases with increase in the surface activity of the substance.

---o0o---

To summarise the discussion of studies of the kinetics of the adsorption of SAS at a solution–air interface, it can be concluded that at the present time the main regular features of this process have been outlined, and a number of regular features established, making it possible to advance to reach various conclusions about the characteristic features of the kinetics of the adsorption of a given SAS.

At the same time, a number of problems have not been completely clarified or have not been clarified at all: the influence of the sign and magnitude of the charge and the positions of the polar groups in the SAS molecule on the value of β and on the adsorption mechanism; the relationship between the rate of deformation of the surface and the adsorption-kinetic characteristics of the SAS; the mechanism of processes of structure formation in the surface layer, including processes involving a change in its structure with time; the influence of temperature on the kinetics of the adsorption of different SAS; and the analysis of the energy

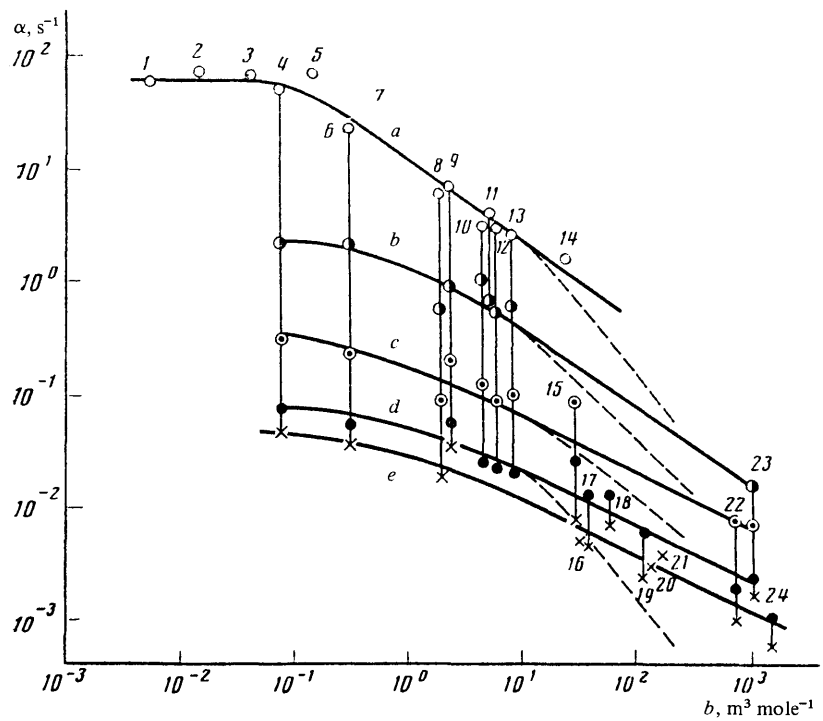

Figure 4. Dependence of the desorption rate constant α on the adsorption equilibrium constant for different surface-active substances. The numbering is the same as in Fig. 2 (from data in Refs. 38, 78, 81, 88, 90, 91, 97–99, 101, 107–110).

characteristics of the transition state. The kinetics of adsorption from multicomponent solutions, and adsorption at a liquid–liquid interface, have been very little studied. The solution of these problems will facilitate the development of the general theory of surface phenomena, will give information on the surface forces, structure, rheology, and intermolecular interactions in adsorption layers, and will provide a basis for the development of new criteria for the synthesis and selection of highly effective SAS and compositions acting under non-equilibrium conditions.

The Heterogeneous-catalytic Activation of Nitrogen and Oxygen Molecules

G.I.Panov

Data on the activation of molecular nitrogen on metals and metal nitrides have been analysed and compared with the previously observed regular features of the activation of oxygen on oxide catalysts. The similarity in the mechanisms of the isotopic exchange of O_2 and N_2 makes it possible to examine from a single viewpoint questions relating to the prediction of catalytic action in reactions involving these molecules.
The bibliography contains 92 references.

I. INTRODUCTION

A large number of papers have been devoted to the study of the reactivity of oxygen. The results of these studies have been summarised in a number of reviews, including a recently published work[1] dealing with the catalytic activation of oxygen. The activation of nitrogen has been much less extensively studied, although this question is of equal theoretical and practical interest and importance.

In the examination of the problem of the activation of nitrogen, it is necessary first of all to take account of the exceptionally high bond energy in the N_2 molecule, which is greater than the energy of practically all other chemical bonds. This feature creates two difficulties. The first is associated with thermodynamic restrictions, since no other bonds which might be formed by nitrogen are capable of replacing the energy expended in the rupture of the original nitgrogen–nitrogen bond. As a result, the range of thermodynamically "allowed" reactions in which the nitrogen molecule may be involved is very narrow. Apart from metals, hydrogen is practically the only substance with which molecular nitrogen reacts (to give ammonia), although the course of even this reaction is complicated by the equilibrium conditions. The non-existence of a wide range of reactions is the main reason why the chemical properties of the nitrogen molecule have been insufficiently studied.

The second difficulty is kinetic in character, and is related to the need to activate such a strong bond; this can be explained in terms of the concept of energy compensation, formulated in Ref.2. In chemical transformations, bond rupture takes place in the starting materials, making it necessary to overcome a definite energy barrier E, which in the limit may correspond to the sum of the energies of the broken bonds ΣD_i. In fact, however, such high values of E are not observed, since on moving along the reaction path, some of the energy required for the rupture of the old bonds is compensated by the energy liberated in the simultaneous formation of new bonds. The extent of the compensation is the decisive factor determining the rate of a chemical reaction.

It is this phenomenon that reveals the essential feature of catalytic action. The catalyst, forming part of the activated complexes of the principal stages, increases the degree of compensation η

$$\eta = \frac{\sum D_i - E}{\sum D_i}$$

and thus lowers the activation energy of the reaction.[2] It is clear that the higher the energies of the bonds involved in the reaction, the more efficient the catalyst must be from the viewpoint of energy compensation in order to ensure a given reaction rate. Thus for example in the dissociative adsorption of a molecule A_2, the activation energy of adsorption will represent the non-compensated part of the dissociation energy $D(A_2)$:

$$E = (1 - \eta) D(A_2) ,$$

Thus for equal values of η, the activation energy of the adsorption of nitrogen will be almost twice that of oxygen, in view of the corresponding difference in the values of $D(N_2)$ and $D(O_2)$ (Table 1). This probably also explains the fact that there are only a few catalysts capable of activating nitrogen, whereas catalytic properties in reactions involving molecular oxygen are shown by a wide range of different chemical substances.[3]

The activation of molecules in a reaction is usually due to a weakening of a bond as a result of electron transfer in a particular direction. From this viewpoint, however, the positions of the orbitals in the nitrogen molecule are extremely unfavourable. The energy of the highest occupied orbital is −15.3 eV, which corresponds to the exceptionally high ionisation potential of the nitrogen molecule (1500 kJ mole^{-1}). On the other hand, the nitrogen molecule has a high first

unoccupied orbital, and electron transfer to this orbital is also energetically unfavourable, since it requires the expenditure of 352 kJ mole^{-1}.[4] It is thus difficult to bring N_2 into a reactive state either by transferring electrons to the molecule or by withdrawing electrons from it.

The values of the dissociation energies (D), ionisation potentials (I), and electron affinities (A) for the N_2 and O_2 molecules[5] are compared in Table 1.

Table 1. Characteristics of the nitrogen and oxygen molecules.

Molecule	D, kJ mole^{-1}	I, kJ mole^{-1}	A, kJ mole^{-1}
N_2	942	1500	−352
O_2	494	1163	42

The activation of nitrogen is particularly important in the synthesis of ammonia. Because of its great practical interest, the synthesis of ammonia is one of the few reactions which has attracted the close attention of scientists over a long period of time. There is hardly another reaction for which such a large number of varied catalysts has been tested.

If reference is made strictly to the activation of nitrogen, however, the synthesis of ammonia can hardly be regarded as a comprehensive test reaction. In the first place, in this case it is necessary to activate not only nitrogen but also hydrogen. In the second place, as shown below, some catalysts which are able to convert the nitrogen molecule into a reactive state are unstable in the presence of H_2, although their study is extremely important for an understanding of the general features of the activation of nitrogen.

From this viewpoint, a unique position is occupied by the method of isotopic exchange, which makes it possible to study the activation of molecules of a given kind in "pure" form, without the introduction of any additional components into the system. When applied to a diatomic gas, this method requires the study of two independent reactions taking place under conditions of adsorption equilibrium or hetero-exchange, that is the redistribution of the isotopes between the surface (s) and the gas phase:

$$^{15}N^{15}N+{}^{14}N_s\rightarrow{}^{14}N^{15}N+{}^{15}N_s$$

and homomolecular exchange, that is the redistribution of the isotopes between molecules of the gas phase:

$$^{14}N^{14}N+{}^{15}N^{15}N\rightarrow 2{}^{14}N^{15}N\ .$$

This raises the important question of whether the activation of nitrogen with respect to these simplest reactions is typical of its activation with respect to other reactions, in particular the synthesis of ammonia. The very first study by Taylor[6] in 1939 detected a qualitative relationship; it was found that the isotopic exchange and the synthesis of ammonia take palce in the same temperature range. Subsequent studies confirmed repeatedly that catalytic activities in the reactions of isotopic exchange and the synthesis of ammonia always change in the same sense.[7,8] Isotopic exchange has been little used to study the activation of nitrogen, and has been used chiefly to investigate the mechanism of the synthesis of ammonia. Thus most published studies have been carried out using iron or promoted iron catalysts, which are the most active and whose practical value far exceeds that of all other catalysts.

The fact that there have been insufficient systematic studies probably explains the absence of reviews of the isotopic exchange of nitrogen, apart from the brief summaries in Refs.8 and 9. This is probably also related to a large extent to the low reliability of the results, particularly those obtained in the study of metals. This last feature is due primarily to the fact that metallic catalysts, both in the synthesis of ammonia and more particularly in isotopic exchange, are very sensitive to the degree of preliminary reduction and to the presence of oxygen-containing poisons.[10-12]

The catalytic properties in the isotopic exchange of N_2 have been studied not only for Fe but also for the following metals: Cr, Co, Ni, Cu,[7] Mo,[13-15] Ru,[16,17] Ta,[18] W,[6,14,19] Re,[14,20] and Os.[21] Many of the studies are qualitative in character, and give information only on the temperature range in which exchange was observed. Reliable data which might be reduced to comparable conditions have apparently been obtained only in a few comparatively recent studies and are restricted to two metals, Fe[10,17,22] and Ru.[17]

More reliable data on the isotopic exchange of N_2 have been obtained on metal nitrides. In addition to Mo_2N, studied earlier,[22] a fairly wide range of nitrides, including those of Li, Cu, the alkaline earth metals, the lanthanides, and uranium have now been studied in this reaction. Compared with metals, it is easier to obtain reliable results using nitrides, since these catalysts are not highly sensitive to the presence of oxygen-containing poisons.[23-25]

Thus a fairly large amount of experimental material has now been published, and in subsequent sections an attempt will be made to analyse this material and to compare it with the regular features previously established for the activation of O_2 on oxides.

II. THE ISOTOPIC EXCHANGE OF OXYGEN AND REACTIONS INVOLVING EXTENSIVE OXIDATION

Extensive isotopic-exchange studies of the activation of molecular oxygen on metal oxides have been carried out.[1,26-30] These studies have played a decisive role in establishing the regular features of extensive oxidation reactions. Rigorous kinetic equations have been derived for the redistribution of the isotopes in simultaneous hetero-exchange and homo-exchange,[31-33] and these have stimulated considerably the subsequent development of the method.

Depending on the number of surface oxygen atoms taking part in the exchange act, three types of exchange are possible in an M–O_2 system: 1) without the participation of surface oxygen, 2) with the participation of one surface oxygen atom, and 3) with the participation of two surface oxygen atoms. Analysis of the kinetic relationships makes it possible to calculate the rates for these types of exchange (w_1, w_2, w_3), which are related to the observed rates of hetero-exchange, w_r, and homo-exchange, w_k, as follows:[31-33]

$$w_r=w_2/2+w_3 \qquad (1)$$

$$w_k=w_1+w_2+w_3\ . \qquad (2)$$

All three types of exchange are observed on oxides under different conditions, but the case of greatest interest for catalysis corresponds to the mechanism of exchange of the third type, which is the predominant type (and often the only type) at high temperatures, that is the range in which

oxidative reactions take place. This exchange is limited by the equilibrium dissociative adsorption and desorption of oxygen, and it can be regarded as resulting from the reversible dissociation of a surface layer of the oxide. From Eqns.(1) and (2), for the third typd of exchange, $w_r = w_k$.

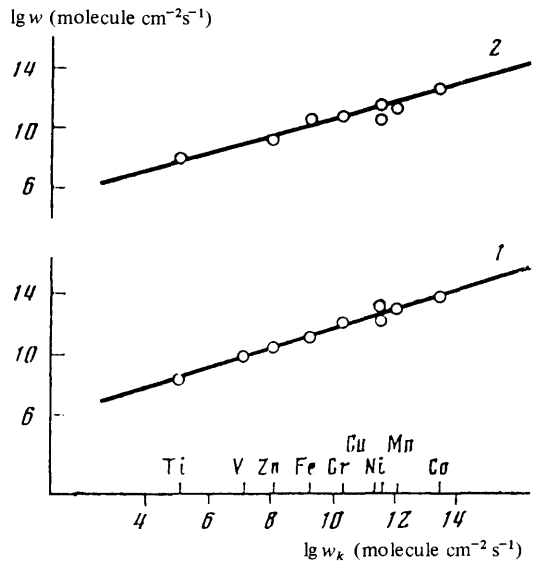

Figure 1. Comparison of the rates of the oxidation of hydrogen (*1*) and methane (*2*) with the rate of the isotopic exdhange of oxygen w_k on oxides.[34]

Comparison of the catalytic properties of a wide range of oxides in the isotopic exchange of O_2 and in extensive oxidation reactions showed changes in the same sense, illustrated in Fig.1. This is a general relationship, and is observed for the oxidation of not only hydrogen and methane, but also CO, NH_3, acetylene, benzene, and other substances.[34] Subsequent studies established the essential features of this relationship. Thus the nature of the limiting stage is the same in all cases, and, as in isotopic exchange, is related to the removal of oxygen from the catalyst surface.[35] Although the rates of the oxidation of different substances may differ considerably, the same regular feature is always observed: the activation energy of the reaction is lower, and its rate higher, the smaller the heat of adsorption of oxygen $q(O_2)$ on the catalyst surface:

$$E = E_0 + \alpha q(O_2) \,. \qquad (3)$$

Eqn.(3) shows that a certain fraction α of the heat of adsorption appears in the activation energy of extensive oxidation E. This regular behaviour is also seen in oxidative reactions on catalysts of other types, in particular metal carbides.[36]

The strength of the bond formed by oxygen with the catalyst surface also plays an important role in reactions of partial oxidation.[3,37]

The dependence of the activation energy of isotopic exchange $E(O_2)$ on $q(O_2)$ is even more direct than in the case of oxidative reactions. It can be seen from Fig.2 that for oxides characterised by the third type of exchange, the equality $E(O_2) = q(O_2)$ is observed, and this makes the isotopic-exchange method particularly effective for the study of the reactivity of surface oxygen, since it makes it possible to characterise quantitatively the heat of adsorption of O_2.

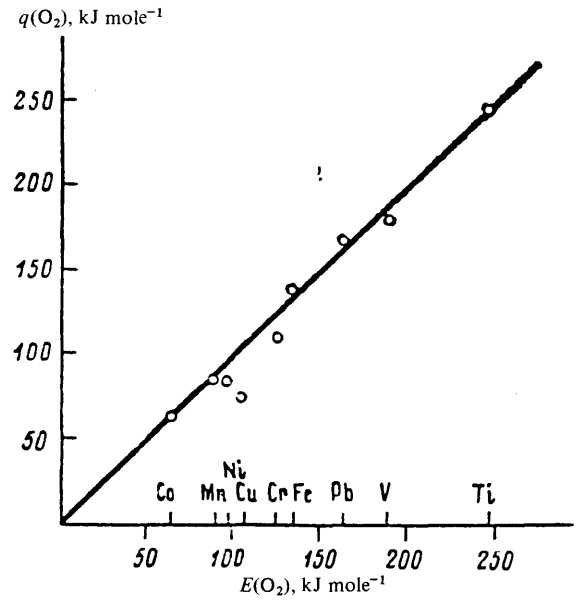

Figure 2. Relationship between the activation energy of isotopic exchange and the heat of adsorption of oxygen on metal oxides.[28]

The dependence of the rate and the pre-exponential factor for isotopic exchange on the heat of adsorption of oxygen is shown in Fig.3 (from the data in Refs.38 and 39).

The regular features observed make it possible to use data on the isotopic exchange of oxygen to predict the catalytic properties of oxides in extensive oxidation reactions and make it of considerable interest to attempt to establish a corresponding relationship between the isotopic exchange of nitrogen and the synthesis of ammonia.

III. NITRIDES AS AMMONIA SYNTHESIS CATALYSTS

Attempts to use metal nitrides as catalysts for the synthesis of ammonia were made as early as the end of the last century.[40] In the early studies, insufficient attention was paid to the phase and chemical composition of the specimens after the experiments, and the catalytic activity was usually attributed to the metal.[41] Subsequent studies showed that under the conditions of the synthesis of ammonia, some metals are converted into their nitrides, among which uranium nitride was found to be a highly active catalyst.[42] It was on uranium nitride, and also on metallic osmium, that Haber was first able to obtain high yields of ammonia which left no doubt about the promising possibilities provided by the catalytic method for the synthesis of NH_3.

Since the nineteen-sixties, there has been an increase in interest in nitrides as ammonia synthesis catalysts. This has also been related to the problem of the applicability of ideas about the mechanism of the synthesis, developed mainly in the study of iron catalysts, to catalysts of other classes. The

basic information on the catalytic properties of nitrides in the synthesis of NH_3, obtained since 1960, is given in Table 2. The data for a doubly promoted iron catalyst are also given for comparison. It can be seen that most of the nitrides studied are transition metal nitrides. The interest in nitrides of this class is related to the fact that transition metals and their compounds usually show an increased catalytic activity in redox reactions.[49,50]

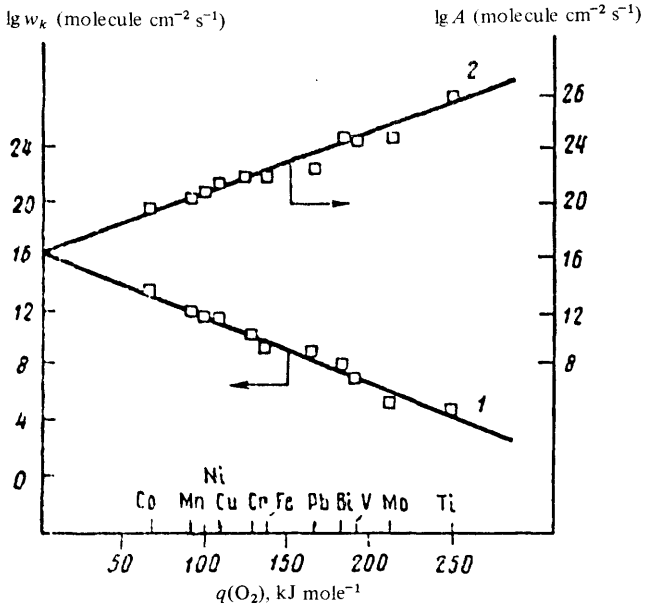

Figure 3. Dependence of the rate (*1*) and the pre-exponential factor (*2*) for the isotopic exchange of O_2 on oxides at 573 K and a pressure of 1.33 kPa on the heat of adsorption of oxygen.

The reaction of ammonia synthesis is reversible, and its rate is considerably reduced by ammonia. This makes it difficult to compare the activities of different catalysts. For a quantitative comparison it is often necessary to have data on the values of the rates at the same temperature, pressure, and NH_3 concentration at the outlet from the reaction vessel.[51] For the nitrides studied, this comparison in many cases is impossible, because of the large differences in the NH_3 concentration. Nevertheless, it is qualitatively clear that all the nitrides given in Table 2, including transition metal nitrides, with the exception of UN_x, have a low catalytic activity. The most active of them, Mo_2N, to which the largest number of studies has been devoted (including Ref. 52, where it was observed for the first time that the ammonia synthesis mechanisms on Mo_2N and on an iron catalyst are the same), is much less active than promoted iron.

A noteworthy feature is the large difference in the rates of ammonia synthesis on uranium nitride. The α-U_2N_3 specimen studied in Ref. 47 was found to be less active by several powers of ten than the UN_x specimen studied by Haber.[42] Similar differences were observed in the study of the isotopic exchange of N_2.[53] An α-U_2N_3 specimen prepared by the direct reaction of the metal with nitrogen at 972 K was also found to be 10^4–10^5 times less active than a specimen with the composition $UN_{1.70}$, prepared under milder conditions by nitriding the hydride, previously obtained from the metal. The values of the heat of adsorption of nitrogen on these specimens differ by 120 kJ mole^{-1}. This marked dependence of the adsorption and catalytic properties of uranium nitride on the chemical composition for similar crystal structures is extremely unusual, and its explanation requires further studies.

*****Doubly promoted iron catalyst.

The attention of research workers has recently been drawn to the so-called ionic nitrides, formed by the electropositive elements of groups I, II, and III of the periodic system.[54] These elements have an increased reactivity with respect to nitrogen. Of particular interest is lithium, which is the only element that reacts vigorously with N_2 even at room temperature to give the phase Li_3N.

Various alkaline earth metals (Ca, Sr, Ba) react with nitrogen to give not only the nitrides M_3N_2 but also other stable compounds, namely the subnitrides (M_2N) and pernitrides (M_3N_4, MN_2), which show a number of interesting properties. In the subnitrides, the bonds between the metal atoms are partly preserved, as indicated by the metallic character of their electrical conductivity,[55,56] so that these compounds are similar to the metal-like nitrides of the *d* elements. The pernitrides, on the other hand, contain an N–N bond, so that the hydrolysis of these compounds leads to the partial liberation of hydrazine instead of NH_3. The possibility of obtaining hydrazine by this method probably stimulated a number of studies of the physicochemical properties of nitrogen-containing compounds of the alkaline earth elements.[57–59]

The possible formation of various chemical compounds with nitrogen suggests that the nitrides of this class may be interesting materials from the viewpoint of the activation of molecular nitrogen. Their study has followed two directions: 1) the study of the activation of molecular

nitrogen and its state on a surface by isotopic exchange;[24,25,60-63] 2) the study of the synthesis of ammonia as a reaction for which the activation of nitrogen is the limiting stage.[25,53,61]

These studies open up the possibility of determining how general are the regular features established for oxides, molecular oxygen, and oxidative reactions, and whether they are applicable to other reactions and systems.

The subsequent analysis, in addition to ionic nitrides, will also consider catalysts based on Fe,[22] Ru,[17] and Mo_2N,[22] for which sufficiently reliable data on the isotopic exchange of N_2 and the synthesis of NH_3 are available. Among the catalysts based on Fe and Ru, the examination will be restricted to the simplest systems consisting of metallic iron and ruthenium without promoting additives.

IV. THE KINETICS AND MECHANISM OF THE ISOTOPIC EXCHANGE OF NITROGEN

The nitrides of the metals of groups I, II, and III of the periodic system are most frequently understood to be the stoichiometric compounds with the compositions M_3N, M_3N_2, and MN respectively.[54,64] Detailed studies have shown, however, that in a number of cases these compounds cannot be obtained at all.[65] Table 3 shows that the stoichiometry of the nitrides in fact does not always correspond to the composition expected on the basis of classical ideas. Moreover, some of these nitrides (strontium and barium nitrides and uranium nitride with the approximate composition $UN_{1.70}$) in general have a variable chemical composition, which changes considerably with change in the conditions.[53,60]

Table 3. Kinetic characteristics of the isotopic exchange of nitrogen (573 K, 52 Pa).

**Inactive up to 973 K.

The principal results of studies of the kinetics and mechanism of the isotopic exchange of nitrogen can be summarised (Table 3). In general, all three possible types of exchange are observed on nitrides. As in the case of oxides, however, the change by the third type of mechanism most frequently predominates (its proportion $\kappa = w_3/w_k$ is equal or close to 1). Thus exchange takes place chiefly as a result of the reversible dissociation of the surface layer of the nitride. Exceptions are the nitrides of lanthanum, praseodymium, and erbium, which have a very low catalytic activity and have not been studied in detail.

The same regular feature is also observed for metallic catalysts. The isotopic exchange on Fe takes place only by the third type of mechanism.[22] A detailed analysis of the kinetics of exchange on Ru has not been carried out, but the similarity in the rates of hetero-exchange and homo-exchange indicates that the third type of exchange also predominates in this case.[17]

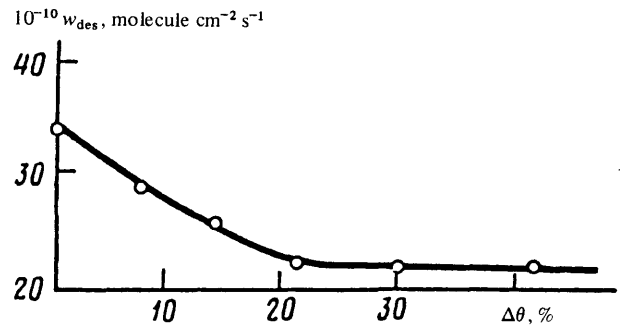

Figure 4. Dependence of the rate of desorption of nitrogen at 593 K on the quantity of nitrogen removed from the surface of $BaN_{0.62}$ (% of a monolayer).

Many nitrides, particularly those with variable chemical composition, show a high mobility of the nitrogen atoms in the crystal lattice. Thus for Sr and Ba nitrides,[60] the quantity of nitrogen taking part in exchange, x_{exch}, amounts to 50–60 surface monolayers at 550 K. This means that the "movement" of nitrogen to a depth of several tens of monolayers takes place more rapidly than exchange between the surface and the gas phase. In the case of the nitride $UN_{1.70}$[53] at this temperature, the exchange involves all the nitrogen of the solid phase ($x_{exch} = x_v$). The high rate of self-diffusion of nitrogen makes it impossible to determine whether the surface is uniform or non-uniform, since in either case the rapid movement means that the nitrogen on all parts of the surface acquires an equal probability of exchanging with the gas phase. The very fact that rapid movement takes place, however, indicates that if there is any non-uniformity, it can hardly be clearly defined. This is confirmed by experiments on the desorption of nitrogen from a barium nitride surface, the results of which are given in Fig. 4.[62] The rate of desorption shows an extremely weak dependence on the quantity of nitrogen removed, and after 20% of the nitrogen of the surface monolayer has been removed, its subsequent removal does not lead to any decrease in the rate of desorption. This is related to the fact that, as a result of the high rate of diffusion, a change in the degree of surface covering is compensated by the migration of nitrogen from the bulk of the $BaN_{0.62}$.

According to Ref. 67, self-diffusion also takes place at a high rate in the adsorbed layer of nitrogen on the surface of a promoted iron catalyst. For oxides, the mobility of oxygen is less characteristic. Among oxides, however, there are

also catalysts (MoO_3, V_2O_5) in which movement takes place throughout the entire volume, although this occurs at much higher temperatures.[28]

The kinetic order n of the exchange of nitrogen can be considered. For oxygen on oxides characterised by the third type of exchange, the order of the reaction is generally close to 0.5.[68] Table 3 shows that this regular feature is also observed for nitrogen. This pressure dependence was explained[68] by assuming that the limiting stage of the third type of exchange is the reversible dissociative adsorption of nitrogen

$$N_2+[\ ]+(\ )\rightleftarrows[N]+(N) \qquad (4)$$

to give firmly bound [N] and weakly bound (N) surface forms. These forms are present in equilibrium, as a result of rapid transformation:

$$[N]+(\ )\rightleftarrows[\ ]+(N)\,.$$

Since isotopic exchange takes place under conditions of adsorption equilibrium, the rate of exchange w_3 can be expressed as the rate of adsorption or desorption, and, in accordance with Eqn.(4), is described by the expression

$$w_3=k_a p(1-\theta_1)(1-\theta_2)=k_d\theta_1\theta_2 \qquad (5)$$

where p is the nitrogen pressure, and k_a and k_d the rate constants of adsorption and desorption respectively.

Assuming Langmuir adsorption at a high degree of covering of the surface by the firmly bound form ($\theta_1 \cong 1$) and a low degree of covering by the weakly bound form ($\theta_2 \ll 1$), it follows from Eqn.(5) that

$$w_3=\frac{k_a}{b_1^{0.5}}p^{0.5}$$

where b_1 is the adsorption coefficient for the firmly bound form. This dependence of the reaction rate on the nitrogen pressure corresponds to the experimentally observed order of the exchange reaction by the third type of mechanism.

A detailed explanation was also given in Ref.69, where it was assumed that the exchange takes place via the following stages:

$$N_2+[\ ]\rightleftarrows[N_2] \qquad (6)$$

$$[N_2]+[\ ]\rightleftarrows 2[N]\,. \qquad (7)$$

If stage (6) is slow, this also leads to a reaction of order 0.5 with the condition that $\theta[N_2] \ll 1$ and $\theta[N] \cong 1$. The assumption that molecular adsorption is the rate limiting stage can hardly be correct, however.

The higher orders observed on various nitrides, and also on metallic ruthenium, can probably be attributed to additional contributions from the mechanisms of the first and second types.

Thus there is an extensive analogy between the mechanism of the exchange of N_2 and O_2. The specific features of N_2, however, are superimposed on its exchange and a number of characteristics, revealed chiefly at low temperatures. An example is provided, in particular, by the so-called low-temperature exchange.

Most oxides, previously subjected to vacuum treatment at 673–873 K, after cooling are capable of bringing about homomolecular exchange by the first type of mechanism at a high rate. This exchange, which takes place with a very low activation energy, is due to the existence of anion vacancies on the surface and is observed at reduced temperatures down to liquid-nitrogen temperature. The mechanism of the low-temperature exchange probably involves a redistribution of the bonds in a four-atom complex consisting of two adsorbed diatomic molecules.[1] There is only a very small quantity of oxygen in the molecular form on the oxide surface, and it generally cannot be detected experimentally.

In the case of nitrides, the formation of anion vacancies as a result of the removal of nitrogen on high-temperature vacuum treatment does not lead to low-temperature exchange. It cannot be observed on metallic catalysts either.[70] This is apparently due to the much greater stability of the N_2 molecule, compared with O_2, which makes a redistribution of the bonds between nitrogen atoms in the low-temperature range impossible.

This is also probably responsible for another characteristic feature of nitrides. Some of them, namely Sr_2N and $BaN_{0.62}$, at low temperature are capable of binding a considerable quantity of nitrogen in the molecular form,[62] and the state of this nitrogen will be examined in the next section.

V. THE MOLECULAR FORM OF ADSORBED NITROGEN

Comparison of the rates of the separate stages with the rate of the catalytic process as a whole provides an effective method for studying the mechanism of reactions, and is particularly widely used in the study of oxidative processes.[71] The homomolecular exchange of nitrogen involves the following stages: adsorption; surface processes leading to a redistribution of the isotopes: and desorption.

Isotopic exchange is studied under conditions of adsorption equilibrium, when the rates of the adsorption and desorption stages are equal. The ratio between the rate of the reversible adsorption (desorption) and the rate of the surface processes is one of the factors determining the reaction mechanism. It was the comparison of the rate of desorption with the rate of isotopic exchange that made it possible to establish an interesting characteristic feature of Sr and Ba nitrides with respect to molecular nitrogen.[62]

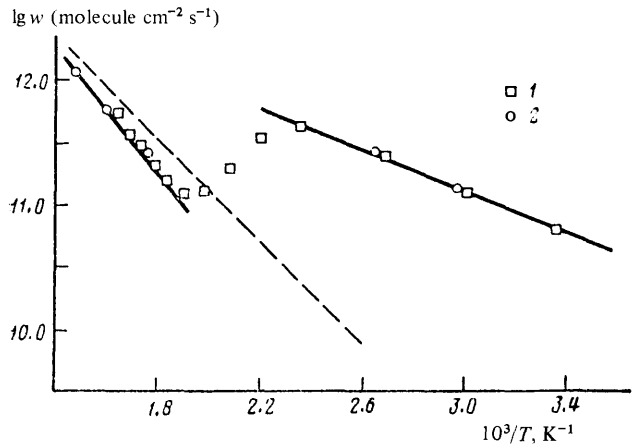

Figure 5. Temperature dependence of the rates of the desorption (*1*), hetero-exchange (*2*), and homo-exchange (broken straight line) of nitrogen on barium nitride.[62]

Fig.5 gives the temperature dependence of the rate of the desorption of nitrogen from the surface of $BaN_{0.62}$. The rate of desorption corresponds to the equilibrium degree of covering of the surface at the temperature of the experiment and a

nitrogen pressure of 52 Pa, that is it was measured for the same state of the surface as the rate of exchange. It is possible to distinguish three ranges in which this dependence has different forms: the high-temperature range (525–608 K), where the rate of desorption coincides with the rate of hetero-exchange; the low-temperature range (300–425 K), where the rate of desorption is 10–100 times the rate of homo-exchange; and the intermediate range, in which the rate increases with decrease in temperature. The explanation for this form of the dependence is that in addition to the atomic form of nitrogen, which is involved in the exchange in the high-temperature range, a weakly bound form of N_2 appears on the surface with decrease in temperature, and determines the nature of the desorption and exchange in this range.

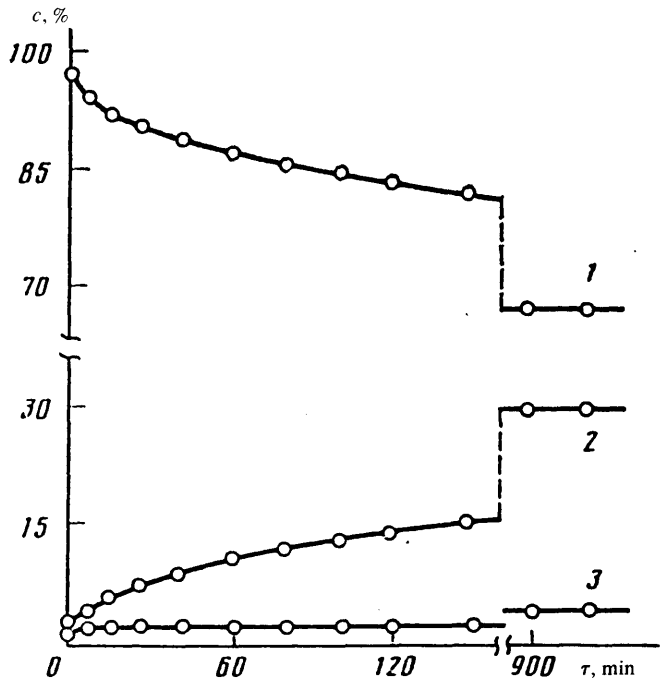

Figure 6. Dependence of the concentration c of the isotopic forms of the nitrogen molecules in the gas phase on the duration of exchange on $BaN_{0.62}$ (333 K, 52 Pa): *1*) $^{15}N^{15}N$, *2*) $^{14}N^{14}N$, *3*) $^{14}N^{15}N$.

To investigate the nature of the weakly bound form, the hetero-exchange of nitrogen on barium nitride was studied at 373 K and 333 K.[62] The kinetics of the process at 333 K are shown in Fig.6. Only a change in the concentration of the molecules $^{14}N^{14}N$ and $^{15}N^{15}N$ is observed, and there is practically no formation of mixed molecules $^{14}N^{15}N$. Thus only the reversible transfer of molecules between the surface and the gas phase takes place in the system, leading to hetero-exchange, and there is no redistribution of the atoms between the nitrogen molecules. This indicates that the low-temperature form of nitrogen is molecular in character, and also that it is inert with respect to homo-exchange.

A similar picture is observed for strontium nitride, where molecular nitrogen may be present in unexpectedly large quantities. Fig.7 gives the temperature dependence of the concentration of nitrogen in an Sr_2N specimen.[72] It can be seen that in the range 623–423 K, the concentration of nitrogen changes comparatively little, but with subsequent decrease in temperature, an abrupt change takes place, and N_2 is adsorbed in quantities corresponding to 20 surface monolayers, or ~13% of the initial concentration of nitrogen in the specimen. Experiments on the adsorption of a mixture of $^{14}N^{14}N$ and $^{15}N^{15}N$ molecules showed that all the nitrogen absorbed at a temperature below 423 K is in the molecular form and can be desorbed into the gas phase without change in the isotopic composition.

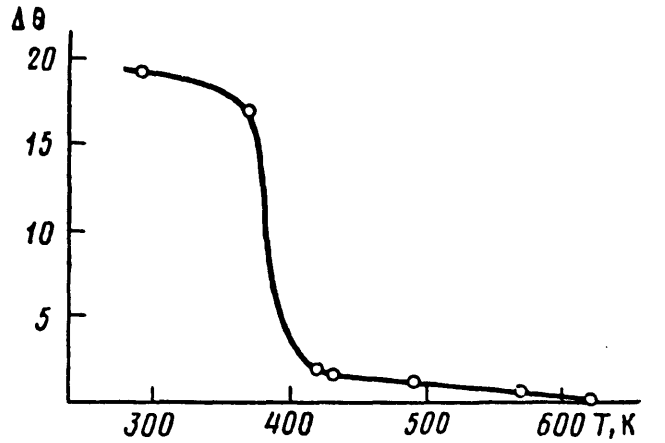

Figure 7. Change in the nitrogen concentration ($\Delta\theta$, number of monolayers) in Sr_2N with change in temperature at a pressure of 52 Pa.

This raises the question of the state of the bound nitrogen molecules. In this case it is clearly impossible to speak of physical adsorption, which is observed on many metals close to 100 K.[73] In this case there is evidently a more extensive chemical interaction. It may be assumed that in the general case, nitrogen passes through all oxidation states from 0 to −3 in the course of the reaction. If it is assumed that two-electron transitions takes place, intermediate compounds corresponding to the formal valence states N_2^0, N_2^{2-}, N_2^{4-}, and N^{3-} should be formed.[72] The nitrogen molecule shows an important feature which distinguishes it from other unsaturated compounds: in the rupture of the triple bond N ≡ N, the greater part of the energy is used up in the rupture of the first bond (527 kJ mole^{-1}); 260 kJ mole^{-1} is used up in the rupture of the second bond, and only 159 kJ mole^{-1} in the rupture of the third. This makes preferable the many-electron reduction of N_2 with the transfer of four or six electrons to the nitrogen molecule.[75] Thus the reaction with metals usually finishes with the complete rupture of the N ≡ N bond and the formation of nitrides, which can be regarded as derivatives of ammonia.

In some cases, however, mainly for alkaline earth metal nitrides, the reaction with nitrogen may lead to the formation of pernitrides.[76] The unusual features of these compounds is that a certain proportion of the nitrogen present preserves a nitrogen–nitrogen bond, so that hydrolysis gives not only NH_3 but also hydrazine, indicating according to the authors of Ref.74, that pernitrides contain nitrogen as the ion N_2^{4-}.

Interesting results have been obtained in extensive studies to find methods for the low-temperature activation of nitrogen in metal complexes in solution.[75,77] Contrary to existing ideas, it was found that complexes containing N_2 as ligand in the coordination sphere of the metal are encountered extremely widely. Moreover, it was possible to obtain catalytic systems based on Ti[77] and Mo,[75] capable of bringing about the catalytic fixation of nitrogen.

In many cases, however, the molecular nitrogen in the coordination compounds is in the inactive state, and attempts to involve it in any chemical reaction lead to the liberation of free N_2. It was of interest to determine whether the nitrogen absorbed in molecular form by strontium and barium nitrides is reactive. It was noted above that this form is not active in homomolecular exchange. It is also incapable of reacting with hydrogen. The introduction of H_2 into the system leads to the absorption of hydrogen and the displacement of nitrogen in the molecular form into the gas phase without the formation of even traces of NH_3.

Hydrolysis is widely used to study the reactivity of nitrogen in coordination compounds. This reaction has been used to test two series of strontium nitride specimens· the specimens of series *A*, containing molecular nitrogen in quantities corresponding to ~20 monolayers, and the specimens of series *B*, obtained from series *A* after desorption of the molecular form.[72] The hydrolysis was carried out using an oxidising agent (ammonium vanadate), which is incapable of reacting with NH_3 but which readily reacts with stronger reducing agents, for example hydrazine.

Table 4. Hydrolysis of strontium nitride.

Specimens	10^6 [N_2], mole g^{-1}	10^6 W_O, mole g^{-1}	10^6 W_B, mole g^{-1}	
			N_2H_4	N_2H_2
Series *A*	330	680	170	340
Series *B*	~0	20	6	12

Symbols: [N_2] is the concentration of the molecular form of nitrogen in the specimen; W_O the consumption of the oxidising agent; and W_B the concentration of the reducing agent in the hydrogenolysis products, calculated as hydrazine and di-imide.

The averaged results of the experiments are given in Table 4, and show that the consumption of the oxidising agent is determined practically completely by the presence of molecular nitrogen in the specimens. If it is assumed that the direct product of the hydrolysis is hydrazine, the calculations show that the quantity of N_2H_4 liberated corresponds to only half of the nitrogen combined in the molecular form. This gives grounds for assuming that the hydrogenolysis is undergone by a derivative of not hydrazine but di-imide, in which a double bond N=N is preserved. The protonation of this compound should give N_2H_2, whose reducing equivalent is half that of N_2H_4. With this assumption, the observed consumption of the oxidising agent corresponds satisfactorily to the concentration of molecular nitrogen in the specimens.

Thus the molecular form of nitrogen detected on strontium and barium nitrides, although insufficiently activated to react with H_2 or to take part in homomolecular exchange, is capable of being converted into the combined state as a result of the hydrolysis of the nitrides. It may be assumed that the nitrogen in this form is present as the N_2^{2-} group, analogous to the peroxide group O_2^{2-} in oxygen-containing compounds. Some of these oxygen-containing compounds also decompose with the liberation of molecular oxygen without rupture of the peroxide bond.[78]

The possible formation of derivatives of di-imide in the reaction of metal complexes with nitrogen was discussed in Ref. 75.

VI. THE HEAT OF ADSORPTION OF NITROGEN AND THE ACTIVATION ENERGY OF THE ISOTOPIC EXCHANGE OF N_2

In the isotopic exchange of oxygen on oxides, taking place by the third type of mechanism, the magnitude of the activation energy coincides satisfactorily with the heat of adsorption of oxygen.[28] Since the isotopic exchange of nitrogen also takes place by the third type of mechanism, it was of interest to determine whether the same regular feature applies to nitrogen.

The heats of adsorption of nitrogen on nitrides have been measured by two methods:[79] the calorimetric method and the kinetic isotopic method proposed in Ref. 63. The essential features of the last method are as follows. In the measurement of the rates of adsorption w_{ads} and desorption w_{des}, the observed change in pressure in the gas phase is determined by the difference between w_{ads} and w_{des}. Thus the rates are usually measured either under conditions of adsorption equilibrium, when $w_{ads} = w_{des}$ (the isotopic exchange method), or, on the contrary, at a distance from equilibrium, when one of these quantities is negligible compared with the other. In a system in which exchange is taking place by the third type of mechanism, these two processes can be distinguished using isotopes, by arranging the experiment in such a way that at the initial moment of time the adsorption flux is represented by one isotope, and the desorption flux by the other. In this case the adsorption and desorption can be measured independently while they take place simultaneously both under equilibrium conditions and at a certain distance from equilibrium. By changing the temperature for a fixed degree of covering of the surface, it is possible to determine the activation energy of adsorption and desorption, and hence the heat, which is denoted q_{kin} to distinguish it from the quantity q_{cal} determined calorimetrically. Table 5 shows that the two methods give similar results.[79]

Table 5. The heat of adsorption and the activation energy of the isotopic exchange of nitrogen.[79]

Nitride	Sr_2N	$BaN_{0.62}$	CeN	$UN_{1.70}$	α-U_2N_3
q_{cal}, kJ $mole^{-1}$	60	115	125	170	240
q_{kin}, kJ $mole^{-1}$	60	90—140	—	—	225
$E(N_2)$, kJ $mole^{-1}$	55	50	130	105	225

Comparison of the activation energy of isotopic exchange $E(N_2)$ with the heat of adsorption of nitrogen (Table 5) showed that the values agree satisfactorily for strontium and cerium nitrides and α-U_2N_3. $BaN_{0.62}$ and $UN_{1.70}$, however, show an appreciable discrepancy, which was attributed[79] to the partial binding of nitrogen by bulk layers of the nitride.

Barium nitride and the uranium nitride $UN_{1.70}$ can readily undergo a change in chemical composition with change in the conditions. Since in the measurement of the heat of adsorption, a pressure higher than the equilibrium pressure is established at the initial moment, it is natural to expect that this may lead not only to the adsorption of nitrogen on the surface but also to its transfer from the surface into the bulk, which corresponds to two processes:

$$N_2 + 2[\ ]_s \rightarrow 2[N]_s + q_s \quad (8)$$

$$N_2 + 2[\ ]_v \rightarrow 2[N]_v + q_v \quad (9)$$

Here, $[\ ]_S$ and $[\ ]_V$ represent unoccupied positions on the surface and in the volume respectively. In this case the measured heat is

$$q_{meas} = \frac{n_s}{n} q_s + \frac{n_v}{n} q_v$$

where n_S and n_V are the numbers of molecules transferred from the gas phase to the surface and to the volume respectively; $n = n_S + n_V$. When $q_V > q_S$, this leads to a value of q_{meas} which is higher than the heat of adsorption q_S. Similarly, the redistribution of nitrogen between the surface and the volume also leads to distortion of the true value of the heat of adsorption when the kinetic method is used.

In some cases, the process of volume binding according to Eqn.(9) may predominate, as is probably the case for $BaN_{0.62}$ and $UN_{1.70}$. In the equilibrium diagram, uranium nitride $UN_{1.70}$ lies in the range of compounds of variable composition bounded by the phases U_2N_3 and UN_2. The heat of adsorption of nitrogen on this specimen (170 kJ mole^{-1}) is close to the heat of the reaction

$$UN_{1.51} + 0.09\,N_2 \rightarrow UN_{1.69}$$

which amounts to 185 kJ mole^{-1}.[80] The heat of adsorption of nitrogen on barium nitride (115 kJ mole^{-1}) also does not differ greatly from the heat of the process

$$6Ba_3N + N_2 \rightarrow 4Ba_3N_2$$

which equals 140 kJ mole^{-1}.[55]

The influence of bulk processes has also been noted in the measurement of the heats of adsorption of oxygen on various oxides.[81] Since oxides have an extremely stable chemical composition and a comparatively low oxygen mobility, however, this does not lead to significant discrepancies between the values of $E(O_2)$ and $q(O_2)$. Distortion of the values obtained for the heat of adsorption may also take place in the case of metallic catalysts, because of solution processes in the layers of metal next to the surface. It must therefore be borne in mind that the measured value of the heat of adsorption may not always characterise the bond energy of the surface species taking part in the catalytic process.

Unlike the heat of adsorption, the activation energy of isotopic exchange is measured under conditions of adsorption equilibrium. In this case, therefore, there are no secondary processes leading to the values of q which are too high. Thus Table 5 shows that the discrepancy (where it exists) is observed only in the direction of an increase in q above E. The activation energy of isotopic exchange apparently corresponds to the true value of the heat of adsorption. For systems with a labile chemical composition, isotopic exchange probably provides the most reliable method for determining it.

VII. THE DEPENDENCE OF THE CATALYTIC ACTIVITY IN ISOTOPIC EXCHANGE REACTIONS ON THE HEATS OF ADSORPTION OF NITROGEN AND OXYGEN

Table 3 shows that the rate of the isotopic exchange of nitrogen on different catalysts differs by many powers of ten. It cannot be related to any physicochemical characteristics of the catalysts. As in the case of oxides, it may be assumed that the bond energy of the surface nitrogen should be of the greatest interest from this viewpoint. Thus Fig.8, constructed from the data in Table 3, shows a distinct relationship between the catalytic activity and the heat of adsorption $q(N_2)$, for which the value of $E(N_2)$ was used.

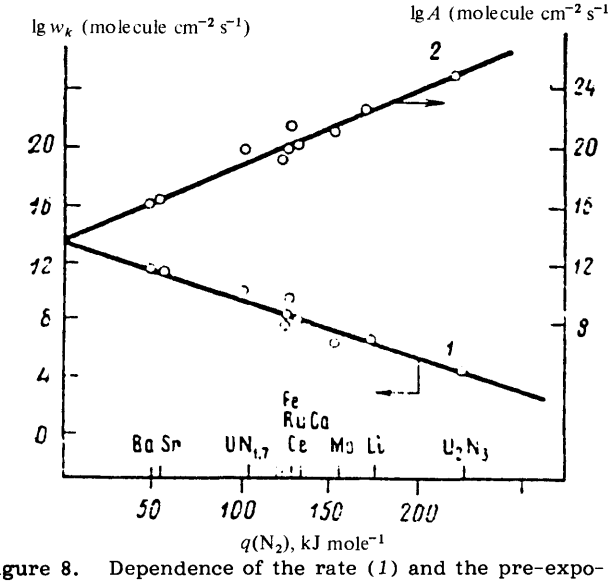

Figure 8. Dependence of the rate (*1*) and the pre-exponential factor (*2*) of the isotopic exchange of N_2 on nitrides and metallic iron and ruthenium (573 K, 52 Pa) on the heat of adsorption.

The highest activity in the isotopic exchange of nitrogen is shown by strontium and barium nitrides, which have the minimum heat of adsorption, equal to ~50 kJ mole^{-1}. The rate of exchange of nitrogen on these catalysts is one hundred times the rate of exchange on Fe. The lowest activity is shown by α-U_2N_3, on which the heat of adsorption of nitrogen is 225 kJ mole^{-1}. Overall, an increase in the heat of adsorption by 175 kJ mole^{-1} in the series of nitrides and metals examined leads to a decrease in the rate of exchange by a factor of 10^7. There is a simultaneous increase in the pre-exponential factor, corresponding to the existence of a compensation effect.

The heat of adsorption of nitrogen on magnesium nitride is probably even higher than that on α-U_2N_3, and this specimen does not show appreciable activity up to 973 K.[25]

A similar relationship is observed for the isotopic exchange of oxygen on oxides, as can be seen by comparing Fig.8 and Fig.3. Moreover, this similarity is not only qualitative, but also quantitative, as can be clearly seen from Fig.9, which gives simultaneously the dependence of the isotopic exchange of nitrogen and the isotopic exchange of oxygen, carried out

under identical conditions, on the corresponding values of the heats of adsorption. The fact that the relationships coincide is extremely unexpected, and indicates that the chemical nature of the reacting molecules and the chemical nature of the catalysts are important primarily in the way in which they influence the heat of reaction. If the heats are equal, the rates of exchange are approximately the same, irrespective of whether the system contains molecular nitrogen or oxygen.

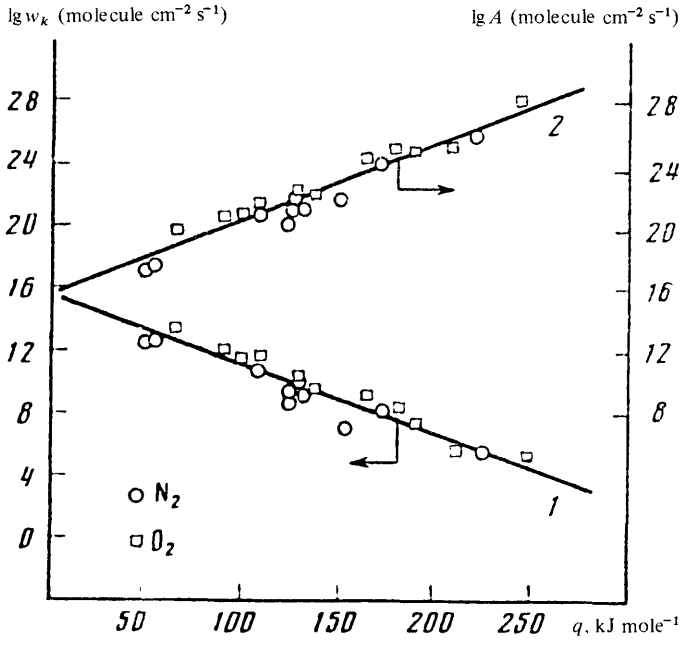

Figure 9. Dependence of the rate (*1*) and the pre-exponential factor (*2*) of the isotopic exchange of nitrogen and oxygen (573 K, 1.33 kPa) on the heat of adsorption.

The similarity in the entropy factors is probably because the entropies of the free molecules of nitrogen and oxygen are similar and the exchange mechanisms are the same. It is more difficult to understand why the values of the activation energy of isotopic exchange of nitrogen and oxygen are equal with identical values of q, since in the case of N_2 the reaction at each stage involves bonds whose energy is 450 kJ mole^{-1} greater than for O_2. The only explanation for this fact is probably that in the dissociative adsorption of both N_2 and O_2 there is almost complete compensation of the energy required for rupture of the bonds in these molecules, by the energy of the reaction of the resulting atoms with the surface. In other words, the heat of adsorption makes the principal contribution to the energy barrier of the equilibrium adsorption–desorption process.[82]

There are a number of facts which show an analogy between the observed regularity and the energy characteristics of more complex catalytic reactions. Thus in Ref. 83 it is the heat of the process that is used to characterise the reactivity of the substances being oxidised, and its use makes it possible to describe satisfactorily the regular features of the complete oxidation.

Of considerable interest is the numerical value of the coefficient α in Eqn.(3), which shows the fraction of the heat of adsorption of oxygen $q(O_2)$ appearing in the activation energy of the oxidative reaction. Since in different reactions the removal of oxygen takes place in different activated complexes, the coefficient α should apparently change with variation of the chemical character of the reacting molecules. Analysis of a large number of oxidative reactions has shown, however, that the value of α remains approximately constant and equal to ~0.5 in all cases.[83] This coefficient is also equal to ~0.5 for a number of other reactions, including the reaction of ammonia synthesis.[85] The coefficient α has also been found to be constant in the isotopic exchange of nitrogen and oxygen, in spite of the difference in the chemical character of the O_2 and N_2 molecules, the only difference being that the coefficient α in both cases is equal to 1, since the quantities E and q are equal.

Finally, to return to the fact that the relationships for nitrogen and oxygen in Fig. 9 are identical, it should be noted that the rate of exchange, in addition to the heat of adsorption, is also determined by the proportion of the active surface. Thus if the surfaces of the catalysts being studied are biographically non-uniform, the non-uniformity cannot be strongly defined. Otherwise, it would be necessary to assume the existence of some universal law of distribution of the active centres of the surface with respect to energy for all the catalysts which have been compared.

VIII. ESTIMATION OF THE RATE OF THE SYNTHESIS OF AMMONIA FROM DATA ON THE ISOTOPIC EXCHANGE OF N_2

The present section considers first those predictions about the synthesis of ammonia that can be made using data on the exchange of nitrogen. It has been noted that in the limiting stages of oxidation reactions, the removal of oxygen from a catalyst surface takes place via different activated complexes, which, in addition to oxygen, also contain various fragments of the substance being oxidised. Naturally, these complexes are not formed in isotopic exchange. Thus from the rate of exchange of O_2 it is possible to predict only the relative change in the rates of oxidation in a given series of catalysts. The synthesis of ammonia under conditions not too far removed from equilibrium, however, takes place by the Temkin–Pyzhov mechanism, whose limiting stage is the adsorption of nitrogen, that is a stage which is present in "pure form" in isotopic exchange. In this case, exchange data make it possible to calculate not only the relative values but also the absolute values of the rates of synthesis.[22,86]

The equation for calculating the rate of the synthesis of ammonia has the following form:[22]

$$w_c = w_k(p/p^* - 1) \qquad (10)$$

where w_c is the rate of the synthesis of ammonia, measured at a partial pressure of nitrogen in the reaction mixture p; p^* is the volatility of the nitrogen adsorbed on the catalyst under the conditions of the synthesis reaction; and w_k the rate of the isotopic exchange of N_2 at a nitrogen pressure equal to p^*. The value of p^* is calculated from the equation

$$p^* = \frac{1}{K_p}\frac{p^2(NH_3)}{p^3(H_2)}$$

where $p(NH_3)$ and $p(H_2)$ are the partial pressures of ammonia and hydrogen respectively in the reaction mixture, and K_p the equilibrium constant of the reaction

$$N_2 + 3H_2 \rightleftharpoons 2NH_3$$

Thus Eqn.(10) shows that the activity of the catalysts in the

synthesis of ammonia should be proportional to their activity in isotopic exchange, measured under identical conditions.

Some data on the activity of nitrides in the synthesis of NH_3 [25,53,61,66] are given in Table 6, which also gives for comparison the data for the promoted iron catalyst SA-1.[61] It can be seen that Mg nitride, which is inert in the isotopic exchange of nitrogen, is also inactive in the synthesis of ammonia. The lanthanides, except for cerium, have a low activity in exchange, and show appreciable activity in the synthesis only in the temperature range close to 800 K, whereas CeN and $UN_{1.70}$ are active in both reactions. Even a qualitative examination shows, however, that in most cases, particularly on the nitrides of Sr and Ba, which are of greatest interest (the expected rate of synthesis should be 100–1000 times that on Fe), the experimentally measured rate is found to be much lower than that calculated from data on the isotopic exchange of nitrogen using Eqn.(10), or even close to zero.

Table 6. The activity of nitrides in the synthesis of ammonia at a pressure of 98 kPa.

Nitride	T, K	$[NH_3]$, mole %	lg w (molecule $cm^{-2}s^{-1}$)		Phase composition after the synthesis

The discrepancy may be due to two factors: either the reaction does not take place by the Temkin–Pyzhov mechanism, so that the assumptions on which the calculation is based are incorrect, or side reactions take place under the synthesis conditions, leading to a decrease in the rate of the catalytic reaction. Subsequent studies have shown[66] that the factor responsible lies not in a change in the mechanism but in the physicochemical characteristics of the nitrides, which are examined below.

IX. THE STABILITY OF NITRIDES. THERMODYNAMIC ESTIMATIONS

The study of the synthesis of ammonia has revealed extremely significant differences in the behaviour of nitrides. Some nitrides, including those of the lanthanides and uranium, have been found to be stable in a nitrogen–hydrogen mixture;[66] in this case the formation of ammonia is the result of a catalytic process. X-Ray diffraction data have shown that the phase composition of the original catalysts remains unchanged after the reaction (Table 6). The nitrides of another group, namely those of lithium and the alkaline earth metals, are unstable and undergo phase transformations during testing. In this case, the formation of ammonia is also observed under the conditions of the experiment, but this results not from a catalytic process but from a chemical reaction between the nitride and the hydrogen of the gas phase. The formation of ammonia stops completely after the nitride has been converted into the hydride.

The ability to form hydrides is well known for the electropositive metals of groups I, II, and III of the periodic system.[87] To understand the characteristic features of the behaviour of nitrides and to determine the possible range of their stable operation, it is appropriate to examine the thermodynamic properties from the viewpoint of the stability of the nitrides in a nitrogen–hydrogen mixture.

It will be assumed that the original system contains either a nitride phase, for example M_3N, or the corresponding hydride phase MH. It will be assumed that the nitrogen pressure is 25 kPa, and the hydrogen pressure 75 kPa. To estimate the stability of a given phase, it is necessary to determine the free energy of the reaction:

$$6MH + N_2 \rightarrow 2M_3N + 3H_2 \qquad (11)$$

Since the change in the heat capacity in this reaction is slight, it will be assumed that

$$\Delta G^0_T = \Delta H^0_{298} - T\Delta S^0_{298}$$

In addition to reaction (11), the formation of NH_3 is also possible in the system being considered. Since the free energy of formation of ammonia is extremely small, however, this possibility will not be taken into account, since the calculations are only approximate.

Table 7. Stability of nitrides in a nitrogen–hydrogen mixture.

Compound	$-\Delta H^0_{f,298}$, kJ $mole^{-1}$	$-\Delta S^0_f$, J $mole^{-1}$ K^{-1}	Stability range
Li_3N	197	79	>600 K
LiH	91	69	—
Mg_3N_2	462	202	unlimited
MgH_2	75	127	—
Ca_3N_2	440	210	>700 K
CaH_2	189	131	—
Sr_3N_2	391	225	>600 K
SrH_2	177	158	—
Ba_3N_2	364	243	>800 K
BaH_2	179	156	—
CeN	327	107	unlimited
CeH_2	253	181	—
U_2N_3	374	334	unlimited
UH_3	117	186	—

Table 7 gives the original thermodynamic data, taken from Ref.87–91, and the results of an estimation by the present authors of the temperature range of stability of the nitrides. In agreement with experimental observations of the phase composition of the specimens after the experiments (Table 6), the calculation showed that the nitrides of the lanthanides and uranium are stable throughout the entire temperature range. According to the calculation, the nitrides of lithium and the alkaline earth metals should be stable only at temperatures above 600–800 K, and that their hydrides are stable at lower temperatures. In fact, the situation for the nitrides of lithium and the alkaline earth metals is found to be even less favourable. Thus in the presence of H_2 these systems can also form mixed compounds containing nitrogen and hydrogen (amides and imides), whose existence cannot be taken into account, since their thermodynamic properties are unknown. As a result of the existence of these compounds, the range of stability of the nitrides of the metals of groups I and II is displaced to much higher temperatures, which are of no interest for catalysis, because of the low equilibrium yields of NH_3.

The catalytic activity of the actual mixed phases is low. Thus in the presence of the mixed phase formed by strontium, the formation of ammonia is not observed up to 873 K.[92]

In the case of the unstable nitrides, hydrogen also has a strong and irreversible deactivating influence on the isotopic exchange of N_2.[25]

An interesting representative of the group of unstable nitrides is barium nitride, for which the conversion into the hydride takes place particularly readily, leading to a high rate of formation of ammonia in the low-temperature range (470–570 K). The reaction of barium nitride with H_2 takes place in two stages.[92] In the first stage, after the introduction of the nitrogen–hydrogen mixture, vigorous absorption of H_2 takes place without the liberation of ammonia, and is complete with the formation of the compound $BaN_{0.6}H_{1.8}$. This overall composition probably corresponds not to any individual substance but to a mixture of nitrogen- and hydrogen-containing compounds.

In the second stage, hydrogenation takes place with the liberation of NH_3. The total quantity of ammonia formed corresponds closely to the initial concentration of nitrogen in the nitride, and is independent of whether the nitrogen–hydrogen mixture of pure H_2 is passed over the specimen. This indicates that the nitrogen of the gas phase is not involved in the catalysis process, and that NH_3 is formed only as a result of the hydrogenation of the nitride.

Barium hydride can be reconverted into the nitride by heating in an atmosphere of nitrogen, to give a cyclic process for preparing ammonia.[92]

Unlike other metals, copper cannot form hydrides. The nitride Cu_3N is thermodynamically unstable ($\Delta H^0_{f\ 298} = 75$ kJ mole^{-1}), which, like the nitrides of Fe[45] and Ge,[43] readily decomposes in the presence of hydrogen to give metallic copper and an equivalent quantity of ammonia.

X. COMPARISON OF THE EXPERIMENTAL AND CALCULATED RATES OF SYNTHESIS OF AMMONIA

The calculation of the rate of synthesis of NH_3 from isotopic exchange data is obviously meaningful only for stable nitrides. Table 6 shows that the highest activity corresponds to uranium nitride, on which the rate of ammonia synthesis is close to the rate of the same process on an iron catalyst. A high activity is also shown by cerium nitride, and this has stimulated the examination of a fairly large number of lanthanides in order to find in this series other catalysts capable of bringing about the synthesis of ammonia at a high rate. However, in this reaction as in isotopic exchange, the activity of all the other nitrides was found to be lower by several powers of ten than that of CeN.

This result is extremely unexpected, since the lanthanide nitrides have the same crystal structure and similar thermodynamic and chemical properties. The difference must be attributed to differences in the electrical characteristics, since CeN has the highest electrical conductivity of nitrides in this series.[54] An interesting feature is that a similar regularity is also observed in the series of lanthanide oxides, where the maximum electrical conductivity and the maximum activity in the oxidation of hydrogen correspond to the element next to cerium, namely praseodymium.[30]

The calculated and experimental rates of ammonia synthesis are compared in Fig.10, taken from Ref.53. The broken straight line corresponds to the equality $w_{calc} = w_{expt}$. (It should be noted that Fig.10 cannot be used to reach conclusions about the relative activity of catalysts, since the data for different catalysts relate to different conditions.) It can be seen that for the nitrides of cerium and molybdenum and for metallic iron, there is satisfactory agreement between the calculated and measured rates, whereas for uranium nitride a considerable discrepancy is observed, and w_{expt} is smaller than w_{calc} by a factor of more than 10.

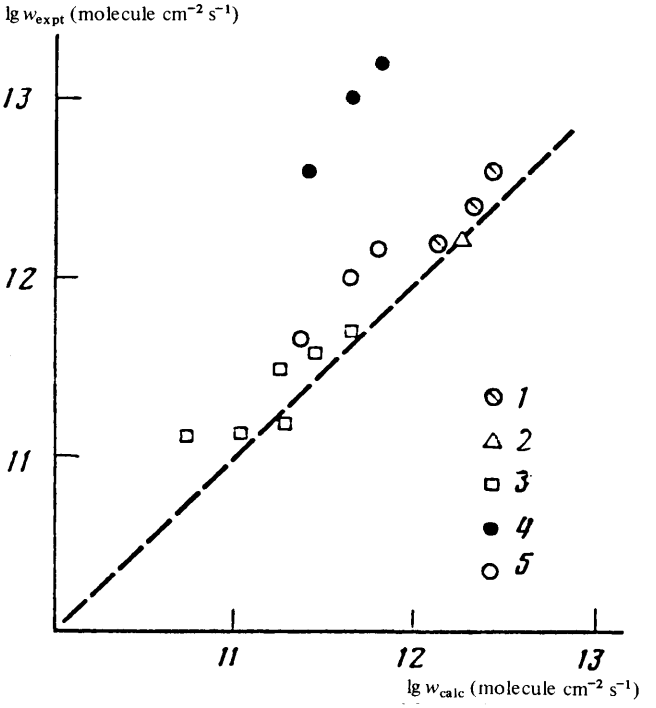

Figure 10. Comparison of the experimental and calculated rates of ammonia synthesis on Fe (*1*), Mo_2N (*2*), CeN (*3*) and on $UN_{1.70}$ without allowance (*4*) and with allowance (*5*) for the influence of H_2.

It is natural to assume that the fact that the rate of ammonia synthesis is lower than the calculated value in this case may be due to the deactivating influence of hydrogen, although the presence of hydrogen cannot bring about phase transformations in uranium nitride. This was confirmed in a study of the influence of H_2 on the isotopic exchange of nitrogen.[53] The introduction of hydrogen into the system leads to its appreciable absorption and is accompanied by a decrease in the rate of the isotopic exchange of N_2. The retardation by hydrogen in this case is reversible, and when the exchange is subsequently carried out in pure nitrogen, the activity is completely restored. The theoretical calculation of the rate of ammonia synthesis on uranium nitride with allowance for the influence of hydrogen on the activation of N_2 [53] leads to satisfactory agreement with experiment (Fig.10).

Hydrogen has no deactivating action and has no influence on the isotopic exchange of nitrogen on a cerium nitride catalyst.[24]

Thus for nitrides, as for metallic catalysts, where the deactivating action of hydrogen has no significant influence or can be taken into account, the isotopic exchange of N_2

provides an adequate characteristic of the activation of molecular nitrogen and its ability to take part in the ammonia synthesis reaction.

---o0o---

The results examined in the present review show the general character of the mechanism and regular features of the catalytic action of oxides in the activation of molecular oxygen and extensive oxidation reactions on the one hand, and the catalytic action of metals and nitrides in the activation of molecular nitrogen and the synthesis of ammonia on the other. This makes it possible to approach from a single viewpoint the problem of selecting catalysts for the range of reactions being considered.

It is not excluded that this general character may be even wider and may be observed in other systems, where the activation of a diatomic molecule takes place by dissociative adsorption on a catalyst surface. It is therefore of interest to carry out comparative studies of a number of analogous systems, and in particular to compare the catalytic action of hydrides in the isotopic exchange of H_2 and hydrogenation, and of chlorides in the isotopic exchange of Cl_2 and chlorination.

It may also be noted that the activation of nitrogen, that is a molecule which is often placed in a unique position because of its inertness, is in fact not an exceptional phenomenon. It obeys the same regular features as the activation of molecular oxygen.

The Coupled Reactions of Oxidation by Hydrogen Peroxide

T.M.Nagiev

The results of basic studies of chemical coupling in the gas-phase oxidation of various substrates by hydrogen peroxide have been analysed. The general characteristics of the mechanism of chemical coupling in gas-phase and liquid-phase oxidation by hydrogen peroxide have been examined.
The bibliography contains 81 references.

I. INTRODUCTION

Many reactions of practical importance involving the direct oxidation of various substrates by molecular oxygen do not correspond to present-day requirements, since practically all existing technical processes take place with a low selectivity.

In the development of present-day oxidation processes in chemical technology, the use of chemically combined forms of oxygen (O_3, H_2O_2, ROOH, etc.) and the principles of coupled processes are acquiring increasing importance.

Interest in the study of oxidation in coupled chain reactions has increased considerably as a result of the work of Academician N.M.Emanuel' and his school,[1,2] who were the first to formulate the concept of radical forms of coupled chemical reactions: "...the radicals generated by one of the reactions taking place in the system act as active reagents for another reaction which does not occur to a significant extent by itself under these conditions".

This statement forms the basis of the mechanism of the coupled oxidation of various substrates by hydrogen peroxide.

The present review examines reactions involving coupled oxidation by hydrogen peroxide, in which it has been shown that H_2O_2 can be used effectively both to discover new chemical reactions and to intensify and simplify the technology of oxidation processes of practical importance.

Hydrogen peroxide has various applications, and its world production has been estimated as several hundred thousand tons.

The use of H_2O_2 in industry in most cases has led to an improvement in the quality of production, a decrease in its cost, a decrease in environmental pollution, and increase in productivity, simplification of the technology, etc.

Because of its intermediate position in the redox triad

$$O_2 \underset{-2H}{\overset{2H}{\rightleftarrows}} H_2O_2 \underset{-2H}{\overset{2H}{\rightleftarrows}} H_2O$$

H_2O_2 shows a dual reactivity, and can act as an electron donor or as an electron acceptor, depending on the nature of the substrate.

Studies of reactions involving H_2O_2 have dealt chiefly with methods of preparation, the mechanism of the homogeneous and heterogeneous decomposition of H_2O_2, and the use of H_2O_2 as polymerisation initiator and as oxidising agent for the liquid-phase oxidation of organic substrates using transition metal compounds or enzymes as catalysts. Until recently there were practically no published data on the use of H_2O_2 as an oxidising agent in the gas phase.

II. CHEMICAL COUPLING IN GAS-PHASE OXIDATION BY HYDROGEN PEROXIDE

The use of hydrogen peroxide as an oxidising agent in the gas phase (as shown below) makes it possible to oxidise effectively aromatic compounds, alcohols, halogen-containing compounds,[3] and even nitrogen.[4] It is assumed that the oxidation is due to the existence of chemical coupling.[5,6] The primary reaction in this case is

$$H_2O_2 + H_2O_2 \rightarrow \underset{\text{intermediates}}{[\dot{O}H,\ H\dot{O}_2]} \rightarrow 2H_2O + O_2 \quad \Delta G^{\circ}_{298} = -58.8 \text{ kcal mole}^{-1} \qquad (1)$$

The $HO_2^{\bullet}$ free radicals formed in this reaction bring about the oxidation of the substrate according to the overall equation

$$H_2O_2 + \text{acceptor} \rightarrow \text{reaction products} . \qquad (2)$$

In the H_2O_2–acceptor–H_2O system, hydrogen peroxide is converted into the active form as the radical $HO_2^{\bullet}$ (in which the acceptor–donor properties of H_2O_2 are preserved), which transfers the inductive action of the primary reaction to the secondary reaction. The $HO_2^{\bullet}$ radical acts as it were as the intermediary agent between the coupled reactions, and the "active oxygen" in it is responsible for the selective oxidation.[6]

1. The Coupled Dehydrogenation of Various Substrates by Hydrogen Peroxide

Experimental studies to detect chemical coupling in gas-phase oxidation by hydrogen peroxide[6,7] were carried out in a flow system using an integral reaction vessel (ideal displacement conditions), whose design made it possible to introduce H_2O_2 into the reaction zone.

To determine which species is responsible for oxidation in the RH–H_2O_2–H_2O system, the model system chosen was the coupled dehydrogenation of ethylbenzene by a 15% aqueous solution of hydrogen peroxide and by molecular oxygen. For comparison of the results, the O_2 was supplied in quantities equivalent to its concentration in 15% aqueous H_2O_2 solution.[7,8]

Experiments on the coupled dehydrogenation of ethylbenzene (ETB) in the range 580–620 °C showed that the use of hydrogen peroxide gives high yields of styrene, equal to 39.3 mass % and 90 mass %, calculated respectively for the initial ETB and the ETB reacted, at 620 °C. At the end of the reaction, no condensation products (CP) were detected, and the volatile products consisted chiefly of CO_2, in quantities not exceeding 1% by weight.

In the dehydrogenation of ethylbenzene by molecular oxygen, the yields of styrene are much lower (8–10 mass %) than in the first case, and condensation products are formed in quantities of up to 1.7% by wt. on the walls of the quartz reaction vessel. In addition, the quantity of O_2 in the gaseous products reaches 80 % by volume, whereas the gaseous products of the conjugated dehydrogenation by hydrogen peroxide do not contain molecular oxygen. Thus the dehydrogenating agent in the system is hydrogen peroxide, that is the coupled dehydrogenation by hydrogen peroxide takes place by a mechanism which differs fundamentally from that of high-temperature oxidation by molecular oxygen. Although by itself the formation of an oxygen atom by the decomposition of H_2O_2 in a hydrocarbon medium by a heterogeneous process is unlikely, nevertheless to eliminate the possibility of the participation of the atoms of O_2 in the dehydrogenation, the decomposition of nitrous oxide was used as a source of oxygen atoms: [9]

$$N_2O \rightarrow N_2 + O^{\cdot}$$

The degree of decomposition of N_2O in the presence of butane and cyclohexane at 500–600 °C is 25 mole % and 30 mole % respectively, [10,11] indicating that the decomposition of N_2O is independent of the presence of hydrocarbons in the medium.

In addition to unsaturated compounds, a large number of side products (H_2, CH_4, C_2H_6, C_2H_4) were found in the products of the transformation of C_4H_{10}. The dehydrogenation of C_6H_{12} in the presence of H_2O_2 is also characterised by a much higher selectivity at higher degrees of conversion, compared with the reaction in the presence of N_2O, where the only active intermediate species is atomic oxygen (see Table 1). [11,23]

Table 1. The coupled dehydrogenation of cyclohexane with the participation of hydrogen peroxide and nitrous oxide. [11,23]

System	C_6H_{10}, mass %	C_6H_8, mass %	C_6H_6, mass %	Selectivity, %
$C_6H_{12}+H_2O_2$	20	4	3	88
$C_6H_{12}+N_2O$	9	2	7	80

Thus the mechanism of dehydrogenation by hydrogen peroxide differs from that of oxidative dehydrogenation by molecule oxygen and nitrous oxide. The participation of an oxygen atom as an active reaction centre in the conjugated oxidation of the substrate by hydrogen peroxide is therefore unlikely, and elementary reactions involving it need not be considered in the reaction mechanism. This conclusion is confirmed by a study of the dehydrogenation of butane both by hydrogen peroxide and by nitrous oxide. [10]

To establish the possibility that surfaces influence the nature of the reaction of H_2O_2 with hydrocarbons, the conjugated dehydrogenation of various alkylbenzenes was studied in reaction vessels treated with inorganic salts. [12] The results of these experiments indicate that in all cases the reaction shows an appreciable sensitivity to the nature of the surface of the reaction vessel. The yields of the desired products decrease in the order:

$$B_2O_3 > \text{untreated reaction vessel} > K_2B_4O_7 > KBr > KCl > BaBr_2$$

The results correlate with data from Ref. 13, where it was shown that a quartz surface treated with metal salts influences the rate of the destruction of $HO_2^{\cdot}$ radicals, which decreases in the same salt sequence. This indicates that the surfaces which are most active in chain termination as a result of the destruction of $HO_2^{\cdot}$ are least favourable for the conjugated dehydrogenation of hydrocarbons.

The kinetic estimation of the decomposition of H_2O_2 to $HO_2^{\cdot}$ and $^{\cdot}OH$ free radicals is of interest in this connection. The decomposition of H_2O_2 in the gas phase has been fairly well studied, and takes place by the following mechanism: [14–16]

	$\lg A$, $cm^3 mole^{-1} s^{-1}$	E, kcal $mole^{-1}$
$H_2O_2 + M \xrightarrow{k_1} 2\dot{O}H + M$	17.08	45
$H_2O_2 + \dot{O}H \xrightarrow[k_2]{} HO_2^{\cdot} + H_2O$	13.0	1.8
$HO_2^{\cdot} + \text{wall} \xrightarrow{k_3} HO_{2\,ads}$	1.0	8.2
$^{\cdot}OH + \text{wall} \rightarrow OH_{ads}$	0.3	7.0

where M is the total number of molecules in the reaction volume, and A the pre-exponential factor.

According to this scheme

$$\frac{[HO_2^{\cdot}]}{[\dot{O}H]} = \frac{k_1}{k_2}[H_2O_2] \qquad (3)$$

which makes it possible to estimate the ratio of the concentrations of the active centres in the system.

Under the conditions of the experiment, [4] the ratio (3) usually lies in the range 10^3–10^7, that is the concentration of the radical $HO_2^{\cdot}$ in the gas phase is many powers of ten greater than that of $^{\cdot}OH$.

Thus dehydrogenation in the presence of H_2O_2 evidently takes place by a free-radical mechanism, and the rate of the process is determined mainly by the concentration of $HO_2^{\cdot}$ in the system.

The mechanism of dehydrogenation by hydrogen peroxide can be illustrated by several examples.

The kinetics and yield of the products of the dehydrogenation of ETB by hydrogen peroxide [7,17] in the temperature range 500–600 °C at volume rates of supply of ethylbenzene of 0.2–0.8 h^{-1} and ratios $C_6H_5C_2H_5 : H_2O_2$ in the range from 1:1 to 1:4 depend on the ratio of the surface area (S) to the volume (V). Under optimum conditions the yield of styrene reaches 40% by weight with a selectivity of 90% by weight.

The mechanism of the process involves the following elementary stages: [17]

$$H_2O_2 \rightarrow 2\dot{O}H - 52.0 \text{ kcal mole}^{-1} \qquad (4)$$

$$H_2O_2 + \dot{O}H \rightarrow H\dot{O}_2 + H_2O + 26.7 \text{ kcal mole}^{-1} \qquad (5)$$

$$C_6H_5C_2H_5 + \dot{O}H \rightarrow C_6H_5\dot{C}_2H_4 + H_2O + 42.9 \text{ kcal mole}^{-1} \qquad (6)$$

$$C_6H_5\dot{C}_2H_4 \rightarrow C_6H_5C_2H_3 + H - 52.7 \text{ kcal mole}^{-1} \qquad (7)$$

$$C_6H_5C_2H_5 + H\dot{O}_2 \rightarrow C_6H_5\dot{C}_2H_3 + H_2O + \dot{O}H + 26.7 \text{ kcal mole}^{-1} \qquad (8)$$

$$H_2O_2 + H \rightarrow H_2O + \dot{O}H + 68.4 \text{ kcal mole}^{-1} \qquad (9)$$

$$C_6H_5C_2H_5 + HO_2^{\cdot} \rightarrow C_6H_5\dot{C}_2H_4 + H_2O_2 + 14.7 \text{ kcal mole}^{-1} \qquad (10)$$

$$HO_2^{\cdot} + \text{wall} \rightarrow HO_{2\,ads} \qquad (11)$$

$$^{\cdot}OH + \text{wall} \rightarrow OH_{ads} \qquad (12)$$

This scheme includes three paths for the chain formation of styrene in the $C_6H_5C_2H_5$–H_2O_2–H_2O system.

The hydroxyl radical formed in elementary stage (4) is consumed in the bulk phase by two possible reactions, (5) and (6). Comparison of the kinetic parameters of the elementary stages (5) and (6), whose activation energies are 1–2 kcal $mole^{-1}$ [14] and 5–8 kcal $mole^{-1}$ [18] respectively, shows that the rate of reaction (5) is much greater than that of reaction (6). Thus in the $C_6H_5C_2H_5$–H_2O_2–H_2O system, of

the two paths by which $^{\cdot}OH$ are consumed, stage (5) is more probable. A noteworthy feature is that the formation of hydrocarbon radicals by the reaction $RH + {}^{\cdot}OH \rightarrow R^{\cdot} + H_2O$ would have led, in subsequent stages of development of the process, to the formation of new free radicals $RO^{\cdot}$ and $RO_2^{\cdot}$. Their transformations should lead to the appearance of oxygen-containing substances and products of oxidative cracking in the reaction products, in addition to unsaturated compounds.[19] The products of the dehydrogenation of ethylbenzene do not include organic oxygen-containing compounds, however; at relatively low yields of styrene (about 20 mass %), products of oxidative cracking are not detected either.[7]

Thus the elementary reaction (8) is apparently the most probable.[17] Usually, the activation energy of stage (10) $E_{10} > 12.5$ kcal mole^{-1} ($\lg A_{10} = 9.4$ cm^3 mole^{-1} s^{-1}),[20] and for stage (8), E_8 does not exceed 11.0 kcal mole^{-1} ($\lg A_8 = 9.6$ cm^3 mole^{-1} s^{-1}).[17,21] For chain termination reactions by the destruction of the free radicals $^{\cdot}OH$ and $HO_2^{\cdot}$ on the walls of the quartz reaction vessel, their accommodation coefficients were determined:[13,17] $\varepsilon_{OH} = 0.5 \times 10^{-6}$ and $\varepsilon_{HO_2} = 0.2 \times 10^{-5}$.

Thus estimation of the rates of the elementary stages (4) to (12) indicates that coupled dehydrogenation is an unbranched chain reaction, in which chain propagation involves two stages:

$$H_2O_2 + \dot{O}H \xrightarrow{k_5} H\dot{O}_2 + H_2O \qquad (5)$$

$$C_6H_5C_2H_5 + H\dot{O}_2 \xrightarrow{k_8} C_6H_5\dot{C}_2H_3 + H_2O + \dot{O}H \qquad (8)$$

overall reaction

$$C_6H_5C_2H_5 + H_2O_2 = C_6H_5C_2H_3 + 2H_2O \qquad (13)$$

The proposed mechanism and the method of stationary states gave a kinetic equation[21] for the reaction rate which adequately describes the experimental data in the temperature range 500–620 °C:

$$-d[\mathrm{ETB}]/dt = k_{\mathrm{eff}}[\mathrm{ETB}][H_2O_2]$$

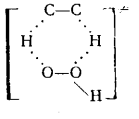
$$k_{\mathrm{eff}} = \frac{k_1 k_8}{k_{11}} = 0.35 \cdot 10^{16} \exp(-55300/RT) \text{ litre mole}^{-1}\text{s}^{-1}$$

The expression for k_{eff} does not contain the rate constant of reaction (5), so that the limiting step in chain propagation is reaction (8), which involves $HO_2^{\cdot}$.

The dehydrogenation of ethylbenzene by hydrogen peroxide (13) is a coupled reaction, since it is induced by the decomposition of H_2O_2 (the primary reaction). Both processes in the system are complex, and take place via a common intermediate active species, the $HO_2^{\cdot}$ radical,[7,22] and in the mechanism of the conjugated dehydrogenation a central position is occupied by the new elementary stage

$$\text{>CH–CH<} + HO_2^{\cdot} \rightarrow \text{>C=C<} + H_2O + \dot{O}H \qquad (5)$$

This reaction involves the formation of the six-membered transition state



which subsequently decomposes to give H_2O, alkene, and the free radical $^{\cdot}OH$, which is more active than the original $HO_2^{\cdot}$.

Thus the available theoretical and experimental data lead to a new and chemically specific mechanism of conjugated dehydrogenation, involving the primary (inducing) reaction of H_2O_2 decomposition and the secondary (induced) reaction of conjugated dehydrogenation.[6]

The use of H_2O_2 makes it possible to carry out effectively the incomplete dehydrogenation of cyclohexane to cyclohexene and cyclohexadiene; under other conditions this reaction is thermodynamically difficult.[23]

The conjugated dehydrogenation of cyclohexane by hydrogen peroxide can take place over a wide temperature range (450–630 °C) at different volume rates of supply of cyclohexane (0.1–1.0 h^{-1}) and H_2O_2 concentrations of 5–30% by weight. Under the optimum conditions at 580 °C, a conditional contact time $\tau = 4.2$ s, and a volume ratio of cyclohexane to aqueous H_2O_2 solution (20% by weight) of 1:3, the yields of cyclohexene and cyclohexadiene are 20% by weight and 4% by weight respectively, with a selectivity with respect to double bonds of 97% by weight.

Fig. 1 gives typical kinetic curves showing the consumption of cyclohexane and the accumulation of reaction products at 580 °C; the kinetic curves for the accumulation of cyclohexadiene and benzene are *S*-shaped.[23] These kinetic data indicate that the reaction products (cyclohexadiene and benzene) are formed by the successive dehydrogenation of the more saturated analogues. Thus the reaction products are formed in the successive stages:

		$\lg A_{\mathrm{eff}}$, cm^{3}mole^{-1}s^{-1}	E_{eff}, kcal mole^{-1}
$H_2O_2 +$	$C_6H_{12} \xrightarrow{k_{\mathrm{eff}\,1}} C_6H_{10} + H_2O$	24.95	63.0
	$C_6H_{10} \xrightarrow{k_{\mathrm{eff}\,2}} C_6H_8 + H_2O$	23.95	53.0
	$C_6H_8 \xrightarrow{k_{\mathrm{eff}\,3}} C_6H_6 + H_2O$	22.86	49.0

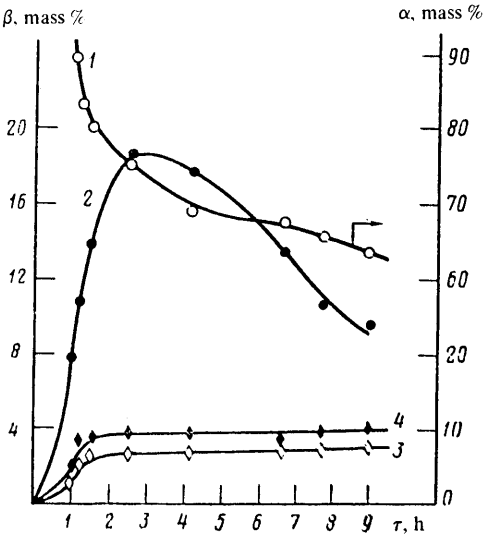


Figure 1. Kinetic curves giving the consumption (α) of cyclohexane (*1*) and the accumulation (β) of cyclohexene (*2*), cyclohexadiene (*3*), and benzene (*4*) in the coupled dehydrogenation of cyclohexane; $V_0 = 0.237$ h^{-1}, ratio C_6H_{12} : 20% aqueous H_2O_2 solution = 1:3 (by volume), 580 °C, τ is the conditional contact time.[23]

Each of the successive reactions described by the chain unbranched scheme (4), (8), and (11) represents a combination of the stages of chain initiation, propagation, and termination.

A system of kinetic equations providing an adequate description of the experimental data has the form:[24,25]

$$-\frac{d[C_6H_{12}]}{dt} = k_{eff\,1}[C_6H_{12}][H_2O_2]$$

$$-\frac{d[C_6H_{10}]}{dt} = k_{eff\,1}[C_6H_{12}][H_2O_2] - k_{eff\,2}[H_2O_2][C_6H_{10}]$$

$$\frac{d[C_6H_8]}{dt} = k_{eff\,2}[H_2O_2][C_6H_{10}] - k_{eff\,3}[H_2O_2][C_6H_8]$$

The overall dehydrogenation process is effectively described by a chain radical scheme with the following rate constants for the reaction of $HO_2^{\cdot}$ with cyclohexane and alkenes:

			lg A, $cm^3 mole^{-1} s^{-1}$	E, kcal $mole^{-1}$
$HO_2^{\cdot}$ +	C_6H_{12}			
	$C_6H_{10} \rightarrow \dot{O}H + H_2O$ +	C_6H_{10}	11.65	15.2
		C_6H_8	10.65	13.2
	C_6H_8	C_6H_6	9.86	9.2

The high selectivity of the process (95–99% by weight) and the absence of oxygen-containing reaction products makes it possible to eliminate a number of technological operations involving the separation of an appreciable quantity of components difficult to separate. Moreover, the high selectivity makes possible more complete utilisation of the raw materials.

An important task is the synthesis of pyridine bases and their derivatives, and the preparation of the corresponding N-oxides.[26] The realisation of the mechanism of chemical coupling in the oxidation of 4-ethylpyridine (4-ETP) by hydrogen peroxide[27] led to the development of a new method for obtained 4-vinylpyridine (4-VNP) and 4-vinylpyridine N-oxide. In a reaction vessel made entirely of quartz, in the range of volume rates of supply of 4-ETP 0.065–0.783 h^{-1} at a ratio of 4-ETP and 20% aqueous H_2O_2 solution of 1:3, the reaction takes place with a high selectivity up to 640 °C. Under the optimum conditions (620 °C), the yield of 4-VNP is 20.9% by weight with a selectivity of 92% by weight. Under the same conditions in a reaction vessel filled with quartz granules, the yield of 4-VNP increases considerably and amounts to 44.3% by weight with a selectivity of 96% by weight (Table 2).[28]

Table 2. Influence of the S/V ratio on the yield of 4-VNP.[28]

S/V ratio, cm^{-1}	Yield of 4-VNP (mass %) in relation to temperature, °C		
	600	620	640
Empty reactor, $S/V = 0.8$	15.2	20.9	21.8
With quartz packing, $S/V = 8.2$	39.1	44.3	46.7

The increase in the yield of 4-VNP when the reaction zone is filled with quartz granules is probably related to the fact that under the conditions studied, in a reaction vessel with quartz packing, the homogeneous decomposition of H_2O_2 is accompanied by the heterogeneous decomposition

$$H_2O_2 + \text{wall} \longrightarrow \dot{O}H + \text{wall–OH} \qquad (14)$$

With chain initiation by reaction (14) there is a gain of energy relative to the homogeneous reaction, equal to the heat of formation of the M–OH bond. Other conditions being equal, increase in the value of the factor S/V apparently leads to an increase in the concentration of active centres and hence in the yield of desired product.

The kinetic parameters of the overall reaction and the stage involving the reaction of 4-ETP with $HO_2^{\cdot}$ are given below:[29]

	lg A, $cm^3 mole^{-1} s^{-1}$	E, kcal $mole^{-1}$
4-ETP + H_2O_2 = 4-VNP + $2H_2O$	23.8	51.0
4-ETP + $HO_2^{\cdot}$ → 4-VNP + H_2O + $^{\cdot}OH$	10.8	10.2

In the liquid phase and at low temperatures, H_2O_2 can be used for the N-oxidation of pyridine bases, using organic acids and their anhydrides as catalysts. The synthesis of N-oxides without the use of a catalyst is of interest, since components giving decomposition products difficult to remove from the system are introduced.

The oxidation of 4-ETP by hydrogen peroxide showed that the maximum yield of 4-VNP N-oxide (Fig. 2)[30] is achieved at 300 °C. Under the optimum conditions at this temperature, the chief reaction product is 4-VNP N-oxide, the yield of which is 33% by weight with a selectivity of 98%. Increase in temperature from 200 °C to 300 °C increases the yield of N-oxide, probably because of an increase in the rate of the production of active centres in the decomposition of H_2O_2. Further increase in temperature from 300 °C to 400 °C leads to a decrease in the yield and the selectivity of formation of 4-VNP N-oxide. At a temperature of 400 °C, 19.8% 4-VNP, 91% pyridine, and only about 7% by weight of the N-oxide are formed.

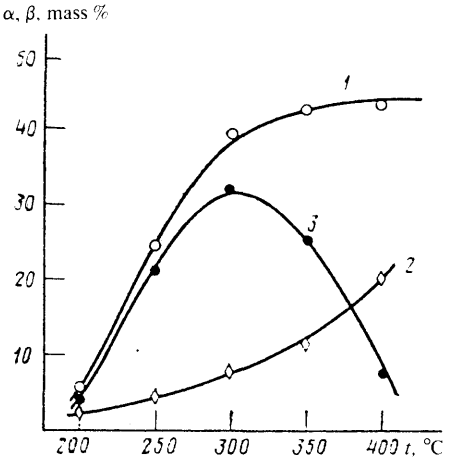

Figure 2. Influence of temperature on the degree of conversion (α) of 4-ETP (*1*) and the yields (β) of 4-VNP (*2*) and 4-VNP N-oxide (*3*) in the coupled oxidation of 4-ETP; $V_0 = 0.045\ h^{-1}$, [4-ETP]:[H_2O_2] = 1:3, H_2O_2 concentration 30% by weight.[30]

Thus depending on the oxidation conditions, the coupled oxidation of 4-ETP by hydrogen peroxide can be directed towards the formation of 4-VNP or its N-oxide.

The possible coupled dehydrogenation of alkenes by hydrogen peroxide was confirmed by the dehydrogenation of propene to allene and of isopentenes to isoprene.[31,32]

The familiar oxidative dehydrogenation of propene to allene in the presence of iodine[33] at a temperature of 625–700 °C is characterised by low yields of allene, 3.6% by weight, and a

low selectivity of its formation (6% by weight). In the case of the coupled dehydrogenation of propene under the optimum conditions (at 700 °C), the yields of allene and methylacetylene are ~20% by weight and 10% by weight respectively[34] (Fig.3). With increase in temperature above 700 °C, the yield of methylacetylene continues to increase, whereas that of allene decreases.

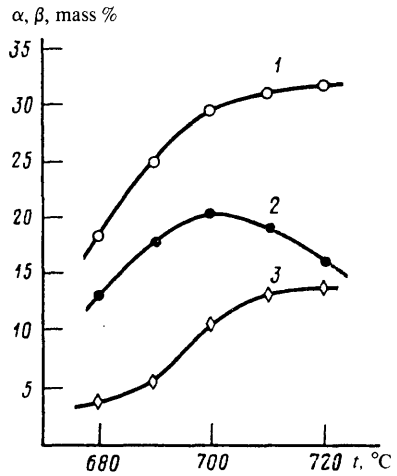

Figure 3. Influence of temperature on the degree of conversion (α) of propene (*1*) and the yields of allene (*2*) and methylacetylene (*3*) in the coupled dehydrogenation of propene; contact time 0.045 s.[34]

Fig.4 indicates that the coupled dehydrogenation of isopentenes with isomer compositions close to that of industrial fractions gives a fairly high yield of isoprene (25% by weight, with a selectivity of 75% by weight).[32] An advantage of this reaction over the oxidative catalytic dehydrogenation of isopentenes,[35] in spite of the relatively low selectivity, is the absence of the effect of retardation of the process by reaction products.

Of practical interest is the coupled dehydrogenation of industrial fractions of di-isopropylbenzene containing 57% *m*-di-isopropylbenzene and 34% *p*-di-isopropylbenzene by weight;[36] the yield of *p*-di-isopropenylbenzene in the dehydrogenation product reaches 30% by weight. The authors cited[36] compared the results with data on the catalytic dehydrogenation of di-isopropylbenzene on Shell-105 catalyst, and concluded that the yield and selectivity of the process are much higher in the coupled dehydrogenation of *p*-di-isopropylbenzene.

There are other examples of the preparation of alkenes of practical importance by coupled dehydrogenation, and these are considered below.

To some extent, the increase in the production of chloroalkenes[37] by existing technology is restricted by the loss of chlorine in byproducts, so that the development of methods for the dehydrogenation of chloroalkanes free from this disadvantage appears promising.

The oxidative dehydrogenation of ethyl chloride by air over a catalyst consisting of chromium oxide deposited on Al_2O_3 [38] is of interest in this connection. This process has a low yield and selectivity, however, since at the optimum temperature of 367 °C the yield of vinyl chloride is 17% by weight for a degree of conversion of 21% by weight. Some of these unsatisfactory features can be eliminated by the development of a new method for obtaining vinyl chloride, namely the coupled dehydrogenation of ethyl chloride by hydrogen peroxide.[39] Under the optimum conditions at a temperature of 450 °C, the yield of vinyl chloride is 37.8% by weight for a degree of conversion of 52% by weight, which is more than double the values for the process in Ref.38. It should be borne in mind the halogenoalkenes with more complex structures can also be synthesised in this way.

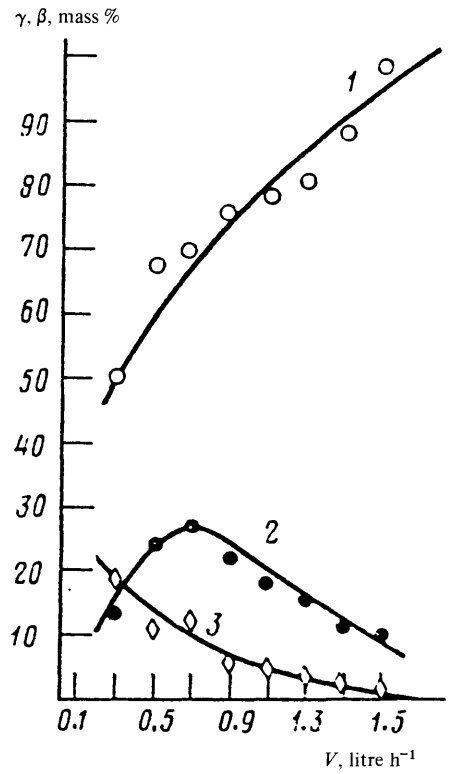

Figure 4. Influence of the rate of supply of the mixture of isopentenes and nitrogen ($V_{iso\text{-}C_5H_{10}} : V_{N_2} = 1:10$) on the selectivity of the coupled dehydrogenation (γ) (*1*), the yield of isoprene (*2*), and the total yield of side products (*3*); rate of supply of 20% aqueous H_2O_2 solution 0.185 ml h^{-1}, temperature 553 °C.[32]

The oxidative dehydrogenation of organic alcohols provides a relatively new approach to the development of industrial processes for obtaining aldehydes and ketones.[40–42] In this respect, the most successful from the technological viewpoint is the method for obtaining acetaldehyde by oxidising ethanol (at 350–490 °C) in an alcohol–air mixture in the presence of fused vanadium oxide or alkali metal vanadates catalysts with alkali metal sulphates or chlorides as promoters.[42] The yield of the desired product is 65.9% by weight, calculated on the alcohol passed, for a degree of conversion of 69.2% by weight. An unsatisfactory feature of the method[42] is the relatively low yield of the desired product and the increase in the complexity of the process with the use of an expensive catalyst.

To simplify the process and increase the yield of product, the oxidative dehydrogenation of C_2H_5OH has been carried out[43] by means of hydrogen peroxide by a conjugated mechanism. By varying different parameters of the reaction in the range 450–550 °C, it is possible, without using catalysts, to achieve fairly high yields of acetaldehyde (up to 87% by weight with a selectivity of not less than 97% by weight).

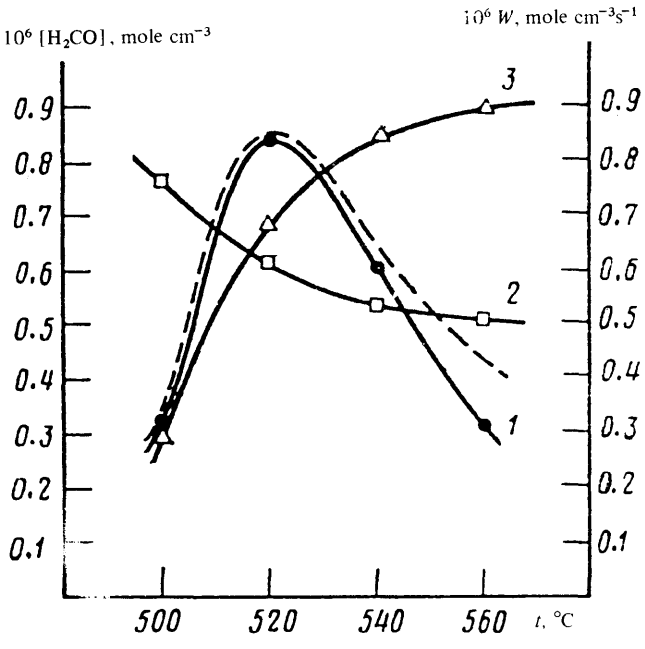

Figure 5. Temperature dependence of the H_2CO concentration (*1*) and the rates of accumultation (W) of $HO_2^{\cdot}$ (*2*) and $^{\cdot}CH_3$ (*3*) in the oxidation of methane by hydrogen peroxide; [CH_4] : [25% aqueous H_2O_2 solution] = 1 : 1, contact time τ = 1.2 s; the broken line gives the calculated curve for the accumulation of H_2CO.[50]

The high efficiency of the use of H_2O_2 in the oxidation of alcohols can also be illustrated by the dehydrogenation of s-butyl alcohol (2-BA) to methyl ethyl ketone (MEK). The oxidative dehydrogenation of 2-BA to MEK is now carried out using as catalysts metals such as gold and silver;[44,45] in the temperature range 520–600 °C, the yield of MEK is 70–85% by weight with a selectivity of 93–96% by weight. In spite of the high selectivity and degree of conversion to MEK, the presence of various side products such as acetaldehyde, acetone, diacetyl, CO, and CO_2 creates additional technological difficulties in the separation of MEK from the reaction medium.

In the liquid-phase oxidation of 2-BA,[46] although it is possible to avoid the use of precious metal catalysts, the characteristics of the process (the yield of MEK is 23.5% by weight with a selectivity of 79.4% by weight) are much inferior to those of the catalytic processes. Moreover, at 115–135 °C, it is necessary to use a pressure of 9–20 atm, to carry out the process and also to use initiating additives to decrease the induction period. The coupled dehydrogenation of 2-BA by hydrogen peroxide is free from most of these disadvantages, and makes it possible to increase the selectivity to 99% by weight, and to simplify the technology of the process, since it can be carried out at atmospheric pressure without using catalysts or special additives. The process is carried out in the gas phase at 460–560 °C with a yield of MEK of 26–44% by weight.

The possibility of obtaining unsaturated hydrocarbons and their derivatives by the conjugated decomposition of H_2O_2 and dehydrogenation of organic compounds indicates that this method is to some extent general.

2. The Coupled Oxidation of Methane to Formaldehyde by Hydrogen Peroxide

A large number of studies in the last ten years have been devoted to the incomplete oxidation of methane. The increased interest in the development of this method is due to the fact that methane is a practically inexhaustible natural raw material, whose possible utilisation will make it possible to satisfy completely the requirements of the national economy for methanol and formaldehyde.

The study of the mechanism of the oxidation of methane by oxygen in the presence of small quantities of H_2O_2 [47,48] has shown that H_2O_2 has a promoting action in the formation of formaldehyde. The intermediate species formed in the reaction are the free radicals $HO_2^{\cdot}$ and $CH_3O_2^{\cdot}$, whose transformations give the final reaction product H_2CO. In this reaction, H_2O_2 remains an intermediate product and accumulates in extremely small quantities.[47] The main oxidising agent is molecular oxygen, and the mechanism of the oxidation with added H_2O_2 does not differ significantly from the mechanism of the oxidation by O_2 in the absence of H_2O_2.

At the same time, the oxidation of various substrates by hydrogen peroxide in the gas phase takes place by a mechanism which is different from that involving molecular oxygen.[48]

The oxidation of methane to formaldehyde can be carried out with a high efficiency by the coupled oxidation of CH_4 in the presence of H_2O_2.[49,50]

The yield of H_2CO in the oxidation of CH_4 by hydrogen peroxide passes through a maximum with increase in the reaction temperature (Fig.5).[50] This form of the dependence is clearly related to the fact that H_2CO undergoes secondary reactions at temperatures above 520 °C. The maximum yield of H_2CO (39% by weight) calculated on the methane passed is reached at 520 °C, and at higher temperatures H_2CO is oxidised to CO. The concentration of CO in the reaction products increases with increase in temperature.

In the oxidation of methane by hydrogen peroxide, the following reaction becomes important:

$$CH_4 + OH^{\cdot} \rightarrow CH_3^{\cdot} + H_2O \quad \lg A = 12.5\ cm^3 mole^{-1} s^{-1}\ E = 2.0\ kcal\ mole^{-1} \qquad (15)$$

The concentration of $HO_2^{\cdot}$ in the H_2O_2–H_2O–CH_4 system will be determined by the ratio of the rates of reactions (5) and (15). At a molar ratio $CH_4 : H_2O_2$ = 1 : 1, corresponding to the optimum condition for obtaining formaldehyde, the ratio $[HO_2^{\cdot}]/[^{\cdot}OH] = 0.22 \times 10^4$, and the rates of the elementary reactions (5) and (15) with allowance for the reaction

$$CH_3^{\cdot} + HO_2^{\cdot} \rightarrow H_2CO + H_2O \qquad (16)$$

are practically equal and lie in the range $(0.46–0.60) \times 10^{-6}$ mole cm^{-3} s^{-1}.

Thus the radical $^{\cdot}OH$ formed in reaction (4) reacts with H_2O_2 and CH_4 at practically identical rates.

In this respect, the oxidation of CH_4 by hydrogen peroxide occupies a unique position, since in the presence of other compounds, for example ethylbenzene, cyclohexane, etc., the concentration ratio $[HO_2^{\cdot}]/[^{\cdot}OH] \gg 10^4$,[17] that is the main active centre is $HO_2^{\cdot}$. Under the optimum conditions for the

oxidation of methane, the concentrations of $^{\cdot}CH_3$ and $HO_2^{\cdot}$ are related by the inequality $[HO_2^{\cdot}]/[^{\cdot}CH_3] < 10^2$. This indicates that the cross recombination by reaction (16) is the main route to the formation of H_2CO. Other alternative routes to the formation of formaldehyde have been examined,[15] such as:

	$\lg A$, $cm^3 mole^{-1} s^{-1}$	E, kcal $mole^{-1}$	
$\dot{C}H_3 + H\dot{O}_2 \rightarrow CH_3\dot{O} + \dot{O}H$	13.51	≈ 0	(17)
$CH_3\dot{O} + \dot{C}H_3 \rightarrow H_2CO + CH_4$	13.4	≈ 0	(18)

The elementary stages (17) and (18) apparently do not play a signficant role, since the formation of the methoxy radical by reaction (17) should have led to the accumulation of methanol in the system by reaction (19), and this is not observed:[50]

$$CH_3\dot{O} + CH_4 \rightarrow CH_3OH + \dot{C}H_3 \qquad (19)$$

The addition of CH_3OH to the CH_4–H_2O_2–H_2O system leads to the unambiguous conclusion that CH_3OH is not an intermediate product of the selective oxidation of CH_4 by hydrogen peroxide.[50,51]

Under the conditions of the selective oxidation of CH_4 by hydrogen peroxide, the formation of CO and CO_2 is not observed, so that at relatively low temperatures and short contact times, the elementary stages involving their formation were not included in the proposed mechanism for the oxidation of CH_4.

In addition, the following stage was not taken into account in the oxidation scheme[15]

$$CH_4 + H\dot{O}_2 \rightarrow \dot{C}H_3 + H_2O_2 \quad \lg A = 13.3\ cm^3 mole^{-1} s^{-1}\ E = 18\ kcal\ mole^{-1}$$

since it has a low probability, because of its high activation energy. Chain termination as a result of the destruction of $^{\cdot}CH_3$:[51]

$$^{\cdot}CH_3 + wall \rightarrow CH_{3\,ads} \quad \lg A = 0.68\ s^{-1}\ E = 13.3\ kcal\ mole^{-1} \qquad (20)$$

was added to the elementary reactions (4), (5), (11), (12), (15), and (16).

The overall equation for the coupled oxidation of methane by hydrogen peroxide taking account of these stages has the following form:

$$CH_4 + 2H_2O_2 = H_2CO + 3H_2O \qquad (21)$$

These studies indicated that the most probable mechanism is one in which the chemical coupling between the decomposition of H_2O_2 and the oxidation of methane takes place through common intermediates, namely the free radicals $^{\cdot}OH$ and $HO_2^{\cdot}$.[50]

The proposed mechanism of formation of H_2CO was used to compile the following system of kinetic equations, which provide an adequate description of the experimental data (see Fig.5):[50]

$$-\frac{d[CH_4]}{dt} = k_{15}[CH_4][\dot{O}H]$$

$$\frac{d[\dot{O}H]}{dt} = 2k_4[H_2O_2][M] - k_5[H_2O_2][\dot{O}H] - k_{15}[CH_4][\dot{O}H] - k_{12}[\dot{O}H]$$

$$\frac{d[H\dot{O}_2]}{dt} = k_5[H_2O_2][\dot{O}H] - k_{16}[\dot{C}H_3][H\dot{O}_2] - k_{11}[H\dot{O}]_2$$

$$\frac{d[\dot{C}H_3]}{dt} = k_{15}[CH_4][\dot{O}H] - k_{16}[\dot{C}H_3][H\dot{O}_2] - k_{20}[\dot{C}H_3]$$

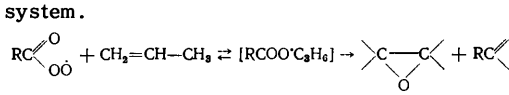
In the calculation, on the basis of Ref.52, it was assumed that the pre-exponential factor for the elementary stage (16) $\lg A_{16} = \lg A_{17}$. It was assumed that the activation energy of the recombination of the free radicals is close to zero.

Thus these studies gave the conditions for the selective coupled oxidation of methane by hydrogen peroxide to give formaldehyde, and a mechanism was proposed for the process.

3. The Coupled Oxidation of Propene by Hydrogen Peroxide

The catalytic epoxidation of alkenes by combined oxygen (ROOH, H_2O_2, peroxyacids) in the liquid phase has been discussed in a detailed review,[53] where it is possible to find detailed information on the kinetics and mechanism of the homogeneous catalysis of these processes in the presence of compounds of group V and VI elements.

Of particular interest is a single-stage method for obtaining alkene oxides by the conjugated oxidation of the alkenes with other organic compounds which are more easily oxidised, namely aldehydes, ketones, etc.[2,24] The active oxygen of peroxide radicals is used for the epoxidation of the alkene in this system.



These studies showed that it is possible in principle to carry out the epoxidation of alkenes by peroxide radicals, the simplest representative of which is the $HO_2^{\cdot}$ radical.

In recent years, from considerations of cost and availability, increasing use is being made of H_2O_2 as an oxidising agent for the selective oxidation of propene.[55] In the direct epoxidation in the liquid phase, however, hydrogen peroxide has a low reactivity, and it is therefore necessary to use various means of activating it, such as the reaction with carboxylic acids or with various inorganic anhydrides, which is accompanied by the formation of active compounds. In some studies,[56,57] the epoxidising agents used were peroxyacids formed by the reaction of H_2O_2 with formic and acetic acids. Of particular interest in this connection are the reactions involving the epoxidation of alkenes by peroxyacids at the moment of their formation from the acid anhydrides and H_2O_2. In the formation of alkene oxides by the reaction of the alkenes on the series of oxides of Ti, W, V, Ge, Mo, U, and Ru as catalysts, the most effective catalysts are tungsten oxides or tungstic acid, formed by the reaction of the oxides with H_2O_2.[58]

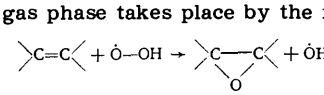
A non-trivial route to the synthesis of the important products propylene oxide, acrolein, and allene is provided by the gas-phase oxidation of propene by hydrogen peroxide by a coupled mechanism.[31,59]

Studies of the mechanism of the gas-phase and liquid-phase oxidation of hydrocarbons are giving a clear indication of the range in which a particular reaction path takes place, in relation to the specific conditions under which it is carried out.[60]

Thus depending on the conditions of the process (temperature, contact time, component ratio, H_2O_2 concentration, S/V ratio), the reaction of propene with hydrogen peroxide may lead to the epoxidation of propene, or to its oxidation to acrolein, or to coupled dehydrogenation.

In the range 500–580 °C, the main reaction is the coupled epoxidation of propene by hydrogen peroxide (Fig.6), and under the optimum conditions the average yield of propene oxide is 50 mass %.[59]

As already noted, in the gas-phase coupled oxidation by hydrogen peroxide in a flow system under stationary conditions, the $HO_2^{\cdot}$ concentration is greater than the $^{\cdot}OH$ concentration by several powers of ten. This fact, and also published data[53] on the epoxidation of alkenes by alkyl peroxide radicals, indicate that the epoxidation of alkenes by $HO_2^{\cdot}$ radicals in the gas phase takes place by the reaction:



The rate of epoxidation by alkyl peroxide radicals is determined by their structure. In the epoxidation of propene by hydrogen peroxide in the gas phase at 500–580 °C and a

contact time $\tau = 4.4$ s, the activity of $HO_2^{\cdot}$ as epoxidising species is greater than that of $RO_2^{\cdot}$.

The range 580–600 °C is an intermediate range in which the epoxidation of propene is accompanied by the simultaneous oxidation of propene to acrolein at a comparable rate. At 600–640 °C and $\tau = 1.2$ s, the main reaction product is acrolein, and its yield may reach 80 mass %.

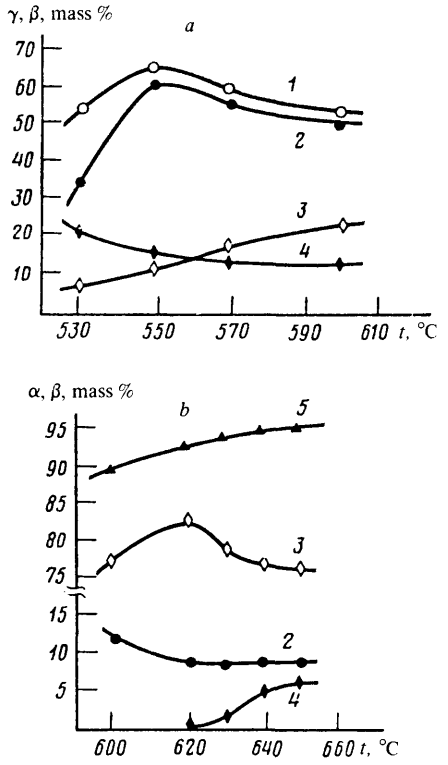


Figure 6. Temperature dependence of the selectivity (γ) (*1*), the yields (β) of propene oxide (*2*), acrolein (*3*), and side products (*4*), and the consumption of propene (α) (*5*) in its conjugated oxidation by hydrogen peroxide: *a*) 30 mass % H_2O_2, $V_{H_2O_2} = 1.3$ ml h^{-1}, $V_{C_3H_6} = 150$ cm^3 h^{-1}; *b*) 10 mass % H_2O_2, $V_{H_2O_2} = 3.78$ ml h^{-1}, $V_{C_3H_6} = 900$ cm^3 h^{-1}.[59]

Increase in temperature above 680 °C and $\tau = 0.045$ s leads to the formation of allene and methylacetylene as a result of the coupled dehydrogenation of propene (Fig. 3), and under the ultimate conditions the yields of these products are ~20% by weight and ~10% by weight respectively.[34]

Thus depending on the conditions, the coupled oxidation of propene may take place in three preferential directions:

$$CH_2{=}CH{-}CH_3 + H_2O_2 \rightarrow \left\{ \begin{array}{l} \rightarrow CH_2{-}\underset{\diagdown O \diagup}{CH}{-}CH_3 \\ \rightarrow CH_2{=}CH{-}CHO \\ \rightarrow CH_2{=}C{=}CH_2 \end{array} \right\} + \text{unwanted products}$$

In this system, as in the oxidations by hydrogen peroxide examined above, the coupling occurs according to schemes (1) and (2).[6]

It has thus been possible to determine the boundaries of the different mechanisms for the coupled oxidation of propene by hydrogen peroxide in relation to the conditions (temperature and contact time), and also to determine the intermediate ranges of the mechanisms of epoxidation and mild oxidation.

4. Coupled Oxidative Fixation by Hydrogen Peroxide

The problem of obtaining combined nitrogen from atmospheric nitrogen can now be solved by both reductive[61,62] and oxidative fixation. Several reactions for oxidising N_2 under severe conditions are known, for example the oxidation of N_2 by oxygen in an electric arc or plasma or under the influence of ionising radiation.[63] The direct oxidation of N_2 by oxygen is endothermic, and its realisation requires considerable expenditure of energy and gives low yields. It is therefore of considerable interest to develop nitrogen-fixation systems in which the principles of coupled reactions can be used.

The use of these principles in the oxidation of N_2 by hydrogen peroxide provides a new method for the fixation of nitrogen under conditions which are comparatively mild for reactions of this type.

The oxidation of nitrogen by hydrogen peroxide in a flow integral reaction vessel[64–66] makes it possible to obtain a yield of combined nitrogen of about 19% by weight.[68]

The mechanism of the oxidation of elementary nitrogen by hydrogen peroxide to N_2O includes a stage involving the reaction of N_2 with the $HO_2^{\cdot}$ radical, formed by the decomposition of H_2O_2:[69]

$$\begin{array}{l} H_2O_2 + \dot{O}H \rightarrow H\dot{O}_2 + H_2O \\ N_2 + H\dot{O}_2 \rightarrow N_2O + \dot{O}H \\ \hline N_2 + H_2O_2 = N_2O + H_2O \quad \Delta G^{\circ}_{298} = -4.5 \text{ kcal mole}^{-1} \end{array} \qquad (22)$$

Nitrous oxide was identified by mass spectrometry and gas-adsorption chromatography. The aqueous fraction of the reaction products, assumed to contain nitrogen-containing acids, was analysed by mass spectrometry and by a qualitative test with $AgNO_3$,[67] although the latter does not exclude the possible formation of unknown forms of combined nitrogen which react with $AgNO_3$ to give a precipitate.

The effective rate constant of reaction (22), determined from the experimental data,[70] is:

$$k_{22} = 10^{14.46} \exp(-45\,700/RT) \text{ litre mole}^{-1}\text{s}^{-1}$$

The second-order rate constant for H_2O_2, calculated from the overall equation

$$H_2O_2 + M \rightarrow \text{products}$$

is

$$k_{\text{eff}} = 10^{14} \exp(-46300/\text{RT}) \text{ litre mole}^{-1}\text{s}^{-1}$$

The proposed mechanism makes it possible to obtain relationships which provide an adequate description of the experimental data in the temperature range 450–600 °C at an H_2O_2 concentration in the aqueous solution of 15–30% by weight at supply rates of 1–5 litre h^{-1} nitrogen and 8–24 ml h^{-1} H_2O_2.[71]

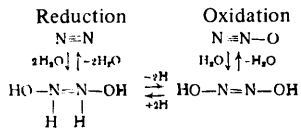
At 450 °C, the only product is nitrous oxide, the quantity of which amounts to 4% by weight, calculated on the original nitrogen. Beginning at 500 °C, the formation of combined nitrogen in the aqueous fraction of the reaction products is also observed, probably in the form of nitrogen-containing acids, the quantity of which increases to approximately 0.1% by weight with increase in the contact time.

Thus these studies have detected a new nitrogen-fixation system, which makes it possible to bind molecular nitrogen in an oxidative medium, as a result of chemical induction.

A distinguishing feature of the coupled oxidative fixation of N_2 by hydrogen peroxide is that the process takes place under relatively mild conditions compared with other similar reactions (at atmospheric pressure and at temperatures which are much lower than those usually required for the oxidation of nitrogen by oxygen).

In the biological fixation of molecular nitrogen, two different routes to its activation in the earliest stages of its fixation are possible: by reduction on the one hand and by oxidation on the other.[71] There is no proof, however, of oxidative fixation in the initial stages, although it is energetically more favourable.

According to Burris and Wilson, the following mechanism is involved in the initial stages of the biochemical fixation of N_2:[71]



In the oxidative part of this scheme, the question of the formation of nitrous oxide is not clear. Since hydrogen peroxide can induce chemical reactions, however, it has been possible to carry out the oxidative fixation of N_2 to N_2O by an energetically favourable path. All these studies make possible a new approach to the investigation of the mechanism of the biological fixation of N_2 and provide a new aspect to the nitrogen cycle.

III. CHEMICAL COUPLING IN LIQUID-PHASE OXIDATION BY HYDROGEN PEROXIDE

The catalytic decomposition of H_2O_2 in the liquid phase in the presence of iron(II) salts, discovered by Fenton,[72] is described by the following stepwise mechanism:[73]

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH^- + \dot{O}H$$
$$Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + \dot{H}O_2 + H^+$$
$$Fe^{2+} + \dot{O}H \rightarrow Fe^{3+} + OH^-$$
$$Fe^{3+} + \dot{H}O_2^- \rightarrow Fe^{2+} + H^+ + O_2^{\cdot-}$$
$$Fe^{2+} + \dot{H}O_2 \rightarrow Fe^{3+} + HO_2^-$$
$$H_2O_2 + \dot{O}H \rightarrow H_2O + \dot{H}O_2$$
$$H_2O_2 + O_2^{\cdot-} \rightarrow O_2 + OH^- + \dot{O}H$$

Salts of copper, chromium, vanadium, cobalt, and other transition metals can also be used to catlayse the decomposition of H_2O_2.

The catalytic generation of $^{\cdot}OH$ radicals, taking place as a result of the alternate oxidation and reduction of iron(II) and iron(III) ions, makes it possible to obtain free radicals at temperatures much lower than in thermal homolysis.

The free radicals formed in the reaction can react with practically any organic compound in acidic solutions.[74]

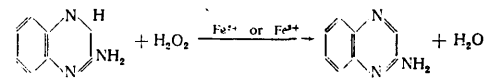
The oxidation of benzene in an aqueous solution of hydrogen peroxide in a Fenton system, which is taken as a classical example of a coupled process,[5] can be considered. The addition of an iron(II) salt to the C_6H_6–H_2O_2–H_2O system leads to the oxidation of benzene to phenol and biphenyl according to the following mechanism:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + \dot{O}H$$
$$Fe^{2+} + \dot{O}H \rightarrow Fe^{3+} + OH^-$$
$$C_6H_6 + \dot{O}H \rightarrow \dot{C}_6H_5 + H_2O$$
$$\dot{C}_6H_5 + \dot{O}H \rightarrow C_6H_5OH$$
$$\dot{C}_6H_5 + C_6H_5 \rightarrow C_6H_5 - C_6H_5$$

In this system, the phenomenon of induction is due to the fact that both reactions, that is the oxidation of C_6H_6 and Fe^{2+}, take place through common intermediate species, namely $^{\cdot}OH$ free radicals.[5]

As noted above, Fe^{2+} ions are effective catalysts for the decomposition of H_2O_2, so that the chemical conjugation in this system will not differ from that described in the previous section.[6]

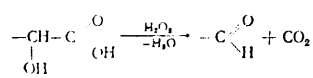
2-Amino-3,4-dihydroxyquinoxaline is comparatively readily dehydrogenated to give 2-aminoquinoxaline by H_2O_2 in the presence of traces of iron ions:[75]



The dehydrogenation takes place as a result of the reaction of the $^{\cdot}OH$ free radicals with the H(3) and H(4) hydrogen atoms of 2-amino-3,4-dihydroquinoxaline. The iron ions possibly bring about additional activation of the substrate molecule.

Free radicals also apparently play an important role in the degradation of carbohydrates by Ruff's method.[76]

The reaction of α-hydroxyacids with H_2O_2 in the presence of iron(III) salts takes place according to the overall equation:



In the successive transformation of D-glucose into D-arabinose

the stage involving the transformation of the aldonic acid into the 2-ketoaldonic acid is a dehydrogenation reaction. The role of H_2O_2 in this reaction is probably similar to that described above: the oxidising agents in this case are the highly active species formed by the decomposition of H_2O_2 in the presence of iron ions as catalyst.

The conjugated reactions of the decomposition of H_2O_2 and the oxidation of H_2CO and HCOOH in the presence of platinised graphites and Pt/(Pb with added Pb) was demonstrated in Ref.78. These studies showed that the ratio of the oxidation products is influenced significantly by the grade of graphite, the Pt deposition conditions, the reagent concentrations, and the percentage concentration of added Pb.

The detailed mechanism of the oxidation of dihydroxyfumaric and tartaric acids by hydrogen peroxide in the presence of iron and copper ions was studied in Ref.79.

In the gas phase under the conditions of conjugated oxidation by hydrogen peroxide, the $HO_2^{\cdot}$ concentration (2×10^{-9} mole cm^{-3}) is greater by many powers of ten than the $^{\cdot}OH$ concentration (7×10^{-13} mole cm^{-3}), and the ratio of the initial concentrations of $HO_2^{\cdot}$ and $^{\cdot}OH$ is about 10^4.[50]

In accordance with Eqn.(3), however, when the hydrogen peroxide is extensively diluted ($[H_2O_2] = 10^{-13}$ mole cm^{-3}), the system will contain chiefly $^{\cdot}OH$ radicals, and these will be responsible for the subsequent transformation of the substrate.

Since the reaction of the substrate with $^{\cdot}OH$ and $HO_2^{\cdot}$ radicals leads to the formation of different products, the composition of the products should depend on the degree of dilution of H_2O_2. According to Ref.80, $^{\cdot}OH$ brings about nonselective oxidation, whereas $HO_2^{\cdot}$ brings about the selective gas-phase oxidation of substrates by hydrogen peroxide. Thus in an RH–H_2O_2–H_2O system, decrease in the concentration of the reagents leads to an increase in the degree of conversion and a decrease in the selectivity of the reaction, whereas a decrease in the concentration of the reagents

usually leads to an increase in the selectivity and a decrease in the yield of the reaction products. This situation is observed not only in the case of extremely low concentrations of H_2O_2 in the aqueous solution, but also in a liquid-phase (Fenton) system, in which the principal active centre is $^{\cdot}OH$.

Thus in a Fenton system it is impossible in principle to achieve highly selective oxidation of the substrate.

IV. THE ABILITY OF HYDROGEN PEROXIDE TO INDUCE OXIDATION, AND POSSIBLE NEW APPLICATIONS

The mechanism of chemical coupling in oxidation by hydrogen peroxide can be formulated as follows: the ability of hydrogen peroxide to induce chemical reactions is due to its decomposition to give active centres which take part in another reaction which does not take place spontaneously (for example nitrogen fixation, dehydrogenation, etc.).

An interesting question is whether more complex peroxy-compounds such as organic hydroperoxides and peroxides can induce chemical reactions.

The mechanism of the chain decomposition of the initiator most widely used in chemistry, namely di-t-butyl peroxide,[81] can be examined in this connection:

$$(CH_3)_3COH + \dot{C}H_2C(CH_3)_2\dot{O} \rightarrow CH_2\!\!<\!\!\overset{O}{}\!\!>\!\!C(CH_3)_2$$

$$(CH_3)_3COOC(CH_3)_3 \rightarrow 2(CH_3)_3CO^{\cdot} \rightarrow 2(CH_3)_2CO + 2\dot{C}H_3 \rightarrow C_2H_6$$

$$\downarrow RH \qquad\qquad \downarrow RH$$

$$(CH_3)_3COH + \dot{R} \qquad CH_4 + R^{\cdot}$$

Di-t-butyl peroxide decomposes in the gas phase at 300 °C or in solution at pH ≥ 7 in different directions by a complex chain mechanism to give different reactions products: $(CH_3)_2COH$, $CH_2\!\!<\!\!\overset{O}{}\!\!>\!\!C(CH_3)_2$, CH_4, C_2H_6, and $(CH_3)_2CO$. The variety of chain decomposition paths is related to the formation of several active intermediate compounds, $(CH_3)_3CO^{\cdot}$, $^{\cdot}CH_2C(CH_3)_2O^{\cdot}$, $^{\cdot}CH_3$, and $R^{\cdot}$, whose transformation in the presence of the substrate (RH) gives a large number of side products.

Thus if attempts are made to use organic peroxides as components in conjugated reactions of mild oxidation, the above considerations related to the large number of active centres present a serious obstacle. In this system, the decomposition of the organic peroxide is accompanied by the chain oxidation of the substrate by different active centres to give the corresponding reaction products. Thus the absence of selectivity and the large number of chain reactions which can be initiated by organic peroxides create serious difficulties in the use of these hydroperoxides to induce reactions which do not take place spontaneously.

The ability of hydrogen peroxide to induce oxidative transformations of chemical substances as a result of chemical coupling not only extends the ways in which it can be used in new non-traditional directions but also leads to a deeper understanding of the mechanism of the action of H_2O_2 in many systems.

It can be confidently state that extension of the ranges of application of chemical coupling in general and in oxidation reactions in particular will stimulate progress in this field.

This will lead finally to the development of fundamentally new chemical-technological oxidation processes, corresponding to present-day requirements, that is the economic utilisation of energy resources and raw materials and an increase in the unit power of chemical reactors, without leading to environmental pollution. The low cost of H_2O_2 production by existing technology (chiefly by the anthraquinone method) provides a basis for increasing the use of H_2O_2 in modern industry. Thus the development of processes of oxidation by hydrogen peroxide corresponds to present-day requirements.

These studies raise another extremely important question for chemical technology, related to the unification of chemical production. It is surprising that unification, a powerful means of scientific and technical progress which has transformed many branches of industry, has hardly been introduced in chemical technology. This situation has probably arisen because almost every chemical reaction introduced has its own specific characteristics, which make it impossible to unify both chemical processes as a whole and individual technological units. To these characteristics can be added the use in industrial processes of specific catalysts with different compositions and structural properties, the formation of side products whose utilisation represents an independent problem, the purification of the desired product from side products, and the use of increased pressures and different phase states of the components of the reaction system.

The solution of the problem of the unification of chemical production will be found not in the development of separate chemical-technological processes differing considerably in their technological and chemical aspects, but in the development of chemical systems in which chemical reactions of the same type, having many common characteristics, can be realised.

Coupled reactions involving the oxidation of different substrates by hydrogen peroxide can justifiably be included among such chemical systems.

Advances in the Development of Methods for the Epoxidation of Olefins

V.G.Dryuk

Data obtained in recent years on the epoxidising agents and the mechanism of their interaction with olefins are surveyed. Different types of hydroperoxides as well as certain short-lived epoxidising intermediates of the molecular and radical types functioning *in situ* are examined.
The results of the stereospecific epoxidation of aliphatic and alicyclic compounds using the directing influence of functional groups (OH, COOH, R, SiR_3, etc.) are presented.
The bibliography includes 225 references.

I. INTRODUCTION

In terms of the character of the behaviour of the reagent and the substrate, the epoxidation of olefins has much in common with a whole series of reactions regarded as models of biological monoxygenation[1]—the oxidation of amines, phosphines, sulphides, Schiff bases, azo-compounds,[2-4] arenes,[5] alkanes,[6] etc. For this reason, new information about the synthesis and mechanism of action of any of the epoxidising agents acquires general theoretical importance for the development of ideas about liquid-phase oxidation as a method of organic chemistry and for the understanding of many biological processes.

The chemistry of oxiran has developed in two directions. One of these involves the industrial manufacture of the practically most important epoxy-compounds: the oxides of ethylene, propene, but-1-ene, butadiene, styrene, epichlorohydrin, and a wide assortment of aliphatic cyclic mono- and di-epoxy-compounds produced on a small scale.[2-7] The second direction is associated with the important role of oxirans in the living processes of the plant and animal world. Properties of epoxidised terpenoids, carotenoids, and steroids,[2] the juvenile hormonal activities of many natural and synthetic epoxy-compounds,[8-10] and the toxic and carcinolytic properties of epoxide-containing intermediates, formed in the oxidation of aromatic hydrocarbons,[11] have been widely investigated.

The physiological activity of many natural compounds containing epoxide oxygen has led to the problem of the development of the synthesis of their analogues and of a wide set of methods for stereospecific and regiospecific epoxidation. Considerable advances have been achieved in this field,[12] using on a wide scale the directing influence of neighbouring functional groups (OH, COOH, SiR, etc.). In its turn, the discovery of the stereochemical consequences of epoxidation has become a powerful means for the elucidation of the mechanism of the oxidation of various objects.

The aim of the present reivew was to give a systematic account of epoxidising agents and to elucidate the common features and differences in the mechanisms of their formation and action on olefins†.

The central place in the review is occupied by the expoxidation of olefins by peracids, which is the reaction most fully investigated in close association with solvation and association phenomena. The importance of data obtained in this connection is determined by the fact that many reactions involving hydroperoxides proceed, like the Prilezhaeva reaction, in a complex system of donor–acceptor interactions and combine both heterolytic and homolytic processes.

II. ORGANIC PERACIDS

Since the publication in 1974 of Prilezhaeva's fundamental monograph,[2] considerable progress has been achieved in the development of the methods of epoxidation by peracids. The methods for the synthesis of anhydrous peracids, in the first place the lower (C_1–C_4) peracids, based on the acylation of hydrogen peroxide by carboxylic acids or anhydrides in the presence of acid catalysts, have attracted constant interest.[13-16] Aqueous peracetic acid has acquired industrial importance.[17] Polymeric peracids have been synthesised by the interaction of carboxylated polystyrene with hydrogen peroxide in methanesulphonic acid.[18]

Crystalline perbenzoic acid is obtained by an improved method from benzoyl chloride[19] and by the alkaline hydrolysis of benzoyl peroxide.[20] Many olefins have been epoxidised by perbenzoic acid and its ring-substituted analogues at the instant of formation from the corresponding acid chloride and potassium peroxide in the presence of an interphase transfer catalyst.[21,22]

†A systematic consideration of the mechanism of the epoxidation of olefins by oxygen is outside the framework of this review.

m-Chloroperbenzoic acid is widely used for the synthesis of oxirans, which are sensitive to acids, in the presence of buffers (aqueous solutions of Na_2CO_3, $NaHCO_3$, Na_2HPO_4).[23-27]

There has been a continuation of studies on the synthesis of peracids by the oxidation with atmospheric oxygen of aldehydes: acetaldehyde, propionaldehyde, butyraldehyde, isobutyraldehyde,[28-30] *p*-toluic aldehyde,[31] pentafluorobenzaldehyde,[32] *p*-methoxycarbonylbenzaldehyde.[33]

Monopermaleic,[34-38] mono-, di-, and tri-chloroperacetic,[34-41] and 2,4-dinitroperbenzoic acids[42] have been used successfully for the epoxidation of electron-deficient olefins. The catalytic influence of organic nitrogen-containing bases (amines, pyridine, urea, guanidine, etc.) and inorganic bases on the reaction of acid anhydrides with peroxides has been demonstrated.[37,43-46] The method used in the employment of perphthalic acid has been improved.[47-49] Perphthalic acid *in situ* and in the crystalline form[47,50-52] as well as *p*-methoxycarbonylperbenzoic acid[33] are oxidants which are promising in practice. The epoxidising capacity of many peracids can be deduced from the relative rates of epoxidation of allyl bromide by peracetic, performic, monochloroperacetic, perbenzoic, monoperphthalic, and monopermaleic acids at 40 °C in acetic acid, which are respectively 1.0, 1.54, 1.70, 1.84, 8.7, and 15.1.[48]

The rate constants for the epoxidation of 1,4-dibromo-2-methylbut-2-ene with monochloroperacetic (at 10 °C) and dichloro-, trichloro-, and trifluoro-peracetic (at 2 °C) acids are in the ratios 1 : 13 : 1000 : 2700, although the differences between the overall efficiencies of these acids are not so significant. Furthermore, trichloroperacetic acid is more effective than its fluorine-containing analogue, since the enhancement of the electron-accepting influence of the substituents entails a decrease of the equilibrium concentration of peracid in the reaction of acid anhydrides with hydrogen peroxide, while the losses of active oxygen owing to decomposition increase.[45]

The most important application of peracids is epoxidation of electron-deficient olefins, which requires concentrated solutions of peracids, in many cases with added buffering bases. A series of studies have therefore been carried out on the mechanism of the interaction of peracids with olefins over a wide range of reactant concentrations and acid–base properties of the medium.[48,53-56] It was found that in multicomponent solutions with strong complex formation via hydrogen bonding the interaction of an olefin with a peracid proceeds as a complex process, the kinetics and direction of which depend to a high extent on the proton-donating and proton-accepting properties of the medium. Many of the experimental facts established under these conditions cannot be accounted for by the mechanism adopted, which presupposes the involvement in the reaction only of the unsolvated peracid molecule with an intramolecular hydrogen bond.[2]

It is striking that the epoxidation of the olefin proper competes as a rule with the spontaneous or olefin-induced decomposition of peracids. On the other hand, when the conditions are altered, the olefin can suppress the spontaneous decomposition of the peracid.[53-56] It has been shown by kinetic methods that the intermediate olefin–peracid complex disproportionates in many cases into isomerisation or epoxide ring-opening products, bypassing the oxiran formation stage.[57] The influence of solvation of the final result of the reaction has been demonstrated in relation to the epoxidation of diallyl maleate by permaleic acid in solvents of similar basicity: diethyl ether and tetrahydrofuran (THF).[58] Many oxirans are formed in the former case, while the epoxide ring opening products are formed in THF.

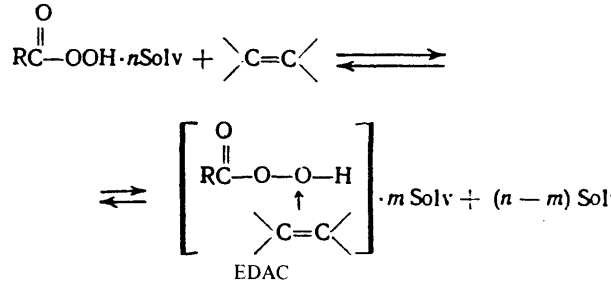
Experiments[54,66] on the epoxidation of olefins by peracids under the conditions of a gradual increase of the initial concentration of the base (dimethylformamide (DMF) in solution, which is known[59] to entail a change in the structure of the associated peracid species, are extremely instructive. Initially an increase of the DMF concentration reduces k_{epox}, as was to be expected,[2] and subsequently, in a rigorously defined range of its concentrations, the homolytic olefin-induced decomposition of acids is observed. Finally, the region of the induced decomposition is rapidly replaced by the region of the inhibition of the spontaneous decomposition of RCO_3H. The epoxidation constant k then increases significantly, although the degree of association of the peracid with the base increases.

The induction and inhibition of the decomposition of peracids by olefins depend specifically and to a large extent on the conditions governing solvation and association with the bases.[56] Purified peracids (95–99%) also decompose extremely vigorously under the influence of an olefin and, with increase of the concentration, the contribution of the decomposition process increases.

The epoxidation reaction and the accompanying reactions of peracids undergo autocatalysis or inhibition[55,56] up to the complete cessation of the reaction in the presence of still considerable concentrations of the reactants in solution.[60] The second order of the reaction is observed only at high acid concentrations, for example, when peracids synthesised from acid anhydrides are used. Under these conditions, the acid and oxiran (a base) formed in the reaction do not alter significantly the acid–base properties of the medium.

The so-called dilution effect is characteristic of the Prilezhaev reaction and the competing processes:[55,56,60,61] with decrease of the concentration of the reactants and following the dissociation of intermolecular hydrogen bonds, the specific rate (k) diminishes and the activation parameters (E_{act}, $\Delta S^{\neq}$) vary within wide limits. In many cases a kind of "organic" version of the salt effect is observed: an artificial increase of the concentration of associated species of the type of $RCO_2^-.BH$ increases the rate of the process,[56,60,62] which indicates an appreciable charge separation in the activated complexes.

It follows from the above that the olefin attacks the peracid incorporated in a system of intermolecular bonds. The donor–acceptor ("soft") interaction of the reactants competes with the "hard" complex formation reaction of the peracid via hydrogen bonding and, as a result of the substitution of the ligands, the solvent, or the base (Solv) in the solvation shell, the olefin produces a new association complex, a π-complex or an electron donor–acceptor complex (EDAC):



EDAC

The EDAC concentration is comparable to those of the reactant and, when present in a sufficient excess, the olefin is capable of fully solvating the peracid by accelerating the epoxidation process so that it is several times faster.[56,63-65]

The EDAC formation stage is responsible for the autocatalysis and inhibition of the epoxidation reaction. The autocatalysis is caused by the fact that the acid formed in the

reaction promotes the desolvation of the peracid, as a result of which the equilibrium in the formation of EDAC is constantly shifted to the right, controlling the rate of reaction as a whole. The autocatalysis may be manifested also as a consequence of the rapid increase of the molar ratio [olefin]/[RCO_3H] during the reaction.[56] The inhibition of the epoxidation can occur in its turn when the peracid is involved in complex formation with the oxiran as a base via hydrogen bonding (in the presence of highly pure, 95–99%, peracids) or with associated species with the type $RCO_2^-.\overset{+}{B}H$.[60] An increase of the excess of the olefin relative to RCO_3H and an increase of temperature weaken the inhibiting effect of the bases and their associated species.

Thus the rate and direction of the Prilezhaev reaction are determined by the nature of the peracid associated species. Many spectroscopic studies[61,66–69] and quantum-chemical calculations[2,69–72] have been devoted to the establishment of their structure. It is known that in inert solvents at low temperatures peracids form monomers with a weak intramolecular hydrogen bond, while in concentrated solutions they produced dimers.[2,66,67] The barrier to rotation about the O–O bond is insignificant (1.00–4.00 kcal mol^{-1}).[68–70] The available information about the geometry of the monomers is not unambiguous. According to the results of certain quantum-chemical calculations,[2,70] the peracid molecule is planar. However, it has been established that the *p* electron of the neighbouring nitrogen and oxygen atoms in the molecules of hydrazine, hydrogen peroxide, and many peroxy-compounds[68,73] tend to leave the energetically unfavourable eclipsed position (the *gauche*-effect).

The displacement of the *p* electrons of the external peroxide oxygen atom from the conjugation plane of the *p* and π electrons of the R–C(=O)–O– unit in the peracid molecule is reflected in the fact that, in terms of its proton activity, it is greatly inferior (by 3.5 orders of magnitude) to the related normal acid.[2,68] These ideas agree with the calculation of dipole moments of RCO_3H by Swern and co-workers[74] (the dihedral angle θ between the COO and OOH planes is 72°) and also with quantum-chemical calculations[70,71] (θ = 40–60°). It has been noted that the *s-trans*-conformation is just as characteristic of peractic acid as the *s-cis*-conformation.[72] The *s-trans*-structure has been attributed to *o*-nitroperbenzoic and perpelargoric acids (θ = 146°) on the basis of X-ray diffraction analysis.[70]

Calculation has shown[69] that the $RCO_3H.RCO_2H$ associated species is much more stable than the dimer $RCO_3H.RCO_3H$ and that not only the carbonyl[71] but also the peroxide oxygen atom, linked to the >C=O group, can function as the proton acceptor in the formation of the latter dimer.

Experimental and calculated data make it possible to infer that the peracid molecule can exist in both *syn*-chelated and transoid forms. It must be assumed that in solutions the conformation of RCO_3H is influenced significantly by the nucleophilic effects of the solvent, the reagent, and other components on the acid proton and the peroxide oxygen atom.

The infrared spectra of dilute solutions of peracids show that in basic solvents (dioxan, THF, etc.) the free RCO_3H monomer is virtually absent—the ν(OH) band undergoes a 70–90 cm^{-1} bathochromic shift.[67–69] The ^1H NMR spectra of solutions of *m*-chloroperbenzoic (85%) and perlauric (99.5%) acids in the concentration range 0.2–2 M also lead to the conclusion that in a basic medium the peracid is wholly solvated, although the degree of proton transfer to the solvent varies within a wide range.[61,69] At a sufficiently high concentration, ensuring the emergence of the peracid molecule from the solvent cage, the signal of the protons becomes narrow and intense, which indicates their equivalence, attained as a consequence of the rapid exchange in the chain of hydrogen bonds. Acid admixtures appreciably accelerate the formation of associated chain species.

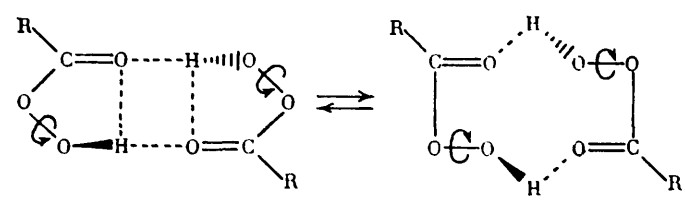
Spectroscopic data and the general theoretical ideas about the acid–base interactions in organic media[60] permit the conclusion that the state of the solutions of peracids, containing admixtures of acids and bases, is characterised by a multiplicity of different types of associated species, differing in the degree of proton transfer to the base (B) or the conjugate base (A), although, within certain concentration ranges and for certain ratios of the acid and basic components, specific dominant forms of the associated species are produced.

Using the "from the structure of the peracid to the mechanism" principle[2] as a guide, the probable mechanisms of the interactions of olefins with peracids can be represented as follows.

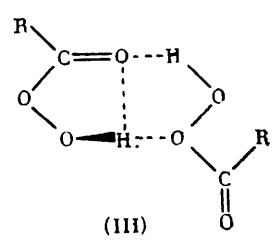
In inert solvents, at low concentrations of the peracid, which exists mainly in the monomeric form, the Bartlett–Lynch mechanism probably operates.[2] However, the character of the proton transfer remains obscure. Thus dilution of the solution with pure (99%) peracid, which leads to the dissociation of the intermolecular hydrogen bonds, reduces the k_{eff} for the epoxidation reaction, although it was to be expected that an increase of the fraction of the monomer would have the opposite influence. The rate constants for the epoxidation of hex-1-ene in benzene (1 M, 30 °C) at perlauric acid concentrations of 1.5 and 0.5 M are 1.15×10^{-4} and 0.84×10^{-4} litre mol^{-1} s^{-1} respectively. Thus, even a weak intermolecular interaction between the peracid monomers and dimers exerts an appreciable electrophilic cooperative effect on the elimination of the acid anion.

The preferred migration of the proton in the "olefin–peracid" transition state to the "internal" peroxide and not the carbonyl oxygen atom has been demonstrated by calculation.[75]

Peracid dimers appear in solution with increase of concentration. The combination of cisoid and transoid conformers leads to the following possible structures:

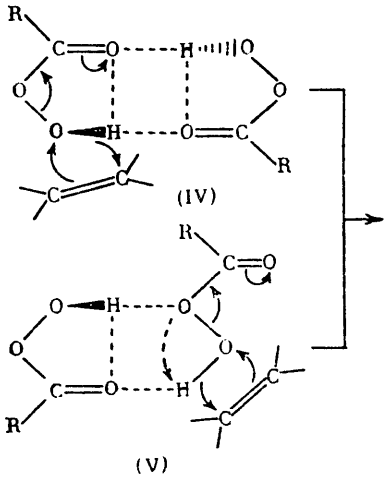


(I) (II)



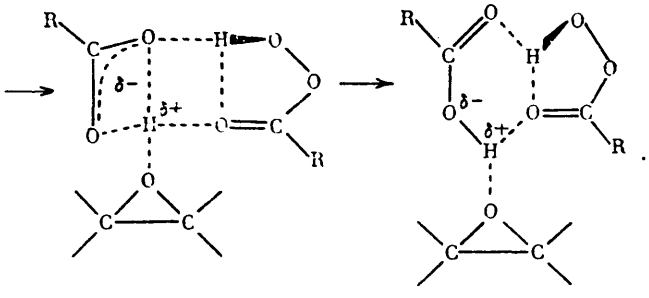
(III)

The formation of dimers promotes the epoxidation reaction—k_{eff} increases:



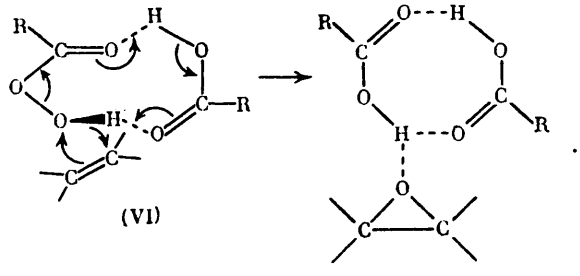
(IV)

(V)



The dimeric form II is less favourable in the epoxidation reaction, since the approach of the olefin to the external peroxide oxygen is blocked by the second peracid molecule.

In the presence of acids, associated species of the type $RCO_3H.RCO_2H$ are formed together with the dimers RCO_2H. $.RCO_2H$, which appreciably accelerates the epoxidation reaction:

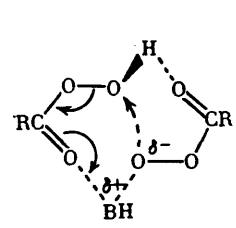


(VI)

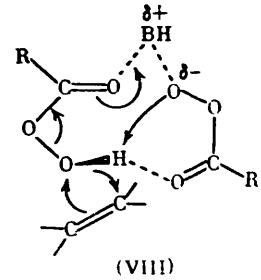
It can be seen, that in conformity with the minimum displacement principle,[76] only intermolecular proton transfer leads to the optimum structure of the acid dimer.

Small amounts of added base are inserted in the acid associated species without causing their complete decomposition#.[59] The base binds to the proton in the dimer (I) and promotes the transformation of the *s-cis*-conformers into the *s-trans*-conformers (VII) and permits the donor–acceptor interaction of the peroxide atoms and in the limiting case the decomposition of the peracid.[61]

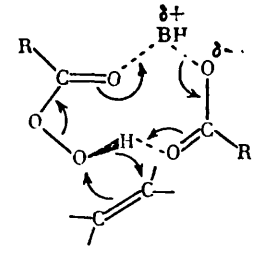
#The associated species $RCO_2^-Na^+.RCOOH$ is known to be very stable.[77]



(VII)



(VIII)

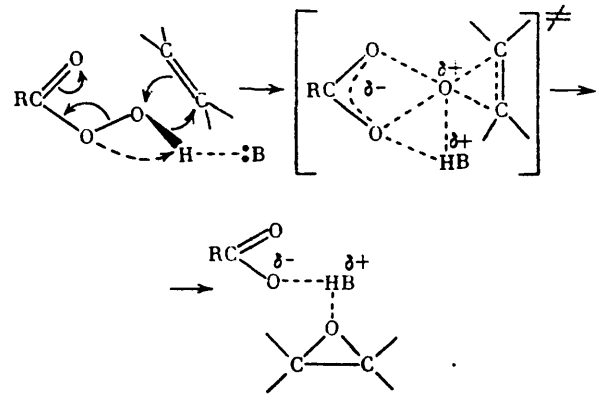


(IX)

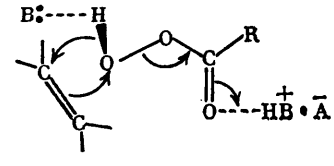
On the other hand, in the presence of an olefin, the epoxidation reaction behaves as the competing pathway (VIII). The epoxidation mechanism (IX) develops similarly when the base is incorporated in the associated species $RCO_3H.RCO_2H$.

The intramolecular migration of the proton in (VIII) and (IX) is less favourable than the intermolecular migration. In the intramolecular transfer in (VIII) the base would have been found to the weaker acid (RCO_3H) while in (IX) an anomalous acid dimer would have been formed.

At high concentrations of the base or after dilution with a basic solvent, the chelate complexes of the peracid decompose.[59] The peracid molecule linked to the base apparently exists, like peresters and acyl peroxides,[68,72] in the form of *s-trans*-conformers and proton transfer takes place in a solvent cage with participation of the conjugate base of the acid:



In the presence of large amounts of acids and bases, the relay proton transfer is most probable:



In the chelate complexes (VI), (VIII), and (IX) the non-coplanar attack on the olefin can induce the radical decomposition of the peracid with formation of carbon dioxide and an alcohol.

The data obtained in quantum-chemical and stereochemical studies of the π-complex and the "olefin–peracid" transition state[75] are fully consistent with the ideas described above, which were developed at a qualitative level. However, it has been stipulated that the attack by the peracid is directed to the carbon of the olefin double bond and not to the π-electron cloud.[78,79]

The study of the kinetics of the epoxidation of deuteriated styrene derivatives[79] established that the replacement of H by D in the α-position hardly influences the rate of reaction ($k_H/k_D = 0.99$), while deuteriation of the β-carbon atom leads to an appreciable isotope effect ($k_H/k_D = 0.82$). Since the secondary isotope effect is caused in the given instance by a change in the hybridisation of the carbon atom in the olefin double bond ($sp^2 \rightarrow sp^3$), the authors assume that only the formation of the C_β–O bond is manifested in the transition state. However, according to the proposed mechanism, the peracid functions as a nucleophile, which is consistent with the fairly well established fact that the peracid is electrophilic and the olefin nucleophilic.[2] One cannot rule out the possibility that the absence of an isotope effect in the deuteriation of the C_α atom is caused by the shielding influence of the bulky phenyl group.

For the interpretation of the structure of the "olefin–peracid" transition state (TS), it is useful to employ the idea that the elements of π- and σ-complex formation are combined in the structure of the protonated epoxide ring.[80,81] The reaction constant for the epoxidation of a number of olefins by a strong peracid, for example, monopermaleic acid,[56] is small in absolute magnitude ($\rho^* = -0.56$). According to the Bell–Evans–Polanyi principle, the nature of the transition state is in this case closer to that of the starting materials and the π-component predominates in its structure. The epoxidation by a weak peracid (peracetic acid)[56] is characterised by a high constant $\rho^* = -1.39$, the transition state resembles the final products, and the contribution of σ-complex formation increases. In terms of the molecular orbital (MO) method, the ring formation process is represented as a combination of the donor–acceptor overlapping of the bonding π_b orbital of the olefin with the σ^*_{O-O} orbital of the peracid and the dative interaction of the non-bonding orbital of the peroxide oxygen with the antibonding π^*_{antib} orbital of the olefin. The fact that the substituted propenes $CH_2{=}CH{-}CH_2{-}X$ (X = halogen or OR) are epoxidised with greater difficulty than the related 1,4-disubstituted but-2-enes, contrary to the hypothesis that the influence of the substituents is additive, can be accounted for from this standpoint.[82] The synchronous occurrence of the two types of orbital overlapping on formation of the oxiran ring apparently imposes definite requirements on the symmetry of the activated complex, as a result of which the asymmetrically substituted olefins are in a less favourable position.

In the alkaline epoxidation of polar multiple bonds, the sign of ρ^* changes[83] and the dative interaction becomes of decisive importance in the cyclisation stage.

Certain new stereochemical features of the reactions of olefins with peracids have been established, indicating that the rate of reaction and its direction are determined not only by electronic factors but also by the relaxation properties of the reactant molecules incorporated in the associated structure of the solution.

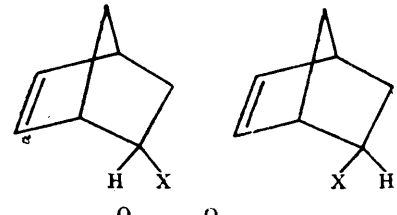
Previously it was believed[2,84] that the rate of reaction of the aliphatic compounds is independent of the steric influence of the substituents (especially alkyl substituents) at the reaction centre. However, it was found[85] that an alternative effect is characteristic of aliphatic reactants, namely the dependence of k_{eff} on the number of carbon atoms in the olefin (C_6–C_9) and the peracid (C_1–C_{12}) is represented by broken lines. Consequently, the alternating changes in the conformation of the R residue and of the molecule as a whole as the carbon chain grows can exert an unfavourable influence on the stage in which the reactants approach one another and are coordinated.

It is of interest to note that in a basic solvent (ethyl acetate) the long-chain RCO_3H proved to be unexpectedly more effective oxidants than the lower peracids (R = H or CH_3). This finding can be explained by the hydrophobic character of the massive alkyl component, which hinders the solvation of the peracid molecule. On the other hand, in an inert solvent (benzene), which does not solvate peracids, the strength of the latter is determined by the electronic factor: with increase of the bulk of R, the epoxidising capacity of RCO_3H diminishes.

Steric hindrance due to the increase in the size of the reactant molecules is observed also in other reaction series. Thus the loss of active oxygen in the epoxidation of allyl bromide by peracids in the series peracetic–perpropionic–perbutyric–perlauric increases owing to their induced decomposition[48] and the rate of epoxidation of the first olefin double bond in the diallyl esters of dicarboxylic acids $ROOC(CH_2)_nCOOR$ [58] increases only with increase of n from zero to two; subsequently k_{epox} diminishes.

The solvation of functional groups remote from the reaction centre has a significant influence on the rate of epoxidation.[58,82,86] Such solvation probably causes, by the increase of size, some loss of degrees of freedom by the reactant molecules and diminishes the probability of their effective collisions. In particular, it has been established that the rate of epoxidation (k_2) of the monoepoxides of the diallyl esters of dicarbocylic acids is much lower than the rate of formation (k_1) of the first epoxide ring ($k_1/k_2 = 4$).[58] When $n \geq 2$, this fact cannot be accounted for by the electron-accepting influence of the epoxide ring.

The decrease of the rate of epoxidation of the remote olefin double bond in sorbic acid esters[82] is caused by the increase in the size of the alcohol residue in the ester group. The character of the influence of the functional groups on the rate of epoxidation of the *exo*- and *endo*-isomers of substituted norbornanes is also determined by the solvation conditions:[86]



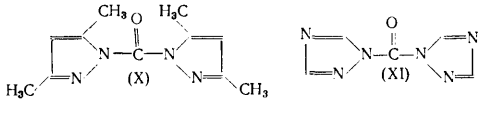
In the *exo*-position the substituents which tend to become involved in complex formation via hydrogen bonding (CO_2H, $CONH_2$) are "available" for the formation of intermolecular hydrogen bonds, while in the *endo*-position they are shielded by the carbon skeleton of the molecule. For this reason, the catalytic effect of the COOH group and the inhibiting influence of the basic $CONH_2$ group are manifested much more strongly in the *exo*-position. Certain nucleophilic groups ($CONH_2$, OH) in a series of *endo*-derivatives of norbornene exhibit an anchimeric cooperative effect on the epoxidation reaction.

III. HETEROANALOGUES OF PERACIDS

Derivatives of carbonic acid $X-\overset{\overset{O}{\|}}{C}-OOH$, where X represents nitrogen- or oxygen-containing functional groups, and the compounds $X-\overset{\overset{NR(H)}{\|}}{C}-OOH$ containing the azomethine group instead of the carbonyl group are close to organic peracids as regards their effectiveness. A characteristic feature of their chemical behaviour is an increased tendency towards decomposition[87,88] caused in the first place by the catalytic influence of the basic nitrogen-containing functional groups and rings[56,61] and in the second place the tendency towards decarboxylation of the monofunctional derivatives of carbonic acid, formed in the stage involving the transfer of active oxygen to the substrate. The decomposition of the heteroanalogues of peracids[87] leads to the formation of singlet oxygen, which is significant evidence for the heterolytic reaction mechanism and is consistent with the ideas developed by the present author.[56,61] The ability of the olefin to inhibit the decomposition reaction has also been noted.

Compounds of the above series are synthesised from hydrogen peroxide and the reaction concerned involves either nucleophilic substitution at the carbon atom of the carbonyl group or the nucleophilic addition to the azomethine or nitrile group.

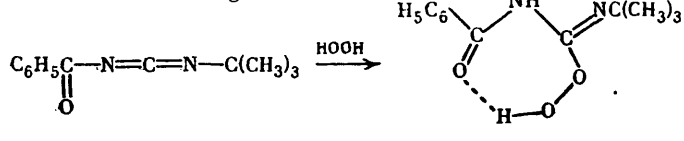
It has been noted that, in contrast to SeO_2, dialkyl carbonates and CO_2 do not form peracids in their reactions with H_2O_2, whereas peroxycarbamic acids, capable of epoxidising reactive alkenes of the type of cyclohexene, are formed from derivatives of dimethylpyrazole (X) and 1,2,4-triazole (XI):[87,88]



Among the hydroperoxy-derivatives of carbonic acid, mention should be made of *N*-benzoylperoxycarbamic acid ($C_6H_5-\overset{\overset{O}{\|}}{C}-NH\overset{\overset{O}{\|}}{C}-OOH$) and *O*-benzylperoxycarbonic,[89] and *O*-ethylperoxycarbonic acids[90,91] ($ROC(=O)OOH$), obtained by treating hydrogen peroxide with benzoyl isocyanate ($C_6H_5\overset{\overset{O}{\|}}{C}-N=C=O$) in the first case and by compounds of the type $R-O-\overset{\overset{X}{|}}{\underset{\underset{O}{\|}}{C}}-X$, where R = $C_6H_5CH_2$ or C_2H_5 and X = Cl or $OCOCH_2C_6H_5$, in the last two cases.

The rates of epoxidation of *trans*-stilbene at 25 °C in benzene by *O*-benzylperoxycarbonic, perbenzoic, and *m*-chloroperbenzoic acids are in the ratios 7.12 : 4.27 : 15.0, while *N*-benzoylperoxycarbamic acid is 200 times more effective than perbenzoic acid, which is undoubtedly assisted by the possibility of the elimination of carbon dioxide from the "olefin–peracid" complex.

Carbodiimide is less reactive in the reaction with hydrogen peroxide than isocyanates and gives rise to peracid heteroanalogues only in the presence of electron-accepting substituents at the nitrogen atom:[87]



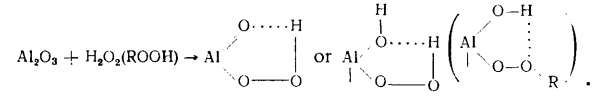
A similar peroxy-group is produced by cyanates ($RO-C\equiv N$),[87] benzonitrile,[92] and cyanamide ($H_2N-C\equiv N$),[93] which react with hydrogen peroxide via Paine's mechanism.[2] A method for the epoxidation of styrene by a mixture of acetonitrile and hydrogen peroxide in an alkaline medium with added Na_2HPO_4 has been proposed.[94]

A most powerful oxidant with the tentative structure $[(CH_3)_2\overset{+}{N}=CH-OOH]P\bar{O}_2Cl_2$, which epoxidises cyclenes at −80 °C, is formed in the H_2O_2–Vilsmeier reagent system.[95]

IV. INORGANIC PERACIDS

Inorganic peracids are employed as a rule at the instant of formation on treatment of the anhydrides (oxides), chlorides, and salts of acids with hydrogen or alkali metal peroxides. The possibility of their application is limited by the high acidity of the medium, which promotes the opening of the epoxide ring, and by the tendency towards decomposition, which increases in parallel with increasing strength of the peracids. A decrease of the pH of the medium is attained when acid salts are used. Naturally, the oxidising power of the hydroperoxide intermediate is then also lowered.

Vanadium, molybdenum, tungsten, selenium,[96–105] boron,[106] arsenic,[107] and aluminium[108] oxides have been used for epoxidation. They give rise to an epoxidising agent, for example:



The fact that the peracid and not hydrogen peroxide is involved in the epoxidation reaction has been confirmed by the kinetics of the oxidation of allyl bromide,[97] allyl alcohol,[98] and maleic and fumaric acids and their salts[99–103] by hydroperoxide derivatives of orthovanadic, tungstic, and molybdic acids. The above unsaturated acids are not oxidised by organic peracids.

Many derivatives of stilbene, chalcone, and acenaphthylene have been epoxidised by alkane- and arene-persulphonic acids,[21] obtained by the interaction of the corresponding chlorides ($C_6H_5SO_2Cl$, Cl_3CSO_2Cl, $CH_3C_6H_4SO_2Cl$, etc.) with potassium peroxide in the presence of a crown-ether as the phase-transfer catalyst. The broad spectrum of the activity of these reagents is probably due to the fact that they can function both in the undissociated state (RSO_2-OOH), executing an electrophilic attack on the multiple bond of, for example, stilbene, and in the form of the corresponding peroxide-anion (RSO_2-OO^-), which is capable of attacking the polar olefin double bond of the chalcone, like the hydroperoxide anion (HOO^-).

Peroxymonophosphoric acid epoxidises *trans*-stilbene but does not permit the isolation of cyclohexene, styrene, and α-methylstyrene oxides[109] because of the high acidity of the medium. It has been noted that the rates of epoxidation of *trans*-stilbene by H_3PO_5 and CH_3CO_3H are comparable, while the Baeyer–Villiger reaction is 100 times faster when perphosphoric acid is used. These differences are due to the fact that the rate-limiting stage in the oxidation of a ketone, namely the rearrangement of an acylhydroxyalkyl peroxide, is sensitive to acid catalysis, which is undoubtedly more effective in perphosphoric acid.

Benzeneperoxyseleninic acid has found application in the synthesis of epoxides.[96,110,111] Mixtures of areneseleninic acid ($X=C_6H_4Se(=O)OH$, where X = NO_2, Cl, COOH, etc.) and

30–90% hydrogen peroxide epoxidise alkenes in the presence of phosphate buffer. The acid is used in catalytic amounts (0.5–5%).

It has been shown in relation to allyl alcohols and diolefins that a perseleninic acid is less stereoselective and regioselective than carboxylic peracids and alkyl hydroperoxides, which indicates its highly electrophilic nature.

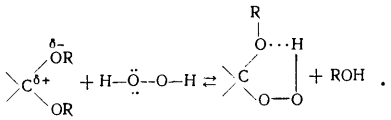
Presumably the replacement of the OH group by OOH in the acid reagent takes place also in the epoxidation of tetracyanoethylene with hydrogen peroxide containing added $HClO_4$.[112]

Triphenylsilyl hydroperoxide (Ph_3SiOOH) behaves like peracids in relation to olefins, ketones, and allyl alcohols,[109] although its structure is similar to that of alkyl hydroperoxides. The comparatively high epoxidising capacity of Ph_3SiO_2H is due to the dative interaction of the lone electron pairs of the neighbouring atoms (O, N, and halogen) and the unoccupied *d* orbitals of silicon, which is typical for silicon compounds.

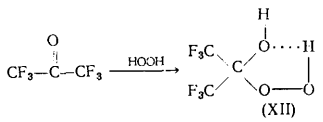
V. EPOXIDATION BY HYDROPEROXIDES ACTIVATED BY ELECTRON-ACCEPTING SUBSTITUENTS

The replacement of carbonyl oxygen in the peracid molecule by another, stronger electron acceptor (OH, OP, NP_2) leads to a series of hydroperoxides, which have lower oxidation potentials than peracids but do not lose their epoxidising capacity.

Rebek proposed a series of hydroperoxyethers,[87,113] obtained by the interaction of acetals, ketals, or orthoesters with 90% hydrogen peroxide, as epoxidising agents:



The products of the addition of hydrogen peroxide to the carbonyl group in ketones containing electron-accepting groups, namely tetrachloro-,[114] hexachloro- and hexafluoroacetones,[87,115,116] are more effective oxidants:



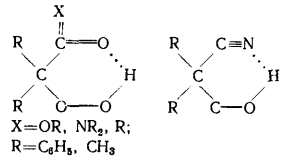
(XII)

The reagent (XII) epoxidises cyclic and acyclic olefins at 0 °C with a 60–93% yield of oxirans, while at an elevated temperature it oxidises ketones and esters.

A series of oxo-compounds (chloral, benzoin, acetophenone, acetoacetic ester, pentachlorobutanone, glucose, etc.) have been investigated in the epoxidation of cyclododecatriene and dicyclopentadiene.[117,118] It was found that the best results are achieved at 50–60 °C in the absence of a solvent. The rate of reaction is to a large extent determined by the diffusion constant. In particular, chloral generates the most reactive hydroperoxide, superior in its strength to the adduct of hexachloroacetone. Reagents of the above type make it possible to obtain monoepoxides in 25–95% yield virtually without an admixture of diepoxides.

The azomethine group in pyridinium salts and Schiff bases behaves similarly to the carbonyl group of ketones in the presence of hydrogen peroxide,[87] but the yield of oxirans is then low (3–45%).

The α-hydroperoxides of ketones, esters, nitriles, and amides,[119] formed in their autoxidation in the presence of potassium t-butoxide,[120] are epoxidising agents whose strength is comparable to that of peracetic acid:



X=OR, NR_2, R;
R=C_6H_5, CH_3

These reagents act stereospecifically on olefins—the *syn*-epoxyalcohol is formed preferentially in the epoxidation of 2-cyclohexanol. However, in contrast to peracids, the ester α-hydroperoxide oxidises *trans*-stilbene more easily than the *cis*-isomer, while *trans*-β-methylstyrene is oxidised more readily than cyclohexene. The selectivity of the reagent diminishes greatly when chloroform is replaced by benzene as the solvent.

The weak epoxidising capacity of the hydroperoxy-derivative of pyrazole, which is structurally similar to natural products, namely 4a-hydroperoxides of flavin, has been demonstrated.[121]

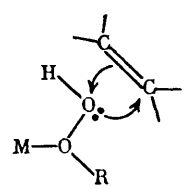
It is of interest to note the results of the oxidation of styrene by atmospheric oxygen on the styrene–oxygen copolymer as the template.[122,123] The dioxetan fragment of the copolymer

has been considered as the possible epoxidising group. An alternative version of the mechanism may involve epoxidation by the hydroperoxy-groups produced from the CH and CH_2 units in the α-position relative to the benzene ring or the peroxide bridge.

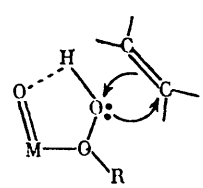
VI. HYDROPEROXIDE EPOXIDATION OF OLEFINS CATALYSED BY TRANSITION METALS

The state and principal trends in the development of the method have been fairly completely described in a monograph.[3] At the same time, it has been noted that the mechanism of the epoxidation of olefins by alkyl hydroperoxides and, in particular, the mechanism of the stage involving oxygen transfer to the substrate has not been ultimately elucidated.

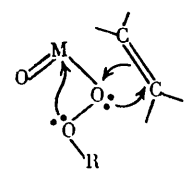
Most investigators have adopted mechanisms involving the formation of the complexes (XIII) and (XIV):[3,124]



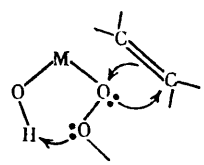
(XIII)



(XIV)



(XV)

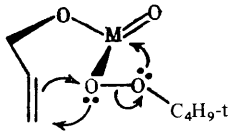


(XVI)

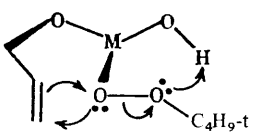
However, this is open to the objection that, according to the structures of compounds (XIII) and (XIV), the internal O(1) oxygen atom and not the more nucleophilic external O(2)

oxygen atom functions as the centre for the coordination with the catalyst in RO(1)O(2)H. This mechanism does not explain the exceptional reactivity of allyl alcohols.[125,126] Having examined the stereochemistry of the oxidation of the latter, Sharpless proposed mechanisms in which compounds (XV) and (XVI) are formed.[125,127] Preliminary experiments with the aid of tracer atoms showed that the ROOH molecule itself and not the peroxy-compound of the catalyst is involved in the stage responsible for the oxygen transfer.[128,129]

All the conditions for the simultaneous coordination of the catalyst to the peroxide oxygen and the allyl hydroxy-group exist in the complexes (XV) and (XVI), while in compounds (XIII) and (XIV) such interaction is ruled out on geometrical grounds:

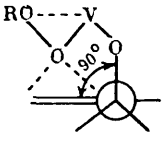


(XV)

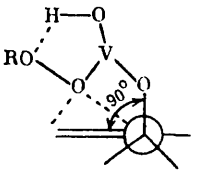


(XVI)

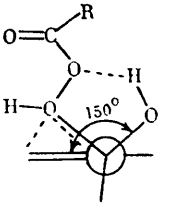
In their study of the stereochemical aspects of the epoxidation of cycloalkenols, Itoh et al.[126] determined the most probable geometry of the transition state when the alkyl hydroperoxides (XV) and (XVI) and the peracids (XVII) are used:



(XV)

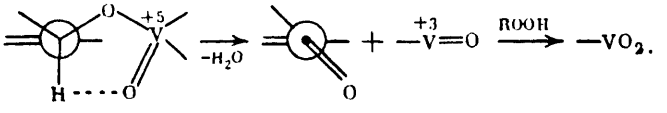


(XVI)



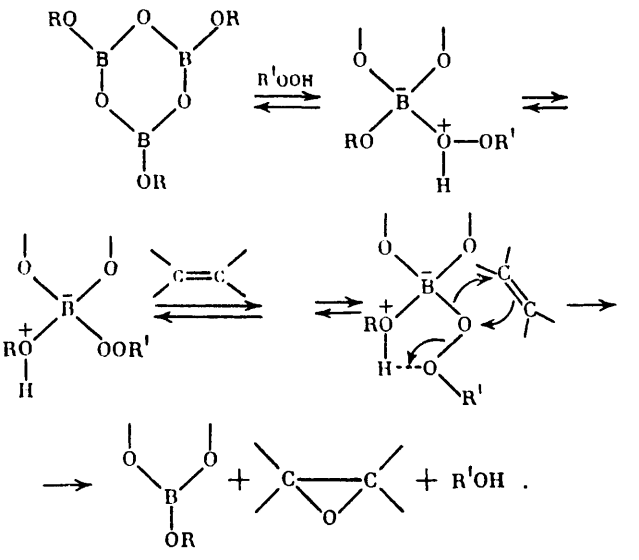
(XVII)

In the case of secondary allyl alcohols with a fixed conformation, which prevents formation of the complexes (XV) and (XVI) with a quasi-axial disposition of the OH group, the oxidation is by the oxygen of oxovanadium with subsequent regeneration of the oxidant by the hydroperoxide:

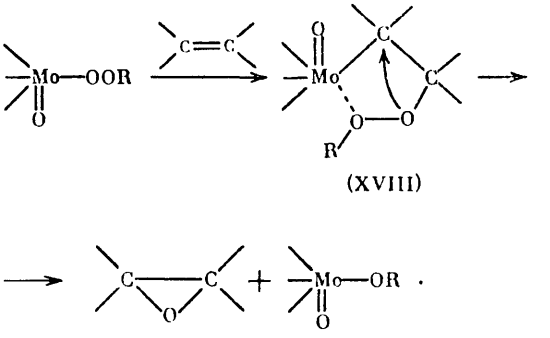


The ability of the metals employed in the oxidation reaction to form three-membered peroxy-compounds [128,129] makes a shift of the central atom from the active oxygen to the alkoxide anion in compound (XV) entirely realistic. Under other acid–base conditions, the "proton" mechanism (XVI), corresponding to the idea of nucleophilic substitution at the peroxide oxygen atom, may be preferable.[55] The relative contributions of the mechanisms (XV) and (XVI) are apparently determined by the ratio of the oxo- and hydroxylated forms of the catalyst.

In the light of the ideas described concerning the role of aprotic and protic acids, epoxidation in the presence of borates[130] can proceed as follows in the peroxide oxygen transfer stage:

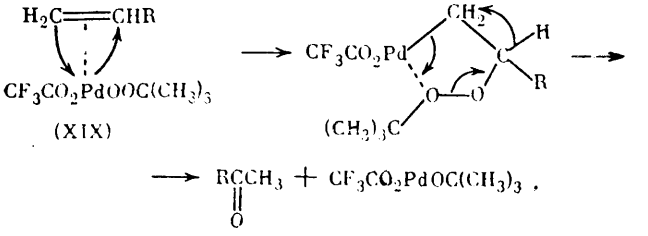


A mechanism has been proposed for the hydroperoxide epoxidation with formation of a five-membered metal peroxide complex (XVIII):[131]



(XVIII)

The above mechanism is based on the analogy with the oxidation of terminal alkenes to methyl ketones by peroxy-compounds of palladium (XIX):



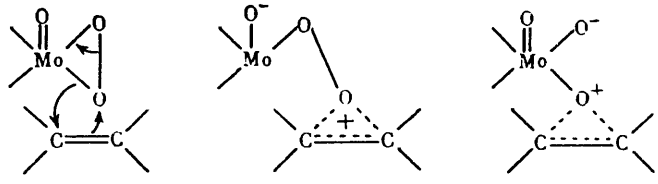
(XIX)

However, the reactions considered are significantly different in their nature. In contrast to molybdenum compounds, palladium compounds form complexes with olefins not only via donor–acceptor interactions but also via a dative interaction and are probably capable of adding to the double bonds. The formation of a C–Pd bond is indicated by the involvement in the reaction of only the terminal double bond, with a sterically accessible carbon atom, and also by the unusual hydride shift§. On the other hand, the formation of Mo–C and V–C

§ In the isomerisation of epoxy-compounds to aldehydes or ketones, the unoccupied orbital accepting the hydride anion arises at the more substituted carbon atom.[57]

bonds is unlikely, while the formation of five-membered complexes analogous to (XVIII) is inconsistent with experimental epoxidation data.[2,132] In particular, the comparable rates of epoxidation of cyclohexene and norbornene (an effective 1,3-dipolarophile)[132] are evidence against the 1,3-dipolar addition to the double bond.

The operation of ionic mechanisms in which compounds (XXI) and (XXII) are formed in organic (non-polar) media appears less probable than the synchronous mechanism involving the formation of compound (XX):



(XX) (XXI) (XXII)

The autoacceleration and inhibition effects, indicating that the competing associative process can promote or conversely hinder the insertion of the alkyl hydroperoxide and then the olefin in the coordination sphere of the catalyst, are characteristic of the alkyl hydroperoxide epoxidation[3] and of a series of heterolytic reactions of hydrogen peroxide and peracids.[55,56]

VII. STEREOSELECTIVITY AND REGIOSELECTIVITY OF THE HYDROPEROXIDE EPOXIDATION

Henbest and Wilson laid the foundations of stereoselective epoxidation having established that the allyl hydroxy-group in cyclohexenol is coordinated to the peracid and promotes *cis*-epoxidation.[133] The rate of reaction is then higher by an order of magnitude than in the case of the corresponding cyclohexenyl acetate.

Alkyl hydroperoxides showed an even greater selectivity in the oxidation of cyclic and saturated alcohols (see Table) in the presence of vanadium and molybdenum compounds.[126, 134–137] 2-Cyclohexanol was oxidised more readily than cyclohexene, while cyclohexene was more reactive when a peracid was employed.[134]

It is striking that the epoxidation of C_6–C_9 cycloalkenols with *m*-chloroperbenzoic acid (MCPBA) is accompanied by a change in the direction of attack by the reagents on passing from a seven-membered to an eight-membered ring (see Table). This finding can be accounted for by the conformational changes arising following an increase in ring size. On the other hand, under the conditions where a vanadium catalyst is used the coordination of the OH group to the central atom is so strong that it alters the conformation and ensures the *syn*-attack by the oxidant. A *syn*-directing influence is also shown by the hydroxy-group in 3-cyclohexenol.[134] In this case the molybdenum catalyst is more effective than the vanadium catalyst.

The most probable geometry of the transition state in the epoxidation of cyclohexenols by peracids and ROOH has been published by Itoh et al.[126] (see Section VI).

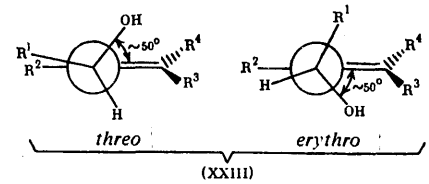
It is of interest to note the highly selective formation of *cis*-epoxyalcohols in the oxidation of cyclenes by atmospheric oxygen in the rpesence of vanadyl acetylacetonate[138] with the intermediate formation of allyl hydroperoxides. The catalytic reaction of the cycloalkenyl hydroperoxides themselves has been investigated[139] (see Table). The exclusive formation of *cis*-epoxyalcohols suggests that the epoxidation is intramolecular.

The directing influence of the hydroxy-group has been used successfully also in the hydroperoxide epoxidation of acyclic systems. A high regioselectivity (84–93%) has been attained in the catalytic epoxidation of geraniol, linalool,[134] and certain analogues of farnesol[140] by t-butyl hydroperoxide (see Table). ROOH epoxidises the allyl 2,3-double bond, while peracids oxidise preferentially the more remote 6,7-double bond.

The possibility of the selective hydroperoxide epoxidation of allyl alcohols of the type of (XXIII) (see Table) has been demonstrated.[136,141]

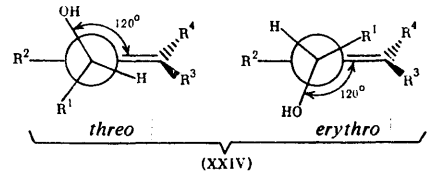
The Table shows that peracids exhibit a high stereoselectivity only for a specific structure of the alkenol (with $R^2 = H$). The presence of a single substituent at the C(3) atom in the *trans*-position lowers the stereoselectivity.[142]

The probable dihedral HO–C–C=C angles in the transition states leading to the *threo*- and *erythro*-isomers in oxidation of (XXIII) by ROOH and of (XXIV) by a peracid have been calculated:[140]



threo *erythro*

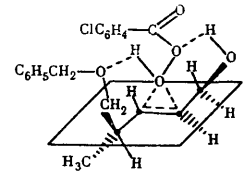
(XXIII)



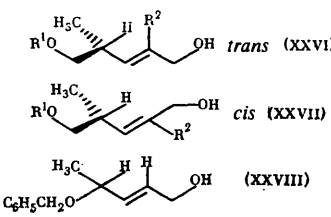
threo *erythro*

(XXIV)

An unusual effect of the joint directing effect of the hydroxy-group and the ester oxygen atom, as in (XXV), has been observed in the epoxidation of the olefinic alcohols (XXVI) and (XXVII), where $R^1 = C_6H_5CH_2$ or H and $R^2 = H$, CH_3 or $Si(CH_3)_3$, by MCPBA.[143,144] The stereoselectivity reaches 86–96%.



(XXV)



trans (XXVI)

cis (XXVII)

(XXVIII)

The high effectiveness of the joint influence of the substituents in the *cis*-isomer is determined, according to the authors,[144] by the geometry of the most stable conformation (XXVII). A similar effect of the functional groups in compound (XXVIII) was not observed.[145]

The directing influence of the bulky trialkysilyl group at the C(2) atom of the alkenol (see Table) is extremely effective.[144–146] In the final epoxyalcohol it can be readily substituted by hydrogen on treatment with $(n\text{-}C_4H_9)_4NF$ in DMF.

Evidently the discovery of the most stable conformation of the alkenol in the ground state and the selection of the corresponding substituents are extremely useful in carrying out the reaction with the expected stereochemical results, although the method,[147] based on the estimation of the relative stabilities of the diastereoisomeric transition compounds in accordance with the Curtin–Hammett principle, is more universal for the prediction of the mode of synthesis.

The stereoselectivity and regioselectivity of the epoxidation of certain substituted alkenes and cycloalkenes.

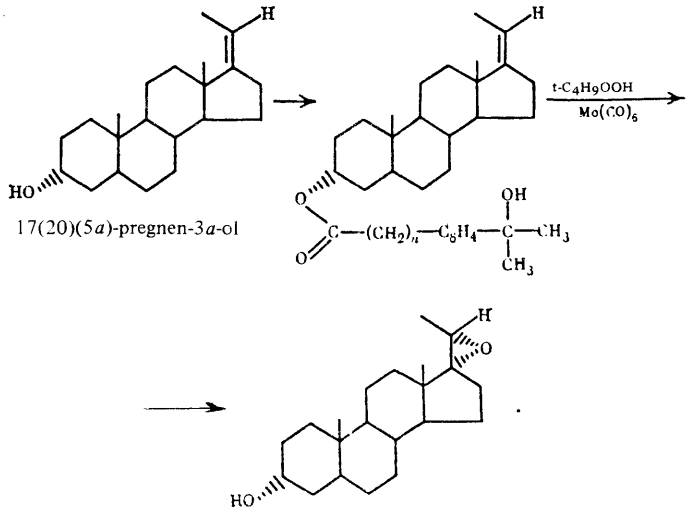
Estimation of the strain induced by the interaction of the substituents in the 1-, 2-, and 3-positions in the allyl alcohol makes it possible to predict the structure of the optimum transition state and the result of the reaction as a whole, which has been demonstrated for a series of examples described in the literature.

The stereochemical course of the epoxidation reactions of acyclic 3- and 4-alkenols has been investigated only for individual examples (see Table). Thus pent-4-en-2-ol exhibits only a weak 1,3-asymmetric induction in its reactions with various oxidants,[148,149] while 4-alkenols are epoxidised by t-C_4H_9OOH with a high stereoselectivity (1,4-asymmetric induction).[150]

The stereospecific epoxidation of the olefin bond in steroids[151] and acyclic polyenes[152] has been carried out making use of the influence of a very remote OH group. For this purpose, it was acylated by a hydroxylated reagent (template). The size and geometry of the template enabled

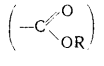
the OH group present in it to cooperate with the oxidant:



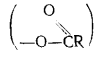
The asymmetric epoxidation of allyl alcohols by alkyl hydroperoxides has been carried out in the presence of vanadium and molybdenum complexes incorporating chiral ligands: hydroxamic acids[127] and *N*-alkylephedrin.[153] The asymmetric induction reached 50%.

The influence of other functional groups on the stereoselectivity of the epoxidation has also been investigated (see Table). The epoxidation of certain βγ-unsaturated acids of the cyclohexene series by peracids has been studied.[154] The tendency towards *cis*-epoxidation relative to the carboxy-group (54–79%) has been observed in inert solvents. The methyl esters of the above acids are epoxidised independently of the medium with the preferential formation of the *trans*-isomers (60–64%). The oxidation of *trans*-1,2-dihydrophthalic acid by MCPBA leads exclusively to mono- and di-epoxides with the *cis*-disposition of neighbouring epoxy- and carboxy-groups even in a weakly basic solvent—ethyl acetate.[155]

The presence of the carboxylate



or acyloxy-group

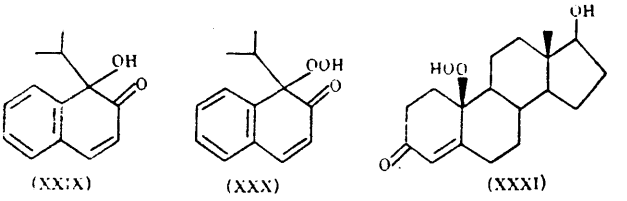


in the ring usually leads to the *trans*-orientation of the oxidant.[133,154,156,157] Nevertheless, when such substituents accumulate, for example, in the case of dimethyl *trans*-1,2-dihydrophthalate[158] or the tribenzoate of cyclopentenetriol,[159] a specific *syn*-directing influence is manifested (see Table).

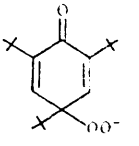
It has been established that the stereochemistry of the epoxidation of the lactone of 2-hydroxy-4-pentenylacetic acid by peracetic acid depends significantly on the nature of the solvent, indicating a relation between the conformation of the molecule and the conditions governing the solvation of the functional group.[160] The mode of epoxidation of unsaturated rings of moderate size does not exhibit a definite dependence on the orientation of the epoxy-group present in them.[161–163]

Dynamic conformational analysis of the epoxidation of substituted five-, six- and seven-membered cyclic olefins and certain bicyclenes[164] showed that the direction of attack by the reagent involving the least conformational distortions predominates. The principles developed in the last study quoted can be used in the planning of a stereospecific synthesis.

The stereoselective synthesis of epoxides from chalcones and naphthoquinones has been carried out with the aid of alkaline hydrogen peroxide or ROOH.[165–168] The use of chiral quaternary ammonium salts based on quinine and quinidine as phase-transfer catalysts made it possible to achieve an excess of one of the enatiomers to the extent of 25–55%. The epoxidation of 1-hydroxy-1-isopropylnaphthalen-2(1*H*)-one (XXIX) with alkaline hydrogen peroxide[169] takes place exclusively in the *trans*-position relative to the hydroxy-group. On the other hand, the intramolecular oxidation of the multiple bond in compounds (XXX),[170] (XXXI),[171] and (XXXII)[172] leads to *cis*-epoxyalcohols:



(XXIX) (XXX) (XXXI)

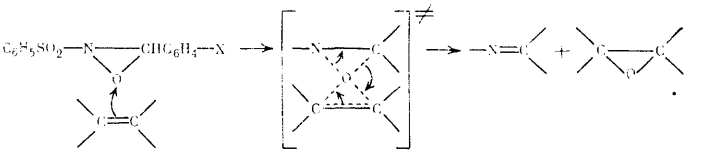


(XXXII)

A rigorously selective intramolecular epoxidation of the multiple 14,15-bond occurred in peracids derived from polyenoic acids: eicosa-*cis*-5,8,11,14-tetraenoic and eicosa-*cis*-8,11,14-trienoic acids.[173] The intramolecular oxidation of hydroperoxides obtained from certain orthoesters and ketals[113] by the method described in Ref. 112 takes place with the olefin double bond much less remote from the peroxide oxygen.

VIII. OXAZIRIDINES AND HETEROCYCLIC EPOXIDISING INTERMEDIATES

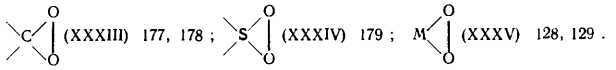
Oxaziridines containing electron-accepting substituents are capable of oxidising sulphides, amines, organometallic compounds, and olefins:[174]



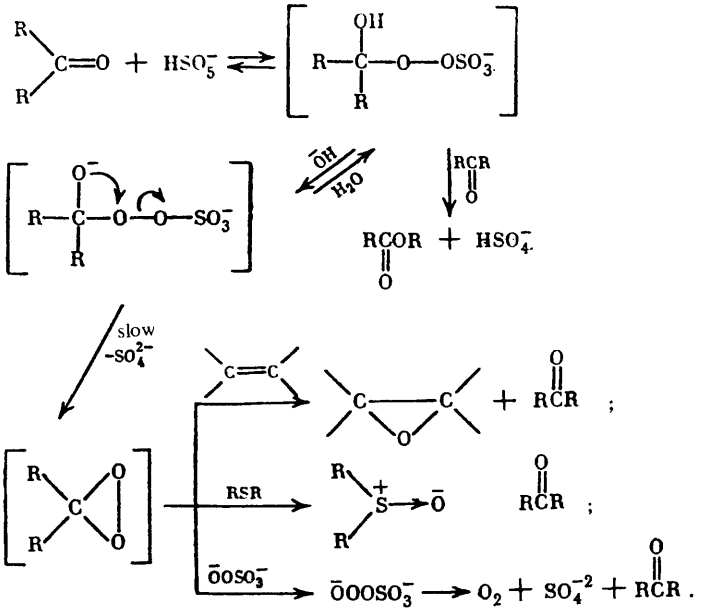
For example, *trans*-stilbene is epoxidised by 2-arenesulponyl-3-aryloxaziridines at 60 °C in the course of 10–12 h with a 95% yield of the epoxide¶.

¶ For comparison, one may note that under severe conditions oxirans are capable of transferring oxygen to phosphines (150 °C),[175] while sulphur dioxide can transfer oxygen to ethylene (400 °C).[176]

In certain reactions involving peroxy-compounds, ozone, or singlet oxygen, the formation of highly reactive intermediates (XXIII) and (XXIV), resembling an oxaziridine, has been postulated:



The peroxy-compounds of certain transition metals (XXXV) have been isolated and investigated as epoxidising agents. The formation of the dioxiran (XXIII) has been suggested in the decomposition of potassium peroxymonosulphate (potassium Caroate—$KHSO_5$) in the presence of a ketone: [177]



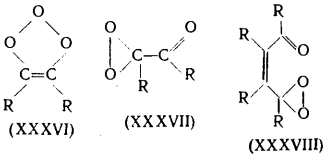
In water at pH 7.5 and a temperature of 2–10 °C the dioxiran epoxidises, also in the absence of a ketone, αβ-unsaturated ketones, acids, and their esters (which cannot be oxidised either by peracids or potassium Caroate) as well as the usual olefins. The Baeyer–Villiger reaction takes place at a negligible rate under these conditions. The reaction is rigorously stereospecific, which rules out the involvement of the carbonyl oxide

in it.

As a very powerful oxidant, the dioxiran can transfer active oxygen to the peracid anion with the subsequent formation of singlet oxygen. The rate of decomposition of the peroxymonosulphate anion is described by the equation [180]

$$W = k\cdot[HSO_5^-]\,[\text{ketone}]\,[\bar{O}H].$$

It has been suggested that the ozonisation of alkynes [178,181] results in the formation, together with peracids, of the epoxidising intermediates (XXXVI) and (XXXVII), the dioxiran (XXXVII) oxidising alkenes non-stereospecifically:

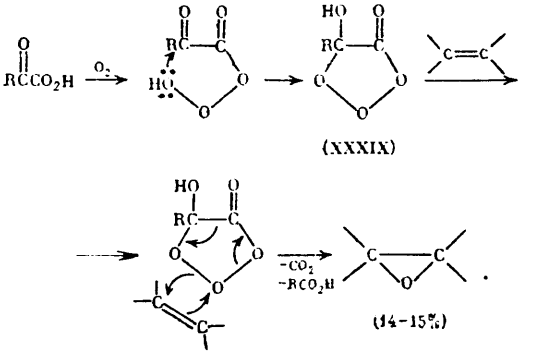


Compounds (XXXVI) and (XXXVII) are extremely reactive and epoxidise olefins at −70° and −25 °C respectively.

The dioxiran (XXXVIII) is regarded as an intermediate which transfers oxygen in the epoxidation of tetramethylethylene to the endoperoxides of furan and its derivatives. [182]

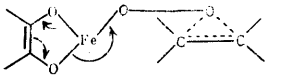
The sulphur-containing analogue of dioxiran (XXXIV) or its isomer sulphenyl oxide ($S=\dot{O}-\bar{O}$) is formed, according to Martin and Martin, [179] under the conditions of the oxidation of a compound of tetracovalent sulphur by hydrogen peroxide in the presence of cyclohexene or norbornene at −78 °C. An increase of temperature to room temperature completes the epoxidation reaction.

The oxidative decarboxylation of α-ketoacids with the aid of singlet oxygen, which proceeds via the trioxolan (XXXIX) capable of transferring oxygen to olefins, including tetracyanoethylene, in the temperature range from −100° to −150 °C, has been described: [183]

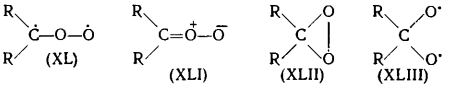


IX. THE OXENOID MECHANISM. CARBONYL OXIDE AND ITS ANALOGUES

By analogy with carbenoid, the term oxenoid is applied to the kinetically unstable species capable of transferring oxygen with a sextet of electrons to the substrate and of being converted into a neutral molecule. In his study of the enzymic oxidation of olefins by molecular oxygen, [184] Hamilton proposed the "enediol–Fe–O_2" oxenoid model, which transfers oxygen to the substrate:



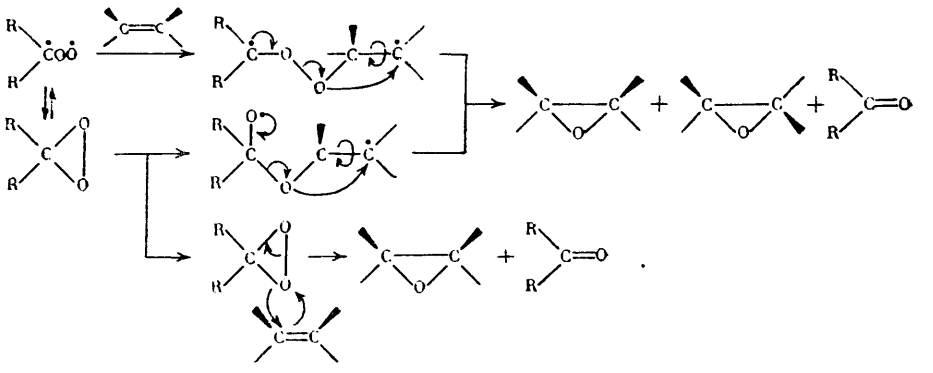
However, it has been suggested [185] that the consumption of peroxide in such systems proceeds via a radical chain mechanism. The "carbonyl oxide" (XL) or (XLI) (the Criegee intermediate) is a typical oxenoid. The dioxiran (XLII) and "methylene dioxide" (XLIII) are isomers of compound (XL): [178, 186–188]



Quantum-chemical calculation has shown that, as regards energy, the dioxiran is more favourable by 33.7–36 kcal than carbonyl oxide and by 15 kcal than methylene dioxide. [189,190]

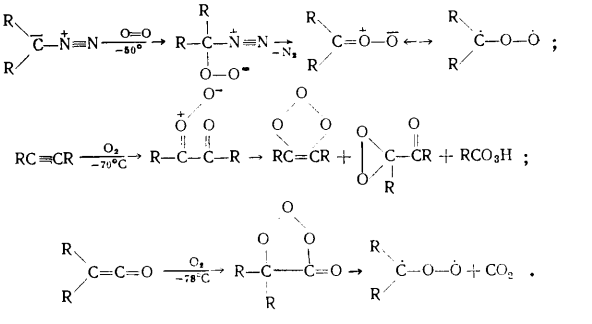
The oxenoid mechanism presupposes the involvement of any of the species indicated in the epoxidation reaction. One cannot rule out the possibility that the olefin can induce the homolytic rupture of the bonds in compound (XLII), abolishing the results of the interaction of olefins with compound (XL), (XLII), and (XLIII).

The epoxidation of olefins by carbonyl oxide and its isomers allows the formation of a biradical intermediate and rotation about the σ-bond: [186,187,191]



This mechanism is supported by the partial stereospecificity of the reaction. For example, *trans*-hex-3-ene gives rise to 99% of the *trans*-epoxide and 1% of the *cis*-isomer, while *cis*-hex-3-ene produces 95% of the *cis*-epoxide and 5% of the *trans*-isomer.

Carbonyl oxide is formed when diazomethane is treated with singlet oxygen[186] and when acetylenes,[178] ketenes,[187,188] and olefins[191] are ozonised:



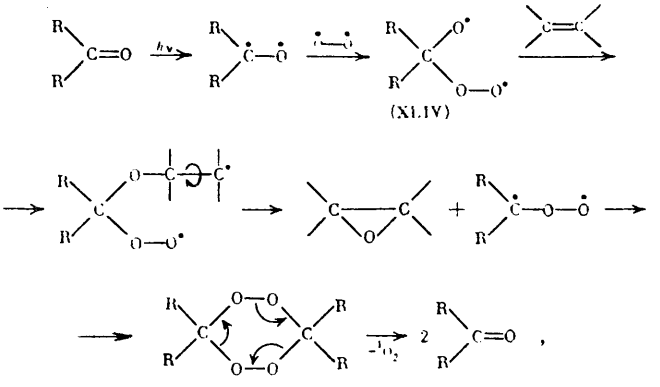
The ozonisation of olefins is known to lead to the formation of ozonides—the products of the coupling of Criegee intermediates with a carbonyl compound. However, in the presence of tetracyanoethylene, which is an effective 1,3-dipolarophile and which is not ozonised at a low temperature (−78 °C), epoxytetracyanoethane is formed in a quantitative yield.[192] Tetramethylethylene and norbornene are not epoxidised under these conditions.

It follows from the study of Gillies[191] that other electron-deficient olefins, namely symmetrically fluorinated ethylenes, can be epoxidised by carbonyl oxides. Ozonolysis of perfluoro- and 1,2-difluoro-ethylenes differs from that of the geminal difluoro-olefins and the usual alkenes. The study of the deuteriated substrates showed that the reaction takes place with partial cleavage of the olefin and with attack by fluorocarbonyl oxide on the olefin.

Evidently the introduction of an electron-accepting substituent into carbonyl oxide weakens its nucleophilic properties and its ability to attack the carbonyl group, permitting an electrophilic attack on the olefin.

By analogy with the dioxiran (XXXVII), the trioxides (XXXVI) and (XXXIX) and the sulphenyl oxide (XXXIV), mentioned above, may be included among oxenoid oxygen transferring agents.

The biradical (XLIV), formed as an intermediate in the photochemical oxidation of many cyclic and acyclic olefins sensitised by aliphate α-diketones or benzophenone, is also regarded as a probable epoxidising agent:[193]

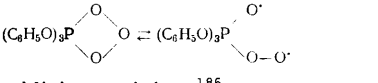


(XLIV)

Regardless of the geometry of the initial olefin, only the *trans*-epoxide is formed in the reaction. Benzophenone is then hardly consumed and, despite a fivefold excess of the olefin, a high yield of the oxiran is ensured.

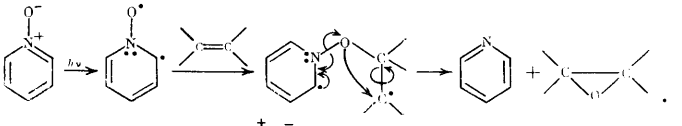
One should note that certain related photochemical epoxidation reactions in the presence of benzoin[194] and α-ketoacids[195] have been explained by the epoxidising action of acylperoxy-radicals. In this case the sensitisers are consumed as reactants.

The analogue (XLIV), which is a triphenylphosphite ozonoid,



exhibits a weak epoxidising activity.[186]

The *N*-oxides of nitrogen-containing heterocycles,[196,197] idosobenzene,[198] and phenylbenozyldiazomethane (azibenzil) are oxenoid reagents in the presence of oxygen.[199] Oxygen transfer to olefins by the *N*-oxide takes place under the conditions of photolysis at −70 °C and is characterised by the absence of stereo specificity: a *cis*-olefin gives rise to a 1:1 mixture of the *cis*- and *trans*-epoxides. Preliminary isomerisation of the *N*-oxides to oxaziridines is ruled out, because the latter epoxidise olefins stereospecifically.[176] The epoxidation mechanism can be accounted for if the *N*-oxide fragment $-C=\overset{+}{N}-\bar{O}$ is regarded as a heteroanalogue of carbonyl oxide:



Iodosobenzene ($C_6H_5-\overset{+}{I}-\bar{O}$) epoxidises and hydroxylates hydrocarbons in the presence of catalysts: iron αβγδ-tetraphenylporphyrinate and chlorodimethylferriprotoporphyrin. The system is very sensitive to the structure of the olefin

and the catalyst ligands. It has been suggested that iodosobenzene transfers oxygen to the substrate via a "catalyst–oxygen" intermediate.

A complex epoxidising olefins is formed from azilbenzil $C_6H_5COC(N_2)C_6H_5$ on interaction with oxygen in the presence of palladium acetate. The reaction with *cis*-olefins loses its stereoepcificity. It is believed[199] that the catalyst accelerates the decomposition of azibenzil and promotes the formation of a ketocarbene–oxygen complex, which plays the role of oxenoid.

The action of an alkaline solution of xenon trioxide and sodium perxenate (Na_4XeO_6) on an olefin has been investigated.[200,201] In contrast to certain inorganic oxides (OsO_4, MnO_4^-), which induce *cis*-1,2-hydroxylation, XeO_3 produces only epoxides, like peroxide reagents.

The ratio of the rates of epoxidation of norbornene and cyclohexene is small (2.4–2.7) and is evidence against a five-membered transition state characteristic of 1,3-dipolar addition.

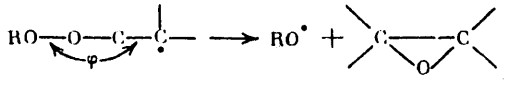
At the same time the weak stereospecificity of the reaction rules out the possibility of the operation of a typical synchronous mechanism with a three-membered transition state. The reaction apparently proceeds via the oxenoid mechanism involving the formation of a weakly bound bridged three-membered complex, permitting homolytic ring opening and rotation about the σ-bond.

X. SOME ASPECTS OF RADICAL EPOXIDATION

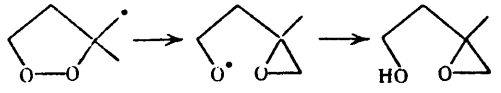
The epoxidation of olefins by alkyl- and acyl-peroxy-radicals has been described in a review.[122] Reaction of this type are non-stereospecific, which indicates a multistage mechanism of the formation of the ring. According to Sawaki and Ogata,[194] the *trans*-selectivity of the epoxidation by acylperoxy-radicals follows from the relative stabilities of the two possible transition states in the epoxide ring closure stage—the state with the transoid disposition of the bulkiest substituents is preferable.

The radical adduct $(CH_3)_2\overset{\vdots}{N}{-}O{-}O^{\cdot}$, formed in the epoxidation of many olefins by oxygen in the presence of amines and a Lewis acid ($ZnCl_2$), has been considered as an analogue of an acyl peroxy-radical.[202] Under the influence of the amine, the oxirans are converted into aminoalcohols under the conditions of the synthesis, although in the case of cyclooctene the intermediate oxiran was isolated.

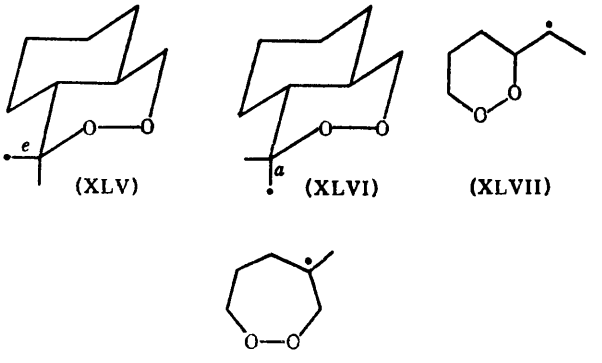
Important data about the stereochemistry of the epoxide ring closure in peroxyalkyl radicals have been published.[203,204] It has been shown that an angle close to 180° between the bonds of the leaving alkoxy-radical and the attacking carbon atom carrying the unpaired electron is a condition for the homolytic substitution at the peroxide oxygen atom (S_H):



Thus the formation of epoxyalcohols in accordance with the scheme



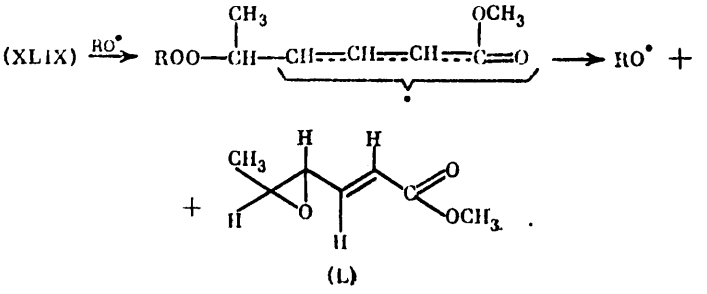
has been observed only in the radicals (XLV) and (XLVII) and not in their analogues (XLVI) and (XLVIII):



(XLV) (XLVI) (XLVII)

(XLVIII)

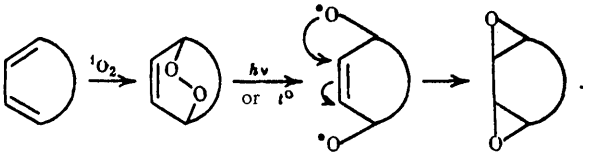
In contrast to the typical non-stereospecific epoxidation of olefins by alkyl- and acyl-peroxy-radicals, conjugated dienones and diene esters are epoxidised by molecular oxygen strictly stereo- and regio-selectively at the γδ-double bond.[205] For example, methyl sorbate (XLIX) forms exclusively the *E*, *E*-epoxide (L):



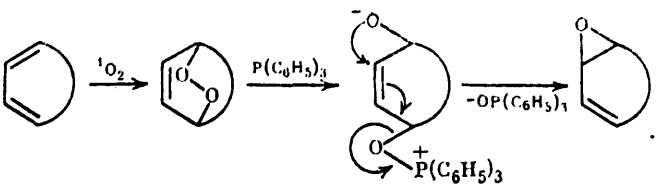
(L)

The stereospecific free-radical epoxidation of 7,8-dihydroxy-7,8-dihydrobenzo[*a*]pyrene by the hydroperoxides of polyunsaturated aliphatic acids has been noted.[206]

In the synthesis of bisepoxides from cyclic 1,3-dienes, the method used involved the oxygenation of the latter compounds by singlet oxygen with subsequent photochemical or thermal isomerisation of the resulting *endo*-peroxides:[207]



This entails the exclusive formation of *cis*-diepoxides. The deoxygenation of the *endo*-peroxide by triphenylphosphine leads to monoepoxides:

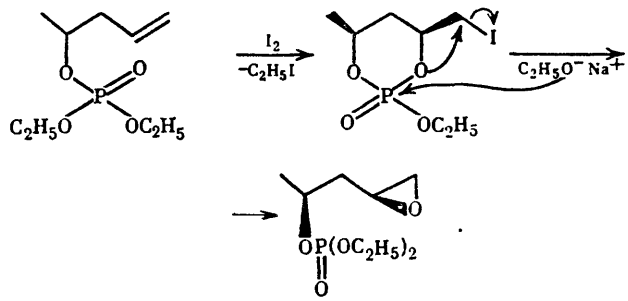


Combination of the above methods with the methods for the oxidation of olefins with the aid of peracids and via halogenohydrins gives rise to the possibility of the specific synthesis of di-, tri-, and poly-epoxides from hepta and octa-trienes

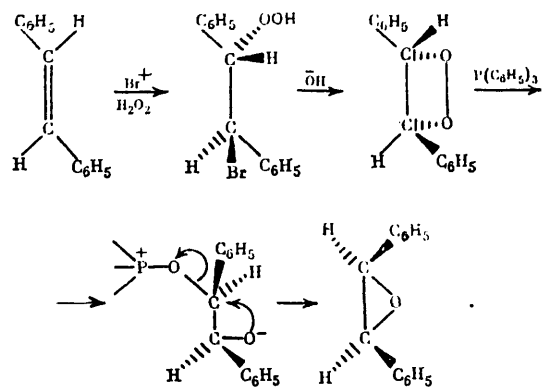
as well as other cyclic polyenes.[162,163,208] The strained system of the cyclopentadiene *endo*-peroxide gives rise to many side products on thermolysis (epoxyketones, ketoalcohols, and others).[209] On the other hand, in the case of substituted cyclopentadienes the yield of diepoxides is much higher.

XI. THE SYNTHESIS OF OXIRANS BASED ON INTRAMOLECULAR NUCLEOPHILIC SUBSTITUTION

A number of methods for the stereospecific synthesis of oxirans have been proposed. Bartlett and Jernstedt[148] achieved a highly stereoselective epoxidation of 3-alkenols by the iodination of the corresponding phosphates:[148]

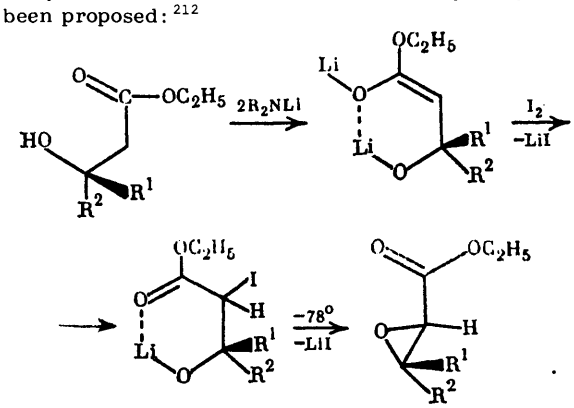


A stereoselective conversion of *trans*-stilbene into the *cis*-epoxide with a threefold inversion of the substrate[209] has been achieved via the deoxygenation of dioxetan with triphenylphosphine:



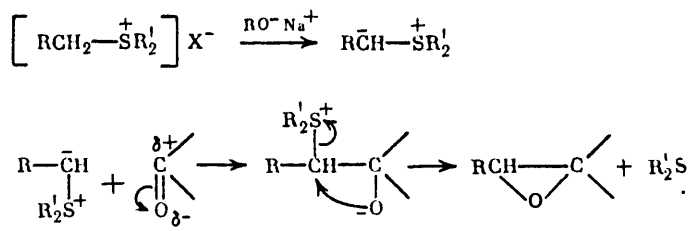
The deoxygenation of cyclo-1,3-diene *endo*-peroxides takes place similarly in the presence of triphenylphosphine.[207] The halogenoactonisation procedure has been used for the epoxidation of unsaturated acids[210] and alcohols:[211]

A new method for the stereoselective synthesis of αβ-epoxyesters by the oxidation of the dianions of β-hydroxyesters has been proposed:[212]



The high degree of asymmetric induction in such syntheses is due to the conformational features of the intermediate cyclic complexes, which make one of the pathways to the electrophilic addition to the double bond preferable.

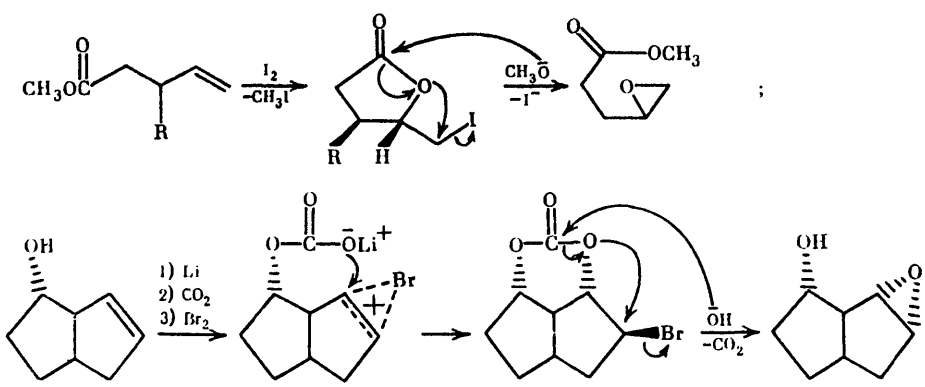
The method of synthesis of oxirans based on the coupling of sulphonium ylides to oxo-compounds has been described in several reports:[213–215]

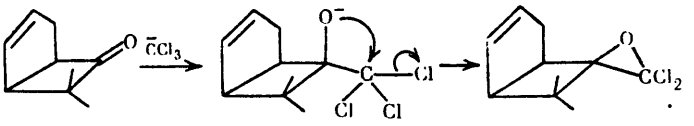


An alkyl phenyl sulphide can be the leaving group in an alkaline medium in the presence of a hydroxy-group in the α-position,[91] which has been used in the synthesis of an optically active epoxide–disparlure.

A series of new syntheses, in which the epoxide ring is closed by the Darzens method have been described, for example, the epoxyannelation of the carbanions of β-ketoesters and β-diketones to 1,4-dichlorobutan-2-one[216] and the condensation of α-mercaptocarbonyl compounds with 2-chloroacrylonitrile in the presence of tetraalkylammonium iodide as the catalyst.[217]

Under the conditions where a phase-transfer catalyst is used, dichloroepoxides, which readily rearrange to the chlorides of carboxylic chloroacids, have been obtained from ketones and chloroform in an alkaline medium:[218]





The epoxidation of styrene and cyclohexene by sodium hypochlorite, catalysed by transition metal complexes in the presence of a phase-transfer catalyst, has been described.[219]

Oxirans can be obtained from vicinal diols by treating the latter with an equimolecular amount of tosyl chloride and powdered sodium hydroxide.[220] The epoxide ring is reduced after the tosylation of one hydroxy-group.

The C_2–C_{18} alkane-1,2-diols are dehydrated with formation of epoxides also in the gas or liquid phase at 250–550 °C in the presence of basic catalysts (AcONa, $Na_2B_4O_7$, Na_3PO_4, etc.).[221] The thermolysis of chlorohydrin esters at 150–250 °C in the presence of catalysts (ammonium of phosphonium salts) leads to the same result.[222]

The survey of the literature data makes it possible to differentiate five types of mechanisms of the epoxidation of olefins.

The first type includes many-centre synchronous mechanisms of the transfer of oxygen by the peroxide reagent to the substrate, which are completely stereospecific.[56,125,126,143] The synchronous mechanism is characteristic of many instances of hydroperoxide oxidation in the presence of protic or aprotic acids and bases whose composition constantly varies during the reaction. The competing associated processes taking place in such systems, in particular the non-equilibrium solvation of the reactants, exert a major influence on the rate and direction of the chemical reactions, producing a number of kinetic effects: autocatalysis, inhibition, dependence of the specific rate (k) and the activation parameters on the concentrations of the reactants and acid–base associated species, etc.

The second type involves an ionic mechanism which operates in the epoxidation of polar olefin bonds by hydrogen peroxide or alkyl hydroperoxides in an alkaline medium.[56,83,166] In the aliphatic series, *trans*-selectivity due to the rotation about the C–C bond in the intermediate carbanion, is observed.

The next type involves a radical asynchronous mechanism, presupposing the formation of a monoradical[122] or biradical[186,193,196] intermediate complex whose life span is sufficient for the inversion of the configuration of the initial olefin. A conformational equilibrium, mainly in favour of the *trans*-isomer of the oxiran, is then established, which renders the reaction non-stereospecific. An exceptional case of *cis*-selectivity has been described.[223]

Stereospecific radical epoxidation also occurs.[122,205]

Reactions whose mechanism is based on the nucleophilic closure of the epoxide ring constitute a separate group. The following are the usual leaving groups: Hal,[148,211,218] SR_2,[213,214] and OH.[220,221] The electrochemical epoxidation can be included in the same type.[224,225]

The Chemistry of Organic Compounds Containing the Thiodiimide Group

A.V.Zibarev and G.G.Yakobson (deceased)

Data on the methods of synthesis, the electronic and steric structures, and reactivities of organic compounds containing the thiodiimide group—N=S=N—are surveyed.
The bibliography includes 172 references.

I. INTRODUCTION

Heterocumulenes containing a quadrivalent dicoordinate sulphur atom are highly reactive and have unusual steric and electronic structures.[1] Among them, substances whose molecules incorporate the thiodiimide group $-N=S=N-$† are of special interest from both the theoretical and practical standpoints. Apart from the synthetic possibilities arising from these substances, the increased interest in them is associated with the fact that they can be regarded as the simplest oligomeric analogues of the polymeric sulphur nitride $(SN)_x$[2]— a molecular metal and superconductor.[3,4] The informal character of the analogy is confirmed by the electrophysical properties of certain thiodiimides. In particular, poly(arylene thiodiimides) $(-Ar-N=S=N-)_n$ are semiconductors and exhibit photoconduction with a spectral sensitivity extending to the near infrared,[5,6] while a series of low-molecular-weight thiodiimides can be used as highly sensitive pigments in electrophotographic processes and in the generation of an image by means of photoelectrophoresis.[7]

The present review examines critically and gives a systematic account of the available information about the methods of synthesis, structure, and reactivity of open-chain compounds in which the thiodiimide group is linked to two organic or organoelemental moieties. Whenever possible, a comparison is made with the polymeric sulphur nitride $(SN)_x$. Heterocyclic compounds containing the $-N=S=N-$ group, such as 2,1,3-thiadiazole and its derivatives, naphthol[1,8-*c*,*d*]-1,2,6-thiadiazine, etc., are not given special considerations. Studies on the coordination chemistry of organic thiodiimides, a review of which has been published recently,[8] are not examined either.

During the preparation of the review for the press, a survey of the chemistry of aza-analogues of sulphur dioxides, including thiodiimides, was published.[9] The present review was written from a somewhat different standpoint and is of a more specialist character, so that these two publications do not overlap but rather supplement one another.

†The $-N=S=N-$ group does not have a generally accepted name in Soviet literature. We prefer to refer to it as the thiodiimide group following the authors of the following monograph: S.N.Borisov, M.G.Voronkov, and E.Lukevics, "Kremneorganicheskie Proizvoidnye Fosfora i Sery" (Organosilicon Derivatives of Phosphorus and Sulphur), Izd.Khimiya, Leningrad, 1968, p.202.

II. SYNTHESIS

Organic compounds containing the thiodiimide group can be synthesised from primary amines and elemental sulphur under conditions of the Pishchimuka reaction. However, this simplest reaction is one of the least investigated.

The most general method of synthesis of the compounds considered involves the interaction of primary amines with the halides of bivalent or quadrivalent sulphur or with *SS*-dihalogenosulphimines, which can be regarded as monoimino-derivatives of quadrivalent sulphur halides. Another general method of synthesis of thiodiimides involves the condensation of *N*-sulphinylamines or *N*-sulphinylamides. This procedure is partly related to the first group of reactions by the fact that *N*-sulphinylarylamines are the starting materials for the synthesis of *N*-aryl-*SS*-dichlorosulphimines.[10]

The third group of reactions, which lead to organic thiodiimides, are those of *NN*-dichloroamides with dichloromono- and dichlorodi-sulphanes, elemental sulphur, or *SS*-dichlorosulphimines, as well as the reactions of *N*-chlorobenzamides with sulphur. It may be[11,12] that these reactions proceed via the intermediate formation of thionitroso-compounds[13] or their dimers.

Sulphur nitride $(SN)_4$ and trithiazyl trichloride $(NSCl)_3$, whose synthetic possibilities have not apparently been as yet exhausted, serve as interesting sources of sulphur–nitrogen fragments for organic thiodiimides. The same compounds also function as starting materials in the synthesis of the polymeric sulphur nitrides $(SN)_x$.[3,4,14]

1. *NN*-Dialkylthiodiimides

NN'-Dialkylthiodiimides are obtained by the reaction of aliphatic amines with sulphur tetrahalides (or their monoimino-derivatives)[15-22] or with dichloromonosulphane.[18,23] They are also formed on thermolysis of *N*-thiosulphinyl-alkylamines[24] and on reaction of *N*-halogenoalkylamines with bis-(dimethylamino)-sulphane.[25] αα'-Bis(dialkylamino)-ααα'α'-tetrachloro-substituted thiodiimides are formed on interaction of cyanomides with dichloromonosulphane:[26]

$$AlkNH_2-\left[\begin{array}{l}\xrightarrow[-HX]{SX_4} AlkN=SX_2 \xrightarrow[-HX]{AlkNH_2}\\ \xrightarrow[-HX]{SCl_2} (AlkNS)_x \xrightarrow[-S]{\Delta}\end{array}\right] \rightarrow (AlkN=)_2S;$$

$X = Cl, F;$

$$t\text{-}BuN=S=S \xrightarrow[-S]{\Delta} (t\text{-}BuN=)_2S;$$

$$Alk_2N-CN \xrightarrow[-S_2Cl_2]{SCl_2} (Alk_2N-CCl_2-N=)_2S\ .$$

Bis(perfluoroalkyl)thiodiimides have been synthesised from *SS*-dichloro-*N*-polyfluoroalkylsulphimines and trifluoromethylamine and its *NN*-dichloro-derivative.[27] In addition, *N*-heptafluoroisopropyl-*N'*-heptafluoroisopropylsulphenyl- and bis(heptafluoroisopropylsulphenyl)-thiodiimides are formed in low yields on interaction of thiazyl fluoride NSF with perfluoropropene.[28]

2. *NN'*-Bis(trimethylsilyl)thiodiimide and Related Compounds

NN'-Bis(trimethylsilyl)thiodiimide is formed on interaction of sodium *NN*-bis(trimethylsilyl)amide with thionyl chloride,[29] sulphur dioxide, or dichloromonosulphane[30] and also on interaction of trithiazyl trichloride with hexamethyldisilazane:[31]

$$\left.\begin{array}{l}(Me_3Si)_2NNa \xrightarrow{SOCl_2,\ SO_2\ \text{or}\ SCl_2} \\ (Me_3Si)_2NH \xrightarrow[-HCl]{(NSCl)_3}\end{array}\right\rangle \longrightarrow (Me_3SiN{=})_2S\,.$$

The reaction between trithiazyl trichloride and the corresponding tertiary amines is a more general process, which makes it possible to obtain bis(trimethylgermyl)- bis(trimethylstannyl)-, and bis(trimethylplumbyl)-thiodiimides in addition to the bis(trimethylsilyl) derivatives:[32]

$$(Me_3M)_3N \xrightarrow[-Me_3MCl]{(NSCl)_3} (Me_3MN{=})_2S\ ;$$
$$M = Si,\ Ge,\ Sn,\ Pb\,.$$

A group of monosilylated thiodiimides have been obtained by the single-stage reaction of *N*-sulphinylamines with lithium *NN*-bis(trimethylsilyl)amide,[33] while *N*-t-butyl-*N'*-trimethylsilylthiodiimide has been obtained by the reaction of *N*-sulphinyl-trimethylsilylamine with lithium t-butyldiorganylfluorosilylamides.[34] The latter substance has also been synthesised from *N*-t-butyl-*SS*-dichlorosulphimine and lithium *NN*-bis(trimethylsily)amide:[135]

$$(Me_3Si)_2NLi \left\langle \begin{array}{l} \xrightarrow{RNSO} R{-}N{=}S{=}N{-}SiMe_3\ ; \\ \xrightarrow[-LiCl;\ -Me_3SiCl]{t\text{-}BuN{=}SCl_2} t\text{-}Bu{-}N{=}S{=}N{-}SiMe_3\ ; \end{array}\right.$$
$$R = Et,\ t\text{-}Bu,\ Ph,$$
$$t\text{-}BuNLi \xrightarrow[-LiF;\ -1/n(-SiR_2O-)_n]{Me_3SiNSO} t\text{-}Bu{-}N{=}S{=}N{-}SiMe_3\,.$$
$$\quad |$$
$$\quad R_2SiF$$

N-Heptafluoroisopropyl-*N'*-trimethylsilylthiodiimide has been obtained from *N*-sulphinylheptafluoroisopropylamine and $(Me_3SiN{=})_2S$.[36]

A general procedure, consisting of the interaction of equimolar amounts of bis(trimethylsilyl)thiodiimide with arenesulphenyl chlorides, has been proposed for the synthesis of *N*-arenesulphenyl-*N'*-trimethylsilylthiodiimides:[2]

$$(Me_3SiN{=})_2S \xrightarrow[-Me_3SiCl]{ArSCl} Ar{-}S{-}N{=}S{=}N{-}SiMe_3\,.$$

N-Pentafluorobenzenesulphenyl-*N'*-trimethylsilylthiodiimide has been obtained from trithiazyl trichloride and *N*-pentafluorobenzenesulphenyl-*N*-trimethylsilylamine.[31]

Monosilylated thiodiimides are also formed in the reaction of sulphur nitride $(SN)_4$ with *N*-trimethylsilyl-substituted secondary alkylamines.[37] Bis(trimethylstannyl)thiodiimide has been synthesised by the reaction of $(SN)_4$ with *N*-trimethylstannyldimethylamine[38] or with tris(trimethylstannyl)amine:[39]

$$(SN)_4 \left\langle \begin{array}{l} \xrightarrow{(Me_3Sn)_3N\ \text{or}\ Me_2SnNMe_2} (Me_3SnN{=})_2S\ ; \\ \xrightarrow{Me_2SiNAlk_2} Me_3Si{-}N{=}S{=}N{-}S{-}NAlk_2\,. \end{array}\right.$$

3. *N*-Alkyl-*N'*-arylthiodiimides

N-Sulphenylaniline combines with lithium *N*-alkyl-*N*-trimethylsilylamides in petroleum ether. Subsequent reaction of the adducts with aluminium chlorides leads to *N*-alkyl-*N'*-phenylthiodiimides:[40]

$$\begin{matrix} Alk \\ Me_3Si \end{matrix}\!\!>\!NLi \xrightarrow{Ph{-}NSO} \left[\begin{matrix} Alk \\ Me_3Si \end{matrix}\!\!>\!N{-}SO{-}N\!<\!\begin{matrix} Ph \\ Li \end{matrix}\right] \longrightarrow$$

$$\xrightarrow[-Al(OSiMe_3)_3]{AlCl_3} Ph{-}N{=}S{=}N{-}Alk\ ; \qquad Alk = Me,\ Et\,.$$

4. *NN'*-Diarylthiodiimides

The first diarylthiodiimides have been obtained by the condensation of *N*-sulphinylarylamines under the influence of metallic sodium.[41] *N*-Sulphinylaniline and its derivatives containing electron-donating substituents in the aromatic ring enter into this reaction. The yield of the products does not exceed 40%, which is probably associated with the elimination of sulphur from the thiodiimides on treatment with sodium to give azo-compounds. *N*-Sulphinylarylamines containing electron-accepting substituents do not undergo this reaction.[41]

N-Sulphinylarylamines also condense on treatment with alkali metal alkoxides, amides, and hydrides and dimsylsodium,[42–45] derivatives containing both electron-donating and electron-accepting groups in this ring undergoing the reaction. The most effective catalysts are alkali metal alkoxides and dimsylsodium. The yields of *NN'*-diarylthiodiimides are significantly higher than in the condensation of *N*-sulphinylamines under the influence of sodium.[42–45] The mechanism of the condensation of *N*-sulphinylarylamines on treatment with bases[43] is illustrated in Scheme (1) below

$$Ar{-}N{=}S{=}O \xrightarrow{B^-} \left[Ar{-}\overline{N}{-}S{=}O \;\big|\; B\right] \xrightarrow{Ar\text{-}NSO} \longrightarrow$$
$$\longrightarrow \left[\begin{matrix} Ar{-}N{-}S{=}O \\ \quad\quad\ \backslash B \\ \overline{O}{-}S{=}N{-}Ar \end{matrix}\right] \xrightarrow{-B^-} \qquad (1)$$
$$\rightarrow \left[\begin{matrix} Ar{-}N{=}S{-}O \\ \quad\quad\ | \\ Ar{-}N{-}S{=}O \end{matrix}\right] \xrightarrow{-SO_2} (Ar{-}N{=})_2S\,.$$

It has been reported that the condensation of *N*-sulphinylaniline to give diphenylthiodiimide proceeds on treatment with zerovalent nickel complexes; however, the yields are low (12–20%). Substituted *N*-sulphinylanilines (4-Me-, 4-EtCO-) do not react.[46]

The most general method of synthesis of symmetrical diarylthiodiimides involves the interaction of arylamines with sulphur tetrafluoride.[47–50] Compared with other procedures, this method gives higher yields of purer products. Arylamines containing both electron-donating and electron-accepting groups,[48] including polyfluoroarylamines,[49,50] enter into this reaction. An essential condition is the removal of the hydrogen fluoride evolved during the reaction. Trimethyl- and triethyl-amines[47,48] as well as sodium fluoride[49,50] have been used as HF acceptors. In the first stage of the reaction the corresponding *N*-aryl-*SS*-difluorosulphimine is formed from the amine and sulphur tetrafluoride and then gives rise to the thiodiimide by reacting with a second arylamine molecule:

$$R{-}NH_2 \xrightarrow[-HF]{SF_4} R{-}N{=}SF_2 \xrightarrow[-HF]{R{\cdot}NH_2} (R{-}N{=})_2S\ ;$$
$$R = Ar,\ Ar_f\ .$$

The last reaction leads to a convenient procedure for the synthesis of asymmetric *NN'*-diarylthiodiimides. Its synthetic possibilities have been demonstrated in relation to the interaction of arylamines with *N*-aryl-*SS*-dichlorosulphimines,[10,51] *SS*-dichloro-*N*-pentafluorophenylsulphimine,[52,53] and *SS*-difluoro-*N*-polyfluoroarylsulphimines.[50,52] The reactions proceed smoothly and with satisfactory yields. Triethylamine, pyridine, and sodium fluoride have been used to combine with HCl and HF.[10,50-52]

The interaction of SF_4 with *N*-aryliminotriphenylphosphoranes also leads to the diarylthiodiimides. The reaction proceeds via the intermediate formation of *N*-aryl-*SS*-difluorosulphimines, which also makes it possible to obtain asymmetric derivatives:[54]

$$Ph_3P{=}NAr \xrightarrow[-Ph_3PF_2]{SF_4} Ar{-}N{=}SF_2 \xrightarrow[-Ph_3PF_2]{Ph_3P{=}NAr'} Ar{-}N{=}S{=}N{-}Ar'\ .$$

On treatment with sulphur tetrachloride, aniline is chlorinated in the ring and a thiodiimide is not then formed.[47] However, on reaction with dichlorodisulphane in the presence of pyridine, certain aromatic amines react to form *NN'*-diarylthiodiimides, the yields of the pure products exceeding 70%:[55]

$$Ar{-}NH_2 \xrightarrow[-HCl;\ -S]{S_2Cl_2} (Ar{-}N{=})_2S\ ;$$
$$Ar = 4\text{-}C_6H_4{-}N{=}N{-}C_6H_5,\ 4\text{-}ClC_6H_4,$$
$$4\text{-}EtOCOC_6H_4,\ 1\text{-naphthyl}.$$

The reactions of pentafluoroaniline[56] and 2,4-di(t-butyl)-6-methylaniline[1] with dichloromonosulphane also lead to the corresponding thiodiimides. The second product of the reaction of 2,4-di(t-butyl)-6-methylaniline with SCl_2 is 2,4-di(t-butyl)-6-methyl-*N*thiosulphinylaniline.[1] It is noteworthy that, on reaction with a large excess of dichloromonosulphane, arylamines form *N*-aryl-*SS*-dichlorosulphimines.[57]

A convenient preparative version of the synthesis of *NN'*-diarylthiodiimides using S_2Cl_2 and SCl_2 as sources of sulphur involves the interaction of the latter with aryl-*NN*-bis(trimethylsilyl)amines. *N*-Thiosulphinylanilines and thionitrosoarenes are probably formed as intermediates in these processes.[58]

It has been shown in relation to the 2,4-di(t-butyl)-6-methyl derivative that the photolysis of *N*-thiosulphinylanilines leads to diarylthiodiimides.[59] The thermolysis of 2,4-di(t-butyl)-6-methyl-*N*-thiosulphinylaniline in boiling benzene leads to the formation of benzoisothiazole and an arylamine,[59] while the thermolysis of 2,4,6-tribromo-*N*-thiosulphinylaniline affords the corresponding thiodiimide.[24]

Diarylthiodiimides have also been synthesised under the conditions of the Pishchimuka reaction[60] and on interaction of *SS*-dichloro-*N*-pentafluorophenyl-sulphamine with hexamethyldisilathiane:[24]

$$Ar{-}NH_2 \xrightarrow[Hg(HNAc)_2]{S_8} (Ar{-}N{=})_2S\ ;$$
$$Ph_f{-}N{=}SCl_2 \xrightarrow[-Me_3SiCl]{S(SiMe_3)_2} [Ph_f{-}N{=}S{=}S] \xrightarrow[-S]{} (Ph_f{-}N{=})_2S\ .$$

Yet another method leading to the synthesis of diarylthiodiimides involves the transamination of *NN'*-di(arenesulphonyl)thiodiimides. In the reaction of arylamines with *NN'*-di(benzenesulphonyl)thiodiimide in molar proportions of 1:1, one sulphonyl-amino-group is replaced by an arylimino-group and *N*-aryl-*N'*-benzenesulphonylthiodiimides are formed. When the latter are treated with aniline or arylamines containing electron-donating substituents in the ring, either the arylimino- or benzenesulphonyl group is displaced. If the arylimino-group contains no electron-accepting substituents, the benzenesulphonylimino-group is displaced and *NN'*-diarylthiodiimide is produced. Aromatic amines containing electron-accepting groups in the ring do not react with *N*-aryl-*N'*-benzenesulphonylthiodiimides. The diamides of *N*-arenesulphonylamino- or *N*-arylimino-sulphurous acids are apparently formed as intermediates in the transamination reaction of *NN'*-di(arenesulphonyl)thiodiimides:[61]

$$(PhSO_2N{=})_2S \xrightarrow[-PhSO_2NH_2]{ArNH_2} Ar{-}N{=}S{=}N{-}SO_2{-}Ph \xrightarrow[-PhSO_2NH_2]{Ar'NH_2} Ar{-}N{=}S{=}N{-}Ar'\ .$$

5. *N*-Aryl-*N'*-arenesulphenylthiodiimides

N-Aryl-*N'*-arenesulphenylthiodiimides can be obtained by the reaction of the amides and imides of arenesulphenic acids with *N*-aryl-*SS*-dihalogenosulphimines and also with trithiazyl trichloride:[53]

$$Ph_f{-}S{-}NH_2 \xrightarrow[-HF]{Ph{-}N{=}SF_2} Ph_f{-}S{-}N{=}S{=}N{-}Ph\ ;$$
$$(PhS)_2NH \xrightarrow[-PhSCl;\ -HCl]{Ph_f{-}N{=}SCl_2} Ph{-}S{-}N{=}S{=}N{-}Ph_f\ ;$$
$$PhS{-}NH{-}Ph \xrightarrow[-HCl]{(NSCl)_3} Ph{-}S{-}N{=}S{=}N{-}Ph\ .$$

6. *N*-Aryl-*N'*-arenesulphonylthiodiimides

N-Aryl-*N'*-arenesulphonylthiodiimides can be obtained either by the transamination of bis(benzenesulphonyl)thiodiimides on treatment with an equimolar amount of an arylamine or by the reaction of *N*-arenesulphonyl-*SS*-dichlorosulphimines.[61,62] The only thiodiimide containing a heteryl substituent at the N=S=N group, namely *N*-benzenesulphonyl-*N'*-2-pyridylthiodiimide, has been obtained by the transamination of bis(benzenesulphonyl)thiodiimide with 2-aminopyridine and has been identified in the form of adducts with diene hydrocarbons.[63]

7. *NN'*-Di(arenesulphonyl)thiodiimides

When *NN*-dichloroamides of arenesulphonic acids are heated with sulphur in the absence of a solvent, chlorine is evolved and bis(arenesulphonyl)thiodiimides are produced in quantitative yields. It has been suggested that one of the intermediates in this reaction is the thio-analogue of a nitroso-compound, namely $Ar{-}SO_2{-}N{=}S$:[64]

$$Ar{-}SO_2{-}NCl_2 \xrightarrow[-Cl_2]{S} (Ar{-}SO_2{-}N{=})_2S \xleftarrow[-SO_2]{} O{=}S{=}N{-}SO_2{-}Ar\ .$$

However, heating of the *NN*-dichloroamides of pentafluorobenzene-sulphonic acid with sulphur affords the corresponding *SS*-dichlorosulphimine.[11]

The reactions of the *NN*-dichloroamides of arenesulphonic acids with sulphur chlorides and *N*-arenesulphonyl-*SS*-dichlorosulphimines, of arenesulphonamides[64] and hexamethyldisilathiane[24] with *N*-arenesulphonyl-*SS*-dichlorosulphonimines, and of *N*-arenesulphonyl-*SS*-bis(trimethylsilyl)sulphimines with dichloromonosulphane[24] also leads to bis(arenesulphonyl)-thiodiimides.

Another method of synthesis of bis(arenesulphonyl)thiodiimides involves the condensation of *N*-sulphinylarenesulphonamides. On treatment with $AlCl_3$ and tertiary amines, it occurs at 110–125 °C and at room temperature respectively, the yields of the bis(arenesulphonyl)thiodiimides being almost quantitative.[65]

Bis(benzenesulphonyl)thiodiimide has been obtained by heating *N*-sulphinylbenzenesulphonamide with *NN*-bis(trimethylsilyl)benzenesulphonamide:[66]

$$Ph{-}SO_2{-}NSO \xrightarrow[-(Me_3Si)_2O]{(Me_3Si)_2N{-}SO_2{-}Ph} (Ph{-}SO_2{-}N{=})_2S\ .$$

8. *N*-Arenesulphenyl-*N'*-arenesulphonylthiodiimides

N-Arenesulphenyl-*N'*-arenesulphonylthiodiimides are formed in low yields (5–7%) on reaction of trichloromethanesulphenyl chloride with the amides of arenesulphinic acids in boiling tetrachloroethylene. The main products of this reaction, whose mechanism is obscure, are diaryl disulphides and ammonium chloride:[67]

$$Ar{-}SO_2{-}NH_2 \xrightarrow[-(ArS)_2;\,-NH_4Cl]{Cl_3C{-}SCl} Ar{-}SO_2{-}N{=}S{=}N{-}S{-}Ar\ ;$$
$$Ar = Ph,\ Tol,\ 4\text{-}Cl{-}Ph\ .$$

N-Arenesulphinyl-*N'*-arenesulphonylthiodiimides have also been synthesised by the transamination of *NN'*-bis(arenesulphonyl)thiodiimides. For example, a mixed *N*-sulphenyl-*N'*-sulphonylthiodiimide is formed in satisfactory yield in boiling benzene from 2-nitrobenzenesulphenamide and ditosylthiodiimide; the reaction is catalysed by pyridine. In the presence of pyridine, the transamination of ditosylthiodiimide is also observed on treatment with *N*-sulphinylarenesulphenamides, but the yields are in this case only 10–17%. *N*-2-Nitrobenzenesulphenyl-*N'*-tosylthiodiimide has been synthesised from *SS*-dichloro-*N*-tosylsulphinamine and 2-nitrobenzenesulphenamide:[68]

$$(TosN{=})_2S \xrightarrow[-TosNX]{ArSNX} Tos{-}N{=}S{=}N{-}S{-}Ar \xleftarrow[-HCl]{ArSNH_2} TosN{=}SCl_2\ ;$$
$$X = H_2,\ SO;\ Ar = 2\text{-}O_2N{-}Ph\ .$$

9. *NN'*-Bis(arenesulphenyl)thiodiimides

The most general method of synthesis of bis(arenesulphenyl)thiodiimides involves the interaction of bis(trimethylsilyl)thiodiimide with arenesulphenyl chlorides.[2] This method makes it possible to obtain also asymmetric *NN'*-bis-(arenesulphenyl)thiodiimides by a two-stage reaction. In the reaction of bis(trimethylsilyl)thiodiimide with arenesulphenyl chloride in molar proportions of 1:1, the first stage involves the formation of *N*-arenesulphenyl-*N'*-trimethylsilylthiodiimide, which can be made to react with a secondary arenesulphenyl chloride molecule.[2]

$$(Me_3Si{-}N{=})_2S \xrightarrow[-Me_3SiCl]{ArSCl} Ar{-}S{-}N{=}S{=}N{-}SiMe_3 \xrightarrow[-Me_3SiCl]{Ar'SCl} \rightarrow Ar{-}S{-}N{=}S{=}N{-}S{-}Ar'.$$

Compounds containing a five-membered sulphur–nitrogen chain are also formed when sulphur nitride $(SN)_4$ reacts with diazo-compounds[7,69] and arylmagnesium bromides[70–72] but in the latter case the main products are diaryl disulphides:[71]

$$(SN)_4 \begin{cases} \xrightarrow{ArMgBr} [(SN)_4\cdot 2ArMgBr] \xrightarrow{H_3O^+} (Ar{-}S{-}N{=})_2S; \\ \xrightarrow[-N_2]{R_2CN_2} (R_2C{=}N{-}{-}N{=})_2S + R_2C\!\!<\!\!\begin{matrix}S\\ \diagup\diagdown\\ CR_2\end{matrix} \end{cases}.$$

Apart from the reactions listed above, several other processes leading to bis(arenesulphenyl)thiodiimides are known. Thus, when *N*-2-nitrobenzenesulphenyl-*N'*-tosylthiodiimide is refluxed in a mixture of benzene and morpholine (catalyst), it is symmetrised to form bis(2-nitrobenzenesulphenyl)thiodiimide. The same product has been obtained from *N*-2-nitrobenzenesulphenyl-*SS*-dichlorosulphimine and 3-nitroaniline and from 2-nitrobenzenesulphenamide and dichloromonosulphane.[68]

N-Benzenesulphenyl-*N'*-pentafluorobenzenesulphenylthiodiimide[53] and bis(pentafluorobenzenesulphenyl)thiodiimide[73] have been obtained by treating *N*-benzenesulphenyl-*N'*-pentafluorobenzenesulphenylamine and *NN*-bis(pentafluorobenzenesulphenyl)amine respectively with trithiazyl trichloride. Bis(pentafluorobenzenesulphenylthiodiimide) has also been obtained from SF_4 and pentafluorobenzenesulphenamide.[74] Bis(benzenesulphenyl)thiodiimide has been synthesised from thiodithiazyl dichloride $S_3N_2Cl_2$ and phenylmagnesium bromide.[72] The reaction of the tetrathiotetraimide $(SNH)_4$ with the corresponding arenesulphonyl chloride yielded bis(2,5-dichlorobenzenesulphenyl)- and bis(2,5-6-trichlorobenzenesulphenyl)-thiodiimides:[75]

$$(NSCl)_3 \xrightarrow[HCl]{RS{-}NH{-}SPh_f} R{-}S{-}N{=}S{=}N{-}S{-}Ph_f\ ;$$
$$R = Ph,\ Ph_f$$
$$(SNH)_4 \xrightarrow[-HCl;\,-SO_2]{ArSO_2Cl} (Ar{-}S{-}N{=})_2S\ .$$

10. *N*-Aryl-*N'*-phosphorylthiodiimides

Thiodiimides containing the phosphoryl group are formed when the *NN*-dichloroamides of dialkylphosphoric acids react with *SS*-dichlorosulphimines or hexamethyldisilathiane. It has been suggested that one of the intermediates in the latter reaction consists of thionitroso-compounds.[76] *N*-Phenyl-*N'*-(phenylphosphoramidyl)thiodimide has been obtained by the reaction of aniline with *SS*-dichloro-N-dichlorphosphoryl-sulphimine:[62]

$$(AlkO)_2P(O)NCl_2 \begin{cases} \xrightarrow[-Cl_2]{Cl_2S{=}NR} (AlkO)_2P(O)N{=}S{=}NR\ ; \\ \xrightarrow[-Me_3SiCl]{S(SiMe_3)_2} [(AlkO)_2P(O)N{=}]_2S\ ; \end{cases}$$
$$R = Alk,\ SO_2Ar,\ P(O)(Alk)_2\ ;$$
$$Cl_2P(O)N{=}SCl_2 \xrightarrow[-HCl]{PhNH_2} Ph{-}N{=}S{=}N{-}P(O)(HNPh)_2.$$

11. *NN'*-Diaroylthiodiimides

Diaroylthiodiimides are produced (a) by the condensation of *N*-sulphinylbenzamides or by the reaction of benzamides with thionyl chloride, (b) by the reaction of *N*-chlorobenzamide with sulphur, and (c) by the reaction of *NN'*-diaroylamides of sulphoxylic acid with the *NN*-dichloroamides of sulphonic acids. All the reactions take place in the presence of pyridine. Dibenzoylthiodiimide has also been obtained by the reduction of methyl *N*-chloroiminobenzoate with sulphur or *N*-benzoyl-*SS*-dichlorosulphimine:[77,78]

$$\left.\begin{array}{l} ArCONH_2 \xrightarrow{SOCl_2} ArCO{-}NSO \xrightarrow{-SO_2} \\ ArCONHCl \xrightarrow{S} \\ (ArCONH_2)S \xrightarrow[-Ar'SO_2NH_2;\,-HCl]{Ar'SO_2NCl_2} \end{array}\right\} \longrightarrow (ArCO{-}N{=})_2S;$$
$$PhC(OMe){=}NCl \xrightarrow[-MeCl]{S \text{ or } -MeCl,\,-Cl_2}{Cl_2S{=}N{-}COPh} (PhCO{-}N{=})_2S\ .$$

One of the mechanisms proposed for the interaction of *N*-chlorobenzamides with sulphur[77] involves the dehydrochlorination of *N*-chlorobenzamide with pyridine and the subsequent interaction of aroylnitrene with sulphur. The second mechanism proposed is illustrated schematically below:

$$ArCONCl \xrightarrow{S} ArCO{-}NH{-}SCl \xrightarrow[-Cl_2]{ArCONHCl} \rightarrow (ArCONH)_2S \xrightarrow[-HCl]{Cl_2} (ArCO{-}N{=})_2S\ .$$

The interaction of the *NN*-dichloroamide of pentafluorobenzoic acid with sulphur leads to *SS*-dichloro-*N*-pentafluorobenzoylsulphimine.[11]

12. *NN'*-Bis(alkoxycarbonyl)thiodiimides

Bis(alkoxycarbonyl)thiodiimides have been synthesised from *NN*-dichlorourethanes on treatment with sulphur, dichloromonosulphane, or *N*-alkoxycarbonyl-*SS*-dichlorosulphimines. The reactions take place readily on heating the starting materials in the absence of a solvent and are accompanied by the evolution of chlorine:[79]

$$AlkO{-}CO{-}NCl_2 \xrightarrow[-Cl_2]{S,\ or\ SCl_2,\ or\ Cl_2S{=}N{-}COOAlk} (AlkOCO{-}N{=})_2S\ ;$$
Alk = Me, Et .

13. *N*-Alkyl(acyl)-*N'*-bromothiodiimides

N-Alkyl(acyl)-*SS*-dichlorosulphimines react with *N*-bromohexamethyldisilazane to form *N*-alkyl(acyl)-*N'*-bromothiodiimides:[80]

$$(Me_3Si)_2NBr \xrightarrow[-Me_3SiCl]{R{-}N{=}SCl_2} R{-}N{=}S{=}N{-}Br\ ;$$
$R = Alk_2C(CN),\ ArCO{-},\ ArSO_2{-}$

14. Compounds Containing More than One N=S=N Group in the Sulphur–Nitrogen Chain

When bis(trimethylsilyl)thiodiimide reacts with dichloromonosulphane in molar proportions of 2:1, 1,7,bis(trimethylsilyl)trithiotetranitride is formed, its sulphur–nitrogen chain consisting of two thiodiimide groups linked by a sulphide bridge.[81] The same substance has been obtained by the reaction of trithiazyl trichloride with hexamethyldisilazane.[31,82] 1,7-Bis(pentafluorophenyl) and 1,7-di-t-butyl-trithiotetranitrides have been synthesised from pentafluoro-*NN*-bis(trimethylstannyl)aniline and $S_3N_2Cl_2$ [83] or from *N*-t-butyl-*N'*-trimethylsilylthiodiimide and dichloromonosulphane[33,84] respectively:

$$\left.\begin{matrix}(Me_3Si{-}N{=})_2S \xrightarrow[-Me_3SiCl]{SCl_2} \\ (Me_3Si)_2NH \xrightarrow[-HCl]{(NSCl)_3}\end{matrix}\right\} \rightarrow (Me_3Si{-}N{=}S{=}N{-})_2S\ ;$$

$$Ph_f{-}N(SnMe_3)_2 \xrightarrow{S_3N_2Cl_2} (Ph_f{-}N{=}S{=}N{-})_2S\ ;$$

$$Me_3Si{-}N{=}S{=}N{-}Bu\text{-}t \xrightarrow[-Me_3SiCl]{SCl_2} (t\text{-}Bu{-}N{=}S{=}N{-})_2S$$

1,9-Diarylpentathiotetranitrides,[2] compounds which are known at present to have the longest (for non-polymeric molecules) sulphur–nitrogen chains, are obtained by the reaction of *N*-2-nitrobenzenesulphenyl- and *N*-2,4-dinitrobenzenesulphenyl-*N'*-trimethylsilylthiodiimides with dichloromonosulphane:

$$Ar{-}S{-}N{=}S{=}N{-}SiMe_3 \xrightarrow[-Me_3SiCl]{SCl_2} (Ar{-}S{-}N{=}S{=}N{-})_2S\ .$$

When an attempt was made to obtain an even longer sulphur–nitrogen chain by the reaction of dichloromonosulphane with 1,7-bis(trimethylsilyl)trithiotetranitride, only sulphur nitride $(SN)_4$ was obtained.[81]

15. Poly(arylenethiodiimides)

The condensation of aromatic *NN'*-disulphinyldiamines catalysed by potassium or lithium t-butoxides leads to poly(arylenethiodiimides). Polymers with *p*-phenylene units in the chain are almost insoluble in organic solvent. The derivatives containing *m*-aniline units are soluble in some cases; they are apparently macrocyclic. The determination of the molecular weight of a soluble polymer obtained from bis(3-*N*-sulphinylamino-4-methoxyphenyl)methane yielded a value corresponding to the octamer.[5,6]

Poly(arylenethionitrides) have been obtained from sulphur nitride $(SN)_4$ and phenylenebisdiazoalkanes.[85] The determination of the molecular weight of one of them (R = Ph, Ar = C_6H_4) showed that it is a trimer:

$$RC{-}Ar{-}CR \xrightarrow[-N_2]{(SN)_4} \rightarrow (-Ar{-}C{=}N{-}S{-}N{=}S{=}N{-}S{-}N{=}C{-}Ar{-}\underset{\displaystyle S}{\overset{\displaystyle C}{\diagup\diagdown}}{-})_n\ .$$

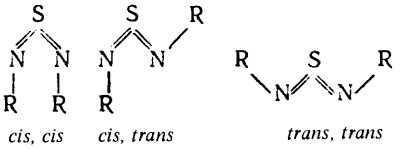
III. GEOMETRY AND ELECTRONIC STRUCTURE

Dialkyl-, diaryl-, and bis(arenesulphonyl)-thiodiimides exist predominantly in the form of *cis,trans*-isomers with a small admixture (in solution) of *trans,trans*-isomers. When a longer sulphur-nitrogen chain is incorporated in the composition of the compound, the thiodiimide group is retained as an independent structural unit, but the molecules of bis(arenesulphenyl)thiodiimides now have the *cis,cis*-geometry. Five-membered sulphur–nitrogen chains in organic derivatives are just as planar as the "infinite" $(SN)_x$ macromolecules.

The electronic structure of the thiodiimide group in organic derivatives is extremely sensitive to the influence of substituents and is capable of undergoing a significant rearrangement under their influence. In aromatic derivatives the thiodiimide group conjugated with organic fragments is a weak electron donor and transmits the electronic effects of substituents. At the same time many important details of the electronic structure of the organic thiodiimides remain obscure and require further study.

1. The Geometry of the Molecules of Organic Thiodiimides

Theoretically, organic thiodiimides can exist in the form of three geometrical isomers:



cis, cis *cis, trans* *trans, trans*

According to electron diffraction[86] and X-ray diffraction[86,87] data, the molecules of dimethylthiodiimides in the gas phase and of di-*p*-tolyl- and ditosyl-thiodiimides in the crystalline form have the *cis,trans*-configuration, the bond lengths and valence angles of which are given in Table 1. The lengths of the SN bonds in the thiodiimides are significantly closer to

the value for the sulphur–nitrogen double bond (1.52 Å) than for the single bond (1.74 Å). The distance between the nitrogen atoms rules out a valence interaction between them.[87]

Table 1. Parameters of the molecules of certain organic thiodiimides R–N=S=N–R.*

R	Bond lengths, Å				Valence angles, deg		
	SN_{cis}	SN_{trans}	NR_{cis}	NR_{trans}	RNS_{cis}	RNS_{trans}	NSN
Tol	1.53	1.56	1.46	1.41	131	118	117
Tos	1.52	1.52	1.68	1.69	125	117	115
Me	1.53	1.53	1.46	1.46	125	117	114

*According to the data of Kuyper et al.[86] and Leandri et al.[87]

The carbon, nitrogen, and sulphur atoms in the molecule of dimethylthiodiimide lie in the same place.[86] However, analysis of the vibrational spectra of bis(trimethylsilyl)thiodiimide led Herbrechtshmeier et al.[88] to the conclusion that the planar conformation of the $(SiN=)_2S$ fragment with C_{2v} or C_s point symmetry is ruled out and that a non-planar conformation with C_2 point symmetry is most probable.[88]

There is a deviation from planarity also in the molecule of di-*p*-tolyl-thiodiimide: in the crystalline state the planes of the aromatic rings form dihedral angles of 21.9° and 39.9° with the plane of the NSN atoms;[87] it may be that this is associated in the first place with the characteristic features of the crystal packing.

In solution dialkyl-[22,89] and diaryl-thiodiimides[48] exist in the form of an equilibrium mixture of the *cis,trans*- and *trans,trans*-isomers according to ^{13}C and ^1H NMR, the former isomer being always present in a greater amount. In the case of the dimesitylthiodiimide, only the *trans,trans*-isomer is present for steric reasons.[48] The activation energy for the interconversion of the isomers of diarylthiodiimide is in the range 11–12 kcal mol^{-1} and the frequency factor is approximately 10^{13} s^{-1}, which is usual for unimolecular reactions with an unstrained transition state. The electron-donating groups in the 4,4'-positions in the aromatic rings diminish the rate of interconversion of the isomer. The rates of the interconversions of the isomers of dialkylthiodiimides are lower than those for the diaryl derivatives.[22,48]

The increase in the length of the sulphur–nitrogen chain on passing from diaryl- to bis(arenesulphenyl)-thiodiimides is accompanied by changes in molecular geometry. According to X-ray diffraction data, the arenesulphenyl fragments in the molecules of bis(benzenesulphenyl)thiodiimide[90] and bis-(4-chlorobenzenesulphenyl)thiodiimide[91] are located in the *cis,cis*-positions relative to the central N=S=N unit. The distances between the nitrogen atoms and the central sulphur atom typical for SN double bonds agree well with the values found for di-*p*-tolylthiodiimide (Table 1). The distances between the nitrogen atoms and the sulphur atoms at the edges (1.66 Å) have the usual values for SN single bonds, in which there is the possibility of some d_π–p_π overlap.[91] The distance between the extreme sulphur atoms (3.29 Å) greatly exceeds the length of the covalent SS bond, but is somewhat smaller than the sum of the van der Waals radii of two sulphur atoms, which may indicate a weak interaction. The valence angle at the central sulphur atom is 124° and those at the nitrogen atoms are 129° and 126°.[91]

The most characteristic features of the steric structure of the bis(4-chlorobenzenesulphenyl)thiodiimide molecule is its close approximation to planarity (a single plane with an average deviation of the atoms of 0.11 Å and a maximum deviation of 0.24 Å can be adopted for the entire molecule) and the virtual collinearity of the axes of the aromatic rings (the projections of the lines passing through the Cl and S atoms in each of the 4-chlorobenzenesulphenyl groups onto the plane of the molecule form an angle of 190°).[91] However, the benzene rings in the bis(benzenesulphenyl)thiodiimide molecule have been rotated by 30.8° relative to the average plane of the nitrogen and sulphur atoms.[90]

The latest of the open-chain thiodiimides whose real geometry is known is 1,5-bis(diphenylmethyleneimino)trithiodinitride $Ph_2C=N-S-N=S=N-S-N=CPh_2$. The central sulphur atom of the molecule is located on a twofold symmetry axis; the valence angle at this atom is 124°. The substituents are located in the *cis,cis*-positions relative to the central N=S=N unit. The five central atoms of the sulphur–nitrogen chain are located in the same plane (with deviations within the limits of 0.04 Å), while the remaining two nitrogen atoms deviate from this plane by 0.49 Å. The SN bond lengths in the =S=N–S–N= fragment are respectively 1.55, 1.66, and 1.69 Å; the valence angles at the nitrogen atoms of the central N=S=N unit are 126°.[92,93]

It is of interest to compare the geometry of the molecules of organic thiodiimides with the geometry of the macromolecules of the polymeric sulphur nitride $(SN)_x$, which consist of chains of alternating sulphur and nitrogen atoms.[3,4] If one isolates an arbitrary NSN fragment in the $(SN)_x$ macromolecule, then the chain is continued in the *cis,trans*-positions, in a manner resembling the disposition of the substituents in the *cis,trans*-positions relative to the thiodiimide group in dialkyl, diaryl, and bis(arenesulphonyl) derivatives. However, the SN bond lengths in $(SN)_x$, which alternate (1.63 and 1.59 Å), appreciably exceed those in the thiodiimide group. The valence angles at the sulphur atoms in the $(SN)_x$ molecule are 106°, which is much less than the angle at the sulphur atom of the thiodiimide group. The valence angles at the nitrogen atoms (120°) are somewhat greater than the angles at the nitrogen atom of the N=S=N group linked to a *trans*-substituent, but are smaller than at the nitrogen atom linked to a *cis*-substituent.

2. The Electronic Structure of the Molecules of Organic Thiodiimides

(a) Electronic spectroscopic data and the results of quantum-chemical calculations. According to the data of Schouten and Oskam[94] and Kroner et al.,[95] the He(I) photoelectron spectra of dialkylthiodiimides contain three distinct peaks separated from a series of poorly resolved bands (with the exception of the spectrum of the diethyl derivative in which five peaks are resolved[94]). The interpretation of the spectra in terms of the Koopmans theorem on the basis of the quantum-chemical calculation by the LCAO-MO SCO method in terms of the CNDO/2 valence approximation, including the 3*d* AO of sulphur in the basis set, showed[94] that the first ionisation potential (IP) corresponds to the removal of an electron from the π MO made up of the d_{yz} AO of sulphur and the p_z AO of nitrogen. The next two bands correspond to the ionisation of orbitals of the σ type, the first of which constitutes a symmetrical combination of the AO ("unshared pairs") of nitrogen and sulphur and the second an antisymmetric combination of the AO ("unshared pairs") of nitrogen without the participation of the AO of sulphur. The fourth

band (usually a shoulder against the background of the ionisation of the σ skeleton) corresponds to the ionisation of the π MO made up of the p_z AO of nitrogen and sulphur. Comparison of the results of calculations by the CNDO/2 method for the *cis,trans*- and *trans,trans*-isomers of dimethylthiodiimides shows certain differences between the one-electron MO energies while their sequence is the same.[94] The MO in Table 2, which summarises the photoelectron spectroscopic data for dialkylthiodiimides, are therefore classified in terms of the irreducible representations of the symmetry point group C_{2v} of *trans,trans*-dimethylthiodiimide.

Table 2. The vertical ionisation potentials (IP) and one-electron MO energies of dialkylthiodiimides $(AlkN=)_2S$.*

IP, eV				One-electron MO energies**, eV (Alk = Me)		Assignment*
Me	Et	iso-Pr	t-Bu	*cis, trans*	*trans, trans*	
9.16	8.90	8.75	8.61 (8,65)	12.37	12.25	a_2 (a_2)
9.86	9.62	9.43	9.06 (9,01)	13.37	13.03	a_1 (a_1)
10.55	10.26	10.05	9.57 (9,60)	13.58	14.15	b_1 (b_2)
11.91	11.62	11.34	11.10 (11,1)	14.81	14.90	b_2 (b_1)
12.85	12.2	11.7	11.6	16.45	16.84	b_1

*According to the data of Schouten and Oskam[94] (the data of Kroner et al.[95] are given in brackets).
**Quoted with the sign reversed.

The substitution of the alkyl groups by trimethylsilyl groups alters the sequence of the MO. Interpretation of the He(I) photoelectron spectrum of bis(trimethylsilyl)-thiodiimide on the basis of the quantum-chemical calculations in terms of the MINDO approximation using the Koopmans theorem showed that the first three vertical IP (IP_1 = 9.2 EV) correspond to the MO with a predominant contribution by the AO of nitrogen: the non-bonding $a_2(\pi)$ MO made up of the p_z AO of nitrogen and the antisymmetric (b_2) and symmetrical (a_1) combinations of the AO of the "unshared pairs" of nitrogen.[96]

However, one should note that the interpretation of the photoelectron spectra on the basis of theoretical calculations alone, which are usually semiempirical, is not reliable and must be treated with caution. Calculations in terms of the CNDO approximation frequently yield an incorrect sequence of the orbitals, in particular certain σ MO are placed above the π MO.[97]

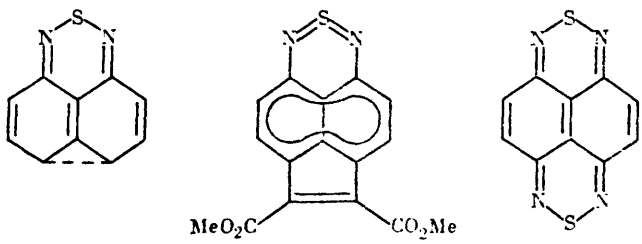
An increase in the length of the sulphur–nitrogen chain entails a decrease of the first IP. Thus IP_1 = 7.85 eV for 1,7-bis(trimethylsilyl)trithiotetranitride.[96]

Organic thiodiimides containing aromatic substituents have not been investigated by photoelectron spectroscopy with the exception of naphtho[1,8-*cd*]-1,2,6-thiadiazine, whose He(I) spectrum proved to be similar to that of 2-methyl-naphtho-[1,8,*de*]-1,2,6-triazine. A great similarity has also been observed between the electronic absorption spectra. The interpretation of the spectra based on calculations by the extended Hückel method and in terms of the MINDO/3 approximation has been carried out on the assumption that the bands in the electronic absorption spectra are associated with $\pi \rightarrow \pi^*$ transitions and that the Koopmans theorem holds for the photoelectron spectra; this interpretation showed the observed similarity between the spectra is due to the similarity between the structures of the valence levels. Thus it follows that, in considering the thiodiimide group, one can neglect the structure with quadrivalent sulphur (−N=S=N−) and the group can be described in terms of the superposition of structures of type (2). In terms of the LCAO-MO theory, this means that the 3*d* AO of sulphur are unimportant for the ground and excited states of the thiodiimide group:[98]

$$R-\bar{N}-\overset{+}{S}=N-R \longleftrightarrow R-N=\overset{+}{S}-\bar{N}-R \,. \qquad (2)$$

However, one can adduce certain considerations in support of the view that the conclusions valid for a system such as naphtho[1,8-*cd*]-1,2,6-thiadiazine can be hardly extended to derivatives of an organic compound with the thiodiimide group, at any rate without special stipulations.

In the first place, one should note that the 3*d* AO of sulphur, which appear in semiempirical quantum-chemical calculations, are usually no more than correction functions applied to an incorrect basis set, which are of purely methodological importance,[99] and the results of such calculations cannot serve as reliable arguments in the solution of the problem of the involvement or non-involvement of the 3*d* AO of sulphur in the formation of a chemical bond. The 3*d* AO of sulphur are capable of participating effectively in the formation of a chemical bond only when there is a large positive charge on the sulphur atom. The population of the 3*d* AO is usually small and their role consists of not so much in increasing the strength of the bonds as in converting the non-bonding MO into bonding MO and in decreasing the anti-bonding character of the antibonding MO.[100] The charge on the sulphur atom of naphtho[1,8,-*cd*]-1,2,6-thiadiazine is unknown, but in certain thiodiimides (see below) it is sufficiently high to permit the involvement of the 3*d* AO of sulphur in bonding. Furthermore, naphtho[1,8-*cd*]-1,2,6-thiadiazine has a number of features which distinguish it from open-chain thiodiimides. In particular, one can consider the quinonoid structures (A) for this compound with a formal π-bond between the carbon atoms in the 4- and 5-positions, which agrees with the fact that it reacts with bis-(methoxycarbonyl)acetylene to form the acenaphthothiadiazine (B) via [12π + 2π]-cycloaddition and aromatisation.[101] The position of the ^{15}N NMR signal of naphtho[1,8-*cd*]1,2,6-thiadiazine in a weaker field compared with that of diphenyl-thiodiimide can be accounted for[102] by the contribution of this structure. Naphtho[1,8-*cd* : 4,5-*c'd'*]bis-1,2,6-thiadiazine, which is a very close analogue of naphtho[1,8-*cd*]-1,2,6-thiadiazine, is a weakly aromatic compound and its structure (C) probably contributes to its ground state.[103]



(A) (B) (C)

Organic compounds containing the thiodiimide group have not been investigated systematically by X-ray electronic spectroscopy. The determination of the bond energies E_b of the internal levels of the nitrogen and sulphur atoms in di-t-butylthiodiimide [$E_b(S_{2p_{3/2}})$ = 166.9 eV; $E_b(N_{1s})$ = 398.4 eV][95] and bis(trimethylsilyl)thiodiimide [$E_b(S_{2p})$ = 164.9 eV; $E_b(N_{1s})$ = 397.5 eV][81] showed that the E_b for the N_{1s} level and hence the effective charge on the nitrogen atom can change significantly as a function of the substituents to

which the N=S=N group is linked.# This agrees with the results of measurements of the effective charges on the sulphur atoms in organic thiodiimides by X-ray fluorescence spectroscopy. The positive charges within the volume defined by the covalent radius, determined from the shifts of the S K_α lines, vary within the following ranges (in units of the electronic charge): 0.28–0.33 for diarylthiodiimides, 0.24–0.36 for *N*-aryl-*N'*-polyfluoroarylthiodiimides, and 0.25–0.35 for bis(polyfluoroaryl)thiodiimides.[50] The charge on the sulphur atom in these compounds exceeds that in bis(pentafluorophenyl)disulphide, the X-ray spectroscopic study of which (S $L_{II,III}$ spectrum) showed that the 3*d* AO of sulphur are not involved in the formation of the chemical bond in this compound.[105] Thus the charges on the sulphur atom in the thiodiimide group linked to aryl and (or) polyfluoroaryl substituents do not rule out the possibility of the involvement of the 3*d* AO of sulphur in chemical bonding.

The distribution of the 3*p* electrons of the sulphur atoms among the MO in diarylthiodiimides and *N*-aryl-*N'*-polyfluoroarylthiodiimides (according to S K_β spectra) resembles that in aromatic sulphides. On passing to bis(polyfluoroaryl)thiodiimides, the character of the distribution of the 3*p* electrons of sulphur among the MO changes sharply and becomes similar to the distribution of the 3*p* electrons of sulphur among the MO in SO_2.[50] This result has been interpreted[50] as a consequence of the significant weakening of the effectiveness of the p_π–p_π interaction between the heteroatom and the polyfluoroaryl group linked to it compared with the aryl group;[106] this shows that the electronic structure of the thiodiimide group is extremely sensitive to the influences of the substituents and can undergo an appreciable rearrangement under such influence. An alternative explanation consists in a possible increase of symmetry from C_s to C_{2v} on passing from diaryl- to bis(polyfluoroaryl)-thiodiimides (i.e. on passing from the *cis,trans*-configuration to the *trans,trans*-configuration), but direct structural information does not exist.

The agreement between the effective charges on the sulphur atoms in the molecules of bis(4-methyl-2,3,5,6-tetrafluorophenyl)thiodiimides[50] and the polymeric sulphur nitride $(SN)_x$ [107] molecules makes it possible to compare[108] the S K_β spectra of these compounds directly in terms of the scale of the transition energies. The comparison shows that, in the short-wavelength region (~2468–2473 eV), where transitions from the π^* antibonding and π bonding MO are manifested in the S K_β spectrum of the sulphur nitride $(SN)_x$,[107] the spectra are similar as regards the form of the spectral line and the energies of its structural elements. From this it follows that populated π^* MO, antibonding in sulphur–nitrogen bonds, exist in bis(polyfluoroaryl)thiodiimides.

Calculations of the MO of dimethylthiodiimide in terms of the CNDO/2 approximation taking into account the 3*d* AO of sulphur showed[94] that the π^* antibonding MO in this molecule is unoccupied, being only virtual (LUMO). The antibonding π^* MO in the ground state can be populated only as a result of the interaction of the group π orbitals of the NSN fragment with the group π orbitals of the aromatic rings. The existence of the π interaction of the NSN group with aromatic substituents is also indicated by the changes in the relative intensities and width of the bands in the S K_β spectra of thiodiimides with aromatic (including polyfluorinated) substituents when the groups in the 4,4'-positions in the rings are varied.[50] This interaction leads to the existence of a series of many-centre MO, embracing both the NSN fragment and the aromatic rings, i.e. to the delocalisation of the π bonding throughout the molecule, which is outwardly expressed by the ability of the thiodiimide group to transmit the electronic influences of the substituents. A study of the ^{19}F NMR spectra of the compounds C_6F_5–N=S=N–C_6H_4–X-4 showed[50] that the relative chemical shift (relative to X = H) of the signal of the *p*-fluorine atom in the pentafluorophenyl ring is satisfactorily correlated with the Hammett σ_p constant of the substituent X.

In the electronic spectra of the organic thiodiimides R–N=S=N–R the long-wavelength absorption maximum undergoes a bathochromic shift on passing from alkyl or acyl derivatives (R = alkyl, AlkOCO, or $ArSO_2$) to monoaryl and further to diaryl derivatives.[51] In a series of symmetrical diarylthiodiimides both electron donating and electron accepting substituents in the 4,4'-positions in the rings induce a bathochromic shift of the long-wavelength absorption maximum[51] (Table 3). The characteristic long-wavelength absorption bands of symmetrical diarylthiodiimides are almost insensitive to the influence of solvents, while symmetrical derivatives of the type 4-$O_2NC_6H_4N$=S=NC_6H_4X-4 and $C_6H_5SO_2N$=S=NC_6H_4X-4 exhibit negative solvatochromism.[51] The long-wavelength absorption band in the electronic spectra of compounds of the latter two types is extremely sensitive also to the character of the substituents in the aromatic rings.[109] Electron-donating substituents X shift the absorption maximum towards longer wavelengths and the magnitude of the shift of λ_{max} (relative to the λ_{max} of the analogous compound with X=H) is satisfactorily correlated with the Hammett or Taft constant for the majority of substituents X. Electron-accepting substituents X hardly influence the position of the maximum or shift it towards shorter wavelengths. On the basis of the facts described, it has been concluded[109] that the band considered is apparently associated with the electron transfer not through the entire π system of the molecule but mainly through the unoccupied 3*d* AO of the sulphur.

*In the gas phase.

An increase in the length of the sulphur–nitrogen chain is accompanied by a bathochromic shift of the long-wavelength of the absorption maximum, which has been interpreted[2] as a consequence of the increase of the electron delocalisation along the chain. λ_{max} of the long-wavelength band varies

#Provided that this result is not associated with an error in calibration. The spectrum has been calibrated[95] in accordance with the exact value $E_b(C_{1s})$ = 285.0 eV;[104] Lidy et al[81] could not deal with this question in detail. According to Lindberg and Hedman,[104] the absolute values of E_b quoted in the early studies, based on a calibration in terms of the C_{1s} line, must be increased by 1 eV. If this applies to the study of Lidy et al,[81] then the E_b for the N_{1s} level in the compounds under discussion are virtually identical.

in the range 382–413 nm for the compounds $ArSN{=}S{=}NSiMe_3$, 448–476 nm for $(ArSN{=})_2S$, and 580–587 nm for $(ArSN{=}S{=}N)_2S$. Since electron-accepting substituents in aryl rings increase slightly the bathochromic shift, the delocalisation of the π bonding apparently embraces also the aromatic rings.[2]

Theoretical interpretation of the electronic absorption spectrum of diphenylthiodiimide on the basis of the p_π model of sulphur shows that the properties of this and similar compounds described here are associated with the presence of the quasi-polymethine chromophore NSN and the idea that the 3*d* AO of sulphur are involved is not essential for their understanding.[110] The long-wavelength absorption band is associated with the $\pi \rightarrow \pi^*$ transitions. The first excited state of diphenylthiodiimide can be described, in terms of the "molecules in the molecule" method, by a superposition of the locally excited (LE) configuration of the thiodiimide group and the configuration with charge transfer (CT) from the N=S=N fragment to the phenyl group. Comparison of the calculated spectroscopic characteristics of diphenylthiodiimide and the hypothetical *N*-hydro-*N'*-phenylthiodiimides indicates the importance of the presence of two phenyl substituents in the molecule of the former compound. The study of the interaction between the LE configuration of the N=S=N group and the N=S=N–phenyl CT configuration showed that the energy level of the first excited state is split by the CT configuration with participation of the second benzene ring.[110]

The energies of the $\pi \rightarrow \pi^*$ transitions in dimethylthiodiimides, benzo-2,1,3-thiadiazole, and naphtho[1,8-*cd*]-1,2,6-thiadiazine, evaluated from the results of the calculation by the CNDO/2 method using the virtual orbital approximations for the excited states, agree directly with experiments. The inclusion of the 3*d* AO of sulphur in the basis set lowers the HOMO energy, which increases the energy of the electronic transition and impairs the agreement between the theoretical and experimental values.[111]

For organic compounds containing the thiodiimide group, non-empirical quantum-chemical calculations have not been made. According to a calculation by the CNDO/2 method with inclusion of the 3*d* AO of sulphur in the basis set, the sulphur atom in dimethylthiodiimide has an effective positive charge of 0.21 e, induced, according to the analysis of the orbital populations, by the SN π-bond.[94] According to Grunwell and Danison,[112] in the CNDO/2 calculations for *NN'*-dimethylthiodiimide and the hypothetical *NN'*-dihydrothiodiimide, the effect of the inclusion of the 3*d* AO of sulphur in the basis set is expressed predominantly by the achievement of a satisfactory agreement between the SN bond lengths and the experimental values and by the stabilisation of the planar conformation via the so-called π' bonding. The inclusion of the 3*d* AO of sulphur does not influence the symmetries of the HOMO and the LUMO, but the geometrical isomerism does affect the symmetry of the HOMO.[113]

According to a calculation in terms of the CNDO/2 approximation, without taking into account the 3*d* AO of sulphur,[110] the distribution of electron density within the limits of the NSN fragment of diphenylthiodiimide is ylide-like but with a considerable amount of SN double bond character, which can be reproduced by a superposition of structures (2) while the valence state of the sulphur atom is intermediate between its state in the thiocarbonyl group and in the thiophen molecule. In relation to the benzene ring, the thiodiimide group in the ground state of the molecule may behave as a weak π donor.[110]

According to the same calculation,[110] the order of the SN π-bond in diphenylthiodiimide is 0.659. The study of the π-bond orders in dimethylthiodiimide and heterocycles containing the N=S=N groups such as naphtho[1,8,*cd*]-1,2,6-thiadiazine, benzo-2,1,3-thiadiazole and 2,1,3-thiadiazole in terms of the CNDO/2 approximation, with and without the inclusion of the 3*d* AO of sulphur in the basis set, has shown that, although there is a definite amount of the SN double bond character in 2,1,3-thiadiazole (the SN π-bond order is 0.428 or 0.379; here and henceforth the first value has been obtained taking into account 3*d* AO of sulphur), its structure is best described by a formula with bivalent sulphur. On passing to benzo-2,1,3-thiadiazole, the amount of the SN double bond character increases, but the SN π-bond order (0.542 and 0.481) is nevertheless lower than in naphtho-[1,8-*cd*]-1,2,6-thiadiazines (0.641 and 0.647) in which it almost agrees with the π-bond order in dimethylthiodiimide (0.651 when account is taken of the 3*d* AO of sulphur). The latter factor can be interpreted as evidence in support of the thiodiimide structure, with quadrivalent sulphur, of naphtho-[1,8-*cd*]-1,2,6-thiodiazine. When the 3*d* AO of sulphur are included in the basis set, the SN π-bond order does not change in this compound, from which it follows that the quadrivalent state of sulphur does not by itself indicate, as is usually assumed, the involvement of the 3*d* AO of sulphur in bonding.[113] Indeed the π-bond in organic thiodiimides, as well as in other heterocumulenes containing quadrivalent sulphur, is described with the aid of MO of the allyl type,[1] made up in the case of thiodiimides of the *p* AO of the nitrogen and sulphur atoms oriented at right angles to the plane of the molecule.

(b) Vibrational spectroscopic data. Special studies[77,114,115] of thiodiimides enriched with ^{15}N have shown that the stretching vibration frequencies of the SN bonds are extremely sensitive to the character of the substituents to which the thiodiimide group is linked (Table 4), but it is difficult to establish general characteristic features. Thus, on passing from dialkyl- to diaryl-thiodiimides, the symmetrical SN stretching vibration frequency falls, while the antisymmetrical frequency increases.[114] The frequency ν_{as}(SN) for dibenzoylthiodiimide is in the range of values for diarylthiodiimides, while ν_s(SN) for the benzoyl derivative is much greater than for aryl derivatives (Table 4). On passing from diaryl- to bis(polyfluoroaryl)-thiodiimides, the stretching vibration frequencies of the SN bond increase, which probably indicates an increase of the SN bond force constants and orders as a consequence of the weakening of the p_π–p_π interaction between NSN and the polyfluoroaryl group compared with the aryl group.[115]

Table 4. Vibration frequencies (cm^{-1}) of the thiodiimide group in the compounds R–N=S=N–R.

*The position of the band is difficult to determine owing to its overlap with the bands due to the polyfluoroaryl group.[115]
**Absent from the infrared spectrum.[115]

On excitation of the Raman spectrum of di-*p*-tolylthiodiimide by radiation at a wavelength of 458 nm (the maximum of the long-wavelength absorption in the electronic spectrum of this compound is at 434 nm[51]), a resonance increase in the intensities of all the bands occurs in the range 700–1400 cm^{-1},

which indicates an effective delocalisation of the π-bonding in the molecule. The intensities of the ν_s(SN) and ν_s(PhN) bands increase to the greatest extent, which indicates that the long-wavelength absorption band in the electronic spectrum of di-*p*-tolylthiodiimide is associated with a transition accompanied by an appreciable redistribution of charge between the N=S=N group and the aromatic rings.[114] This observation agrees well with the results of a theoretical interpretation of the electronic spectra of diarylthiodiimide[110] (see previous Section).

The substituents X in the compounds 4-$O_2NC_6H_4N$=S=NC_6.H_4X-4 decrease the symmetrical stretching vibration frequency of the nitro-group in their infrared spectra, while electron-accepting substituents behave in different ways—they either decrease or increase the frequency, $\Delta\nu$ being in no way correlated with the Taft constant. This led to the conclusion[109] that there is no direct transmission of the effect of the conjugation of the substituent X to the second ring via the thiodiimide group and that an interaction of this kind is limited to the sulphur atom.

From the relation between the antisymmetrical stretching vibration frequency of the nitro-group and the constant σ_p^0, the σ_p^0 for the 4-$O_2NC_6H_4N$=S=N and C_6H_5CON=S=N groups were calculated from the IR spectroscopic data for bis(4-nitrophenyl)- and *N*-benzoyl-*N'*-4-nitrophenyl-thiodiimides as 0.2 and -0.3 respectively, from which it follows that the first group is electron-accepting and the second is electron-donating in relation to the benzene ring.[78]

The inductive influence of the C_6H_5N=S=N group has been estimated from the IR spectrum of *N*-benzenesulphonyl-*N'*-phenylthiodiimide on the basis of the finding that the average stretching vibration frequency of the SO_2 group is sensitive mainly to *I* effects.[78] It was assumed that $\nu_s(SO_2)$ and $\nu_{as}(SO_2)$ are 1164 and 1248 cm^{-1} respectively. The frequency $\nu_s(SO_2)$ = 1164 cm^{-1} agrees with the results of other studies dealing with the IR spectra of *N*-arenesulphonyl-*N'*-aryl- or bis(arenesulphonyl)-thiodiimides,[65,109] but the frequency $\nu_{as}(SO_2)$ = 1248 cm^{-1} disagrees with these results. According to Wucherpfennig and Kresze,[65] $\nu_{as}(SO_2)$ in the IR spectra of thiodiimides of the type $(R-SO_2-N=)_2S$ is in the range 1340–1355 cm^{-1}, while according to Lutskii et al.[109] the band at 1330 cm^{-1} in the spectrum of *N*-benzenesulphonyl-*N'*-phenylthiodiimide is associated with $\nu_{as}(SO_2)$. The conclusion[78] that $\sigma_I \cong 0.2$ for the C_6H_5N=S=N group becomes controversial as a result of this finding.

The vibrational spectra of compounds with sulphur–nitrogen chains longer than N=S=N have not been studied systematically. If the known group frequencies of the F_3CS fragment are excluded from the IR spectrum of bis(trifluoromethanesulphonyl)thiodiimide, we find that ν_{as}(NSN) = 940 cm^{-1}, ν_s(NSN) = 651 cm^{-1}, and δ(NSN) = 503 cm^{-1}.[116] The explanation of such a marked decrease of the frequencies is based on the concept of the pulsation of the entire SNSNS fragment, in which mainly nitrogen vibrates as a consequence of the large difference between the masses and the π-electron system of the central (multiple) SN bonds extend over the entire sulphur–nitrogen skeleton, which equalises the bond orders to 1.5. The appreciable decrease of the ν_{as}(SN) frequency on passing from ArSN=S=N–$SiMe_3$ (ν_{as} = 1194–1202 cm^{-1}) to $(ArSN=)_2S$ (ν_{as} = 1138–1146 cm^{-1}) and $(ArSN=S=N)_2S$ (ν_{as} = 1080–1100 cm^{-1}) has been explained analogously.[2] An alternative explanation is associated with the possible difference between the molecular geometries: if bis(arenesulphonyl)thiodiimides have the *cis,cis*-geometry, then *N*-arenesulphenyl-*N'*-trimethylsilylthiodiimides are most likely to have the *cis,trans*-geometry.[2]

The concept of the decrease of the SN vibration frequency is a consequence of the increased electron delocalisation in the sulphur–nitrogen chain with increase of its length appears attractive but apparently agrees poorly with structural data. On passing from diaryl- to bis(arenesulphenyl)-thiodiimides, the lengths of the bonds in the central N=S=N units hardly change and the complete equalisation of the π-bonds suggested by Haas and Schott[116] does not exist (see above).

(c) ^{15}N NMR spectroscopic data. In this Section all the chemical shifts quoted in the original studies relative to different standards have been recalculated in relation to nitromethane; the positive values correspond to upfield shifts.

The ^{14}N NMR signal of diphenylthiodiimide (solution in ether) is at ~72 p.p.m.,[117] whereas the ^{15}N NMR signal is at ~114 p.p.m. [solution in dimethyl sulphoxide (DMSO)] according to other data.[102] It is known that, within the limits of experimental error, the chemical shifts are the same for the ^{14}N and ^{15}N nuclei when the spectra are recorded under identical conditions.[118] The discrepancy between the results of Yavari et al.[102] and Mason et al.[117] is too great to be caused by the difference between the solvents, the chemical shift quoted for nitrogen in diphenylthiodiimide in these investigations is clearly erroneous. Since it is known[119–121] that certain thiodiimides interact with DMSO, the result of Mason et al.[117] appears to be less reliable.

Comparison with the closest analogues, namely *N*-sulphinylarylamines, has shown that the NMR signals of nitrogen in the spectra of diarylthiodiimides are located in a somewhat higher field. For example, the ^{14}N NMR signal of diphenylthiodiimide has undergone an upfield shift relative to the signal of *N*-sulphinylaniline by approximately 18 p.p.m.[117,122] It is of interest to note that the chemical shift of the ^{14}N NMR signal in the spectrum of diphenylthiodiimide is the same as that of pyrimidine.[117]

On passing from diphenylthiodiimide to *N*-pentafluorophenyl-*N'*-phenylthiodiimide and further to bis(pentafluorophenyl)thiodiimide, the ^{15}N NMR signal undergoes an upfield shift.[50] Analogous shifts on passing from hydrocarbon analogues to perfluorinated derivatives are observed also for many other classes of aromatic nitrogen-containing compounds.[50,123,124] Comparison of ^{15}N NMR and S K_β spectroscopic data for thiodiimides has shown that the chemical shift of the nitrogen signal is influenced primarily by the changes in the character of the interaction of the nitrogen atom with aromatic rings and not with sulphur atoms.[50] According to a calculation in terms of the CNDO/2 approximation[110] and ^{13}C NMR data,[125] the thiodiimide group is electron-donating in relation to the benzene ring ($\sigma^+ = -0.1$ for the C_6H_5N=S=N group[125]). The weakening of the p_π–p_π interaction of the NSN group and the aromatic rings on passing from diaryl- to bis(polyfluoroaryl)-thiodiimides[50,115] therefore entails an increase of π-electron density at the nitrogen atom. An increase of electron density (negative charge) on the nitrogen atom leads to a decrease of the absolute value of the paramagnetic term in the expression for the shielding constant and hence to an increase of the shielding and an upfield shift of the ^{15}N NMR signal.[118]

Table 5. The constants σ_R^0 and σ_I of complex substituents R containing the thiodiimide group.*

C_6F_5NSNS	0.10	−0.08			

*According to the data of Brands and Golloch.[127]

Apart from the effective atomic charge, the chemical shifts of nitrogen depend on the average energy ΔE of the electronic excitations which correspond to the circulation of the electron around the nucleus when the electron is described by a point charge. In this case the lower ΔE, the greater the deshielding. The energy ΔE can be estimated from the energy of the long-wavelength bands in the electronic absorption spectra associated with the $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions.[123] The additional stabilisation of the σ MO of planar molecules or groups relative to π MO when the hydrogen atoms are fully substituted by fluorine (the "perfluoro-effect") leads to a hypsochromic band shift in the electronic absorption spectra caused by the $\sigma \rightarrow \pi^*$ and $n \rightarrow \pi^*$ excitations.[123,126] On passing from diphenyl- to bis(pentafluorophenyl)-thiodiimide, the long-wavelength absorption band in the electronic spectrum shifts towards shorter wavelengths (Table 3). This band is usually attributed to $\pi \rightarrow \pi^*$ excitations[110,111] but in the spectra of diaryl- and bis(polyfluoroaryl)-thiodiimides it is fairly broad and apparently can mask the band associated with the $n \rightarrow \pi^*$ excitations. If this is indeed so, on passing from diphenyl- to bis(pentafluorophenyl)thiodiimide, ΔE increases, which also leads to an upfield shift of the ^{15}N NMR signal.

(d) Data obtained by other methods. The constants σ_R^0 and σ_I presented in Table 5 have been calculated from the ^{19}F NMR spectroscopic data for thiodiimides containing the pentafluorophenyl substituent.[127]

Compounds of the type $C_6H_5SO_2N{=}S{=}NC_6H_4X\text{-}4$, $4\text{-}O_2NC_6H_4N{=}S{=}NC_6H_4X\text{-}4$, $(ArN{=})_2S$, and $C_6H_5CON{=}S{=}NAr$ have been investigated by the method of dipole moments.[18,109] The results were interpreted on the assumption that the molecules exist either in the *cis,cis*-configuration[109] or *trans,trans*-configurations.[78] However, thiodiimides with aromatic substituents exist in solution in the form of an equilibrium mixture of the *cis,trans*- and *trans,trans*-isomers with the *cis,trans*-isomer predominating.[48] This finding casts doubt on the conclusions[78,109] based on the study of the dipole moments.

In the mass spectrum of the *N*-pentafluorophenyl-*N'*-phenylthiodiimides the peaks of the $C_6F_5N^+$ and $C_6H_5NS^+$ ions predominate over the peak of the $C_6F_5NS^+$ ion. Such fragmentation is explained by the powerful polarising action of the pentafluorophenyl group, which weakens one of the sulphur–nitrogen bonds in accordance with the scheme[128]

$$Ph_f{-}N{=}S{=}N{-}Ph \longleftrightarrow Ph_f{-}\bar{N}{-}\overset{+}{S}{=}N{-}Ph \dashrightarrow \xrightarrow[-2e^-]{+e^-} Ph_f{-}\dot{N}{-}\overset{+}{S}{=}N{-}Ph\,.$$

IV. CHEMICAL PROPERTIES

The most characteristic reactions of organic compounds containing the thiodiimide group are those with nucleophiles and cycloaddition. The reactivity of the N=S=N fragment depends significantly on the character of the groups linked to it and as a rule decreases with increasing electronegativity of the latter. According to frontier orbital theory, in the reactions of nucleophiles with electrophiles (in the given case with thiodiimides) the interaction of the HOMO of the nucleophile with the LUMO of the electrophile is most important.[129] However, the excited states of the molecules of organic thiodiimide have been scarcely investigated. Different conclusions about the true mechanisms of many reactions with their participation are therefore at present hardly possible. In particular, one cannot rule out the possibility that not all reactions with what are formally nucleophiles do indeed involve nucleophilic attack on the sulphur atom of the thiodiimide group. It is extremely likely that many reactions of thiodiimides proceed with the intermediate participation of thionitroso-compounds.

It has been shown for a large number of examples[130] that the chemical properties of organic thiodiimides are close to those of sulphur dioxide and *N*-sulphinylamines. At first sight, this is entirely natural, since both thiodiimides and *N*-sulphinylamines are aza-analogues of SO_2. On the other hand, it has been shown that the positive charges on the sulphur atoms and the distribution of the 3*p* electrons of sulphur among the MO are appreciably different for SO_2, *N*-sulphinylarylamines, and thiodiimides with aromatic substituents at the nitrogen atom.[131] Hence, one may imagine that the properties of the excited states can also differ and one should therefore expect some differences in reactivity. The latter do indeed exist. For example, whereas tris(trimethylstannyl)amine forms an adduct with bis(pentafluorophenyl)-thiodiimide,[132] in its reaction with *N*-sulphinylpentafluoroaniline it forms *NN*-bis(trimethylstannyl)pentafluoroaniline and trimethylstannylthionylimide.[83]

1. Thermolysis

Dimethylthiodiimide decomposes slowly even at room temperature.[16,17] The t-alkyl derivatives are more stable. The pyrolysis of di-t-butylthiodiimide at 265 °C results in a 60% yield of isobutene. The reaction is apparently concerted. The pyrolysis of diphenylthiodiimide at 200 °C affords azabenzene with a 66% yield.[133] It has been suggested that this reaction takes place with participation of a thiadiazirine intermediate.[113] The thermolysis of bis(2,4-di-t-butyl-6-methylphenyl)thiodiimide in boiling benzene leads to the corresponding arylamine and benzothiazole.[59]

2. Interaction with Nucleophiles

All organic thiodiimides tend to hydrolyse; the hydrolysis products are the corresponding amines or amides and sulphur dioxide. Bis(arylsulphenyl)thiodiimides, whose hydrolysis leads to arenethiols, sulphur dioxide, and ammonia are an exception.[134] The hydrolytic stability of thiodiimides decreases with enhancement of the electron accepting properties of the substituents at the N=S=N groups. Thus bis(arenesulphinyl)- and bis(alkoxycarbonyl)-thiodiimides are readily hydrolysed even by atmospheric moisture,[64,79] while bis(pentafluorophenyl) thiodiimide hydrolyses faster by more than an order of magnitude than bis(4-chlorophenyl)-thiodiimide under identical conditions.[49]

The interaction of bis(benzenesulphonyl)thiodiimide with aliphatic alcohols yields esters of *NN'*-bis(benzenesulphonyl)-amidoiminosulphurous acid.[135] Ditosylthiodiimide interacts analogously with benzyl alcohol and oximes. In this case the esters formed are unstable and decompose giving rise to the final reaction products:[136]

$$(TosN{=})_2S \begin{cases} \xrightarrow{PhCH_2OH} TosN{=}S(HNTos)OCH_2Ph \rightarrow \\ \qquad \rightarrow TosNSO + PhCH_2NHTos; \\ \xrightarrow{PhCH{=}NOH} TosN{=}S(HNTos)ON{=}CHPh \rightarrow \\ \qquad \rightarrow TosNSO + TosNH_2 + PhCN; \\ \xrightarrow{Ph_2C{=}NOH} TosN{=}S(HNTos)ON{=}CPh_2 \rightarrow \\ \qquad \rightarrow TosNSO + PhC(=NPh)HNTos. \end{cases}$$

Ditosylthiodiimide interacts with aliphatic sulphides, including cyclic sulphides, as nucleophiles. The products are the corresponding *SS*-dialkyl-*N*-tosylsulphimines and elemental sulphur.[137]

Bis(arenesulphonyl)thiodiimides react with compounds containing the O=X bond (X = C, S, P, or As):[120]

$$(ArSO_2{-}N{=})_2S \xrightarrow{-SO_2}$$

$\xrightarrow{Ar'CHO}$ $Ar'CH{=}N{-}SO_2Ar$;

$\xrightarrow{PhCONMe_2}$ $PhC(=N{-}SO_2Ar)NMe_2$;

$\xrightarrow{HCONMe_2}$ $Me_2NCH{=}N{-}SO_2Ar$;

$\xrightarrow{Me_2SO}$ $Me_2S{=}N{-}SO_2Ar$;

$\xrightarrow{R_3PO}$ $R_3P{=}N{-}SO_2Ar$;

$\xrightarrow{Ph_3AsO}$ $Ph_3As{=}N{-}SO_2Ar$;

R=Me, Et, Ph.

Dibenzoylthiodiimide reacts analogously with DMSO.[121] The interaction apparently begins with nucleophilic attack by the O atom of the O=X group on the S atom of the thiodiimide group:

$$(ArSO_2N{=})_2S \xrightarrow{R_nX{=}O} \left[\begin{array}{c} ArSO_2\bar{N}{-}S{=}NSO_2Ar \\ | \\ R_n\overset{+}{X}{-}O \end{array}\right] \rightarrow$$

$$\rightarrow \left[\begin{array}{c} ArSO_2N{-}S{=}NSO_2Ar \\ | \quad | \\ R_nX{-}O \end{array}\right] \xrightarrow{-R_nX{=}NSO_2Ar}$$

$$\rightarrow [ArSO_2{-}NSO] \xrightarrow[-SO_2]{R_nX{=}O} R_nX{=}NSO_2Ar .$$

In those cases where the intermediate *N*-sulphinylamine does not react with the oxygen-containing compound, the reaction stops in the first stage. For example, the interaction of *N*-benzenesulphenyl-*N'*-phenylthiodiimide with DMSO results in the formation of *N*-benzenesulphenyl-*SS*-dimethylsulphimine and *N*-sulphinylaniline.[120] The reaction of ditosylthiodiimide with sulphoxides leads to similar products, namely *SS*-disubstituted *N*-tosylsulphimines and *N*-sulphinyltoluene-*p*-sulphonamide. The conversion of chiral sulphoxides into sulphimines in different solvents proceeds via different mechanisms. In pyridine at 0 °C the reactions are termolecular and proceed with inversion of the configuration at the sulphur atom; in benzene the reactions take place with retention of the configuration and are bimolecular.[119]

The reactivity of thiodiimides with respect to compounds having an O=X bond decreases with decreasing electronegativity of the substituents at the nitrogen atom. Thus diarylthiodiimides containing nitro-groups or chlorine atoms in the 4,4'-positions in the rings react with aldehydes like the bis(arenesulphonyl)derivatives, while diphenylthiodiimide and diarylthiodiimides containing electron-donating substituents do not react with aldehydes, sulphoxides, and phosphine oxides.[120]

Dibenzoylthiodiimide does not react with aromatic aldehydes, but in the presence of benzamide the reaction proceeds readily with formation of *NN'*-diaroylamidals. The thiodiimide behaves simultaneously as a dehydrating agent and an additional source of the amide:[121]

$$ArCHO + PhCONH_2 + (PhCON{=})_2S \xrightarrow{-SO_2} ArCH(NHCOPh)_2$$

Dibenzoylthiodiimide reacts with trichloroacetaldehyde to form *NN'*-diacetylchloral amidal. In the presence of aluminium chloride, the reaction leads to *N*-benzoylchloral imine.[121]

Phosphine sulphides and dialkylthioamides of carboxylic acids react with bis(arenesulphonyl)thiodiimides like the corresponding oxygen-containing compounds to form phosphazo-compounds or amidines. On reaction with bis(arenesulphonyl)thiodiimides, thiobenzamide and phenylthiourea are converted into 1,2,4-thiadiazole and 1,2,4-thiadiazolidine derivatives:[120]

$$(ArSO_2N{=})_2S{-}$$

$\xrightarrow{R_3P{=}S}$ $R_3P{=}NSO_2Ar$;

$\xrightarrow{RC(=S)NR_2}$ $RC(=NSO_2Ar)NR_2$;

$\xrightarrow{PhC(=S)NH_2}$  ;

$\xrightarrow{PhHNC(=S)NH_2}$ 
NN-Dibenzoylarenesulphonamides and arenesulphonylphthalimides have been obtained respectively on heating bis(arenesulphonyl)thiodiimides with benzoic or phthalic anhydride.[120]

The reaction of bis(benzenesulphonyl)thiodiimide with dialkylamines results in the formation of dialkylammonium salts. The *NN*-dialkylamides of *N'N''*-bis(benzenesulphonyl)-amidoiminosulphurous acid are probably formed in the first stage. They have acid properties and react with a second dialkylamine molecule.[135] *N*-Aryl-*N'*-benzenesulphonylthiodiimides are symmetrised in the presence of secondary amines; the symmetrisation is accompanied by the formation of the dialkylammonium salts from the bis(benzenesulphonyl) derivative:[135]

$$PhSO_2{-}N{=}S{=}N{-}Ar \xrightarrow{Alk_2NH} (ArN{=})_2S +$$

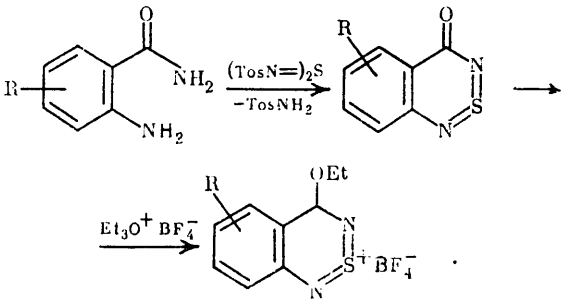
$$[(PhSO_2N)_2SNAlk_2]^- [Alk_2NH_2]^+ .$$

Tris(trimethylstannyl)amine and some of its derivatives add to bis(polyfluoroaryl)- and bis(arenesulphonyl)-thiodiimides in equimolar proportions:[132]

$$(R{-}N{=})_2S \xrightarrow{(Me_3Sn)_2NR'} \begin{array}{l} Me_3SnN\diagup R \\ \qquad\quad \diagdown S{=}NR' \\ Me_3SnN\diagup R \end{array} ;$$

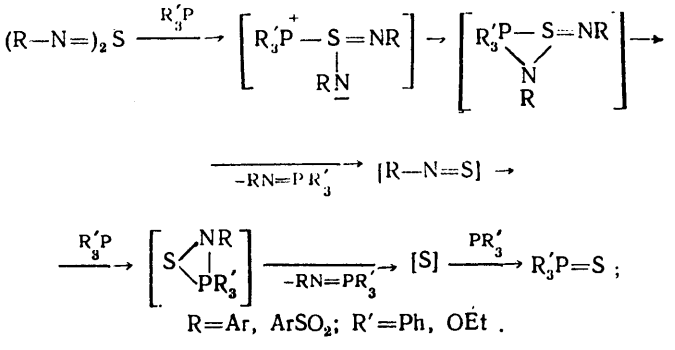
R=C_6F_5, R'=Me_3Sn, Me, C_6F_5; R=4-$ClC_6H_4SO_2$, R'=Me.

The interaction of thiodiimides with aromatic amines was examined above (see Section II). The reaction of bis(benzenesulphonyl)thiodiimide with *o*-phenylenediamine leads to benzo-2,1,3-thiadiazole.[61] Substituted 2-amino-benzamides interact with ditosylthiodiimide to form cyclic products whose alkylation gives rise to benzo-2,1,3-thiadiazinium salts:[138]

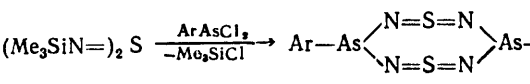


Bis(arenesulphonyl)- and diaryl-thiodiimides react with phosphines and phosphites. The interaction of bis(arenesulphonyl)thiodiimides and diarylthiodiimides containing electron-accepting substituents in the ring with triphenylphosphine leads to triphenylphosphine sulphide and phosphazo-compounds.[120] On heating with triphenylphosphine, *N*-t-butyl-*N'*-trimethylsilylthiodiimide decomposes analogously to the corresponding iminophosphoranes and phosphine sulphide.[33] The reactivity of thiodiimides towards phosphines diminishes with increasing electronegativity of the substituents at the nitrogen atoms. Thus triphenylphosphine reacts exothermically with bis(arenesulphonyl)thiodiimides, while the reaction with bis(4-nitrophenyl)thiodiimide takes place only on heating. Diarylthiodiimides containing electron-donating substituents do not react with triphenylphosphine.[120]

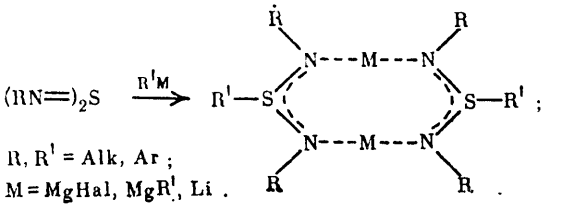
The interaction of bis(arenesulphonyl)- and diaryl-thiodiimides with phosphites is accompanied by the formation of phosphorothioates and phosphazo-compounds.[43,120] The initial stage of the reaction of bis(arenesulphonyl)- and diarylthiodiimides with phosphines and phosphites apparently consists in the nucleophilic attack by the phosphorus atom on the sulphur:[43,120]



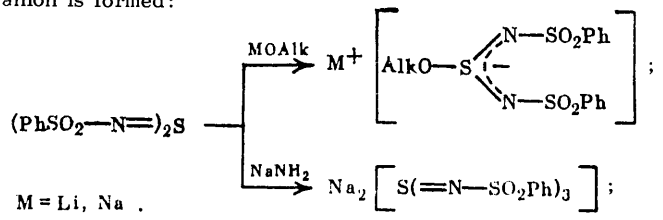
The reaction of triphenylphosphine with dibenzoylthiodiimide takes place differently and leads to benzonitrile, elemental sulphur, and triphenyl-phosphine oxide.[121] The interaction of bis(trimethylsilyl)thiodiimide with phenyl- and mesityl-dichloroarsines leads to the corresponding dithiatetrazadiarsocines:[139]



Organomagnesium and organolithium compounds add quantitatively to dialkyl- and diaryl-thiodiimides. This reaction has been used as the basis of a convenient method for the quantitative analysis of organometallic compounds:[140]

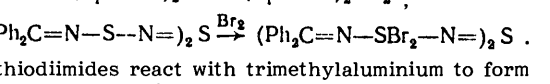


Bis(arenesulphonyl)- and bis(trifluoromethanesulphonyl)-thiodiimides react with lithium and sodium alkoxides to form stable salts of anions and contain a tricoordinate sulphur atom according to X-ray diffraction data. The interaction with dry CsF proceeds analogously. When bis(benzenesulphonyl)thiodiimide is treated with sodium amide, a stable salt containing the tris(benzenesulphonylimido)sulphide anion is formed:[141]



3. Interaction with Electrophiles

When thiodiimides are allowed to react with fluorine, the *SS*-difluoro-derivatives are obtained.[142] Bromination of 1,5-bis(diphenylmethyleneamino)trithiodinitride takes place apparently in the 1,5-positions in the sulphur–nitrogen fragment:[69]

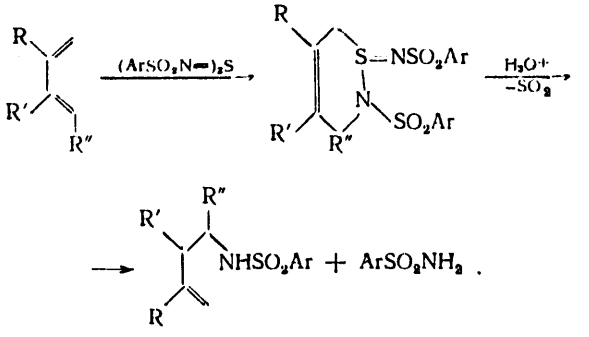


Diarylthiodiimides react with trimethylaluminium to form complexes of the type $\{Me_2Al[ArNS(Me)NAr]\}_2$, in which the sulphur atom is methylated.[143]

4. Cycloaddition Reactions

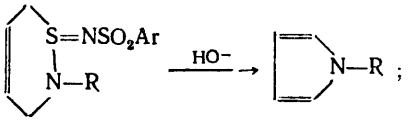
Organic thiodiimides are capable of undergoing the $[4\pi + 2\pi]$ and $[2\pi + 2\pi]$-cycloaddition reactions. The former are represented by the 1,4-cycloaddition to 1,3-dienes and the 1,3-cycloaddition to diphenylketen and the latter by the 1,2-cycloaddition to heterocumulenes and olefins.

Bis(arenesulphonyl)thiodiimides react exothermically with 1,3-dienes at room temperature to form 1-arenesulphonyl-imino-2-arenesulphonyl-3,6-dihydro-1,2-thiazines.[64,65,144] Acid hydrolysis of the adduct affords arenesulphonamides, sulphur dioxide, and arenesulphonyliminobut-3-enes:[144]



Bis(alkoxycarbonyl)- and diaroyl-thiodiimides react analogously with dienes.[77,79]

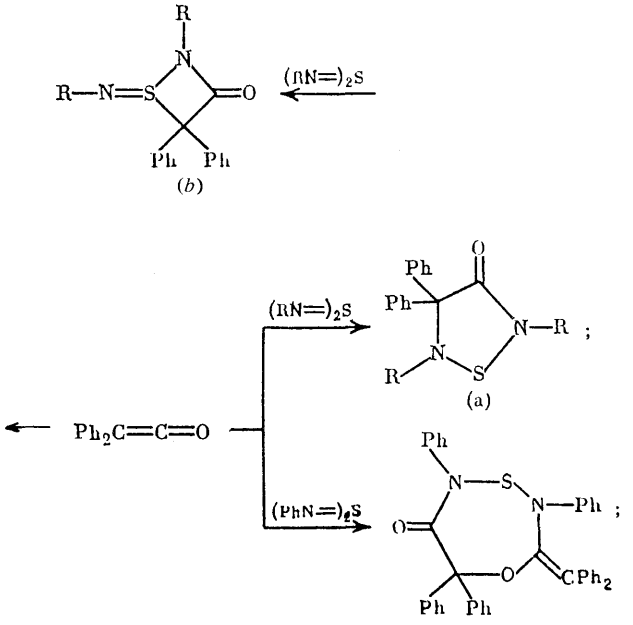
Asymmetric thiodiimides having non-equivalent SN bonds, for example *N*-alkyl- and *N*-aryl(heteryl)-*N'*-arenesulphonylthiodiimides react only via the SN bond remote from the sulphonyl group.[63,80,145] Acid hydrolysis of thiazines proceeds in the same way as for 2-arenesulphonyl- and 2-alkoxycarbonyl-derivatives, but treatment of 1-arenesulphonylimino-2-aryl(heteryl)-3,6-dihydro-1,2-thiazines with an alcoholic solution of alkali makes it possible to obtain *N*-arylpyrroles[145] and 2-(1-pyrrolyl)pyridines:[63]



R=Ar, 2-Py .

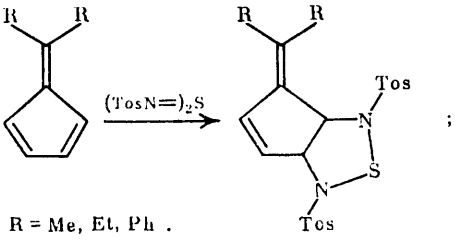
The rate of reaction of thiodiimides with 1,3-dienes depends on the character of the substituent at the nitrogen atom. Whereas bis(arenesulphonyl)thiodiimides react with evolution of heat, *N*-aryl-*N'*-arenesulphonylthiodiimides react only on heating. Electron-accepting substituents in the aryl group accelerate the reaction, while electron-donating substituents retard it.[145] Dialkyl-, diaryl-, and *N*-alkyl-*N'*-bromo-, and *N*-benzenesulphenyl-*N'*-benzenesulphonyl-thiodiimides do not enter into the cycloaddition reaction with 1,3-dienes.[18,68,80]

Ditosyl-, diphenyl, and bis(4-ethoxycarbonylphenyl)-thiodiimides react with diphenylketen at 70–80 °C to form 1,3-adducts with reduction of sulphur(IV) to sulphur(II)—2,5-diaryl[bis(arenesulphonyl)]-3,3-diphenyl-1,2,5-thiadiazolidin-4-ones are formed.[146–148] At −15–0 °C the reaction of diphenylketen with ditosylthiodiimide and di-t-butylthiodiimide proceeds as 1,2-cycloaddition,[146,148] while the reaction with diphenylthiodiimide at 6–8 °C results in the formation of perhydro-2-diphenylmethylene-3,5,7,7-tetraphenyl-1,4,3,5-oxathiadiazepin-6-one, whose structure has been confirmed by X-ray diffraction:[148]



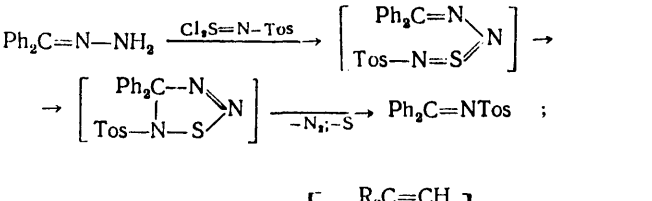
(a) R = Tos, Ph, 4-EtOCOC$_6$H$_4$;
(b) R = Tos, t-Bu.

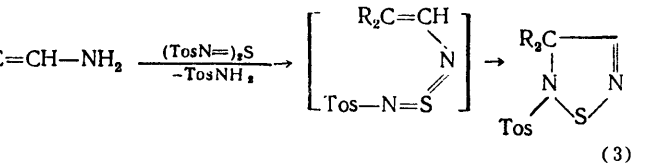
Di-t-butylthiodiimide reacts with dichloroketen at 70 °C to form a 1,2-cycloaddition product.[149] Dialkyl- and diarylthiodiimides react with bis(trifluoromethyl)thioketen to form the corresponding keten imines. No data confirming the mechanism have been obtained, but one cannot rule out the possibility that the reaction proceeds via five- or four-membered rings—the products of the initial cycloaddition of the thiodiimides.[150] Ditosylthiodiimide enters into a 1,3-cycloaddition reaction with 6,6-disubstituted fulvenes at −10–−15 °C:[151]



R = Me, Et, Ph .

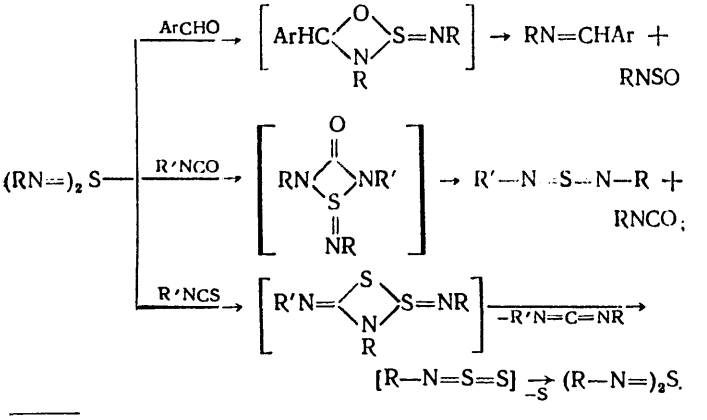
An unusual intramolecular 1,3-cycloaddition of the thiodiimide group to the azomethine bond probably takes place in the reaction of *SS*-dichloro-*N*-tosylsulphimine with benzophenone hydrazone, which leads to a Schiff base, elemental nitrogen, and sulphur.[152] The reaction [153]





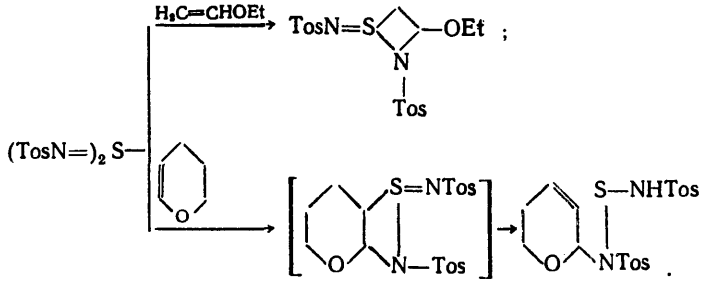
(3)

probably includes the transamination and intramolecular cycloaddition stages. Certain reactions of di-t-butylthiodiimide, such as those with aldehydes,§ isocyanates, and isothiocyanates probably proceed via the [2π + 2π]-cyclo-addition stage. The cyclic adducts decompose in such a way that fragment exchange reactions are observed ultimately:[154]

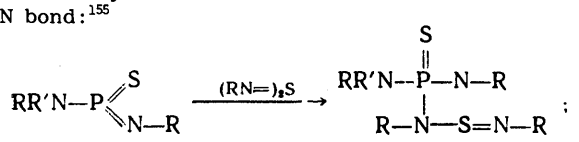


§ Levchenko and Ugarov[120] regard this reaction as nucleophilic (see Subsection 2).

Yet another example of 1,2-cycloaddition is provided by the reaction of ditosylthiodiimide with "electron-rich" olefins (vinyl ethers):[1,137]

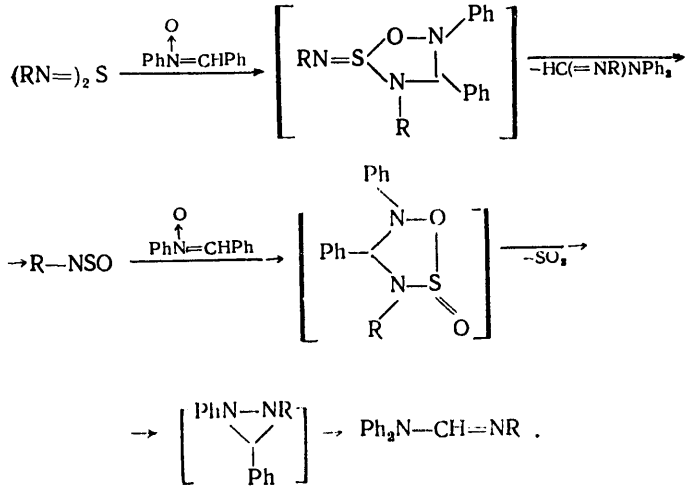


It is of interest to note that thiodiimides undergo 1,2-cycloadditon not only to a carbon–carbon double bond but also to a P=N bond:[155]

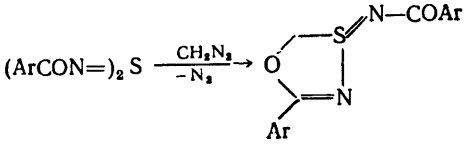


R = t-Bu, R′ = Me_3Si .

Bis(arenesulphonyl)- and dibenzoyl-thiodiimides readily react with *CN*-diphenylnitrone to form respectively *N*-arenesulphonyl-*N′N′*-diphenylformamidines[120] and *N*-benzoyl-*N′N′*-diphenylformamidines.[121] One cannot rule out the possibility that the reaction begins with 1,3-dipolar cycloaddition of the nitrone at the thiodiimide group and involves subsequent decomposition of the adduct:



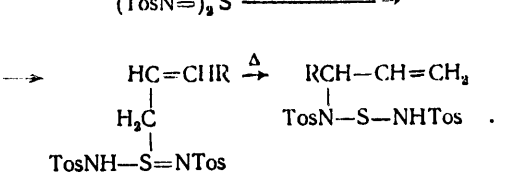
The reaction of diaroylthiodiimides with diazomethane, leading to 3-aroylimino-5-aryl-1,3,4-oxathiazolines,[156] probably includes cheletropic cycloaddition of singlet carbene to the quasi-buta-1,3-diene system formed by the C=O and S=N bonds of the initial thiodiimide:



Theoretical study of the cycloaddition reactions of thiodiimides has shown that the thermal 1,4- and 1,3-cycloaddition reactions are symmetry-allowed; the 1,2-cycloaddition is symmetry-allowed only for the *cis,trans*-isomer and can take place via the overlap of the HOMO of the thiodiimide and the LUMO of the olefin.[113]

5. The Ene Synthesis

Ditosylthiodiimide reacts with many alkenes to form allylsulphinamides capable of undergoing a 2,3-sigmatropic rearrangement on further heating:[119,157,158]

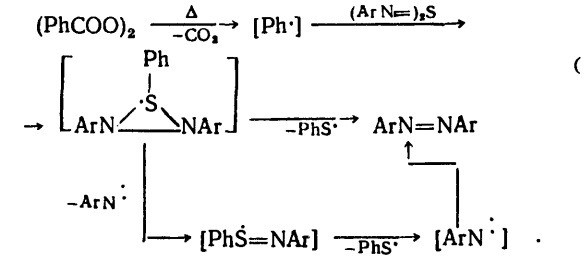


The relative reactivities of ene compounds and the regio- and stereo-selectivity of the reaction have been studied in detail.[158] The preparative application of this reaction for the synthesis of primary allylamines has been examined in a review.[159]

6. Interaction with Free Radicals

Di-t-butylthiodiimide readily combines with radicals of the type $R_n\dot{M}$ [for example, $F_3\dot{C}$, $Me_3\dot{S}i$, $(n\text{-}Bu)_3\dot{S}$, $F_3C\dot{S}$, and $(EtO)_2\dot{P}O$] with formation of the relatively stable nitrogen-centred radical t-Bu$\dot{N}$SN(Bu-t)MR_n.[160]

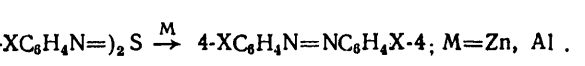
The interaction of diarylthiodiimides with the phenyl radical proceeds differently when equimolar amounts of benzoyl peroxide and the thiodiimide are refluxed in benzene. The reaction leads to biphenyl, diphenyl disulphide, and the corresponding azo-compound. The mechanism proposed for it is illustrated in Scheme (4). Arylnitrenes also participate in the reaction to a slight extent:[161]



(4)

7. Elimination of Sulphur by Metals

The reaction of diphenylthiodiimide with metals leads to azobenzene, probably via an intramolecular pathway, since a mixture of analogues (with X=X and X=Ph in the Scheme presented below) gives rise to azobenzene and 4,4′-diphenylazobenzene; 4-phenylazobenzene is not then formed:[41]



8. Oxidation

When *N*-2-nitrobenzenesulphenyl-*N'*-tosylthiodiimide was oxidised with lead tetraacetate, potassium permanganate, or selenium dioxide, toluene-*p*-sulphonamide and bis(2-nitrophenyl) disulphide were identified.[68] The interaction of dimethyl- and di-t-butyl-thiodiimides with ozone yielded the corresponding nitroalkanes and *N*-sulphenylalkylamines:[25]

$$(AlkN{=})_2S \xrightarrow{[O_3]} AlkNO_2 + AlkNSO\ .$$

9. Reduction

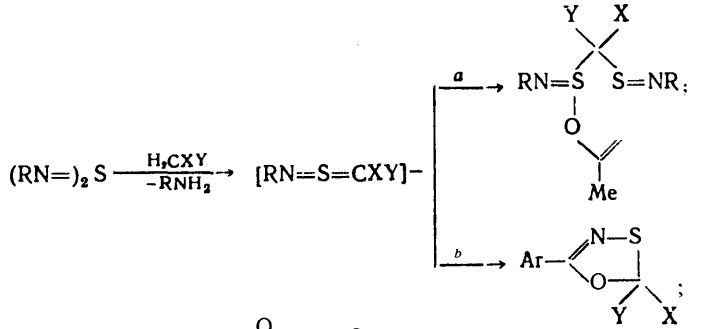
NN'-Bis(arenesulphonyl)-, *NN'*-diaroyl-, and *N*-aryl-*N'*-benzene-sulphonyl-thiodiimides are readily reduced by thiophenols:[136,162]

$$R{-}N{=}S{=}N{-}R' \xrightarrow[-(ArS)_2]{ArSH} R{-}NH{-}S{-}NH{-}R'\ .$$

Ditosylthiodiimide is also reduced to bis(*N*-tosylamino)sulphane by hyrazobenzenes, hydroquinone, catechol, and dihydronaphthalenes—in most cases under mild conditions.[136]

10. Interaction with CH-acids

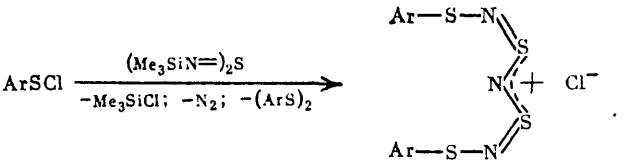
NN'-Bis(arenesulphonyl)thiodiimides react with acetylacetone in acetoacetic and malonic esters in proportions of 1:1 to form 4,6-bis(arenesulphonylimino)-3-oxa-4,6-diathiacyclohex-1-enes.[163] When dibenzoylmethane is treated with bis(benzenesulphonyl)thiodiimide, tetrabenzoylthiirane is obtained,[163] while treatment of 5,5-dimethylcyclohexane-1,3-dione (dimedone) with the same thiodiimide affords compound (I).[164] CH-acids with lower pK_a, for example, malonodinitrile or bis(arenesulphonyl)methanes, do not react with bis(arenesulphonyl)thiodiimides.[163] The reaction of diaroylthiodiimides with acetylacetone, dibenzoylmethane, and dimedone gives rise to 1,3,4-oxathiazole derivatives.[165] It has been suggested[163–165] that *S*-imides are present as intermediates in these reactions:



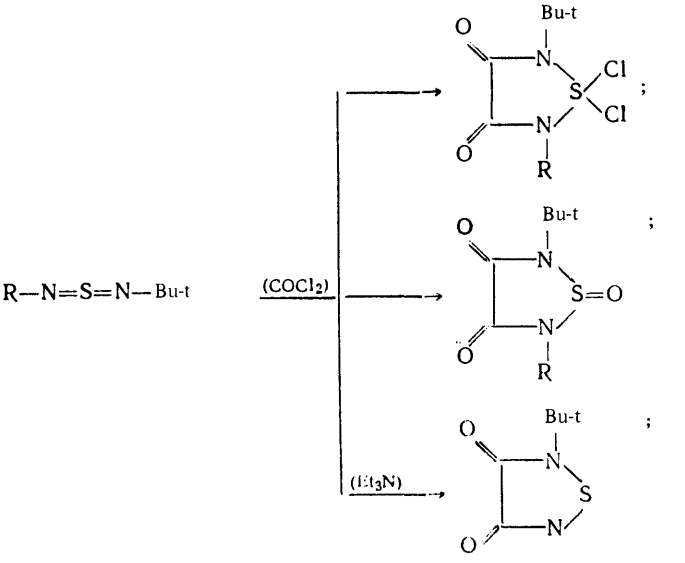
a) R=ArSO$_2$; X=Y=COMe; X=COMe, Y=CO$_2$Et
b) R=ArCO; X=Y=COMe; X=Y=COPh .

11. Other Reactions

Bis(trimethylsilyl)thiodiimide interacts with 4-tolyl- and 4-chlorobenzenesulphenyl chlorides to form the corresponding 1,7-diaryltetrathiotrinitride cations, diaryl disulphide, and molecular nitrogen:[166]



The reaction of thiodiimides with oxalyl chloride in absolute CCl_4 with cooling leads to 1,1-dichloro-2,5-diorganyl-1,2,5-thiadiazolidine-3,4-diones.[167] When the reaction was carried out without cooling, 2,5-diorganyl-3,4-dioxo-1,2,5-thiadiazolidine 1-oxides were obtained, while in the presence of triethylamine the product was 2,5-diorganyl-3,4-dioxo-1,2,5-thiadiazolidines:[168]



R=Ph, t-Bu.

The molecular ions derived from diaryl-, *N*-pentafluorophenyl-*N'*-phenyl-, and bis(pentafluorophenyl)-thiodiimides cyclise according to mass-spectrometric data, losing the *ortho*-substituent in the aromatic ring and forming ions of the benzothiadiazole type with an even number of electrons.[128,169] Diphenylthiodiimide also eliminates sulphur, apparently from the thiadiaziridine isomer of the molecular ion with formation of an azobenzene molecular ion.[128,169] Molecular ions derived from compounds with longer sulphur–nitrogen groups, namely –S–N=S=N– and –S–N=S=N–S–, are fragmented both by the direct cleavage of the sulphur–nitrogen chain and after an intramolecular rearrangement, which leads to the formation of four- and five-membered rings. The contribution of the direct fragmentation increases with increasing length of the sulphur–nitrogen chain. The transition from phenyl derivatives to pentafluorophenyl derivatives has a relatively weak influence on the principal fragmentation reactions, despite the large chemical difference between the C_6H_5 and C_6F_5 groups.[126]

Thus the chemistry of organic compounds containing the thiodiimide group constitute an interesting and developing branch of modern organoelemental chemistry. Further development of this field will probably be associated with the study of compounds containing long acyclic sulphur–nitrogen fragments and also with the synthesis and investigation of the chemical properties of selena- and tellura-analogues of organic thiodiimides, about which little is known at present (see, for example, Refs.121 and 170–172).

Physicochemical Aspects of the Conversion of Proteins into Food Products

V.B.Tolstoguzov, E.E.Braudo, V.Ya.Grinberg, and A.N.Gurov

A general physicochemical approach to the problem of the conversion of protein into food products is examined. The results of studies on processes involving the formation of gels from proteins and polysaccharides—the principal macromolecular components of food—are analysed. The phenomena involving the non-equilibrium formation of complexes by proteins and anionic polysaccharides as well as the limited thermodynamic compatibility in protein-polysaccharide-water and protein-protein-water systems are discussed. The applied aspects of the phenomena indicated are briefly noted.
The bibliography includes 127 references.

CONTENTS

I. Introduction 1025
II. The formation of gels from proteins and polysaccharides 1026
III. Complex formation in solutions of proteins and anionic polysaccharides 1032
IV. Thermodynamic compatibility of proteins and polysaccharides in solution 1034

I. INTRODUCTION

The conversion of proteins and other foods into high quality food products is carried out to ensure a wide-scale application of these substances in man's diet. The preparation of new forms of food (NFF), i.e. food products manufactured by the industrial processing of natural foods, has developed vigorously in recent years.[1] The problem of the economically rational employment of traditional and non-traditional food resources has been solved thereby. The problem of the processing of proteins and polysaccharides as the principal macromolecular components of food belongs to the field of the physical chemistry of polymer solutions; it also has a direct bearing on the modelling of multicomponent biopolymer systems and in addition on the synthesis and employment of polymers for medical purposes.

The questions associated with the conversion of protein into various forms of food can be divided into two groups: (1) structure formation in proteins mixed with other foods in order to obtain food products with a specified structure and physicochemical properties; (2) the imparting of the necessary colour, flavour, and smell to the products with the aid of food dyes and flavouring and aromatic agents and also their enrichment in aminoacids, vitamins, and other essential dietary factors.

This subdivision is, however, arbitrary because the flavour, colour, and smell of a product are associated with its structure and physicochemical properties. Thus the perception of taste arising when food is eaten depends on its mechanical properties, swelling, syneresis, wetting, etc. The vapour pressure of aromatic substances over a food product is determined to a large extent by the sorption of the substances in the bulk of the lipid and aqueous phases, including solubilisation by proteins, and also on the internal and external interfaces. It is natural that the introduction of various additional components into the product can induce the desorption of aromatic, flavouring, and dyeing agents and can alter the structure and physicochemical properties of the product.

In this review only problems concerning the first group, i.e. the physicochemical aspect of the conversion of the protein into NFF will be examined. These questions are analysed from the standpoint of the general physicochemical approach to the problem of the processing of protein developed during recent years. The development of this approach was based on two self-evident considerations. Firstly, food products are multicomponent systems and, secondly, in most cases they are solids and at the same time contain a large amount of water (more than 50%). This is a combination of composition and properties characteristic of gels. In other words, the majority of solid food products can be regarded as gels of proteins and other foods from the physicochemical standpoint. Hence it follows that the principal task faced by investigators is to obtain gels with the necessary composition, structure, and physicochemical properties.[1]

However, it appeared necessary to supplement this general physicochemical task by two others. It is natural to wish to convert any one kind of protein into a wide assortment of food products, which necessitates the preparation of liquid and gel-forming systems with a wide variety of properties. Hence follows the task of regulating the solubility of a protein, its ability to stabilise disperse systems, its ability to form gels, etc. This complex set of physicochemical characteristics, determining the structural functions of protein in non-processed systems, is designated by the concept "functional properties of the protein".[2,3]

The converse problem, namely the preparation of a given dietary product from different proteins, is also important. The fundamental physicochemical phenomena and characteristics common to all proteins are therefore of greatest interest. Processes based on phenomena of this kind should apparently be distinguished by their simplicity, should be susceptible to technological treatment, and should be "universal with respect to the protein".

This review discusses three fundamental physicochemical phenomena underlying the modern methods for converting protein into NFF: the formation of gels from proteins, polysaccharides, and their mixtures, the formation of complexes of proteins and anionic polysaccharides, and the limited thermodynamic compatibility in solution of proteins and polysaccharides and also of proteins with one another. The applied aspects of the problem are only briefly considered in this review. They are discussed in greater detail in a monograph.[1]

II. THE FORMATION OF GELS FROM PROTEINS AND POLYSACCHARIDES

The main physicochemical task arising in the manufacture of NFF consists in the development of methods for the preparation of gels (single-phase and two-phase) with a specified and controllable composition, structure, and mechanical and other physicochemical properties.

The problem of the preparation of NFF is to some extent close in its character to other physicochemical problems arising in the manufacture of polymer articles via a solution—in particular in the processing of technical polymers.[4,5] This analogy is, however, by no means complete. In the first place the fundamental multicomponent nature of the processed food systems and of the final products, together with the wide variety of the functions performed by individual components, is responsible for the complexity and the multiplicity of aspects of the physicochemical problems associated with the regulation of the composition and properties of the products, which is not usually characteristic of technical polymers. The second important feature of food systems, which distinguishes them from technical polymers, is that in the former case the gel state is characteristic not only of the intermediates but also of the final products. Accordingly, there arises a complex set of requirements which must be met by the physicochemical properties of the finished food products as gels. These properties determine in their turn the food value and the organoleptic and technological characteristics of the products.[6]

Three types of processes for the conversion of liquid solutions of biopolymers into the gel state are used in the preparation of NFF: thermotropic, ionotropic, and lyotropic gel formation. In the first case the change in the temperature of the solution plays the main role, in the second case it is the change in the ionic composition of the system, and in the third the change in the concentration of the biopolymer. The last type of gel formation constitutes the basis of the technology of the manufacture of protein products with a porous structure, but the nature of the processes occurring under these conditions has been very little studied.[6]

An example of ionotropic gel formation is the preparation of calcium alginate and pectinate gels. The technology of the manufacture of pasta, cereals, and potato products is based on these processes.[7-12] In the preparation of three-dimensional food products based on calcium alginate and pectinate gels, the main difficulty consists in ensuring the homogeneity of their structure, because the high rate of the interaction of calcium ions with the molecules of polyuronides precludes a satisfactory mixing of the reactants. The known methods for the preparation of isotropic calcium alginate and pectinate gels are apparently based on the regulation of the activity of calcium ions in the reaction system.

The ionotropic gel formation process has found a wider application in the preparation of one- and two-dimensional gels, i.e. fibres and films.[13,14] The diffusion of precipitant ions into solutions of polyuronides is used in such cases. Gels with a well developed phase structure, reproducing the structure of many biological tissues, are obtained in this way.[1,15-18] Among the methods for the ionotropic fibre formation, the matrix spinning process has been studied systematically. This procedure makes it possible to process proteins regardless of their spinnability and to regulate the functional properties of the fibres within wide limits.[19-21] The calcium ion-stabilised interfacial absorption layers containing proteins and polyuronides ensure an exceptionally high resistance of emulsified food products to coalescence.[22]

A method whereby the boundary conditions for ionotropic gel formation can be characterised has been developed.[23] It consists in the determination of the minimum concentrations of reactants sufficient to fix the shape of a drop of the polyelectrolyte solution introduced into a solution of a polyvalent metal salt. Fig.1 illustrates gel–liquid solution diagrams for sodium alginate–polyvalent metal chloride systems. At comparatively low concentrations of the cross-linking agent, namely the polyvalent metal ion, the boundary gel formation conditions are determined by the ion-exchange equilibrium constant. With increase in the concentration of the cross-linking agent, conditions are reached under which the boundary concentration of the polyelectrolyte ceases to depend on the concentration of the polyvalent metal ion. This polymer concentration has been called the "critical gel formation concentration". It apparently depends on the molecular weight and the conformation of the macromolecules. The method indicated is particularly convenient for the determination of the conditions for the formation of gels from anionic polysaccharides in the presence of proteins,[22] which is important in the solution of many applied problems, for example, in the conversion of the polysaccharide phase of a two-phase liquid protein–polysaccharide–water system into the gel state (see below).

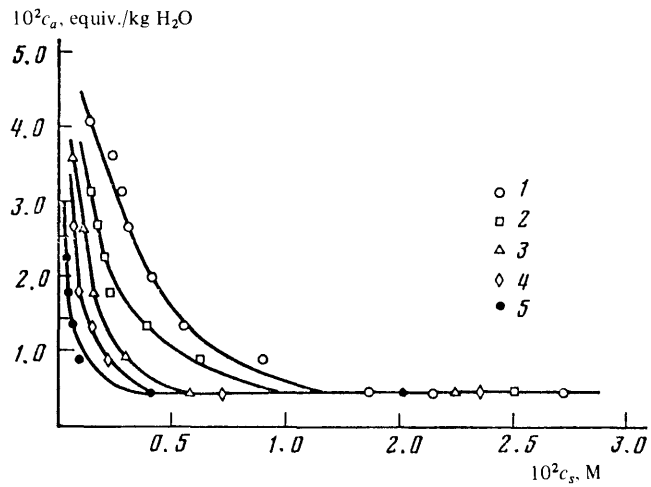

Figure 1. The boundary conditions for gel formation in the sodium alginate–polyvalent metal chloride systems;[22] c_a = concentration of sodium alginate; c_s = concentration of polyvalent metal chloride: *1*) $CaCl_2$; *2*) $SrCl_2$; *3*) $BaCl_2$; *4*) $CuCl_2$; *5*) $LaCl_3$.

Thermotropic gel formation has been investigated in relation to soya bean globulins (SBG), ovalbumin, and also gelatin and many polysaccharides. The thermotropic gel formation from solutions of proteins and polysaccharides has also been investigated, which constitutes the next step in the modelling of multicomponent food systems.[6]

1. The Thermotropic Formation of Gels from Globular Proteins

Thermotropic gel formation is a consequence of the thermal denaturation of globular proteins.[24-28] The study of the thermal denaturation of SBG in a dilute solution by the

method of precision scanning calorimetry[29] showed that the 7*S*-component of the globulin fraction denatures at lower temperatures than the 11*S*-component (Fig.2).[30] The temperature and enthalpy of the denaturation of the principal SBG components increase linearly with increased NaCl concentration. The slope of this relation (for the denaturation temperature), which is equal to the lyotropic constant K_S, is unusually high—about 20 K mol^{-1} litre^{-1}. The ratio of the lyotropic constant to the denaturation temperature, which characterises the magnitude of the lyotropic effect, increases linearly with increasing mole fraction of the hydrophobic units in the protein molecule. The unusually strong influence of NaCl on the denaturation temperature of the principal SBG components can be explained by the comparatively high content of hydrophobic units and their complete masking in the native state. The differences between the enthalpies and entropies of transport of the denatured and native forms of the principal SBG components from water to an NaCl solution are positive and also increase linearly with increasing salt concentration. This shows that the influence of the salt on the thermal denaturation of SBG is based on the decreased degree of hydration of the protein.

The influence of the gel formation conditions on the structure of thermotropic SBG gels has been investigated by the stress relaxation and electron microscopic methods.[31,32] It has been established with the aid of the multifactorial extreme experimental design method that the variation of the modulus of shear of the above gels as a function of temperature and the duration of heating has a single maximum and that its position (95° ± 5 °C; 35 ° 5 min) is independent of the protein concentration. At the same time the relaxation properties of SBG gels depend exclusively on the heat treatment temperature. The explanation is that the temperature (but not the duration) of the heat treatment determines the composition of the SBG components involved in the gel formation process.

The relaxation properties of thermotropic SBG gels can be characterised unambiguously by the parameter $\bar{H} = -[\partial F(\tau)/\partial \ln(\tau)]$, where $F(\tau)$ is the normalised relaxation function, representing the ratio of the relaxation moduli at a certain time τ and at $\tau_0 = 1$ min. In the range from 70° to 115 °C the dependence of the parameter $\bar{H}$ on the heat treatment temperature is linear (Fig.2). According to scanning calorimetric data, the content of the denatured forms of the 11*S*-globulin increases monotonically with increase in temperature over this range and hence also the degree of its involvement in the gel formation process. The deviation of the $\bar{H} = f(T)$ relation from linearity above 115 °C is apparently induced by the increasing contribution of degradative processes.

Experimental data on the isothermal stress relaxation in SBG gels at different concentrations have been generalised in the form of a concentration-invariant relaxation curve as a result of its reduction with respect to the modulus but without its reduction with respect to time.[33] Analogous results have been obtained also in the study of the rheological properties of thermotropic ovalbumin gels and also the gels of a number of anionic polysaccharides.[34] The absence of reduction with respect to time shows that the rate of relaxation processes in gels is independent of the polymer concentration, which is a characteristic of a microheterogeneous gel structure, in many respects similar to that of micellar surfactant solutions. An increase of the polymer concentration in a solution with a microheterogeneous structure leads to an increase in the number of structural elements—associated macromolecular species, without altering the composition and structure of such species. The latter factor determines the concentration invariance of the rate of relaxation processes as well as other intensive properties of the solution. Thus a study[35] of the concentration dependence of the relative activity coefficient of counterions† in solutions of anionic polysaccharides showed that, after the tentative transition to the region of semidilute solutions, this quantity becomes constant.

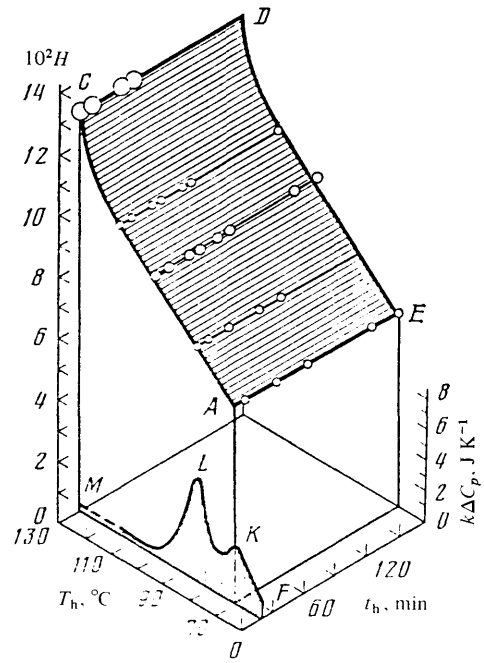

Figure 2. Dependence of the slope of the normalised relaxation function for the thermotropic gels of the globulin fraction of soya beans at 25 °C ($\bar{H}$) (left-hand ordinate axis) on the temperature and duration of the heat treatment in the gel formation process (the *ACDE* surface). Thermogram for a solution of the globulin fraction is plotted on the facing plane (the right-hand ordinate axis; k = scaling factor, the value of which is unimportant) obtained at a scanning rate of 2 K min^{-1} (the *FKLM* curve).[30]

The parameters for the reduction of the relaxation curves with respect to the modulus is proportional to the equilibrium modulus of elasticity. Operating with this parameter, it is possible to determine the scaling relations for the equilibrium modulus of elasticity despite the fact that this modulus cannot be measured for the majority of the protein and polysaccharide gels investigated owing to the low rate of the relaxation process. The concentration dependence of the equilibrium modulus of elasticity of SBG,[33] ovalbumin, as well as a gelatin and agar[36] gels is described by the theoretical Hermans relation[37] derived for a model of the gel formation process as a random reversible association of linear

† The relative activity coefficient of an ion is the ratio of its activity coefficient in the test solution to its activity coefficient in the solution of its chloride at the same equivalent concentration.

identical macromolecules without cyclisation and with formation of network nodes via a bimolecular mechanism.

Hydrophobic interactions play a leading role in the thermotropic formation of gels from SBG. Thus thermotropic SBG gels are soluble in 8 M urea solution, but are insoluble in 0.01 M solution of β-mercaptoethanol, a substance which ruptures disulphide linkages. Under the influence of urea, thermotropic SBG gels and native proteins decompose into virtually identical subunits or their dimers. On the basis of ^{1}H NMR data, it has been suggested that the packing densities of the polypeptide chains in the structural elements of gels and in the subunits of native proteins are comparable. In the 17.5% gel, one structural element consists of ~20 subunits.

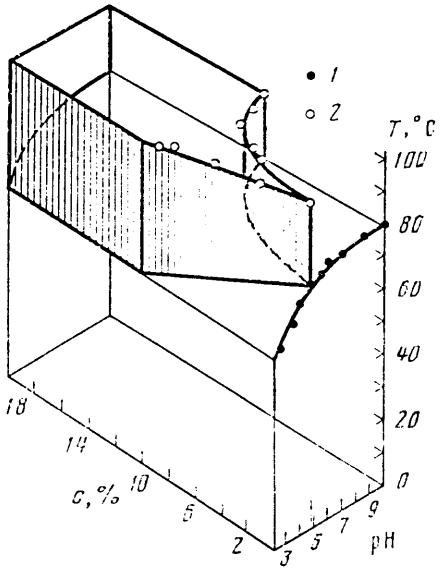

Figure 3. The phase diagram for the ovalbumin–water system at different temperatures, pH, and protein concentrations [*1*) pH dependence of the denaturation temperature; *2*) pH dependence of the gel formation threshold]; the region of the gel state is shown shaded and the isoelectric point is indicated by an arrow.

Taking into account the decisive importance of hydrophobic interactions in the formation of SBG gels, one can assume that the gel-forming capacity of these proteins is correlated with the Tanford–Bigelow hydrophobic parameter, which is defined as the average free energy for the transfer of a polypeptide chain unit from the hydrophobic interior of the protein macromolecule to an aqueous environment.[38,39] According to this criterion, the gel-forming capacity of the monomeric forms of the basic soya bean globulins should decrease in the sequence 2,8*S*-globulin > *B* > β > α > *A*, where *A* and *B* are respectively the acid and basic subunits of 11*S*-globulin and α and β are the heavy and light subunits of the 7*S*-globulin. Analysis of the sol fraction showed that the acid subunits of the 11*S*-globulin do indeed have the lowest gel forming capacity among the monomeric forms of the basic soya bean globulins and accumulate in the sol fraction during gel formation.

According to the results of Maleev and Gasan,[40] the denaturation temperature of ovalbumin gels is almost independent of the ovalbumin concentration in solution. The phase diagram for the ovalbumin–water system is illustrated in Fig.3#. The dependence of the critical gel formation concentration of albumin on the pH passes through a sharp minimum near the isoelectric point (IEP), which means that the rate of gel formation and the functionality of the ovalbumin molecules at the IEP are maximum. It is known[41] that the negative contribution of the charge fluctuations to the chemical potential of the protein in solution is significant precisely at the IEP.

As in the case of SBG gels, the dependence of the modulus of elasticity of the ovalbumin gels on the temperature and the duration of heat treatment has a single maximum§. The optimum gel formation time (30 min) is independent of pH, but the optimum temperature, which is 80 °C under conditions remote from the IEP, increases sharply in the pH range 4.0–5.5. Gels formed under conditions remote from the IEP consist of a single phase, while those produced in the vicinity of the IEP consist of two phases. Each of these groups is characterised by its own mechanical relaxation function. Since the temperature and duration of the heat treatment of the solution, the pH, and the protein concentration (*c*) influence only the equilibrium modulus of elasticity, all the relaxation curves obtained can be described by two normalised relaxation functions corresponding respectively to single-phase and two-phase gels.

The form of the generalised relaxation curve for ovalbumin gels¶ (Fig.4) makes it possible to assign these gels to the systems at the beginning of the zone corresponding to the transition from the vitreous to the highly elastic state.[42] The mechanical relaxation curves for the gelatin,[43] maltodextrin,[44] and a number of anionic polysaccharide[45–48] gels have an analogous character. The form of the relaxation curves shows that the relaxation processes localised in the associated macromolecular species making up the three-dimensional network are retarded.[34] On the other hand, during a time interval corresponding to about seven decadic orders of magnitude, the temperature-invariant relaxation curve for the SBG gel[33] has the form characteristic of amorphous cross-linked polymers at the end of the transition zone or at the beginning of the zone corresponding to the plateau.[42]

2. The Thermotropic Formation of Gels from Polysaccharides

In constrast to the formation of globular protein gels, the processes involving the thermotropic formation of polysaccharide gels are in most cases reversible. By virtue of the relative simplicity of the chemical structure of polysaccharides, an inter-relation between the chemical structure

of biopolymers of this class, their conformation, and their gel-forming capacity can be traced.[49-51] Like other thermotropic gels, particularly gelatin gels, the thermotropic polysaccharide gels are formed when the quality of the solvent is impaired. Gel formation must be preceded by a stage in which macromolecular associated species are formed and the gel is produced as a result of the combination of these species in a three-dimensional network.[52] Certain features of the relaxation behaviour of the polysaccharide gels, which follow from the gel formation mechanism described, are discussed in the previous Section.

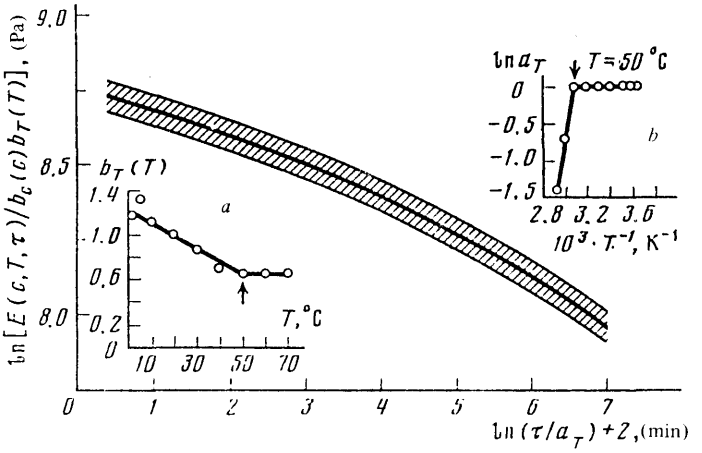

Figure 4. $c-T$ invariant generalised relaxation curve for single-phase thermotropic ovalbumin gels reduced to the state with c_0 = 10% and T_0 = 50 °C [E = relaxation modulus, c = protein concentration, T = temperature, τ = time, $b_c(c) = E(c, T, \tau)/E(c_0, T, \tau)$, and $b_T(T) = E(c, T, \tau)/E(c, T_0, \tau)$ are the parameters of the reduction of the modulus with respect to the concentration and temperature, and a_T = parameter of the reduction of time with respect to temperature]; the half-width of the shaded band is equal to the standard deviation of the experimental points from the average curve; the temperature variations of the parameters of the reduction of the modulus and time with respect to temperature are shown in the inserts *a* and *b*.

The thermotropic formation of pectin gels takes place at pH 4 in the presence of substances which reduce the activity coefficient of water (sucrose, glycerol, etc).[55] The gel-forming capacity of pectins depends critically on the degree of their esterification (DE). This dependence is determined by at least two factors: (1) the influence of the DE on the flexibility of the pectin chain, which is responsible for the possibility of the appearance of the optimum number of contact zones in gel formation; (2) the influence of the DE on the free energy of the intermolecular interactions in the contact zones. Apparently the first factor is of decisive importance, since the maximum strength and moduli or elasticity of the gels are attained for DE ≅ 50%,[56,57] i.e. when the flexibility of the pectin chain is a maximum.[35,58] The rate of gel formation for this DE is a minimum.[56] Spectroturbidimetric study of the structure of the gels showed# that, under these conditions, systems with minimum dimensions of the structural elements, which corresponds to the maximum strength of the gel, are formed (Fig.5).

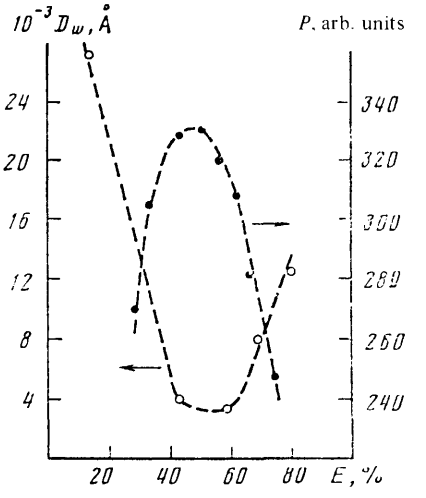

Figure 5. Dependence of the effective diameter of the structural elements (D_w) and of the stability (P)[57] of pectin gels on the degree of esterification (E) of pectin; pectin concentration 1%; pH 2.2; solvent—1:1 water–glycerol mixture.

The study of the time variation of the structure and properties of gels has shown that there exist two types of networks: the thermodynamically stable and metastable networks. The latter type includes the maltodextrin[44] and methylcellulose hydrogels†. On prolonged storage, these gels pass into a past-like state, which is manifested, in particular, by a decrease of the heat of fusion of maltodextrin gels. According to electron microscopic data,[44] the structural elements of the maltodextrin gel network rearrange after a time and form isodiametric associated species. The opposite direction of the structure-forming process has been observed for gelatin gels.[53] The stability of such gels increases with time.[54] The moduli of elasticity of pectin[45] and other anionic polysaccharide gels vary analogously. For these polymer–solvent systems, the gel state is thermodynamically stable.

†E.V.Grishchenkova, E.E.Braudo, and V.V.Tolstoguzov, Colloid and Polymer Sci., 1985, **263** (in the press).

The standard enthalpy of decomposition of the pectin gel network nodes in mixtures of water with sucrose[45] and glycerol[48] is 7–39 kJ mol^{-1}. Such low enthalpies are characteristic of solutions of semirigid-chain polymers incapable of conformational transformations under gel formation conditions. The formation of network nodes in such systems is not accompanied by appreciable losses of conformational entropy. The gel formation process therefore becomes thermodynamically favourable even for a small decrease of enthalpy. This type of gel formation has been called non-cooperative.[34]

An analogous picture has been observed for maltodextrin gels. For a 20% gel, the decomposition of the network nodes is characterised by the following thermodynamic

#I.G.Plashchina, Abstract of Candidate's Thesis in Chemical Sciences, Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow, 1984.

parameters: $\Delta H^0 = 25$ kJ mol^{-1},[34,44] $\Delta S^0_{25\,^\circ C} \cong 32$ J mol^{-1} K^{-1}; $\Delta G^0_{25\,^\circ C} \cong 15$ kJ mol^{-1}.

The formation of gels from gelatin proceeds quite differently. The standard enthalpy of decomposition of the network nodes of a 5% gel is 300 kJ mol^{-1}.[34,43] In this case (the cooperative mechanism of gel formation) the appearance of network nodes is accompanied by the formation of helices from the flexible macromolecules capable of conformational transformations. The high enthalpy of the gel formation process compensates for the large losses of conformational entropy.

Among the anionic polysaccharides investigated, the galactans converted into the sulphate form, namely κ-carrageenan and furcellaran, are conformationally labile. On cooling their solutions to room temperature, both polysaccharides undergo the coil–helix conformational transformation.[49] The formation of these polysaccharide gels is promoted by certain metal ions, including potassium ions.

In the existing theories the formation of helices from κ-carrageenan macromolecules is regarded as the primary process in gel formation,[59-61] as happens in the formation of gelatin gels.[62] The function of the metal ions promoting the formation of the κ-carrageenan gel reduces to promoting helix formation[63] and to participation in the formation of contacts between the helical sections of the macromolecules. However, it has been shown that the κ-carrageenan macromolecular associated species and gel network are formed under the influence of potassium ions above the temperature range of the coil–helix conformational transition. Thus the effective size of the κ-carrageenan macromolecular associated species does not change in the conformational transition.[64]

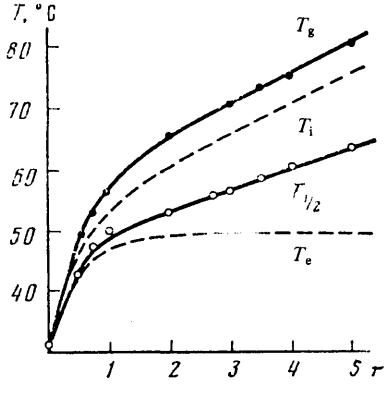

Figure 6. Dependence of the gel formation temperature (T_g) and the temperature of the onset (T_i), middle ($T_{1/2}$), and end (T_e) of the coil–helix transition of a 1.5% solution of κ-carrageenan on the KCl concentration; r = ratio of the equivalent concentrations of KCl and κ-carrageenan.

According to Plashchina et al,[46] the melting point of the 1.5% κ-carrageenan gel exceeds the temperature of its complete conversion into the helical form by 13°. Fig.6 illustrates the dependence on the KCl concentration of the gel formation temperature of the 1.5% κ-carrageenan solution and also the temperature of the onset, the middle, and the end of the coil–helix transition in this solution§. Evidently, at [KCl] > 3.7×10^{-2} M, the gel formation temperature is above the helix formation temperature range. It has been suggested that the κ-carrageenan gel network is formed as a result of the cross-linking of the polysaccharide macromolecules by the potassium ions, forming coordinate bonds with the hydroxy-groups. An essential condition in the formation of the gel network is the neutralisation of the charge of the sulphate groups by the potassium ions.

The conformational state and the stability of the conformations of the macromolecules determine the thermorheological behaviour of the κ-carrageenan gels§. Fig.7 illustrates the temperature dependence of the highest Newtonian viscosity of the 1.5% gel in terms of the variables of the De Guzman–Arrhenius equation. It is seen that the experimental temperature range can be divided into three regions:

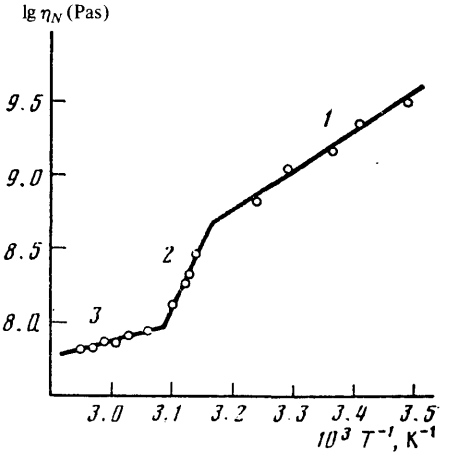

Figure 7. Temperature dependence of the maximum Newtonian viscosity (η_N) 1.5% κ-carrageenan gel.

(1) t < 41 °C—the temperature range in which the helical conformation of the macromolecules is stable (ΔH^0 = 36 kJ mol^{-1}, $\Delta S^0_{25\,^\circ C} \cong 135$ J mol^{-1} K^{-1}; $\Delta G^0_{25\,^\circ C} \cong -4$ kJ mol^{-1} [34]);

(2) 41 °C ≤ t < 52 °C—the region of the helix–coil conformational transition ($\Delta H^0 = 235$ kJ mol^{-1}; $\Delta S^0_{41\,^\circ C} \cong 775$ J mol^{-1} K^{-1}; $\Delta G^0_{41\,^\circ C} \cong -9$ kJ mol^{-1} [34]);

(3) 52 °C ≤ t ≤ 66 °C—the temperature range in which the κ-carrageenan gel network is formed by macromolecules which have lost their helical structure ($\Delta H^0 = 11$ kJ mol^{-1}).

It is seen from the thermodynamic parameters presented that in region 2 the character of the gel formation is cooperative. In regions 1 and 3 the gel formation is non-cooperative: in the former case this can be accounted for by the stability of the helical conformation, as a result of which the polysaccharide assumes the properties of a semirigid-chain polymer, while in the latter case it can be explained by the impossibility of the appearance of the helical conformation.

Apparently the higher stability of the helical conformation of furcellaran, due to the lower content of sulphate groups compared with κ-carrageenan, is responsible for the non-cooperative character of the formation of this polysaccharide gel in a mixture of sucrose (70%) and water up to 50 °C ($\Delta H^0 = 19$ kJ mol^{-1}).[34,47]

§I.G.Plashchina, I.R.Muratalieva, E.E.Braudo, and V.B.Tolstoguzov, Carbohydr.Polymers, 1985, 5 (in the press)

Thus non-cooperative gel formation is largely characteristic of the polysaccharides investigated. It has been observed for a polysaccharide with a highly rigid chain (pectin), for polysaccharides with a helical conformation stable under the experimental conditions (maltodextrin, furcellaran, and κ-carrageenan below 41 °C), and also in gel formation above the temperature range of the helix–coil transition (κ-carrageenan above 52 °C).

3. The Formation and Properties of Thermotropic Gels Containing Proteins and Polysaccharides

The following types of multicomponent gels have been differentiated:[1,65,66]

(1) Filled gels in which one of the macromolecular components functions as the gel-forming agent, while the others play the role of fillers. Gels filled with particles of a disperse phase can also be included in this group.

(2) Mixed gels in which there are two or more networks formed by different gel-forming agents. The necessary conditions for the formation of mixed gels are thermodynamic compatibility of the gel-forming agents in solution and the absence of a specific interaction between them.

(3) Complex salts whose three-dimensional network is formed by the products of the interaction of different macromolecular components.

The properties of the mixed and complex gelatin and calcium and sodium alginate and pectinate gels have been summarised in a review[66] and in a monograph.[1]

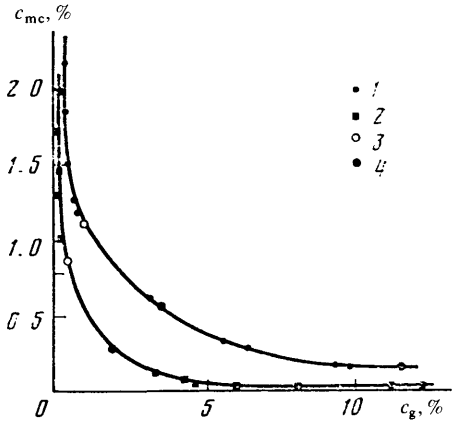

Figure 8. The phase diagram of the gelatin–methylcellulose–water system at 35 °C;[67] c_{mc} and c_g are the concentrations of methyl cellulose and gelatin: 1) binodal curve at pH 3.0; 2) binodal curve at pH 4.75 (isoionic point of gelatin); 3) threshold point; 4) critical point.

The formation of mixed and single-phase unfilled gel is limited by the low compatibility of the macromolecular components in the absence of complex formation between them. Fig.8 presents the phase diagram for the gelatin–methylcellulose–water system at 35 °C (at this temperature none of the components form a gel).[67] It is seen from the figure that the compatibility of gelatin with methylcellulose increases somewhat as the pH of the system shifts from the isoelectric point of gelatin. This can be explained by the suppression of the self-association of gelatin induced by the Coulombic interaction due to charge fluctuations as a consequence of the increasing electrostatic repulsion.[68] The introduction of NaCl does not lead to an appreciable increase of compatibility, since the decrease in the degree of self-association of gelatin is compensated by the increase in the degree of self-association of methylcellulose under the influence of NaCl. The asymmetry of the gelatin–methylcellulose–water phase diagram, which is characteristic of quasi-binary protein–polysaccharide systems, is striking.[69]

In the absence of complex formation, an enhancement of structure formation in individual components of single-phase multicomponent gels, i.e. the development of intramolecular and intermolecular contacts between the macromolecules of one component at the expense of the polymer–solvent contacts, is observed. This phenomenon is due to the excluded volume effect.[6,70,71]

An important example of a process determined by the development of intramolecular polymer–polymer contacts is provided by the coil–helix transition. Fig.9 illustrates the influece of dextran on the mutarotation of gelatin in solution at 6 °C. It is seen that the presence of only 0.2% of dextran, which is 5% of the concentration of gelatin, induces a sharp acceleration of the conformational transition of the latter. There is a simultaneous increase of the rate of gel formation. The coil–helix transition leads to the expansion of the region of incompatibility of gelatin and dextran.[72]

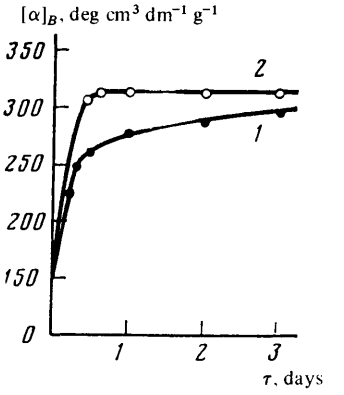

Figure 9. The influence of dextran on the mutarotation of a 4% gelatin solution;[72] $[\alpha]_B$ = specific optical rotation at λ = 436 nm: 1) water; 2) 0.2% dextran solution.

The enhancement of structure formation in the components of a mixed gel is manifested also by a decrease of the critical gel formation concentration¶. Fig.10 shows that a mixed gel of gelatin and agarose is formed at concentrations of the polymeric components such that each separately is still incapable of forming a gel network. An analogous phenomenon has been noted for mixed thermotropic agar and bovine serum albumin gels.[73]

The study of the viscoelastic properties of gelatin gels containing globular proteins or a polysaccharide (dextran) showed that the presence of fillers affects the effective

¶A.M.Gotlieb, I.G.Plashchina, E.E.Braudo, and V.B.Tolstoguzov, Colloid Polymer Sci., 1985, 263 (in the press).

number of gel network nodes (the equilibrium modulus of elasticity), while the rate of relaxation processes remains unaltered in most cases.[72,74]

The properties of multicomponent gels naturally depend on their phase state. In certain cases extrema appear on the gel property–composition curves, which may be attributed to a transition from the single-phase to the two-phase state. Such a transition in the region of the filler concentration corresponding to the minimum pliability (the maximum modulus of elasticity) has been established for the gelatin–dextran–water system by electron microscopy.[72] The decrease of pliability in the single-phase state can be accounted for by the increase of the effective number of gelatin gel network nodes under the influence of the filler (dextran) by virtue of the excluded volume effect. In the two-phase state the drops of the phase enriched in dextran form defects in the gelatin gel network.

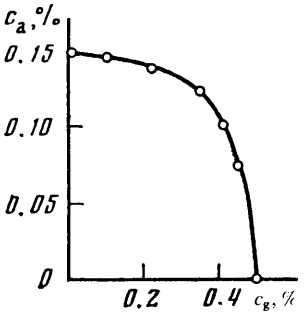

Figure 10. Dependence of the critical concentration for gel formation on the composition of the gelatin–agarose–water mixture at 8 °C; c_g = gelatin concentration; c_a = agarose concentration.

It has been suggested that in the general case the region of filler concentrations corresponding to the onset of the increase in the pliability and in the degree of swelling of gels be called the limit of the structural compatibility of the filler and the gel matrix.[6] This limit depends both on the nature of the matrix and on the molecular characteristics of the filler.[74,75] The character of the influence of the molecular weight of dextran on the limits of its structural (thermodynamic) compatibility with the gelatin gel matrix can be seen from Fig.11.[72]

In the region of the two-phase state each of the polymeric components is concentrated in one of the phases. In this case the properties of the mixed gels are determined primarily by those of the continuous phase. When the composition of this system is varied within wide limits, phase inversion, accompanied by a change in the properties of the gel, takes place.[6,36,75,76]

III. COMPLEX FORMATION IN SOLUTIONS OF PROTEINS AND ANIONIC POLYSACCHARIDES

The interaction between proteins and anionic polysaccharides has been studied by many workers and certain aspects of this phenomenon have been surveyed in a number of reviews.[77–81] The first systematic studies, which were devoted mainly to the nature of the phase separation in solutions of proteins and anionic polysaccharides (i.e. to the formation of complex coacervates or insoluble complexes), showed that the protein–polysaccharide complexes (PPC) are stabilised mainly by electrostatic forces. On the other hand, the complex formation between anionic polysaccharides and proteins, demonstrated in a number of studies at a pH above the isoelectric point of the protein (where the macroreactants bear like charges),[82–86] as well as the complex formation between neutral polysaccharides and proteins (not lectins),[87,88] indicate a significant role of the secondary non-electrostatic interactions in the stabilisation of protein–anionic polysaccharide complexes.

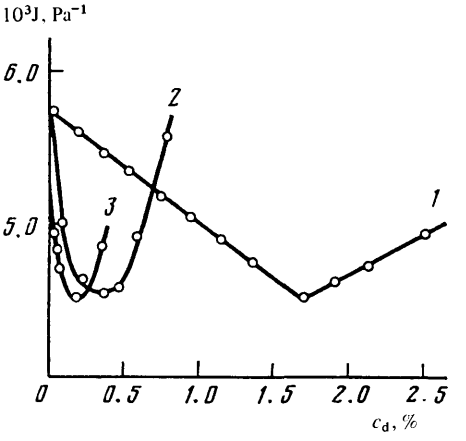

Figure 11. The influence of the dextran concentration (c_d) on the pliability J of 10% gelatin gels;[72] molecular weight of dextran: *1*) 20 kD; *2*) 65 kD; *3*) 500 kD.

The functional properties of the PPC, such as solubility, surface activity, and rheological characteristics, differ significantly from the analogous properties of the initial macroreactants and, what is especially important, can be regulated within wide limits.

Water-soluble PPC are of interest for the food technology, but their structures and properties have been little studied. The investigation of the equilibrium nature of the PPC, the nature of the forces stabilising them, the molecular structure of the PPC and the bound protein, and the functional properties of the complexes is urgently required.

1. The Non-Equilibrium Complexes

Studies of the formation of the PPC have shown that, at sufficiently low pH and ionic strengths, the latter do not correspond to equilibrium: their properties and in particular their solubilities† depend on the method of preparation.[89] Thus, when solutions of the macroreactants are mixed under the conditions of vigorous complex formation (at a pH below the IEP), "mixing complexes" (M-complexes), which are sparingly soluble in water, are formed. On the other hand,

† The terms "soluble" and "insoluble" which we use in relation to the non-equilibrium complexes are arbitrary, since strictly speaking they should refer to a stable thermodynamic equilibrium.

on slow titration of the solution, when conditions in the medium change in such a way that the interaction gradually intensifies, readily soluble "titration complexes" (T-complexes) are produced.

The difference between the solubilities of the M- and T-complexes are clearly manifested in nephelometric titration (Fig.12). The turbidity of the system serves in this instance as a semiquantitative characteristic of the yield of the insoluble PPC.

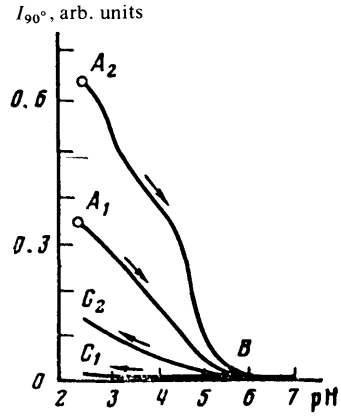

Figure 12. Nephelometric titration curves for solutions of complexes of bovine serum albumin and dextran sulphate in proportions, by weight, of 1:1 and 2.3:1 (the A_1BC_1 and A_2BC_2 curves); overall concentration of macroreactants 0.1 g litre^{-1}.

The differences between the solubilities for the M- and T-complexes (aggregation hysteresis) are particularly marked for the PPC of highly sulphated polysaccharides such as dextran sulphate and heparin. Furthermore, a high aggregation stability is characteristic of the solutions and suspensions of these PPC: the light scattering and the wave exponent (sensitive to changes in the size of the scattering particles) can be constant for several days at room and elevated (40–50 °C) temperatures.

The non-equilibrium PPC have been studied in greatest detail in relation to the complexes of the high-molecular-weight dextran sulphate with proteins, in particular with bovine serum albumin (BSA).[90] The character of the interaction of BSA with dextran sulphate varies sharply as a function of the pH. In the range 5.6 $\leqslant$ pH $\leqslant$ 8.5 (the range corresponding to a relatively weak interaction) the properties of the PPC are independent of the method of their preparation, which indicates the equilibrium character of the complex formation. Analysis of the composition of the water-soluble complexes at pH 5.6 showed that the sorption of BSA by dextran sulphate is non-cooperative, i.e. the protein–protein interaction does not have an appreciable influence on the binding of the protein to the polysaccharide. Under these conditions, the PPC are not aggregated: each particle consists of one dextran sulphate molecule.

In the vicinity of the isoelectric point of BSA (5.0 < pH < 5.6) the composition of the soluble complexes is also independent of the way in which they are prepared, but does depend strongly on the pH. At the same time, in the above pH range the aggregation hysteresis is already observed (Fig.12)#.

The fact that in the above pH range a transition is observed from a uniform distribution of the protein molecules between the dextran sulphate chains to a non-uniform distribution is of particular interest. Two discrete fractions of the complex appear in the solution—the rapidly sedimenting α-fraction and the slowly sedimenting β-fraction. Analysis by the method of high-speed sedimentation and gel chromatography showed that the ratio of these fractions varies steadily: with increase of the fraction of BSA in solution, the proportion of the α-fraction rises and that of the β-fraction falls. At the same time the sedimentation coefficients of these fractions also increase. They both consist of a BSA–dextran sulphate complex but differ in composition: the α-fraction is enriched in the protein while the β-fraction is depleted in the latter. The non-uniform distribution of the protein between the polysaccharide chains can be accounted for by the cooperative character of its sorption.[91,92] The transition from the non-cooperative sorption of the BSA to the cooperative sorption is apparently due to the intensification of the interactions between the protein molecules in the PPC species or the decrease of the pH which can be accounted for in its turn by the decrease of the overall charge of the protein, hindering, at a higher pH, the mutual approach of the protein globules.[93,94]

At pH $\leqslant$ 5.0 the sorption of the BSA becomes irreversible. Under these conditions, the α-fraction of the M-complexes of any composition is precipitated. On the other hand, the α-fraction of the T-complexes is readily soluble, provided that the ratio of BSA and dextran sulphate does not exceed 4:1 by weight (critical mixture composition). For a BSA : dextran sulphate ratio of 4:1 and above, the T-complexes are fully precipitated. This ratio also corresponds to the complete disappearance of the β-fraction, which is soluble regardless of the way in which the complexes have been prepared.

The aggregation of the protein–dextran sulphate complexes and the aggregation hysteresis are observed also in concentrated urea solutions. Since the aggregation of proteins in this medium is suppressed, presumably the secondary interactions (hydrogen bonds and hydrophobic interactions) do not play a decisive role in stabilising the aggregates of the protein–dextran sulphate complexes (both equilibrium and non-equilibrium). The formation of non-equilibrium aggregates is apparently due to electrostatic interactions. At the same time the number of ionic bonds between the macroreactants is independent of the way in which the complexes have been obtained, since hysteresis in the sorption of protons is not observed in the potentiometric titration of BSA–dextran sulphate solutions. One can therefore assume that the differences between the M- and T-complexes are caused by the different distributions of the protein molecules between the polysaccharide chains: the T-complexes consist of species with a single dextran sulphate chain (monomatrix complexes), while the M-complexes (the α-fraction) consist of three-dimensional intertwined networks made up of dextran sulphate chains cross-linked by the protein (polymatrix complexes).

Thus mixing of BSA and dextran sulphate solutions at pH < 5.0 (for all the ratios investigated) leads to the appearance of a highly aggregated α-fraction, produced as a result of the cross-linking of the random network of the dextran sulphate chain by the protein, together with the readily soluble β-fraction. In the T-complexes

#V.B.Tolstoguzov, V.Ya.Grinberg, and A.N.Gurov, J.Agric.Food Chem., 1985, 33, 151.

obtained when the complex formation equilibrium is "frozen" at pH ~5.0 with subsequent transition to the same conditions as those for the M-complexes, the α-fraction remains soluble up to the protein : dextran sulphate ratio of 4 : 1 by virtue of the electrostatic repulsion between the species bearing like charges and containing one dextran sulphate chain.

2. The Influence of Temperature on the Structure of the Protein Bound in a Complex with the Polysaccharide

The formation of complexes with anionic polysaccharides makes it possible to prevent the thermal coagulation of the protein,[95] which can evidently be explained by the immobilisation of the protein molecules in the complex, preventing the formation of aggregates on denaturation. For example, the coagulation of the BSA–dextran sulphate complex and the absence of the free protein is not observed up to 100 °C (at pH 5.6). The circular dichroism method makes it possible to observe the denaturation of the bound protein to the same high extent as that of the free protein. However, the denaturation of the bound protein is non-cooperative, in contrast to that of the free protein, and is therefore not accompanied by a thermal absorption peak characteristic of the thermal denaturation of free proteins.

3. The Use of the PPC for the Regulation of the Surface Properties of the Protein

The complexes of proteins with anionic polysaccharides have a number of advantages over the initial proteins by virtue of their surface activity. Thus they can ensure a higher stability of emulsions of the "oil–water" type.[96] Fig.13 presents stability diagrams for model emulsions of n-decane in aqueous solutions of BSA and its complexes with dextran sulphate (the latter shows no surface activity and does not itself stabilise emulsions). It can be seen that, over a wide range of protein concentrations, the stability of the emulsions of n-decane in solutions of the complexes is significantly greater. The differences between the emulsifying properties of the protein and its complexes with dextran sulphate diminish with increasing ionic strength, disappearing completely under conditions where the complexes are decomposed.

An analogous increase of the stability of emulsions when the PPC is used instead of the protein has been observed for casein–carrageenan, casein–pectin, human serum albumin–dextran sulphate, and certain other complexes.

It is important to note that the PPC make it possible to regulate the rheological characteristics of the emulsions within wide limits. In particular, one of the versions of the highly viscous (stuffing-like) emulsions stabilised by protein–anionic polysaccharide complexes has been used in the manufacture of cooked sausages.[97]

The properties of the interfacial adsorption layers formed by the PPC have not so far been investigated. However, presumably the structural organisation of the PPC at the interfaces is similar to that which is obtained in complex gels. The formation of the latter and their properties have been investigated in greatest detail in relation to gels of the gelatin–sodium alginate[98,99] and gelatin–pectin[100] complexes, for which significant differences from gelatin gels have been observed. In contrast to the latter, the gelatin–sodium alginate complexes do not melt in the range 30–40 °C and exhibit only an abrupt increase of pliability while retaining other elastic properties up to 100 °C. It is significant that the gel formation in PPC solutions can be observed under conditions where the individual macroreactants do not form gels. An example is provided by the thermoreversible complex gel of casein and sodium alginate§.

IV. THERMODYNAMIC COMPATIBILITY OF PROTEINS AND POLYSACCHARIDES IN SOLUTION

Multicomponent mixtures of polymers are as a rule of a heterophase type; compatibility is attained only when the mixing is accompanied by the evolution of heat. From the standpoint of the technology of the preparation of new forms of food, the study of the thermodynamic compatibility in solutions of the principal classes of food polymers, namely proteins and polysaccharides, was of great interest.

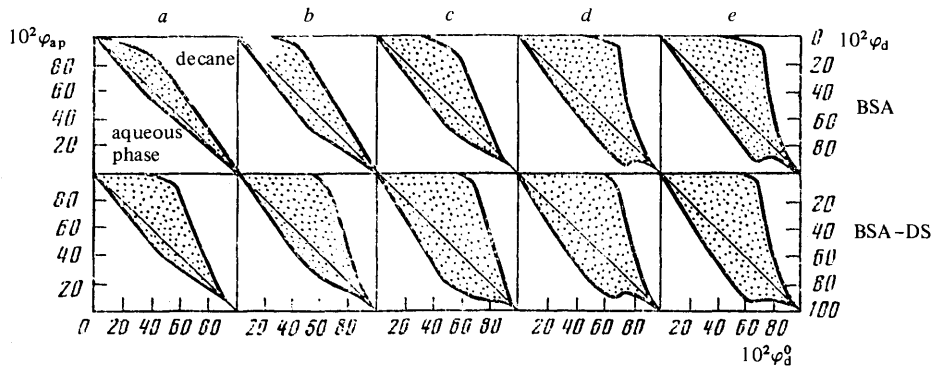

Figure 13. Stability diagrams for n-decane emulsions in aqueous solutions of bovine serum albumin (BSA, upper row) and its complex with dextran sulphate in proportions, by weight, of 1 : 1 (BSA–DS, lower row) at pH 4.0 and an ionic strength of 0.01; ϕ_d^0 = volume fraction of n-decane in the system, ϕ_{ap} = volume fraction of separated aqueous phase, ϕ_d = volume fraction of separated n-decane; BSA concentration (%): *a*) 0.025; *b*) 0.05; *c*) 0.10; d) 0.30; *e*) 0.50.[96]

1. Thermodynamic Compatibility in Protein–Polysaccharide–Water Systems

Although the limited thermodynamic compatibility of gelatin and polysaccharides in solution was observed as early as the end of the previous century[101] and since then has been the subject of a series of studies,[68,102–108] the systematic investigation of thermodynamic compatibility in solutions of polysaccharides and proteins, in the first place globular proteins, was begun only in recent years.

The phenomenology of the limited thermodynamic compatibility in solution has been investigated[68,106,109–114] for the principal classes of proteins and polysaccharides. The fact that the phenomenon of limited thermodynamic compatibility is general has been demonstrated with more than 80 protein–polysaccharide–water systems. All these systems undergo liquid-phase separation with the preferential concentration of the macromolecular components in different phases. This occurs at a fairly high overall concentration of the macromolecular components (usually above 4%) under conditions ensuring the suppression of the association of heterotypical macromolecules and favouring the association of isotypical macromolecules. The principal conditions governing limited thermodynamic compatibility differ for systems containing neutral, carboxylated, and sulphated polysaccharides.

The thermodynamic compatibility of casein[110,111] and the globular fraction of soya beans[112] with different polysaccharides has been studied in greatest detail. Data concerning the influence of the most important thermodynamic variables (pH, ionic strength, temperature, and the molecular weight) on the compatibility of protein and polysaccharides have been obtained. They have been published[110–113] in the form of three-dimensional phase diagrams. As a rule the compatibility diminishes as the pH approaches the isoelectric point of the protein and also with increase of the concentration of the low-molecular-weight salt, temperature, and the molecular weight of the polysaccharide. The sulphated polysaccharides are a known exception. In this case the compatibility increases as the pH approaches the isoelectric point of the protein. The region of total compatibility exists in the vicinity of this point.

The protein–neutral polysaccharide–water and protein–sulphated polysaccharide–water systems have a lower consolute point below a certain concentration of the low-molecular-weight salt. If the salt concentration is below this threshold value, the protein and the polysaccharides indicated are completely compatible. The threshold concentration of the salt depends on its composition and on the pH. The influence of the salt on the thermodynamic compatibility of proteins and neutral polysaccharides is not generally correlated with the positions of the salts in the lyotropic series.

In order to elucidate the nature of thermodynamic compatibility a thermorheological study of the single-phase protein–neutral polysaccharide–water systems has been carried out at different ionic strengths corresponding to the complete or limited compatibility of the macromolecular components at higher concentrations.[114] The excess activation energies for viscous flow, determined by the protein–polysaccharide interaction, were calculated. Positive values of this parameter are characteristic of the conditions ensuring the complete compatibility of the components in the system while negative values are characteristic of systems with limited compatibility, which indicate the predominance of the attraction and repulsion forces respectively between heterotypical macromolecules. Thus it was possible to demonstrate the formation of weak protein–neutral polysaccharide complexes in media with a low ionic strength, where the components are thermodynamically compatible, and their decomposition at a higher ionic strength, i.e. under the conditions of the limited thermodynamic compatibility of proteins and neutral polysaccharides.

2. Thermodynamic Compatibility in Protein–Protein–Water Systems

Data concerning the thermodynamic compatibility of proteins have also appeared recently. It has been shown for nine systems[115] that under certain conditions proteins belonging to different classes in Osborn's classification are compatible only to a limited extent in an aqueous medium. The phase diagrams for certain protein *1*–protein *2*–water systems¶, obtained by the method of the phase volume ratio,[116] are presented in Figs.14 and 15.

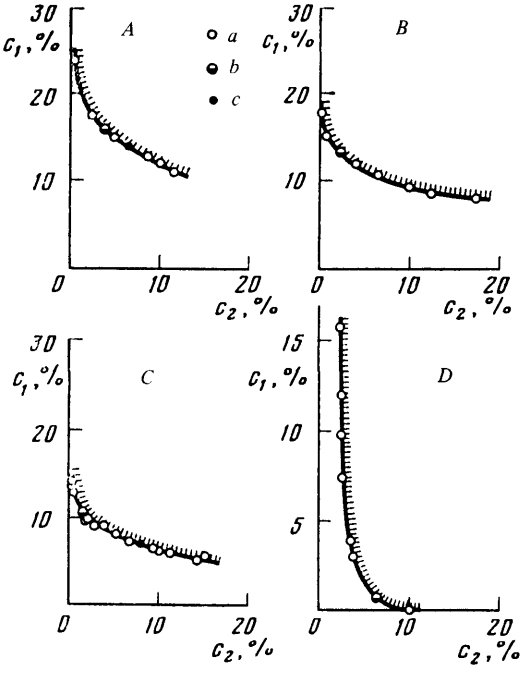

Figure 14. Phase diagrams for certain protein (1)–protein (2)–water systems at 20 °C: *A*) ovalbumin (1)–casein (2)–water (pH 6.6); *B*) ovalbumin (1)–globulin fraction of soya beans (2)–water (pH 6.6); *C*) casein (1)–globulin fraction of soya beans (2)–water (pH 6.9); *D*) casein (1)–gliadin (2)–water (pH 11); c_1 and c_2 are the weight concentrations of proteins (1) and (2) in the system: *a*) points on the binodal curve; *b*) layer separation threshold; *c*) consolute point.

Analysis of the equation of state for polymer *1*–polymer *2*–solvent systems by the Flory–Huggins method leads to characteristics which determine the form of their phase diagrams.[117] In particular, the layer formation threshold, i.e.

¶V.I.Polyakov, O.K.Kireeva, V.Ya.Grinberg, and V.B.Tolstoguzov, Nahrung, 1985, 29, 153.
V.I.Polyakov, I.A.Popello, V.Ya.Grinberg, and V.B.Tolstoguzov, Nahrung, 1985, 29 (in the press).

the point at which the binodal curve is tangential to the straight line making equal intercepts on the coordinate axes, should be displaced towards the axis corresponding to the polymer with the lower molecular weight, while the consolute point (the point of intersection of the binodal curve and the rectilinear diameter) should be displaced towards the axis of the polymer with the lower lyophilicity. These features are valid for mixtures of proteins in a common solvent.

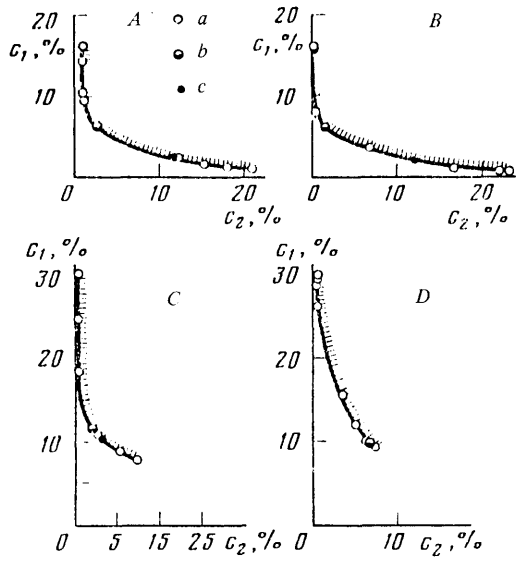

Figure 15. Phase diagrams for certain protein (1)–protein (2)–water systems: *A*) gelatin (1)–globulin fraction of fodder beans (2)–water (t = 40 °C, pH 7.0); *B*) gelatin (1)–11*S*-globulin from fodder beans (2)–water (t = 40 °C, pH 7.0); *C*) ovalbumin (1)–thermotropic ovalbumin cluster (2)–water (t = 20 °C, pH 6.8); *D*) bovine serum albumin (1)–thermotropic ovalbumin cluster (2)–water (t = 20 °C, pH 6.8); conditions in the preparation of the thermotropic ovalbumin cluster: temperature 100 °C, duration of heat treatment 60 min, protein concentration 5%, method of concentration—lyophilisation.

The above result shows that the equation of state indicated is applicable regardless of the model (freely jointed chains on a lattice[118,119]) on the basis of which it has been obtained.

The possibility of regulating the thermodynamic compatibility of proteins is of some interest. One of the effective ways of achieving such regulation is thermotropic aggregation of the protein. It is known[120] that heating above the denaturation temperature leads to the formation of soluble clusters of protein molecules when the concentration of the protein does not exceed the gel formation threshold.[121] The size, shape,[122] and probably the hydrophilic properties of the accessible surfaces of these clusters can be altered by varying the conditions in the heat treatment of the protein solution. The extent to which the heat treatment influences the compatibility of proteins is indicated by the phase diagrams *C* and *D* in Fig.15. In the native state BSA and ovalbumin are fully compatible in an aqueous medium. However, the thermotropic ovalbumin clusters are incompatible not only with BSA but also with native ovalbumin.

3. Practical Utilisation of Two-Phase Liquid Systems

(a) Concentration and purification of proteins. A low layer-formation threshold and a high ratio of the protein and polysaccharide concentrations at the consolute point are typical for the phase diagrams of protein–polysaccharide–water systems. In other words, the protein–polysaccharide–water systems separate into different phases which differ sharply in the concentrations of the macromolecular components, namely into a highly concentrated phase enriched in the protein (the polysaccharide content is not more than 0.5%) and a dilute polysaccharide phase. A new method of concentrating protein solutions, called membrane-free osmosis, is based on this phenomenon.[69] In particular, it has been used to concentrate proteins of defatted milk with the aid of apple pectin. The concentration of milk proteins to 30% is achieved at a polysaccharide concentration in the system of 1%. The high productivity, by virtue of the large area of the interface, the simplicity of the apparatus, and the relatively high energy efficiency may be included among the advantages of the process.

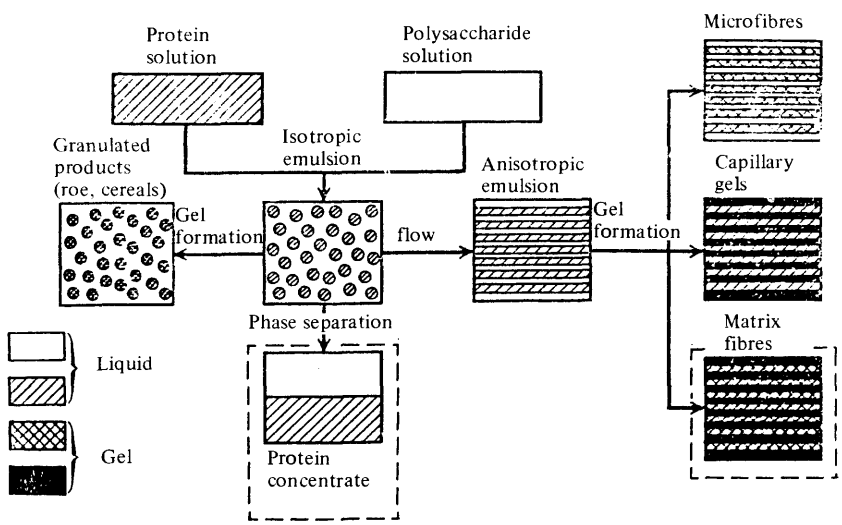

Figure 16. Scheme for the employment of two-phase protein–polysaccharide–water systems in the processing of protein.[1,66]

Yet another possibility of the practical utilisation of the phenomenon of the limited thermodynamic compatibility of proteins and polysaccharides in solution is based on the fact that protein–lipid complexes are less compatible with polysaccharides than lipid-free proteins. This effect has been used to remove lipids from the globulin fraction of baker's yeast proteins.[123,124] The lipid content in the protein preparation was thus reduced to 0.1%.

(b) The manufacture of new forms of food by processing two-phase liquid systems. The extensive possibilities for the preparation of NFP by processing two-phase liquid systems of the "water in water" type have been demonstrated in recent years. Such systems are formed by thermodynamically incompatible solutions of proteins and polysaccharides or different proteins. A general scheme for the processes involved in the processing of two-phase liquid systems to produce NFP[1,66] is illustrated in Fig.16. It includes the deformation of the two-phase liquid system in a flow and the conversion of one or both phases into a gel.

The possibility of attaining high degrees of deformation of the two-phase liquid system is ensured by the low interfacial tension; an approximate equality of the viscosities of the two phases is also necessary.[125] The ratio of the viscosities of the phases together with the dimensions of the particles of the disperse phase and the rate of shear determine the structure of the two-phase liquid systems in a stream and the possibility of processing them.[126]

On passing to the gel state in a flow, the particles of the disperse phase form protein microfibres. Depending on the volume fraction of the disperse phase, it is possible to obtain both short fibres and infinitely long fibres. In the latter case the formation of a gel is preceded by the coalescence of the deformed disperse particles. This process has been called spinning without a drawplate.[126] For high degrees of deformation, granulated products can be obtained in which the grains are anisodiametric to different extents.

When the dispersion medium is converted into a gel in a flow, gels filled with liquid cylinders oriented in the direction of the flow, the so-called gels with a capillary structure, are produced. The stability of these gels at right angles to the direction of orientation of the capillaries increases with increasing rate of shear.[125,127] For high degrees of filling, the continuous phase consists of the fibre cross-sections. Finally, there is a possibility that both phases of the deformed two-phase liquid system are converted into a gel. Gels filled with fibres oriented in the direction of the deformation, which are anisotropic in their mechanical properties, are obtained in this way.

All the principal versions of the processing of proteins in two-phase liquid systems under the conditions of high degrees of deformation of the disperse particles (not less than 10) are of practical importance in the preparation of analogues of meat products—fibres and textured materials.
