Physicochemical Problems in the Preparation of Defect-free Monocrystals of Lanthanum Hexaboride

M.M.Korsukova and V.N.Gurin

The physicochemical basis of the preparation of single crystals of stoichiometric lanthanum hexaboride (a promising new material for emission electronics) is discussed. It is shown that stoichiometric defect-free monocrystals can be prepared only by allowing for the form of the homogeneity region in the phase diagram of the crystalline compound. Studies of defects in the crystal structure are reviewed, and their results are shown to be related to the form of the homogeneity of lanthanum hexaboride. Some physicochemical properties and some possible applications of lanthanum hexaboride monocrystals are examined.

The bibliography includes 150 references.

CONTENTS

I. Introduction

II. Homogeneity region of lanthanum hexaboride and preparation of monocrystals of stoichiometric composition

III. Methods of preparing lanthanum hexaboride monocrystals

IV. Some properties of lanthanum hexaboride monocrystals

I. INTRODUCTION

Lanthanum hexaboride is used in several new instruments (electron microscopes, microanalysers, Auger spectrometers) to study the surface and other properties of materials of various types. However, the preparation of perfect and very pure single crystals of lanthanum hexaboride for use in the cathodes of these instruments still presents some unsolved problems. This is because of the difficulty in controlling the chemical composition and in achieving a high level of structural perfection, and also in establishing adequate quality control.

Many papers have been published on lanthanum hexaboride, dealing mainly with the preparation of LaB_6 monocrystals, with studies of their composition, structure, and properties, and with their emission properties and practical applications. We have recently published a comprehensive review[1] of work on the preparation of LaB_6 monocrystals and on their properties and potential applications, but little emphasis was placed on the physicochemical conditions needed to prepare very perfect LaB_6 monocrystals.

The aim of the present review is to highlight the physicochemical problems underlying the preparation of stoichiometric and defect-free monocrystals of LaB_6.

II. HOMOGENEITY REGION OF LANTHANUM HEXABORIDE AND PREPARATION OF MONOCRYSTALS OF STOICHIOMETRIC COMPOSITION

Though lanthanum hexaboride has been known for a long time,[2] we have little reliable information on the phase diagram of the La–B system and especially on the homogeneity region of LaB_6. The phase diagram of the La–B system was first described by Johnson and Daane,[3] and a modified diagram was subsequently published to include new data.[4] In the most recent publications[5,6] the part of the phase diagram of the La–B system containing the compound LaB_6 is examined. At present two compounds have been reliably identified in the La–B system: 1) LaB_4, which melts incongruently at 2073 K with formation of LaB_6 and of a liquid phase containing 66.7 at.% of B,[3] and 2) LaB_6, which melts congruently at 2988 K.[4,5]

The compound LaB_4 has a tetragonal crystal lattice (UB_4 structure type) with lattice constants $a = 7.324 \pm 0.001$ Å and $c = 4.181 \pm 0.001$ Å;[7] its homogeneity region is very narrow.

The compound LaB_6 has a cubic lattice (CaB_6 structure type).[8] Its crystal structure can be treated as body-centred cubic, with La atoms and octahedra of B atoms occupying positions analogous to those of the Cs^+ and Cl^- ions in the CsCl structure.[9] Each lanthanum atom is surrounded by 24 boron atoms, and each boron atom forms five B–B bonds: four with boron atoms in the same octahedron and the fifth with a boron atom from a neighbouring octahedron.

Published information on the homogeneity region of LaB_6 is inconsistent, and describes the region as broad[3,10] or as relatively narrow.[5,6,11–16] However, in either case the defect structure of the LaB_6 crystal is attributed to defects in the metal (La) sublattice (assumed to be few in the case of a narrow region). The lattice constant of the LaB_6 crystal is found (experimentally) to be unaffected by the defect density.[5,11,17,18] Lastly, some workers have detected a LaB_9 phase with the same structure, and lattice constant, as the LaB_6 phase.[5,19]

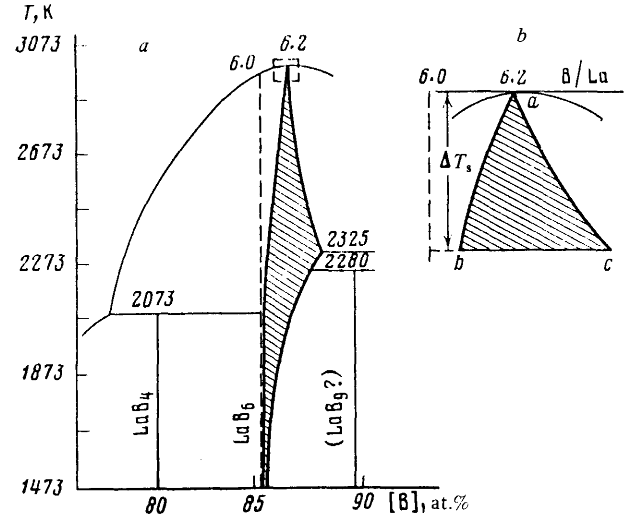

Figure 1. Part of the La–B phase diagram:[5] *a*) is the homogeneity region of LaB_6 *b*) is an enlarged presentation of the high-temperature part of LaB_6 homogeneity region, showing the supercooling ΔT_S.

Existing data on the La–B system suggest a number of conclusions of direct relevance to the preparation of stoichiometric single crystals of LaB_6. Fig.1 shows a part of the phase diagram of the La–B system including the existence region of lanthanum hexaboride.[5] We note that the homogeneity region of LaB_6, which begins at ~2073 K, broadens rapidly as far as 2325 K (the temperature of the LaB_6–B eutectic) and remains fairly wide up to T_m (the melting point of LaB_6) (the "upper" part of the homogeneity region has been described[6] as "narrow" because it is slightly shifted from the stoichiometric composition B/La = 6, and the same description is used in Ref.5). The deviation of the singularity for lanthanum hexaboride from the stoichiometric proportion B/La = 6 is, in fact, substantial: approximately 0.2 atom fraction of B, i.e. to $LaB_{6.2}$. The homogeneity region of the hexaboride is widest (from $LaB_{6.1}$ to $LaB_{6.7}$) at T_{eut} = 2325 K. Inspection of this region near the singularity, i.e. at T_m of lanthanum hexaboride (see Fig. 1*b*), leads to important conclusions regarding the actual composition of the monocrystals obtained from melts at these temperatures (for example, by zone melting).

Thus, if the supercooling of a melt of stoichiometric composition in the crystallisation volume reaches the value ΔT_S the composition of the resulting hexaboride monocrystals is described by the point *b* (for example, $LaB_{6.1}$). Since ΔT_S can vary from a fraction of a degree to hundreds of degrees, and is not easy to control, especially at high temperatures, the composition of the grown crystals can also be uncontrolled. If the composition of the melt at the beginning of the crystallisation corresponds to the point *a* (i.e. to $LaB_{6.2}$) the resulting monocrystals will also have this composition. On the other hand if the initial composition deviates on either side of the point *a* the composition of the resulting crystals will correspond to points on the *ab* or *ac* boundaries of the homogeneity region. This provides our first important conclusion: if the published data[5] for the La–B phase diagram are correct, the preparation of lanthanum hexaboride monocrystals of stoichiometric composition by a liquid-phase method, i.e. from the corresponding melt, is impossible.

Another important aspect of this problem is that the compound LaB_6 dissociates fairly strongly at $T = T_m$. Hence in order to prepare monocrystals from the melt we need to apply an overpressure of a few tens of atmospheres. We also know that at T_m of lanthanum hexaboride the La partial vapour pressure is much higher than the pressure of B.[20] Therefore in order to prepare a melt of the required initial composition (for example, $LaB_{6.2}$) we must introduce the correct B/La component ratio into the initial charge. This means that LaB_6 monocrystals prepared from the stoichiometric melt will always contain an excess of B and consist of a two-phase system or of a solid solution of B in LaB_6. These solid solutions can decompose into LaB_6 and B at low temperatures due to the narrowing of the homogeneity region. This assumption is confirmed to some extent by the presence of B inclusions in LaB_6 monocrystals.[21]

The strong narrowing of the LaB_6 homogeneity region below 2280 K, accompanied by a shift of the left-hand boundary which brings it almost exactly to the stoichiometric LaB_6 composition at 1673–1773 K, suggests another conclusion: LaB_6 monocrystals of stoichiometric composition can be prepared only by methods which are applicable at temperatures not higher than 1673 K.

III. METHODS OF PREPARING LANTHANUM HEXABORIDE CRYSTALS

Only three of the four methods of preparing monocrystals of refractory compounds (according to our classification[22]) have so far been applied to the growth of LaB_6 monocrystals: gas-phase, liquid-phase, and solution methods. We shall consider the special features of each of these methods separately, and compare their technological advantages and their potential suitabilities for the production of stoichiometric monocrystals.

1. The Gas-Phase Method

This method consists in the transport of the substance to be crystallised through the gas phase to the substrate by generating a temperature or concentration gradient between the source and the substrate or by chemical gas-transport reactions. Depending on the chosen method of transport, the monocrystals are grown in a vacuum or in the presence of a carrier. Halogens or halogen–hydrogen mixtures are often used in the preparation of LaB_6 (see Table 1). In any particular method the following crystal growing procedures can be used: a) sublimation, or ΔT transport (when the substance to be crystallised has a high vapour pressure and a congruent evaporation); b) chemical, or Δc transport (when the vapour pressure is low); c) transport of the substance to be crystallised in an electric arc (for a low vapour pressure and a high melting point); d) chemical reaction in the gas phase (in which the synthesis precedes the crystallisation of the substance). Only Δc transport[23,24] and chemical reactions[25,26] have been used so far, from the above list, to prepare LaB_6 monocrystals:

$$La_2O_3 + H_2 + BCl_3 \rightarrow LaB_6 + HCl$$

$$LaCl_3(g) + 6BCl_3(g) + (21/2)H_2(g) \rightarrow LaB_6(s) + 21HCl$$

Table 1. Preparation of LaB_6 monocrystals by the gas-phase method.

Method of preparation	Preparative conditions			Characteristics of the resulting crystals		Refs.
	T, K	time, h	other conditions	shape and size, mm	other characteristics	
Δc transport Br_2 carrier	1423–1173	–	initial charge LaB_6 powder, Ar inert gas	needles; 0.50 × 0.15 × 2.00	colour violet	[23]
Δc transport carriers (H_2 + BBr_3) or H_2 + Br_2)	1273–1573	–	initial charge LaB_6, substrate sintered LaB_6	⟨100⟩ whiskers, pyramidal crystals	–	[24]
Chemical reactions	zone *A* 1273; zone *B* 1623–1723	3	initial charge pressed La_2O_3; substrate graphite	{100}cubes, {111}cubo-octahedra; 1 × 1 × 1	colour purple	[25]
Chemical reactions	1373–1623	0.5–2	substrate graphite, $BCl_3/LaCl_3$ = 10:1, atmospheric pressure	⟨100⟩ whiskers; l = 2–5, thickness 0.001–0.020; ⟨100⟩ pyramids	colour purple (lattice constant a = 4.151 A); colour blue (lattice constant a = 4.155 A)	[26]

The control of crystal growth processes is complicated by the need to monitor and control several factors within closely specified limits: the rates of evaporation, the concentrations of the initial components in the carrier gas, the temperature gradient, etc. Data on the preparation of LaB_6 monocrystals by the gas-phase method are shown in Table 1.

The possibility of growing oriented and regular whisker structures of various elements and compounds by a gas-phase method, using Δc transport, is of great practical interest.[24]

The results in Table 1 show that LaB_6 monocrystals produced by the gas-phase method are usually facetted, and grow preferentially in a <100> direction. However, they tend to be small, and difficult to use as single-crystal samples in physical experiments. Furthermore, their precise chemical composition has never been reported, except for a list of impurities.[26] The same paper[26] gives the lattice constants of the LaB_6. Most other reports merely describe the colour of the crystals, which varies from purple to blue, the latter being ascribed to an excess of boron in the sample. However, this interpretation cannot be tested unambiguously because of the lack of chemical analyses. In view of the relatively low temperatures and other conditions used in the gas-phase method, and noting the data on the homogeneity region in Fig.1, it would appear that stoichiometric LaB_6 crystals can be produced, in principle, by this method. The main difficulty here is the need for exact control over the initial concentrations, which determine the La : B ratio in the monocrystal, and also the need for fine adjustment of many other factors (mentioned above) known to affect the stoichiometry of the growing LaB_6 crystals.

Another shortcoming of the gas-phase method (especially for the growth of crystals by using chemical reactions) is the possibility of co-depositing impurity phases such as boron with the LaB_6. As reported,[26] this danger can be avoided by using a BCl_3 concentration much lower than the value corresponding to the stoichiometric ratio $BCl_3/LaCl_3$ = 6. The coprecipitation of boron is entirely suppressed at $BCl_3/LaCl_3 < 2$.

The gas-phase method has not so far produced monocrystals of adequate quality and size. However, further developments (including the use of seed crystals) may result in the production of large and perfect LaB_6 crystals. Another promising line of research is aimed at the production of regular whisker structures of LaB_6, which may find practical application.[24]

2. The Liquid-phase Method

The liquid-phase method consists in passing the substance to be crystallised through a heated zone in which a temperature gradient is maintained, or in moving the zone relative to the sample. The compound, which can enter the zone either in the liquid or in the solid state, is first melted and then crystallised. The wide variety of possible technological variants of this method has led to the development of a large number of different techniques for growing single crystals.[22]

Only the zone melting method has been used for growing monocrystals of LaB_6, in the crucible-free form which avoids contact between the hexaboride melt and any container material. Data on the preparative conditions and characteristics of LaB_6 monocrystals prepared by zone melting are summarised in Table 2. The ingot for zone melting is previously prepared as a rod of the required diameter: the quality of the final product is largely determined by the composition and purity of these ingots. Various heating methods are used to generate the molten zone in the sample. Thus, relatively large (4–7 mm in diameter) monocrystals (or polycrystalline ingots) have been obtained with high-frequency[27,31] or electron-beam heating.[21] Thinner monocrystals (~1 mm diameter or less) have been prepared successfully by electric arc or laser methods of heating.[28] Dissociation and evaporation of the LaB_6 are avoided by carrying out the zone melting operation in an atmosphere of purified gas (usually argon).[27–30] Nitrogen, hydrogen, and helium have also been used.[21] The concentration of impurities can be lowered to the 10^{-3}–10^{-4}

wt.% level by repeated zone passes (see Table 2). It is reported[29] that a single zone pass can lower the impurity concentration (transition metals of Groups IV–VIII, Cu, Al, Ca, etc.) by a factor of 13–69, i.e. almost to the 10^{-2}–10^{-3} wt.% level, increasing to a factor of 315 (10^{-3} wt.%) after three passes.

Table 2. Preparation of LaB_6 monocrystals by the liquid phase (zone melting) method.

Preparative conditions			Characteristics of the monocrystals		Refs.
composition of initial billet c^{p}_{Σ}, wt.%	atmosphere; pressure, mmHg	formula	impurities, wt.%	growth direction; crystal size, mm	
LaB_6: 99.9	Ar; $1.1 \cdot 10^4$	LaB_6	non detected (3 zone passes)	not determined; $l = 60$, $d = 7$	[27]
$LaB_6 > 99.0$; $LaB_6 + (1.6-2)$	N_2; 20	La_xB_6, where $0.85 < x < 1.0$	$c^{p}_{\Sigma} < 0.1$ (microprobe) (1 zone pass)	not determined; $l = 25$, $d = 3.6$	[21]
LaB_6; $c^{p}_{\Sigma} = 0.485$	Ar; 760	–	$c^{p}_{\Sigma} = 0.043$ (2 zone passes)	⟨100⟩; $l = 60$, $d = 1.1$	[28]
$LaB_{6.00\pm0.03}$; $LaB_{5.99}$ and $LaB_{5.81}$	Ar; 52	$LaB_{6.00\pm0.15}$, $LaB_{5.86}$, $LaB_{5.72}$	$c^{p}_{\Sigma} = 0.0045$ (3 zone passes)	⟨100⟩; $l = 23-26$, $d = 0.25-1.50$	[29, 30]

Notes: c^{p}_{Σ} is the total impurity concentration; l is the length and d is the diameter of the crystal.

In most of this work the initial LaB_6 had a stoichiometric composition. However, some workers used specially prepared initial samples which were deficient in lanthanum (i.e. contained added boron). In this way it was shown[21] that in order to produce good-quality billets boron powder must be added to the LaB_6 powder (2 mole boron to 1 mole LaB_6). The resulting monocrystals were of good quality, but they contained an excess of boron as well as the LaB_4 phase. The presence of LaB_4 can be attributed to the high rate of crystallisation used in those experiments,[21] which was an order of magnitude greater than normal values.

The LaB_4 had an oriented distribution, and its presence had almost no effect on the sharpness of the Laue diagrams of the LaB_6 monocrystals. A seed crystal containing an excess of boron (86.9% B) was used[28] in addition to seeds of stoichiometric composition. By studying the melting points of the samples it was concluded that the composition of the crystals corresponding to the highest melting point is shifted from the stoichiometric value towards the boron-rich side. This observation anticipated the publication[5] of the phase diagram of the La–B system. In addition, the LaB_4 phase was detected in samples prepared from billets of stoichiometric composition. Its presence was attributed to incongruent melting of the LaB_6.

As was stated above, according to data[5] obtained by the liquid-phase method (see Fig.1), the preparation of stoichiometric LaB_6 by this method (including zone melting) is impossible even when non-stoichiometric initial ratios of La to B are used to allow for differences in evaporation rate at the growth temperature. However, some workers[27,31,33] have assigned the formula LaB_6 to their lanthanum hexaboride crystals on the basis of chemical analysis (and within the precision of that method, see Table 2). We should stress that, unfortunately, the exact quantities of B and La in the resulting LaB_6 monocrystals are not stated in those papers, and no indication is given of the precision of the chemical analysis. Therefore it is difficult to establish the exact ratio of B to La in those samples and the exact formula of the hexaboride.

This shortcoming is not found in an analytical investigation[30] specially aimed at determining the stoichiometry of the grown LaB_6 crystals (see Table 2) and at identifying the impurities in the samples. All the monocrystals were found to be deficient in boron both in respect of their stoichiometric composition and in respect of the composition of the initial ingot, but they were free from inclusions of the LaB_4 phase. Relatively large amounts of carbon were detected in the crystals. The low boron content was attributed[30] to the formation of a compound between boron and carbon by the reaction of carbon with the LaB_6 melt (but no experimental evidence for this suggestion is given). On the evidence of chemical analysis and density data these workers concluded that the boron sublattice contained defects and that La atoms could be accommodated in the sites of the missing octahedra of boron atoms.

Thus the liquid-phase method can be used to prepare reasonably large monocrystals of high purity, but it has serious disadvantages such as a variable and non-stoichiometric composition of the resulting LaB^6 crystals and the presence (in some cases) of LaB_4 and B inclusions.

3. Crystallisation from Solutions

The solution method consists in the mass (or seeded) crystallisation of refractory compounds from metallic, salt, or hydrothermal solutions. The crystallisation takes place at a fixed (or variable) solution supersaturation, produced by evaporating the solvent or by lowering the temperature and by the corresponding decrease in solubility of the substance to be crystallised. The crystallisation is controlled by using a seed crystal immersed in the solution, and by establishing special regimes of solvent evaporation and cooling the system or adding feed material to it.[22]

The variants of this method differ in the nature of the solvent (elements, compounds, metals, salts) and in its relationship to the solute (i.e. in its ability to form compounds with it).[22] One of the main attractions of the solution method is the possibility of obtaining different morphological modifications of the monocrystals (needles, plates, isometric crystals), and also the relatively low temperatures of the growth processes and their technological simplicity. So far, only crystallisation from solutions in metallic melt and electrocrystallisation have been used to prepare monocrystals by the solution method. Information on the crystals prepared by these methods is given in Table 3.

Let us examine in greater detail the solution method, which appears to offer the most promising possibilities for the production of stoichiometric LaB_6 crystals. To control the crystallisation of LaB_6 from solution in Al we need information on the phase equilibria in the ternary La–B–Al system at different temperatures, and also data on the polythermal section of the LaB_6–Al phase diagram. If these data are available we can establish the following:

1) the temperature dependence of the solubility of LaB_6 in an Al melt;

2) the phase relationships and interconversion during crystallisation.

However, the phase diagram of the La–B–Al system has not so far been determined. The reported[46] isothermal section of the phase diagram at 873 K shows that ternary compounds are not formed on this section and that the LaB_6 is in equilibrium with the Al, indicating the possibility of preparing LaB_6 crystals from the Al melt. Since the LaB_4–Al equilibrium does not appear on the isothermal section, the LaB_4 phase cannot crystallise and contaminate the LaB_6 crystals. There is no information on the temperature dependence of the solubility of LaB_6 in an aluminium melt: the composition of the initial charge is usually calculated approximately by equating the solubility of LaB_6 to that of boron in aluminium at the given temperature. This estimate is only a rough approximation, and apparently too high, but at present we have no better way of defining the crystallisation regime of the LaB_6.

An overall representation of the crystallisation regimes can be based on the data in Fig.2, which shows a polythermal section with a metastable region in the phase diagram of refractory compound (MN)–solvent metal (R) systems, together with possible variants of the mass crystallisation regime.

The metastable region, defined by the full curves, is divided into two parts by the dot-and-dash curves, corresponding to the spontaneous formation of singlet nuclei (part *I*, temperature range T_1–T_2) and to massive nucleation (part *II*, range T_2–T_3), but not so massive as in the labile region below T_3. After being heated to the required temperature and held at that temperature for the time needed for the synthesis and homogenisation of the molten solution the system can be cooled according to several regimes, of which the most effective is $A_1B_1C_1D_1$. After a hold at the temperature A_1 the system is rapidly cooled to the temperature B_1 to form a relatively small number of nuclei, then the temperature is raised to C_1 to redissolve the more unstable nuclei (in order to decrease the number of nuclei and thus obtain larger crystals), and lastly the system is cooled along the line C_1D_1, which is parallel to the solubility curve of the crystallising compound. Other regimes (see Fig.2) yield smaller and less perfect monocrystals, and are only used for special reasons.[47]

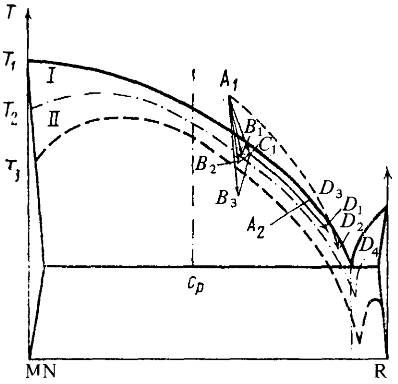

Figure 2. Metastable region (diagrammatic) in a polythermal section of the MN–R phase diagram and mass crystallisation regimes (from Ref.47).

LaB_6 monocrystals of stoichiometric (or near-stoichiometric) composition are obtained by crystallising the system by the solution method according to the LaB_6–Al polythermal section (Fig.3), starting from the temperature 2073 K at which the left-hand edge of the homogeneity region begins to follow the stoichiometric composition towards lower temperatures. This

property of the system imparts some substantial advantages to the solution method as compared with other methods of producing LaB_6 crystals of stoichiometric composition.

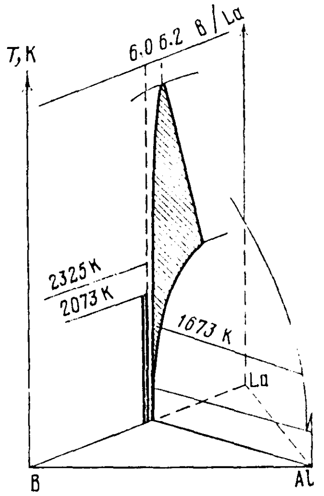

Figure 3. Polythermal section (diagrammatic) of the LaB_6–Al phase diagram (from Ref.47).

The LaB_6 crystals are usually prepared as follows. Known weights of boron and lanthanum (in stoichiometric proportions) are placed in an alundum crucible or boat together with the aluminium, heated in an argon atmosphere to the required temperature, held at this temperature for several hours in order to homogenise the melt, and after rapidly lowering and again raising the temperature the system is brought to 873 K by forced cooling (see Fig.2).[47] The fundamental condition for successful crystallisation is that the point $B_{1(2)}$ must always lie within the metastability region (preferably, in its upper part). The following mass crystallisation regimes can be defined (Fig.2): $A_1B_1C_1D_1$ (the optimum); $A_1B_2C_1D_1$ (a possible regime for a broad homogeneity region of the crystallising substance); A_1D_2 (an "incorrect" regime, leading to the deposition of very small crystals); $A_2D_3D_4$ (a possible regime for a low synthesis temperature).

After being cooled the aluminium ingots are dissolved in dilute HCl, NaOH, or KOH to isolate the LaB_6 crystals. La_2O_3 can be used as one of the initial components instead of metallic La: in this case the reaction $La_2O_3 + B + Al \rightarrow LaB_6 + Al_2O_3 +$ other products takes place in the aluminium melt.[44,48]

In the temperature range 1473–1773 K (see Table 3) the LaB_6 crystallises from solution in an Al melt in three morphological modifications: needles, plates, or isometric cubic crystals (Fig.4*a* and 4*b*), the needles and plates being much larger than the cubic crystals. It was reported[38] that under stated experimental conditions (see Table 3) the needle-like crystals greatly outnumber those of other morphologies. For example, at a cooling rate of 75 K h^{-1} the numerical ratio of the crystals of different habit (needles : plates : cubes) was 76 : 23 : 1. It is also reported[43] that this ratio depends on the concentration of LaB_6 in the Al: increasing the concentration increases the proportion of platelets in the crystals.

From the Laue patterns of the crystals it was concluded[49] that the plates and needles have {100} cube faces, i.e. the plates have a large (100) face (several mm^2 in area) and the needles are elongated in the <100> direction. This is confirmed by data on the etching behaviour of the monocrystals.[38,42] Some crystals have smooth faces, others show conical projections and growths steps, and skeletal growth forms are also found (in the shape of hollow cubes and needles), denoting a high degree of supersaturation during the growth (Fig.4*b*). It was shown[49] that many monocrystals have a block structure, with a maximum mis-orientation of 2° in platelets and much smaller (~10′) in needles (the mis-orientation of the blocks was calculated from photographic enlargements of the Laue spots).

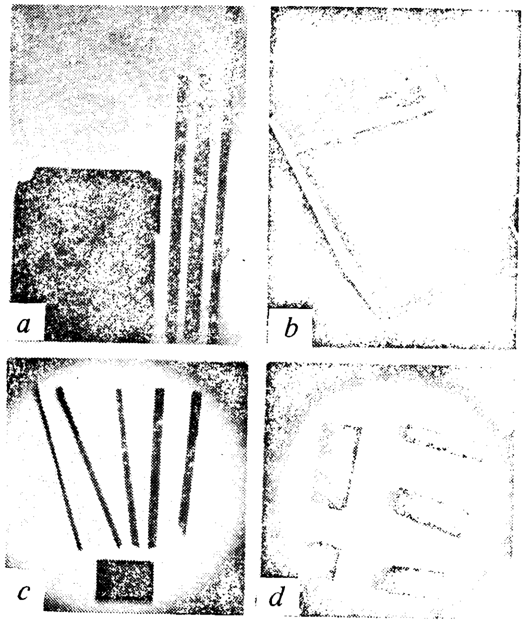

Figure 4. General shape of monocrystals of lanthanum hexaboride and of solid solutions of the $La_{1-x}M_xB_6$ type crystallised from aluminium: *a*) needles and plates of LaB_6; *b*) cubic LaB_6 crystals; *c*) $La_{1-x}Ce_xB_6$ solid solution; *d*) $La_{1-x}Tb_xB_6$ solid solution; magnification x6 (*a*, *c*, *d*) and x500 (*b*).

The composition of the LaB_6 monocrystals was determined quantitatively only in two investigations,[42,44] aiming to establish the effect of the B/La ratio in the initial ingot on the composition of the resulting crystals. In one of these studies[42] chemical analysis showed that the composition of the crystals obtained for a stoichiometric initial ratio of the components generally corresponds to the formula $LaB_{6.0}$. An initial ratio of 12 : 1 yields crystals deficient in boron ($LaB_{5.86}$). Other workers[44] varied the B/La ratio between 4 : 1 and 8 : 1 but could not detect any difference between the compositions of the resulting crystals. The reported composition in this case corresponded to a deficit of boron in the lanthanum hexaboride crystals. We should stress that in spite of the use of an excess of boron in the initial charge there has not been a single report of the deposition of a LaB_9 phase by crystallisation from an Al melt.

Aluminium inclusions have been detected in some LaB_6 crystals.[38,42] This type of solvent entrainment is observed at high rates of growth of the crystals from solution.[50] The crystallisation regime should be defined so as to avoid the formation of extraneous inclusions.

The crystallisation from Al solutions yields lanthanum hexaboride crystals of various colours: from a bright purple to violet and blue. There have been attempts to associate the blue colour with the presence of finely divided inclusions of free boron[13] or with a small lanthanum defect[3,6,19] (for example, the La content was found[6] to be 66 wt.%). However an X-ray microprobe analysis of crystals of different colour prepared by the solution method detected identical boron concentrations in all the crystals.[44] It was reported[49] that after brief etching in dilute HNO_3 all the crystals display a bright purple colour gradually turning to blue on long exposure to air. The conclusion[44,49] was that the differences in colour between the crystals are due to differences in the state of the surface (mainly, the presence of an oxide film).

The total impurity content of these LaB_6 monocrystals according to spectrographic analysis is 0.005–0.05 wt.% (see Table 3), i.e. fully comparable with the purity of the crystals prepared by zone melting (Table 2). Obviously, even purer crystals can be prepared from purer starting materials by exploiting the distribution coefficients of the various impurities.

LaB_6 monocrystals containing the ^{10}B and ^{11}B isotopes, needed in various investigations,[49] have also been prepared by crystallisation from a solution in molten Al.

In an attempt to improve the emission properties of LaB_6 cathodes, monocrystals of solid solutions of the type $La_{1-x}.M_xB_6$ have been prepared,[40,44,48,51,52] where M is a rare-earth (Ce, Gd, Tb, Pr, Nd, Sm, Dy, Y) or an alkaline earth metal (Ba), and x varies between 0.02 and 0.70 atom fraction. These are similar in size to the pure LaB_6 crystals (needles and platelets, see Figs.4c and 4d). It was reported[44] that the composition of the solid solution crystals is not exactly correlated with the initial component ratio. The discrepancy between the initial LaB_6/MB_6 ratio and the composition of the crystals can be as high as ±15 mole % in some crystals. Other workers[52] find this scatter to be less than 8 at.%.

Another method (electrocrystallisation from molten salt solutions) has been used to prepare fairly large cubic monocrystals of LaB_6 (see Table 3). The most significant feature of this method is that electrolysis of the molten salts (or oxides) is carried out at constant temperature. The driving force of the crystallisation process is the applied potential gradient. Electrolysis has been carried out at a constant voltage between 1.85 and 2.1 V, which gives the cathodic current density (20–40 mA cm^{-2}) needed for crystal growth. Unfortunately, the composition and impurity content of the LaB_6 crystals (grown on a seed) is not quoted,[45] and these results cannot be compared with those obtained by other methods.

A comparison of all the methods of preparing lanthanum hexaboride crystals (Table 4) shows that the highest temperatures are used in the liquid-phase methods; in the gas-phase and the solution methods the maximum temperatures are similar, and lower than T_m for lanthanum hexaboride by almost a factor of two; the liquid-phase method offers the highest rate of growth of monocrystals. Though each of these methods (in principle) can be used, with appropriate seeds, to grow single crystals oriented in any required crystallographic direction, this has been achieved, in practice, only in the liquid-phase method. Different morphological modifications of idiomorphic monocrystals can be obtained only by the solution method. The limiting impurity concentrations in monocrystals prepared by the different methods are approximately equal. Allowing for the shape of the LaB_6 homogeneity region (especially in crystallisation by the solution method) leads to the production of stoichiometric or very nearly stoichiometric monocrystals. The liquid-phase method often produces inclusions of LaB_4 and B, while inclusions of Al are obtained when the solution method is used.

The most perfect monocrystals are grown by the solution method, with the smallest block misalignment and the lowest dislocation density. Single crystals of a prescribed shape can be prepared only by solution and by liquid-phase methods (in the latter case, by using Stepanov's profiling method[53]). These aspects should not be forgotten when comparing the future prospects of the various methods. On the whole it is difficult to identify any one method as superior to all others. Each method has its advantages and disadvantages, and each can yield monocrystals of adequate quality. In view of the practical requirement for monocrystals in needle or platelet form for the preparation of hot or cold emission cathodes, and of the difficulty of growing those crystals by the liquid-phase method, the solution method of growing LaB_6 crystals of stoichiometric composition offers some advantage over the other methods.

Table 4. Comparison of methods of preparing LaB_6 monocrystals.

Parameters	Methods		
	gas phase	liquid phase	solution
	Preparative conditions		
Temperature range, K	1273–1723	above 2988 (degree of superheating not quoted)	1073–1773
Growth time or rate of pulling (or cooling)	0.5–3 h	18–420 mm h^{-1}	5–75 K h^{-1}
Other features and prospects of the method	preparation of oriented regular structures	growth on seeds	growth of crystals in a prescribed orientation; electrocrystallisation
	Characteristics of resulting monocrystals		
Maximum size, mm	$l = 5$ (needles), $d = 2 \times 10^{-5}$	$l < 120$ (rods), $d = 1–10$	needles 10.0 × 0.5 × 0.4; platelets 6.00 × 7.00 × 0.15; cubic crystal 6 × 6 × 5
Impurity content, wt.%	at the limit of sensitivity of the microprobe	$10^{-1}–10^{-4}$	Al up to 2×10^{-1} – $(5–10) \times 10^{-3}$
Structural perfection (misorientation of the blocks)	no data	between 20″ and a few degrees	platelets up to 2°, needles up to 10′
Dislocation density, cm^{-2}, and face	$10^4–10^5$; (100)	$10^6–10^7$; (100)	$10^3–10^5$; (100)
Possibility of preparing monocrystals of stoichiometric composition	yes	no	yes

These conclusions are confirmed by X-ray structural studies[17,54,55] of three LaB_6 monocrystals prepared by the solution method with different B/La ratios in an Al melt and at different temperatures (B/La = 9:1 and 5:1 at 1673 K; B/La = 9:1 at 2073 K). The results on the crystal structure of LaB_6, shown in Table 5, were unexpected. Instead of defects in the lanthanum sublattice, which could have been expected in boron-rich compositions,[3,10] full occupancy of the lanthanum positions and a small defect density in the boron sublattice were observed in all three crystals, irrespective of their composition. It follows that the data on the homogeneity region of LaB_6 (see Fig.3), at least those at 2073 K and below, need to be re-examined: it appears that the boundary coinciding with the line of stoichiometric composition should be the right (rather than the left) solidus line. With this exception the shape of the homogeneity region should be as outlined in Ref.6.

Table 5. Data on the structure of LaB_6 (from Refs.54 and 55).

Structure parameters	Crystal No.1	Crystal No.2	Crystal No.3
Position of boron atom, x_B	0.19956 (16)	0.19957 (15)	0.19948 (14)
Occupancy and position factor of the boron, %	96.4 (7)	97.2 (5)	98.2 (5)
Isotropic temperature factor of the lanthanum U_{iso}, Å^2	0.00535 (3)	0.00551 (2)	0.00525 (2)
Anisotropic temperature factor of the boron, Å^2: U_{11} $U_{22} = U_{33}$	0.0031 (2) 0.0044 (2)	0.0032 (2) 0.0046 (1)	0.0031 (2) 0.0046 (1)
Divergence factor R, %	1.36 (935 reflections)	1.10 (1224 reflections	1.15 (1190 reflections)
B/La atomic ratios:			
from X-ray analysis data	5.76	5.80	5.86
from chemical analysis data	5.7	—	6.8

Notes. The standard errors are shown in brackets. The following initial ratios in the melt and temperatures were used: crystal No.1, B/La = 9:1, T = 1673 K; crystal No.2, B/La = 5:1, T = 1673 K; crystal No.3, B/La = 9:1, T = 2073 K.

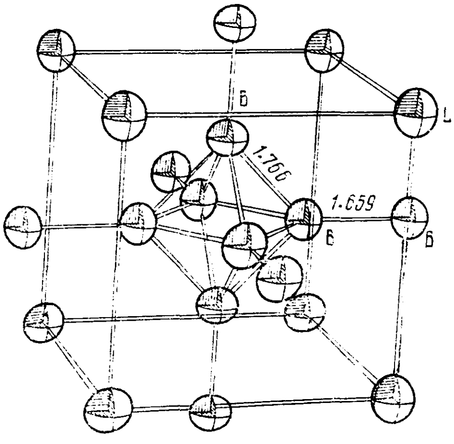

Figure 5. Crystal structure of LaB_6; the thermal vibration ellipsoids of the atoms are taken from Refs.54 and 55.

Another important result of these studies[54,55] is the recognition of a large anisotropy in the thermal vibrations of the boron atoms (see Fig.5 and Table 5). It is clear that the thermal vibrations of the boron atoms are weaker in the direction of the bond between octahedra than in the direction of the bonds within the octahedron. This conclusion is consistent with the results of studies of LaB_6 monocrystals by Raman spectroscopy,[56,57] according to which the force constants of the B–B bonds between octahedra and within the octahedra are 2.18 and 1.28 mdyn Å^{-1} respectively. We should also stress that the amplitude of the thermal vibrations of the La atoms is greater than that of the B atoms (see Table 5). This suggests a rigid boron sublattice with lanthanum atoms vibrating relatively freely in its interstitial sites. These aspects of the crystal structure of lanthanum hexaboride are responsible for many of its properties, discussed in the next section.

IV. SOME PROPERTIES OF LANTHANUM HEXABORIDE MONOCRYSTALS

In this section we shall aim as far as possible to discover the relationship between the properties and the composition of LaB_6 monocrystals.

1. Electrophysical Properties

The electrophysical properties of LaB_6 monocrystals have been studied mainly on samples prepared by zone melting.[27,58,59] The results confirm the metallic nature of LaB_6, previously established for polycrystalline samples.[10] Hall effect measurements on samples of two types (prepared with 1 pass and 3 passes of the molten zone respectively) gave the same value of the Hall constant (R_H) in both cases: in other words, this constant is independent of the purity of the crystals.[27] The carrier concentration calculated from R_H is ~1 electron per La atom, which agrees with the band structure of the hexaborides of tervalent rare-earth metals suggested in the early publications.[60,61] An important characteristic of LaB_6 monocrystals is the ratio of the electrical conductivities at 300 and 4.2 K ($\rho_{300}/\rho_{4.2}$). We know that the electrical conductivity of metals at room temperature is determined mainly by the scattering of the conduction electrons on acoustic phonons, whereas at liquid-helium temperatures it is determined by scattering at impurity atoms and lattice defects.[62] Therefore this ratio is very sensitive to the quality of the crystals: the fewer impurities and defects are present in the crystal, the lower will be the residual electrical resistance $\rho_{4.2}$, and the higher the ratio $\rho_{300}/\rho_{4.2}$. Thus, for melted polycrystalline samples (1 zone pass) containing 10^{-1}–10^{-2} wt.% of impurities the ratio was 20–45,[27,59] whereas for the purer monocrystals (3 zone passes) containing ~10^{-3}–10^{-4} wt.% of impurities the ratio was 200–450,[27,58] and even as high as 740.[63] In monocrystals prepared by the solution method the ratio $\rho_{300}/\rho_{4.2} \cong 200$ [35] corresponds to the lower limit for the zone-melted crystals. However, we should remember that the error in measuring this quantity may be large in the case of small crystals.

A study[58] of the temperature dependence of the electrical resistance of a zone-melted monocrystal ($\rho_{300}/\rho_{4.2} = 450$) in the range 360–4.2 K has shown the need to allow for the contribution from the scattering of electrons on optical phonons, which becomes appreciable at ~100 K. At 300 K this contribution accounts for ~30% of the total resistivity of the LaB_6. The scattering of electrons on optical phonons is an important difference between LaB_6 and metallic elements, which confirms the ionic nature of the interactions between the boron and lanthanum sublattices.[60] A study of the dynamic resistance of a LaB_6 monocrystal at 1.7 K by the point contact spectroscopy method confirmed the predominance of electron–phonon interaction processes in the scattering of electrons.[64]

Experimental studies of magnetoresistance and of the de Haas–van Alphen effect have been made on monocrystals prepared by solution and liquid-phase methods,[35,63,65] using models of the Fermi surface for LaB_6 which were consistent both internally and with calculations of the band structure of LaB_6.[66,68] According to those measurements[35,63,65] the conduction band of LaB_6 is very wide, and the conduction electrons have a negligibly small *s* character owing to the hybridisation of the 5*d* orbitals of the lanthanum atoms with the 2*s*–2*p* orbitals of the boron atoms. A study of the energy structure of the valence band by determining the angular dependence of the photo-emission from the (100) faces of a LaB_6 single crystal prepared by zone melting[69] revealed the presence of several sub-bands in positions agreeing to within ~0.5 eV with calculated results.[67]

Information on the band structure can also be obtained from the reflectance spectra, which have been studied on polycrystalline samples prepared by zone melting and on films of LaB_6 in the energy range 0.05–6 eV.[25,70–74]

2. Optical Properties

The optical properties of LaB_6 monocrystals were first studied over a wide range of energies (0.05–40 eV) on laminated crystals (mosaics of platelets) prepared by the solution method.[75,76] The reflectance spectrum of LaB_6 (curve *1* of Fig. 6*a*) shows a deep minimum at an energy of 2.1 eV, due to the interaction of light with the conduction electrons. It corresponds to a sharp maximum in the loss function ($-\mathrm{Im}\,\varepsilon^{-1}$, curve *3* of Fig. 6*b*). At energies greater than 2.1 eV we observe a steep increase in the imaginary part of the dielectric constant ε_2 (curve *2* of Fig. 6*b*), indicating band-to-band transitions (direct band gap) of the electrons from the valence band to the conduction band, whose lowest levels are filled with electrons. Hence the spectra of the optical constants in present energy range are determined both by the conduction electrons and by the inter-band transitions, and therefore the frequency ω_{min} corresponding to R_{min} is not equal to the plasma frequency ω_p. By separating the contribution from the conduction electrons (ε^e) (curve *4* of Fig. 6*b*) to the real part of the dielectric constant ε_1 (curve *1* of Fig. 6*b*) we can determine the true value of the plasma frequency ω_p. Inspection of the characteristic loss function ($-\mathrm{Im}\,\varepsilon^{-1}$, curve *3* of Fig. 6*b*) establishes the presence of a broad maximum at energies of 27–30 eV, due to the onset of plasma vibrations of the valence electrons. The calculated energy of these vibrations is 20 eV, i.e. we find (as in the case of the conduction electrons) a shift in the energy of the plasma vibrations as a result of band-to-band transitions. The similarity between the spectral dependence of the characteristic loss functions for LaB_6 and for the betarhombohedral modification of elemental boron suggests that the role of the boron atom in the formation of the spectrum of the hexaboride is dominant in the high-energy region.[76]

The boron sublattice of LaB_6 also determines the form of the Raman spectrum, which was studied on monocrystals prepared by zone melting.[56,77] The spectra were measured on polished (100) and (111) surfaces of monocrystals. Several peaks were observed, and assigned to three modes of lattice vibration active in the Raman region:

	From Ref.56	From Ref.77	
A_{1g}	1258 cm^{-1}	1262 cm^{-1}	B-B bond
E_g	1120 cm^{-1}	1138 cm^{-1}	B-B bond
F_{2g}	682 cm^{-1}	688 cm^{-1}	distortion of the boron sublattice

A peak at 214 cm^{-1}, attributed to scattering on defects of the crystal structure, was also observed.[77] A similar peak at 208 cm^{-1} was observed[58] in $La_{1-x}Ba_xB_6$ monocrystals (where $x = 0.02-0.046$) and attributed to the local perturbation of the symmetry produced by the replacement of La by Ba.

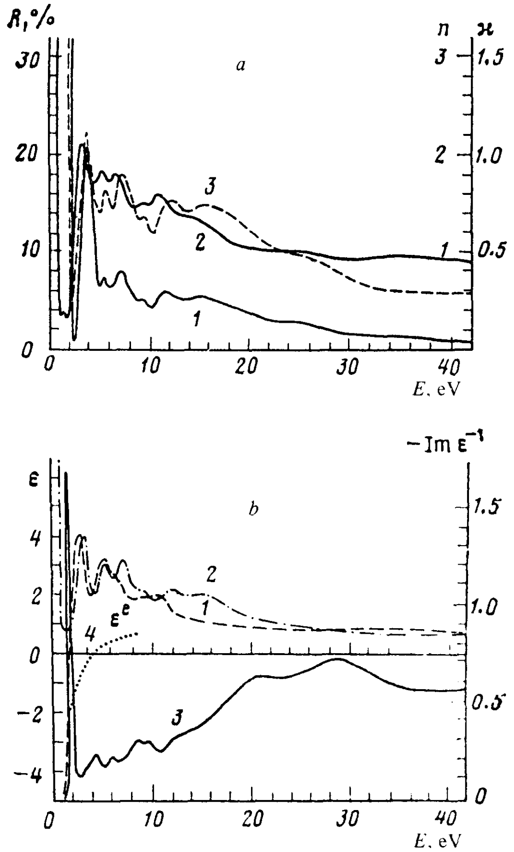

Figure 6. Dependence of the optical constants of LaB_6 on the energy *E* of the incident radiation;[75,76] *a*) reflectance *R* (*1*), refractive index *n* (*2*), and extinction coefficient κ (*3*); *b*) real (ε_1, *1*) and imaginary (ε_2, *2*) parts of the dielectric permeability function and of the loss function ($-\mathrm{Im}\,\varepsilon^{-1}$, 3).

3. Mechanical Properties

The elastic properties of LaB_6 are also determined mainly by the boron sublattice, as shown by measurements of the elastic constants of LaB_6 on samples cut in the <001>, <110>, and <111> directions from single crystals prepared by zone melting:[57]

$$C_{11} = 45.33 \times 10^{10}\ \mathrm{Pa}$$
$$C_{12} = 1.82 \times 10^{10}\ \mathrm{Pa}$$
$$C_{44} = 9.01 \times 10^{10}\ \mathrm{Pa}$$

The anisotropy factor is $A = 2C_{44}/(C_{11} - C_{12}) = 0.41$. Young's modulus, calculated for the <100> direction, is 45.18×10^{10} Pa, while the value calculated from the force constants of the bonds in the boron sublattice between octahedra and within the octahedra[56] is 40×10^{10} Pa. This good agreement is interpreted[57] as evidence that the elastic constants of LaB_6 are determined by the rigid boron sublattice. The large ionic contribution to the bond between the boron and the metal sublattice accounts for the anisotropy factor $A < 1$ in LaB_6 (a value usually found in ionic crystals).

Young's modulus for polycrystalline LaB_6 prepared by zone melting is 39.24×10^{10} Pa,[78] i.e. it is slightly lower than for the monocrystals. It is interesting to note that a theoretical calculation of Young's modulus for LaB_6 [79] gave a value of 47.09×10^{10} Pa, i.e. in these monocrystals the measured Young's modulus is very close to the theroretical value.

Data on the micro-hardness of LaB_6 monocrystals prepared by various methods are shown in Table 6. They cover a wide range, but since the measurements were carried out with different loads it is difficult to compare the results. There is an obvious tendency for the micro-hardness to decrease with increasing load on the indentor. Furthermore, the micro-hardness measured with a Vickers pyramid (H_V) is different from that measured with a Knoop pyramid (H_K), which is a characteristic of brittle materials.[80] The brittleness of LaB_6 is found to be similar to that of silicon.[80]

Table 6. Micro-hardness of LaB_6 monocrystals measured by different methods. •

The anisotropy of the micro-hardness has been studied on monocrystals prepared by zone melting[80] and by the solution method.[81] In a study[81] of the anisotropy of the hardness (polar anisotropy) on the (100) face the maximum hardness was found with the longer diagonal of the indentor oriented in the <010> direction, and the minimum in the <011> direction (the difference between the two measurements was 300 kgf mm^{-2}). Ref.80 describes a study of the reticular anisotropy of the micro-hardness, showing that the maximum value of H_K occurs in the (100) plane, where the density of La atoms is a maximum, and the minimum occurs in the (111) plane.

4. Emission Properties

Because of the extensive use of LaB_6 cathodes in various types of electronic device, data on the thermo-electronic work function ϕ of the material are of interest. The cathode current density I_c during thermo-electronic emission is described by the Richardson–Dushman equation

$$I_c, \text{A cm}^{-2} = AT^2 \exp(-e\varphi/kT) \quad (1)$$

where T is the temperature of the cathode (K), e is the charge on the electron, and A is the Richardson constant. The work function ϕ can be determined by two methods: 1) graphically, from the slope of the linear plot of $\lg(I/T^2)$ against e/kT (we shall call this value of the work function ϕ_R), and 2) by calculation from formula (1), assuming a value of the Richardson constant of $A = 120$ cm^{-2} K^{-2} (we shall call this value ϕ_{ef}). Both ϕ_R and ϕ_{ef} values are used in published work, though according to some workers[83] the use of ϕ_{ef} is preferable.

The results of various workers on the work function of polycrystalline LaB_6 and of LaB_6 monocrystals have recently been critically examined in Refs.83 and 84 respectively.

Storms and Mueller[83] examine in detail the various factors responsible for the large scatter of the measurements of work function on polycrystalline LaB_6: deviations from stoichiometry in the bulk of the sample, differences in composition of the surface whose emission is measured, the temperature of the experiment, and the hold time of the sample at this temperature, the presence of impurities in the sample and in the residual atmosphere, and many other factors. For polycrystalline samples of composition in the range $LaB_{5.85}$–$LaB_{6.50}$ the surface composition at 1500 K varied between $LaB_{6.032}$ and $LaB_{6.047}$, the work function ϕ_{ef} was 2.91–2.93 eV, and ϕ_R was 3.15–3.12 eV. Surprisingly, a further increase in the overall boron content produces an increase in ϕ_{ef} and a decrease in ϕ_R (a sample of composition $LaB_{8.6}$, with a surface composition $LaB_{6.1}$, gave $\phi_{ef} = 3.17$ and $\phi_R = 2.21$ eV).

Evidently, these factors must affect the measured work function also in the case of monocrystals. Furthermore, the work function of the LaB_6 sample depends on the crystallographic direction, as in metals with body-centred cubic, face-centred cubic, or close-packed hexagonal crystal lattice. Data on the emission properties of monocrystals prepared by liquid-phase and by solution methods are shown in Table 7. We note that the scatter in the ϕ values is large also in monocrystals. Nevertheless the anisotropy in the work function with respect to the crystal orientation is clearly observable: $\phi_{(100)} \leq \phi_{(110)} \leq \phi_{(111)}$.

It would be interesting to compare the work functions of monocrystals differing in purity and in composition. Unfortunately, this comparison is possible only in a few cases because of the inadequate specification of the experimental materials in much of the published work. Thus, boron-rich crystals prepared by zone melting ($La_{1-x}B_6$) and having a high impurity concentration[21] have a higher work function (on all faces) than crystals with a boron deficit ($LaB_{5.86}$) containing very few impurities.[30,84] The work function of the (100) face of LaB_6 monocrystals[89,90] prepared by a solution method[37–39] and containing ~10^{-2} wt.% of impurity is close to that of crystals prepared by zone melting and having a similar impurity concentration.[21,31]

By using modern methods of studying solid surfaces such as Auger electron spectroscopy (AES) and low-energy electron diffraction (LEED) the effect of impurities on the work function of LaB_6 monocrystals has been demonstrated more clearly. In particular, it has been shown[91] that the carbon present in the sample prepared by zone melting with one zone pass diffuses to the surface on heating the sample and forms a monolayer of graphite which is stable for a long time even at 1500 K. This effect increases the work function of LaB_6.

It has been shown[84,90,92] that carbon and oxygen are the main impurities on the (100), (110), and (111) surfaces of LaB_6 monocrystals. Their bond to the surfaces is fairly strong, and they are completely removed only by heating the sample to ~1700 K in a vacuum of 10^{-8}–10^{-10} mmHg. Studies of the oxidation kinetics at room temperature of clean (100), (110), and (111) surfaces of LaB_6 monocrystals showed that at oxygen pressures of 10^{-7}–10^{-9} mmHg O_2 adsorption raises the work function of these faces by 1.6, 1.3, and 1.1 eV respectively.[92–96] Raising the temperature to 1700 K strengthens the oxidation, and produces an increase of 2.4 eV in the work function of the (100) face[92] and a decrease in the emission current.[90,91] A large decrease in emission current is produced also by hydrogen, methane, and water vapour.[90] It has been established that rearrangement of the (110) monocrystal surface with formation of (111) facets takes place in an oxygen atmosphere at ~10^{-6} mmHg and 1700 K, leading to an increase in the work function of the (110) face and a decrease in emission current.[86,98]

Table 8. Atomic ratio B/La on the surface of different faces of LaB_6 monocrystals prepared by solution and by liquid-phase methods.

Face	B/La	Measurement method	Refs.	Face	B/La	Measurement method	Refs.
Solution method				Liquid-phase method			
(100)	2.3—2.6	AES	[36]	(100)	4.1 ± 0.1	AES	[84]
(100)	2.33—2.60	AES	[92]	(100)	4.0	UPS	[101]
(100)	2.0	AES	[1]	(110)	5.4 ± 0.1	AES	[84]
				(111)	5.9 ± 0.2	AES	[84]

The nature of the work function anisotropy in different faces of the LaB_6 monocrystals is also of interest. Studies of these faces by AES, LEED, UPS (ultraviolet photoelectron spectroscopy), and XPS (X-ray photoelectron spectroscopy) have shown[36,84,87,92,93,99–101] that the Ba/La ratio on the monocrystal surface increases in the sequence (100) < (110) < (111) (see Table 8). The work function decreases in the same order, i.e. the greater the density of La atoms on the surface, the lower is the work function. This observation is unexpected, since the opposite effect is found on elemental metals: ϕ increases with the density of metal atoms on the surface. The explanation of this anomaly probably resides in the atomic structure of the surface in the different faces of the LaB_6 crystals.[102,103,106,112] According to current views, the (100) surface consists of a plane of La ions, whereas in the (110) and (111) faces the La ions are displaced from their equilibrium positions by ~1.66 and 1.2 Å respectively (Fig.7), i.e. the greater the displacement of the La ions "from within" towards the surface, the lower is the work function. According to some workers[100–103] the difference in work function of the LaB_6 faces is explained by differences in the electrical dipole moments created by the positively charged La^{3+} ions and the octahedra of B atoms in the surface layer: the work function of the (100) and (110) faces is lower than that of the (111) face because their dipole moment is higher.

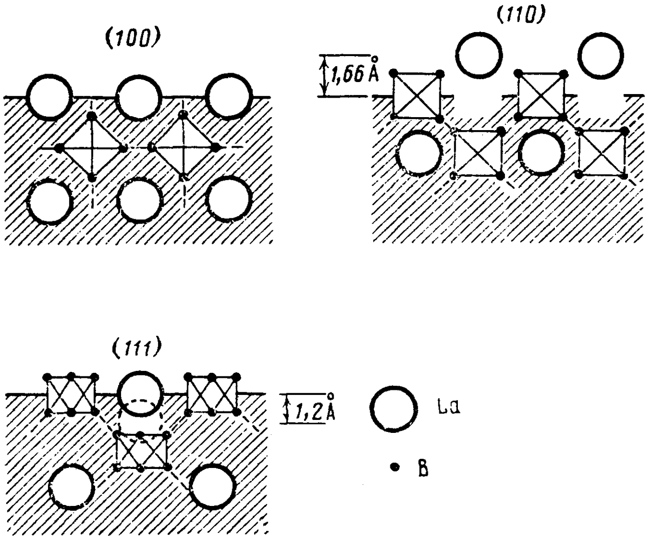

Figure 7. Surface structure of different faces of the LaB_6 crystal (from Ref.103).

Recent studies[104–106] of the energy structure of the LaB_6 surface have identified several peaks in the region of 1.5 to 3 eV below the Fermi level from the UPS spectra of the (100), (110), and (111) faces. These peaks are attributed to the so-called "dangling" bonds, i.e. to uncompensated bonds of the surface boron atoms.[107] The peaks disappear when oxygen is adsorbed on the LaB_6 surface, indicating an interaction between the oxygen atoms and the uncompensated boron bonds.[96] Adsorbed oxygen (or other gases) can form a dipolar surface layer which alters the surface potential and therefore also the work function.[94–96]

However, residual gases, including oxygen, can increase the emission rather than impair the emission properties.[108,109] Thus, it was found[109] that at an oxygen partial pressure of 10^{-10}–$(1-3) \times 10^{-9}$ mmHg the work function of the (210) face is ~0.2 eV lower than for the clean surface, and the emission is correspondingly higher. No explanation has yet been suggested.

Problems of adsorption on the surface of LaB_6 monocrystals are of practical as well as of theoretical interest in relation to the controlled modification of the emission characteristics by the simultaneous adsorption of several elements. For example, it has been shown[110] that the adsorption of Cs on the clean (100) and (110) faces of a LaB_6 crystal lowers the work function from 2.78 to 1.97 and 1.88 eV respectively. However, if the Cs is adsorbed on the same surfaces previously covered with oxygen the work function falls to 1.35 and 1.47 eV respectively. These surface coatings were found to have a reasonable thermal stability: thus, the Cs is desorbed from a clean

(100) surface of the LaB_6 crystal at ~900 K, whereas on a surface previously coated with oxygen desorption takes place at ~1150 K.[111] The work function of the clean (100) face may not be the lowest, of course. Higher-index faces have also given low values of the work function: $\phi_R = 2.3$ eV for the (321) face,[85] $\phi_{ef} = 2.41$ eV for (364),[84] $\phi = 2.2$ eV [112,113] and $\phi_R = 2.48$ eV for (210).[102]

Another method of improving the emission properties of LaB_6 monocrystals relies on doping the material. We know that the work function is given by the expression

$$\varphi=\chi-\mu \qquad (2)$$

where χ is the difference between the electrical potentials in the bulk of the metal and in the vacuum near the surface, and μ is the chemical potential of the electron gas in the metal ($\mu \approx E_F$, where E_F is the Fermi energy).[82] By varying χ or μ (for example, by doping) we can vary the work function of the LaB_6 in the required direction. In this respect the most promising materials are solid solutions based on LaB_6 in which some of the La atoms are replaced by other materials, especially rare-earth and alkaline-earth metals.

The emission properties of some solid solutions have been measured both on monocrystals and on polycrystalline samples.[51,52,88] It was found that the work function of the (100) face of the solid solution is higher than that of the LaB_6 crystals, and relatively insensitive to the nature of the added metal. It was also shown[52] that the surface of crystals of the LaB_6 solid solutions gradually become enriched in La (with respect to the bulk) at high temperatures as a result of the preferential evaporation of the second metallic component. These materials show a characteristic instability of the emission current.[88] Similar phenomena have been observed in polycrystalline solid solutions of the MB_6 type, where M = La, Y, Sc.[114] Nevertheless further work on these materials should be of interest.

Studies of field emission from LaB_6 monocrystals are also of great theoretical and practical interest in connection with the development of new materials for auto-emission cathodes.[115–117]

The first studies of field emission in an ion beam were carried out with monocrystals prepared by liquid-phase[115,118] and by solution methods.[119] It was shown that the image of a LaB_6 point in He ions at 78 K has an irregular structure. The quality of the image was worse than for metal points. However, later workers obtained images of LaB_6 points with a regular structure.

Studies of the effect of various gases (hydrogen,[120] neon, oxygen, and hydrogen[121]) on the image from a LaB_6 point revealed a rearrangement in a hydrogen atmosphere from low-index faces into faces with higher indices of the type of {012}, {013}, {112}, etc., whereas in the presence of oxygen the surface becomes strongly disordered, with cluster formation. The hydrogen reacts primarily with the surface B atoms,[120] and the oxygen with both the La and the B atoms.[121]

A study[122] of the mechanism of formation of images from points of LaB_6 and $La_{0.58}Sm_{0.42}B_6$ monocrystals in helium, neon, and hydrogen ions showed that only the metal ions (La or La and Sm) contribute to the formation of the image. However, others[121] assume that the main contribution to the formation of images of the points in He and Ne is from the uncompensated bonds of the boron atoms in the octahedra. This point of view is confirmed to some extent by studies of LaB_6 by the atomic probe method, with mass spectrometric analysis of the ions produced by field evaporation.[123,124]

Swanson[84] measured the work function and the field emission current of monocrystal points, and he concluded that LaB_6 has no real advantage as a field emitter over other refractory compounds. However, by generating microscopic projections on a point from a <100> LaB_6 monocrystal an emission current of ~10^{-5} A was obtained from the projection,[125] corresponding to a source brightness of ~10^{11} A cm^{-2} steradian^{-1}.

Nevertheless further studies of LaB_6 in an ion beam are of interest both from the standpoint of a more detailed understanding of the surface structure at the atomic level and to explain the mechanism of image formation from points of compounds. Furthermore it has been shown[102] that the evaporation under the influence of a field and the reconstruction of a surface can affect the concentration of La atoms, and therefore also the work function of the various faces. This work is extremely relevant, because using a thermo-emission cathode made of monocrystalline LaB_6 in an electron gun produces a spotty emission,[126,127] which can be eliminated (while at the same time increasing the brightness of the image) by operating the cathode in the thermal-field emission mode.[109]

5. *Some Practical Applications*

Because of the unique combination of physicochemical properties offered by LaB_6 its practical applications are extremely varied, and we shall only dwell on the most interesting and important results (in our opinion). The use of LaB_6 as a thermo-electronic emitter in the cathodes assemblies of various types of device should be mentioned first. The advantages of cathodes made of sintered LaB_6 over tungsten cathodes for use in scanning electron microscopes have long been recognised.[128–130]

The preparation of LaB_6 monocrystals stimulated the production of monocrystalline thermo-emission cathodes, the study of their characteristics, and the search for possible alternatives to oxide and tungsten cathodes.[88,106,118,126,131–143] The operating characteristics of a monocrystalline LaB_6 cathode used in commercial equipment (microanalysers and Auger spectrometers) in place of a tungsten cathode have been measured.[106,133,134] The LaB_6 cathode is shown to be brighter than the tungstem cathode (2×10^5 A cm^{-2} steradian^{-1} and 1.5×10^4 A cm^{-2} steradian^{-1} respectively), and to have a more stable emission current (better than 1×10^{-3} A h^{-1}). It was also shown[134] that a cathode consisting of a LaB_6 point with a <100> orientation can produce a cathode current density of ~50 A cm^{-2}, combined with an operating life of more than 300 h. An electron gun with a cathode made from a zone melted LaB_6 single crystal cut in the <100> direction has been developed,[135] giving an optimum brightness of 2.5×10^5 A cm^{-2} steradian^{-1} at a cathodic current density of 50 A cm^{-2}. A cathode with a monocrystal oriented in the <100> direction was reported[84] to give a current density of ~10 A cm^{-2} at 1600 to 1700 K; under these conditions the rate of evaporation of the cathode was ~1 μm year^{-1}.

The successful replacement of a rhenium cathode by a monocrystalline LaB_6 cathode in a commercial mass spectrometer has been claimed.[136] The life of the LaB_6 cathode is 10 times greater than that of the rhenium cathode, and its working temperature is lower (1750 K instead of 2500 K), which allows thermally unstable compounds to be analysed. The replacement[139] of a tungsten cathode in a micro-focus X-ray source by a LaB_6 monocrystal has given a 20 times higher current density at the target with an operational life of ~800 h.

A monocrystalline LaB_6 cathode has been fitted[140] to an electron microscope, giving a brightness of 2×10^6 A cm^{-2} steradian^{-1} and a stable operation time of over 100 h; the resolution of the microscope was 0.14 nm.

Another promising application of monocrystalline LaB_6 cathoodes is in the production of integrated circuits by electron-beam lithography.[138] A very precise and fast lithographic system has been based[141] on a monocrystalline LaB$_6$ cathode consisting of a flattened point, giving an electron beam 6.4 × 6.4 μm in cross-section and a current density of 10A cm^{-2}.

Work is also in progress on improved designs of cathode assemblies[142] and on optimised conditions for using the monocrystalline LaB$_6$ cathodes.[143] Thus a new method of attaching the monocrystal of lanthanum hexaboride to the cathode assembly gives a working life of 1000 h at a cathode working temperature of 1800 K.[142]

Considerable effort is devoted also to the use of polycrystalline LaB$_6$. For example, it has been shown that cathodes made from hot-pressed or sintered polycrystalline LaB$_6$ are potentially useful for high-current ion sources in atomic technology,[144-147] especially for the production of a high-density plasma in apparatus of the "Tokamak" type.[145,146] Sintered LaB$_6$–ZrB$_6$ compositions have also been studied with the aim of improving the mechanical and emission properties of LaB$_6$ cathodes.[148]

Powdered LaB$_6$ has been used in the isotopic analysis of iodine,[149] and found to give a relative sensitivity better than materials like the W–Th alloy, ZrC, Hf, and Re.

A study of the catalytic activity of the clean surface of LaB$_6$ powders towards the hydrogen–deuterium isotope exchange has been reported.[150] At 159 K the specific activity of LaB$_6$ is two orders of magnitude greater than the activity of γ-Al$_2$O$_3$, and only slightly lower than the activity of Pt or Ni.

---o0o---

Thus the preparation of perfect monocrystals of LaB$_6$ by any of the methods examined requires accurate information on the La–B phase diagram, and in particular on the homogeneity region of LaB$_6$. Another important requirement is a very accurate characterisation of the resulting LaB$_6$ crystals in both composition and structure, to allow these data to be related to the other properties of the material. Only by establishing these relationships can the controlled production of perfect and defect-free LaB$_6$ monocrystals, by any method, be achieved.

Electrochemical Behaviour of Phenols

T.A.Kharlamova and G.A.Tedoradze

The literature data on the electrochemical behaviour of phenol and its adsorption on various anodic materials (platinum, graphite, gold, and lead dioxide) are surveyed and the influence of the rate of application of the potential, temperature, pH, the rate of rotation of the electrode (stirring) on the maximum oxidation current of phenol and its half-wave potential is examined. The present concept concerning the mechanism of the primary electrode reaction is analysed and the possibility of the extensive oxidation of phenol is considered. The influence of a series of substituents [OH, CH_3, NO_2, Cl, C_6H_4, COOH, C_2H_5, and $C(CH_3)_3$] on the principal characteristics of the potentiodynamic relations is examined and the possibility of a correlation between the half-wave potentials $E_{1/2}$ of substituted phenols and the Hammett constants is analysed.
The bibliography includes 66 references.

I. INTRODUCTION

In connection with wide scale industrial use of phenols, two problems have arisen: the development of convenient and selective methods for their analysis and the removal of phenols from the waste water in industrial undertakings. The latter is related to the high toxicity of phenols and the difficulty of decomposing them by the usual chemical means. Electrochemical methods, especially anodic oxidation, proved to be sufficiently effective for the solution of both problems, which is the reason for the increased interest of investigators in the electrochemistry of phenols.

The aim of the present review is to survey the factual data which have accumulated concerning the oxidation of phenols on anodes.

II. THE PLATINUM ELECTRODE

1. Potentiodynamic Measurements

There is a distinct oxidation wave on the voltage–current curve obtained in the oxidation of phenol on stationary and rotating platinum anodes. A typical form of such curves is illustrated in Fig.1. At a phenol concentration $c_{ph} < 1 \times 10^{-4}$ M under both stationary and dynamic conditions, a single wave is observed with a distinct limiting current and there is a linear relation between the limiting current and c_{ph}. At $c_{ph} > 1 \times 10^{-4}$ M, a decrease of the current is observed on the voltage–current curves, which is due to the inhibition of the electrochemical oxidation process and the linear relation between the maximum current and c_{ph} breaks down—the current increases more slowly than the concentration.[1-3]

It has been noted that during the measurement of the potentiodynamic relation, a readily visible yellow-brown polymeric product is formed on the anode. In order to investigate the kinetics of the growth of this polymer film, ellipsometric measurements have been made in the electrochemical oxidation of phenol in 0.5 M H_2SO_4 solution.[4] Optical studies have shown that, at low potentials (~1 V relative to the reversible hydrogen electrode in the same solution), the rate of growth of the film is low and its thickness is proportional to the square root of the electrochemical oxidation time. The rate of formation of the film increases sharply as the potential shifts towards high positive values (≥2 V) (Fig.2); under these conditions, its thickness reaches on average 1000–10 000 Å.

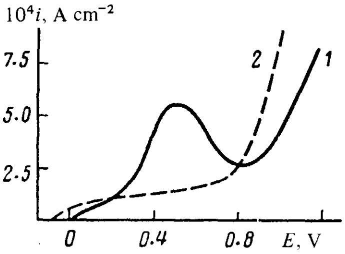

Figure 1. Potentiodynamic curve for phenol ($c_{ph} = 1 \times 10^{-3}$M) in a saturated borax solution at a platinum anode (i = current density; rate of application of potential $v = 40 \times 10^{-3}$ V s^{-1}; pH 9.5; 20 °C): *1*) supporting electrolyte plus phenol; *2*) supporting electrolyte.[3]

The observed decrease of the current on the potentiometric curve is in fact explained by the strong adsorption of the reaction products and the blocking by the latter of the anode surface.[1-3] Levina et al.[5], who investigated the electrochemical oxidation of phenol in 1 *N* H_2SO_4 solution, assumed that the decrease of the current is caused by the adsorption of oxygen, which cannot occupy the anode surface at low anodic potentials owing to the adsorption of phenol. Such competition for sites on the surface does indeed occur in the case of organic substances and must be taken into account.[6] However, in the study of the electrochemical oxidation of phenol in aqueous 1 *N* H_2SO_4 and NaOH solutions, the possibility of the formation on the anode surface of a film consisting not only of polymer molecules strongly bound to the surface but also of soluble products has been considered.[7,8] It has been suggested that, at low (<0.2 M) and higher concentrations, products of the second and first types predominate respectively.

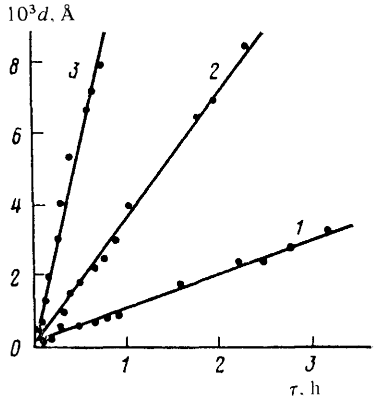

Figure 2. The rate of growth of the polymer film on the platinum electrode (d = thickness of film, τ = time) at three different potentials in a 0.5 M H_2SO_4 + 0.1 M C_6H_5OH solution; potential (V): *1*) 2.08; *2*) 2.15; *3*) 2.28.[4]

Judging from the shapes of the potentiodynamic curves, which have a deep minimum, the process should have ceased in the passivation region as the polymer film grew. Furthermore, it is well known that benzoquinone can be obtained in a satisfactory yield by the preparative oxidation of phenol. It has been suggested[8] that the oxidation of phenol in the passivation region requires that a barrier be overcome, the barrier consisting of the adsorbed polymer film. This phenomenon, involving charged transfer to the adsorbed film, is well known in polarography (the Loshkarev effect†) and involves the electrochemical reaction of a substance which has diffused towards the anode through the adsorbed layer which inhibits the process. In the case of phenol yet another explanation of the process under the conditions of the complete surfave coverage of the polymer film is possible: benzoquinone is formed on oxidation of the polymeric substance and phenol molecules are used to renew this polymer film.

The observed oxidation current depends to a large extent on the state of the surface of the anode, so that identical preliminary treatment of the electrode surface is necessary in order to obtain reproducible results. A positive effect of heat treatment[2] and of electrochemical treatment[1,3] on the surface has been noted. There is no unanimous view concerning the problem of the ratio of the maximum currents on the oxidised and reduced platinum surfaces.[1,7,11]

With increase of pH to 9.0, the oxidation half-wave potential $E_{1/2}$ shifts towards less positive values and, on further increase of pH, remains almost constant.[2] Although the $E_{1/2}$ for irreversible processes lacks the thermodynamic significance of the half-wave potential for reversible processes, its variation nevertheless provides an idea about the range of potentials in which the electrochemical process takes place. The observed shift of the phenol oxidation potential when the pH changes by unity is ~60 mV.[3]

It has been stated that the maximum phenol oxidation current depends on the pH of the medium.[2,3,5,12] However, the published data are exceptionally contradictory. Thus an appreciable change in the maximum oxidation current at pH from 5.0 to 11.0 has not been noted by Hedenburg and Freiser,[2] or Kharlamova et al.[3] and Levina et al.[5] observed in a neutral medium a decrease of the maximum phenol oxidation current compared with the currents in acid and alkaline media, while Zeigerson and Gileadi[12] altogether failed to observe the phenol oxidation current in acid and neutral solutions. They explained[12] the lack of the current by the fact that two reactions take place on the clean electrode surface—the oxidation of phenol and the formation of a layer of adsorbed phenoxy-radicals, and, as soon as the degree of surface coverage approaches unity, the rates of both reactions fall to zero, i.e. complete passivation of the process takes place. Passivation is observed at a fully determined potential, which depends on the concentration of the substance and the pH. In this connection, we may recall that phenol may be oxidised also in the passive region (see above). Evidently the authors[12] did not note the small difference between the supporting electrolyte current and the current in the presence of phenol.

The maximum current is influenced by the rate of application of the potential ν: with its increase, the maximum current rises and the rate of increase depends on the initial phenol concentration. An increase in the rate of application of the potential hardly affects the $E_{1/2}$ for the oxidation of phenol.[1]

An increase in the solution temperature (from 20° to 60 °C) entails a rise in the maximum phenol oxidation current. The temperature coefficient in an aqueous buffer solution is 2.5 to 2.9% per degree,[1,3] which may indicate a non-diffusional nature of the maximum current.

The results examined show that, for a correct interpretation of the anodic process, it is essential to possess quantitative data for the adsorption of phenol on the electrode at different potentials.

2. Adsorption

The dependence of the degree of electrode surface coverage by phenol in 0.1 *N* H_2SO_4 solution on the potential (in the range from −0.3 to +1.0 V) has been determined by the potentiodynamic pulse method (Fig.3).[13] In an analogous solution and in the same range of potentials an extremely weak dependence of the degree of adsorption on the potential in the range from −0.1 to +0.4 V [relative to the normal hydrogen electrode (n.h.e.)] has been found, in agreement with Levina et al.[13], and is described by the Temkin isotherm.[14] According to Levina et al.[13] and Kazarinov et al.[14], the adsorption kinetics obey the Roginskii–Zel'dovich equation.

The dependence of the degree of adsorption of phenol on the potential at different pH has been determined with the aid of rapid galvanostatic pulses taking into account the surface roughness factor and the amount of adsorbed oxygen.[3] It follows from Fig.4 that the degree of adsorption of phenol

†M.A.Loshkarev and Yu.M.Loshkarev, in "Vol'tamperometriya Organicheskikh i Neorganicheskikh Soedinenii" (Voltage–Current Measurements for Organic and Inorganic Compounds), Izd.Nauka, Moscow, 1985, p.35.

on the anode is almost independent of pH. If it is supposed that phenol is oxidised to CO_2 and H_2O, i.e. that the number of electrons involved in the reaction is $n = 28$, then the degree of adsorption per unit true surface is 4×10^{-10} mol cm^{-2}, which agrees with the data of Kazarinov et al.[14]

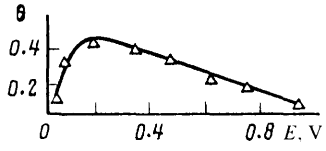

Figure 3. Dependence of the standard surface coverage of the platinum electrode θ in a 1×10^{-4} M solution of phenol on the electrode potential in 0.1 *N* H_2SO_4 solution (the potentials were measured relative to the reversible hydrogen electrode in the same solution).[13]

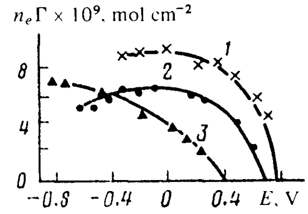

Figure 4. Dependence of the adsorption of phenol (from a 1×10^{-3} M solution) on the platinum anode on the potential at pH 1.6 (curve *1*), 7.5 (curve *2*), and 9.5 (curve *3*) taking into account the roughness factor and the amount of adsorbed oxygen (the potentials were measured relative to the 0.1 *N* calomel electrode) (n_e is the number of electrons involved in the process).[3]

Chronopotentiometric measurements in 0.1 *N* NaOH solution in the presence of 0.05, 0.1, and 0.4 M phenol[8] have shown that the amount of electricity corresponding to the transition time (i.e. the time during which a stationary current is established) falls with increase of the current and reaches a limiting value of 27.2×10^{-3} C cm^{-2} at the high polarising current density of 6×10^{-2} A cm^{-2}. In this case diffusion does not affect the transition time. During this period, the charging process takes place, the amount of charge generated exceeding by a factor of ~60 that necessary for the monolayer coverage of the platinum surface with oxygen. Hence it is concluded that the current is consumed in the formation of polymolecular phenol adsorption layers.

There exist data concerning the adsorption of a substituted phenol (*p*-nitrophenol) on the platinum anode at high anodic potentials (>1.0 V).[15] The dependence of the degree of adsorption of *p*-nitrophenol on the potential, obtained on platinised platinum in 0.1 *N* $HClO_4$ solution by the radioactive tracer method, shows that, starting from 1.3 V, the degree of adsorption rises sharply. This has been explained by the formation of a monolayer in the potential range 0.1 to 0.2 V and the fact that a polymolecular adsorbate layer is produced at $E > 1.0$ V. In determining the intensity of the UV spectra of *p*-nitrophenol and the adsorbed species, the authors[15] calculated the degree of adsorption of *p*-nitrophenol at high anodic potentials taking into account the areas of the electrodes. It was found that it corresponds to the formation of more than 10 adsorbate monolayers. However, judging from the potentiodynamic curve, the inhibition of the phenol oxidation process in acid aqueous solutions begins at a potential of ~1.0 V. For this reason, one cannot rule out the possibility that the observed multilayer adsorption refers not to phenol but to its oxidation product (see above).

Data concerning the influence of chloride ions on the adsorption of phenol are contradictory. It has been stated[16] that phenol is adsorbed more effectively than chloride ions at a concentration of the latter of 0.1 V, but the phenol concentration has not been reported. It follows from the results of an investigation[17] that in 0.1 *N* H_2SO_4 solution the adsorption of phenol (1×10^{-4} M) and the chloride ions (0.1 M) is competitive. The decrease of the degree of adsorption of phenol (1×10^{-3} M) in the presence of chlorides (0.1 M), observed by Kharlamova et al.[3], can also be accounted for by competitive adsorption. Since all the experimental data presented have been determined under different conditions, one cannot obtain a clear idea about the influence of the concentration of chloride ions on the adsorption of phenol.

III. THE GRAPHITE ELECTRODE

1. Potentiodynamic Measurements

On the graphite anode (under stationary and dynamic conditions) in the concentration range 10^{-3}–10^{-6} M, phenol gives rise to a single wave on the voltage–current curve, as on the platinum anode. The phenol oxidation current is greatly influenced by the type of impregnation mass, which, by filling the graphite pores, ensured a constant current density throughout the anode surface.[18,19] A mixture of paraffin with polyethylene is usually employed for impregnation.

The published data make it possible to establish characteristics of the influence of individual factors (the concentration of the substance, the pH of the medium, the rate of rotation of the electrode, etc.) and the appearance of a maximum on the voltage–current phenol oxidation curve. By analogy with the platinum anode, one may expect that the maximum (decrease of the current) will be shown at a specific concentration of the test substance and it does indeed follow from a series of publications[20–22] that, at $c_{pH} = 10^{-4}$ M under stationary conditions, a distinct limiting current is observed, while at $c_{ph} = 10^{-3}$ M there is a maximum. However, the opposite behaviour has also been noted:[23,24] at $c_{ph} = 10^{-4}$ M a maximum was observed, while on raising the concentration to 10^{-2} M and above there was a distinct limiting current. Kharlamova et al.[3] observed a maximum only in 0.1 *N* H_2SO_4 solution at $c_{ph} = 10^{-3}$ M, while in neutral and weakly alkaline medium a distinct limiting current was noted. The appearance of a maximum was probably due to an additional factor which had not been taken into account.

At $c_{ph} \leq 10^{-4}$ M a linear dependence of the maximum current on the phenol concentration is observed, but at $c_{ph} > 10^{-4}$ M the linearity breaks down and the limiting current increases more slowly than the concentration.[20,23,25]

The state of the graphite surface, like that of the platinum anode, influences significantly the phenol oxidation current and a preliminary treatment of the electrode surface is therefore also necessary in this instance. In almost all the published studies the working electrode surface was treated mechanically (with emery paper, an aqueous suspension of alumina, etc.) before recording each potentiodynamic curve. The favourable influence of a two-stage electrode treatment has been noted: brief boiling in ethanol (0.5 min) followed by anodic treatment at the hydrogen evolution potential in 0.1 *N* H_2SO_4 solution for 2–3 min.[3] If the electrode is not treated again after recording one voltage–current curve, then in the repeated experiment two waves appear on the curve.[21]

The phenol oxidation current depends markedly on the pH of the medium, but, as for the platinum anode, the available data differ greatly. Thus the dependence of the maximum current on the pH was found to have a minimum in a neutral medium,[3,26] which can be explained by a decrease of the concentration of the unionised form of phenol. However, in another study[16] a maximum current was observed at pH 1.2, the current diminishing with increase of pH to 3.2, while on a further increase of the pH it remains almost unchanged. Another investigation established[3,27] that the current in an acid medium is higher than in an alkaline medium, on average by ~40%, while in the study of Korshunov et al.[28] the increment in the same pH range was found to be only ~3%.

The rate of application of the potential influences the maximum current. With increase of v by a factor of 2 (from 0.62 to 1.24 mV s^{-1}), the current rises, according to Gaylor and co-workers,[20,21] by a factor of 1.5–1.7, which is much greater than could be expected if the current were controlled by diffusion (it would then have increased by a factor of $2^{1/2}$). In our view, this can most probably be accounted for by the diminution of the role of passivating factors with increase of v, i.e. with decrease of the surface coverage by the polymeric substances.

An increase of temperature (from 20° to 60 °C) entails an increase of the oxidation current. The temperature coefficient in aqueous buffer solution is 0.4% according to Gaylor et al.[20], while according to other data[3,25] it amounts to 1.5–2.0% per degree.

Table 1. The influence of the pH on the half-wave potential for the oxidation of phenol ($E_{1/2}$, V) (relative to the saturated calomel electrode).

pH 1.2	pH 5.6	pH 7.0	pH 8.5	pH 9.0	Refs.
0.93	0.66	0.56	0.55	0.45	[20]
—	0.63	—	—	—	[22]
0.92	—	0.60	—	0.45	[23]
1.05	0.70	0.60	0.60	0.46	[26]

The half-wave potential decreases linearly with increasing pH until the latter reaches the p*K* of phenol, i.e. 9.89. A further increase of the pH does not induce a significant alteration of the half-wave potential.[3,25,26,29–31] Since $E_{1/2}$ for the oxidation of phenol is independent of the composition of the impregnation mass,[15] it is possible to compare its values at different pH obtained by different workers. Table 1 shows that the data agree well with one another.

An increase in the rate of application of the potential leads to a shift of $E_{1/2}$ towards positive potentials.[20]

There are data showing that $E_{1/2}$ is influenced by the phenol concentration. For example, a change in the phenol concentration by a factor of 10 results in a shift of $E_{1/2}$ by 22 mV at pH 5.2.[7,20]

2. Adsorption

The characteristics of the adsorption of phenol on the graphite anode per unit apparent surface at pH from 1.6 to 9.5 have been determined and its degree calculated.[3] Fig.5 shows that the degree of adsorption changes only slightly as the pH is altered.

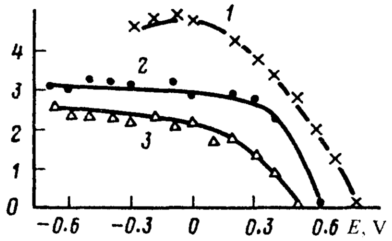

Figure 5. Dependence of the adsorption of phenol (from a 1×10^{-3} M solution) on the graphite anode on the potential at pH 1.6 (curve *1*), 7.5 (curve *2*), and 9.5 (curve *3*) (the potentials were measured relative to the 0.1 *N* calomel electrode).[3]

Comparison of the adsorption and potentiodynamic relations obtained on anodes of the same material has shown that the degree of adsorption of phenol begins to fall at the potential corresponding to the onset of its oxidation and almost ceases when the potential reaches the value corresponding to the maximum rate of oxidation. This is valid for both graphite and platinum anodes.[3]

IV. THE LEAD DIOXIDE AND GOLD ANODES

The electrochemical oxidation of phenol has also been investigated on lead dioxide[32,33] and gold[30] anodes.

On the stationary and rotating lead dioxide anodes in the presence of 0.5 M phenol in sulphuric acid solutions, a distinct anodic wave with a maximum is observed. The inhibition of the anodic process can be explained both by the blocking of the surface by the polymer film[32] and by the adsorption of oxygen.[33] It has been noted that at high positive potentials the film dissolves with the simultaneous evolution of oxygen. This phenomenon, which has not been observed on the platinum electrode (see above), can be evidence in support of the hypothesis that the mechanisms of the oxidation of phenol on platinum and lead dioxide are different.

In order to obtain reproducible results, before recording each anodic curve, the electrode surface was subjected to a preliminary treatment—anodic polarisation at E = +0.8 V [relative to the saturated calomel electrode (s.c.e.)] for 2–10 min.[32] The pH dependence of the oxidation current was investigated for a 0.5 M phenol solution in sulphuric acid at different concentrations (0.5–5 M H_2SO_4).[32] A shift of the current–potential curves of ~250 mV when the pH was altered by unity was then observed. This exceeds by a factor of ~4 the analogous value for the platinum and graphite anodes, which confirms the hypothesis that the phenol oxidation mechanism is different on lead dioxide.

On the gold anode in a solution having the composition $mNa_2SO_4 + nH_2SO_4$, phenol gives rise to a distinct oxidation wave with a maximum. In the pH range 1–14, the dependence of the change in the phenol oxidation half-wave potential on the pH is identical with the dependence obtained for the graphite anode.[30]

V. THE MECHANISM OF THE ANODIC PROCESS

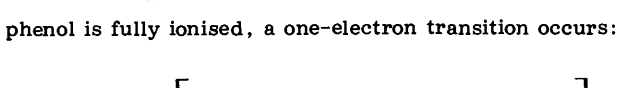
A considerable number of studies devoted to the phenol oxidation mechanism have been published. There exist two sets of views at the present time concerning the mechanism of the primary electrode reaction.[11]

The supporters of the first view believe that the initial stage involves the loss of one electron and the formation of the phenoxy-radical. Calculation based on the dependence of $\lg[I/(I_d - I)]$ on the potential, where I is the instantaneous current and I_d the diffusion current, has shown that the anodic wave corresponds to the transport of one electron.[2] This result apparently refers to a phenol concentration $\leq 1 \times 10^{-4}$ M. However, it is not clear from the above study[2] for which pH the calculation has been carried out. Other evidence in support of the hypothesis that the current is diffusion controlled, apart from the proportionality of the current to the phenol concentration, is not presented in the above publication. However, such a dependence can be observed also for first-order reactions occurring in the kinetic region.

The number of electrons transferred has also been calculated[1] from potentiodynamic curves using the equation relating the electrode potential to the diffusion current. The calculation was performed for a solution with a phenol concentration of 1×10^{-4} M at pH 10.

The supporters of the second view believe that two electrons are transferred in the first oxidation stage and that an intermediate is formed.[21] On the basis of the proportionality of the current to the phenol concentration, it has been concluded that the current is diffusional. These data[21] refer solely to pH 5.2; the range of phenol concentrations employed is not indicated.

It has been shown[11] that the stoichiometry of the phenol oxidation process depends on the pH of the solution. The reaction mechanism has been studied in detail in acetonitrile solution and the results and conclusions have been tested in aqueous buffer solutions. The behaviour of phenol in solution in acetonitrile and water proved to be identical. Thus the oxidation of phenol in an alkaline medium is lower by a factor of ~2 than in an acid medium, which suggests that, in the systems where phenol exists in an unionised state, a two-electron process takes place:



If phenol is fully ionised, a one-electron transition occurs:

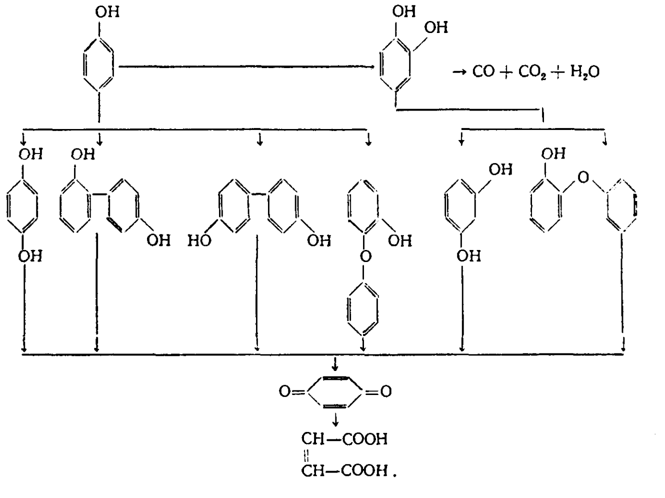
Later publications confirmed the existence of different views on the primary electrode process. In one of them it has been suggested that one hydrogen ion and one electron are involved in the electrode reaction.[26] In another communication[28] it is shown with the aid of the equation for the rotating disc electrode and potentiodynamic relations obtained on the graphite anode in buffer solutions (pH 1–12) that one electron is involved in the phenol oxidation reaction.

However, one should note that the diffusion coefficient was calculated[28] from the Stokes–Einstein equation. The quantity $n = 1$ was obtained for the phenol diffusion coefficient $D = 0.23 \times 10^{-5}$ cm^2 s^{-1}. Since the approximate character of the Stokes–Einstein equation is well known, the value of n calculated in the above study[28] must be treated with caution. Other factors giving rise to doubts about the validity of the calculations in the above investigation should also be noted. Firstly, it is known that the calculations of n and D from the equation for the rotating disc electrode can be performed only in the diffusion region. Furthermore, the above measurements[28] were performed at a single rate of rotation of the disc electrode, which makes it impossible to check in which region the study had been carried out. The conclusion that the measured current is determined by the rate of diffusion was reached solely on the basis of the satisfactory reproducibility of the product $i \cdot \tau^{1/2}$ obtained from chronopotentiometric data for the stationary electrode. Secondly, it has been shown[3] that the electrochemical oxidation of phenol at a concentration of 1×10^{-3} M in acid solutions is partly limited by diffusion, while in an alkaline solution the current is determined by the process kinetics alone. Naturally, in both cases the rotating disc electrode equation is unsuitable for the calculation of n.

The authors[28] were able to observe directly the EPR spectra characteristic of the phenoxy-radicals formed in the first phenol oxidation stage in acid, alkaline, and neutral media.

The mechanism proposed by Gaylor et al.[21] involves the transfer of one electron and one proton in the potential-determining stage and the formation of the $PhO^{\bullet}$ radical. On the other hand, other investigators[7,8,29] confirmed the dependence of the stoichiometry of the oxidation reaction on the pH of the solution observed by Vermillion and Pearl.[11]

It has been shown[34–36] that the first phenol oxidation stage is followed by the formation of unstable products, which enter into subsequent chemical reactions. The nature of these intermediates has not been discussed, but it can be inferred by analysing the final electrolysis products. It has been established that the electrochemical oxidation of phenol is a multistage process, which can be represented by the following scheme:[34–36]



The formation of hydroquinone and *pp'*-biphenol has been demonstrated by cyclic voltage–current measurements in 25% acetone solution in a Britton–Robinson buffer at a rate of application of the potential of 8.33 V min^{-1}.[35] In the oxidation of phenol in 0.05 M HCl solution (at pH 1.3, $\nu = 0.1$ V s^{-1}, $c_{\mathrm{ph}} = 1 \times 10^{-3}$ M) the formation of five reaction products was observed by the same method: *op*- and *pp'*-biphenols, hydroquinone, catechol, and hydroxyhydroquinone.[29] It was shown that all the products are formed as a result of the dimerisation of phenoxy-radicals obtained in the primary one-electron step.

The following mechanism of the total oxidation of phenol on the platinum anode in acid and alkaline media has been proposed:[6,8]

In an alkaline medium	In an acid medium
$\mathrm{PhOH} + \mathrm{OH}^- \rightleftarrows \mathrm{PhO}^- + \mathrm{H_2O}$	$\mathrm{PhOH} \rightleftarrows \mathrm{PhO}^{\cdot} + \mathrm{H}^+ + \bar{e}$
$\mathrm{PhO}^- \rightarrow \mathrm{PhO}^{\cdot} + \bar{e}$	$\mathrm{PhO}^{\cdot} + \mathrm{PhOH} \rightarrow \mathrm{P}_1^{\cdot} + \mathrm{H}^+ + \bar{e}$
$\mathrm{PhO}^{\cdot} + \mathrm{PhO}^- \rightarrow \mathrm{IP} + \bar{e}$	$\mathrm{P}_1^{\cdot} + \mathrm{PhOH} \rightarrow \mathrm{P}_2$
$\mathrm{IP} \rightarrow \text{products} + n\bar{e}$	$\mathrm{PhO}^{\cdot} + \mathrm{PtOH} + \mathrm{H}^+ \rightarrow \text{hydroquinone}$
	$\text{hydroquinone} \rightarrow \text{benzoquinone} + 2\mathrm{H} + 2\bar{e}$

Here $\mathrm{P_1}$ and $\mathrm{P_2}$ are dimers and trimers respectively and IP are intermediate products.

Determinations of the total number of electrons participating in the extensive oxidation of phenol under different conditions have been carried out in a series of studies. The study of the adsorption of phenol on the platinum anode (see Section II) at potentials below that corresponding to the onset of oxidation has shown[13] that phenol hinders the adsorption of oxygen when an anodic pulse is applied and the adsorption of hydrogen when a cathodic pulse is applied. From these data and also taking into account the fact that phenol gives rise to a distinct oxidation wave at positive potentials, the authors postulated the presence on the electrode surface of chemisorbed species of one type whose oxidation requires 4 ± 0.5 electrons. This number of electrons is determined by the fact that phenol is oxidised to $\mathrm{CO_2}$ and in this case 4.6 electrons correspond to each adsorption centre. Since the adsorption of phenol is accompanied neither by dehydrogenation nor electron transfer, the authors suggested that it occurs as a result of the dissociation of the double bonds in the benzene ring and the formation of six Pt–C bonds. In this case the plane of the aromatic ring should apparently be arranged parallel to the electrode surface. At the same time, Izumi et al.[8] and Bjerano et al.[37], who support the radical mechanism, suggest that the phenoxy-radical is adsorbed via the oxygen atom, so that the plane of the aromatic ring is more likely to be arranged at an angle with respect to the surface than parallel to it.

It has been suggested that the total number of electrons participating in the oxidation of one phenol molecule varies as a function of the rate of application of the potential from 3 (for $\nu < 1$ V s^{-1}) to 1.5 (for $\nu > 5$ V s^{-1}).[25] It has been found,[25] by means of calculation with the aid of the theoretical equation for the limiting diffusion current, that $n = 3$. The phenol concentration was then 10^{-6}–10^{-7} M and the dependence of the limiting current on the phenol concentration was linear at a flow rate of the solution relative to the electrode of 1×10^{-4} litre s^{-1}.

The influence of the rate of rotation of the electrode (or of the flow rate of the solution) on the maximum phenol oxidation current have been investigated in a number of studies and it has been shown that in an alkaline medium an increase of the rate of rotation of the platinum wire to 1000 rev^{-1} entails a steady increase of the maximum current.[1] However, it is known that the most reliable principal kinetic characteristics can be obtained with the aid of the rotating disc electrode. For this reason, a detailed study has been made[3] of the influence of the rate of rotation of the electrode on the phenol oxidation current on platinum and graphite disc anodes at different pH of the solution. The graphical method was used to calculate the order of the reaction.[38] Using the true kinetic current and the dependence of the oxidation current on the rate of rotation of the electrode, the authors[3] found that in acid and neutral media the oxidation of phenol (at $c_{\mathrm{ph}} = 1 \times 10^{-3}$ M) formally obeys a first-order equation. In an alkaline medium (saturated borate buffer solution, pH 9.5) the maximum phenol oxidation current remains constant when the rate of rotation of the platinum anode is raised from 160 to 4000 rev min^{-1}, which formally indicates a zero reaction order. The authors attribute this factor[3] to the formation of a strongly adsorbed polymer film on the electrode.

A dependence of the reaction order *P* on the initial phenol concentration in the solution has been observed.[8] The values of $P = (\partial\, \mathrm{ig}i/\partial\, \mathrm{lg}c_{\mathrm{ph}})_e$ were found experimentally at different concentrations in aqueous alkaline solutions (1 *N* NaOH solution) of phenol. It was shown that the order of the reaction is two at $c_{\mathrm{ph}} = 0.1$–0.5 M, while at lower concentrations it approaches unity, which is inconsistent with the data of Kharlamova et al.[3]

High reaction orders have been obtained by Levina et al.[5] Calculation of the order of the reaction on a smooth platinum electrode by the equation $i = kc_{\mathrm{ph}}^P$, where $P = 2.8$–3.0 showed that *P* is almost independent of the potential. The authors[5] attribute the anomalously high reaction orders to the anomalous adsorption properties of phenol at fairly high concentrations in solution (from 0.4 to 2 M). Furthermore, it has been noted that, in contrast to the isotherms obtained at potentials such that the oxidation of phenol does not yet occur, the adsorption isotherms in the range of oxidation potentials have a complex character. The degree of surface coverage initially increases slowly with increase of the phenol concentration, in conformity with the Temkin isotherm. However, after the attainment of the critical phenol concentration (~0.4 M), the surface is rapidly filled by chemisorbed species and the slope of the isotherm changes sharply. It has been suggested that this effect is caused by the surface condensation or heterogeneous polymerisation of phenol molecules.

From our point of view, this explanation conflicts with the known electrochemical properties of phenol. In particular, in the range of concentrations employed by Levina et al.[5], polymer layers on the anode surface can be observed even visually. For this reason, the isotherm apparently actually corresponds to the adsorption of not phenol molecules or their fragments but of the polymeric product. The break point then corresponds to the concentration at which polymerisation is particularly vigorous.

The discrepancies between the calculated reaction orders are probably associated with the fact that the authors measured not the true phenol oxidation current but the current distorted by the adsorption of the incomplete oxidation product. For this reason, the reaction orders indicated above are more likely to be purely formal quantities and therefore do not necessarily reflect the real process mechanism.

The maximum phenol oxidation current on the graphite anode in a buffer solution at pH 4.0 and $c_{\mathrm{ph}} = 5 \times 10^{-7}$ M is proportional to the rate of movement of the solution *u* raised to the power 3/4 [$u = (2.1$–$10.5) \times 10^{-5}$ litre s^{-1}].[39] With increase of phenol concentration, a deviation from this relation is observed, which can also be accounted for by the coverage of the surface of the anode by the reaction product.

Levina et al.[5] examined the question of the possible slow stage in the phenol oxidation process. Direct measurement of the rate of adsorption of phenol showed that it exceeds greatly the rate of the electrochemical oxidation and hence cannot be the slow stage.

As shown above (Section II), the half-wave potential for the oxidation of phenol shifts towards more negative values by ~60 mV per pH unit as the pH increases to 9.0. This suggests that the slow stage in the oxidation of phenol in 0.1 *N* H_2SO_4 solution on platinum is the interaction of OH^-_{ads} with the chemisorbed organic species.[5]

The mechanism of the oxidation of phenol on the lead dioxide anode is different from that on platinum and graphite. It has been noted that the phenol oxidation potential is close to the lead dioxide formation potential in these solutions.[32] This observation served as a basis for a new phenol oxidation mechanism on the lead dioxide electrode, according to which the potential-determining stage is the chemical oxidation of phenol by lead dioxide. The latter is regenerated in the electrochemical process, which requires the transfer of four electrons.[33]

VI. THE INFLUENCE OF SUBSTITUENTS ON THE ELECTROCHEMICAL ACTIVITY

We shall consider the influence of the OH, CH_3, NO_2, NH_2, Cl, C_6H_4, COOH, C_2H_5, and $C(CH_3)_3$ groups substituting hydrogen atoms in the benzene ring on the principal voltage–current characteristics of the oxidation of phenol.

1. The Platinum Anode

The influence of the hydroxy-group in the *m*-, *o*-, and *p*-positions in the benzene ring of phenol on the oxidation current in acid and alkaline aqueous media has been investigated[12] and, as noted previously (Section II), appreciable oxidation of phenol in an acid medium (1 M $HClO_4$ solution) was not observed in this investigation. Resorcinol (1,3-dihydroxybenzene) behaves analogously. However, the introduction of the hydroxy-group in the *o*- and *p*-positions renders the corresponding phenols (catechol and hydroquinone) readily oxidisable. The reversible oxidation of hydroquinone, which proceeds at an extremely high rate, is well known.[40] Catechol is apparently also oxidised reversibly. In an alkaline medium (1 M KOH solution), all three substituted phenols are oxidised, giving rise to maxima on the voltage–current relation. The maximum oxidation currents diminish in the sequence hydroquinone > catechol > resorcinol.

As stated above (see Section II), the appearance of a maximum on the voltage–current curve depends not only on the initial concentration of the corresponding phenol but also on the pH of the medium. This is illustrated by the oxidation of hydroquinone in a strongly acid medium (1 M $HClO_4$):[12] the anodic wave with a maximum appears only at a phenol concentration ≥0.2 M and, when the pH is raised to 3.0, the above concentration falls to 0.1 M. It is also noteworthy that the electrochemical oxidation of resorcinol on the anode surface results in the formation of an insoluble polymeric product, as in the case of phenol.[12]

The maximum resorcinol oxidation current increases with increasing pH, but to a much lesser extent than in the oxidation of phenol. When the pH is raised from 12.0 to 13.7, the increase in the maximum resorcinol oxidation current is ~100 times smaller than for phenol.[12]

The introduction of two hydroxy-groups into the phenol molecule in the 2,3- and 2,4-positions permits the oxidation of the resulting compounds in an acid medium and the maximum 2,4-trihydroxybenzene oxidation current is lower by ~30% than for the 2,3-analogue. In contrast to these compounds, 3,5-dihydroxybenzene is not appreciably oxidised in an acid medium, like the initial phenol. However, it is readily oxidised in an alkaline medium and the maximum current for this process is lower than in the oxidation of phenol by ~70%.[12] The substituent $C(CH_3)_3$ reduces somewhat the maximum substituted phenol oxidation current, the decrease of the current being observed in the following sequence as the position of the substituent is altered: *meta* > *ortho* > *para*.[2] It is believed[2] that, when the concentration of the corresponding phenol is 1×10^{-5} M, the current is limited by diffusion, which does not conflict with the experimentally observed independence of the current of the pH. However, a curve with a maximum, typical for diffusion currents at a stationary electrode, was not obtained.[2]

2. The Graphite Anode

Judging from the published data, all substituted phenols, which will be considered below, are oxidised at the anode and give rise to a single wave on the voltage–current curve. 2,6-t-Butylphenol and 6-t-butyl-2,4-dimethylphenol, which give rise to multiwave curves, are exceptions. The appearance of a maximum on the anodic curves for substituted phenols has been related[22] to $E_{1/2}$: if this potential is less than 0.48 V, a maximum may appear. The character of the current was not considered in the above investigation. However, it follows from the analysis of the literature data that a maximum is observed[23,26,27] on the potentiodynamic curves for the oxidation of many substituted phenols having $E_{1/2} < 0.48$ V (relative to the s.c.e.) at a pH other than in the study discussed above.[22]

The influence of substituents in the *m*-, *o*-, and *p*-positions on the oxidation current of phenols on the graphite anode in an aqueous medium has been examined in a number of studies[20,21,23,26,27,41] and it has been shown that resorcinol, catechol, and hydroquinone are readily oxidised over a wide pH range (1–9). At a catechol concentration of 1×10^{-3} M, a distinct limiting current is observed on the potentiodynamic curve but, with increase of concentration to 1.5×10^{-3} M, a maximum appears.[41]

The data concerning the appearance of a maximum on the voltage–current relations for resorcinol and hydroquinone are contradictory. Results showing the presence of a distinct limiting resorcinol oxidation current at a resorcinol concentration of 1×10^{-4} M [21] and the appearance of a maximum at a concentration of 4×10^{-4} M [26] are available. On the other hand, the presence of a distinct limiting current at a resorcinol concentration of 1×10^{-3} M has been reported.[41] Similar contradictions exist also for hydroquinone. Under identical conditions, and at equal hydroquinone concentrations [$(1.5–0.3) \times 10^{-3}$ M] a maximum has been observed in some studies[20,27,41], while in another[26] it was absent either owing to poor adsorbability or the dissolution of the oxidation product.

Table 2 shows the maximum oxidation current densities for substituted phenols and the initial phenol indicated in different sources differ appreciably from one another.

In the pH range 4–8 the maximum hydroquinone oxidation current hardly changes. The dependence of the resorcinol oxidation current on the pH has been investigated in only one study[22] and for this reason it is impossible to compare these data with other results.

In a number of investigations[20,21,23] the authors assumed without proof that the oxidation currents of aromatic dihydrocompounds ($c \leq 2.5 \times 10^{-4}$ M) are diffusional in nature. The fact that an increase of the rate of polymerisation increases the maximum current[20] cannot be regarded as unambiguous proof of the diffusional nature of the current, since this can be associated with a decrease of the adsorption of the reaction product. The oxidation currents of catechol and resorcinol in a weakly acid medium are higher approximately by a factor of 2 than the corresponding phenol current.[21] Hence, it was concluded that their oxidation requires twice as many electrons as the oxidation of phenol. However, when the solution is made alkaline up to pH 8.5, the maximum phenol, hydroquinone, resorcinol, and catechol oxidation currents become virtually identical (to within ±3%),[23] which may indicate the same process mechanism.

Table 2. The influence of the hydroxy-group on the maximum density of the oxidation currents of phenols (pH 5.0).

*Stationary conditions.

**Dynamic conditions.

An approximate calculation of the number of electrons participating in the primary hydroquinone oxidation electrode process has been carried out[20] from the corresponding potentiodynamic curves from the formula $E_{3/4} - E_{1/2} = 0.55n$. It has been noted that the rate of application of the potential influences n; for example, an increase of v by a factor of 2 induces a decrease of n by unity.

The behaviour of trihydroxybenzenes will be examined in relation to pyrogallol. At a concentration of this compound of 2.5×10^{-4} M in a neutral medium, an oxidation wave with a distinct maximum is observed: the maximum current is lower by ~30% than in the case of phenol.[23]

Several studies have been devoted to the influence exerted by the introduction of one methyl group in the *o*-, *m*-, and *p*-positions in the benzene ring of phenol on the oxidation current.[21-23,26] In aqueous buffer solutions at concentrations of cresols of 2.5×10^{-4} M and at pH from 4 to 11, an oxidation wave with a maximum has been observed. Table 3 presents the maximum oxidation currents for the above compounds. Evidently the data from different sources differ markedly.

A fairly complete idea about the dependence of the maximum oxidation currents of *o*- and *p*-cresols on pH can be obtained from Fig.6 (curves *1* and *2*).[26]

The dimethyl derivatives, namely 2,4-, 2,6-, and 3,4-dimethylphenols, are readily oxidised and distinct anodic waves with maxima are observed.[22,26] The introduction of two methyl groups diminishes the maximum oxidation current compared with phenol on average by 20–30%.[22,26] 3,5-Dimethylphenol, whose oxidation wave has no maximum and the height of the wave does not greatly exceed (by ~5%) the phenol oxidation current, is an exception.[26] The dependence of the maximum oxidation current for 2,6-dimethylphenol on the pH is illustrated in Figure 6 (curve *3*).[26]

Table 3. The influence of the position of the CH_3 substituent on the maximum density of the oxidation currents of phenols (pH 5.6).

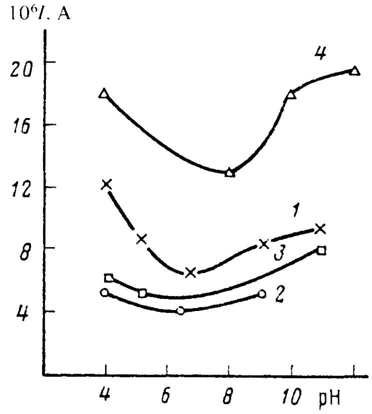

Figure 6. Dependence of the maximum oxidation currents for 4×10^{-4} M solutions of *o*-cresol (curve *1*), *p*-cresol (curve *2*), 2,6-dimethylphenol (curve *3*), and 2,4,6-trimethylphenol (curve *4*) on the pH.[26]

The behaviour of phenol after the introduction of three methyl groups into the benzene ring has been investigated in relation to 2,4,6-trimethylphenol. The absence of a maximum on its oxidation wave in phosphate (pH 7.0), acetate (pH 4.6), and aqueous alcoholic buffer solutions have been noted. The 2,4,6-trimethylphenol oxidation current in the pH range 4–12 exceeds by a factor of almost 2 the maximum phenol oxidation current (Fig.6, curve *4*).[26]

The introduction of one nitro-group into the benzene ring of phenol reduces the maximum phenol oxidation current at pH 8.5.[23,26] However, the data for the extent of this decrease are extremely contradictory. According to some data,[27] the decrease is on average ~90% at pH 8.5, while according to others[23] it is only ~13%. Similar differences in data persist also at other pH values. For example, it has been stated[22] that the maximum *p*-nitrophenol oxidation current at pH 5.6 is greater than that of phenol, while in another study[26] the opposite relation was observed at the same pH.

The oxidation of *m*- and *o*-aminophenols has been observed to generate a one-electron wave with a maximum, while the oxidation of *p*-aminophenol gives rise to a two-electron wave with a maximum.[23,27,31] The introduction of the amino-group into the *m*-position increases the oxidation current on average by 6%, while the *ortho*-substituent reduces the oxidation current by ~19%.[23]

The question of the mechanism of the electrochemical oxidation of aminophenol has been examined.[31] The character of the dependence of $E_{1/2}$ on pH and the analysis of the maximum current and the parameters $E_{1/2}/\Delta pH$ and $\Delta E/\Delta\,.\,\lg\,[i/(i_{\mathrm{lim}}-i)]$ justified the hypothesis that the observed oxidation waves on the graphite anode characterise the oxidation of the phenolic OH group, while the NH_2 group plays the role of an electrochemically inert substituent.

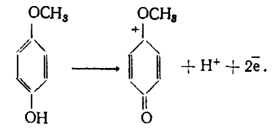
According to the data of Vodzinskii and Semchikova,[23] there is an oxidation wave with a maximum (pH 5.6) on the potentiodynamic curves for the oxidation of monochlorophenol, while other data[22] indicate waves without a maximum (pH 8.5). The difference is probably associated with the difference in the pH of the solution. At pH 5.6 the maximum oxidation currents of *p*- and *o*-chlorophenols are smaller than that of the initial phenol approximately by 15 and 13% respectively, while for *m*-chlorophenol it is greater by ~4%.[22] At pH 8.5 the *p*-chlorophenol oxidation current is lower by ~2% than that of phenol.[23]

A single oxidation wave without a maximum is observed on the potentiodynamic curve for the oxidation of 2,5-dichlorophenol at pH 5.6 and a concentration of 2.5×10^{-4} M, while the maximum oxidation current is lower by approximately 30% compared with phenol.[22]

The maximum oxidation currents for *p*- and *o*-phenylphenols oscillate markedly as the pH is altered: in borate buffer solution (pH 8.5), the current is higher by 6–8%, while in a weakly acid medium (pH 5.6) it is lower by 30–34% than for unsubstituted phenol.[22] The introduction of two phenyl substituents in the 2- and 4-positions lowers the maximum phenol oxidation current by ~31% (pH 5.6).[22]

Phenol with the COOH group in the *o*-position (salicylic acid) has a maximum oxidation current in an alkaline medium (pH 8.5), which is lower by ~31% than that of unsubstituted phenol, while in a weakly acid medium their maximum currents are virtually identical.[22,23] At pH 5.6 *o*- and *p*-ethylphenols have maximum oxidation currents lower by 20–24% than that of unsubstituted phenol, while the maximum oxidation current of *m*-ethylphenol is lower by only ~1.2%.[20,22]

All the monosubstituted methoxyphenols have oxidation currents in a weakly acid medium higher by 8% on average than the maximum oxidation current of the initial phenol.[22] The electrochemical behaviour of *o*-methoxyphenol has been investigated in an acid medium (0.1 M $HClO_4$ solution).[42] Two successive pairs of waves corresponding to the oxidation intermediates 3,3′-dimethoxydiphenoquinone and 3,3′-dimethoxy-4,4′-biphenol, *o*-quinone, and catechol have been observed on the cyclic voltage–current plot. The voltage–current plot for *p*-methoxyphenol (1.13×10^{-3} M) in 2.037 M H_2SO_4 solution shows an oxidation wave with a maximum, which corresponds to a two-electron process:[43]



The introduction of two OCH_3 groups in the 2- and 6-positions in the benzene ring leads to a decrease (at pH 5.6) of the maximum current (by 27%). If the OCH_3 group is introduced in the 2-position in *p*-cresol, the oxidation current increases by ~10%.[22] The influence of the ethoxy-substituents on the oxidation currents of the corresponding phenols was also investigated in the above study;[22] it was found that the *o*-substituent increases the maximum oxidation current of the substituted phenol by ~7%, while the *p*- and *m*-substituents respectively reduce the current by ~2% (this is within the limits of the accuracy of the measurement) and ~19%.

A distinct anodic wave has been observed in the electrochemical oxidation of *p*- and *o*-t-butylphenols in the pH range 5.6–8.5 at a low concentration (~10^{-4} M). The rates of oxidation of these compounds are lower than that of phenol by ~35 and ~55% respectively.[22,23]

The introduction of two and more $C(CH_3)_3$ groups into phenol leads to the appearance on the voltage–current curve of a maximum in aqueous buffer solutions, an example of such behaviour being provided by the oxidation of 2,6-di- and 2,4,6-tri-t-butylphenols.[23] The oxidation current falls in this case (by ~60%). However, it has been reported that 2,4,6-tri-t-butylphenol gives rise to an anodic curve with a distinct limiting current, which is independent of the pH,[44] in conflict with the data of Vodzinskii and Semchikova.[23]

The oxidation of 2,4,6-tri-t-butylphenol at a concentration of 1.11×10^{-3} M in an aqueous ethanol solution (at pH ranging from 0 to 10) at a vitreous carbon anode has been investigated by the cyclic voltamperometric method.[45] A wave with a maximum was observed in an acid medium, while in an alkaline medium two waves with maxima were noted.

After the additional introduction of the t-butyl group into the benzene ring of *o*- and *p*-cresols, the maximum oxidation current in aqueous buffer solutions falls by a factor of ~2.[22]

The appearance of three waves at once without maxima in the oxidation of 6-t-butyl-2,4-dimethylphenol at a concentration of 1×10^{-3} M in an aqueous buffer solution at pH 5.6 has been reported.[20] When the supporting electrolyte is acidified (to pH 1.2), the second wave disappears, while an increase in the alkalinity of the solution (to pH 10) leads to the disappearance also of the third wave. Following an increase of the rate of application of the potential by a factor of 2 (from 0.62 to 1.24 mV s^{-1}), the limiting oxidation current at pH 10 increases by 40–50%, as for unsubstituted phenol. When the temperature is raised by one degree in the range from 20° to 30 °C (at pH 5.6), the maximum currents on all three observed waves increase by 0.8, 2.7, and 5.2%. The temperature coefficients of the maximum currents on the first two waves correspond to the possibility of diffusional control of the oxidation process.

VII. PRACTICAL APPLICATIONS OF THE ELECTROCHEMICAL OXIDATION OF PHENOL AND ITS DERIVATIVES

As shown above, the anodic oxidation of phenol proceeds fairly readily. An important practical application of this process in the purification of phenol-containing waste water arose in this connection. In the solution of this problem, the advantages of the electrochemical method such as efficiency, reliability, low cost, and also the compactness of the electrolysers and the ease of automating the process have been noted.[47,48] Preliminary calculations have shown that, in the successful solution of this problem, the cost of the removal of phenol from 1 m^3 of water by electrochemical oxidation is lower by a factor of ~2 than the cost of the purification of water by ozonization and by a factor of ~5 than the cost of purification by adsorption on activated charcoal.[49] The above advantages of the electrochemical method have attracted the attention of many investigators, as shown by the numerous publications in this field.

The main bulk of studies have been carried out with graphite anodes. According to a review,[50] most of the studies on the electrochemical purification of waste water containing phenol have been devoted to the study of the oxidation of phenol in solutions containing chloride ions. The optimum oxidation conditions are as follows: alkaline medium (pH 9–11), $i = (4\text{–}8) \times 10^{-2}$ A cm^{-2}, and $c_{Cl} \cong 10\%$ for an initial phenol content in the waste water not exceeding 0.5 g $litre^{-1}$. The consumption of electrical energy on the oxidation of 1 g phenol using the electrochemically generated hypochlorite of the corresponding metal is 0.03–0.09 kWh.

The design of the electrolyser is important for the effective electrochemical oxidation of phenol. Electrolysers of the box or filter press types without a diaphragm are normally employed. The latter are preferable, since they make it possible to increase the electrode surface area to the maximum extent in a given volume by reducing the interelectrode gap and the dead space.

A report has been published[51] on the purification of factory waste water containing 2.5 g $litre^{-1}$ of phenol, 201 g $litre^{-1}$ of sodium chloride, and 4.6 g $litre^{-1}$ of sodium hydroxide on apparatus consisting of six BGK-12 baths connected in series. However, according to Sakharnov,[49] the purification was not carried out under optimum conditions.

There are also data indicating the employment of electrolysers with a powdered anode, made up of carbon-graphite materials, for the electrochemical purification of phenol-containing water.[52] The waste water was passed through the pre-polarised powdered anode, which made it possible to prevent the blocking of the pores by phenol and the oxidation products.

Industrial waste water contains as a rule several compounds of organic and inorganic origin; for this reason, an individual approach to the purification of each waste is necessary. Furthermore, the purification conditions developed on artificial solutions are not always suitable for the purification of real waste water. A comparison has been made[53] of the rates of oxidation of phenol in an artificially prepared solution and in industrial tar water. It was shown that the rate of oxidation of phenol in the tar water is close to the rate of its oxidation in the artificial solution, but, when identical amounts of chloride ions are added to the two solutions, the rate of oxidation of phenol in the industrial water increases more slowly than in the artificial solution.

We shall consider examples of the purification of industrial phenol containing waste water in electrolysers with insoluble anodes. In a study[54] of the electrolysis of the waste from the chemical coke industry, the simultaneous removal of oil (to the extent of 96%) by electroflotation and of phenol (to the extent of 30–40%) and cyanides (to the extent of 100%) by electrochemical oxidation was observed. The water was treated on a laboratory electrolyser with a horizontal cathode under which vertically arranged graphite anodes were placed. The electrolyser operating conditions were as follows: $i = 0.01$ A cm^{-2}, $\tau = 40$ min, and $t = 60\text{–}70$ °C. According to preliminary calculations, the cost of the purification of 1 m^3 of the waste water was 10–12 kopecks.[54] The low degree of removal of phenol from water, probably as a result of constructional deficiencies of the electrolyser, is noteworthy.

In the waste water from the Kherson petroleum processing works, it has been possible to reduce simultaneously by electrolysis the concentration of petroleum hydrocarbons from 0.29 to 0.016 g $litre^{-1}$, of phenols from 2×10^{-3} to 6.5×10^{-4} g $litre^{-1}$, of surfactants from 1.8×10^{-2} to 6.1×10^{-3} g $litre^{-1}$, and of inorganic substances from 5.5 to 3.8 g $litre^{-1}$.[55] The experiments were performed in a laboratory electrolyser with a vertical graphite anode and a zinc cathode under static conditions: $i = 8.5 \times 10^{-2}$ A cm^{-2}, $\tau = 40$ min, and $t = 40$ °C. The salt composition of the purified waste in the area of the anode and its design were not indicated in the relevant study,[55] but, judging from the figure quoted, the anode consisted of a rod placed in a spherical flask at a comparatively large distance from the analogous rod cathode. In our view, such design of the electrolyser is unsuitable for the practical electrochemical purification of waste water.

The purification of tar waters in an electrolyser with a cylindrical graphite anode has been reported;[53] at $i = 0.2$ A cm^{-2}, $c_{Cl} = 40$ g $litre^{-1}$, and $t = 60$ °C, the phenol concentration was reduced from 5.2 to 0.75 g $litre^{-1}$, i.e. by 85%, after the operation of the electrolyser for 1 h. However, at such high phenol concentrations it is more useful to employ the regenerative purification procedures.

The electrochemical oxidation of phenols, cyanide, and thiocyanates in the waste water from the enrichment works of the Zyryanovsk Lead–Zinc Combine has been investigated.[56] The experiments were performed in an electrolytic bath without a diaphragm containing graphitised carbon anodes. Before electrolysis, sodium chloride was introduced into the water to be purified; the purification was carried out at $i = 0.35 \times 10^{-2}\text{–}0.80 \times 10^{-2}$ A cm^{-2} and 20 °C. The waste water investigated[56] was characterised by a very low initial concentration of phenols, which diminished by only about 30% during the purification process.

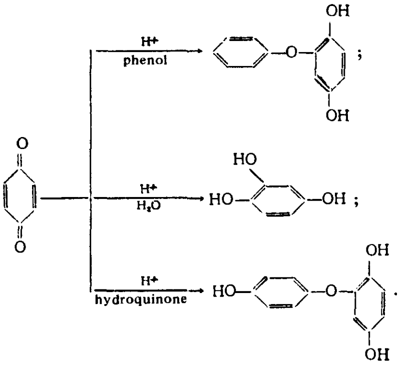
It has been suggested[53] that waste water containing phenols, thiosulphates, thiocyanates, and chlorides be purified by being passed downwards from above through a vertical cylindrical electrolyser with a platinum plate anode and an iron grid cathode. The electrolysis was carried out at $i = 0.8\text{–}0.12$ A cm^{-2} and the duration of the treatment ranged from 5 to 8 h. Under these conditions, the biological consumption of oxygen (BCO) in the waste water was reduced by 95%. However, the necessity to employ platinum as the anode material makes the process significantly more expensive.

The detoxication of the waste water from the coke chemical works by electrolysis at $i = 0.7\text{–}1.0$ A cm^{-2} has been investigated;[56] after electrical treatment for 5 h, the phenol concentration fell from 1.25 g $litre^{-1}$ (1.3×10^{-2} M) to 0.07 g $litre^{-1}$ (7.4×10^{-4} M). The consumption of electrical energy was 165 kWh m^{-3}. It is noteworthy that the process was performed at pH < 7.0, i.e. the conditions were not optimal for the oxidation of phenol by a hypochlorite.

An electrochemical method for the degradation of phenol by electrolysis at anodes with an active magnetite coating has been described.[57] Waste water containing 0.5 g $litre^{-1}$ of phenol and exhibiting a chemical consumption of oxygen (CCO) of 0.229 g $litre^{-1}$ was electrolysed at pH 7 and $i = 1.5 \times 10^{-2}\text{–}3.0 \times 10^{-2}$ A cm^{-2}. After electrical treatment for 2–5 min, the degree of elimination of phenols reached 95% and that with respect to the CCO was 77.8%; the consumption of electrical energy was 37 kWh m^{-3}. It is noteworthy that the use of the magnetite anode is technologically disadvantageous—it is brittle and has a relatively high electrical resistance.

In view of the requirement for large amounts of hydroquinone and alkylhydroquinones, especially in the photo- and cine-industry, the method of their synthesis by oxidising the corresponding phenols is of great practical interest. Such attempts have already been made for a long time,[58–62] but the required substance was obtained in a low yield and was impure. The oxidation process and the composition of the reaction products depend to a large extent on the phenol concentration, the electrolyte temperature, the pH of the solution, and other parameters. Depending on the electrolysis conditions, many compounds are formed, some of which may prove useful.

Under ideal conditions, quinone is formed on the anode and, after reduction at the cathode, is fully converted into hydroquinone. In reality ring-opening products (oxalic and maleic acids) as well as compounds obtained as a result of the total degradation of phenol (carbon dioxide and monoxide) are formed together with the required substance. Tarry substances are also formed in a considerable amount, apparently as a result of secondary reactions,[63,64] which may involve the interaction of *p*-benzoquinone with phenol. In the presence of hydrogen ions, this leads to the formation of phenoxyhydroquinone; under analogous conditions, the interaction of *p*-benzoquinone with hydroquinone affords hydroxyphenoxyhydroquinone. The interaction of *p*-benzoquinone with water in an acid medium leads to the formation of hydroxyhydroquinone:



The above side reactions not only reduce the current and material yield of phenol but also hinder the isolation and purification of the required substance.

An appreciable reduction of the amount of side products formed can be achieved by carrying out the electrolysis of aqueous sulphuric acid solutions (acid concentration 1 to 5 wt.%) in a diaphragm electrolyser with added phenol at a concentration of 0.5–4.0 wt.%.[64,65] During electrolysis, the pH was maintained at <4.0, the anodic potential was 0.9 V (relative to the s.c.e.), the cathodic potential was <–0.4 V, $i = 0.2–0.4$ A cm^{-2}, and $t = 50–60$ °C. Under these conditions, the material yield of hydroquinone was ~50% and the current yield was ~85%.[64] An apparatus which makes it possible to isolate fairly pure *p*-benzoquinone from the reaction mixture has also been described in detail. If conditions optimal for the preparation of *p*-benzoquinone are used, the material yield of alkylquinones is only 20%.

It has been shown[66] that, in acetonitrile solutions, dimethylphenol is oxidised to dimethylquinone. However, the attempts to reduce this substance to the corresponding hydroquinone were unsuccessful. Alkylhydroquinones having the general formula $C_6H_{(6-x)}R_xO_2$ (where R is an alkyl group containing up to four carbon atoms and x ranges from 1 to 3) can be obtained in satisfactory yields by oxidising the corresponding phenols.[66]

The electrochemical oxidation of 2-methyl-, 2,6-dimethyl-, 2,3,6-trimethyl-, and 2,3,5-trimethyl-phenols has been carried out[66] in an electrolyser with a cation-exchange diaphragm. The anode was made from lead dioxide and the anolyte employed consisted of a 1:1 water–acetone mixture containing 0.5 M sulphuric acid; the cathode was made of lead, the catholyte consisted of a 0.5 M aqueous sulphuric acid solution, and $i = 0.12–0.15$ A cm^{-2}. Under these conditions, the material yield of 2,6-dimethyl-*p*-benzoquinone was 86% and the current yield was 55%. At the end of the reaction, the anolyte was transferred to the cathodic compartment and the quinone was reduced to hydroquinone; the yield of 2,6-dimethylhydroquinone (purity 90%) with respect to the phenol which had reacted was 65%. Other alkylhydroquinones were obtained in similar yields.[66] Thus the process leads to the possibility of obtaining hydroquinone also from waste water containing phenol at a fairly high concentration.

---oOo---

Thus the kinetics of electrode processes in the electrochemical oxidation of phenol have been investigated in detail on the basis of extensive experimental data on this subject. It has been shown that phenol-containing waste water can be purified electrochemically and alkylhydroquinones can be obtained; however, some of the problems arising in the practical application of this procedure have not as yet been satisfactorily solved.

In the first place, in the majority of applied studies there has been no scientifically based approach to the selection of optimum process conditions, in particular the current density; for this reason, as regards experimental data, many parameters are selected at random. There is a clear gap between theoretical studies on the kinetics of the oxidation of phenol and practical electrolysis. There is insufficient information about the adsorption of phenol on platinum and graphite anodes and contradictory data have been obtained for the influence of chloride ions on the rate of oxidation of phenol. The cause of the inhibition of the oxidation of phenol observed in kinetic studies has not yet been established. If this could be done, the problem of the activation of the electrode under continuous conditions could be solved.

In the study of the waste water purification processes, little attention has been devoted to the analysis of the electrolysis products; the necessary conditions guaranteeing the complete oxidation of phenol to carbon dioxide and water have not been established. Relatively unproductive and difficult to service electrolysers of the box type are as a rule recommended for the purification of waste water. The question of the application of highly effective electrolysers with bulk electrodes in the purification process has so far been little studied.

The Reactions of Hydrocarbons under the Influence of Transition Metal Atoms and Ions in the Gas Phase at Room Temperature

B.A.Dolgoplosk, I.A.Oreshkin, and T.V.Soboleva

The results of numerous experimental studies of the composition of the products fromed on interaction of hydrocarbons with transition metal atoms or ions in the gas phase at room temperature are surveyed. In all cases organometallic intermediates are formed, their decomposition leading to the final reaction products. The results presented are of great interest for the understanding of the chemical nature of the elementary steps in the reactions of hydrocarbons in heterogeneous catalysis. The bibliography includes 68 references.

I. INTRODUCTION

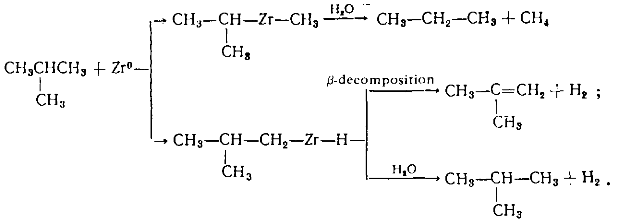
The modern ideas about the mechanisms of the elementary steps in the reactions of hydrocarbons under the influence of transition metals in heterogeneous catalysis presuppose the preliminary dissociative adsorption of the hydrocarbons on the catalyst surface with formation of radical-like fragments, which consist of hydrocarbon groups or hydrogen atoms, and are in some way linked to the heteroatoms, and are capable of migrating from one active centre of another. As a rule catalytic reactions proceed with participation of a large number of active centres; this applies particularly to the hydrogenolysis and skeletal isomerisation reactions of hydrocarbons under the influence of transition metals. In view of the lack of direct experimental approaches to the study of the chemistry of the elementary steps in heterogeneous catalysis, the idea that different active centres and intermediate hydrocarbon species, whose chemical nature is obscure, participate in different reaction stages is frequently resorted to. In earlier publications, we examined the chemistry of the elementary steps in hydrogenation, dehydrogenation, hydrogenolysis, and deuterium exchange processes on the basis of the idea that the primary reaction involves the oxidative addition of hydrocarbons to a transition metal atom on the surface with subsequent decomposition of the resulting organometallic compound.[1-3] Thus it has been suggested that hydrogenation in heterogeneous systems proceeds via stages in which the olefin adds to the H–N hydride bond and that a hydrogen molecule adds to the C–M bond with regeneration of the initial hydride derivative, while the dehydrogenation reaction includes a stage in which the hydrocarbon undergoes oxidative addition to the reduced metal with subsequent β-decomposition of the organometallic intermediate. This made it possible to explain the primary formation of but-1-ene observed in the heterogeneous catalytic dehydrogenation of butane. The specific deuterium-exchange reactions involving various hydrocarbons in the initial stages and the mechanism of the autohydrogenation of unsaturated hydrocarbons have also been examined on the basis of these ideas. The pathways leading to the decomposition of organometallic compounds of transition metals frequently used in heterogeneous catalysis (Ni, Co, Pt, Pd, W, Mo, Rh, Cr, etc.) have been recently studied in detail in relation to various alkyl and aryl derivatives. They decompose mainly via β-elimination, which leads to the formation of equimolar amounts of alkenes and alkanes, and α-decomposition accompanied by the formation of extremely reactive carbene and carbyne species and recombination products produced from the hydrocarbon groups linked to the metal. The chain metathetical reactions of olefinic hydrocarbons under the influence of W, Mo, Re, and Ta compounds are known to be initiated by the carbene complexes formed on α-decomposition of organometallic compounds. The mechanisms of all these reactions have been described in detail in a series of reviews.[4-8] Naturally, the metal atoms which retain the greatest number of free coordination sites and whose reactivity approaches that of isolated atoms are the most reactive in the oxidative addition reactions of hydrocarbons. The metal atoms on the crystal faces, in dislocations, and, as will be shown below, in the gas phase and in the hydrocarbon matrix may play a similar role.

Not only zerovalent metals but also metals in low oxidation states are sometimes fairly active in similar reactions, as shown for the addition of toluene to biscyclopentadienyltungsten[9] and of triphenylphosphine to a series of Group VIII metals.[10] The contribution of the homolytic decomposition of the organometallic compounds, accompanied by the formation of free radicals is small and thus should apparently increase with increase of reaction temperature. However, a high selectivity of the action of catalysts at elevated temperature is incompatible with the occurrence of free-radical stages in the process, which indicates the need to take account of other pathways which have been investigated for the reactions of organometallic intermediates.

Numerous publications devoted to the study of the reactions of hydrocarbons with metal atoms in hydrocarbon matrices at reduced temperatures or with metal ions in the gas phase at room temperature have appeared recently. The composition of the products of these reactions shows that the latter take place via stages in which the metal adds to the C–H or C–C bond with subsequent reaction of the organometallic intermediate. These investigations are of great interest for the understanding of the chemical nature of the elementary steps in heterogeneous-catalytic reactions of hydrocarbons and can serve as an experimental basis for the examination of the reaction mechanisms. This review presents a survey of the results of the published studies in this field.

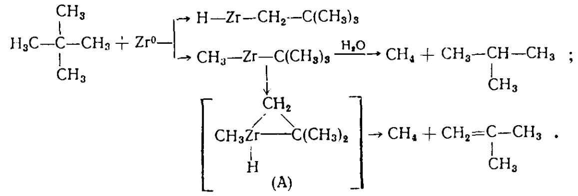
II. THE REACTIONS OF HYDROCARBONS WITH METAL ATOMS

The possibility of the chemical interaction of metal atoms with alkanes was established for the first time in 1979.[11] The authors showed that the reaction of zirconium atoms, obtained by evaporation in a high vacuum, with isobutane or neopentane in a matrix begins already at -196 °C. Heating of the hydrocarbon matrix to room temperature is accompanied by the evolution of a certain amount of hydrogen and of traces of methane. Subsequent hydrolysis of the matrix leads to the formation of considerable amounts of hydrogen and C_1–C_4 hydrocarbons in the case of isobutane and C_1–C_5 hydrocarbons in the case of neopentane. The main products of the first reaction were isobutene and methane and those of the second were methane, isobutane, and isobutene. The results enabled the authors to conclude that the zirconium undergoes oxidative addition to the C–H or C–C bonds of isobutane and neopentane with subsequent decomposition of the organometallic compounds formed:



(1)

The following reaction mechanism has been proposed for neopentane:



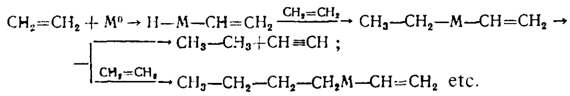
(2)

The presence of isobutane in the products of the reaction of zerovalent zirconium with neopentane is apparently associated with the hydrolysis of the organometallic compounds formed as a result of the insertion of the metal in the C–C bond. Although the hypothesis of the formation of the intermediate state (A) is controversial, it is difficult to imagine other pathways leading to the formation of isobutene and methane—products which are characteristic of the reaction of neopentane under the conditions of heterogeneous catalysis at high temperatures.

It has been shown[11] that many other transition metals (Ti, V, Cr, Mn, Fe, Ni, Co, Mo, and W) can undergo oxidative addition to isobutane under the same conditions with formation of the decomposition products of the organometallic intermediates.

The decomposition products of organometallic intermediates have been detected in studies[12,13] of the condensation of zerovalent nickel vapour on pentane, 2,3-dimethylbutane, methylcyclopentane, and cyclopentane at -196 °C.

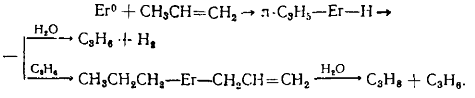
The interaction of the vapours of metallic ytterbium, samarium, and erbium, with ethylene, propene, and allene and also the reaction of erbium with cyclopropane at -196 °C have been investigated.[14] Organolanthanide compounds stable at room temperature were obtained. The product of the reaction of erbium with propene, apparently a π-allyl complex, proved to be soluble in tetrahydrofuran (THF). A small amount of hydrogen was found among the products of the hydrolysis of the organometallic compounds obtained in all the systems. The composition of the main hydrolysis products depended on the nature of the metal and the hydrocarbon. Thus the hydrolysis of the ethylene matrix with ytterbium and samarium led to the formation of C_1–C_6 hydrocarbons, which indicates the oligomerisation of ethylene under the influence of organometallic lanthanide compounds. The main hydrolysis product in the erbium–ethylene system was methane (90%):



(3)

The methane formed is apparently the product of the hydrolysis of the carbide produced as a result of the interaction of the zerovalent metal with acetylene. An analogous explanation was put forward by ourselves[3] in a study of the mechanism of the autohydrogenation of olefins.

Propyne, propane, propene, and the initial allene were found among the principle hydrolysis products in the reaction involving allene or in this reaction the products were propane, propyne, and the initial propene. On the basis of the considerations concerning the role of the organometallic intermediates and their decomposition pathways put forward in our earlier studies,[1-3] the reactions of propene can be accounted for in terms of the mechanisms



(4)

The hydrolysis of the erbium–cyclopropane matrix led to the formation of mainly the propane–propene fraction, propyne, and the initial cyclopropane. The data obtained led to the conclusion that the reactions in the systems investigated have a complex mechanism and that oxidative addition of the metal to the C–H bond takes place in all cases.

The oxidative addition of lanthanides to the C–H bond has been observed for hydrocarbons containing weakly acidic hydrogen. Thus the interaction of ytterbium, samarium, and erbium with hex-1-yne at -196 °C leads to the formation of lanthanide hydride compounds.[15] The formation of neodymium hydride in the decomposition of its butyl derivatives, obtained by the exchange reaction of $(C_5H_5)_3Nd$ with n-BuLi, has been observed.[16]

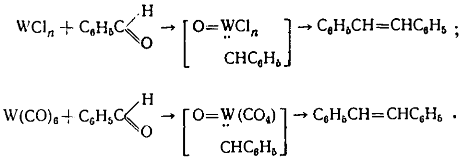
An infrared spectroscopic study of the photoinitiated reaction of copper atoms in a methane matrix at -261 °C demonstrated[17] the formation of organometallic compounds of the type CH_3MH. The formation of analogous compounds on photoinitiation had been observed earlier[18,19] in the reactions of iron, cobalt, copper, manganese, and lanthanide atoms with methane at -253 °C.

The infrared spectroscopic method made it possible to establish the insertion of a photoexcited iron atom in the C–H bond of ethane and propane at -263 °C.[20] The formation of a metallocyclobutane derivative, the product of the insertion in the C–C bond, was observed for cyclopropane.

The reaction of ethylene with cobalt, rhodium, nickel, and palladium atoms at -261 °C was investigated by infrared spectroscopy under conditions involving matrix isolation.[21] The formation of only the π-complex with ethylene was observed in all cases; this may be regarded as the primary reaction stage leading to the insertion of the metal in the C–H bond at higher temperature.

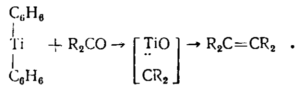
III. THE REACTIONS OF CARBONYL COMPOUNDS WITH METALS IN LOW OXIDATION STATES

Not only the atoms of transition metals but also their other forms corresponding to low oxidation states can enter into the oxidative addition reactions. This has been established for the interaction of aldehydes and ketones with tungsten and titanium compounds in which the metal is in a reduced state. Thus it has been shown that the addition of benzaldehyde to the WCl_6-2RLi system in THF at room temperature induces the rapid formation of stilbene.[22] According to the data of Fujiwara et al.,[23] the $WCl_6-LiAlH_4$ system is just as active in this reaction, while tungsten and molybdenum carbonyls have somewhat lower activities. The formation of olefins from carbonyl compounds in the electrochemical reduction of WCl_6 has been observed.[24] The formation of stilbene as a result of the oxidative addition of benzaldehyde to reduced metals can be represented schematically as follows:



(5)

Ledon et al.[25] investigated the reductive dimerisation of aldehydes and ketones under the influence of a zerovalent titanium complex–bisbenzenetitanium. The reactions of benzophenone and acetone with bisbenzene-titanium at 75–80 °C in THF led to the formation of tetraphenylethylene and tetramethylethylene respectively in quantitative yields. Presumably the reaction proceeds via the mechanism



$$\underset{C_6H_6}{\overset{C_6H_6}{\overset{|}{\underset{|}{Ti}}}} + R_2CO \rightarrow \left[\underset{CR_2}{\overset{}{\underset{\cdot\cdot}{TiO}}}\right] \rightarrow R_2C{=}CR_2 \ .$$

(6)

IV. OXIDATIVE ADDITION OF HYDROCARBONS TO TRANSITION METAL IONS

Numerous studies devoted to the gas-phase reactions of hydrocarbons at room temperature and in a high vacuum with the univalent ions of a whole series of transition metals (Rh^+, Fe^+, Co^+, Ni^+, Cr^+, and Sc^+) have been published recently. The reactions of alkanes,[26–36] alkenes,[31,37–40] cyclic hydrocarbons,[26,27,35,41,42] and their derivatives, namely alkyl halides,[43–47] alcohols,[44,45] aldehydes and ketones,[48–50] ethers,[48,49] amines[51,52] and nitro-compounds,[53] have been investigated. Transition metal ions have been obtained with the aid of laser radiation,[26–28,37,41,46] by thermal ionisation,[32–36, 40,42,50,53] or under the influence of the electron impact.[29–31,38, 39,43,45,47–49,51,52] The gas-phase reactions of the ions were investigated mass-spectrometrically. Naturally, the energy levels of the metal ions transferred to the gas phase differ significantly depending on the nature of the metal and the conditions of their formation which indicates influence on the character of the product formed, in particular on the relative contributions of the reactions involving insertion in the C–H and C–C bonds. In this connection, the high reactivity of the isolated metal atoms and ions in the gas phase means that their interaction with hydrocarbons at room temperature leads to the formation of the same products as in heterogeneous catalysis at high temperatures.

The composition of the primary products of the interaction of hydrocarbons with Rh^+, obtained by irradiating rhodium foil with a laser beam in the presence of the reacting hydrocarbon, has been investigated mass-spectrometrically.[26] The contribution by secondary reactions does not exceed 10%. The results of this study, presented in Table 1, are of significant interest for the understanding of the chemical nature of the elementary steps in the catalytic reactions of hydrocarbons under the influence of individual metal atoms or ions.

In the reactions of ethane and propane, olefins bound in complexes are formed quantitatively (or almost quantitatively), while the reactions of n-butane, n-pentane, and 2,3-dimethylbutane give rise to dienes with evolution of the corresponding amount of H_2. Trienes bound in complexes are formed from n-heptane and n-octane with evolution of three H_2 molecules.

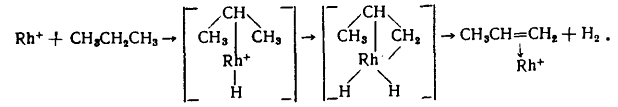
Table 1. The composition of the primary products of the reactions of Rh^+ with alkanes at room temperature.[26]

Alkane	(RhA)+	Yield $(RhA^+)^*$, %	Neutral products
C_2H_6	$RhC_2H_4^+$	100	H_2
C_3H_8	$RhC_3H_6^+$	94	H_2
n-C_4H_{10}	$RhC_4H_6^+$	100	$2H_2$
iso-C_4H_{10}	$RhC_4H_8^+$	43	H_2
	$RhC_4H_6^+$	48	$2H_2$
n-C_5H_{12}	$RhC_5H_8^+$	88	$2H_2$
iso-C_5H_{12}	$RhC_5H_8^+$	97	$2H_2$
neo-C_5H_{12}	$RhC_5H_{10}^+$	15	H_2
	$RhC_5H_8^+$	29	$2H_2$
	$RhC_4H_8^+$	13	CH_4
	$RhC_4H_6^+$	34	H_2, CH_4
n-C_6H_{14}	$RhC_6H_{10}^+$	49	$2H_2$
	$RhC_6H_8^+$	33	$3H_2$
	$RhC_6H_6^+$	18	$4H_2$
$CH_3-\underset{CH_3}{\underset{\vert}{CH}}-\underset{CH_3}{\underset{\vert}{CH}}-CH_3$	$RhC_6H_{10}^+$	100	$2H_2$
n-C_7H_{16}	$RhC_7H_{10}^+$	94	$3H_2$
n-C_8H_{18}	$RhC_8H_{12}^+$	91	$3H_2$
Cyclopropane	$RhC_3H_4^+$	76	H_2
	$RhCH_2^+$	11	C_2H_4
Cyclopentane	$RhC_5H_6^+$	100	$2H_2$
Cyclohexane	$RhC_6H_8^+$	65	$2H_2$
	$RhC_6H_6^+$	35	$3H_2$

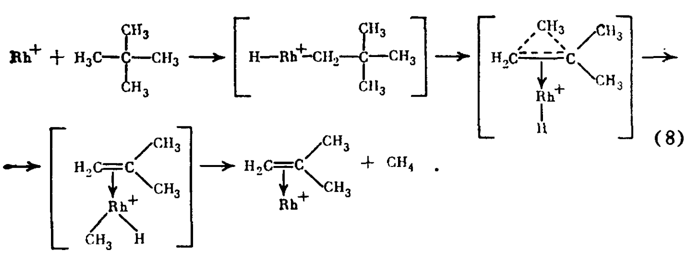
*Relative to theoretical yield.

The principle products of the reaction of n-hexane are complexes of a diene and triene as well as benzene, which is apparently formed from the linear triene via the intermediate cyclohexadiene. It has been shown[54,55] that the dehydrocyclisation of hexane to benzene in heterogeneous catalysis at high temperatures proceeds via consecutive stages involving the formation of an olefin, a diene, a triene, and cyclohexadiene. Complexes of isobutene and butadiene are formed in approximately equal amounts from isobutane. The formation of butadiene indicates the occurrence of skeletal isomerisation together with dehydrogenation. The neopentane reaction products are of special interest. Apart from the isopentene and isoprene complexes, arising as a result of consecutive steps involving the isomerisation of neopentane and its dehydrogenation, complexes of butene and butadiene with the metal, formed as a result of the decomposition of the hydrocarbon skeleton with the simultaneous evolution of CH_4 and H_2, were also detected. As expected, a complex of cyclopentadiene is formed in a quantitative yield from cyclopentane, while the complexes of cyclohexadiene and benzene are formed from cyclohexane. It is of interest to note that a complex of methylene carbene was formed in a yield of approximately 11% from cyclopropane. All these reactions are characteristic of heterogeneous catalysis by transition metals at high temperatures.

It has been concluded[26] that the primary step is the oxidative addition of the hydrocarbon with formation of the organometallic derivative and the decomposition of the latter leads to the final reaction products. Thus the following mechanisms have been proposed for propane and neopentane:



(7)

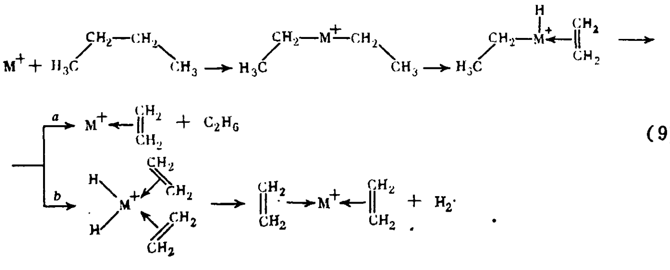


(8)

It is noteworthy that the insertion of the metal in a C–H bond in the methyl group, and not in the methylene group as in Eqn.(7), appears to us preferable, since this involves the formation of a more stable primary organometallic intermediate. The decomposition of the latter via the β-elimination pathway leads to the formation of the same reaction products.

The reactions of normal and branched alkanes as well as cycloalkanes with Ti^+ ions obtained by the action of laser radiation on titanium foil were investigated in a subsequent study.[27] The Ti^+ ions are inserted mainly in the C–H bonds of hydrocarbons, leading to the formation of products similar to those obtained in the presence of Rh^+ ions.

The reactions of Fe^+, Co^+, and Ni^+ ions with a series of normal alkanes ranging from propane to heptane have been investigated.[28] The Fe^+, Co^+, and Ni^+ ions were obtained by the same method as the Rh^+ and Ti^+ ions. It was found that the Ni^+ and Co^+ ions are mainly inserted in a C–C bond with formation of unsaturated products of the decomposition of the carbon skeleton:



(9)

If the metal is inserted in the $CH_2–CH_3$ bond in n-butane, then the same reaction leads to the formation of propene and methane. Diethylcobalt, obtained by the reaction of ethyllithium with $CoCl_2$, is known to decompose only via pathway (9a), leading to the formation of equimolar amounts of ethane and ethylene.[56] Such products can arise not only via each stage involving the formation of a hydride derivative, as in reaction (9a), but also as a result of the disproportionation of two ethyl groups bound to the metal. Reaction (9b), which leads only to ethylene, does not occur in this case. It may be that this reaction is specific to metal ions. In the case of Fe^+, the insertion in a C–H bond with subsequent formation of an olefin is observed together with the above reaction.

The study of the reactions of a series of olefins, ranging from ethylene to hexene isomers, in the presence of Fe^+ ions obtained with the aid of laser radiation has shown that the composition of the primary reaction products depends on the nature of the olefin.[37] Ethylene, propene, and isobutene did not react with Fe^+ ions under these conditions. n-Butenes give rise to quantitative yields of products of the insertion in a C–H bond. In contrast to n-butenes, methylbutenes produce considerable amounts of products of the insertion in a C–C bond. In the reactions of n-pentenes and hexenes, the last of the reactions indicated becomes the main one.

The reactions of Fe^+, Co^+, and Ni^+ ions with cyclic hydrocarbons, namely cycloalkanes and cycloalkenes, have also been investigated.[41] In this case the reaction involving the insertion of the metal ion in a C–C bond is the main one, which is the reason for the formation of products of the dehydrogenation and rupture of the carbon skeleton, as has been noted for the reactions of Co^+ and Ni^+ with n-alkanes.

It has been established that the presence of the hydride ligand[57] influences significantly the reactivity of the metal ions. This conclusion was reached on the basis of the study of the reactions of FeD^+, CoD^+, and NiD^+ with a series of alkanes ($C_1–C_5$) and alkenes (C_2 and C_3) in the gas phase. The FeD^+, CoD^+, and NiD^+ ions were generated by the reaction of the Fe^+, Co^+, and Ni^+ ions, obtained by laser radiation, with deuteriated nitromethane or methyl nitrite:

$$M^+ + CD_3NO_2 \xrightarrow[-NO]{} MOCD_3^+ \xrightarrow[-CD_2O]{} MD^+ ;$$
$$M^+ + CD_3ONO \xrightarrow[-NO]{} MOCD_3^+ \xrightarrow[-CD_2O]{} MD^+ . \qquad (10)$$

It was found that the FeD^+, CoD^+, and NiD^+ ions are inserted mainly in C–H bonds of the alkanes, in contrast to the Co^+ and Ni^+ ions, which, as shown above, give rise mainly to products of the insertion in a C–C bond. NiD^+ and CoD^+ are then capable of reacting with ethane, while NiD^+ is capable of oxidative addition even to methane.

It was noted above that the Fe^+ ion does not react with ethylene and propene. On the other hand, FeD^+ and CoD^+ can undergo oxidative addition to the C=C bond of propene and NiD^+ also to the C=C bond of ethylene.

According to the data of Jacobson and Freiser,[58] $CoCH_3^+$ as well as MH^+ ions are inserted solely in a C–H bond of aliphatic alkanes, starting with propane. This fact has been established in a study of gas-phase reactions of $CoCH_3^+$ with a series of alkanes ranging from methane to hexane isomers. The $CoCH_3^+$ ions were obtained by the reaction of Co^+, generated by laser radiation, with methyl iodide:

$$Co^+ + CH_3I \rightarrow CoCH_3^+ + I . \qquad (11)$$

The authors showed that methane and ethane do not react with $CoCH_3^+$. The evolution of mainly methane and the formation of dehydrogenation products were observed in the reactions with participation of $C_3–C_6$ alkanes. In the reactions of 2,2-dimethylpropane and 2,2-dimethylbutane, methane is the main neutral reaction product (insertion in a C–C bond).

The $FeCH_3^+$ ions, obtained by the same method as the $CoCH_3^+$ ions, do not react with aliphatic alkanes.[58] The reactions of the $NiCH_3^+$ ions have not been investigated, since they could not be obtained by the above method. The formation of NiI^+ and not $NiCH_3^+$ was observed in the reaction of Ni^+ with methyl iodide.

The gas-phase reactions of the $CoCH_3^+$ and $FeCH_3^+$ ions with a series of cyclic hydrocarbons—cycloalkanes ranging from C_3 to C_6 as well as cyclopentene and cyclohexane—were subsequently investigated.[59] These ions are inserted mainly in C–C bonds of cyclopropane and cyclobutane, forming alkyl (ethyl or propyl) complexes and ethylene. It had been shown earlier that the Fe^+ and Co^+ ions, obtained by means of laser radiation, do not react with cyclopropane.[41] In the reactions of cyclopentane, cyclohexane, cyclopentene and cyclohexene with $CoCH_3^+$, the formation of only the dehydrogenation products (the complexes of cycloalkenes or cycloalkadienes) and the corresponding neutral products (methane and hydrogen) was observed. The $FeCH_3^+$ ions do not enter into this reaction. In the case of cyclopentene and cyclohexene the oxidative addition to a C–H bond is the only reaction for both $CoCH_3^+$ and $FeCH_3^+$.

In one of the most recent studies,[60] the gas-phase reactions of the $FeCH_2^+$ and $CoCH_2^+$ ions with aliphatic alkanes are investigated. The method of preparation of the MCH_2^+ ions was based on the reactions of the Fe^+ and Co^+ ions, generated by laser radiation, with epoxyethane or cycloheptatriene:

$$M^+ + C_2H_4O \rightarrow MCH_2^+ + CH_2O$$
$$M^+ + \text{cyclo-}C_7H_8 \rightarrow MCH_2^+ + C_6H_6 \quad (12)$$

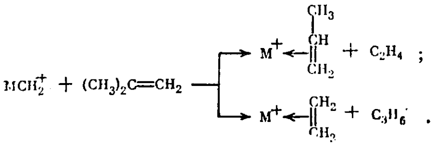
The study of the reactions of the $CoCH_2^+$ and $FeCH_2^+$ ions with alkanes, ranging from methane to hexane isomers, led to the conclusion that the oxidation addition of the hydrocarbon to the metal ion proceeds predominantly via the insertion into the C–H bonds of the alkanes and to a lesser extent the C–C bonds. The $CoCH_2^+$ ion reacted with all the alkanes investigated except methane, while the $FeCH_2^+$ ions reacted with alkanes starting from propane.

The gas-phase reactions of the $FeCH_2^+$ and $CoCH_2^+$ ions with olefins, ranging from ethylene to hexene, and also with butadiene, acetylene, and propyne have also been studied.[61] The reactions of $FeCH_2^+$ and $CoCH_2^+$ with ethylene lead to the formation of only the M^+ ion and the corresponding neutral product C_3H_6. The authors suggest that the interaction of $CoCH_2^+$ with ethylene may entail its insertion both in a C–H bond with formation of propene and in the C=C bond with formation of cyclopropane. The reaction of the $FeCH_2^+$ ion may result in the formation of propene alone. The study of the interaction of ethylene with MCD_2^+ ions established the occurrence of a metathetical reaction, which was inferred from the presence of the products MCH_2^+ and $C_2H_2D_2$. Thus two processes take place:

$$MCD_2^+ + CH_2{=}CH_2 \rightarrow MCH_2^+ + CD_2{=}CH_2\ ; \quad (13a)$$

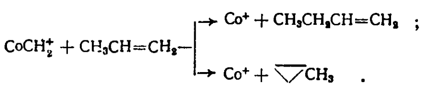
(13b)

In the case of ethylene the contribution by reaction (13a) is small, amounting to 20% for the $FeCH_2^+$ ions and only 2% for the $CoCH_2^+$ ions. However, the contribution of the metathetical reaction increases significantly in the case of propene and isobutene. Thus the main product of the reaction of MCH_2^+ with propene is the ion of ethylene bound in a complex, while isobutene gives rise mainly to the ions of ethylene and propene bound in complexes:



(14)

Apart from the ions indicated, the M^+ ions were found in the products of the reactions of MCH_2^+ with propene and isobutene, as well as the compounds C_4H_8 in the former case and C_5H_{10} in the latter. The authors[61] believe that the $CoCH_2^+$ ions can be inserted both in a C–H bond of propene to form but-1-ene, and in the C–C bond to form methylcyclopropane:



(15)

In the reaction of $FeCH_2^+$, only the insertion in a C–H bond is possible. In contrast to propene, isobutene gives rise to an appreciable amount of $MC_4H_6^+$ ions. n-Butenes give rise to the same main reaction product as isobutene. A complex set of products has been obtained in the reactions of pentenes and hex-1-ene. The main products of the reaction of the MCH_2^+ ions with butadiene were the M^+ ion and the corresponding neutral compound C_5H_8, which is cyclopentene according to the authors. In the case of acetylene and propyne, a single reaction leading to the formation of M^+ was observed in each case together with the products C_3H_4 (from acetylene) or C_4H_6 (from propyne). The authors[61] suggest that only the insertion of the carbene in a C–H bond with formation of an allene or propyne is possible in the first of the above reactions.

The reactions of alkanes with the Fe^+, Co^+, and Ni^+ ions[32–35] and of alkenes and cycloalkanes with Co^+[40,42] have been investigated by the method of ion beams. The ions were obtained by the thermal ionisation of metals formed on decomposition of the corresponding chlorides. The composition of the products of the reactions of alkanes ranging from butane to octane with the Fe^+, Co^+, and Ni^+ ions having a kinetic energy of approximately 0.5 eV permitted the same conclusion as that reached by Jacobson and Freiser,[28] namely that the Ni^+ and Co^+ ions are inserted preferentially in a C–C bond and that this is accompanied by insertion in a C–H bond in the case of Fe^+.

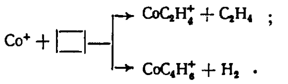
The study of the interaction of Co^+, having a kinetic energy of approximately 1 eV, with alkenes ranging from ethylene to hexenes[40] showed that ethylene and propene do not react with the metal ions under these conditions. In the case of isobutene the products of the insertion of Co^+ in a C–C bond was found. The reactions of n-butenes with Co^+ led to the formation of mainly a diene bound in a complex and of the corresponding neutral product (H_2). In the reactions of pentenes and hexenes, the insertion in both C–H and C–C bonds was observed.

The results obtained in a study[42] of the gas-phase reactions of Co^+ ions, having a kinetic energy of approximately 1 eV, with cycloalkanes ranging from cyclopropane to cyclohexane diverge somewhat from the data of Jacobson and Freiser.[41] Under these conditions, the Co^+ ions react with cyclopropane with formation of $CoCH_2^+$ and ethylene:

(16)

The absence of the reactions of cyclopropane with Fe^+, Co^+, and Ni^+, generated by the influence of laser radiation, is apparently associated with the fact that these ions exist mainly in the ground and insufficiently excited electronic states and do not have a high kinetic energy compared with the ions used in the ion beam method.

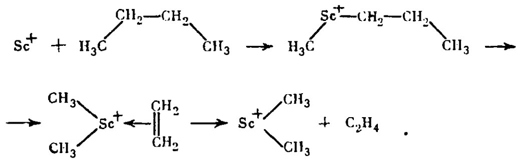
The reactions of Co^+ with cyclobutane, cyclopentane, and cyclohexane lead to the formation of dehydrogenation products and the products of the dissociation of the ring C–C bond according to Armentrout and Beauchamp.[42] For example, the reaction of Co^+ with cyclobutane proceeds as follows:



(17)

The gas-phase reactions of the FeH^+ ions, obtained by electron impact from 1,1-dimethylferrocene, with methane, ethane, and butane have been investigated for low kinetic energies of the ions.[62] It has been shown that methane and ethane do not react with FeH^+. The reaction of n-butane leads to the formation of the products of the insertion of FeH^+ in a C–H bond of the alkane, which agrees with data[57] for the analogous reactions of the FeD^+, CoD^+, and NiD^+ ion obtained by the reaction of metal ions with nitromethane or metal nitrite.

The reactions of Sc^+ ions having a kinetic energy of approximately 0.5 eV with alkanes ranging from propane to hexane in the gas phase have been recently investigated.[36] The Sc^+ ions were obtained by the thermal emission method at 2500 K. It was found that the reaction of propane with Sc^+ proceeds similarly to the reactions of alkanes with the Fe^+, Co^+, and Ni^+ ions. The main products are complexes of Sc^+ with propene (68%) and ethylene (27%). The reaction of n-butane leads to the formation of large amounts of the complex $Sc(C_2H_6)^+$ and ethylene respectively. Analysis of the thermochemical data led the authors[36] to the conclusion that the complex $Sc(C_2H_6)^+$ had the dimethylscandium structure. $Sc(CH_3)_2^+$ may be formed on insertion of Sc^+ to the terminal C–C bond of n-butane:



(18)

or to a C–H bond in the CH_2 group, which also leads to the formation of the dimethylethylene intermediate. The insertion of Sc^+ in a C–H bond leads to the formation of dehydrogenation products, which are, according to the authors' hypothesis, metallocyclobutane derivatives and not olefins and dienes bound in complexes as for other ions.

The gas-phase reactions of the Fe^+, Co^+, Ni^+, Cr^+, and Ti^+ ions with alkanes have also been investigated in other studies.[29,30] The metal ions were obtained by electron impact on the corresponding carbonyls (the Fe^+, Co^+, Ni^+, and Cr^+ ions) or the chloride (the Ti^+ ions). In their studies of the reactions of the Fe^+, Co^+, Ni^+, and Cr^+ ions with perdeuteriobutanes having the normal or isostructure, the authors concluded that the composition of the reaction products depends on the nature of the metal and the alkane. Table 2 presents the relative rate constants for the reactions of M^+ with butanes in the initial stage and shows that, in the presence of the Cr^+ ions, approximately 60% of the reaction steps involve the insertion of the metal in a C–D bond with subsequent formation of an olefin and a diene bound in complexes with Cr^+, while about 40% involve the insertion in the C_2–C_3 bond of butane with subsequent formation of ethylene. The insertion in the C_1–C_2 and C_3–C_4 bonds is not observed. The contribution by the reaction involving the insertion in the C_2–C_3 bond of n-butane increases sharply for Fe^+ and Co^+ with the corresponding fall of the rate of insertion in the C–H bonds. The formation of small amounts of complexes of propene with Fe^+ and Co^+ indicates the partial occurrence of the reaction also involving the C_1–C_2 (C_3–C_4) bonds. The reaction in which Fe^+, Co^+, and Ni^+ are inserted in a C–C bond is decisive for isobutane; the decomposition of the organometallic intermediate leads to the formation of a propene complex. The contribution by reactions involving the insertion in a C–H bond, which lead to an isobutene complex, is comparatively small.

In reactions of the Ni^+ ions with n-butane[29] and also with the C_4–C_7 alkenes, only insertion in a C–H bond takes place with subsequent β-decomposition of the organometallic compound and the formation of an olefin and hydrogen.

V. OXIDATIVE ADDITION OF OTHER ORGANIC COMPOUNDS TO TRANSITION METAL IONS

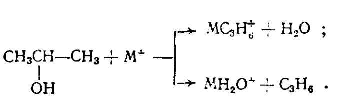
In conclusion we shall consider briefly the reactions of metal ions with derivatives of hydrocarbons containing various functional groups.

The gas-phase reactions of transition metal ions with aryl halides have been studied in relation to the interaction of the Fe^+ and Co^+ ions with CH_3I,[43] CH_3Br,[43] C_2H_5I,[44] and iso-C_3H_7Cl,[45] of the Ni^+ ions with CH_3I [44,45] and C_2H_5I,[45,45] of the Cr^+ ions with C_2H_5I,[44] and of the Fe^+ ions with C_6H_5Cl.[47] The above ions were obtained by electron impact on the corresponding metal carbonyls. The gas-phase reactions of Ti^+, obtained by laser radiation, with CH_3X (X = Cl, Br, or I), C_2H_5Cl, C_6H_5Cl, and $(CH_3)_2CHCl$ have been investigated.[46] The formation of the products of the oxidative addition to the C–Hal bond were observed in all cases. It is well known that RHal add analogously to active zerovalent metals in solution. The addition of alkenyl halides to $Ni(CO)_4$, leading to the formation of π-allyl derivatives,[63] and the addition of alkyl halides to zerovalent cobalt and other zerovalent metals[64,65] may serve as examples.

Table 2. The relative rate constants for the formation of the products of the reactions of M^+ with butanes.[30]

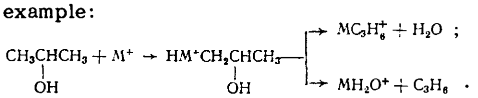
M^+	n-C_4D_{10}				iso-C_4D_{10}	
	$MC_2D_4^+$	$MC_3D_6^+$	$MC_4D_6^+$	$MC_4D_8^+$	$MC_3D_6^+$	$MC_4D_8^+$
Cr^+	0.22	0	0.16	0.16	0	0.09
Fe^+	0.53	0.07	0.04	0.04	0.46	0.09
Co^+	0.53	0.09	0	0.13	0.82	0.15
Ni^+	0.14	0.02	0	0.07	0.29	0.04

The gas-phase reactions of the Fe^+, Co^+, and Ni^+ ions, arising as a result of the electron impact on the corresponding metal carbonyls, with methyl, ethyl, and isopropyl alcohols have been studied.[44,45] The above ions induce the formation of mainly the products of oxidative addition to the C–OH bond with subsequent dehydration of the alcohols. $MC_2H_4^+$ ions were the main products of the reactions of the Fe^+, Co^+, and Ni^+ ions with ethyl alcohol, while approximately equal amounts of the $MC_3H_6^+$ and MH_2O^+ ions were found in the products of the reaction with isopropyl alcohol:



$$CH_3CH(OH){-}CH_3 + M^+ \rightarrow \begin{cases} MC_3H_6^+ + H_2O\ ; \\ MH_2O^+ + C_3H_6\ . \end{cases} \qquad (19)$$

In the given instance the reaction proceeds via the classical pathway involving the β-decomposition of the organometallic compounds. It is noteworthy that the analogous decomposition products can arise also when M^+ is inserted in a C–H bond, for example:



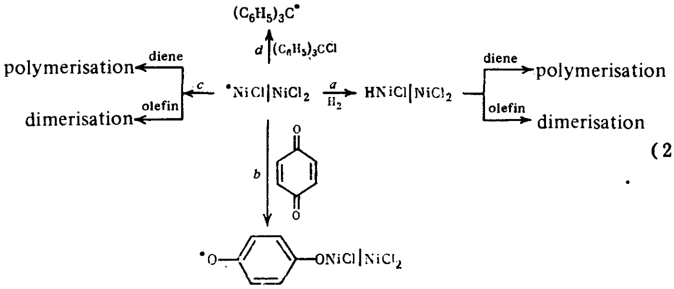
$$CH_3CH(OH)CH_3 + M^+ \rightarrow HM^+CH_2CH(OH)CH_3 \rightarrow \begin{cases} MC_3H_6^+ + H_2O\ ; \\ MH_2O^+ + C_3H_6\ . \end{cases} \qquad (20)$$

The gas-phase reactions of Fe^+ and Co^+ ions with acetaldehyde, acetone, ethyl methyl ketone, and isopropyl methyl ketone have been studied[49,50] as well as the reactions of Fe^+ ions with a series of other ketones—simple, mixed, unsaturated, and cyclic, also propionaldehyde and butyraldehyde.[49] The reaction of Co^+ ions with formaldehyde has been investigated.[50] Fe^+ ions have been obtained by the action of laser radiation,[49] while Co^+ ions have been generated by thermal ionisation.[50] The reactions involving Co^+ ions have been studied using a low kinetic energy of the ions. The composition of the products of the reactions with aldehydes and ketones depends on the nature of the carbonyl compound.

Thus acetone, formaldehyde and acetaldehyde give rise to only the $M(CO)^+$ ions—the products of oxidative addition to the C—C=O or H—C=O bonds. In the reactions with participation of ketones and aldehydes, there is a longer alkyl chain and the fraction of the products of oxidative addition to a C—H bond increases, while in the reactions with ketones having substituents at the α-carbon atoms and cyclic ketones there is an increase in the fraction of the products of oxidative addition to a C—C bond.

The gas-phase reactions of Fe^+ ions, obtained by the action of laser radiation, with ethers (dimethyl, diethyl, and di-isopropyl ethers, two mixed ethers—butyl methyl and isopropyl methyl ethers, and a cyclic ether—tetrahydrofuran) have been investigated.[49] The composition of reaction products depends on the nature of the ether. Thus dimethyl ether gives rise to only $FeCH_2O^+$ ions and correspondingly CH_4 (insertion in the C—O bond). The oxidative addition to the C—O bond predominates also for diethyl, di-iso-propyl, and isobutyl methyl ethers. For butyl methyl ether, the dehydrogenation reaction leading to the formation of $FeC_5H_{10}O^+$ and correspondingly H_2 is the dominant process.

It was already noted above that metal ions entering the gas phase under the influence of laser and especially electron irradiation are much more reactive than the ions of the same metals on the surfaces of catalysts and that even at room temperature hydrocarbons undergo more extensive reactions in the presence of such ions even at room temperature than in heterogeneous catalysis at not unduly high temperatures. It is noteworthy that metal subhalides, obtained on heating salts at 200—300 °C in a high vacuum and remaining in the matrix comprising halides, are to some extent analogous of metal ions. They are known to function as catalysts with selective activity in reactions with olefins at the usual temperatures. It has been shown[66,67] that small amounts of the ·NiCl species, detected by EPR in an $NiCl_2$ matrix, exhibit catalytic activity in diene polymerisation and ethylene dimerisation reactions at low temperatures.



(21)

The reactions via pathways *a* and *c* lead to the polymerisation of dienes and the oligomerisation of olefins, while along pathways *d* and *b* the system loses activity and triphenylmethyl and semiquinonoid radicals appear respectively. Analogous subhalides with catalytic activity in the above reactions arise when other metal halides are used.[66] One can also note that certain metal oxides, heated in a high vacuum at 400—500 °C for a long time, acquire the ability to catalyse deuterium exchange in hydrocarbons at low temperatures.[68] It may be that under the given conditions defects due to the formation of a small number of metal atoms in a more reduced state can arise in the catalyst matrix and are able to participate in the oxidative addition of hydrocarbons and deuterium.

The metal atoms formed on vaporisation in a high vacuum with their subsequent condensation in the hydrocarbon matrix[11] approach heterogeneous metallic catalysts as regards the character of their action on hydrocarbons although in this instance too isolated atoms are naturally more reactive than the atoms on the surface. It is well known that in the latter case the active centres are distributed on the crystal faces or in dislocation, where the metal atom retains a fairly large number of coordination vacancies and is able to pass to the oxidised state after combining with the hydrocarbon to form an organometallic intermediate.

---o0o---

It follows from the data presented that, on coming into contact with an isolated metal atom at low temperatures, hydrocarbons undergo reactions analogous to their reactions in heterogeneous catalysis at higher temperatures. The reaction intermediates are in all cases organometallic compounds of transition metals, whose decomposition pathways have been thoroughly investigated in the temperature range 20—100 °C. Complex reactions of hydrocarbons (hydrogenation, dehydrogenation, skeletal isomerisation, hydrogenolysis, and deuterium exchange) can take place not only on an *ensemble* of metal atoms but also at an individual atom via stages involving the formation of organometallic intermediates arising as a result of the addition of the metal atom to C—H, C—C, and C—O bonds. The experimental data presented in this review are therefore of special interest for the understanding of the chemical nature of the elementary steps in heterogeneous catalysis.

Norbornadienes in the Synthesis of Polycyclic Strained Hydrocarbons with Participation of Metal Complex Catalysts

U.M.Dzhemilev, R.I.Khusnutdinov, and G.A.Tolstikov

The advances achieved in recent years in the synthesis of polycyclic hydrocarbons, including those containing functional substituents, from norbornadiene and its derivatives using metal complex catalysts are surveyed. The homo- and codimerisation reactions of norbornadienes with olefins, dienes, and acetylenes, involving the $[2_\pi + 2_\pi]$-, $[2_\pi + 2_\pi + 2_\pi]$-, and $[4_\pi + 4_\pi]$-addition under the influence of transition metal complexes are examined. Data on the synthesis of norbornadiene trimers as well as the physicochemical and spectroscopic characteristics of a whole series of unique hydrocarbons are presented. The mechanisms of the reactions indicated are discussed.
The bibliography includes 173 references.

INTRODUCTION

Since the publication of Schauzer' review,[1] devoted to the problems of the synthesis of strained skeletal hydrocarbons from bicyclo[2.2.1]hepta-2,5-diene [norbornandiene (NBD)] (I) by methods involving metal complex catalysis more than ten years have elapsed. During this period, particularly in recent years, this field of chemistry has continued to develop vigorously. As a result, extensive theoretical and experimental data have accumulated, being concentrated mainly in publications and patents which are not readily accessible to many chemists. Even superficial analysis of the latest data on the synthesis of skeletal compounds indicates increasing importance of NBD as the key and fundamental monomer for the synthesis in a single stage of unique polycyclic strained hydrocarbons, among which NBD homodimers, trimers, and codimers are of greatest interest and practical value. The hydrogenated NBD dimers are widely used in the USA for the synthesis of high-density and high-energy multipurpose hydrocarbon rocket fuels.[2]

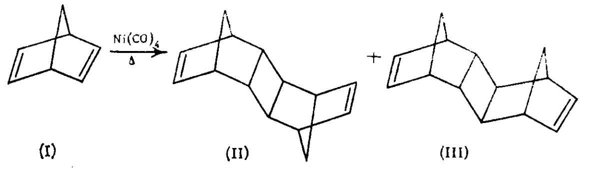
The transformations of norbornadienes into the corresponding cyclic dimers and trimers proceed as a rule under the influence of low-charge nickel, cobalt, iron, and rhodium complexes; manganese, chromium, titanium, palladium, and iridium compounds are used to a lesser extent. Active catalysts are obtained by reducing complexes of the above metals, soluble in organic solvents, with AlR_3, MgRR′, and their derivatives. Transition metal complexes containing electron-donating or electron-accepting ligands in their coordination spheres are used in many instances.

The literature data are described systematically in the present review on the basis of the nature of the central metal atom, since in the majority of cases the direction and structural selectivity of cyclo-oligomerisation of norbornadienes are determined by precisely this factor.

II. THE HOMODIMERISATION OF NORBORNADIENE UNDER THE INFLUENCE OF METAL COMPLEX CATALYSTS

1. Catalytic Systems Based on Nickel Compounds

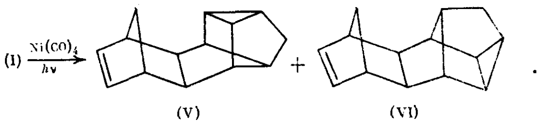
The cyclodimerisation of NBD via the $[2_\pi + 2_\pi]$addition mechanism was achieved for the first time by Bird et al.[3] using nickel tetracarbonyl as the catalyst. It was established subsequently[4-6] that $Ni(CO)_4$ promotes the formation of a mixture of isomers consisting of *endo,trans,endo*-pentacyclo[8.2.1.$1^{4,7}$.$0^{2,9}$.$0^{3,8}$]tetradeca-5,11-diene (II) and the *endo,trans,exo*-isomer (III) whose overall yield and composition depend significantly on the dimerisation conditions.



For example, when a mixture of NBD and $Ni(CO)_4$ with the ratio $Ni(CO)_4 : NBD = 1 : 100$ is refluxed for 6.5 h, a mixture of the isomers (II) and (III) is obtained in a quantitative yield in proportions of 1 : 3.[5] When the reaction is carried out in benzene, the content of the dimer (III) increases markedly to give (II) : (III) = 1 : 5.[6]

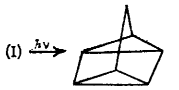
Complexes of unknown composition and structure, obtained when one of the three NBD $[2_\pi + 2_\pi]$dimers, namely *exo,trans,exo*-pentacyclo[8.2.$1^{4,7}$.$0^{2,9}$.$0^{3,8}$]tetradeca-5,11-diene (IV) or NBD itself is treated with nickel tetracarbonyl, drive the NBD cyclodimerisation reaction exclusively towards the formation of the isomer (III).[5] The yield of compound (III) varies from 69 to 91% depending on the conditions used in preparation of the complexes indicated.

The direction of the $[2_\pi + 2_\pi]$reaction changes when the NBD cyclodimerisation is carried out in the presence of catalytic amounts of $Ni(CO)_4$ with simultaneous UV irradiation. The $[2_\pi + 2_\pi + 2_\pi]$dimers (V) and (VI) are formed exclusively in these experiments in an overall yield of ~11%: [5]



(V) (VI)

Unfortunately, the authors[5] hardly discussed the mechanism of this interesting reaction. Under the conditions of UV irradiation, quadricyclane (QC) is probably formed initially and readily dimerises to the cyclic dimers (V) and (VI) under the influence of low-charge nickel carbonyl complexes containing in the coordination sphere NBD molecules together with carbon monoxide:



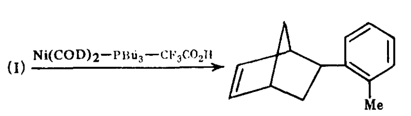
QC

This mechanisms has been confirmed by the results of studies[7-9] according to which quadricyclane is converted into $[2_\pi + 2_\pi + 2_\pi]$dimers and codimers in fairly high yields in the presence of complex catalysts based on nickel, palladium, and rhodium compounds.

The replacement of $Ni(CO)_4$ by $Ni(CO)_2(PPh_3)_2$ in the photoinitiated NBD cyclodimerisation reaction leads to the formation of the *exo,trans,exo*-isomer (IV) with a high selectivity.[10]

Cyclisation of the $[2_\pi + 2_\pi]$ type remains the principal pathways in the NBD dimerisation reaction using as catalysts zerovalent nickel complexes containing olefin, diene, and organophosphorus ligands in the coordination sphere. For example, $Ni(COD)_2$ (where COD = cyclo-octa-1,5-diene) converts NBD into the *exo,trans,exo*-dimer (IV) with a selectivity of 96.5%.[11] When triphenylphosphine is introduced into the composition of $Ni(COD)_2$, the selectivity in the formation of the dimer (IV) falls to 66.1% owing to the increase of the fraction of the *endo,trans,exo*-isomer (III).[12]

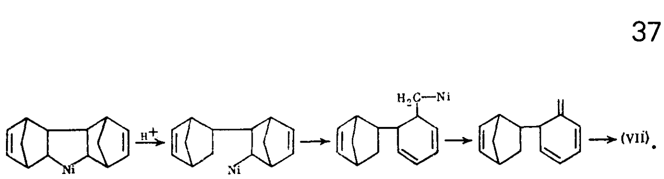
The dimerisation of NBD proceeds quite differently in the presence of the $Ni(COD)_2$–PBu_3 catalytic system promoted by CF_3CO_2H;[12] the only reaction product is then 5-exo-(o-tolyl)norborn-2-ene (VII), whose yield is 30%:



(VII)

Without the addition of trifluoroacetic acid, a mixture of NBD $[2_\pi + 2_\pi]$dimers (II)–(IV) was obtained in a yield of 60%, but the isomeric composition was not investigated.[12]

An analogous conversion of NBD into compound (VII) takes place in the presence of complexes of the type $NiX_2.PBu_3$ in solution in isopropylamine.[13] The introduction of $NaBH_4$ into the nickel–phosphine complex makes it possible to increase the yield of the product (VII) to 81.5%.[13] According to the authors,[13] the reaction proceeds via a mechanism whose first stage involves the activation of NBD via coordination with the central metal atom in the formation of the metallocyclic compound (VIII). In the presence of CF_3COOH, the latter undergoes a series of consecutive reactions leading to the formation of the dimer (VII):



(VIII)

Acrylonitrile complexes, which have been studied in detail by Schrauzer and Eichler[14] and which catalyse the dimerisation of NBD predominantly to the *endo,trans,exo*-isomer (III), play an important role in the series of nickel-containing catalysts of the dimerisation of NBD via the $[2_\pi + 2_\pi]$ addition mechanism.

The introduction of phosphines into acrylonitrile complexes of nickel increases the overall yield of dimers, which consist as a rule of the isomers (III) and (IV), to 80%, the selectivity in the formation of the isomer (III) being 98%.[14,15] It has been established that the ratio of the concentrations of the dimers (III) and (IV) is correlated with the electron density at the nickel atom: with increase of the effective charge on the central metal atom, the fraction of the isomer (III) also rises. Unfortunately, these data are insufficient to establish the detailed mechanism of the NBD cyclodimerisation reaction.

Thus the cyclodimerisation of NBD under the influence of nitrile complexes of nickel proceeds with the preferential formation of the *endo,trans,exo*-isomer (III) regardless of the nature and structure of the organophosphorus activator-ligands. With increase of reaction temperature, the fraction of this product in the reaction mixture increases.

Catalytic systems based on $Ni(CN)_2$ and phosphinites, phosphonites or phosphites are active in the cyclodimerisation of NBD also in the absence of a reducing agent.[16,17] For example, the catalyst prepared from $Ni(CN)_2$ and $PPh_2(OBu)$ converts NBD into a mixture of three possible $[2_\pi + 2_\pi]$ isomers (II)–(IV) in proportions of 62 : 5 : 33 and an overall yield of ~90%.

Under the reaction conditions, catalytically active nickel complexes are apparently formed on reduction of Ni^{2+} ions by the initial diene or the dimerisation products to Ni^+ or Ni^0. For example, in the presence of the complex $[Ni(acac)_2.(IV)]$, NBD is converted into the dimer (IV) in an overall yield of 53%.[4]

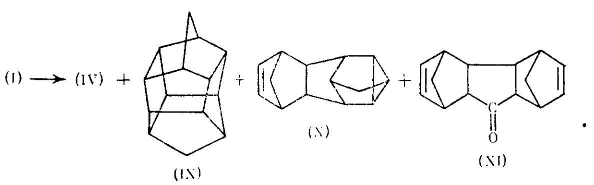
It is noteworthy that two- and three-component catalytic systems prepared from $Ni(acac)_2$, $AlEt_3$, and PPh_3, are much more productive than other known nickel-containing catalysts whose efficiency does not exceed 50–100 moles of the required product per gramme-atom of nickel.[4,11,18-23] Furthermore, the catalysts indicated are active in the dimerisation of NBD over a wide temperature range (20–200 °C) and effect the reaction both in the presence of solvents and in their absence. The yield of the mixture of dimers (II)–(IV) then varies from 40 to 87%. There is no doubt that these catalysts are extremely promising for the industrial application of the process.

The foregoing permits the conclusion that nickel-containing complex catalysts catalyse the cyclodimerisation of NBD via the $[2_\pi + 2_\pi]$ mechanism with formation of pentacyclic hydrocarbons regardless of the nature of the anion attached to the metal atom and also of the structure of the ligands and the reaction conditions.

2. Iron-containing Catalysts in Norbornadiene Dimerisation Processes

Iron-containing catalysts, which are frequently used in NBD dimerisation processes, are characterised, in contrast to the nickel catalyst, by a wider spectrum of their activity. Depending on the nature of the selective complex (ligand environment, oxidation state of iron) and the reaction conditions, they successfully effect all three variants of the NBD cyclodimerisation via the $[2_\pi + 2_\pi]$-, $[2_\pi + 2_\pi + 2_\pi]$-, and $[4_\pi + 4_\pi]$-addition mechanisms.

The formation of the NBD dimer in the presence of $Fe(CO)_5$ was first observed as early as 1959,[24] but the product obtained could not be identified. The above report[24] stimulated studies on the cyclodimerisation of NBD with participation of iron complexes. The complexes $Fe(CO)_5$, $Fe_2(CO)_9$, and $Fe_3(CO)_{12}$ were tested as catalysts of the dimerisation of NBD.[25-27] It was found that all the iron carbonyls exhibit catalytic activity in the NBD cyclo-oligodimerisation and lead to the formation of a complex mixture of hydrocarbons and carbonyl compounds. The dimers (IV), (IX), and (X) and the polycyclic ketones (XI), whose overall yields do not exceed 20%, were detected in the products.



The dimers (IV) and (IX) were identified as *exo,trans,exo*-pentacyclo[8.2.1.1^{4,7}.0^{2,9}.0^{3,8}]tetradeca-5,11-diene and heptacyclo[6.6.0.0^{2,12}.0^{3,7}.0^{4,11}.0^{5,9}.0^{11,14}]tetradecane, but final evidence for the correctness of these structures was obtained somewhat later.[28,29] The authors were unable to establish the structure of the hexacyclic dimers (X).

Iron nitrosyl complexes, distinguished by a high activity, productivity, and selectivity of their action, have been used[30] for the cyclodimerisation of NBD. The $[2_\pi + 2_\pi]$dimers (III) and (IV) were obtained exclusively in ~98% yield when $Fe(CO)_2(NO)_2$ was used.[30,31]

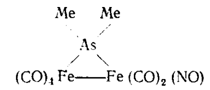
The study of Jolly et al.[30] initiated the systematic search for and development of highly active catalysts for the selective cyclo-oligomerisation of NBD. A whole series of iron nitrosyl complexes were obtained and investigated in the course of several years and certain characteristics of their action in NBD reactions were discovered.[32-43]

In particular, it was established that the catalytically active species responsible for the formation of the NBD dimer molecules was the coordination-unsaturated complex $Fe(NO)_2^*$,[30,31,39,40,42] which is probably formed under the reaction conditions when nitrosyl ferrates interact with NBD or its dimers.

Similar results were obtained in the electrochemical and chemical reduction of $[Fe(NO)_2Cl]_2$ in the presence of PPh_3.[39,40,42] The complex $[Fe(NO)_2Cl]_2$ is converted quantitatively into $Fe(NO)_2^*$ and the compounds $Na[Fe(CO)_3NO]$ and $Hg[Fe.(CO)_3NO]_2$ are converted into $Fe(CO)_2(NO)_2$, which the authors believe readily dissociates into CO and $Fe(NO)_2^*$.[44] Regardless of the structure and nature of the initial complex, only the $[2_\pi + 2_\pi]$dimers (III) and (IV) are formed in the presence of the systems indicated.

These results show that the mechanism of the cyclodimerisation of NBD under the influence of different iron nitrosyl complexes remains unchanged. The nature of the reductant hardly affects the yield of the dimers (III) and (IV) and the reaction selectivity. When powdered zinc is used as the reducing agent, the degree of conversion of NBD depends markedly on the nature of the solvent. Thus high yields of dimers (93%) have been obtained in acetone and tetrahydrofuran (THF). When the reaction is carried out in toluene, methanol, and acetonitrile, the yield of dimers falls.[38] In the presence of the $[Fe(NO)_2Cl]_2/AgBF_4$ catalytic system, best results are obtained in the dimerisation of NBD in pure methylene chloride. The selectivity in the formation of the dimer (IV) then amounts to 94% for a degree of conversion of NBD of 76%. It is noteworthy that $AgBF_4$ is the most effective promoting agent among the cocatalysts tested.

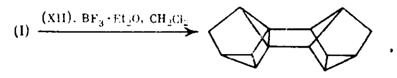
A high catalytic activity and selectivity in the reaction of the cluster compound (XII), which belongs to be class of iron carbonyl nitrosyl complexes considered, has been observed recently. At 60 °C in benzene, it converts NBD quantitatively into the *exo,trans,exo*-dimer (IV).[45,46]



$$(CO)_3Fe\overset{AsMe_2}{\text{——}}Fe(CO)_2(NO)$$

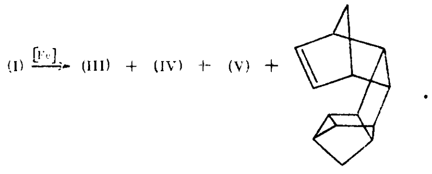
(XII)

A unique instance of a change in the selectivity in the dimerisation of NBD has been observed when an equimolar amount of $BF_3.OEt_2$ was added to compound (XII).[45] The only reaction product is the dimer (XIII), namely *endo,endo*-heptacyclo[8.4.0.0^{2,12}.0^{3,8}.0^{4,6}.0^{5,9}.0^{11,13}]tetradecane ("Binor-S"), formed via $[4_\pi + 4_\pi]$cycloaddition:



(XIII), (100%)

An author of several patents,[4,19,47] who used the $Fe(acac)_3$–$AlEt_3$ and $Et_2Al(OEt)$ catalytic systems for the dimerisation of NBD, achieved major successes in the synthesis of pentacyclic and hexacyclic NBD dimers. Iron acetylacetonate, reduced with triethylaluminium, catalyses the dimerisation of NBD with formation of a mixture of four hydrocarbons (III), (IV), (V), and (XIV):



(XIV)

The hexacyclic isomers (V) and (XIV) have been identified by Scharf et al.[48] The ratio of the isomers formed and the overall yield depend on the reaction conditions and the method of preparation of the catalyst. The addition of the olefin to the catalyst prepared at 0 °C and heating at 40 °C for 20 h result in the formation of a mixture of dimers of the following composition in a yield up to 97%: 63.6% (III), 24.3% (IV), and 12.1% [(V) + (XIV)].[4] The simultaneous addition of NBD solutions of $Fe(acac)_3$ and $AlEt_3$ to the reactor heated to 140–200 °C makes it possible to obtain mixtures of the isomers (III)–(V) and (XIV) containing 64–72% of hexacyclic hydrocarbons.[49-51]

The use of 1,2-bis(diphenylphosphino)ethane (BPE) and replacement of triethylaluminium by diethylaluminium chloride in the $Fe(acac)_3$–AlR_3 catalytic system make it possible to increase the selectivity in the formation of the *exo,exo-dimer* (VI) to 80–90%,[52,53] while the addition of triphenylphosphine alters the direction of the reaction towards the preferential formation of the *endo,endo*-isomer (XIV).[54]

Biscyclo-octatetraeneiron and the catalytic system obtained by reducing $FeCl_3$ with isopropylmagnesium chloride catalyse the dimerisation of NBD to the isomers (IV) and (VI) with the preferential formation of the latter.[55] When $FeCl_3$ is reduced with triethylaluminium or sodium, a catalyst active in the $[2_\pi + 2_\pi + 2_\pi]$cycloaddition is also obtained.[56]

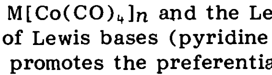
Thus, among the iron-containing NBD dimerisation catalysts investigated, the highest activity and productivity (up to 1000 moles of NBD converted per gramme-atom of iron) is shown by catalytic systems of the Ziegler–Natta type: $Fe(acac)_3-AlR_3(AlEt_3)$ or $Et_2Al(OEt)$. They are superior to the analogous nickel catalysts because of the consistently high yield of the dimers (70–90%) and the better reproducibility of the results.

3. Dimerisation of Norbornadiene in the Presence of Cobalt Catalysts

Cobalt compounds exhibit an exceptionally high catalytic activity in the cyclo-oligomerisation reactions of NBD. The first report of their use for the dimerisation of NBD dates back to 1961;[26] however, the above communication does not contain experimental details. In a classical study[28] devoted to the determination of the stereochemistry of the NBD $[2_\pi + 2_\pi]$ dimers, it was later shown that $Co_2(CO)_8$ combined with PPh_3 converts NBD into a mixture of two $[2_\pi + 2_\pi]$ isomers: the *endo,trans,exo*-isomer (III) and the *exo,trans,exo*-isomer (IV) with a (III) : (IV) ratio of 1 : 10.

Interesting results have been obtained in the dimerisation of NBD in the presence of the $Co(CO)_3(NO)$ catalyst isoelectronic with the complex $Fe(CO)_2(NO)_2$.[30] It was found that the former effects $[2_\pi + 2_\pi]$cycloaddition. In these experiments $[2_\pi + 2_\pi + 2_\pi]$dimers were formed together with compound (IV). The quantitative composition of the hexacyclic hydrocarbons (V) and (XIV) is not stated in the above communication. Furthermore, the dimer (IV) can be obtained with a selectivity up to 98% when the complex $[Co(NO)_2Cl]$ or $[Co(NO)_2Br]$, promoted with $AgPF_4$ or $NaBPh_4$, is used as the catalyst.[32,34–36].

In studies[1,57,58] of the catalytic properties of cobalt compounds in the cyclo-oligomerisation reactions of cyclic olefins and dienes, it has been observed that complexes of the type $M[Co(CO)_4]_n$ (where M = Zn, Cd, or Hg) effect the stereospecific dimerisation of NBD via the $[4_\pi + 4_\pi]$mechanism with formation of "Binor-S" (XIII) (in 95% yield). The structure of compound (XII) could not be demonstrated for a long time. However, the specific synthesis by the Wolff–Kishner reduction of the diketone (XV) [59,60] made it possible to establish finally that the dimer (XIII) has, as already suggested,[57,58] the structure of *endo,cis,endo*-heptacyclo$[8.4.0.0^{2,12}.0^{3,8}.0^{4,6}.0^{5,9}.0^{11,13}]$tetradecane.

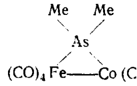


(XV) → (XIII) .

In order to carry out the cyclodimerisation of NBD to compound (XIII) under the influence of the catalysts investigated, it is essential to have cocatalysts of the type BF_3, SbF_3, $AlBr_3$, and $BF_3.OR_2$, whose greatest efficiency is achieved when the ratio of $M[Co(CO)_4]_n$ and the Lewis acid is 1 : 8. The introduction of Lewis bases (pyridine and triethylamine) into the catalysts promotes the preferential formation of pentacyclic and hexacyclic dimers.[57,61]

Dinuclear and polynuclear cobalt catalysts of the cyclodimerisation of NBD to the penta-, hexa-, and hepta-cyclic dimers (III), (IV), (V), (XIII), (XIV) were subsequently obtained and investigated. The activity and selectivity of the action of these catalysts depend greatly on the nature of the anion in the coordination sphere of the central metal atom and also on the structure of the cocatalyst (Lewis acid), the nature of the solvent, and the reaction conditions.[57,59,62–69] For example, the trinuclear complex (XVI) converts NBD into a 1 : 1 mixture of the dimers (XIV) and (XIII). When the Lewis acid $BF_3.OEt_2$ is introduced into the catalyst, the process can be directed towards the formation of compound (XIII) (in ~100% yield):[45,46]

$$(IV) \xleftarrow{(XVI)} (I) \xrightarrow{(XVI)+BF_3\cdot OEt_2} (XIII) .$$



(XVI)

The study of the kinetics of the cyclodimerisation of NBD to "Binor-S" (XIII) in the presence of the dinuclear catalyst $(Ph_2C_2)Co(CO)_6$ established that the reaction is first order with respect to the catalyst and that the activation energy is ~38.58 kcal mol^{-1}.[63]

Systems obtained by reducing $Co(acac)_2$ with organoaluminium compounds have a high catalytic activity in the NBD dimerisation reactions. The dimers (III) (29%) and (IV) (62%) and the $[2_\pi + 2_\pi + 2_\pi]$dimers (X) (yield 9%) of unknown composition are formed in the presence of the $Co(acac)_2-AlEt_3$ system:[4]

$$(I) \longrightarrow \underset{29\%}{(III)} + \underset{62\%}{(IV)} + \underset{9\%}{(X)} .$$

The authors note[53] that the direction of the NBD cyclodimerisation can be completely altered by employing the three-component $Co(acac)_2-1,2$-bis(diphenylphosphino)ethane–Et_2AlCl system as the catalyst. In this case the dimer (VI) is formed quantitatively. The replacement of the bisphosphine by PPh_3 leads to the formation of the isomer (XIII).[61]

Thus the cobalt-containing catalysts are extremely effective in the synthesis of the heptacyclic NBD dimer "Binor-S", which has found extensive applications in the synthesis of diamond-like structures.

4. Complexes Based on Rhodium in the Norbornadiene Dimerisation Processes

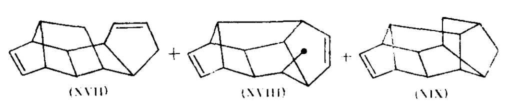
It is noteworthy that rhodium catalysts are distinguished by a low selectivity in the NBD dimerisation processes and as a rule lead to the formation of a complex mixture of polycyclic hydrocarbons. The fundamental studies on the application of rhodium-containing catalysts in the NBD dimerisation reactions have been carried out by Katz and co-workers (Columbia University). These investigators were able to isolate and identify a whole series of NBD dimers and trimers with the aid of modern physicochemical methods. Unfortunately, they investigated and tested only a limited number of rhodium complexes capable of effecting the dimerisation or trimerisation of NBD.

For example, the dimerisation of NBD in the presence of the 5% Rh/C catalyst takes place relatively selectively; NBD is then converted into a mixture of the isomers (IV), (V), and (XIV) in 53% yield:[71]

$$(I) \xrightarrow{Rh/C} \underset{4\%}{(IV)} + \underset{84\%}{(V)} + \underset{12\%}{(XIV)}$$

In the presence of Wilkinson's complex $[Rh(PPh_3)_3Cl]$, the dimerisation of NBD is accompanied by the skeletal isomerisation of the *exo,endo*-hexacyclo$[9.2.1.0^{2,10}.0^{3,8}.0^{4,6}.0^{5,9}]$tetradec-12-ene (V) to the hydrocarbons (XVII), (XVIII), and (XIX):[29,72]

$(I) \longrightarrow (V) + (IX) +$



(XVII) + (XVIII) + (XIX) .

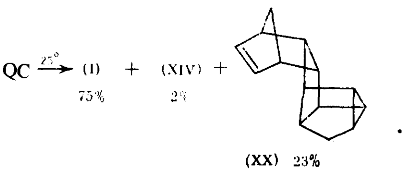
The introduction of an additional amount of PPh_3 into the complex $[Rh(PPh_3)_3Cl]$ hardly affects the direction of the dimerisation reaction,[29] but the composition of the cyclodimerisation products changes appreciably under these conditions.

The rhodium catalysts obtained by reducing $[Rh(PPh_3)_3Cl]$ with Et_2AlCl or $EtAlCl_2$ convert NBD into "Binor-S" (XIII) in an almost quantitative yield.[73] Analogous results have been obtained using catalytic systems with a fairly complex structure: $Rh(NBD)_2PF_6–PPh_3$, $P(OPh)_3]$ or $[Rh_4(CO)_{12}–BF_3.OEt_2]$.[64,71] The dimerisation of NBD under the influence of complexes of the type of $Rh(NBD)_2BF_4$ results in the formation of mainly the hexacyclic dimers (V), (VI), and (XIV):[75]

$$(I) \xrightarrow{[Rh]} \underbrace{(V) + (VI)}_{60\%} + \underset{10\%}{(XIV)} \;.$$

A selective method of synthesis of the dimer (V) using rhodium catalysts has been proposed by Japanese workers.[13] The authors used the catalytic system $Rh(C_8H_{14})Cl–CF_3CO_2H$ (C_8H_{14} = cyclo-octene; Rh : CF_3COOH = 1 : 4).

It is noteworthy that, in contrast to other catalysts, the rhodium complexes are capable of converting quadricyclane (QC) into the corresponding NBD dimers. For example, when quadricyclane is treated with the carboxylate complex $[Rh(NBD)AcO]_2$ in methylene chloride at room temperature, NBD is mainly formed together with a small amount of the hexacyclic dimers (XIV) and (XX). The *endo,exo*-isomer (XX) has been obtained by a catalytic process only under the conditions indicated:[7]



It is believed[76] that the initial NBD plays the role of a reductant in relation to the rhodium(II) carboxylate complexes. According to these workers,[76] the NBD dimerisation process begins only after the conversion of rhodium(II) into rhodium(I) under the influence of NBD. The rhodium(I) complex formed under these conditions is an effective catalyst of the $[2_\pi + 2_\pi + 2_\pi]$cyclo-dimerisation of NBD. It has been noted[74] that the activity of the rhodium trifluoroacetate complexes is higher by an order of magnitude than that of the acetate complexes. Fairly active catalysts of the dimerisation of NBD to a mixture of compounds(V) and (XIV) have been obtained by reducing $Rh(acac)_3$ with the organoaluminium compounds Et_2AlCl and $EtAlCl_2$.[77]

The above studies exhaust the available literature data on the use of rhodium complexes in the cyclodimerisation reactions of NBD. It follows from the results presented above that catalysts based on rhodium salts and modified by Lewis bases or acids have universal properties and make it possible to obtain seven of the nine of the known NBD dimers. However, only a limited number of rhodium complexes have so far been investigated and tested as catalysts of the cyclo-oligomerisation of NBD and its derivatives can lead to the creation of new highly effective catalytic systems for the selective synthesis of polycyclic hydrocarbons with the unique structure from NBD and its derivatives.

5. Dimerisation of Norbornadiene in the Presence of Other Catalysts

Apart from the nickel-, iron-, cobalt-, and rhodium-containing catalysts, systems based on chromium, manganese, palladium, and iridium compounds as well as phenyl-lithium are used for the cyclodimerisation of NBD.[9,78,80,164]

In particular, the photolysis of chromium hexacarbonyl in solution in NBD leads to the formation of a mixture of pentacyclic hydrocarbons consisting of the *endo,trans,endo*-(II), *endo,trans,exo*-(III), and *exo,trans,exo*-(IV) isomers in

proportions of 1.4 : 1.0 : 1.8 respectively.[78] According to Carbonaro et al.,[79] manganese catalysts are active in the NBD cyclodimerisation reaction, but the authors do not present detailed data on the yield and composition of the dimers formed.

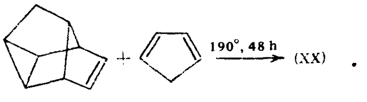
The possibility of using palladium complexes for the selected conversion of quadricyclane (QC) into a mixture of the dimers (V) and (VI) in a high yield have been demonstrated in a recent communication:[9]

$$\mathrm{QC} \xrightarrow{\mathrm{Pd_2(DBA)_3(CHCl_3)}} \mathrm{(V)} + \mathrm{(VI)}\ ;$$

$$\mathrm{DBA} = \mathrm{PhCH{=}CH{-}CO{-}CH{=}CHPh}\ .$$

Phenyl-lithium reacts with bicyclo[2.2.1]hepta-2,5-diene in ether and gives rise to a mixture of two NBD dimers whose yield depends on the ratio of the initial reactants.[80]

The NBD dimer (XX), which is difficult to synthesis, can be obtained in ~77% yield from deltacyclene (XXI) and cyclopentadiene by the Diels–Alder reaction:[48,81]



(XXI)

6. The Physicochemical Properties of Norbornadiene Dimers

Out of the fourteen theoretically possible NBD dimers, capable of being formed only as a result of bond cyclisation via reactions of the $[2_\pi + 2_\pi]$, $[2_\pi + 2_\pi + 2_\pi]$, and $[4_\pi + 4_\pi]$ types, nine have been actually synthesised. The physicochemical characteristics of these compounds as well as their hydrogenated derivatives are presented in the Table. The formation of other NBD dimers, namely (XVIII) and (XIX), which are the products of further reactions (skeletal rearrangement) of the hexacyclic isomers, has been noted in a series of studies.[29,72]

The theoretically possible NBD dimers are presented below.†

(1) Pentacyclic hydrocarbons: pentacyclo[$8.2.1.1^{4,7}.0^{2,9}.0^{3,8}$]deca-5,11-dienes—the products of the NBD $[2_\pi + 2_\pi]$dimerisation:

(XXVI)
(not obtained)

Owing to the complexity of their structures, the determination of the stereochemistry of the NBD dimers required much effort by investigators. In analysing the available data, one must note that the most convincing and unambiguous conclusions concerning the structure of polycyclic hydrocarbons can be obtained using the entire range of modern spectroscopic methods.[28,29] Studies of the ^{13}C NMR spectra of all the known NBD dimers and their hydrogenated derivatives are therefore of undoubted interest and practical value.[87]

III. THE HOMO- AND CO-DIMERISATION OF SUBSTITUTED NORBORNADIENES

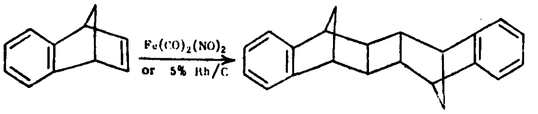
The early studies on the catalytic reactions of substituted NBD includes those on the homocyclodimerisation of 1-, 2-, and 7-methylbicyclo[2.2.1]hepta-2,5-dienes under the influence of the complexes $\mathrm{Ni[P(OPh)_3]_4}$ and $\mathrm{Fe(acac)_3{-}AlEt_3}$.[20,21,49,51] The authors believe that mainly $[2_\pi + 2_\pi]$- and $[2_\pi + 2_\pi + 2_\pi]$-dimers are formed in these experiments, but the

---

† The names of compounds (II)–(VI), (IX), (XIII), (XIV), (XX), and (XXII)–(XXVI) have been revised in accordance with new recommendations.[82,83]

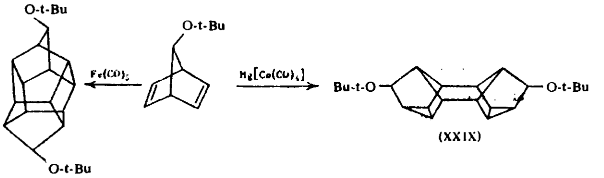
individual products were not isolated and identified. Unfortunately, the above communications do not contain data on the basis of which one could estimate and compare the activities of the substituted NBD in reactions catalysed by transition metal complexes.

Regardless of the nature of the catalyst [5% Rh/C or $Fe(CO)_2(NO_2)$], benzonorbornadiene is converted exclusively into compound (XXVII): [81,92]



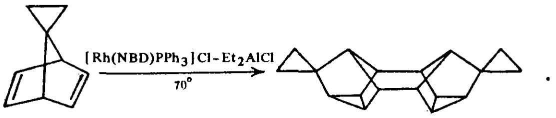
(XXVII), *exo, trans, exo*

According to Ennis et al., [86] 7,14-dimethylheptacyclo-$[8.4.0.0^{2,12}.0^{3,8}.0^{4,6}.0^{5,9}.0^{11,13}]$tetradecane is formed on dimerisation of 7-methylnorbornadiene under the influence of the catalyst $(NBD)_2Co_2(CO)_4$–$BF_3.OEt_2$. [85] It was established that the introduction of the fairly bulky t-butoxy-group in the 7-position, which is most remote from the double bond, does not have an appreciable influence on the stereospecificity of the dimerisation reaction. Depending on the nature of the catalyst, either 6,13-di-t-butoxyheptacyclo-$[6.6.0^{2,12}.0^{3,7}.0^{4,11}.0^{5,9}.0^{11,14}]$tetradecane (XXVIII) or the disubstituted "Binor-S" (XXIS) is formed: [60,88–90]



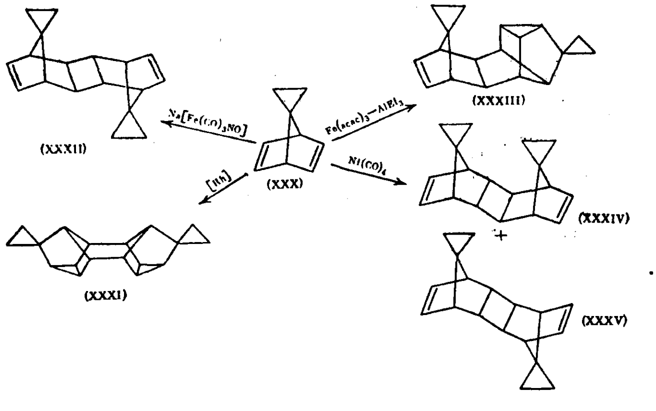
(XXIX)

The reactions of 7,7-disubstituted NBD, namely spiro{bicyclo[2.2.1]hepta-2,5-diene-7,1^1-cyclopropane} (XXX), were investigated for the first time in fair detail in a number of studies. [91,92,94] The [4_π + 4_π]cyclodimerisation of compound (XXX), achieved recently with formation in a single stage of the nonacyclic compound (XXXI), is evidence for the exceptional effectiveness of the method involving metal complex catalysis in the synthesis of strained skeletal hydrocarbons.[91]

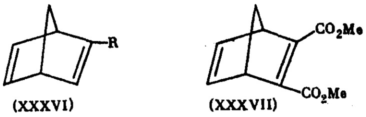


(XXX) (XXXI), 95%

It has been established [93–95] that the reactivity of compound (XXX) in cyclodimerisation reactions is not inferior to that of NBD, for which it has been possible to obtain the [2_π + 2_π]- and [2_π + 2_π + 2_π]dimers:



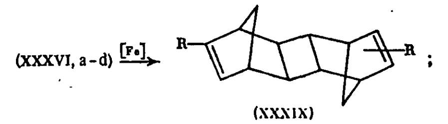
The results of the study of the catalytic homo- and codimerisation of 2- and 7-substituted NBD (XXVI, a–g), (XXX), and (XXXVII) in the presence of the complexes $Fe(CO)_2(NO_2)$ and $Na[Fe(CO)_3(NO)]$ were published for the first time by Dzemilev and co-workers: [93,95]



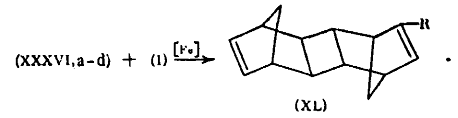
(XXXVI) (XXXVII)

R = Me(a), CH_2OH(b), CH_2OMe(c), CO_2Me(d), Cl(e), CHO(f), CH_2OAc(g)

It was found that only the dienes (XXXVI, a–d) and (XXX) are involved in the homodimerisation reaction and in codimerisation with NBD, the products being the 5(6),11-disubstituted and 5-monosubstituted *exo,trans,exo*-pentacyclo-$[8.2.1.1^{4,7}.0^{2,9}.0^{3,8}]$tetradeca-5,1-dienes (XXXIX) and (XI):



(XXXIX)



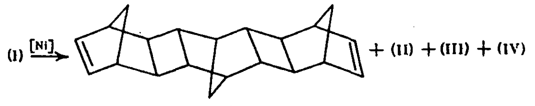
(XL)

The selectivity in the formation of the *exo,trans,exo*-dimers is fairly high (≥91%).

The substituted NBD (XXXVI, e–g) do not form homodimers. The reduced reactivity of the dienes (XXXVI, e–g) may be caused by the change in the energy of the π orbitals as a function of the nature of the substituent. However, the results obtained in a study [95] of 2- and 7-substituted NBD by photoelectron spectroscopy permitted a quantitative demonstration that the energy of the π orbitals of the 1,4-diene system in substituted NBD varies only slightly. The authors [95] therefore assume that the low reactivity of compounds (XXXVI, e–g) can be accounted for by their involvement in the formation of coordination-saturated complexes with the central metal atoms, which are relatively inactive in homo- and co-dimerisation processes. This conclusion was confirmed by the fact that even smaller amounts of the above monomers added to the reaction medium deactivate the catalyst and suppress the dimerisation of both NBD and of the substituted NBD (XXXVI, a–d).

IV. THE SYNTHESIS OF NORBORNADIENE TRIMERS

Up to 1983, only two norbornadiene trimers had been obtained and isolated in low yields from a mixture of polycyclic products of the reaction of NBD under the influence of metal complex catalysts based on nickel and rhodium compounds. [4,9–11,18,29,71,72,75,76] For example, in the presence of $Ni(PPh_3)_4$, $Ni(CO)_2$, $(PPh_3)_2$, or Ni^0–PPh_3, NBD is converted into *exo,trans,exo,trans,exo*-octacyclo$[8.8.1.1^{4,7}.1^{13,16}.0^{2,9}.0^{3,8}.0^{11,18}.0^{12,17}]$heneicosa-5,14-diene (XLI) in ~5% yield: [4,10,11,18]

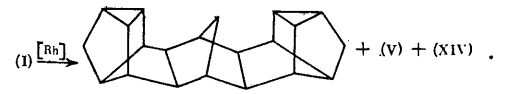


(XLI)

According to Ref.4, the yield of compound (XLI) increases to 40% when the cyclotrimerisation of NBD is carried out in dioxan in the presence of catalytic amounts of $Ni(COD)_2$. Unfortunately, subsequently none of the investigators, including the authors of the present review, were unable to reproduce these results.

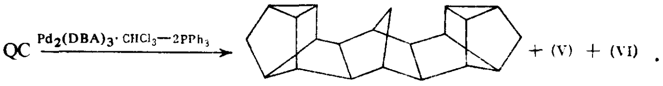
A more reliable method of synthesis of compound (XLI) consists apparently in the cyclocodimerisation of NBD with the *exo,trans,exo*-dimer (IV) in the presence of the $Ni(CO)_2 \cdot (PPh_3)_2$ catalyst.[10]

The saturated trimer (XLII) with two cyclopropane fragments has been obtained by the cyclotrimerisation of NBD with participation of the rhodium catalysts 5% Rh/C, $Rh(NBD)_2BF_4$, and $[Rh(CF_3CO_2)_2]_2$:[71,75,76]



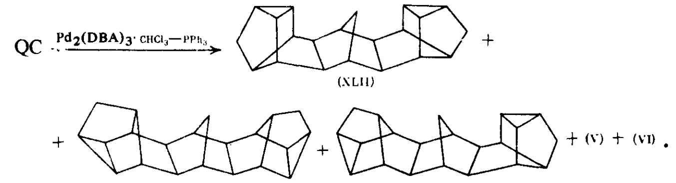
(XLII)

The synthesis of compound (XLII) under the influence of the dibenzylideneacetone (DBA) complex of palladium activated by triphenylphosphine has been reported recently:[9]

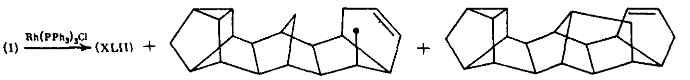


(XLII)

In a later publication[96] it was shown that Itoh's results required significant revision. It was found that the three isomeric cyclic trimers (XLII)–(XLIV) are formed together with the dimers (V) and (VI):

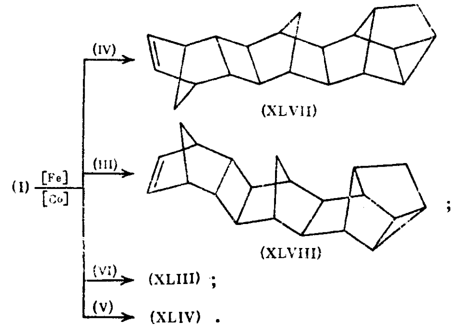


In addition, the trimer (XLII) was synthesised (in a low yield) by heating NBD with Wilkinson's complex $Rh(PPh_3)_3Cl$.[29,72] However, the preparative value of these studies is low, since the isolation of compound (XLII) in a pure form is very difficult owing to the presence in the reaction mass of the skeletal isomerisation products (XLV) and (XLVI):



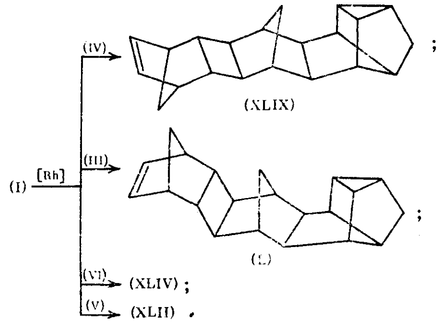
Effective methods have been developed[97] for the synthesis of the trimers (XLIII), (XLIV), (XLVII), and (XLVIII), which had not been described before, by the cyclodimerisation of NBD with the known dimers (III)–(VI) in the presence of the three-component catalytic systems $Fe(acac)_3$–$(Ph_2P$–$CH_2)_2$–Et_2AlCl and $Co(acac)_2$–$(Ph_2P$–$CH_2)_2$–Et_2AlCl. Three of the seven unsaturated NBD dimers, namely compounds (II) (X), and (XIV), whose molecules contain the norbornene fragment with *endo*-substituents, do not enter into the cyclodimerisation reaction with NBD.[97]

These results and also the regioselectivity of the addition of NBD to the "mixed" dimer (III), in which only the *exo*-disubstituted section of the molecule is involved, enabled the authors[97] to explain convincingly the inertness of the dimers (II), (X), and (XIV) by steric factors. It is noteworthy that the catalysts proposed in the above study make it possible to obtain one of the trimers (XLIII) by the direct cyclotrimerisation of NBD:[97,98]



Compounds (XLIII), (XLIV), (XLVII), and (XLVIII) have been formed as a result of the $[2_\pi + 2_\pi + 2_\pi]$-*exo,exo*-cycloaddition of the NBD molecule to the norbornene double bond of the corresponding dimer.

An interesting procedure for the synthesis of the NBD trimers by $[2_\pi + 2_\pi]$-*exo,endo*-cycloaddition has been proposed.[99] This reaction, which is accelerated by various rhodium complexes, namely $RhCl_3.4H_2O$, $Rh(acac)_3$, $[Rh(AcO)_2]_2$, etc., can serve as a convenient and promising method for the preparation of two previously unknown NBD trimers [(XLIX) and (L)] and two which were described previously[99] [(XLII) and (XLIV)].



V. THE CO-OLIGOMERISATION OF NORBORNADIENE WITH UNSATURATED COMPOUNDS

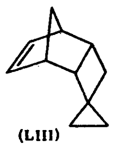
1. The Co-oligomerisation of Norbornadiene with Olefins

Olefins without electron-accepting substituents at the double bond are relatively inactive in cyclocodimerisation reactions with NBD. In particular, when ethylene reacts with NBD in the presence of zerovalent nickel complexes or the three-component cobalt catalyst $Co(acac)_2$–BPE–Et_2AlCl, the yields of 5-vinylnorbornene (LI) [100] and vinylnortricyclane (LII) [101–103] do not exceed 70%.

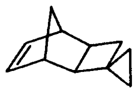
(LI) (LII)

There are literature data indicating the possibility of the involvement of propene in the reaction with NBD,[102] but there are no experimental details in the above communication nor the physicochemical characteristics of the cyclic oligomers obtained.

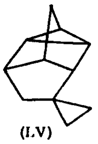
In contrast to the simplest olefins, methylenecyclopropane readily reacts with NBD to form $[2_\pi + 2_\pi]$-, $[2_\pi + 2_\pi + 2_\pi]$-, and $[2_\pi + 2_\sigma]$-codimers. The mode of cyclocodimerisation is determined mainly by the nature of the catalyst. For example, the complex Ni(COD)$_2$ promotes the formation of the $[2_\pi + 2_\pi]$codimers (LIII) and (LIV), the $[2_\pi + 2_\sigma]$codimer (LVI), and the $[2_\pi + 2_\pi + 2_\pi]$codimer (LV),[105] while palladium catalyst afford the $[2_\pi + 2_\sigma]$co-oligomers (LVII) and (LVIII).[106,107] The selectivity in the formation of the codimer (LIII) can be raised to 100% by introducing into the catalyst an equimolar amount of PPh$_3$.[105]



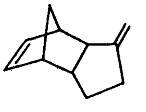
(LIII)



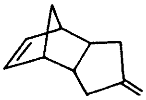
(LIV)



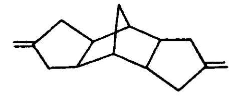
(LV)



(LVI)



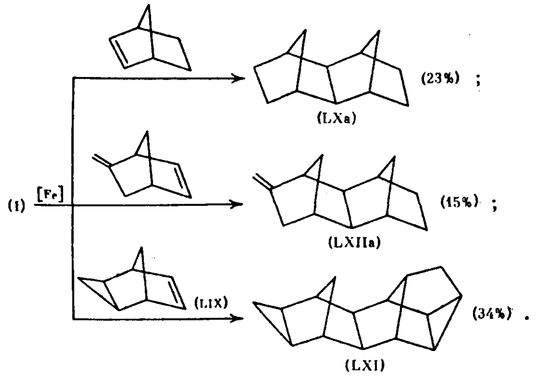
(LVII)



(LVIII)

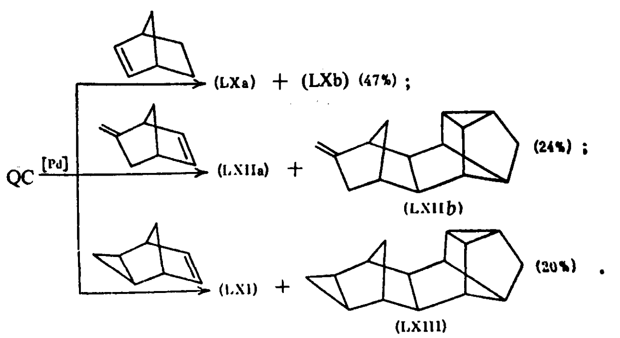
It was established subsequently[101,103,106,108] that cyclic olefins can also be involved in the reaction with NBD. A mixture of polycyclic hydrocarbons (yield ~22%) with a content of compound (VIa) of ~42%, was obtained from NBD and norbornene under the influence of the Co(acac)$_3$–BPE–Et$_2$AlCl catalyst.[101,103,106,108]

The codimerisation of NBD with norbornene, 5-methylenenorbornene and tricyclo$[3.2.1.0^{2,4}]$octa-6-ene (LIX) has been achieved using the Fe(acac)$_3$–BPE–Et$_2$AlCl catalytic system.[109]



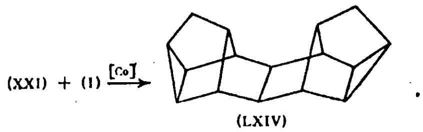
It is essential to note the high stereoselectivity in the activity of the catalytic system indicated. Only the *exo,exo*-codimers (LXa), (LXIIa), and (LXI) were obtained in all the experiments.

An alternative pathway to the synthesis of the hydrocarbons (LXa), (LXIIa), and (LXI) has been described.[96] A distinct characteristics of this method involves the use as the initial monomer not of BD but of its valence isomer—quadricyclane. The reaction is catalysed by the palladium complexes Pd$_2$(DBA)$_3$–CHCl$_3$ and Pd(acac)$_2$–PPh$_3$–AlEt$_3$.

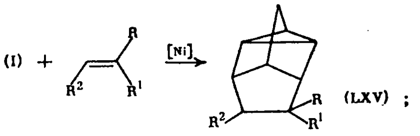


The scheme presented shows that the codimerisation of quadricyclane with cyclic olefins proceeds less selectively. Together with compounds (LXa), (LXIIa), and (LXI), the *exo,endo*-addition products (LXb), (LXIIb), and (LXIII) are present in the mixture. The ratio of the *exo,exo*- and *exo,endo*-isomers is approximately 2 : 3 and depends little on the structure of the cyclic olefins.

The cyclodimerisation of NBD with tetracyclo$[4.3.0.0^{2,4}.0^{3,7}]$non-8-ene has been achieved recently in the presence of the catalytic system Co(acac)$_2$–BPE–Et$_2$AlCl.[110] Under optimum conditions, the yield of the octacyclic compound (LXIV) is 53% relative to the NBD which has reacted:



The introduction of electron-accepting substituents tends to increase the reactivity of olefins in relation to codimerisation with NBD, the reaction proceeding strictly stereoselectively in accordance with the $[2_\pi + 2_\pi + 2_\pi]$addition mechanism with formation of substituted tetracyclo$[4.3.0.0^{2,4}.0^{3,7}]$nonanes (LXV):[8,111-114]

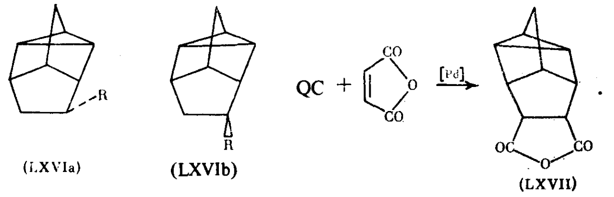


R = CN, CO$_2$Alk, COMe; R^1 = H, Me; R^2 = CO$_2$Me .

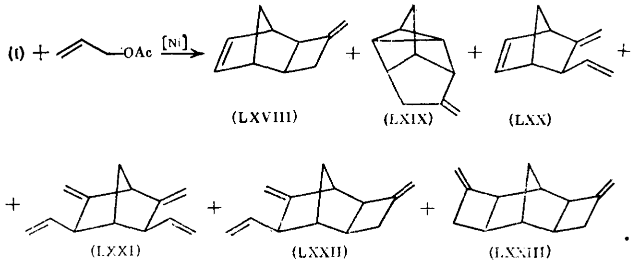
According to the literature,[11,111,119] such cyclodimerisation is catalysed by nickel complexes of different structure: Ni(CO)$_4$, Ni(CO)$_3$(PPh$_3$), Ni(CO)$_2$[P(OPh$_3$)]$_2$, Ni[P(OR)$_3$]$_4$ (R = alkyl or aryl), Ni(COD)$_2$, Ni(CH$_2$=CH–CN)$_2$, Ni(CN)$_2$.(PPh$_3$)$_2$, and Ni(acac)$_2$-PPh$_3$–Et$_2$AlCl. The systems based on bis(acrylonitrile)nickel and Ni(CN)$_2$(PPh$_3$)$_2$ are the most active: the codimerisation of acrylonitrile with NBD take place at 60–80 °C with yields up to 95%.[14,112] Analogous results have been obtained using the Co$_2$(CO)$_8$–PPh$_3$ system.[112]

In terms of their reactivity in codimerisation with NBD, olefins with electron-accepting substituents can be arranged in the sequence acrylonitrile > crotononitrile > methacrylonitrile > dimethyl maleate.[14,112] The ratio of the *exo*-isomer (LXIIIa) and the *endo*-isomer (LXIIIb) in these experiments is determined by the nature of the solvent and the structure of the organophosphorus activators—ligands,[110] and is almost independent of the size of the ester substituent in acrylates.[8] The use of quadricyclane in this reaction instead of NBD increases the yield of the codimer but does not affect the ratio of the *exo*- and *endo*-isomers.[8]

Under mild conditions, quadricyclanes react with maleic anhydride to form the codimer (LXVII) in the presence of the catalytic system $(DBA)_2Pd_2.CHCl_3$–PPh_3.[9]



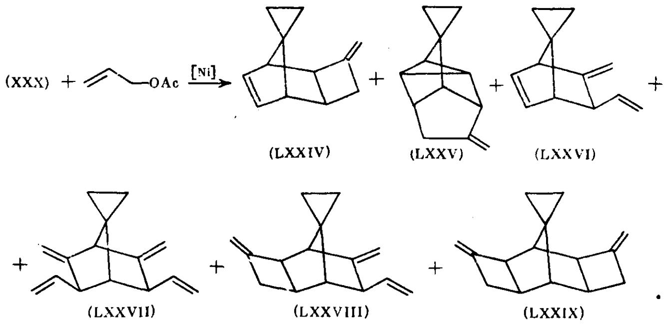
An unusual reaction pathway is observed in the co-oligomerisation of norbornadienes with allyl ethers under the influence of the three-component catalytic system $Ni(acac)_2$–$P(OR)_3$–$AlEt_3$:[120,121]



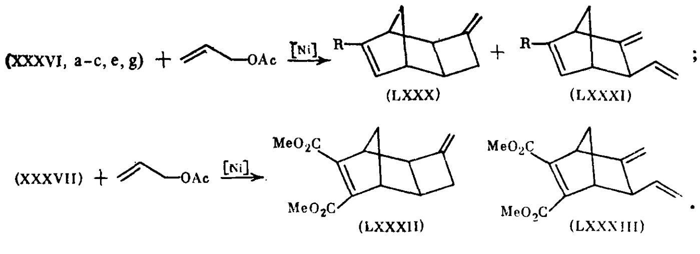
It follows from the above scheme that the reaction formally involves the addition to NBD of one or two allene molecules, but the process proceeds in a complex manner as can be seen from the structure of the products (LXX), (LXXI), and (LXXII).

The isomeric composition of the co-oligomers depends on temprature and the nature and structure of the organophosphorus ligand. At room temperature the main reaction products are the cyclic compounds (LXXVIII) and (LXIX). The most active catalysts have been obtained using alkyl phosphates as the promoting agents.

The co-oligomerisation catalysts are relatively insensitive to the structure of the substituents in the NBD molecule. For example, 7-spiro-cyclopropanenorbornadiene (XXX) reacts with alkyl acetate to form six isomers in an overall yield of ~80%.[120,121]



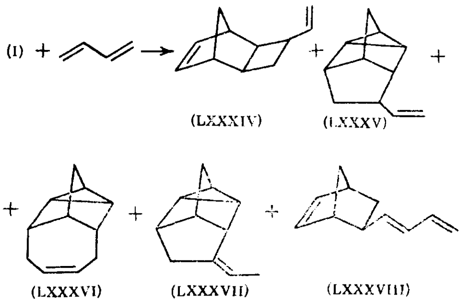
The composition of the reaction product simplifies when 2- and 2,3-substituted NBD are used.



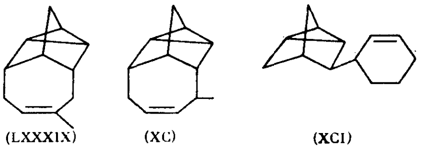
The reaction indicated is general and can serve as a promising method for the synthesis of polycyclic hydrocarbons containing the methylenecyclobutane group, which are otherwise difficult to obtain.[122]

2. The Co-oligomerisation of Norbornadiene with Dienes

The addition of dienes to NBD in the presence of metal complex catalysts based on nickel, iron, cobalt, and manganese compounds has been investigated in detail by Italian workers. Thus the codimerisation of butadiene and NBD results in the formation of a mixture of the polycyclic hydrocarbons (LXXXIV) and (LXXXV) in a high yield.[55,79,101,123,124]



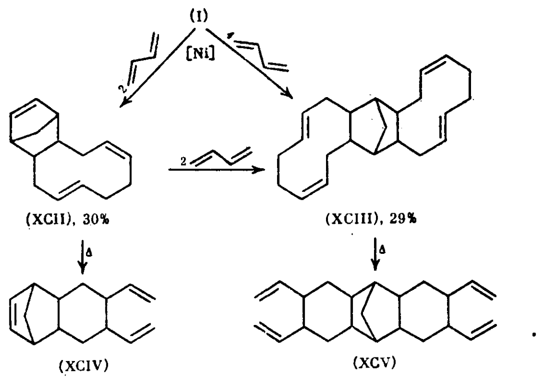
The codimer of 5-butadienylnorborn-2-ene (LXXXVIII) is obtained in a high yield and a selectivity up to 94% in the presence of the $Co(acac)_3$-1,2-bis(diphenylphosphino)ethane–$AlEt_3$ catalytic system.[79,125–127] The use of Et_2AlCl as the reductant tends to alter the direction of the reaction towards the formation of the codimer (LXXXVI).[101,128] The same three-component catalytic system has been used in the codimerisation of NBD with isoprene, piperylene, and cyclohexa-1,3-diene in order to obtain compounds (LXXXIX)–(XCI) respectively.[101,129–132]



According to Ref.133, tetracyclo[$5.4.0.0^{6,10}.0^{9,11}$]undec-3-ene (LXXXVI) can be obtained with a high selectivity from NBD in budadiene in the presence of iron complexes.

The best method of synthesis of compound (LXXXIV) (in a yield of 90%) consists in the [$2_\pi + 2_\pi$]cycloaddition of butadiene to NBD in the presence of the complex $(C_5H_5)Ti(CH_2Ph)_3$ at 135–155 °C.[134–136]

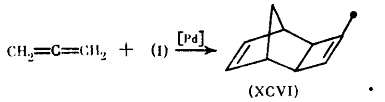
The mixed cyclo-oligomerisation of NBD and butadiene taken in molar proportions of 1 : 6 in the presence of the three-component system Ni(acac)$_2$–AlEt$_2$(OEt)–tris(*o*-biphenylyl) phosphite as the catalyst, results in the formation of compounds (XCII) and (XCIII), which isomerise at 150 °C to compounds (XCIV) and (XCV):[137]



(XCII), 30% (XCIII), 29%

(XCIV) (XCV)

The reaction of 1,2-dienes with NBD and its derivatives is extremely interesting. In the presence of zerovalent palladium complexes,[138,139] the unsubstituted allene reacts with NBD to form exclusively the $[2_\pi + 2_\pi]$cycloaddition product (XCVI):



(XCVI)

Under the influence of the three-component catalyst Co(acac)$_2$–PPh$_3$–Et$_3$AlCl, NBD and compound (XXX) react with allene via both $[2_\pi + 2_\pi]$ and $[2_\pi + 2_\pi + 2_\pi]$ mechanisms:[140]

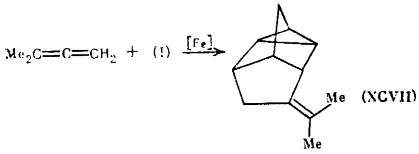
$$\text{(I)} + CH_2{=}C{=}CH_2 \xrightarrow{[Co]} \underset{85\%}{\text{(LXIX)}} + \underset{15\%}{\text{(LXXII)}} ;$$

$$\text{(XXX)} + CH_2{=}C{=}CH_2 \xrightarrow{[Co]} \underset{85\%}{\text{(LXXV)}} + \underset{19\%}{\text{(LXXIX)}} .$$

The main reaction product is a hydrocarbon with the deltacyclane structure, (LXIX) or (LXXV). The co-oligomers (LXXIII) and (LXXIX) are apparently formed in steps but the intermediate $[2_\pi + 2_\pi]$codimers were not detected in the reaction mixture.

A very complex composition of the products (up to 10 isomers) has been obtained in the co-oligomerisation of NBD with 1,1-dimethyl-, 1-cyclopropyl-, and 1-phenyl-allenes with cyclonona-1,2-diene. Their reactivity is inferior to that of allene, which is indicated by the high yield of the co-oligomers (~80%).[140]

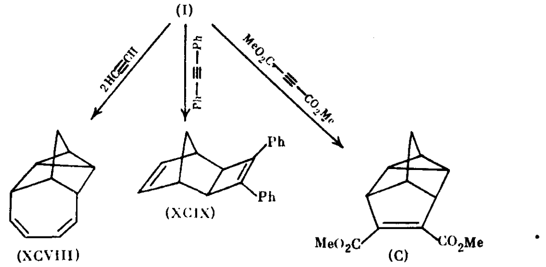
The catalyst obtained by reducing Fe(acac)$_3$ with diethylaluminium chloride directs the reaction of NBD with 1,1-dimethylallene towards the selective formation of the $[2_\pi + 2_\pi + 2_\pi]$codimer (XCVII):[55,123]



(XCVII)

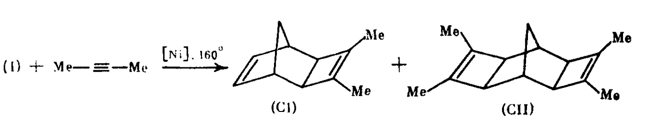
3. The Co-oligomerisation of Norbornadiene with Acetylenes

According to Schrauzer and Glockner,[112] the nickel complexes Ni(CO)$_2$(PPh$_3$)$_2$ and Ni(CN)$_2$(PPh$_3$)$_2$ catalyse the cycloaddition of acetylene, diphenylacetylene, and dimethyl acetylenedicarboxylate to NBD at 120 °C with formation of compounds (XCVIII), (XCIX), and (C):



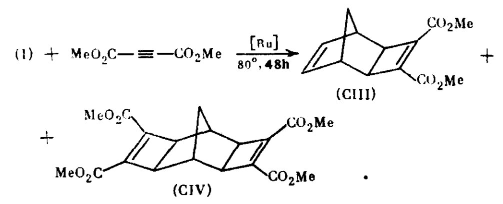
(XCVIII) (XCIX) (C)

The use of tetrakis[tri(2-ethylhexyl) phosphite]nickel increases the yield of compound (XCIX) to 74%.[141] In the presence of the same catalyst, but-2-yne reacts vigorously with NBD via the $[2_\pi + 2_\pi]$ mechanism, affording the tri- and tetra-cyclic hydrocarbons (CI) and (CII):



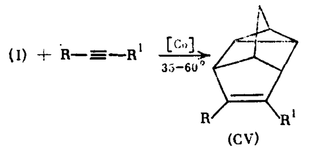
(CI) (CII)

NBD and dimethyl acetylenedicarboxylate interact via an analogous mechanism in the presence of the ruthenium complex [H$_2$Ru(PPh$_3$)$_4$], forming the *exo*-co-oligomers (CIII) and (CIV):[142]



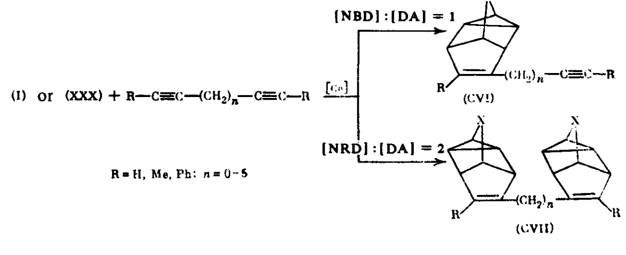
(CIII) (CIV)

Cobalt-containing systems, obtained by reducing Co(acac)$_2$ with Et$_2$AlCl in the presence of biphosphine, exhibit exceptionally high catalytic activity in the $[2_\pi + 2_\pi + 2_\pi]$cycloaddition of NBD to acetylene.[101,143–145] The highest yields of deltacyclene derivatives were obtained in experiments with acetylene and phenylacetylene.



(CV)

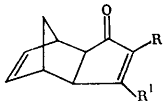
A novel pathway leading to the bisdeltacyclene structures (CVII), which are otherwise difficult to obtain, arises from the co-oligomerisation of NBD and compound (XXX) with diacetylenes (DA) under the influence of the Co(acac)$_2$–PPh$_3$–Et$_2$AlCl catalytic system:[140]



(CVI) (CVII)

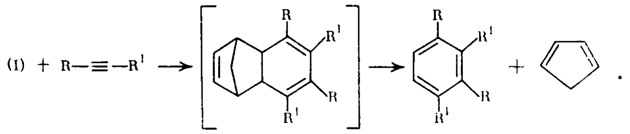
The yields of compounds (CVI) and (CVII) depend significantly on the distance between the acetylene fragments in DA and on the nature of the substituent, reaching 80% for $n \geq 3$ and R = H or Me. By altering the molar ratio of the monomers, the process can be directed towards the formation of the monoadduct (CVI) or the diadduct (CVII). In the reaction involving diphenyldiacetylene, the yield of compound (CVII) does not reach 10%, while 1,3-diacetylene fully polymerises under the reaction conditions.[140]

In the presence of the complexes $Co_2(CO)_8$ or $Fe(CO)_5$, the main products of the codimerisation of NBD with acetylenes are the cyclopentenone derivatives (CVIII).[146,147]



(CVIII)

The use of zerovalent iron and palladium complexes as catalysts of the cyclocodimerisation of NBD with acetylenes leads to the formation of 1,3-di- and 1,2,3,4-tetra-substituted benzenes (CX):[148,149]



(CIX) (CX)

Carbonaro et al.[148] and Suzuki et al.[149] postulated the intermediate formation of the thermodynamically unstable intermediate (CIX), which decomposes into cyclopentadiene and compound (CX).

Thus the co-oligomerisation of NBD with olefins, 1,2- and 1,3-dienes, and acetylenic hydrocarbons under the influence of nickel, palladium, cobalt, and iron complexes can serve as an effective method of the single-state synthesis of mono- and bis-tetracyclo[$4.3.0.0^{2,4}.0^{3,7}$]nonane (deltacyclane), tricyclo[$4.2.1.0^{2,5}$]nonane, and tetracyclo[$5.4.0.0^{6,10}.0^{9,11}$]undecane hydrocarbons.

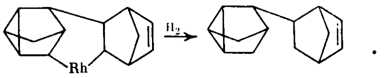
VI. THE MECHANISM OF THE DIMERISATION AND CODIMERISATION OF NORBORNADIENE

The cyclodimerisation and cyclocodimerisation of NBD and its derivatives belong to the so-called pericyclic reactions prohibited by symmetry rules. However, they are catalytically allowed although the causes of this fact have not so far been elucidated.[150–157]

In 1967 Mango and Schachtschneider[150] proposed a theory according to which the interaction of a transition metal atom with olefins entails a change in the symmetry of the highest occupied orbitals and the cyclisation reaction becomes allowed. There exists also another view on the role of the metal in catalysis according to which the role of the neutral catalyst atom consists in reducing the activation energy for the prohibited reaction and not in changing the symmetry of the orbitals in the reactants.[155]

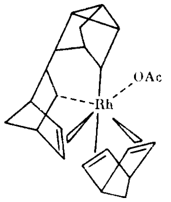
The experimental data accumulated permit the conclusion that the reactions indicated have a multistage mechanism. These include all the principal reactions of metal complex catalysis: coordination, oxidative addition, insertion, and reductive elimination.[9,154]

The key stage in the multistage mechanism of the cyclo-oligomerisation of olefins and dienes is the formation of metallocyclic compounds, which have been isolated and identified with the aid of modern physicochemical methods.[23,158–167] For example, the hydrogenation of a mixture of NBD and $(NBD)_2RhPF_6$ results in the formation of the hydrocarbon (CXII), for which one can postulate only one possible formation pathway—via the rhodacyclohexane organometallic compound (CXI):[162]

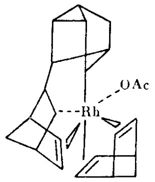


(CXI) (CXII)

The most reliable evidence for the multistage mechanism has been obtained in a study[7] of the isomerisation dimerisation of quadricyclane in the presence of rhodium catalysts. Organorhodium intermediate compounds (CXIII) and (CXIV), responsible for the formation of the molecules of NBD homo- and co-oligomers, have been observed and identified.



(CXIII)



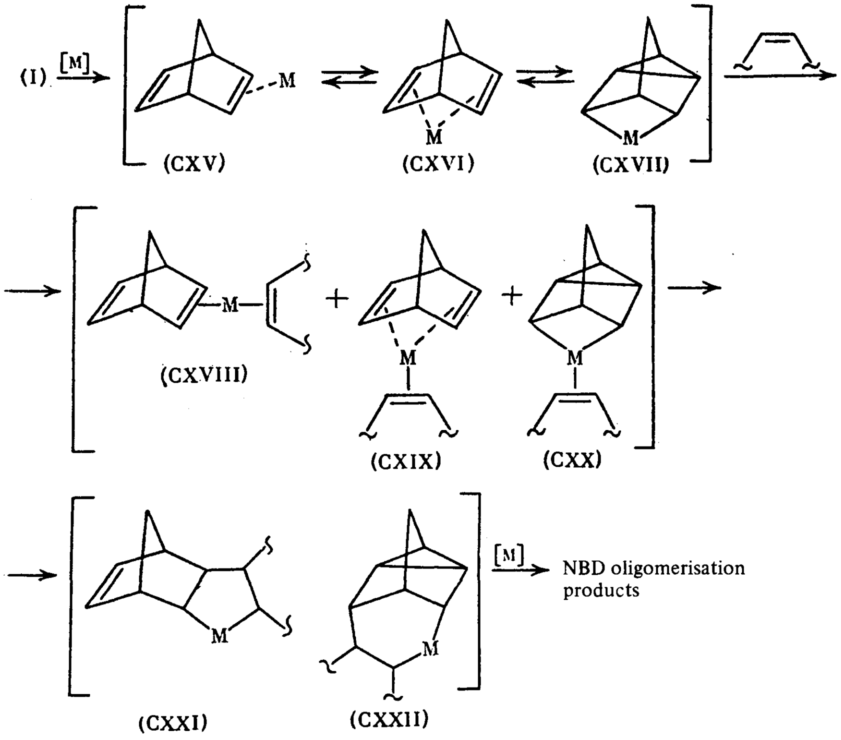
(CXIV)

Similar complexes were obtained in the reaction of hexafluorobutyne with NBD coordinated to rhodium via [$2_\pi + 2_\pi + 2_\pi$]cycloaddition. The structure of the rhodacyclobutane complex was determined by X-ray diffraction.[160] Analogous complexes are known for nickel, ruthenium, and iridium.[158,164,165]

Experimental results[75,88] show that the stereospecific [$4_\pi + 4_\pi$]dimerisation of NBD proceeds at a single centre, whose role is fulfilled by a singly-charged rhodium or cobalt complex.

At the present time there is no single view concerning the individual stages of the mechanism of the dimerisation, trimerisation, and codimerisation of NBD, which can be accounted for by the lack of direct and complete experimental evidence for the validity of a particular mechanism. Despite this, when account is taken of the literature data,[101,168,169] it is possible to postulate what is to some extent a general and universal mechanism of the cycloaddition of NBD involving [$2_\pi + 2_\pi$], [$2_\pi + 2_\pi + 2_\pi$], and [$4_\pi + 4_\pi$] steps on the basis of key catalytic reactions: oxidative addition, insertion, and reductive elimination.

According to this possible mechanism (see Figure), NBD is initially coordinated to the metal with formation of complexes of three types: (CXI)–(CXVII). The equilibrium position in this system is determined by the number of free coordination sites at the metal atom, the nature of the ligand environment, and the charge on the transition metal. It is known that NBD interacts with electrophilic species, forming preferentially compounds containing the nortricyclane system. Consequently, the equilibrium for complexes whose central metal atom has a positive charge is displaced towards the formation of compound (CXVII) and, the greater the charge on the atom, the greater the shift of the equilibrium to the right. Successive coordination of the olefin leads to the intermediates (CXVIII)–(CXX), whose intramolecular reactions proceed either via the synchronous formation of metal—carbon and carbon—carbon σ-bonds or via the insertion of the olefin into the metal—carbon bond with formation of the metallocyclic compounds (CXXI) and (CXXII). The subsequent key stage in the NBD dimerisation and codimerisation reactions is the reductive elimination of the transition metal atom, which can again initiate a new catalytic cycle.



The possible mechanism of the dimerisation and codimerisation of norbornadiene.

The stereochemistry of the isomers formed should be fully determined by the charge on the central metal atom, its coordination number, and its ligand environment.

For the final elucidation of the mechanism of the NBD cycloaddition reaction, it is essential to carry out kinetic studies, to isolate the intermediates, and to investigate their properties in the greatest possible detail.

---o0o---

During the preparation of the manuscript for the press, new communications and studies on the homo- and co-dimerisation of NBD and its derivatives in the presence of transition metal complexes were published.[170–173] The results of investigations of the codimerisation of NBD with cycloheptatriene under the influence of titanium-containing catalysts, with formation of new types of penta- and hexa-cyclic polycyclic compounds,[170] are of greatest interest. Several studies have been devoted to the cyclodimerisation of NBD and of its 7-substituted derivatives via the $[4_\pi + 4_\pi]$cycloaddition mechanism.[171–173]

Pseudoazulenes as π-Isoelectronic Analogues of Azulene

Yu.N.Porshnev, V.A.Churkina, and M.I.Cherkashin

The principal methods of synthesis and the chemical and physicochemical properties of pseudoazulene are described. Attention is concentrated on the latest studies which have not been taken into account in the published reviews. Certain aspects of the uses of pseudoazulene compounds are examined.

The bibliography includes 185 references.

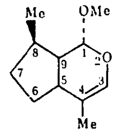
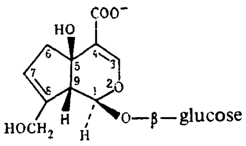
I. INTRODUCTION

Only individual terpenoid representatives of hydrogenated pseudoazulenes of the cyclopentapyran series, such as 1-methoxymyodesert-3-ene (I) which forms part of the structure of *Myoporum deserti* (Myoporaceae) as the iridoid constituent and has been found in plants growing in the moist regions of Australia, have been discovered in nature.[1] The iridoid—the glycoside (II)—present in *Lanthana camara* (Verbenaceae) and detected in 150 plant species in Africa and tropical America, has been identified:

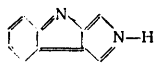


(I)

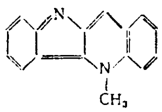


(II)

Individual pseudoazulene systems are components in the structures of alkaloids. Thus the alkaloids sempervirine and alstonine contain the 2*H*-pyrido[3,4-*b*]indole (III) system,[3–7] while the alkaloid cryptolepine has the structure (IV).[8] The hydrogenated indolizine system (V) is present in the molecules of strychnine, securinine, and the Veratrum alkaloids germine, cevine, and protoverine. The 1- and 3-alkylpurines (VI) and (VII) are used as model substances which participate in glycosylation reactions and whose reactivity is equal to that of antibiotics and nucleic acids.[9,10]



(III)



(IV)

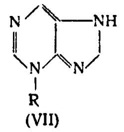
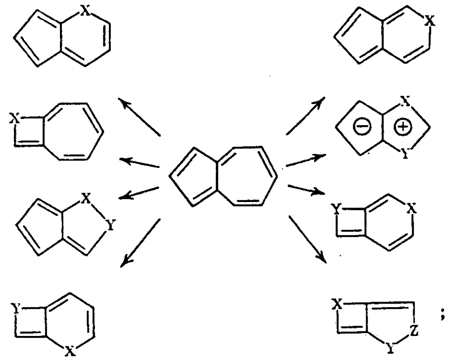
(VI)



(VII)

The advances in quantum chemistry regarding the creation of the theory of aromaticity have promoted an intense development during the last three decades of the chemistry of heterocarbonium aromatic systems, among which analogues of the non-benzenoid aromatic azulene system, namely pseudoazulenes, are of special interest. Formally, they can be obtained by replacing a two-electron carbon–carbon double bond in the aromatic system by the unshared electron pair of the heteroatom, whereupon the aromatic character of the system is usually retained.[11–13] This principle of structural analogy, which has been known for a long time in the benzene–thiophen–furan–pyrrole series, was first applied in 1957 by Boyd[14] and Mayer[15] and later also by other workers[16,17] to a large group of heterocyclic compounds—pseudoazulenes, which are π-isoelectronic analogues of azulene. The chemistry of these systems has only just begun to develop despite the fact that the fundamental studies by Robinson and co-workers[11–13] were published in the first quarter of this century.

According to the above principle, numerous representatives of pseudoazulene systems in which one, two, or three double bonds have been replaced by heteroatoms can be formally obtained from azulene:



X, Y, Z = –O–, –S–, –NR–, –Se–, –Te–.

For the azazulenes (VIII) and (IX), polyazazulenes, and heteroniaazulenes, the analogous "reactions" are also possible.[18,19]

The number of possible systems increases greatly when different heteroatoms are used simultaneously. Dinuclear condensed heterocyclic systems with a nitrogen atom common to both rings, namely quinolizines, are also regarded as the pseudoazulenes (V) and (X).

---

*Azulene systems having this structure are unknown.

They constitute a large independent group of pseudoazulenes, whose chemistry has been described in a monograph.[20] A review has been devoted to the chemistry of the indolizines (V).[21] Almost all the pseudoazulene systems known at the present time are represented in the review of Timpe and El'cov.[22]

The number of existing nitrogen-containing pseudoazulenes is much greater than that of the sulphur- and oxygen-containing compounds; only one pseudoazulene system containing selenium as the heteroatom is known.[23] Systems containing tellurium as well as systems with a four-membered ring are so far unknown, which can be explained by the instability of these products in the former case or the considerable angular ring strain in the latter. The influence of the heteroatom on the electronic structure, the electronic spectra, the stability, and the reactivity has been most fully investigated for pseudoazulene systems in which the unshared electron pair of the heteroatom replaces one double bond in the seven-membered ring of azulene or benzoazulenes. For this reason, we shall confine ourselves to the consideration of the systems presented in Table 1.

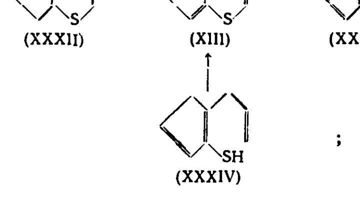
The [*b*]-series pseudoazulenes (XI)–(XIII) and the [*c*]-series pseudoazulenes (XIV) and (XVI) are non-alternant 10π-isoelectronic analogues of azulene. Compounds (XVII) to (XXVI) are isoanalogues of the 14π-electron systems of 1,2-, 5,6-, and 4,5-benzoazulenes. For the 18π-electron systems (XXVII) and (XXX), azulenes with an analogous structure are so far unknown and this is also true of the new pseudoazulene system (XXXI) obtained in 1975.[24] It was initially suggested that pseudoazulenes containing a sulphur atom, an oxygen atom, or an NR group be designated as thialenes,[15] oxalenes,[25] and azalenes[17] respectively. This nomenclature, based on the type of heteroatom, is not always used although it effectively explains the genetic relation with azulene. Specific compounds are usually named in accordance with IUPAC rules, the pyrindines (XI) and (XIV) constituting an exception. The compounds listed in Table 1 are arranged in such a way that the cyclopentane ring is placed on the right-hand side of the main pseudoazulene system, while the heteroatom on the left-hand side is placed in the lower half of the heterocycle. The first carbon atom is located in the upper angle of the cyclopentane component of the main system. The remaining atoms are numbered clockwise, the heteroatom being numbered in accordance with the general sequence. The above nomenclature is most widely used and has already been adopted in a series of well known publications.[14,26–29]

II. METHODS OF SYNTHESIS OF PSEUDOAZULENES

The methods of synthesis of pseudoazulenes differ significantly from those for azulenes, since its molecular skeleton is obtained in different ways, depending on the required pseudoazulene system. The methods of synthesis can be combined, for example, in accordance with the type of the last stage leading to pseudoazulenes. A common stage of this kind in the syntheses of both pseudoazulenes and azulenes is the dehydration of saturated compounds.

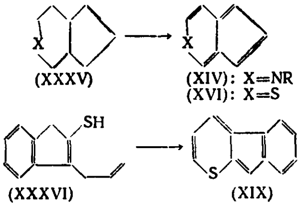
1. Dehydrogenation of Saturated Precursors of Pseudoazulenes

Historically the first and for a long time the only method of synthesis of azulene hydrocarbons was dehydrogenation of bicyclic precursors with the bicyclo[5.3.0]decane structure or the corresponding partly saturated compounds.[30–33] The dehydrogenation of more or less hydrogenated compounds, already having the heterocyclic skeleton of pseudoazulenes, is used only for sufficiently stable compounds. Numerous thialenes, of both [*b*]- and [*c*]-series, namely compounds (XIII), (XVI), and (XIX), have been obtained in this way.



(XXXII) (XIII) (XXXIII)

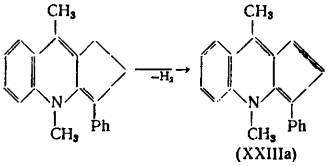
(XXXIV) ;



(XXXV) (XIV): X=NR (XVI): X=S

(XXXVI) (XIX) .

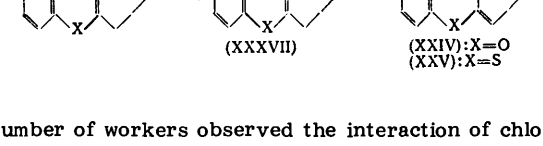
Hydrogenated sulphur-containing heterocycles, for example, compounds (XXXII), (XXXIII), and (XXXV), or the open-chain mercaptans (XXXIV) and (XXXVI),[34] are dehydrogenated in the gas phase over Pd/C at 300–350 °C.[35–38] The overall yield depends on the dehydrogenation stage, which frequently proceeds with a high (~30%) yield; it can also amount to only a few per cent owing to the low activity of the catalyst.[37] However, this method is still the best procedure for the synthesis of not only thialenes but also 2-phenylpyrindine (XIV).[36] Other pseudoazulene systems, for example, substituted 4*H*-cyclopenta[*b*]quinoline (XXIIIa), can also be conveniently obtained in this way,[17] but the dehydrogenation is carried out in boiling xylene for 10 h in an atmosphere of nitrogen with the same catalyst and the yield is 53%.



(XXIIIa) .

On dehydrogenation over Pd/C and also when the Cu_2Cl_2/C catalysts are used at 300 °C or sulphide is used at 300 °C, oxygen-containing precursors [for example, compound (XXXIII, X = O)] give rise to only tarry products.[37]

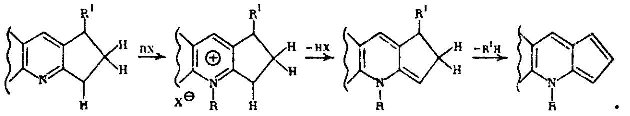
Azulene precursors are dehydrogenated under very mild conditions by chloranil and for this reason, the latter is widely used in the synthesis of azulenes containing substituents unstable at high temperatures.[39–42] For effective dehydrogenation, it is essential that the precursor should already possess a high degree of unsaturation. Chloranil has been used extremely rarely for the synthesis of pseudoazulenes.[25,35] The synthesis of the unsubstituted pseudoazulenes (XXIV) and (XXV) from chromone and thiachromone respectively using the dehydrogenation of compound (XXXVII, X = O or S) by chloranil has been described,[25] but the author did not indicate the dehydrogenation conditions and the reaction products were not isolated in a pure form:



(XXXVII) (XXIV):X=O (XXV):X=S .

A number of workers observed the interaction of chloranil with pseudoazulenes, for example, with 4*H*-cyclopenta[*b*]quinoline (XXIII) and 5*H*-cyclopenta[*c*]quinoline (XXVI), the latter being substituted by the chloranil residue in the 1- and 3-positions.[29,43,44]

Dehydro-compounds of the type of (XXXVIII) can be converted into fully aromatic systems by the multistage elimination of hydrogen atoms in the saturated cyclopentane or cyclopentene rings, or by the dehydrohalogenation of quaternary salts, or by some other elimination reaction:

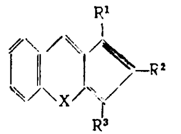


(XXXVIII) (XXXIX) (XL)

The acid-catalysed elimination of water from the hydroxy-derivative (XL, R^1 = OH) proceeds especially effectively.[45,46] It is then essential to maintain appropriate conditions exactly, since pseudoazulenes can be decomposed by acid. An instance of photochemical dehydrogenation is known.[24]

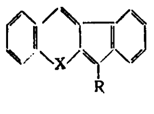
2. Condensation of Aromatic Aldehydes and Ketones

The method considered above is a general procedure for the conversion of compounds already containing the pseudoazulene skeleton into pseudoazulenes proper. Since new C–C and C–X bonds can arise in condensation reactions, it is always possible to select suitable initial compounds which give rise to the pseudoazulene system; dehydrogenation is then altogether unnecessary. The form of the initial compounds can be specified by the required structure of the final product. For example, the condensation of salicylaldehyde or *o*-mercaptobenzaldehyde with aryl-substituted Δ^2-cyclopentenones in the presence of piperidinium acetate in benzene yielded the arylsubstituted benzo[*b*]cyclopenta[*e*]pyrans {or cyclopenta[*b*]chromenes} (XXIVa–c)[14,27,47] and the corresponding thiapyrans {or cyclopenta[*b*]thiachromenes} (XXV*a*):[28]



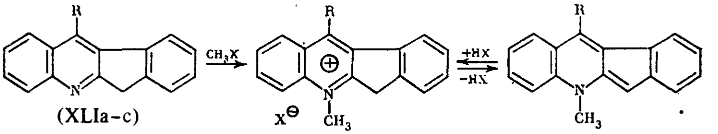
(XXIV a–c): X = O
(XXVa): X=S
a: R^1=R^3=H; R^2=Ph [14, 47]
b: R^1=R^2=Ph; R^3=H [27]
c: R^1=H; R^2=R^3=Ph [28] .

This method is particularly convenient for the synthesis of tetracyclic pseudoazulenes which are sometimes formed in a yield up to 80%. Indeno[2,1-*b*]chromene (XXIXa) and indeno[2,1-*b*] thiachromenes (XXX, R = H) have been obtained by condensing 2-indanone with salicylaldehyde and *o*-mercaptobenzaldehyde respectively.[28,48,49] The condensation of substituted 2-indanones or 2-indanoneimines with salicylaldehyde leads to 5-substituted derivatives of indeno[2,1-*b*]chromene



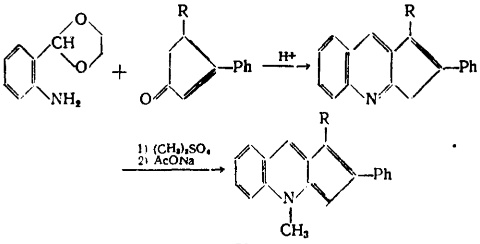
(XXIX a–e): X=O
(XXX): X=S [28.49]
a: R = H (Refs.14,48)
b: R = CH_3 (Ref.50)
c: R = 2-indanyl (Ref.50)
d: R = $COOC_2H_5$ (Ref.50)
e: R = CN (Ref.28) .

However, nitrogen-containing pseudoazulenes cannot be obtained in this way; the attempts to carry out the condensation in a neutral or alkaline medium (alkali in alcohol or piperidine in benzene) do not yield the final products directly. The reaction of the ethylene acetal of *o*-aminobenzaldehyde with phenyl-Δ^2-cyclopentenones does not afford pseudoazulenes under these conditions and it does not even give rise to Claisen condensation products.[51] The condensation of 2-indanone with *o*-aminobenzaldehyde, *o*-aminoacetophenone, or *o*-aminobenzophenone in an acid medium results in the formation of compounds (XLIa–c), dehydrogenated to the optimum extent, which are converted by quaternisation and subsequent alkaline cleavage of the quaternary salts into nitrogen-containing pseudoazulenes (XXVIIIa–c) in approximately 25% yield:[52]



(XLIa–c)
a: R = H
b: R = CH_3
c: R = Ph
(XXVIIIa–c)

Since *o*-aminobenzaldehyde is unstable, it is possible to use its ethylene acetal, whose condensation with 3-phenyl- and 3,4-diphenyl-Δ^2cyclopentenones in alcoholic solution of hydrochloric acid leads to the pseudoazulenes (XXIIIb, c) in good yield (up to 80%):[51,53]

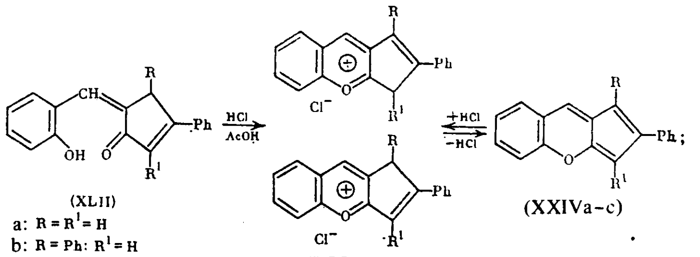


(XXIIIb, c)

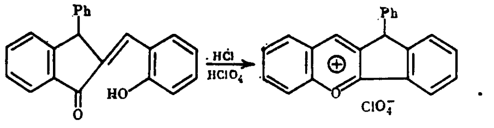
3. Deprotonation of Pyridinium, Quinolinium, Pyrylium, and Thiapyrylium Salts

The deprotonation of heteronium salts as a method of synthesis of pseudoazulene systems is logically a continuation of the previous subsection and is closely related to it in the synthetic sense, because the majority of the intermediates and salts based on them are obtained in this instance by condensing aldehydes and aromatic (and also α,β-unsaturated) ketones. The deprotonation of heteronium salts actually constitutes the dehydrogenation stage, which completes the synthesis of the pseudoazulene, but, since the number of final systems obtained in this way is fairly large and the reaction itself does not proceed smoothly with all salts, we shall consider this stage in a separate Section.

Salicylaldehyde undergoes the Claisen condensation with phenyl-substituted Δ^2-cyclopentenones of 1-indanone in alkaline media with formation of the corresponding hydroxychalcones (XLII) or (XLIII),[54,55] which afford the benzopyrylium salts (XLIVa–c) and (XLV) in a mixture of acetic and hydrochloric acids. However, whereas a solution of the salts (XLIVa–c) gives rise to the pseudoazulenes (XXIVa–c) on dilution with water, compound (XLV) decomposes on hydrolysis in the presence of sodium acetate:[55–57]

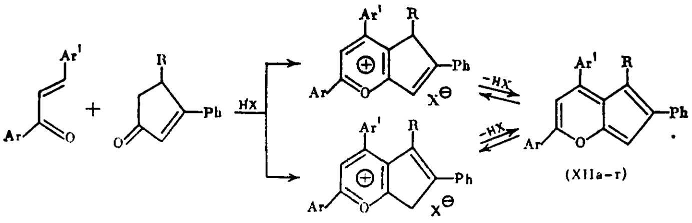


(XLII)
a: R = R¹ = H
b: R = Ph: R¹ = H
c: R = H; R¹ = Ph
(XLIVa–c)
(XXIVa–c) .



(XLIII) (XLV)

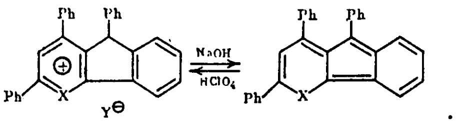
Chalcones and derivatives of phenyl-substituted Δ^2-cyclopentenones condense on treatment with $FeCl_3$ in acetic anhydride into the chloroferrates (XLVIa–d) in 35% yield. On treatment with sodium acetate, both the chloroferrates and perchlorates (XLIVa–d) give rise to cyclopenta[*b*]pyrans (XXIIa–d) in high yields (up to 90%):[47,58,59]



(XLVIa–r) (XIIa–r)

a: R = H, Ar = Ar' = Ph; b: R = Ar = Ar' = Ph; c: R = Ph, Ar = *n*-$CH_3OC_6H_4$, Ar' = Ph; d: R = Ph, Ar = Ph, Ar' = *p*-$CH_3OC_6H_4$; $X^- = FeCl_4^-$, ClO_4^-.

The tetrachloroferrate (XLVI) has been obtained analogously by the reaction of benzylidenacetophenone with 3-phenyl-1-indanone (XLVII) (yield 48%) and was converted into the perchlorate (XLVIII) by treatment with 70% perchloric acid. The condensation of equimolar amounts of acetophenone with 2-benzylidene-3-phenyl-1-indanone gives rise to the chloroferrate (XLVII) in only 20% yield:[55]

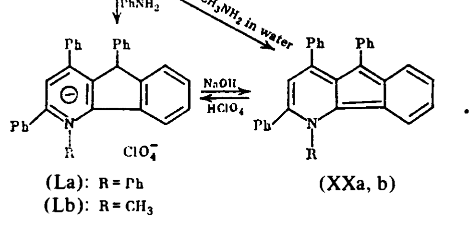


(XLVII): X = O, Y = $FeCl_4$
(XLVIII): X = O, Y = ClO_4
(XLIX): X = S, Y = ClO_4

(XXIa): X = S

On treatment with a 10% aqueous solution of Na_2S and subsequent addition of 20% perchloric acid, the perchlorate (XLVIII) gives rise to the thiapyrylium salt (XLIX) (yield 93%), which is deprotonated with an aqueous alcoholic solution of alkali and sodium acetate to form 2,4,5-triphenylindeno[1,2-*b*]thiapyran (XXIa). Hot water also hydrolyses the salt (XLIX) but more slowly.

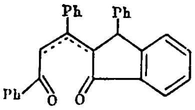
On interaction with aniline, the perchlorate (XLVIII) is converted into the *N*-phenylpyridinium salt (La) in 59% yield. The deprotonation of the salt with aqueous-alcoholic alkali affords 1,2,4,5-tetraphenyl-1*H*-indeno[1,2-*b*]pyridine (XXa). Treatment of the same perchlorate (XLVIII) with 30% aqueous methylamine leads to a 55% yield of 1-methyl-2,4,5-triphenyl-1*H*-indeno[1,2-*b*]pyridine (XXb), which can be converted into the substituted *N*-methylpyridinium perchlorate (Lb):



(La): R = Ph
(Lb): R = CH_3

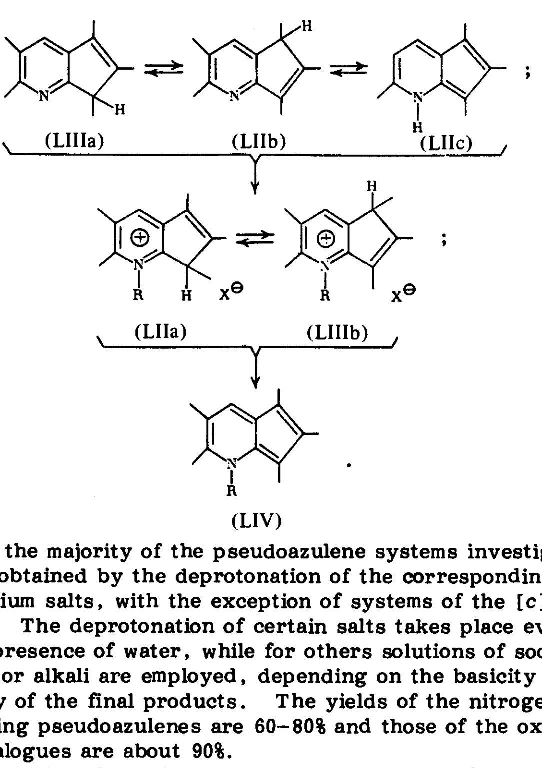
(XXa, b)

Whereas the heteronium salts of phenyl-substituted derivatives of cyclopenta[*b*]chromene (XLIV), cyclopenta[*b*]pyran (XLVI), indeno[1,2-*b*]thiapyran (XLIX), and indeno[1,2-*b*]pyridine (L) produce the corresponding pseudoazulenes on hydrolysis with aqueous-alcoholic solutions of alkali or sodium acetate, indeno [1,2-*b*]chromylium perchlorate (XLV) and indeno[1,2-*b*]pyrylium perchlorate (XLVIII) only regenerate the initial compounds under the same conditions, i.e. 3-phenyl-2-salicylidene-1-indanone (XLIII) and 2-(3-oxo-1,3-diphenylpropylidene)-3-phenyl-1-indanone (LI) respectively.



(LI)

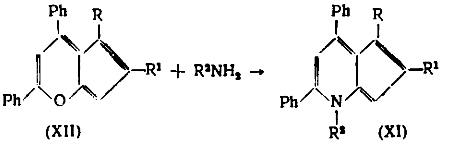
The quaternary salts of nitrogen-containing pseudoazulenes are obtained by the quaternisation of the corresponding heterocyclic bases with alkyl halides or tosylates in aprotic solvents.[28,45,51–53,60] Despite the tautomerism of the base (LII) [the isomers (LIIa–c) are possible], alkylation results in a good yield of the quaternary salts (LIII) (the *C*-alkylation products were detected only in trace amounts). Alkaline deprotonation of the quaternary salts (LIII) leads to the pseudoazulenes (LIV):



(LIV)

Thus the majority of the pseudoazulene systems investigated can be obtained by the deprotonation of the corresponding heteronium salts, with the exception of systems of the [*c*]-series. The deprotonation of certain salts takes place even in the presence of water, while for others solutions of sodium acetate or alkali are employed, depending on the basicity and stability of the final products. The yields of the nitrogen-containing pseudoazulenes are 60–80% and those of the oxygen-analogues are about 90%.

The reactions involving the direct substitution of the heteroatoms in the pseudoazulene systems must also be considered, since they permit the direct transition from, for example, oxalenes to pyrindines:[51,53,55,61,62]



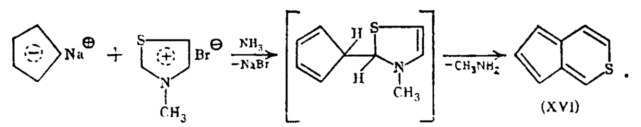
(XII) (XI)

After brief heating of compound (XII) with an excess of aniline, benzylamine, or butylamine in dimethylformamide (DMF), 1-substituted-1*H*-pyrindines (XI) were obtained in good yields.[51–53] If pyrylium perchlorates corresponding to the pyrans (XII) are introduced into the reaction, then the pyrans (XII) are formed as intermediates under the reaction conditions. A decisive factor for the successful occurrence of the reaction is evidently the high boiling point of DMF since, on heating to the boiling point in 10% alcoholic solution of ammonia,[47,58] and also on heating in ethanol with amines, compounds (XII) remain unchanged. Oxalenes, having an oxygen atom linked directly to the aromatic ring, cannot be converted in this way into nitrogen-containing pseudoazulenes. The attempts to convert 5,6-benzoxalene (XXIV) into 4*H*-cyclopenta[*b*]quinoline (XXIII) were unsuccessful (only polymeric products of the condensation of the initial compound were obtained[51,55]).

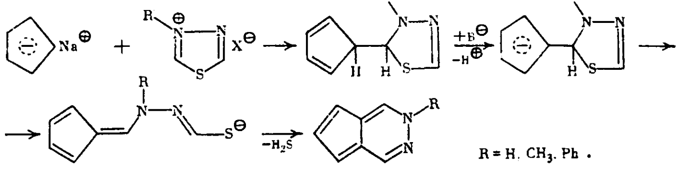
4. Other Methods of Synthesis

Apart from those described above, there exist several more methods of synthesis of pseudoazulenes. Although these are not quite so common, they can be used successfully in certain cases.

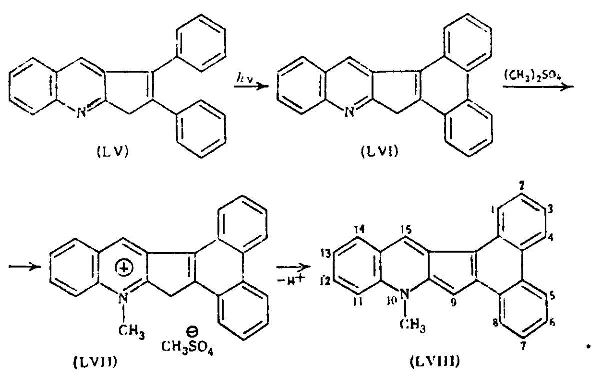
Analogously to the synthesis of the azulene by the Hafner method, the cyclopentadienyl anion can be used to obtain cyclopenta[*c*]thiapyran:[63,64]



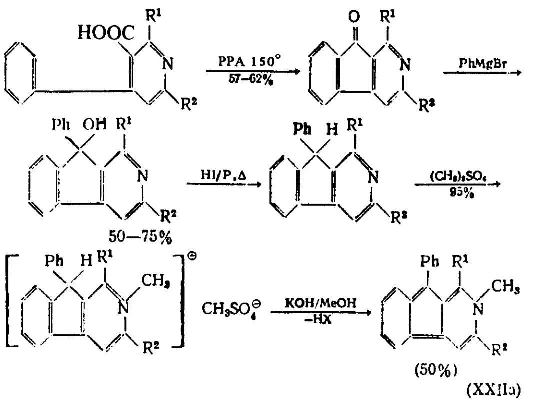
The yield of compound (XVI) is only 10%, but this method actually consists of only a single stage. So far, it has been the only procedure for the synthesis of 2*H*-cyclopenta[*d*]pyridazine:[65]



The photochemical oxidative cyclisation of 1,2-diphenyl-3*H*-cyclopenta[*b*]quinoline (LV) leads to the formation of a new hexacyclic structure (LVI).[24] Subsequent quaternisation with dimethyl sulphate and treatment with sodium acetate afford the fully conjugated polycyclic system (LVIII)—10-methyldibenzo[4,5,6,7]indeno[2,1-*b*]quinoline in 54% yield:

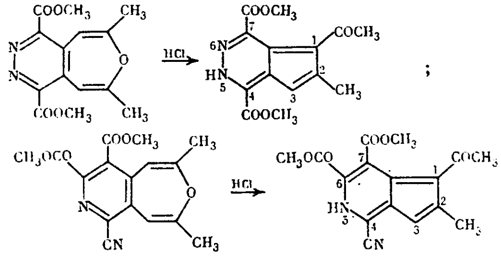


The synthesis of the 2*H*-indeno[2,1-*c*]pyridine derivative (XXIIa) has been described:[66–68]



PPA = polyphosphoric acid.

On treatment with HCl, oxepinopyridazine and oxepinopyridine derivatives are capable of rearranging to the corresponding pseudoazulenes—5*H*-cyclopenta[*d*]pyridazine and 5*H*-cyclopenta[*c*]pyridine:[69]



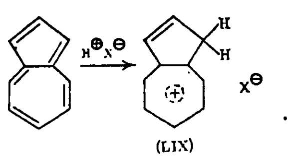
III. CHEMICAL PROPERTIES

The reactivity of pseudoazulenes has so far been inadequately investigated and information concerning the behaviour of many systems in chemical reactions is totally lacking. Data conerning the preferred reaction centres, obtained as a result of quantum-chemical calculations, are examined below. The examples of reactivity known at present are in the main consistent with these theoretical data and indicate a rigorous analogy with the properties of azulene. The enhanced electron density in the five-membered ring and the electron deficiency of the atoms of the heterocycle are responsible for the high reactivity of the former and the passivity of the latter with respect to electrophiles. Like azulene, pseudoazulenes readily form π-complexes with various π-acids: trinitrobenzene, picric acid, etc.

The trinitrobenzene complexes are frequently used for the purification, identification, and isolation of unstable pseudoazulenes, since such complexes readily decompose into their components during chromatography on alumina. Trinitrobenzenates are sometimes introduced into electrophilic substitution reactions,[70] the insoluble trinitrobenzene being subsequently readily removed.

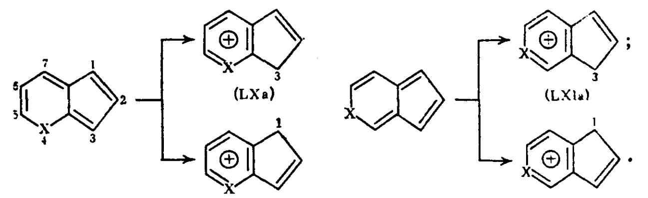
1. Basicity

The high basicity of azulene is responsible for the formation of the azulenium salt (LIX) on treatment with concentrated inorganic acids:[32,33,71]



(LIX)

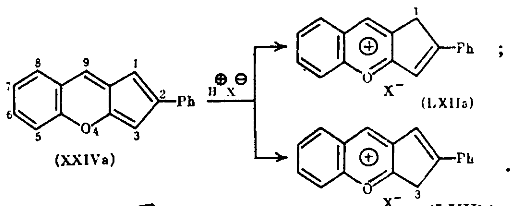
Pseudoazulenes give rise to analogous cations, but there is in this instance a possibility of the formation of two tautomeric forms (LXa, b), because the presence of the heteroatoms disturbs the molecular symmetry. The choice between these cations is of fundamental importance for the establishment of the structure of the salts formed and their derivatives and for the elucidation of the influence of the heteroatom on the electron density of the atoms in the five-membered ring:



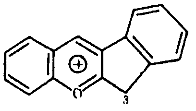
(LXa) (LXb) (LXIa) (LXIb)

According to Anderson and Harrison,[72] the [*c*]-series compounds (X = S) can be protonated in both 1- and 3-positions, but the latter pathway is preferred and for this reason the cation (LXAa, X = S) is usually formed. In the [*b*]-series compounds (X = O or NR) protonation takes place exclusively in the 1-position.[51,57,58,73]

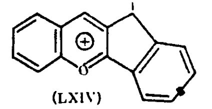
^{1}H NMR data for the pyrylium salts (LXII) have been compared[57] with the corresponding data for the salts (LXIII) and (LXIV) and it was concluded, on the basis of the study of the chemical shifts of the methylene protons (in solution in CF_3.$COOH$) in these compounds, that the protonation of 2-phenylcyclopenta[*b*]chromene (XXIVa) proceeds exclusively in the 1-position with formation of the cation (LXIIa):



(XXIVa) (LXIIa) (LXIIb)



(LXIII)



(LXIV)

The majority of pseudoazulenes are stronger bases than azulenes. The pK_a of the individual pseudoazulenes has been reported in a review[22] (the pK_a of unsubstituted azulene is 1.7). Phenyl-substituted 1*H*-pyrindines (XI) and *N*-methylcyclopenta[*b*]quinolines (XXIII) are protonated even by acetic acid, i.e. their pK_a exceeds 4.5.[51]

The basicities of azulenes and pseudoazulenes are usually characterised by the partition coefficient K_v:[32]

$$K_v = \frac{\text{pseudoazulene concentration in an inert solvent}}{\text{pseudoazulene concentration in aqueous acid}} .$$

The partition coefficient K_v has been measured as a function of the Hammett acidity function H_0 of the aqueous layer. In order to determine the basicity, it is necessary to select the value of H_0 for which the coefficient K_v becomes unity. The Hammett acidity function H_0 ($K_v = 1$) has been measured spectrophotometrically for certain pseudoazulenes containing various heteroatoms.[28] Nevertheless, we assume (in conformity with the data of Weiss and Schoenfeld[74]) that the basicities of these compounds can be determined from the value of H_0 only approximately owing to the different solubilities in the organic solvents of the compounds being compared. For this reason, the H_0 ($K_v = 1$) values can be used only to demonstrate approximately that nitrogen-containing pseudoazulenes are much more basic than oxygen- or sulphur-containing analogues and that the basicity of pseudoazulenes is higher than that of azulenes.

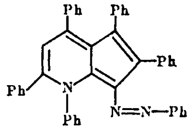
Quantitative data for the reactivities of azulenes and pseudoazulenes in relation to electrophiles have been obtained by measuring the rate of exchange of active hydrogen atoms (in the 1- and 3-positions in both azulene and pseudoazulenes) for deuterium in an acid medium.[74] The rate constant for the exchange in azulenes is lower than in 2,3; 5,6-dibenzoxalene and *N*-methyl-2,3; 5,6-dibenzopyrindine. The authors note that the rates of H–D substitution, measured in a dilute solution of CH_3COOD in CH_3OD for these pseudoazulenes as well as certain azulenes, correspond to the reactivities of these compounds predicted by Borsdorf on the basis of the π-electron densities calculated by the MO-LCAO method (see Section IV).

2. Electrophilic Substitution Reactions

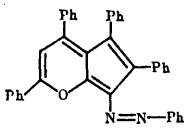
Electrophilic substitution in pseudoazulenes takes place exclusively in the 1- and (or) 3-positions (in the five-membered ring), i.e. is completely analogous to the substitution in azulenes. If both these positions in the five-membered ring are free, then in the majority of cases mixtures of mono- and di-substituted products are obtained and can be separated only by prolonged operations; the predicted preferred sites to which the reactions are directed have not been demonstrated in practice. In the majority of instances, the reactions were carried out using compounds having individually only the 1- or 3-position free. Disubstituted products have been mainly obtained for other compounds.

(a) Azo-coupling. Among inactivated aromatic benzenoid compounds, there are only a few substances capable of entering into the azo-coupling reaction with diazonium salts, whereas for azulenes this reaction is facilitated by the low localisation energy for electrophilic attack in the 1(3)-position. All the azulenes investigated hitherto readily give rise to azo-dyes.[33]

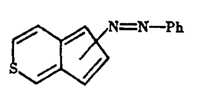
The pseudoazulenes (XIa), (XIIa), (XVI), and (XXIIIb, c) are smoothly coupled to benzene- and *p*-nitrobenzene-diazonium fluoroborates in acetonitrile[51] or in a dioxan–ethanol mixture.[58] Quaternary salts, for example (LXVIII), are formed in the first stage and on treatment with a base (sodium acetate) are converted into azo-compounds in 70–90% yield:



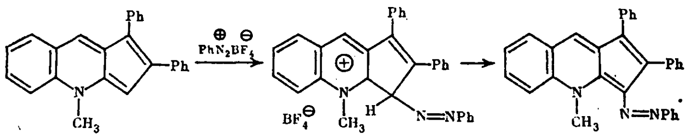
(LXV) from (XIa)



(LXVI) from (XIIa)



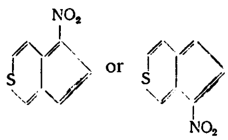
(LXVII) from (XVI)



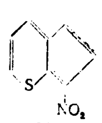
(XXIIIc) (LXVIII) (LXIX)

Azo-dyes of the type (LXIX) have the azo-group in the 3-position, while in 2-phenylcyclopenta[*b*]quinoline (XXIIIb) the azo-group can enter the 1- or 3-position. Indeed, two structurally isomeric azo-dyes have been obtained on azo-coupling, which has been demonstrated by thin-layer-chromatography (TLC); but the isomers could not be separated by crystallisation.[51]

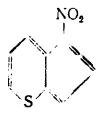
(*b*) *Nitration.* As a result of the sensitivity of pseudoazulenes to strong acids and oxidants, they cannot be nitrated by the nitrating mixture, but nitration can be readily achieved by treatment with $Cu(NO_3)_2$ in acetic anhydride or with tetranitromethane in pyridine.[26,33,34,50,61,72,75] Only mononitro-derivatives of pseudoazulenes are known; the attempts to obtain dinitro-derivatives by treatment with an excess of tetranitromethane in pyridine and also with copper or silver nitrate in acetic anhydride were unsuccessful.[72] The synthesis of nitropseuduazulenes has been described: 3-nitro-1,2,5,7-tetraphenylcyclopenta[*b*]pyran and 3-nitro-1,2;5,6-dibenzoxalene as well as 1(3)-nitrocyclopenta[c]thiapyran (LXX).[61,72] It has been noted that the properties of the product (LXX) preclude a choice between the structures of the 1- and 3-substituted derivatives:



(LXX)

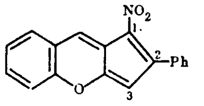


(LXXI)

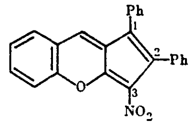


(LXXII) .

On nitration with an excess of tetranitromethane in pyridine, cyclopenta[*b*]thiapyran (XIII) affords two isomeric products (LXXI) and (LXXII), whose structures have not been determined unambiguously. However, it has been established that the reaction of 2-phenylcyclopentachromene (XXIVa) with $C(NO_2)_4$ in pyridine leads exclusively to the 1-nitro-derivative (LXXIII), while the 1,2-diphenylcyclopentachromene is nitrated, as expected, in the 3-position:[75]

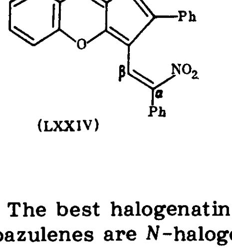


(LXXIII)



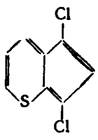
.

The 3-*trans*-styryl derivative of 1,2-diphenylcyclopentachromene is capable of being nitrated at the α-carbon atom of the styryl residue, i.e. in the position most remote from the cyclopentachromene ring and at the same time conjugated with it (the vinylogy principle),[76] forming the nitrostyryl derivative (LXXIV):

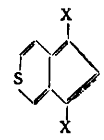


(LXXIV) .

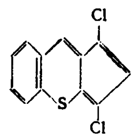
(*c*) *Halogenation.* The best halogenating agents for azulenes[33] and pseudoazulenes are *N*-halogenosuccinimides, whose use makes it possible to obtain mono- and di-halogeno-derivatives in high yields (up to 82%).[26,34,38,50,58,61,72]



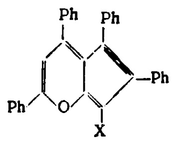
(LXXV)



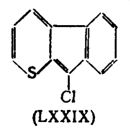
(LXXVI a, b)



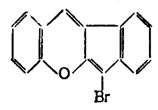
(LXXVII)



(LXXVIIIa, b)



(LXXIX)



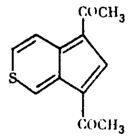
(LXXX)

a:X=Cl
b:X=Br

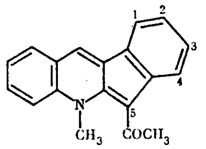
The halogenation of pseudoazulenes without substituents in the 1- and 3-positions yielded the disubstituted products (LXXV),[34] (LXXVIa,b),[61,72] and (LXXVII).[38] The monosubstituted pseudoazulenes (LXXVIIIa, b),[58] (LXXIX),[34] and (LXXX)[26,50] have also been obtained with the aid of *N*-halogenosuccinimides. The attempt to obtain the trichloro-derivatives from cyclopenta[c]thiapyran (LXXVIa) leads only to a polymeric material,[72] while 1,3-dichloroazulene is capable of being chlorinated by *N*-chlorosuccinimide with formation of 1,3,5-trichloroazulene in 17% yield.[77]

(*d*) *Acylation and formylation.* It is known that azulenes are acylated by carboxylic acid chlorides in the presence of aluminium chloride, perchloric acid, or tin tetrachloride with formation of 1-mono- and 1,3-di-acyl derivatives. The reaction with $(CF_3CO)_2O$ takes place almost quantitatively without a catalyst.[33] Azulene has been acylated with the chlorides or bromides of oxalic, malonic, and phenylacetic acids.

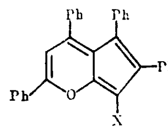
However, none of these methods are very applicable to pseudoazulenes owing to their greater basicity and lower chemical stability. 1,3-Diacetylcyclopenta[c]thiapyran (LXXVIc) has been obtained in only 9% yield by the acylation of compound (XVI) with acetic anhydride in the presence of $SnCl_4$:[61,71]



(LXXVIc)

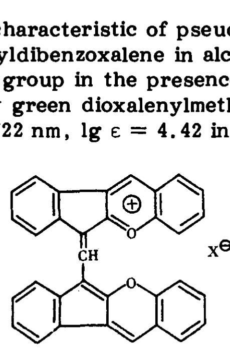


(XXVIIId)



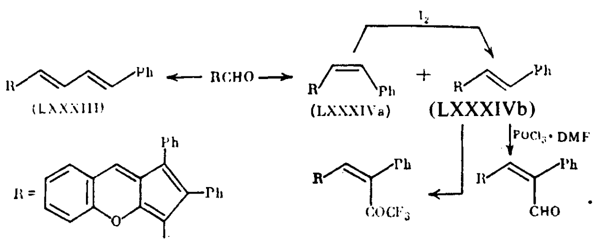
(LXXXI): X=CHO

5-Acetyl-*N*-methyl-1,2;5,6-dibenzoazalene (XXVIIId) has been obtained by reaction with acetic anhydride without a catalyst.[52] The Vilsmeier–Hack reaction is most often employed to synthesise formyl derivatives.[26,50,52,58] Both mono- and di-formylazulenes have been obtained from azulenes by this method.[33] The aldehyde (LXXVI) has been obtained by formylating compound (XIIb) by the complex $POCl_3.DMF$ with isolation of the intermediate phosphorodichloridate $[X = CH = N^+(CH_3)_2.PO_2Cl_2^-]$ in a high yield. The 1,3-dialdehyde has been obtained in 70% yield by heating 2-phenylcyclopentachromene with an excess of the Vilsmeier reagent.[75] The thermal acylation of compound (XXIVa) with malonic acid in the absence of solvents leads to the 1-acetyl derivative.[78] Under mild conditions (treatment with oxalyl bromide in CCl_4 for many days at 20 °C), the pseudoazulenes (XIII), (XXVIII), and (XXIX) form substituted glyoxylic acids, which are decarbonylated to the corresponding carboxylic acids on heating to 70 °C.[79,80] It has been shown[26,52] that a high basicity and ready hydrolytic elimination of the formyl group on heating in the presence of inorganic acids are characteristic of pseudoazulene aldehydes.[26,52] 3-Formyldibenzoxalene in alcoholic solutions[26] splits off the formyl group in the presence of $POCl_3$ and affords the intensely green dioxalenylmethane derivative (LXXXII) (λ_{max} = 722 nm, $\lg \varepsilon = 4.42$ in methanol).

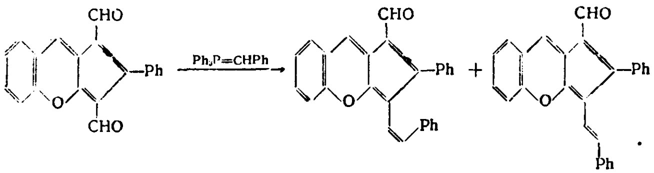


(LXXXII)

The same compound can be obtained from dibenzoxalene and 3-formyldibenzoxalene, analogously to the synthesis of the diazulenylmethane dye obtained by condensing azulene with 1,4-formylazulene.[33] Pseudoazulene aldehydes can be used for the synthesis of other derivatives, for example, polyene derivatives. Thus a series of styrylpseudoazulenes have been obtained by the Wittig reaction[76] from mono- and di-formylcyclopentachromenes. The virtually pure *trans*, *trans*-isomer (LXXXIII) has been obtained by reaction with cinnamylidenephosphorane, while the reaction with benzylidenephosphorane produced the *cis*- and *trans*-isomers (LXXXIVa,b) in proportions of approximately 1 : 2. The *cis*-isomer (LXXXIVa) is converted quantitatively into the *trans*-isomer on treatment with catalytic amounts of I_2 by analogy with the isomerisation of *cis*-*1*-styrylazulene:[81,82]



Compound (LXXIVb) can undergo the electrophilic substitution reaction in the CH=CH–Ph side group (in the α-position in the styryl residue). The increased electron density at the C(1) atom of the 2-phenylcyclo pentachromene system affects the structural selectivity of the Wittig reaction for the 1,3-dialdehyde, which reacts with one equivalent of $Ph_3P{=}CHPh$ to produce the *cis*- and *trans*-3-styrylaldehydes (LXXVa) and (LXXXVb):

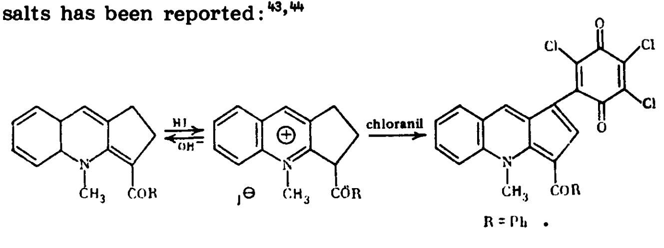


(LXXXVa) (LXXXVb)

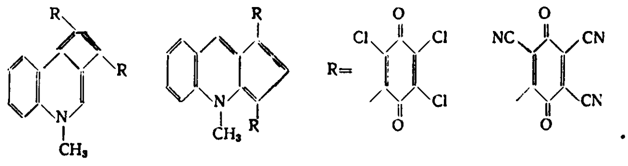
(e) Reactions with organic π-acids. The reaction of 7,7,8,8-tetracyanoquinodimethane (TCQD) with azulenes leads to the formation of products of the 1,6-addition to the quinonoid bond system of TCQD as a result of the initial one-electron oxidation of the donor by the acceptor,[83] exactly as in the reaction of azulenes with tetracyanoethylene.[84,85]

Pseudoazulenes also readily form π-complexes with various acids: trinitrobenzene, picric acid, etc.[7,14,27,32,33] The complexes with trinitrobenzene are frequently used to purify, identify, and isolate unstable pseudoazulenes; these complexes readily decompose into their components in chromatography.

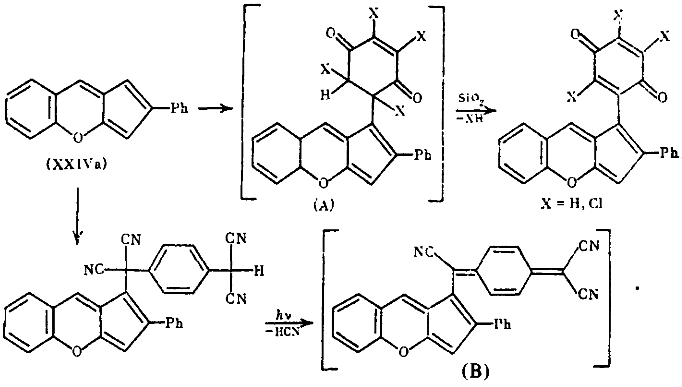
The formation of 1-(3,5,6-trichloro-1,4-benzoquinon-2-yl)-3-benzoyl-4-methyl-4*H*-[*b*]quinindine in 64% yield using chloranil as the dehydrogenating agent for quaternary salts has been reported:[43,44]



The following disubstituted derivatives were later obtained on dehydrogenation of the quaternary salts of hydrogenated pseudoazulenes:[29,45,46]

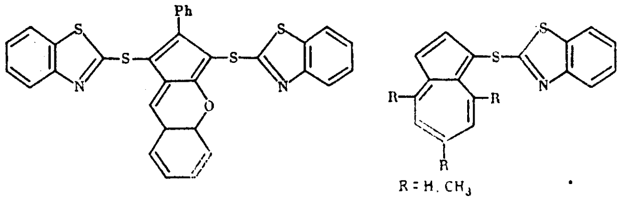


The high reactivity of the 1-position in compound (XXIVa) enables it to participate in reactions involving addition to organic π-acids, for example, to benzoquinone, chloranil, and TCQD, with the ultimate formation of products resulting from the substitution of hydrogen, chlorine, or a CN group. However, the products (A) and (B) proved to be unstable and could not be isolated in a pure state:[86]

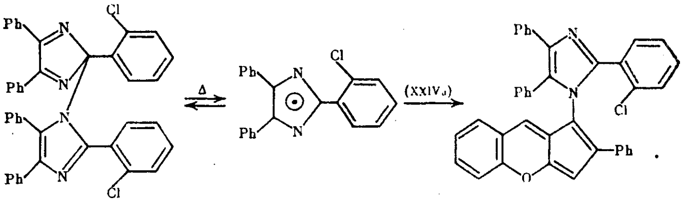


3. Homolytic Substitution

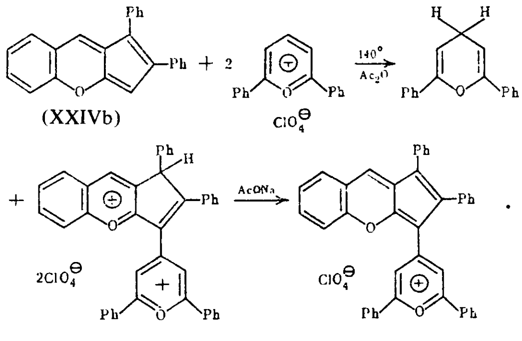
The majority of radical substitution reactions have been thoroughly investigated for azulene derivatives.[31–33,87] Pseudoazulenes, which are no less reactive than azulenes, should also enter into similar reactions, but the literature data on this topic are extremely limited.[22] It is known only that radical species such as 2-benzothiazolylsulphenyl, 2-(*o*-chlorophenyl)-4,5-diphenylimidazolyl, and 2,6-diphenyl-4*H*-4-pyranyl, formed at elevated temperatures, react with compound (XXIVa).[88] When the latter is fused with 2,2-dibenzothiazolyl disulphide (at 200 °C), 1,3-di(benzothiazolylthio)cyclopenta[*b*]chromene is formed in 12% yield; the formation of the mono-substituted benzothiazolylthio-derivative was not then observed, while in the reactions with azulene and 4,6,8-trimethylazulene, only the 1-substituted derivatives were obtained:[89]



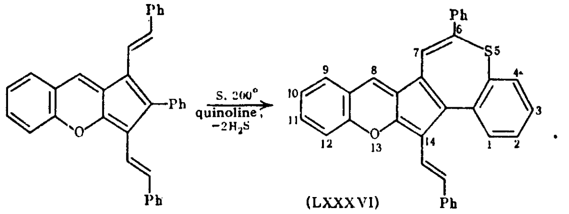
The thermal reaction of 1,2-bis[2-(*o*-chlorophenyl)-4,5-diphenylimidazolyl] with 2-phenylcyclopenta[*b*]chromene leads to the formation of the 1-substituted derivative, as in the reaction with azulene:[90]



The reaction of compound (XXIVb) with 2,6-diphenylpyrylium perchlorate in boiling acetic anhydride leads to the formation of 2,6-diphenyl-4-{1,2-diphenylcyclopenta[*b*]-3-chromylia}pyrylium diperchlorate in 75% yield.[91] It has been suggested that the primary step in this reaction is the one-electron oxidation of the substrate by the 2,6-diphenylpyrylium cation, which leads to the formation of the extremely reactive 1,2-diphenylcyclopenta[*b*]chromenylium radical-cation and the 2,6-diphenyl-4*H*-4-pyranyl radical, which recombine to a doubly charged primary cation:



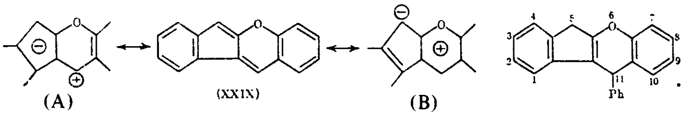
An analogous reaction has been carried between 2,6-diphenylpyrylium perchlorate and 6-heterylazulenes.[92] Other organic compounds with an enhanced electron density at, at least, one of the carbon atoms (*NN*-dimethylaniline[93,94] and 1-methyl and 2-methyl-indoles[95,96]) or substances capable of being readily oxidised to readily stable radical-cations (ferrocene[97]) can also serve as substrates in this reaction. An example of the transmission of the influence of the electron density to the non-benzenoid aromatic ring on the reactivity of the conjugated side chain (vinylogy) is provided by the reaction of 2-phenyl-1,3-distyrylcyclopentachromene with sulphur, which leads to a new heterocyclic system: 6-phenyl-14-styrylbenzo[2',3']thiepino[4',5';2,1]cyclopenta[*b*]chromene (LXXXVI) in 40% yield:[76]



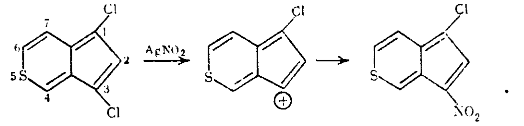
(LXXXVI)

4. Nucleophilic Substitution

The effect of alkyl- and aryl-lithium has been investigated on the pseudoazulene systems (XVIII), (XXIV) and (XXIX).[16,45,46] The hydrocarbon residue then attacks the carbon atom located opposite to the heteroatom. Dihydro-compounds, which can be again dehydrogenated to pseudoazulenes, are obtained by hydrolysing the intermediates. Such reactions are characteristic of π-deficient heterocycles. The system (XXIX), which is isoelectronic with azulene, can be described as a hybrid of resonance structures—those of the pyrylium cation (B) and the anion (A):



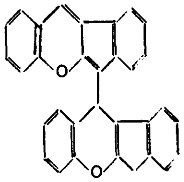
The limiting form (A) is responsible for the sensitivity of dibenzoxalene (XXIX) to nucleophiles, which has been conformed by its reaction with phenyl-lithium, leading to 11-phenyl-5,11-dihydrodibenzoxalene. Dibenzoxalene (XXIX) is resistant to lithium malonate and maleic anhydride; the attempts to replace the oxygen heteroatom by sulphur and nitrogen proved unsuccessful.[26] It is also known that only one chlorine atom, located at the C(3) atom, in 1,3-dichlorocyclopenta[c]thiapyran is substituted by silver nitrite:[72]



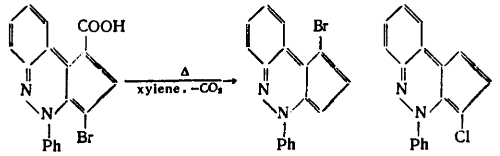
5. Other Reactions of Pseudoazulenes

Apart from the reaction described above, isothialene (XVI) has been substituted by thiocyano-groups using thiocyanogen, which led to 1,3-dithiocyanocyclopenta[c]thiapyran.[61,72] The reaction with $Cu(SCN)_2$ in acetonitrile yielded 1,2-diphenyl-3-thiocyanocyclopenta[*b*]chromene,[98] while that with $Cu(SO_2Ph)_2$ afforded benzenesulphonyl derivatives of 1,2-diphenyl- and 2-phenylcyclopenta[*b*]chromene.[75]

The alkylation of 1,2,5,7-tetraphenylcyclopenta[*b*]pyran with t-butyl chloride in the presence of aluminium chloride has been carried out successfully.[58] Inorganic acids and phosphoryl chloride induced the dimerisation of dibenzoxalene (XXIX) with formation of a dimer having the following structure:[53]



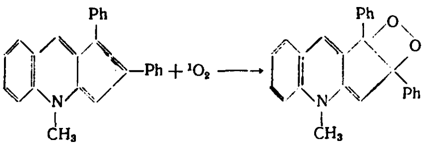
An instance of allylic rearrangement has been described in relation to 4-phenyl-4*H*-cyclopenta[*c*]cinnoline.[99] On being refluxed in xylene, 3-bromo-4-phenyl-4*H*-cyclopenta[*c*]-cinnoline-1-carboxylic acid (LXXXVIII) is decarboxylated with a simultaneous rearrangement, leading to the formation of the bromo-derivative (LXXXVIII):



(LXXXVII) (LXXXVIII) (LXXXIX)

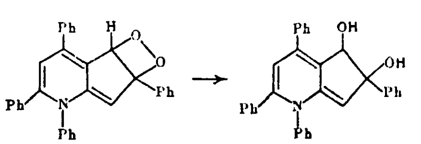
In contrast to the bromoacid (LXXXVII), the corresponding chloroacid is decarboxylated under the same conditions without a rearrangement, forming the chloro-derivative (LXXXIX). It is noteworthy that the decarboxylation of the bromoacid (LXXXVII) leads only to the bromo-derivative which can be obtained by brominating 4-phenyl-4*H*-cyclopenta[*c*]cinnoline by *N*-bromosuccinamide.

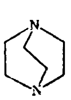
The photosensitised pseudoazulene oxidation processes have been examined.[100] Polyarylcyclopenta[*b*]quinolines, for example, compound (XXIIIc), 1-pyrindines (XI), and cyclopenta[*b*]chromenes sensitise the formation of singlet oxygen on irradiation in air in various solvents and are oxidised by it to dioxetans, which readily decompose with chemiluminescence. Dioxetans also generate $^1O_2$, as a result of which the oxidation reactions undergo self-acceleration:



(XXIIIв) (XC)

The formation of the dioxetan having the structure (XC) has been suggested. The thermal decomposition of the dioxetan (XCI) leads to dihydroxy-compound (XCII):



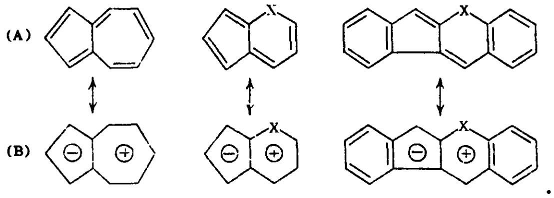


(XCI) (XCII) 10% (XCIII)

The photodecolorisation is retarded in the presence of a typical $^1O_2$ quenching agent—diazabicyclo-octane (XCIII), or a chemical quenching agent—2,5-dimethylfuran, which forms a peroxide. The quantum yields in the decomposition of pseudoazulenes are approximately 2×10^{-3}.

IV. QUANTUM-CHEMICAL CALCULATIONS

The aromaticity of pseudoazulenes is determined by the sextet of π-electrons in the heterocyclic ring, made up of the single unshared electron pair of the heteroatom, located in the *p* orbital axial in relation to the plane of the ring, and four π-electrons of the double bonds. The aromatic sextet of electrons in the five-membered ring is obtained as a result of the possibility of polarisation in the direction from the six-membered ring to the five-membered ring, the conditions in both rings approaching those of an aromatic sextet. For this reason the dipolar structure makes a significant contribution to the electronic structure of pseudoazulenes. The azulene[32] and pseudoazulene[35,38] systems can be represented by resonance hybrid structures, intermediate between the Kekulé form (A) and the dipolar form (B).



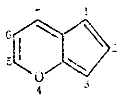
The data for electron distribution obtained for pseudoazulenes by the LCAO-MO method in terms of the Hückel approximation[57,101–110] and by the Pariser–Parr–Pople (PPP) method,[98,101] the reactivity data, and the electronic absorption spectra indicate an azulene-like behaviour of representatives of this class of non-benzenoid non-alternant aromatic compounds. Despite the difficulties associated with the allowance for the contribution by polar structures, the electron deficiency in the six-membered ring and the excess electron density in the five-membered ring have been calculated for all the pseudoazulenes. It follows from the molecular diagram for indolizine that a considerable positive charge is localised on the nitrogen atom and that there is a negative charge on all the carbon atoms except the C(8) atom (six-membered ring).[112] Since different workers have used different sets of parameters, the calculated electron density distributions on the carbon atoms could not be compared directly. The results yielded by the same set of parameters for different systems lead to the following conclusions: the electron density on the carbon atoms decreases from the nitrogen-containing pseudoazulenes to the oxygen-containing compounds as a consequence of the greater electronegativity of oxygen. In the [*b*]-series of pseudoazulenes the carbon atoms of the five-membered ring have a higher electron density than for the [*c*]-series. The presence of a condensed aromatic ring in the 1,2-positions increases the electron density in the five-membered ring, while condensation in the 5,6-positions reduces it. The distribution of electron density on the individual atoms of the five-membered ring is as follows: the 1- and 3-positions have an increased electron density compared with that in the 2-position. In the [*b*]-series the C(1) atom is more electron-deficient than the C(3) atom,[22,98] while in the [*c*]-series the situation changes. In azulene, the 1- and 3-positions are equivalent as a consequence of the symmetry of the molecule, while the 2-position is much more electron-deficient as in pseudoazulenes.[32] The self-consistent field calculations for the azulene molecule[113,114] yielded a somewhat different picture. On average, the five-membered ring carries an excess negative charge, as before, but, in contrast to the result yielded by the simpler Hückel MO method, the atom in the 2-position carries a positive charge.

Electrophilic substitution of non-condensed representatives of pseudoazulenes (XI)–(XVI) is directed preferentially to the 1- or 3-position. If both these positions are free, then they can be attacked simultaneously. Attack by nucleophiles should take place in the 7-position for representatives of the [*b*]-series and in the 4-positions for the [*c*]-series. Radical reactions are directed to the 5-position for the [*b*]-series, while representatives of the [*c*]-series react in the 4-position.[108] Various preferred positions for electrophilic, nucleophilic, and radical substitution reactions follow from the localisation energies A_r, the π-electron densities q_r, or the free valence indices F_r for the individual C atoms. The reactivities of the C atoms of cyclopenta[*b*]pyran (XII) are presented in Table 2.[104]

Table 2. Preferred mode of substitution in the oxalene (XII)*.

Electrophilic substitution		Nucleophilic substitution		Radical substitution		Electrophilic substitution		Nucleophilic substitution		Radical substitution	
$A_r^{\ominus}$	q_r	$A_r^{\ominus}$	q_r	$A_r^{\odot}$	F_r	$A_r^{\oplus}$	q_r	$A_r^{\ominus}$	q_r	$A_r^{\odot}$	F_r
1	3	5	5	5	5	5	6	1	2	3	3
3	1	7	7	1	7	6	7	3	1	2	2
2	2	2	6	7	1	7	5	6	3	6	6

*The reactivity diminishes on moving towards lower rows.



(XII)

It follows from the calculations of the electronic absorption spectra by the Hückel MO method[101,102,104,107] and the PPP method[98,111] that, analogously to azulenes, the long-wavelength band in the range 500–700 nm corresponds to the $S^0 \rightarrow S^1$ transition, while the band in the range 360–390 nm corresponds to the $S^0 \rightarrow S^2$ transition. The absorption in the short-wavelength part of the spectrum is determined by complex transitions. The long-wavelength transition is accompanied by charge transfer preferentially from the five-membered ring to the six-membered heterocycle. Thus the overall negative charge on the atoms of the five-membered ring in 2-phenylcyclopentachromene is reversed on transition to the first excited state (+0.096 against −0.374 in the ground state), while that in the heterocycle diminishes appreciably (to +0.008 against +0.315). The bonds in the rings become to a large extent equalised. The comparatively low intensity of the band can be accounted for by the small change in the dipole moment of the transition ($\Delta\mu = 0.40$ D). Theoretical analysis of the long-wavelength electronic transition has shown that it is determined mainly by the fulvene group, which is a constituent fragment of the pseudoazulene molecule.[98]

It has been demonstrated theoretically[52,111] that the influence of the heteroatom on the absorption spectra of heterocyclic pseudoazulenes is very insignificant. According to a quantum-chemical calculation, the influence of substituents on the energy of the long-wavelength transition is the same as that for azulenes.[108] A bathochromic or hypsochromic shift of the long-wavelength band, induced by the introduction of alkyl groups in different positions in the azulene ring (the Plattner rule), is especially typical for azulenes.[115] The influence of the methyl group in different positions in cyclopenta[*c*]pyran has been calculated[102] and it has been shown that the Plattner rule should hold also for pseudoazulene systems. Inadequate experimental data make it impossible to confirm this postulate.

V. PHYSICOCHEMICAL PROPERTIES

1. Stability

Pseudoazulenes are in most cases deeply coloured, crystalline, weakly basic compounds, which dissolve in aqueous solutions of strong acids with loss of the characteristic colour and are reprecipitated unchanged on dilution with water or aqueous bases and can thus be extracted from organic solvents. In terms of their colour, basicity, and resistance to alkalis, they resemble azulene. In contrast to the majority of azulenes, numerous pseudoazulenes are unstable. Simple unsubstituted representatives of certain systems cannot be isolated in a pure form at all. Phenyl substituents stabilise the system and polyaryl-substituted compounds can be stored for a long time at room temperature without appreciable decomposition. Thus *N*-methyl derivatives of unsubstituted 1-pyrindine,[58] cyclopenta[*b*]quinoline,[45,46] and indeno[1,2-*b*]-pyridine[27] are unstable, while 1-phenyl and 1,2-diphenyl-cyclopenta[*b*]quinolines as well as the tri- and tetra-phenyl derivatives of 1-pyrindine are comparatively stable.[51] Substitution by even one strong electron-accepting substituent is sufficient to achieve the complete stabilisation of the unstable systems. "Picrylation" has an especially powerful stabilising effect.[116] The stability decreases very markedly on passing from sulphur- and nitrogen-containing systems to the oxygen analogues; thus cyclopentathiapyran and 2*H*-pyrindine were synthesised a long time ago,[36,37] while cyclopentapyran is still unknown. The [*c*]-series pseudoazulene systems are more stable than compounds of the [*b*]-series. Cyclopenta[*b*]thiapyran has been isolated in the form of an extremely unstable blue oil;[15] in contrast to this, cyclopenta[*c*]thiapyran[43] is a fairly stable crystalline substance. Under the influence of atmospheric oxygen and light, many pseudoazulenes decompose very rapidly. Solutions in non-polar solvents are preserved for a long time, while in polar solvents, especially in methanol, decomposition is observed over a period of 4–5 h.[51] The stability of pseudoazulenes in relation to bases makes it possible to chromatograph them on alumina.

2. Electronic Absorption Spectra

There is no doubt that the long-wavelength absorption, observed for azulene in the region of approximately 600 nm, is most characteristic for the identification of the compounds considered. Only an indirect comparison of the spectra of pseudoazulenes with those of carbocyclic analogues is possible, since the corresponding polyphenylazulenes and certain polycyclic condensed systems are so far unknown, while many pseudoazulene systems without substituents are unstable. The electronic spectra of 1,2-, 4,5-, and 5,6-benzoazulenes have been compared with those of unsubstituted azulenes.[117–125] Since azulenes phenyl-substituted in the seven-membered ring have the same absorption spectrum as unsubstituted azulenes,[126,127] El'tsov et al.[51] compared the spectra of pyrindines with those of 2-phenylazulene.[128] The comparison showed that the long-wavelength band in the spectra of non-condensed 1-pyrindines has undergone a hypsochromic shift by 60–70 nm compared with the spectra of azulene. Substituents at the nitrogen atom have little influence on the long-wavelength transition and hardly affect the short-wavelength transitions. Pyrindines absorb in approximately the same part of the spectrum as the corresponding oxygen analogues. The influence of phenyl substituents on the direction and magnitude of the shifts of the absorption maxima[16,27,28,48,57] is approximately the same as for azulene. The phenyl group in the 1- or 3-position in cyclopenta[*b*]quinoline induces a 22 nm bathochromic shift (there is a 26 nm shift in the spectrum of azulene[128]). In the oxygen analogue—2-phenylcyclopenta[*b*]chromene—the successive introduction of phenyl substituents into the five-membered ring leads to a bathochromic shift of the long-wavelength band by 42 nm for one phenyl group (the calculated shift is thus 28.2 nm) and by 60 nm for two such groups. The *trans*-styryl group in the 1-position induces a +80 nm shift, while that in the 3-position induces a 60 nm shift. Two *trans*-styryl groups cause a "red" shift by 140 nm without an appreciable change in the oscillator strength.[98] Electron-accepting substituents in the five-membered ring of 4*H*-indeno[2,1-*b*]quinoline cause a hypsochromic shift of the absorption by 30–35 nm, while in the spectrum of the oxygen analogue the shift is by only 5–10 nm.[52] The introduction of electron-accepting substituents in the 3-position in 1,2-diphenylcyclopenta[*b*]chromene results in a hypsochromic shift of the long-wavelength band by approximately 30 nm with an increase of the oscillator strength by a factor of 1.5. The same substituents in the 1-position induce a 10–30 nm bathochromic shift and an increase of the oscillator strength of the band by a factor of 4–5,[98] in contrast to azulene, where a hypsochromic shift is observed exclusively.[31]

The emission spectra of azulene are known to be unusual:[129–132] the fluorescence of azulene and its derivatives corresponds to a very rare $S^2 \rightarrow S^0$ type of transition. Such anomalous luminescence is probably a consequence of the marked splitting of the S^2 and S^1 levels and a greater mutual approach of the S^1 and S^0 levels than for other aromatic systems. It has been found[51,53] that the luminescence of pseudoazulenes is just as anomalous as for azulenes. The quantum yields are 10^{-4}–10^{-5} against 10^{-2} for azulene.[130] As for azulene, the authors did not observe phosphorescence in pseudoazulenes. The structure of the electronic spectra and the luminescence properties of 1,2-benzoxalene derivatives have been examined.[134]

3. Infrared, ^{1}H NMR, and Mass Spectra

Virtually no systematic studies of the IR, ^{1}H NMR, and mass spectra of pseudoazulenes are described in the literature. These data are usually given in the experimental parts of synthetic studies.

The IR spectra of substituted pseudoazulenes contain only insignificant characteristic bands corresponding to the normal absorption of aromatic rings. For example, the spectra of indeno[2,1-*b*]benzopyrans in the range 1560–1660 cm^{-1} have four bands due to the vibrations of the aromatic ring and the C=C stretching vibrations and the moderately intense band at 1230 cm^{-1} has been attributed to the ν(C=O) deformation vibrations of the –C=C–O group.[26] The vibration frequencies of the substituents in the five-membered ring in both azulene and pseudoazulenes are appreciably reduced.[31,58,134,135] If the system contains the CN, CHO, or $COCH_3$ groups in the five-membered ring, then the latter, being substituents of the second kind, promote the polarisation of the system with formation of the structure (B). The ν(C=O) vibration frequencies in the aldehydes (1611 cm^{-1}) and ketones (1598 cm^{-1}) derived from indeno[2,1,*b*]quinoline (XXVIII) are reduced compared with the frequencies in the similar derivatives of indeno[2,1-*b*]benzopyran (XXIX) (1631 cm^{-1} in the aldehydes and 1625 cm^{-1} in the ketones),[103] which can be explained by the smaller electronegativity of the nitrogen atom compared with the oxygen atom, which promotes the formation of a polar structure. In the IR spectrum of 1,3-diacetylcyclopenta[*c*]thiapyran the stretching vibrations at the carbonyl group appear at 1629 cm^{-1}, i.e. at longer wavelengths than the corresponding vibrations of the carbonyl group in 1,2-diacetylazulene, observed at 1638 cm^{-1}.[72] The dependence of the ν(C=O) vibration frequency on the position of the CO group in azulene has been indicated.[136] The authors note that the spectra of 1-phenylacetyl- and 2-phenylacetyl-azulenes contain the absorption bands due to the carbonyl group at 1640 and 1675 cm^{-1} respectively. In the spectra of 1-carbonyl-containing pseudoazulenes of the cyclopenta[*b*]chromene series there is a possibility of the overlap of the frequencies of the aromatic C=C and C=O bonds. The possibility of using the integral intensities of the vibration bands of the bonds and ^{13}C NMR to demonstrate the presence of carbonyl groups has been examined.[137] ^{13}C NMR spectrum of 1,3-diformyl-2-phenylcyclopenta[*b*]chromene in $CDCl_3$ shows two signals with chemical shifts δ of 186.61 and 183.77 p.p.m., corresponding to the carbon atoms of the two formyl groups, and also the signals of the phenyl substituent in the region of 77.25 p.p.m. and the remaining carbon atoms at 118.27–138.86 p.p.m. A considerable upfield shift of the ^{13}C resonance signal of the C=O group compared with acetophenone (196.9), benzaldehyde (190.7), and acetone (204.1) has been noted.[138] It follows from the comparative analysis of the shifts δ of the CHO groups in the ^{13}C NMR spectra, the ν(C=O) frequencies, and the integral intensities of the absorption bands due to the stretching vibrations of the C=O groups in the IR spectra that the CHO groups in the 1- and 3-positions in azulene and cyclopenta[*b*]chromene are strongly polarised, which is comparable to the polarisation of the C=O group in benzotropones.[139] The ^{13}C NMR spectra of unsubstituted azulene and mono- and poly-methylazulenes have been published.[140] The chemical shifts of the methyl groups in different positions in the azulene ring are in the range δ = 12.6–28.5 p.p.m., while the shifts for the C_1–C_{10} atoms are in the range δ = 116–146.9 p.p.m.

The ^{1}H NMR spectrum of azulene[141,142] agrees well with its structure. The ^{1}H NMR spectrum of cyclopenta[*c*]thiapyran has been interpreted.[61] The spectra of its methyl derivatives were examined by Radeglia and Wagner[64] and those of the 1-pyrindine system were considered by Anastassion and Reichmanis.[143] The protons in the 1-, 2-, and 3-positions in azulene are not shielded to the same extent as the corresponding protons in cyclopenta[*c*]thiapyran. It follows from this that the polar structure of pseudoazulenes has a stronger influence on the distribution of electron density in the ground state.[61] The different degrees of shielding of the individual protons in the pseudoazulene nuclei, which should be expected on the basis of calculated data as a consequence of the differences in electron density, do indeed follow from the ^{1}H NMR spectra of these compounds, for example, cyclopenta[*b*]quinoline.[29,43–46] In the ^{1}H NMR spectra of cyclopenta[*b*]pyrylium salts obtained by protonating cyclopenta[*b*]pyran (XII), cyclopenta[*b*]chromene (XXIV), and indeno[2,1-*b*]chromene (XXIX) by $HClO_4$, the signal of the methylene group appears in the range δ = 4.48–4.77 p.p.m. (in CF_3COOH).[57] In the spectrum of the protonated form of 4,6,8-trimethylazulene (in 96% H_2SO_4), the signal of the C(1)H_2 methylene group is observed at 3.56 p.p.m. The strong deshielding influence of the electron-accepting groups $PhSO_2$, CH_3CO, and CF_3CO in the 1-position [the substituted C(1) atom of the trimethylazulene system is protonated] causes a downfield shift of the C(1)–H signal (5.85, 5.40, and 4.80 p.p.m. respectively).[144,145–149] 2-Alkyl derivatives of 6-, and 7-, and 8-ethoxycarbonylindolizines are protonated at the C(3) atom, the protons of the methylene group formed in this process being manifested by a signal at 5.28 p.p.m. with an intensity equivalent to two proton units. The presence of the CHO, NO_2, and $COCH_3$ substituents in the 3-position (in contrast to the 4,6,8-trimethylazulene molecule) alters the centre subjected to protonation, which is directed in this instance to the oxygen atom of the substituent.[150–153]

There are no literature data on the mass spectra of pseudoazulenes containing one heteroatom, although the mass spectra of compounds with several heteroatoms confirm the aromatic character of pseudoazulenes.[23,76,154,155] As for other aromatic compounds, the principal peak is identical with that of the molecular ions; the spectra contain numerous doubly charged ions; there is a small number of low-intensity fragment peaks.

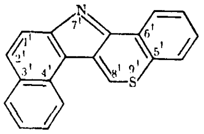
4. The Dipole Moment

Since the five-membered ring is enriched in electrons, the azulene molecule has a dipole moment, the five-membered ring being the negative end of the dipole. The dipole moment of azulene (6.9 D) has been calculated from the electron densities and C–C bond orders; direct measurement yielded 1.04 ± 0.05 D.[156] The theoretical value calculated in terms of the simple MO-LCAO approximation differs very markedly from the above value. However, improved calculations have shown that the charge distribution in azulene is more uniform and the dipole moment is therefore appreciably smaller than the value predicted by the simple MO theory. For example, application of the MO method with allowance for configuration interaction led to 1.88 D.[157] The value closest to the experimental dipole moment (1.33 D)[158] has been obtained by the self-consistent field calculation using variable electronegativities. Improved methods of calculation have shown that the π-electron density at the 2-atom is less than unity, while at the 5- and 7-atoms the densities are more than unity, as a result of which the dipole moment is appreciably reduced.

Pseudoazulenes should possess a dipole moment greater than that of azulene. The measured dipole moment of 5-methyl-5*H*-indeno[2,1-*b*]quinoline is 2.35 D and that of 1,2;5,6-dibenzoxalene is 2.02 D. The substituents in pseudoazulenes have a striking influence, which exceeds the normal values. When electron-accepting substituents (CN, CHO, and $COOC_2H_5$) are introduced into the five-membered ring of 1,2;5,6-dibenzoxalene, the dipole moment increases much more than might have been expected on the basis of the group moments of the substituents.[103] This can be explained by the considerable contribution of the polar structure (B). This contribution is greater the more electronegative the substituent and the greater the polarisability of the pseudoazulene. The dipole moment and the polarisability of azulene in the ground state as well as in the first and second excited states have been examined.[159]

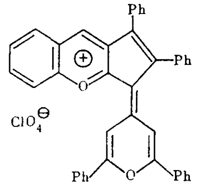
VI. BIOLOGICAL ACTIVITY AND PRACTICAL APPLICATIONS OF PSEUDOAZULENES

Like azulene derivatives, pseudoazulenes have a distinct biological activity. Certain alkylindolizines have a physiological activity analogous to convulsing poisons and induce the paralysis of the muscular and respiratory activity.[160] The Mannich bases obtained from 2-phenyl and 1,2-diphenylindolizines have a depressing influence on the central nervous system.[161–166] Derivatives of indolizine-1-acetic acid have been patented as analgesic and anti-inflammatory agents.[167,168] 2-Furylindolizines exhibit an antimicrobial activity,[169] while 6-methyl-7-(2,4,5-trimethylbenzyl)-2-phenylindolizine shows growth regulating activity.[170,171] The influence of 6*H*-pyrrolo[3,2-*f*]indolizines[172–174] on the cardiovascular system, arterial pressure, and pulse has been investigated; the application of the hydrochloride of 2-ethoxycarbonyl-4-isobutyl-3,6,7,8-tetramethyl-6*H*-pyrrolo[3,2-*f*]indolizine as an antiarrhythmic agent,[175] whose effect is several times greater than that of other antiarrhythmic agents such as quinidine and novocainamide, has been patented. Certain pseudoazulenes exhibit an antitumour activity.[176–179] The carcinogenic activity of condensed polycyclic pseudoazulenes containing the nitrogen and sulphur heteroatoms has been studied. Dibenzo[3,4,5,6]thiapyrano[4,3-*b*]indolenine (XCIV) exhibited the maximum carcinogenic activity:[180]



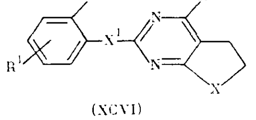
(XCIV)

It has been established that 2-arylindolizines possess no carcinogenic activity.[181] Liquid crystal derivatives of azulene have been obtained recently.[182] 2,6-Diphenyl-4*H*-4-{3*H*-1,2-diphenylbenzo[*b*]cyclopenta[*e*]-3-pyrania}pyrylium perchlorate (XCV) has been proposed as a sensitiser of photoconductivity in order to extend the range of the spectral sensitivity of electrophotographic materials to 800 nm:[183]

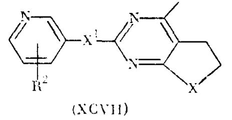


(XCV)

Sulphonamide derivatives of hydrogenated pseudoazulenes of the (XCVI) and (XCVII) types with the following substituents have been patented as herbicidal preparations:[184] R = H, Me, MeO, Hal, NO_2, CF_3, COOAlk, SO_2Alk, OSO_2R, $CF_3CH_2O_3S$, or MeN(OMe)SO_2; R^1 = H, Hal, Alk, or MeO; R_2 = H, Hal, Alk, AlkO, NO_2, COOAlk, or AlkS; R^3 = H, Me, MeO, Cl, or EtO; n = 1 or 2; X = $(CH_2)_n$ or O; X^1 = NHC(Z)NH; Z = O or S.

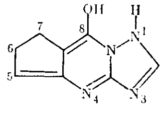


(XCVI)



(XCVII)

Polymers containing the 1,2,4-triazolo[1,3-*a*]pyrimidinyl group have been patented as stabilisers of photographic silver halide materials:[185]



The most promising trend in this field comprises studies on the biological activity and photochemical properties of compounds of the class considered.

Studies of Polyacetylene by Magnetic Resonance Methods

T.S.Zhuravleva

Results obtained in studies of polyacetylene (PA) by magnetic resonance methods are discussed. The structure and properties of the paramagnetic centres in PA are examined, and compared with the structure and the chemical composition of pure and of doped PA (i.e. PA with added electron donors and acceptors).
The bibliography includes 116 references.

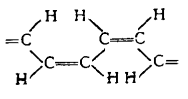
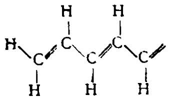
I. INTRODUCTION

In recent years polyacetylene (PA) has attracted much scientific interest because of its unusual electrical properties. An increase in electrical conductivity by 10–12 orders of magnitude has been obtained by adding donor or acceptor impurities (see Ref.1), equivalent to the transition from a dielectric to an "organic metal" with a conductivity $\sigma \cong 10^3\ \Omega^{-1}\ cm^{-1}$. In chemical composition polyacetylene $(CH)_x$ is the simplest of all the polymers with conjugated double bonds, whose conductivity is determined by the presence of impurities; therefore PA has been repeatedly chosen as a model system for studies of this unusual phenomenon. The properties observed in these studies appear to be general, and present in many other conjugated systems. Therefore the conclusions and hypotheses formulated from studies of the properties of PA may be equally applicable to other polymers with conjugated bonds. However, though PA is still the subject of most of the publications on polymers with conjugated bonds, papers on other similar systems have recently started to appear (polyphenylene and its derivatives, polypyrrole, etc.). These studies lack both the generality and the fullness of the work on PA, and in particular they do not provide a complete picture of the physical, chemical, and physicochemical changes resulting from the addition of impurities. Additional interest in the study of polymers with conjugated bonds has recently been stimulated by the development of effective methods of synthesis which allow the production of polymers with reproducible physicochemical properties.

We know[2–4] that the structure of PA consists of polymer chains in the *cis* or the *trans* form,



cis form



trans form

arranged in parallel bundles to form a fibre (or fibril) a few hundreds of Ångstroms thick and several thousands long. The long axes of these fibrils are randomly arranged, but they can be partially oriented by stretching the sample. Within each fibril the polymer chains are close-packed, and form a crystalline structure.[2,3] Thus PA is an unusual type of polycrystalline material, consisting of "crystalline fibrils".

This review discusses the properties of PA prepared by Shirakawa's method,[4] in which a stream of gaseous acetylene is directed at a thin layer of solution containing a Ziegler–Natta catalyst at 195 K. This produces a thin layer of polymeric material with a fibrillar structure. There are alternative methods of preparing PA, for example by first preparing an easily soluble polymer precursor and then heating it to give insoluble PA.[5,6] This material contains few defects, and is largely amorphous. However, most of the published work was done with PA prepared by Shirakawa's method.[4]

The fibrillar structure of PA facilitates its "doping", carried out as follows. The chemical additives ("dopants"), for example the electron-acceptor impurities I_2 or AsF_5, penetrate into the PA fibrils through their surface and interact with the polymer chains or among themselves. The result is the formation of the I_3^- or AsF_6^- anions, while part of the PA chain acquires a positive charge. Thus the addition of chemical impurities is only the first step in the doping of PA: the process includes several chemical changes and is completed by the partial conversion of the PA into an ion-radical salt containing charge transfer complexes.

Both doped and undoped PA have been extensively studied by magnetic resonance methods: ESR, NMR, electron–nucleus double resonance (ENDOR), dynamic nuclear polarisation (DNP), nuclear quadrupole resonance (NQR), and their time-resolved modifications. These methods offer varied and unique information on the structure of the polymer (bond length, size of conjugation regions, etc.), on the nature and properties of the paramagnetic centres, on the extent and nature of the doping, and on the distribution of charge and spin density in the polymer chains of undoped and of doped PA. This paper reviews the experimental studies of the structure and properties of PA by magnetic resonance methods. The theoretical foundations of the magnetic resonance methods and the apparatus used in this work are discussed in several monographs,[7–17] and will not be the object of this review. A generally accepted model of the paramagnetic centre in PA has not yet been proposed, and as a result we still lack a unique terminology. In the present review we shall use general terms such as "paramagnetic defect", "unpaired electron", etc., avoiding as far as possible the term "soliton" applied by some workers to a particular model of defects in PA.

II. PARAMAGNETIC SUSCEPTIBILITY OF PURE PA

Like most conjugated systems, polyacetylene shows paramagnetism. This has been reliably established by studies of its static magnetic susceptibility (Faraday's method)[11] and by ESR measurements.[8,10,11] The paramagnetic susceptibility of *trans*-PA at room temperature is an order of magnitude greater than that of the *cis* isomer, and is equivalent on average to one paramagnetic centre per ~3000 CH units.[1,4,18–25] The molecular weight of the polymer is ~7000, i.e. the chains consist of approximately 400–500 CH units.[26] Obviously, this number depends on the method of synthesis of the PA. However, on average one paramagnetic centre is shared by 6–7 polymer chains.

In the ESR spectra of the *cis* and *trans* PA isomers we find a singlet line[19] with a *g* factor of 2.003, but in the *cis* isomer synthesised at 195 K the ESR signal with $g = 2.003$ is absent.[24,25,27,28] The signal appears only on raising the temperature, and at 300 K the concentration of paramagnetic centres reaches 10^{18} spins g^{-1} (i.e. one spin per 44 000 CH units). If the *cis* isomer at 77 K is irradiated with u.v. light[28] or treated with oxygen[24,25] it develops the same ESR signal as if the temperature is increased. On the other hand if a sample heated to room temperature is exposed to oxygen the amplitude of the ESR signal increases by almost an order of magnitude, and the width of the line (~8 Oe) stays almost unchanged.[24,25,27] The effect of u.v. irradiation and of oxygen on the *trans* isomer differs slightly from their effect on the *cis* isomer. The ESR signal is not increased by u.v. irradiation of the *trans* isomer. On exposure of this isomer to oxygen the signal initially increases, and then decreases,[24,29,30] while the width of the ESR line increases.[24,29]

Heating PA to 423 K produces a large increase in the number of paramagnetic centres according to the ESR results.[21,27,29] We know[31] that at 418 K an exothermic peak (attributed to *cis–trans* isomerisation) appears in the thermogram of polyacetylene. Heating of *cis*-PA produces two effects: *cis–trans* isomerisation and polymer degradation. It was reported[32] that the optimum region for the preparation of *trans*-PA is 413–423 K, because at these temperatures the rate of isomerisation is a maximum while the rate of degradation is still acceptably low.

It has been suggested[4] that the paramagnetism of PA is caused by the presence of defects: *cis*-PA has a more perfect structure, and it contains fewer defects than *trans*-PA. *Cis–trans* isomerisation results in an increase in the defect density of the polymer, accompanied by a corresponding increase in the absolute value of the paramagnetic susceptibility. Similar views are expressed in more recent papers (see, for example, Refs.21 and 27). The ESR signal observed in *cis*-PA at room temperature has been attributed[22,24] to the presence of ~5% of *trans*-PA in the sample. It was suggested that fragments of the *trans* isomer are localised at the ends of the polymer chain, where *cis–trans* isomerisation occurs most readily. Noting the similarity (Fig.1) between the temperature dependences of the concentration of *trans* isomers (obtained from the i.r. spectra) and of free radicals Zanobi and D'Ilario[28] suggested that isomerisation causes breaking of the double bonds with formation of regions containing an odd number of π electrons.

A simple model of a defect in *trans*-PA is the formation of a cross-link between chains.[33] Cross-linking produces a fragment with an odd number of carbon atoms, which contains an unpaired electron. The model in which defects are identified with cross-links is discussed in Ref.34. After the cross-link is established one radical appears in each chain: the energy of this biradical state was calculated by the quantum-chemical INDO method. Other workers[27–29] have expressed similar views on the causes of the effect of oxygen on the ESR signal in PA. Oxygen catalyses the *cis–trans* isomerisation process in PA and initiates the chemical oxidation of PA, i.e. it acts as a dopant of the acceptor type. At the same time the oxygen takes part in chemical reactions with the PA which result in degradation of the latter.

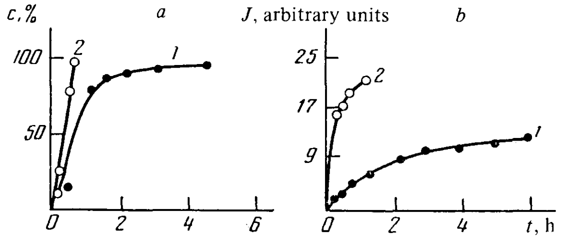


Figure 1. Kinetics of the change in the concentration of the *trans* isomer of PA (from i.r. data) (*a*) and in the concentration *J* of free radicals in PA (from ESR data) (*b*) as a function of the hold time *t* of the sample at 383 K (*1*) and 493 K (*2*) (from Ref.28).

No detailed studies of the effect of oxygen on the structure and properties of PA have yet been reported. Most workers give only a qualitative estimate of the effect of oxygen on their measurements (for example, they quote the dependence of a measured parameter on the time of exposure of the sample to air or to an oxygen atmosphere). However, oxygen has a marked effect on the paramagnetism of PA, as was clearly shown by Bernier and co-workers:[27] in the absence of oxygen these workers observed in *cis*-PA a broad signal from a catalyst present at a concentration of 0.2% of the number of CH groups, but after contact with oxygen this signal was completely suppressed, and was replaced by a narrow ESR signal of increasing intensity which was attributed to *trans*-PA.

Studies of the paramagnetic susceptibility χ of the *trans* isomer at 0.03–300 K have revealed the presence of Curie paramagnetism: the magnetic susceptibility χ_c is proportional to $1/T$.[4,16–18,35–41] Curie paramagnetism has also been observed[4,22,23] in *cis*-PA at 2–295 K. However, according to Tomkiewicz and co-workers[18] the magnetic susceptibility of the *cis* isomer is not described by Curie's law at 4–300 K. The reason for these discrepancies is not clear.

III. TYPES OF PARAMAGNETIC DEFECT IN PURE PA

All the experimental results obtained by ESR, ENDOR, and NMR methods indicate the presence of an unpaired electron in the π system. Careful measurements of the *g*-factor in undoped PA, and also in the *cis* and *trans* isomers doped with AsF_5, showed[19] that in every case

$g = 2.002634 \pm 0.000015$, which is much higher than the g-factor for the free electron (2.0023). These high values of the g-factor are characteristic of an unpaired electron in a π system.[10,11]

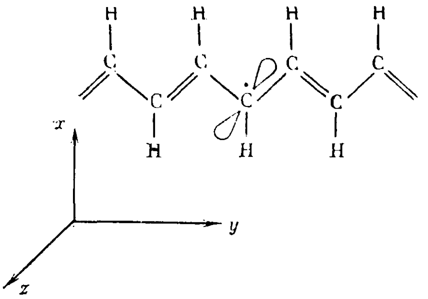

Figure 2. Orientation of the polymer axis with respect to the 2p π orbital of the paramagnetic defect in *trans*-PA.

In an ideal stretched film of $(CH)_x$ all the fibril axes (y) and therefore also the axes of the polymer molecules are oriented in the stretching direction. Partial orientation of the fibrils can be obtained by stretching the sample (film) in a particular direction.[42] The appearance of g-factor anisotropy in such a film can be explained in terms of the nature of the 2p π orbital of the paramagnetic defect (see Fig.2): the unpaired π electrons occupy atomic orbitals perpendicular to the y axis (the fibril axis). ESR measurements[43] in the millimetric region gave very precise values of the g-tensor for the *cis* and *trans* isomers in oriented and in non-oriented samples at temperatures in the range 4.2–300 K. For *cis*-PA they found $g_{\|} = 2.004$ and $g_{\perp} = 2.003$ {where $g_{\|}$ and $g_{\perp}$ are for magnetic fields parallel and perpendicular (respectively) to the axis of the polymer chain}. These values of the g-tensor components agree with published data.[44]

The components of the g-tensor have also been calculated[43] by a special variant of the molecular orbital method[45] for *cis* and *trans* $(CH)_n$ fragments where n is an odd number between 5 and 15. In chains with $n \geqq 9$ the g-factor has become independent of n, and can therefore be interpreted as the g-factor for a long fragment. The calculations were made for structures with C–C bonds of equal length and for structures with alternating double and single bonds. The g-tensors calculated for these two types of structure (with $n \geqq 9$) were equal to the experimental values: according to the calculation $g_{\|} = 2.0034$ and $g_{\perp} = 2.0028$. The g-factor anisotropy ($|\Delta g| = |g_{\|} - g_{\perp}|$) for the 2$p$ π electron in small molecules with conjugated bonds is usually 0.001–0.002.[46] The smaller value of this difference observed experimentally[43,44] can be attributed to a lower level of orientation of the polymer chains.

The components of the hyperfine interaction (HFI) tensor of the electron with the protons and the ^{13}C nuclei for *cis*-PA (with a 99% enrichment in ^{13}C) have been determined[43,47–49] by the ENDOR method (see Section IV). The symmetry of the tensors and the relative values of the isotropic and the anisotropic components suggest that the unpaired electron occupies a π orbital. This conclusion is confirmed by an ENDOR study[50] at 77 K of *cis*-PA films in which the polymer chains had been oriented by stretching the sample.

The presence of an unpaired electron in the π system is observed also in the NMR spectra, because local electronic configurations produce local anisotropic fields which interact with the magnetic nuclei. The high-resolution NMR technique has been used[51] to determine the diagonal elements of the chemical shift tensor (σ_{11}, σ_{22}, σ_{33}) on ^{13}C for the *cis* and *trans* isomers. Both isomers gave values of the tensor components typical of conjugated systems.

A study[52,53] of a mixture of PA isomers and of the pure *trans*-PA isomer by the electron spin echo (ESE) method showed that localised defects (possibly consisting of σ radicals) are present in PA in addition to the delocalised π defects. The concentration of localised defects is approximately 100 times lower than the concentration of delocalised defects, and therefore the magnetic behaviour of the system as a whole is determined mainly by the π defects.

IV. DELOCALISATION REGION OF THE UNPAIRED ELECTRON AND SPIN DENSITIES IN PURE PA

Table 1. Components of the HFI tensor (in MHz) for ^1H and ^{13}C (99% enrichment) in *cis*-PA, calculated from measurements at 136 K (Ref.47).

Index	^1H			^{13}C		
	A_x	A_y	A_z	A_x	A_y	A_z
1	−0.5	−2.1	−1.1	−1.3	−1.3	−2.1
2	−1.8	−7.0	−3.9	−3.1	−3.1	7.0

Detailed studies of spin densities in solids are usually made by the ENDOR method. Table 1 shows the components of the HFI tensors obtained[43,47–49,54] from the characteristic ENDOR frequencies of *cis*-PA 99% enriched in ^{13}C. The experimental ENDOR spectrum for ^1H and ^{13}C is described by two pairs of tensors (of index 1 and 2) corresponding to the two types of carbon and hydrogen atom. The HFI tensor components given in Table 1 were obtained by numerical modelling of the experimental spectrum allowing for all the interactions of the electronic and nuclear spins in all the magnetic fields present in the system and using the appropriate relaxation times. As Table 1 shows, the HFI tensor for ^{13}C is characterised by an axial symmetry and small values of the isotropic HFI constants, typical of defects in the π system. The symmetry and the relative values of the diagonal elements of the tensor for the HFI with the ^1H nuclei are the same as for the α protons.[13] Thus both the symmetry and the value of the tensor elements for ^{13}C and for ^1H unambiguously indicate the presence of a paramagnetic defect (unpaired spin) on a π orbital and the existence of two types of carbon atom with an unpaired electron.

The following spin densities of the unpaired electron on carbon were calculated from the HFI tensors for ^{13}C (Table 1): $|\rho(C_1)| = 0.06$ and $|\rho(C_2)| = 0.02$.[47] Studies by triple electron–electron resonance[47] showed that the spin densities on these two types of carbon atoms have different signs: $\rho(C_1)$ is positive and $\rho(C_2)$ is negative, and these densities are alternating along the polymer chain. The signs and amplitudes of the spin densities suggest a substantial delocalisation of the π orbital on a region of the chain approximately 47 CH units long (i.e. ~100 Å). An estimate of the total number of atoms ($2n + 1 \cong 47$) in the paramagnetic fragment is obtained from the condition $n\rho(C_2) + (n + 1)\rho(C_1) = 1$.[43] The interaction of the paramagnetic defect with the protons in 70% *cis*-PA is also thought[55] to be characterised by two sets of HFI parameters, corresponding to two values of the spin density on the carbon atoms differing in magnitude and in sign. In 70% *cis*-PA the delocalisation region of the unpaired electron was calculated[55] to be 93 CH units, i.e. double the value given in Refs. 43 and 47.

The spin density has been calculated[43] by the methods of Hückel and McLachlan (of which the latter gives a negative spin density in π radicals) for $(CH)_n$ fragments with odd values of n between 3 and 99. Two types of structure were considered: with bonds of equal length and with alternating bond lengths. The latter model of the $(CH)_n$ fragments gave a qualitative agreement with experiment: an alternation of the signs along the chain, but the absolute density values show a large scatter which should prevent the formation of a resolved ENDOR spectrum (though such a spectrum is observed experimentally). The hypothesis of uniform bond lengths in $(CH)_n$ fragments with odd values of n has not so far been tested by any other method. Since the total number of carbon atoms associated with one spin in *trans*-PA is ~3000,[22] the 47 carbon atoms in the fragment with an unpaired electron and equal bond lengths accounts for only 1.6% of the total number of carbon atoms in the sample.[43] A calculation[50] of the frequencies of the ENDOR spectrum using the spin densities specified by the soliton theory[56,57] gave the best agreement with experiment when the corrections for negative spin densities were used. However, no definite conclusion as to the distribution of spin densities could be reached[50] from the ENDOR spectra obtained in this work.

The ENDOR spectrum of *trans*-PA is reported[55,58] to be singlet. The delocalisation of the paramagnetic defect in *trans*-PA is thought[55] to be very extensive, i.e. each carbon atom in the delocalisation region carries only a small fraction of the spin density. Therefore the hyperfine structure (HFS) is unresolved even when the ENDOR method is used.

V. VIEWS ON THE MOTION OF A PARAMAGNETIC DEFECT IN PA

The DNP method[12] has been widely used in studies of the static and dynamic characteristics of unpaired electrons in solids. It was first applied to the study of paramagnetic defects in PA by observing the NMR proton signal[59-61] in a saturated u.h.f. transition at a frequency close to the ESR resonance frequency (ν_e = 8190 MHz). Two extreme cases are possible, depending on whether the electron–nucleus interaction is static or dynamic.[9] For a static interaction the unpaired electrons are "fixed" in space (at least, their jumping frequency is smaller than the NMR frequency, ν_n), and forbidden transitions at the frequency $\nu_e \pm \nu_n$ are induced by the electromagnetic field. This is the so-called solid effect. On the other hand if the unpaired electrons are mobile (on the time scale of the frequency ν_e) the intensity of the NMR signal may be increased at the frequency ν_n (the Overhauser effect). In pure *trans*-PA at 300 K a single Overhauser effect was observed,[61] whereas a mixture of the *cis* and *trans* isomers gave a superposition of the Overhauser effect and of the solid effect. In the mixed samples the proportion of the Overhauser effect increases with the content of the *trans* isomer (see Fig. 3). In Ref. 62 the same signal is obtained as in Ref. 61 for the mixture of isomers, but a weak solid effect is reported, in addition to the Overhauser effect, for the pure *trans*-PA. This discrepancy may be due to an impurity of the *cis* isomer in the latter case.[62] The following conclusions were formulated from the results of Ref. 61: 1) in the *trans* isomer the unpaired electrons are mobile, and the lower limit of their diffusion rate is ~5 × 10^{10} rad s^{-1} (determined from the ESR working frequency ν_e); 2) in *cis*-PA the unpaired electrons are fixed; 3) during the *cis*–*trans* isomerisation some previously fixed unpaired electrons become mobile.

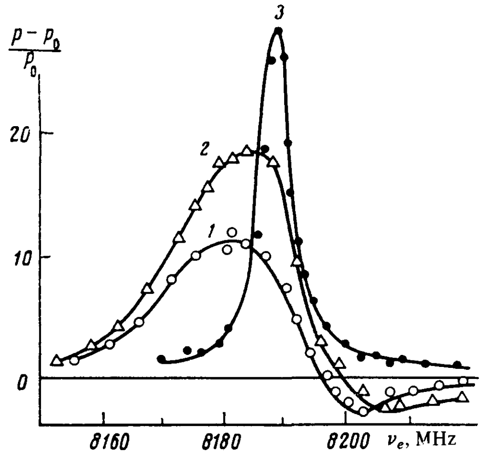

Figure 3. Increase in the amplitude of the ^{1}H NMR signal at different frequencies ν_e of the saturating field for concentrations of the *trans* phase in undoped PA of 50 (*1*), 65 (*2*), and 100% (*3*); T = 300 K (P_0 and P are the NMR signals without microwave saturation and with saturation respectively).

On cooling *trans*-PA we produce a change in the DNP signal: the characteristic signal of the pure Oberhauser effect (observed at room temperature) is replaced at 5.5 K by a signal corresponding to the solid effect.[63,64] The electrons which are mobile at high temperatures are slowed down, and their characteristic frequency, inversely proportional to the time of residence of the unpaired electron near the nucleus (i.e. the characteristic velocity of the electron), becomes smaller than the NMR frequency (10^7 s^{-1}). A smooth change from the Oberhauser effect to the solid effect has been observed[65] during temperature changes from 300 to 4 K (the two effects being comparable at 40–50 K). The exposure of *trans*-PA to oxygen produces the same effect as cooling the sample:[60] the presence of O_2 "freezes" the motion of the unpaired electron. The superposition of the signals corresponding to the Oberhauser effect and to the salt effect in the presence of air has been observed previously in other conjugated polymers.[66]

The study of the components of the g-tensor (ESR in the millimetre band) and of the HFI tensors (ENDOR spectra) for PA at 4–300 K led to the conclusion[43,47] that the paramagnetic centres are mobile in the *trans* isomer and fixed in the *cis* isomer. The presence of mobile paramagnetic centres in *trans*-PA is indicated also by ESE measurements on protonated and deuteriated samples at 4–300 K.[51-53,67,68] Masin and co-workers[69] concluded from the kinetics of the damping of the NMR signal of ^{13}C that unpaired electrons are not generally found in PA. However, it has been pointed out[70] that this conclusion may be valid only for the particular samples studied in that work.[69]

VI. QUANTITATIVE CHARACTERISTICS OF A MOBILE PARAMAGNETIC DEFECT

The motion of the paramagnetic centre in PA is usually described in terms of the measured nuclear (T_{1n}) and electronic (T_{1e}) relaxation times by using formulae for two models of the motion: one-dimensional diffusion of the paramagnetic centre along the polymer chain and three-dimensional diffusion of the nuclear spin polarisation towards a fixed paramagnetic centre. For the first model of the motion a theoretical expression which had been previously applied in studies of the conducting tetracyanoquinodimethane (TCNQM)[61] has been proposed:[71-73]

$$T_1^{-1}(n) = kT\chi\left[\frac{3}{5}d^2 f(\omega_n) + \left(a^2 + \frac{7}{5}d^2\right) f(\omega_e)\right] \qquad (1)$$

Here χ is the normalised spin susceptibility ($\chi = \chi_{mol}/\nu(g\mu_B)^2$, where ν is the concentration of paramagnetic centres); a and d are the constants for the isotropic and the dipolar electron–proton interaction respectively; $f(\omega)$ is the spectral density function; ω_n and ω_e are the Larmor frequencies of the nuclear and the electron spin respectively; μ_B is the Bohr magneton.

Eqn.(1) is valid when the electronic and the nuclear Zeeman energies are much less than kT, i.e. at relatively high temperatures ($T > 4$ K). For the one-dimensional diffusion of the paramagnetic centre, allowing for the HFI, the function $f(\omega)$ takes the form[74]

$$f(\omega) = \frac{1}{(2W_\parallel\omega)^{1/2}} - C_L;\ C_L \approx 0{,}37\frac{L}{W_\parallel} \qquad (2)$$

where $W_\parallel$ is the diffusion rate of the electron along the chain, and L is the size of the delocalisation region.

The quantity $W_\parallel$ is related to the diffusion constant $D_\parallel$ by the expression

$$W_\parallel = D_\parallel b^{-2}$$

where b is the distance between the CH fragments along the chain of *trans*-PA ($b = 2.46$ Å). At low frequencies the one-dimensional diffusion can be perturbed by inter-chain jumps, so that the system behaves as two- or three-dimensional. The transition from one-dimensional to two- or three-dimensional motion occurs at the frequency $\omega_c = W_\perp$, where $W_\perp$ is the rate of inter-chain diffusion.

In the model which assumes diffusion of the polarisation of the nuclear spin towards a fixed paramagnetic centre the expression for $T_1^{-1}(n)$ is[9]

$$T_1^{-1}(n) = \frac{4}{3}\pi\rho T_{1e}^{-1/4}(\mu_B/\gamma_n)^{1/4}\bar{D}^{3/4}\omega_n^{-1/2} \qquad (3)$$

where $\bar{D}$ is the diffusion constant of the polarisation of nuclear spins and ρ is the electronic spin density.

It follows from the usual model[9] of the diffusion of nuclear spin polarisation that $T_1^{-1}(n)$ is independent of the magnetic field strength at a frequency below the value for which $\tau_c < \omega_n^{-1}$, where τ_c is the characteristic damping time of the z-component of the magnetisation of the unpaired electron (assuming an exponential decay), located in the vicinity of a relaxing nucleus. The quantity τ_c is determined by the electronic relaxation time T_{1e} or by the electronic "flip–flop" transition time (more accurately, by the shorter of these two times). Under these conditions $T_1^{-1}(n)$ should be independent of temperature in the region of weak magnetic fields.

Since all the quantities which appear in formulae (1) and (3) are experimentally known we can determing $\bar{D}$ or $W_\parallel$ by measuring $T_1^{-1}(n)$. This determination of the diffusion coefficients of the electronic or the nuclear polarisation becomes incorrect if the system of nuclear spins cannot be characterised by a single spin temperature. Experimental dependences of T_1^{-1}(H) on ω_n at different temperatures have been obtained[61,66,71,75,76] for the protons of *trans*-PA. As Fig.4 shows, the dependence of T_1^{-1}(H) on $\omega_n^{-1/2}$ is linear in the experimental temperature range 0.45–295 K, and the straight line for room temperature passes through the origin whereas the lines for lower temperatures give a finite intercept ($\sim C_L$) on the horizontal axis.[75] Various workers[60,61,66,71,75,77,78] have explained the experimentally observed dependences of T_1^{-1}(H) on T and ω_n by postulating one-dimensional diffusion of the unpaired electron. Some believe[71,75] that even at 4 K 1.5% of the paramagnetic centres are mobile. Values of $W_\parallel = 4 \times 10^{13}$ rad s^{-1} and $D_\parallel = 4 \times 10^{-3}$ cm^2 s^{-1} were calculated[71] for 300 K. This value of the D diffusion coefficient is too high for a dielectric such as polyacetylene, and comparable with the D value for the metallic TCNQM salts.[72]

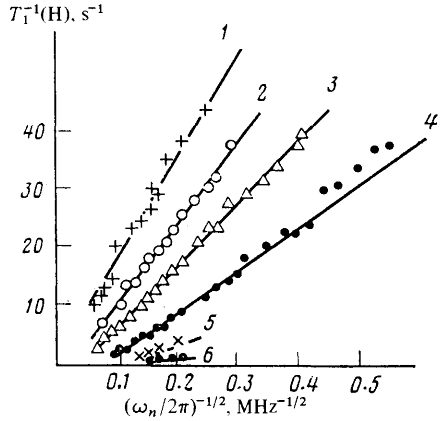

Figure 4. Rate of proton relaxation $T^{-1}(H)$ in *trans*-PA against $\omega_n^{-1/2}$ at 295 (*1*), 77 (*2*), 30 (*3*), 4.2 (*4*), 1 (*5*), and 0.45 K (*6*) (Ref.75).

The $W_\parallel$ value obtained from the ESE spectra[67,68,79] was three orders of magnitude lower than the above. The reason for this discrepancy is not clear, but a likely explanation is inadequacy of the chosen diffusion model. The $W_\parallel(T)$ dependence has been determined[71,75] from experimental data on the dependence of T_1^{-1}(H) on ω_n at different temperatures and on the dependence of the width of the ESR line (ΔH) on T. A similar $W_\parallel(T)$ dependence, i.e. an increase in $W_\parallel$ with T, was obtained from an analysis of the ESE spectra.[67,68,79]

The results of a study of the effect on $T_1^{-1}(n)$ of the isotopic replacement of hydrogen by deuterium[65] at 4.2 K were interpreted[65] by the model of the diffusion of nuclear spin polarisation towards a fixed unpaired electron. The calculated[65] threshold value of the magnetic field for which the $T_1^{-1}(n) \propto \omega^{-1/2}$ dependence (characteristic of one-dimensional diffusion) ceases to apply and the $T_1^{-1}(n)$ dependence becomes independent of the magnetic field is ~3 Oe, which is acceptably close to the experimental value (20 Oe). More recent results obtained[80] with *trans*-PA films (deuteriated, and enriched in ^{13}C) at room temperature are shown in Table 2. The $T_1^{-1}(n)$ values were measured on three samples containing different amounts of ^1H and ^{13}C. We can see from the Table that in the sample with a high concentration of magnetic nuclei $T_1^{-1}(H)$ exceeds $T_1^{-1}(^{13}C)$ by more than an order of magnitude. A similar result is reported in Ref.81, with $T_1^{-1}(H) \propto \omega^{-1/2}$, whereas $T_1^{-1}(^{13}C)$ is independent of frequency. The ^{13}C nuclei (in contrast to the ^1H and ^2H nuclei) show a non-exponential decay: the extent of damping varies with t approximately by a $t^{1/2}$ law. It was found[72] that the ^{13}C nucleus relaxes with two characteristic times (0.3 and 1.5 s), so that we should consider two different velocities: $T_1^{-1}(^{13}C) \cong 3\ s^{-1}$ and $T_1^{-1}(^{13}C) \cong 0.7\ s^{-1}$. Therefore the $T_1^{-1}(^{13}C)$ values given in Table 2 should be interpreted at best as the average of two velocities.

Table 2. Values of $T_1^{-1}(n)$ for three samples of *trans*-PA of different isotopic composition.

Sample	Isotope concentrations		ν, MHz	$T_1^{-1}(H)$, s^{-1}	$T_1^{-1}(^{13}C)$, s^{-1}
	$[^1H]$, %	$[^{13}C]$, %			
1	100	98	90	18±1	—
1	100	98	23	37.3±2	1.9±0.1
1	100	98	11.5	45±3	1.9±0.1
2	2	90	23	—	2.6±0.2
2	2	90	12	—	2.6±0.1
3	2	20	12	—	0.9±0.2
3	2	20	23	—	0.9±0.2

In planning the experiment with samples enriched in ^{13}C it was assumed[80] that $T_1^{-1}(H)$ and $T_1^{-1}(^{13}C)$ would have the same frequency dependence and absolute value, since the HFI constants of the unpaired electron in ^1H and ^{13}C are similar.[10,48,49,68] The assumption is valid if all the nuclear relaxation processes are determined exclusively by interactions with a mobile unpaired electron. From the lack of frequency dependence of $T_1^{-1}(^{13}C)$ (see Table 2) it follows that the results of the ^{13}C are not correctly described by the models which assume diffusion of the polarisation of electrons or nuclei. The following qualitative model of the relaxation for isotopic nuclei in the polymer chain was proposed.[80] In the case of nuclei in a polymer fragment containing a mobile paramagnetic defect the main relaxation channel is the HFI. Equilibrium between these nuclei and the others is reached as a result of the diffusion of nuclear spin polarisation: in other words, according to this model the system of nuclear spins cannot be characterised by a single spin temperature. Obviously, for a quantitative description of the experiments with ^{13}C further theoretical development of the unpaired electron diffusion model is required.† It has been suggested[65] that the views expressed in Ref.80 are the most likely to lead to a convincing explanation of the increasing volume of experimental $T_1^{-1}(n)$ data.

The rate of electronic spin–lattice relaxation T_{1e}^{-1} has been studied[84] in *trans*-PA in the frequency range 5–450 MHz at room temperature. For protonated and deuteriated samples the T_{1e}^{-1} values at frequencies ≥ 20 MHz are accurately described by the $T_{1e}^{-1} \propto \omega^{-1/2}$ relationship, previously established for the rates of proton relaxation.[61,66,71,75,76] The same relationship was obtained by other workers[68,82,83] at higher frequencies (9–17 GHz). At a frequency of ~20 MHz (with a field of ~6 Oe) a deviation from this relationship was observed,[84] and at frequencies < 10 MHz T_{1e}^{-1} was independent of frequency. The T_{1e}^{-1} values for deuteriated PA samples are somewhat lower (by ~50%) than the values for the protonated samples. The observed $T_{1e}^{-1}(\omega)$ frequency dependence was ascribed[84] to the one-dimensional diffusion of the unpaired electron along the polymer chain, and the frequency 10 MHz (3 Oe) was assigned to the inter-chain jumps.

As was stated above, the measurement of $T_1^{-1}(H)$ suggested that the diffusion ceases to be one-dimensional at a field strength of ~20 Oe, which is close to the value inferred from T_{1e}^{-1} data. A study[84] of the dependence of T_{1e}^{-1} on the concentration of paramagnetic centres in PA showed that the T_{1e}^{-1} value is determined by the dipole and hyperfine interactions of the unpaired electron with the protons. The coefficients and rate constants for diffusion of the unpaired electron were also determined,[84] and found to be close to the values determined[60,61,71] from measurements of $T_1^{-1}(H)$. We should stress that the interpretation of the T_{1e}^{-1} data is more unambiguous than the interpretation of the $T_1^{-1}(n)$ data, since the relaxation rate T_{1e}^{-1} is associated only with the diffusion of the unpaired electron.

The addition of dopants (Br_2, I_2, AsF_5) to PA has no effect[61,77,78] on the frequency dependence of the rate of proton relaxation $T_1^{-1}(H) \propto \omega_n^{-1/2}$, but it makes the relaxation rates $T_1^{-1}(H)$ and $T_1^{-1}(^{13}C)$ lower than in the pure PA.[1,67,69,77,78,85] The most marked decrease in these quantities is found by using AsF_5; I_2 and Br_2 have similar effects, almost an order of magnitude lower than that of AsF_5. The value $W_{\parallel} = 1.7 \times 10^{17}$ rad s^{-1} has been calculated[61] for PA doped with AsF_5: this is 10^3 times higher than the analogous value for undoped PA. The anisotropy ($W_{\parallel}/W_{\perp}$) is also not very different from that of the undoped polymer, i.e. ~10^6.

VII. PROPERTIES OF THE PARAMAGNETIC CENTRES IN PURE PA INFERRED FROM THE SHAPE OF THE ESR LINE

The shape of the ESR line depends on the properties of the paramagnetic centres in PA, but its analysis yields little quantitative information.# Early studies of the application of ESR to PA are mainly of historical interest, due to the fact that they stimulated the application of more advanced methods to the study of PA (ESE, ENDOR, and DNP).

The ESR signal in *cis* and *trans* PA is a singlet with $g = 2.0036$ (the measurements of the g-factor and g-tensor are discussed in Section III). Large differences are found between the determinations of the line width (ΔH) by various workers: from 7 to 9.5 Oe for the *cis* isomer[4,23,24,28,5] and from 0.28 to 5 Oe for the *trans* isomer,[60] i.e. the largest scatter occurs in the ΔH values for *trans*-PA. This is

---

†A further theoretical development of this model has appeared in a paper by P.K.Kahol, M.Mehring, and X.Wu (J.Phys.(Paris), 1985, v.46, p.1683).

#The same view is expressed in the theoretical paper by P.K.Kahol and M.Mehring (J.Phys.C, Solid State Phys., 1986, v.19, p.1045), whose aim was to demonstrate the unsuitability of the ESR method for determining spin densities and the delocalisation region of the unpaired electron from an analysis of the shape of the ESR line.

apparently due to differences in the preparative techniques used by different workers, since the parameter ΔH depends on the duration and temperature of the *cis–trans* isomerisation process, on the presence of oxygen, etc.

A special study[60] of the scatter in the measured values of ΔH suggested that the presence of uncontrolled amounts of oxygen is the main reason for the disagreement between the results of different workers. The smallest width of the ESR line obtained[60] by the meticulous application of all possible measures to prevent the access of oxygen to the system during all stages of the sample preparation and of the measurements was 0.44 Oe. This value is slightly higher than the value $\Delta H = 0.28$ Oe given in Ref.86. The line width $\Delta H = 1$ Oe in the spectrum of *trans*-PA is attributed[60] to the presence of 50 p.p.m. of oxygen. Special protective measures are needed to eliminate these very small contaminations.

The change from protonated to deuteriated PA produced a substantial narrowing of the ESR signal,[21,22,40] but a broadening of the ESR line was also reported[24] following the enrichment of *cis* and *trans* isomer samples with ^{13}C. The inconsistent changes in ΔH caused by isotopic replacement are due to differences in the magnetic moments of the nuclei ^{1}H, ^{2}H, and ^{13}C, and suggest the presence of an unresolved HFS. The absence of a resolved HFS in PA was initially attributed to exchange narrowing of the signal (see, for example, Refs.18, 19, 29, and 40). However, this work revealed a strong dependence of ΔH on T, which would not be expected for line narrowing by the exchange mechanism.[22,24,40,87] Fast one-dimensional motion of the paramagnetic centres has been suggested[22,40,60,63,87] as the reason for the narrowing of the ESR line.

The ESR line for *cis*-PA is Gaussian.[1] For the *trans* isomer in the temperature range 0–296 K a Lorentzian line, characteristic of exchange interaction, has been observed.[19] A Lorentzian line was reported[87] even when the temperature was lowered to 2 K, but deviations from this form were later observed. There have been attempts[22,56,60,63] to model the experimental spectrum by allowing for dipole–dipole and hyperfine interactions, repulsion between the electrons, and the one-dimensional diffusion of the unpaired electron along the chain. The model proposed in Ref.60 gives the best description of the experimental results. An analysis of the experimental line by this model showed[60,63] that the shape of the ESR line is different in different samples, and that it depends on temperature and on the presence of oxygen. In other words, it was made clear that the shape of the ESR line is not a fundamental property of PA itself. The width of the ESR line was not calculated exactly,[60] but the broadening due to the motion of the unpaired electron ($\Delta H = 0.15$ Oe) was estimated, and used to calculate the rate of diffusion along the chain $W_{\|} = 8 \times 10^{12}$–$8 \times 10^{13}$ rad s^{-1}. This value of $W_{\|}$ agrees well with the value deduced from measurements of $T_1^{-1}(\mathrm{H})$ (6×10^{13} rad s^{-1}).[59]

This work[60] is the only reported instance of consistent diffusion rates $W_{\|}$ obtained from ESR and NMR measurements. The $W_{\|}$ values obtained by the two methods usually differ by a factor of 10–10^3.[60,88] According to calculations[22] based on an analysis of the ESR line shape ($\Delta H = 4$ Oe) the delocalisation region of the paramagnetic centre in *cis*-PA is ~14 CH units. For *trans*-PA a calculation of the second component M_{2e} of the ESR line[71] gives a delocalisation region of ~10 CH units for the soliton model of the distribution of spin density[56,89] or ~7 CH units if the spin density is assumed to be constant within the delocalisation region. However, by using the ENDOR values[43] of the spin density (see Section IV), which correspond to a delocalisation length of ~50 CH units, we again obtain good agreement between experiment and calculation for M_{2e} in protonated and in fully deuteriated PA. The calculation of the difference ΔM_{2e} by the formula[71]

$$\Delta M_{2e} = M_{2e} - M_{2e}^{*} = 140\Sigma\rho_i^2 \qquad (4)$$

where M_{2e} and M_{2e}^{*} are the second components of the ESR line for protonated and for deuteriated PA respectively, gives similar values for substantially different distributions of the spin density. Thus, $\Delta M_{2e} = 20$ Oe^2 for a constant ρ_i over a fragment 7 CH units long and $\Delta M_{2e} = 14$ Oe^2 for the model in which ρ_i is distributed (with a sign alternation) over 47 CH units.[43] The experimental value of ΔM_{2e} is 20 ± 4 Oe^2.[80]

VIII. CHARACTERISTICS OF DOPED PA FROM THE CHANGES IN PARAMAGNETIC SUSCEPTIBILITY AND FROM THE ESR SPECTRA

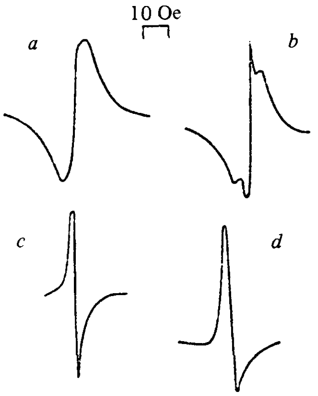

Figure 5. ESR spectra of *cis*-[CH(AsF$_5$)$_y$]$_x$ at room temperature and different dopant concentrations: (*a*) pure PA, (*b*) $y = 5 \times 10^{-4}$, (*c*) $8 \times 10^{-3} \leq y \leq 2 \times 10^{-2}$, (*d*) $y = 0.08$ (Ref.95).

The addition of the dopant Z (at concentration§ y) to PA produces a doped PA of composition (CHZ$_y$)$_x$ which has some of the properties of a metal, including electrical conductivity. According to Dyson's general theoretical considerations[90] on paramagnetic additives in metals an increase in y for (CHZ$_y$)$_x$ can result in asymmetry of the ESR line. In a large enough sample of doped PA, for which the sample thickness is greater than the depth of the skin effect at the ESR frequency, a typical Dyson (asymmetric) ESR line is observed (see Fig.5).[83,86,91–95] If the PA sample is thinner than the skin layer the line stays symmetrical even at high values of y.[96–99] Some workers[3,96,97] observed only one ESR line in PA doped with Li, Na, or Br$_2$, others[84,86,91,95,98] found two lines for p- and n-type dopants at low y, with different widths and a g-factor equal to that of the free electron, but at high doping levels ($y \geq 0.03$) only one line was observed (Fig.5). The combination of a broad and a narrow line is characteristic of different dependences of the intensity and shape of the line on the temperature, u.h.f.

---

§ The concentration y is defined as the number of molecules of dopant per CH unit.

power, and on the presence of NH_3 impurities. The broad line has been assigned[86,91,95,98] to a *trans* fragment in *cis*-PA, and the narrow line to *trans*-PA. According to some workers[86,95,97,98] the change in shape of the ESR line of *cis*-PA as a function of y suggests a large non-uniformity in the distribution of the dopant in the polymer, uniform doping in *cis*-PA being effectively impossible because of the presence of segments of the *trans* isomer. In this sense *trans*-PA is more easy to dope uniformly, but even for this isomer we can only expect a moderate degree of uniformity in the distribution of dopants in the sample.

According to Shirakawa[42] the Curie paramagnetic susceptibility χ_C is very sensitive to the degree of doping non-uniformity: the more uniform the dopant distribution, the lower is χ_C. Various methods of doping have been suggested to improve the uniformity: slow doping at low pressure,[36,37] cylic doping,[95] modified doping,[3] electrochemical doping,[96] etc. The structure of the dopant and its physicochemical properties[95] can also affect the doping uniformity.¶ The I_3^- ion is a linear cylindrical molecule with a diameter of 3.37 Å, and behaves as a weak electron acceptor; AsF_5 and SbF_5 are octahedral [owing to fluorine sharing (Editor of Translation)], with a maximum diameter of 6.24 Å, and have high oxidising power. These properties of AsF_5 and SbF_5 hinder their penetration into the fibrils, and therefore doping with iodine is more uniform than doping with AsF_5 or SbF_5. The formation of a concentration gradient of dopant within the fibril has been suggested[37] as part of a simple model of the dopant distribution which gives a good agreement between calculated and experimental values of the magnetic susceptibility.

Studies[86,91,95] of the ESR spectral changes of *cis*-PA caused by doping showed that doping can initiate *cis–trans* isomerisation, and that this effect is a characteristic of PA. Electrochemical doping of *cis*-PA with lithium did not produce significant changes in the intensity of the ESR signal.[91,96] Doping (like isomerisation) takes place at the surface of the sample in the initial stages). This accounts for the appearance of a compensation effect† in the ESR signal in the initial stages, resulting in slight swelling of the polymer and a small change (by ~15%) in the *cis*/*trans* isomer ratio.[86,95] Lengthy exposure to the dopant results in diffusion along the fibrils,[86,91] which is a slow process, and the *cis-trans* isomerisation now takes place in the bulk of the sample. At this stage of doping the concentration of defects can no longer be significantly decreased by compensation effects.[86]

A threshold concentration of dopant is needed to initiate the isomerisation;[91,96] its value is largely determined by the chosen doping technique.

It has been reported[91] that high rates of introduction of the additive yield smaller y values than lower rates. This is because at high rates the concentration of dopant on the fibril surface can rapidly reach the value which initiates isomerisation. At low doping rates there is time for the dopant to diffuse into the fibril and reach a *trans* segment. Since in *trans*-PA the oxidation potential (ionisation potential) is slightly lower[96] than in *cis*-PA we may expect preferential doping of the *trans* segment. In PA samples containing a large proportion of the *cis* isomer the addition of impurities at first initiates *cis–trans* isomerisation, followed by doping of the *trans* segments. The slight inconsistencies between the threshold values (y) of the dopant concentration reported by different workers can be attributed to differences in the isomer composition of the initial sample or to differences in the doping techniques.[91]

The isomerisation process is followed by charge transfer to the paramagnetic defect, which converts it into the diamagnetic state. This mechanism was established[91] from the time-changes of the ESR spectrum after doping. If the doping process is stopped at the instant when two superimposed singlets appear, after some time (~1 h) the narrow singlet from *trans*-PA disappears, leaving only the signal from *cis*-PA.

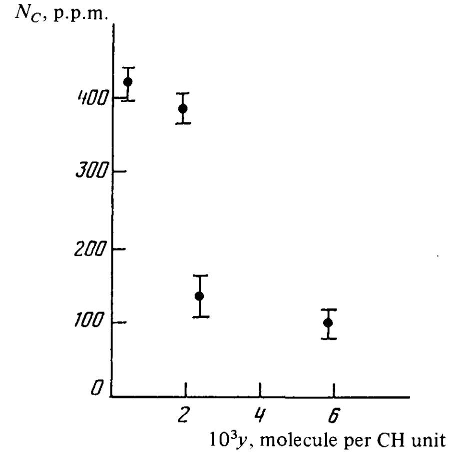

Figure 6. Change in the concentration of Curie spins N_C with the concentration of $AsF_5(y)$ in *trans*-PA (Ref.36).

By combining the ESR method with the Faraday compensation method it was shown that the addition of dopants to the *cis* and the *trans* isomers affects the nature and magnitude of the paramagnetism.[18,20,35-39,83,86] Thus, adding AsF_5 to *trans*-PA was found[36] to lower χ_C more than 400-fold for an increase in dopant concentration from 0.001 to 0.05. The change in spin concentration N_C corresponding to the paramegnetic Curie susceptibility for low concentrations of AsF_5 is shown in Fig.6. For *cis*-PA lightly doped with lithium ($y < 0.003$) the parameter χ_C decreases as y increases.[91] Under these conditions the temperature-independent Pauli paramagnetism is still insignificant (Pauli paramagnetic susceptibility $\chi_P \leq 5 \times 10^{-8}$ cm^3 mole^{-1}). In PA samples with a high concentration of AsF_5 only Pauli paramagnetism was observed[18-20,23,25,35-37,83,93] ($\chi_P \cong 10^{-6}$ cm^3 mole^{-1}). Doping with iodine did not produce Pauli paramagnetism even at high dopant concentrations.[38,39,99] Using AsF_5,[20,36] I_2,[37] and Na[97] as dopants produced a discontinuous increase in χ_P at concentrations in the region of 0.04–0.07. Fig.7 shows the dependence of χ_P on y[100] for samples doped with I_2 and AsF_5, and also the dependence of the conductivity σ on y. Clearly, we have a concentration range ($y < 0.05$) in which χ_P is still small but σ is already approaching the value corresponding to the metallic state. In contrast to

---

†The compensation effect can be described as follows: at low doping levels the effects of donor (or acceptor) additives are suppressed by the subsequent addition of impurities of the "opposite" type i.e. acceptor (or donor) additives respectively.

this report, Pauli paramagnetism was observed[35] at very low concentrations of AsF_5 ($y \cong 0.005$), coupled with a smooth increase in χ_P with increasing y. Later work[101] showed the reason for this discrepancy between the experimental results. In Ref.35 the concentration of paramagnetic centres was determined by the ESR method, which gives a large error in the double integration due to the large asymmetry of the line. In Refs.36 and 100 the Schumacher–Slichter method[102,103] was used, which allows the absolute value of the paramagnetism to be calculated more precisely than the ESR method.

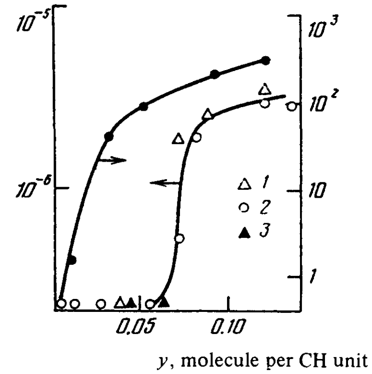

Figure 7. Dependence of the Pauli magnetic susceptibility χ_P and of the conductivity σ on the concentration of AsF_5 and I_3^- dopants.[100] The χ_P value for AsF_5 was obtained by the Faraday method (*1*) and from ESR data (*2*); the value for I_3^- by the Faraday method (*3*).

It has been suggested[4] that the carriers of charge and of paramagnetism are different species in PA, since the conductivity and the magnetic susceptibility have different temperature dependences: $\sigma \propto \exp(-AT^{-1})$ and $\chi_C \propto T^{-1}$. Other workers[19] came to the same conclusion. No correlation was observed[20] between the increase in magnetic spin susceptibility and the increase in σ when small amounts of AsF_5 were added to *trans*-PA (see also Fig.7). Different views are held at present on this behaviour of the electrical and magnetic characteristics of doped polyacetylene.

Some workers[19,20,36,37] interpret their experimental results on the changes in magnetic susceptibility of lightly doped PA in terms of the neutral soliton model.[56,89] However, a detailed examination of the experimental data from this standpoint reveals a number of inconsistencies (see, for example, Refs.20 and 54). Furthermore, neither the results of experiments with strongly doped PA nor the existence of a transition region in the $\chi_P(y)$ relationship are explicable in terms of the soliton model.

An alternative model[18,35] assumes the formation of metal-like regions, analogous to metal granules embedded in a dielectric. However, the application of this model also encounters serious difficulties.

IX. STRUCTURAL CHARACTERISTICS OF PURE AND OF DOPED PA FROM ^{13}C NMR DATA

The NMR signal from ^{13}C nuclei (at their natural enrichment level of 6%) for pure PA, obtained by rotation through the "magic angle", is a narrow line located at 127 p.p.m. for *cis*-PA and 137.4 p.p.m. for *trans*-PA (relative to the Me_4Si signal).[51,52,104] In samples of *trans*-PA with a 30% enrichment in ^{13}C a weak additional peak is observed at 47 p.p.m. (its intensity is 3.4% of that of the main peak). This peak has been attributed[104] to carbon atoms in a state of sp^3 hybridisation, i.e. the carbon atoms of the methylene groups. These groups interrupt the continuous conjugation of the polymer chain, giving an average length of the conjugated regions in *trans*-PA of about 30 CH groups. A content of methylene groups of 3.4% is confirmed by the element analysis, according to which the formula of PA is more accurately written as $(C_{1.00}H_{1.03})_x$ than as $(CH)_x$.

The changes in intensity, shape, and position of the two ^{13}C NMR peaks (127 and 137 p.p.m.) produced as a result of *cis–trans* isomerisation by heating pure *cis*-PA have been studied.[104] The *cis*-PA line is lowered by heating, but its width and position are unaffected. The *trans*-PA line undergoes changes in width and position (by ~1 p.p.m.) as the amount of *trans* isomer increases. This has been interpreted[104] as evidence that 1) the structure of partially isomerised *trans*-PA is different from that of pure *trans*-PA, and very inhomogeneous, and 2) the *cis* isomer has an ordered structure.

Nutation NMR[105] on pure PA prepared from acetylene enriched in ^{13}C (initially containing 6% of $H^{13}C{\equiv}{}^{13}CH$ molecules) showed that two types of bond are present in *trans*-PA, of length# 1.37 and 1.43 Å. The splitting in the nutation NMR spectrum of the two peaks corresponding to these bond lengths is ~300 Hz. If fast interconversion of the two types of bond were possible (as the soliton model stipulates) the two peaks would be replaced by a single peak. Hence we conclude that the interconversion does not take place, or that it takes place slowly (with a frequency much lower than 300 Hz).

Measurements of the second component of the ^1H NMR proton line led to the conclusion[106] that even a small concentration of I_2 ($y \cong 0.05$) causes almost complete *cis–trans* isomerisation, whereas according to ^{13}C NMR data the isomerisation is not complete even at higher doping levels.[107–111] This discrepancy may be attributed to differences in doping method (see Section VIII).

Studies of the ^{13}C NMR spectra of samples of composition *trans*-$[CH(AsF_5)_{0.076}]_x$ and *trans*-$[CHK_{0.09}]_x$ showed[108] that the line shifts produced by doping towards lower fields (+9 p.p.m.) for AsF_5 and towards higher fields (−12 p.p.m.) for K (relative to the line for pure *trans*-PA) are chemical shifts (as also stated in Ref.109). In some earlier work[100,110] a different interpretation of these shifts had been proposed: the Knight shift. However, the Knight shift calculated[108] for these concentrations is only +2 p.p.m. Thus doping produces a change in the π electron density on the carbon atoms. As the π electron density is decreased (or increased) by one electron in the calculation the shift of the ^{13}C NMR line towards lower (or higher) fields is ~160 p.p.m. The reported[108] chemical shifts are satisfactorily consistent with the theoretical estimates (+12 and −14 p.p.m.) for the concentrations of AsF_5 and K used in those experiments.

The analysis of the ^{13}C NMR spectrum of the *trans*-$(CHI_{0.08})_x$ sample[108] showed (allowing for the fact that the true dopant was the I_3^- ion) that practically all the iodine atoms are converted into the I_3^- state and contribute to the charge transfer, and also that the peak at 47 p.p.m. for sp^3 hybridised carbon atoms is significantly stronger than in pure PA. This suggests a very slight degree of chemical compound formation between the iodine and the polymer,

---

#Similar values for the length of the C–C bonds were obtained by M.J.Duijvestijn, A.Manenchijn, J.Smidt, and R.A.Wind, J.Magnetic Resonance, 1985, v.64, p.461.

giving the fragment –CHI–. The volume of the undoped region was estimated[108] as 50%, since in the doped region the concentration of dopant was about double the average.

The ^{13}C NMR spectra for *trans*-$(CHBr_y)_x$ with $y = 0.661$ and $y = 0.103$ contain strong peaks in the 50 p.p.m. region. This indicates not only a high level of chemical compound formation between the bromine and the polymer (formation of the –CHBr– fragment) but also the formation of cross-links between neighbouring polyacetylene chains (the C atoms in the region of the cross-links are also in the sp^3 hybridisation state).[108]

---o0o---

The results of magnetic resonance studies have given valuable information on the structure and properties of pure and of doped PA. The average length of the continuous conjugation regions in the polymer chains has been determined (about 30 CH units), and the alternation of bond length in the chain has been confirmed. It was shown that the paramagnetic centre or defect mainly responsible for all the magnetic properties of PA is the π electron. The delocalisation region of the paramagnetic π defect is found to vary between 7 and 93 CH units. In the *cis* isomer the paramagnetic defects are immobile, but in the *trans* isomer they are mobile at $T \geqslant 50$ K and immobile at $T \leqslant 50$ K. Doping produces various structural and chemical changes in PA (*cis–trans* isomerisation, chemical changes of the dopant additives, reaction of the additives with the polymer, etc.). None of the models so far proposed can explain all the results obtained by magnetic resonance methods for PA: there is no generally accepted account of the mechanism of electronic and nuclear relaxation, various estimates of the size of the delocalisation region of the unpaired π electron are inconsistent, and existing models of the paramagnetic defect cannot explain the extensive group of reported magnetic measurements in a manner consistent with the results of electrical measurements. The ^{13}C high-resolution NMR method (and some of its modifications) appear to be the most promising approach to the structural study of PA.

While this review was being prepared the proceedings of two international conferences and of an international school on organic conductors, including PA, were published.[112–114] Most of the recent publications are new developments of previously formulated ideas, and they do not affect the main conclusions of the present review on the structure of PA. However, two recent papers deserve special mention for suggesting new ideas as well as improved experimental approaches.[115,116]

Holczer and co-workers[115] suggested that many of the effects observed in *trans*-PA could be attributed to surface phenomena, determined by specific aspects of the morphology of the polymer. Calculation shows that in PA synthesised by Shirakawa's method, with a specific surface of 10–100 $m^2 g^{-1}$, ~20% of all the chains (1/5 of the total volume) are in contact with the surface, whereas in a normal solid the proportion of the atoms located in the first surface layer is $\sim 10^{-8}$.

Chien and Schen[116] studied by ESR the effect of the molecular weight (MW) of PA on the magnetic properties. They found that many of the characteristics of PA (concentration of paramagnetic centres in undoped and in doped PA, relaxation times T_{1e} and T_{2e} in the doped isomers) are insensitive to changes in MW between 500 and 870 000. However, in undoped PA the time T_{1e} decreases as the MW increases.

The Radiation Polymerisation of Monomers Adsorbed on Solid Surfaces

M.A.Bruk

The present state of the study of the processes involved in the polymerisation, initiated by radiation, of monomers adsorbed on solid surfaces has been examined. Particular attention has been paid to the results of work on the quantitative description of the elementary stages of polymerisation on a surface.

The bibliography contains 97 references.

I. INTRODUCTION

The processes involved in the polymerisation of monomers adsorbed on solid surfaces have attracted considerable and increasing attention from research workers in the last 20 years. Interest in these reactions is due chiefly to their possible use for the solution of a number of practical problems. These processes are potentially convenient for modifying the surface properties of various solids (in particular mineral fillers, pigments, and chromatographic sorbents) and obtaining new materials (graft polymer fibres, films, and membranes, organic and mineral–organic ion-exchange materials, textile materials of various kinds, etc.).[1–4] In recent years there has been considerable interest in these reactions in connection with the problems of obtaining composite materials by polymerisation filling[5–7] and encapsulation.[8,9] The investigation of the characteristic features of the elementary stages of the polymerisation of monomers on a surface, and their relationship to the nature of the adsorption interaction of the monomers and polymers and the nature and actual structure of the solid support, is undoubtedly of independent scientific importance.

These reactions are initiated using special initiators,[10–14] ultraviolet radiation,[15,16] the mechanochemical method,[17] or an electric discharge.[18] Forms of ionising radiation, namely gamma-rays, X-rays, and fast electrons, are extremely convenient and are widely used in research practice. The processes of radiation-initiated polymerisation on a surface have now probably been most extensively studied. The examination of these processes is the main subject of the present review, which deals chiefly with the reactions involved in the radiation polymerisation of monomers on the surface of inorganic solids in adsorption systems of the "open" type. Polymerisation in clathrate complexes and inclusion compounds, which may be called adsorption systems of the "closed" type, was examined in Refs.19–22.

The topics examined in the present review have been dealt with to some extent in a number of review papers.[1,5,23,24] They have been examined most systematically (from data published up to 1972) in Ref.1; a fairly extensive bibliography is given in Ref.23. All these papers analyse chiefly the overall kinetic relationships for the processes involved in polymerisation on a surface. This is mainly due to the fact that studies of the mechanism and characteristics of the elementary stages in these reactions have been carried out only in recent years. In the present review, particular attention is paid to the results of studies of the elementary stages of the polymerisation. It may be noted that many of the conclusions about the characteristics of the elementary stages of radiation polymerisation on a surface, in particular the reactions of chain growth, transfer, and termination, also apply when other methods of initiation are used.

The reactions examined in the present review are described in the literature in different ways: polymerisation at a "gaseous monomer–solid" interface, grafting from the vapour phase or gas-phase graft polymerisation, polymerisation in adsorption layers, thin-layer polymerisation, etc. All these terms essentially refer to systems consisting of a solid, a monomer adsorbed on its surface (at different degrees of surface coverage, from fractions of a monolayer to tens and hundreds of monolayers), and the vapour of the monomer, present in equilibrium. The present review deals chiefly with systems in which a strong specific interaction between the polymerising group (the C=C bond) of the monomer and the solid (characteristic, in particular, of heterogeneous-catalytic polymerisation) does not take place. In most systems the main contribution to the adsorption interaction with the surface is made by the substituent at the double bond.

II. GENERAL REGULAR FEATURES OF POLYMERISATION ON A SURFACE

1. The Nature of the Active Centres of Polymerisation

The processes involved in radiation polymerisation on a surface have been studied chiefly in the temperature range from −50 °C to +100 °C. Under these conditions, both ionic and radical polymerisation chains may develop.

a) Ionic polymerisation

The irradiation of solids may lead to the production on their surface of various ionic active centres, whose lifetime is usually much greater than that of the ionic active centres in liquid monomers. This fact increases the probability of the development of ionic polymerisation chains on the surface. Unfortunately, there have been comparatively few studies of the processes involved in ionic radiation polymerisation on a surface.

It has been established[25-29] that in the polymerisation of styrene (ST) on various silicon dioxide specimens, the process takes place by cationic and radical mechanisms simultaneously. The polymerisation was carried out at temperatures close to room temperature, in comparatively thick adsorption layers (5–7 monolayers). The proportion of polymer formed by the cationic mechanism increases with increase in the quantity of aluminium impurity in the SiO_2. In specimens containing 10^{-2}–10^{-3}% aluminium, this proportion is 60–80%; at an aluminium concentration of ~1%, practically all the polymer is formed by the cationic mechanism, and, other conditions being equal, the rate of the process is several times that in the absence of impurity.[28] The mechanism of polymerisation in these systems was established by analysing the molecular mass distribution (MMD) of polystyrene (PST) formed under different conditions, including the use of inhibitors of different kinds. The molecular masses (MM) of the PST obtained by the radical mechanism are 10^5–10^6, and those for the cationic mechanism 10^3–10^4. In agreement with this, the gel-chromatograms of the PST show clearly defined bimodal character. The formation of low-molecular-weight PST is inhibited by ammonia, and that of high-molecular-weight PST is inhibited by benzoquinone.[26] The total activation energy of the cationic polymerisation of ST on silica gel is close to zero, and the kinetic order of the reaction with respect to the dose rate is ~0.7 (in the range 0.03–3 Gy s^{-1}).[27] Most of the cationic PST (~90%) is not grafted to the silicon dioxide surface. The radiation-chemical yield of the cationic polymerisation is ~10^4.

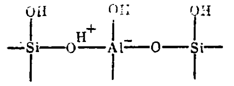
Similar results on the polymerisation of ST on SiO_2 were obtained in Refs.30–32. In an earlier paper,[33] however, a radical mechanism was proposed for the radiation polymerisation of ST on Degussa aerosil.

The low molecular masses of the cationic PST quoted in Refs.25–29 are attributed chiefly to non-degenerate chain transfer to the silicon dioxide surface, and in Refs.30–32 chiefly to effective chain transfer to the monomer. The two factors can apparently play a definitive role. It should be borne in mind, however, that the relative constant for chain transfer to the monomer in the cationic polymerisation of ST in the liquid phase is extremely high ($C_m \cong 2 \times 10^{-2}$ [34]); thus in polymerisation on a surface, chain transfer to the monomer alone may lower the MM of the cationic PST to the values observed experimentally.

In the analysis of the probability of the development of ionic chains in the polymerisation of a given monomer on a surface, it is necessary to take into account, in addition to other factors, the possible drying action of the solid on the system, due to the strong adsorption bonding of water.

The low-temperature radiation polymerisation of isobutene (IB) on silica gel (SG) has been studied.[35-37] The EPR spectrum of the IB–SG system, irradiated at −196 °C and −78 °C, indicates the presence of terminal polymer radicals $\sim\!-CH_2-\dot{C}(CH_3)_2$, showing that polymerisation takes place directly at the temperature of irradiation. The inhibiting influence of added methylamine on the yield of the terminal polymer radicals and the polymer indicates a cationic polymerisation mechanism. It is suggested that the terminal polymer radicals are formed as a result of the recombination of the growing cationic polymer chains with an electron liberated from a trap. The yield of these radicals depends on the IB concentration on the SG surface, and this dependence correlates with the concentration dependence of the yield of the polymer, determined gravimetrically after the temperature of the irradiated specimens had risen. In the region of the maxima on the two curves, corresponding to monolayer covering of the surface, the radiation-chemical yield of terminal polymer radicals at −196 °C is 1.5; the radiation-chemical yield of the inhibition of the polymerisation G_{in} was estimated by assuming that the number of these radicals is equal to the number of initiated polymerisation chains. It is important to note that the average number of polyisobutene macromolecules formed, determined from the values of the viscosity-average molecular masses ($M_\eta \cong 5000$), was found to be appreciably greater than the number of polymer radicals (by a factor of ~30), from which the authors correctly conclude that chain transfer reactions take place effectively during the polymerisation.

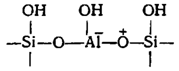
The following views were put forward[35-37] regarding the mechanism of chain initiation and transfer in the polymerisation of isobutene on silica gel. It is assumed that both processes are associated with the existence on the SG surface of Bronsted acidic centres, localised close to impurity aluminium atoms in tetrahedral configuration



$$-\mathrm{Si}(\mathrm{OH})-\overset{H^+}{O}-\mathrm{Al}^-(\mathrm{OH})-O-\mathrm{Si}(\mathrm{OH})-$$

(I)

The protons of these centres cannot initiate polymerisation in the absence of irradiation, since they compensate the negative charge of the aluminium atoms. On γ-irradiation, paramagnetic centres are formed in SG,[38] of the type



$$-\mathrm{Si}(\mathrm{OH})-O-\bar{\mathrm{Al}}(\mathrm{OH})-\overset{+}{\dot{O}}-\mathrm{Si}(\mathrm{OH})-$$

in which the hole is localised on an oxygen atom adjoining an aluminium atom. The proton of this centre is liberated, and can either capture an electron and be stabilised as a hydrogen atom, or add on to an IB molecule and form the carbonium ion $(CH_3)_3C^+$, which brings about polymerisation. The probable participation of the acidic surface centres of SG in the initiation of polymerisation is indicated by the fact that decrease in the acidity of the SG by preliminary treatment with alkali leads to a marked decrease in the yield of polyisobutene.[36]

It is suggested that the main contribution to the mechanism of chain transfer is made by the reaction of the growing macro-cations with the acidic centres of the SG surface of type (I), as a result of which the macro-cation neutralises the charge on the aluminium, and the liberated proton, by reacting with a monomer molecule, starts a new polymer chain. In the opinion of the authors,[35-37] the polyisobutene macromolecules are also formed as a result of the mutual recombination of terminal polymer radicals.

The results of studies of the radiation polymerisation of liquid monomers in the presence of various solid oxides,[39-44] examined in detail in Ref.39, are relevant to the subject of the present review. These studies were generally carried out under conditions in which the liquid monomer was poured over a layer of solid oxide powder; the concentration of the monomer was 40–80 mass %. In these studies, chiefly in work carried out in the Karpov Physicochemical Scientific

Research Institute,[39–41] the idea of a correlation between the semiconducting character of the oxides and the mechanism of polymerisation was put forward. It was shown that the *n*-type (electronic) semiconductors ZnO, TiO_2, and Cr_2O_3 facilitate the development of cationic chains, and the *p*-type (hole) semiconductors MgO, Cu_2O, and NiO the develpment of anionic polymerisation chains.

b) Radical polymerisation

Most studies carried out up to the present have dealt with monomer–support systems in which radiation polymerisation on the surface develops chiefly by a radical mechanism.[1,9,45,46] A radical mechanism of polymerisation is proved using data on the influence on the process of typical radical inhibitors (diphenylpicrylhydrazyl, O_2, benzoquinone) [33,45]† and data on the compositions of the copolymers and the kinetics of copolymerisation on a surface,[47,49] and on the micro-structure of the polymer chains formed.[47] Thus the processes involved in radical polymerisation on a surface have been studied in most detail. Subsequently, unless otherwise stated, radiation polymerisation by a radical mechanism is discussed.

2. The Adsorption Mechanism of Polymerisation

One of the first questions arising in the analysis of the mechanism of polymerisation on a surface, as in the analysis of other surface reactions, is the question of whether this reaction takes place by an "adsorption" mechanism or by a "collision" mechanism. In the first mechanism, the monomer molecules are adsorbed, migrate over the surface, and finally are added on to the active centre situated on the surface (the active terminal unit of the growing chain); the "working" concentration of the monomer is its concentration in the adsorption layer. In the second mechanism, the acts of chain growth take place when monomer molecules from the vapour phase collide directly with the active centre; here, the "working" concentration is the monomer concentration in the vapour phase.

The mechanism of polymerisation was a subject of discussion in the mid-sixties. In Refs.33, 45, and 46 it was concluded from overall kinetic data that polymerisation on a surface takes place by an adsorption mechanism. The main evidence was the decrease in the rate of polymerisation with increase in temperature at a constant monomer vapour pressure. The collision mechanism of polymerisation was developed in Refs.16, 50, and 51. In the opinion of these authors, this temperature dependence of the rate of polymerisation may be due to the destruction of active centres with increase in temperature, and a corresponding decrease in the rate of initiation of polymerisation.[50]

The results in Refs. 9, 47, and 53–55 apparently prove that polymerisation takes place by an adsorption mechanism in the systems studied. The dependence of the rate constants of chain growth k_g on the mechanism of adsorption and on the nature of the adsorption bonding between the monomer and the support, observed in these studies, can be understood only by assuming an adsorption mechanism of polymerisation. For example, as established in Refs.47 and 54, the change in the heat of adsorption of vinyl acetate (VA) on AS/400# in the range of coverage of about half a monolayer is accompanied by a fairly sharp (several-fold) change in k_g. An important feature is that this change in k_g at different temperatures (20 °C and 50 °C) takes place in approximately the same range of coverage, whereas the pressures in the vapour phase, corresponding to this range of coverage, differ by a factor of more than 20.

If the calculations are carried out using as working concentration the surface concentration of adsorbed monomer σ, the temperature dependence of the value of k_g for radical polymerisation is described by the Arrhenius equation with "normal" values of the activation energy of growth E_g.§ Similar calculations using the concentration of the monomer in the vapour phase give negative or anomalously low values of E_g.

In later papers on polymerisation on a surface from the vapour phase,[16,50,51] the authors conclude that polymerisation takes place by an adsorption mechanism.[52]

3. Thermal and Diffusion Processes Accompanying Polymerisation on a Support

For a correct analysis of the kinetics of polymerisation on a surface, it is necessary to estimate correctly the role of macrokinetic factors, such as, in particular, the possible non-isothermal nature of the process and the diffusion retardation in the transport of the monomers in real adsorbent specimens (porous granules, tablets, layers of powder, etc.). Unfortunately, in many papers these factors are not properly analysed.

When the dose rate is not too high, the heating of the specimens in the radiation field, not associated with polymerisation, is usually insignificant. At dose rates of 1–10 Gy s^{-1}, it generally does not exceed fractions of a degree. In the analysis of the possible non-isothermal nature of the system resulting from the heat liberated on polymerisation, it must be borne in mind that although the reaction zone usually makes up only a small fraction of the total volume of the specimen, a significant increase in temperature is possible, because of the low thermal conductivity of the specimens. For specimens of silicon dioxide in the form of tablets or powder with a specific surface of ~200 m^2 g^{-1}, a layer porosity of 80–90%, and characteristic layer dimensions of 0.5–1 cm, the increase in temperature as a result of the polymerisation of MMA and VA for monolayer coverage of the surface and dose rates of the order of 1 Gy s^{-1} is 1–10 K.[56] The increase in temperature increases considerably with increase in the degree of coverage of the surface by the monomer.

The correction to the stationary rate of polymerisation ν_{st}, taking account of the increase in temperature, in the case of experiments in a closed system with a small vapour phase volume ("without maintenance") can be calculated from the expression[57]

$$\nu_{st}/\nu_{st,0}=\exp\left[-\frac{E}{R}\left(\frac{1}{T_0+\Delta T_\infty}-\frac{1}{T_0}\right)\right]\simeq 1+\frac{E}{RT_0^2}\Delta T_\infty$$

---

†Because of the decrease in the "activity" of most inhibitors on a surface,[48] the quantities of inhibitor which are effective are much greater than the stoichiometric quantities.

#Here and subsequently, AS/200, AS/400, etc. denote aerosils treated in a vacuum at 200 °C, 400 °C, etc.

§Thus for example the values of E_g for the polymerisation of VA and methyl methacrylate (MMA) on an aerosil at a monolayer coverage of the surface by monomers are 17 kJ $mole^{-1}$ and 32 kJ $mole^{-1}$ respectively.[55]

where T_0 is the temperature of the thermostat, ΔT_∞ the stationary increase in temperature, E the total activation energy of the process, and $v_{st,0}$ the stationary rate under isothermal conditions. The quantity ΔT_∞ is related to the effective heat of polymerisation $-\Delta H_{eff}$ by the expression

$$\Delta T_\infty = \frac{-\Delta H_{eff}}{c}\,\frac{v_{st}}{a}$$

where c is the heat capacity of the system, and a an experimentally determined parameter characterising the rate of removal of heat from the specimen.

It is more difficult to take account of possible non-isothermal character in experiments in an open system "with maintenance", when an increase in the temperature of the specimen leads to a decrease in the equilibrium concentration of the monomer on the adsorbent; it is then necessary to solve simultaneously the equations for the kinetics of polymerisation, adsorption, diffusion, and thermal conductivity.

The influence of diffusion retardation in the layer of adsorbent on the stationary kinetics of polymerisation can be examined further. When the polymerisation is carried out under conditions in which the formation of the polymer produces a diffusion flux of the monomer in the specimen, the influence of diffusion retardation on the observed stationary rate of polymerisation (v_{st}) is revealed by a deviation of the distribution of the monomer concentration $\sigma(x)$ along the cross-section of the specimen from the equilibrium distribution, leading to a decrease in the observed rate of polymerisation, which starts to depend on the specimen thickness L. In those cases where the average decrease in the monomer concentration $\overline{\Delta\sigma}$ in the specimen is small compared with the equilibrium adsorption σ^*, the rate of polymerisation can be taken as approximately constant over the cross-section of the specimen. $\sigma(x)$ is then described by a simple parabolic law, and $\overline{\Delta\sigma}$ is given[56] by the expression:

$$\overline{\Delta\sigma} = v_{st}L^2/12D_{eff}$$

where D_{eff} is the effective diffusion coefficient of the monomer in the specimen. The coordinate x is measured from the centre of the specimen. The magnitude of the deviation has been analysed,[56] and it was shown, in particular, that in the polymerisation of VA, MMA, and ST on aerosil tablets with a thickness of ~2 mm, compressed at a pressure of 300 kg cm^{-2}, for degrees of coverage by the monomer of about one monolayer, a temperature of 50 °C, and a radiation dose rate of 0.35 Gy s^{-1}, the value of $\overline{\Delta\sigma}$ does not exceed 10% of σ^*.

In the case of polymerisation at low concentrations of adsorbed monomer, however, when it is necessary to carry out the reaction to degrees of conversion close to or greater than σ^*, the influence of diffusion retardation on the observed rate of polymerisation may be considerable. Decrease in the monomer concentration leads to a marked decrease in the value of D_{eff}, and this in turn also increases the influence of diffusion on the rate of polymerisation at low concentrations. Under these conditions, the dependence of the rate on the coordinate x cannot be neglected, and the distribution of the monomer concentration over the cross-section of the specimen for linear termination of the kinetic chains is described by the expression:[58]

$$\sigma(x) = \sigma^* \frac{\mathrm{ch}\{[(k_g/k_x)(v_i/D_{eff})]^{1/2}x\}}{\mathrm{ch}\{[(k_g/k_x)(v_i/D_{eff})]^{1/2}(L/2)\}}$$

where v_i is the rate of initiation, k_g the chain growth rate constant, and k_x the rate constant for linear termination. The observed rate of polymerisation is proportional to $1/L$.

4. Overall Kinetics of Polymerisation

The influence of the support on the rate of polymerisation of monomers on a surface can be examined first. Table 1 gives the values of the radiation-chemical yields for polymerisation in various systems, calculated from published data.[32,47,56] A noteworthy feature is the high values of the polymerisation yields calculated per unit of energy absorbed by the adsorbed monomer, G^*_{pol}; they are much greater than the values for the polymerisation of the same monomers in the bulk.¶ Similar results were obtained in other studies (see Ref.1). Thus for a number of systems, the supports have an appreciable accelerating action on polymerisation. The mechanism of this action will be examined below.

Table 1. Some overall kinetic characteristics of the radiation polymerisation of monomers on a surface (coverage of the surface by monomers about one monolayer, temperature 50 °C, dose rate 0.35 Gy s^{-1}).[32,47,56]

Monomer	Adsorbent	n_i^*	$10^{-4}\,G_{pol}$	$10^{-4}\,G^*_{pol}$	$10^{-4}\,G^b_{pol}$
VA	AS/400	1	0.7	12	3.5**
VA	AS/700	1	0.6	10	3.5**
VA	AS/900	0.8	—	—	3.5**

Notes. The specific surface of the adsorbents is ~200 m^2 g^{-1}. The polymerisation of all the monomers except ST takes place by a radical mechanism; the polymerisation of ST takes place by cationic and radical mechanisms simultaneously on an aerosil surface, and by a radical mechanism in the bulk. Notation: G_{pol} and G^*_{pol} are the radiation-chemical yields of polymerisation on a surface, calculated per 100 eV of energy adsorbed by the entire system and by the monomer respectively; G^b_{pol} the radiation-chemical yield of polymerisation in the bulk ("in the mass") in the initial stages; MA = methyl acrylate; BMA = butyl methacrylate.

*Dose rate range studied 0.05–5 Gy s^{-1}.

**Calculated from published data.[95]

***Methylated aerosil; specific surface ~60 m^2 g^{-1}.

****Temperature 25 °C.

Analysis of the available data shows (see for example Table 1) that in polymerisation on a surface, in contrast to processes in the liquid phase, linear termination of the kinetic chains is observed extremely frequently (the order for the dependence of the reaction rate on the irradiation dose rate, $n_i = 1$); the reasons for this will be examined below.

¶ The values of G^*_{pol} are proportional to the relative or reduced rate of polymerisation v/σ, expressed as fractions of the original quantity of the monomer on the surface in unit time (for example in s^{-1}).

The specific mechanisms of linear termination may be different in different systems. For the polymerisation on an aerosil of vinyl acetate and various other monomers with highly active growing radicals, the mechanism apparently involves degenerate chain transfer to the hydroxide groups of the surface and the formation of radicals whose activity is much lower than that of the growing macro-radicals; kinetically, this appears as chain termination.[47,59] This mechanism is confirmed, in particular, by the fact that with decrease in the concentration of hydroxide groups on the aerosil surface, for example as a result of an increase in the temperature of treatment to 900 °C, the rate of termination in the polymerisation of VA decreases, and n_i deviates from 1 towards lower values.[56] On a methylated aerosil not containing hydroxide groups, $n_i = 0.5$, that is quadratic termination of the kinetic chains takes place.[47] A similar mechanism of termination has been assumed[33] for the polymerisation of MMA on an aerosil; with increase in the quantity of polymer formed on the surface, n_i decreased from 1 to 0.5.

Chain termination associated with the occlusion of the growing macro-radicals is apparently fairly common. Complete "burial" of the growing active centre is not essential. A sufficiently marked decrease in the specific growth rate, due to a decrease in the local concentration of the monomer close to the active centre, will appear kinetically as chain termination. As an experimental indication of the role of occlusion phenomena in chain termination, data[60] on the radiation polymerisation of acrylonitrile (AN) on alumina fibres can be considered. n_i changes from 0.5 to 1 on going from the non-porous to the fine-porous fibre. An occlusion mechanism has been proposed for the deactivation of the growing macro-radicals in the polymerisation of acrylic acid on kaolin.[61] An occlusion mechanism of chain termination in the polymerisation of AN on KSK-2 silica gel was established by EPR.[62] Post-polymerisation and EPR methods have shown that in the polymerisation of MMA on an aerosil at a temperature of 25 °C, kinetic termination of all the growing radical chains is not accompanied by chemical destruction of the macro-radicals; for reasons which are not yet completely clear, the growing macro-radicals at a definite moment undergo occlusion immobilisation, as a result of which the specific growth rate decreases by a factor of ~300; with increase in the temperature of the system (for example to 70 °C), "reanimation" of the kinetic chains is observed.†

There are probably several forms of occlusion, for example: 1) self-occlusion of the chains in the fine pores as a result of the covering of the transport "windows" of the pores as chain growth proceeds; 2) occlusion in pores with small windows (particularly in dead-end pores), taking place as a result of the growth of other chains, which prevent the transport of the monomer into the pore; in this case, as noted by Kabanov (see Ref.1), n_i may be less than 1. It is more difficult to picture the occlusion immobilisation of a macro-radical growing on an open surface. In some systems with extremely weak adsorption interaction of the units of the macromolecule with the surface, deactivation of the macro-radical may take place as a result of a conformational change ("collapse") from an unfolded chain to a compact globule with localisation of the active centre inside the globule. The actual mechanism of the occlusion termination of the growing chains in polymerisation on the surface of solids has not been established for any system.

Linear termination of the growing radical chains on impurities, for example iron ions, is also possible. As far as the mechanism of the quadratic termination of polymerisation chains on a surface is concerned, it is possible that, because of the obvious retardation of the thermal diffusion of the macro-radicals on the surface (see also section V), in some systems a "reactive" or "chemical" mechanism of diffusion will predominate, where the meeting of the growing active centres and their disappearance take place as a result of their movement over the surface during the actual growth reaction.

Study of the temperature dependence of the rate of polymerisation has shown that the corresponding activation energy E_{tot} in different systems varies from 0 to 40 kJ mole^{-1}, and usually decreases with increase in the degree of covering of the surface by the monomer.[55,63] The latter is related[55] to the corresponding decrease in the activation energy of polymerisation chain growth E_g (see section V and Table 3).

High kinetic orders of the polymerisation with respect to the concentration of the adsorbed monomer have been noted.[1,64] The authors cited relate these results to the formation of associates of the monomers on the surface of the support. These results, however, are fully covered by the general concept based on the dependence of the chain propagation rate constant on the nature of the adsorption bonding and also on the degree of covering of the surface by the monomer and the thickness of the adsorption layer; this concept is developed below (see sections V and VI).

III. MOLECULAR AND STRUCTURAL CHARACTERISTICS OF THE POLYMERS FORMED

1. Structural and Conformational Characteristics of the Macromolecules and Their Distribution on the Surface

The structure of the macromolecules formed and their distribution on the support in relation to the processes of radiation polymerisation on a surface has been the subject of special study only in recent years. The molecular mass distribution of the polymers formed in the polymerisation of ST and MMA on silica gels has been studied[25-29,65,66] by gel-permeation chromatography (GPC). The polymerisation was carried out at extremely high monomer concentrations and degrees of conversion. The results were used chiefly for the separate determination of the yields of radical and ionic, grafted and non-grafted polymers. The fraction of grafted PST is very low (15–20%), whereas for polymethyl methacrylate (PMMA) this fraction is 70–80%. Under the conditions studied, ST was polymerised chiefly by a cationic mechanism, and MMA by a radical mechanism. The proportion of grafted PST is higher if the polymerisation is carried out as a result of the post-effect after preliminary irradiation of the silica gel in a vacuum.[29] The influence of the monomer concentration on the MMD of polystyrene obtained by the radiation polymerisation of ST on silica gel has been examined.[31] GPC has been used[67] to study the molecular characteristics of PST formed by the radiation polymerisation of ST in the porous structure of wood.

In the initial stage of the polymerisation of vinyl acetate on aerosil (at degrees of conversion up to one third of an effective monolayer), linear macromolecules are formed, and $\bar{M}_w/\bar{M}_n \cong 2$.[68] On further polymerisation, effective branching of the macromolecules and marked broadening of the MMD take place. In the range of degrees of conversion from one third

---

†See E.Ya.Yunitskaya, Candidate's Thesis, Karpov Physicochemical Scientific Research Institute, Moscow, 1986.

to two thirds of a monolayer (irradiation dose 0.3–0.6 kGy), the width of the MMD increases by a factor of ~3, and the degree of branching by a factor of 2.5. It is suggested that these changes are related to radiolysis of the polymer and chain transfer to the polymer.

Infrared spectroscopy has been used to study the conformational characteristics of the polymers formed in the polymerisation of VA and MMA on aerosil (AS/400 and AS/200), before their separation from the surface.[47,56] It was shown that a fairly high proportion of the units of the PVA and PMMA formed are joined to the aerosil surface by hydrogen bonds (between the CO groups of the polymers and the OH groups of the surface). The proportion of units bonded to the surface increases, in particular, with decrease in the monomer concentration σ at which the synthesis is carried out, and is 70–80% at a concentration lower than one quarter of a monolayer. This indicates that the macromolecules formed under the given conditions have unfolded conformations. If the polymerisation is carried out at high concentrations of the adsorbed monomer (several monolayers or more), the PMMA molecules on the surface apparently have the form of a non-planar coil.

The micro-structure of the macromolecules formed by polymerisation on a surface has been studied by high-resolution ^{1}H and ^{13}C NMR spectroscopy.[47,56] It was established, in particular, that PVA and PMMA synthesised on an aerosil have an atactic structure, similar to that of the polymers obtained by radical polymerisation in the liquid phase. At the same time, the PMMA obtained at low degrees of covering of the surface by the monomer (approximately one quarter of a monolayer) contains a higher proportion of isotactic triads.[56] This is apparently due to the stronger adsorption bonding of both the monomer and the polymer to the surface, and to the more rigid stereochemical control of the acts of chain growth at low values of σ. Poly-n-butyl methacrylate synthesised on an aerosil also contains a higher proportion of the isotactic structure than the liquid-phase radical polymer.[9]

The nature of the distribution of the resulting polymer on the surface is of considerable interest, particularly from the practical viewpoint. A number of authors report that this distribution is markedly non-uniform. In a study of the polymerisation of MMA and ST on MgO and an aerosil, it was concluded from kinetic data that more or less complete "overgrowth" of the surface of the support by the polymers takes place on the formation of 3–6 effective monolayers of the polymers on the aerosil, and 10–20 on MgO.[1,33]

The nature of the distribution of the macromolecules of PST, PMMA, and polyacrylonitrile (PAN) grafted to an MgO surface as a result of radiation polymerisation of the monomers from the vapour phase has been studied.[69,70] The size distribution of the MgO particles was studied by sedimentation in a hydrocarbon medium; the adsorption on the magnesium oxide powders of stearic acid, which can undergo irreversible adsorption on the non-modified regions of the MgO surface, and other characteristics, were also studied. The measurements showed that with increase in the quantity of grafted PST (from 1 to 25 effective monolayers), the aggregates of MgO particles in toluene gradually break down, since the surface of individual MgO particles becomes organophilic. The characteristic size of the aggregates changes from 20 μm to 0.5 μm; the size of an individual MgO particle is 0.01–0.1 μm, that is breakdown of the aggregates is still not complete. Even for the maximum quantity of grafted PST, approximately one third of the MgO surface is not covered by the polymer and retains its ability to absorb stearic acid. A similar picture is observed in the grafting of PMMA and PAN.

It was concluded[69,70] that the radiation grafting of the macromolecules on the surface of mineral carriers is "mosaic" in character. This was attributed to non-uniformity of the original surface; it was assumed that on the surface there are regions on which adsorption and hence polymerisation of the monomers does not take place. In Ref.1, the non-uniformity of the distribution of a grafted copolymer is related to the higher rate of initiation of grafting to the polymer already formed on the surface, compared with the original support. Further studies are required to obtain a more definite answer to the question of the reasons for the non-uniform distribution of polymers on a surface. In all cases, however, in the analysis of this question it is necessary, in particular, to take account of the actual conformation of the macromolecules on the surface.

2. The Efficiency of the Grafting of Macromolecules to a Surface

Even in the earliest papers on the "approach" radiation grafting of polymers from the vapour phase (see Ref.1), attention was drawn to the fact that this method, unlike grafting from the liquid phase, usually gives a very small quantity of homopolymer, indicating that the grafting of the macromolecules has a high efficiency. According to these data, the quantity of non-grafted polymer usually did not exceed 5% of the total concentration of polymer. These results were related to the fact that under the experimental conditions used in these studies (at a fairly low concentration of monomer on the surface), most of the active centres initiating polymerisation are produced from the material of the support, and this may lead to the production of a covalent bond between the macromolecules formed and the support at the initiation stage. It has also been suggested[1,45] that the low-molecular-weight radicals formed in the system on irradiation are unable to initiate polymerisation before their transfer to the vapour phase and disappearance, since the time for which they are present in the adsorbed state τ_a is small compared with the characteristic time of the act of polymerisation chain growth τ_g

$$\tau_a \ll \tau_g \tag{1}$$

It was subsequently established,[26,65,71] however, that the quantity of non-grafted polymer is usually much greater than indicated in the early studies, although it is sufficiently less than that for grafting from the liquid phase. In the polymerisation of VA, AN, and MMA on an aerosil it amounts to 10–50% of the total quantity.[71] In the analysis of these results it must be borne in mind that in most experiments, relationship (1) apparently is not fulfilled. Because of the porosity of real adsorbent specimens (layer of powder, porous tablet, etc.), the total time for which the low-molecular-weight radical is present in the adsorbed state during its diffusion over the specimen to the point of possible disappearance (τ_a^{Σ}), because of repeated re-adsorption on the pore walls, is usually greater than τ_g. Thus most of the low-molecular-weight radicals are able to take part in the polymerisation on the surface.[71]

The total time for which the diffusion species is present in a real specimen can be described by the relationship:[72]

$$\tau_D = l^2/3D_{\mathrm{eff}}$$

where l is half the thickness of the specimen. In typical systems with weak bonding, D_{eff} for the monomer molecules is 10^{-3}–10^{-5} cm^2 s^{-1}.[73] For low-molecular-weight radicals such as the radicals of chain transfer to the monomer and similar radicals, D_{eff} is usually of the same order of magnitude. In most experiments on polymerisation, the fraction of the surface diffusion flux of the monomer in the specimen is fairly high relative to the total,[73] so that τ_a^{Σ} is close to τ_D. Estimation of τ_a^{Σ} for the low-molecular-weight radicals which chain transfer to the monomer in the polymerisation of vinyl acetate on an aerosil (specimen in the form of a tablet with thickness 2 mm and porosity ~80%) gives the value ~10 s (for $\tau_a \cong 10^{-4}$ s), whereas $\tau_g \cong 10^{-2}$ to 10^{-1} s.[55,73] Naturally, the situation must be evaluated separately in each specific case with allowance for the above considerations.

In the analysis of experimental results from the viewpoint of the efficiency of grafting, account must be taken of a number of additional features. Thus the efficiency of grafting is determined by treating the specimens, after polymerisation, with solvents to extract the non-grafted polymer from the surface. To obtain correct results it is necessary to make the correct choice of solvent. On the one hand, it is necessary to take account of the fact that the compound used should not only be a good solvent for the polymer but also displaces it effectively from the adsorbent surface.[71] On the other hand, it is necessary to bear in mind the possibility of the hydrolysis, under the influence of the solvent, of the covalent bond between the macromolecule and the support, or hydrolytic rupture of the main chain of the macromolecule.[65,71,74] The hydrolytic instability of the $\geqslant\mathrm{Si{-}O{-}C}$ bond and the stability of the $\geqslant\mathrm{Si{-}C}$ bond have been noted.[74]

3. Secondary Reactions in the Polymer Chains Formed. The Radiolysis of Polymers on a Surface

An important characteristic feature of the processes involved in radiation polymerisation is that the macromolecules are subjected to the action of radiation for some time after their formation. Attention has been drawn[65,67,68] to the fact that in polymerisation on a surface, various manifestations of the radiolysis of the polymers are observed for very small radiation doses (less than 1 kGy). In polymerisation in the bulk, secondary radiation reactions in the polymers are usually not observed at such low doses. It has been established[68] that there is effective branching of PVA macromolecules on an aerosil, and marked broadening of the MMD in the dose range ~0.5 kGy. A decrease in the number-average values of the molecular mass was observed for PVA with increase in the polymerisation time at doses of ~1 kGy; it was suggested that this effect is due to the sensitising influence of the support on the radiolysis of the macromolecules. Attention has been drawn[65] to the radiation degradation of PMMA on silica gel at doses of 1.2–5 kGy; it was also concluded that this process is accelerated by the support, although the experimental data obtained by comparing the results of the irradiation of PMMA on a silica gel surface and in a "block", on the basis of which this conclusion was reached, are not completely correct, because of the marked differences in the molecular masses of the PMMA specimens compared. The accelerating action of the support on the radiation degradation of PST in the grafting of ST on wood has been reported.[67]

The special study of the radiolysis of polymers on solid surfaces, including the study of model systems in the absence of monomer, is of considerable interest. The action of radiation on PST deposited and grafted on silica gel has been studied.[75] It was shown, in particular, that radiation degradation of the grafted polymer takes place; the radiation-chemical yield of the ruptures is 2. The presence of the homopolymer suppresses the degradation. When PST is irradiated in a "block", cross-linking of the polymer takes place; $G_{c\text{-}l} \cong 0.17$.

Various characteristic features of the radiolysis of polymers deposited on an aerosil and undergoing degradation (PMMA) or mainly cross-linking (polymethyl acrylate, PMA), have been studied.[32]# The polymers were deposited on the aerosil by polymerising the monomers on the surface. The radiation-chemical yield of the ruptures of the main chains of PMMA, G_r^*, determined by measuring the molecular mass of the polymers viscosimetrically and recalculating to unit energy absorbed by the polymer, was much greater for irradiation on the aerosil, compared with the yield of ruptures for the irradiation of PMMA in a "block". When the quantity of polymer deposited on the aerosil is close to an effective monolayer, the value of G_r^* is 5–10 (depending on the conditions of synthesis and hence on the conformation of the macromolecules), whereas for the irradiation of PMMA in a "block", this yield is close to 1. G_r^* decreases regularly with increase in the quantity of polymer on the surface.

The radiation-chemical yield of polymer radicals G_R^* is also much higher for the irradiation of PMMA on a surface. At concentrations of PMMA on the aerosil of ~0.05 and ~0.5 effective monolayer, the initial yield of terminal radicals G_R^*, determined by EPR, has the values ~350 and ~70 respectively, whereas for irradiation of the specimen in a "block", this yield is 3–4. This is due chiefly to the effective transfer of the energy of the radiation, absorbed by the silicon dioxide particles, to their surface and to the polymer adsorbed on it. Similar effects were previously noted in a study of the radiolysis of adsorbed low-molecular-weight hydrocarbons.[76–79]

Another noteworthy feature is that under comparable conditions, G_R^* is much greater than $2G_r^*$. An appreciable proportion of the ruptures of the main chains is apparently localised close to the ends of the macromolecules, and are not detected by measuring the average molecular mass viscosimetrically.

The radiolysis of PMA on an aerosil surface has been studied for specimens containing ~2 and ~4 effective monolayers of the polymer.[32] The original molecular mass of the polymers ($\bar{M}_\eta$) was ~10^7. Irradiation of the specimen in a block leads to effective cross-linking of the PMA; for a dose of 1–1.5 kGy, the concentration of the gel fraction was ~50%. On irradiation on a surface with doses up to 10 kGy, gel formation is not observed, but effective degradation of the macromolecules takes place, and the initial yield is $G_r^* \cong 5{-}10$. On subsequent irradiation, a gel fraction gradually appears. The dose required for the formation of 50% gel fraction in the polymer on the support is 20–50 times that for the "block". It is suggested that this marked suppression of gel formation when PMA is irradiated on a surface is due to a change in the ratio of the yields of ruptures and cross-linkages in favour of the first process, and also to the characteristic topological features of the specimen (the small thickness of the polymer layer, and its distribution in "islets").

Thus the results indicate that there is a marked increase in the rate of radiation degradation and a change in the direction of the processes involved in the radiolysis of the polymers on the surface of silicon dioxide particles. These

results are extremely important, not only for the investigation of the details of polymerisation on a surface but also for the study of the radiation stability of filled polymer materials and their modification by radiation.

IV. THE ADSORPTION AND MOLECULAR TRANSPORT OF MONOMERS ON A SURFACE. SYSTEMS WITH STRONG AND WEAK ADSORPTION BONDING

As noted in section II, radiation polymerisation on a surface usually takes place by an adsorption mechanism. The relation of the characteristic features of the elementary stages of the polymerisation, in particular the reactions of chain growth, to the nature of the adsorption and the surface mobility of the monomers and polymers is therefore a central question in the area being discussed. The analysis of adsorption equilibria and the molecular transport of the monomers in the specimens is also necessary to determine the true concentration of the monomers in the reaction zone.

The equilibrium adsorption of MMA and ST on an aerosil and on magnesium oxide has been studied on a McBain balance.[1] The published conclusion that the adsorption is monomolecular in these systems does not appear fully justified. The heats of adsorption of various monomers on KSK-2 silica gel have been determined calorimetrically.[80,81] The heats of adsorption decrease considerably with increase in the degree of covering of the surface (at degrees of covering less than a monolayer). The equilibrium adsorption of acrylic and methacrylic acids on kaolin has been studied.[61]

The adsorption equilibria, mechanism, and dynamics of the adsorption of a wide range of monomers on silicon dioxide specimens (chiefly aerosil and its modified forms) have been studied in detail.[47,56,73,82] On the basis of the results obtained, the authors cited divide the systems studied into two main groups. In the systems of the first group, the values of the heats of adsorption $-\Delta H_a$ are 30–90 kJ mole^{-1}, and the adsorption is non-localised, reversible, and characterised by a high surface mobility of the monomers. This type of adsorption on SiO_2 is shown by most of the vinyl monomers studied (VA, AN, ST, MMA, tetrafluoroethylene, etc.). These systems were called systems "with weak bonding".

The main adsorption centres on the silicon dioxide surface in these systems are surface hydroxide groups, which form hydrogen bonds with the polar functional groups of the monomer molecules (MMA, AN, VA, etc.) or weak π-complexes with a system of conjugated double bonds (ST). The strength of these adsorption bonds can be characterised to some extent by the magnitude of the displacement of the absorption band of the hydroxide groups of the surface in the region of 3750 cm^{-1} ($\Delta\nu_{OH}$) on adsorption.

In some systems (for example in the adsorption of VA and AN on AS/400), there is a change in the nature of the adsorption of the monomers at a coverage of about half an effective monolayer. In particular, at this degree of coverage there is a decrease in the heat of adsorption, the decrease being particularly marked for VA (~17 kJ mole^{-1}), a marked decrease in the width of the absorption bands in the ^1H NMR spectra of the adsorbates, and a displacement of the absorption band of the carbonyl groups of VA in the infrared spectra.[82]

The systems of the second group are characterised by localised activated adsorption, irreversible at room temperature.[56,73] In these systems the strength of the bonds between the monomer molecules and the surface is close to that of chemical bonds. These systems have been called systems "with strong bonding". Of the systems studied by the authors cited above, the following, in particular, are of this type: acrylic acid on an aminated aerosil, 4-vinylpyridine (4-VP) on a carboxylated aerosil, and 4-VP on an aerosil in the presence of water (in these, ionic bonds are formed). When 4-VP and N-vinylpyrrolidone (N-VP) are adsorbed on an aerosil, ionic bonds are not formed, but the stability of the adsorption complexes and the nature of the adsorption differ considerably from those for systems with weak bonding. Systems with strong bonding are characterised by values of the heats of adsorption of 100 to 200 kJ mole^{-1} and an extremely low surface mobility of the monomers.

The above separation of systems with strong and weak adsorption bonding is to some extent arbitrary. A particular system may "move" from one group to the other, for example when there is a marked change in the surface coverage or the temperature. The characteristics of a number of systems have intermediate values. Nevertheless, the proposed classification is useful, chiefly because of the marked differences in the nature of the processes of monomer polymerisation in the systems of the two groups.

The study of the processes involved in the surface molecular transport of monomers is of considerable interest. Here, the analysis of the possible influence of the surface diffusion of the monomers on the observed rate constant for the growth of the polymerisation chains is of fundamental importance. The coefficients of surface diffusion of the monomers D_s have been determined[56,73] for a number of systems with weak bonding (VA–AS/400, MMA–AS/200, MMA–AS/400, ST–AS/200, and VA–MAS). In these systems at temperatures of about 50 °C and degrees of covering of about one monolayer, $D_s = 10^{-5}$–10^{-3} cm^2 s^{-1}. The values of D_s increase rapidly with increase in temperature (the activation energy of surface diffusion decreases with increase in the concentration of adsorbed monomer σ). Within the monolayer, the values of D_s increase significantly with increase in σ, and in some systems (for example VA–MAS) they pass through a maximum.

Thus systems with weak bonding are characterised by high values of D_s for the monomers, close to the diffusion coefficients in non-viscous liquids. In systems with strong bonding, the values of D_s are much lower; for example, for 4-VP on an aerosil, $D_s = 10^{-8}$–10^{-9} cm^2 s^{-1}.

V. THE QUANTITATIVE STUDY OF THE ELEMENTARY STAGES OF RADICAL POLYMERISATION IN SYSTEMS WITH WEAK BONDING

An extremely important step in the determination of the characteristic features of polymerisation reactions on solid surfaces is the measurement of the rate constants for the elementary stages of these reactions. Considerable progress has been made in this field in the last few years. It has been possible to determine the rates of initiation v_i, the lifetimes of the kinetic chains τ, the growth rate constants k_g, and various other kinetic parameters of the radical polymerisation of a number of monomers on a silicon dioxide surface, initiated by radiation.[48,53–56,73]

Isolated attempts to estimate the growth rate constants for radiation polymerisation on a surface had been made earlier. The values of k_g had been calculated[50,51] for the grafted polymerisation of acrylonitrile on nylon fibre from the vapour phase using the post-effect. In these calculations the authors assume a "collision" mechanism of polymerisation, although in fact the mechanism is one of adsorption. Moreover, the estimation of the concentration of initiating radicals in the surface layer of the fibre was extremely arbitrary.

The authors cited concluded that the values of k_g on the surface are close to those observed in the radical polymerisation of AN in the liquid phase, and at the same time obtained for the activation energy of chain growth E_g a value of zero, which is unlikely for this reaction and which differs considerably from the values established for the radical polymerisation of AN and other monomers in the liquid phase. An attempt was made[81] to estimate the growth rate constant k_g for the radiation polymerisation of MMA on KSK-2 silica gel. The lifetimes of the kinetic chains were determined calorimetrically. In Ref. 81, the rate of initiation of the polymerisation was not determined experimentally;[81] it was assumed, somewhat arbitrarily, to be equal to the yield of paramagnetic centres stabilised in irradiated silica gel at 77 K, determined in Ref. 43. Moreover, it should be borne in mind that the yields of radicals in silica gels irradiated in the presence and absence of adsorbates usually differ considerably. They also depend on the concentration of impurities in the specimens. It was concluded[81] that k_g for MMA for monolayer coverage of the surface by the monomer is close to that for the liquid phase. For the above reasons, this conclusion does not appear completely reliable. The idea that k_g depends on the heat of adsorption and the degree of covering of the surface by the monomer was developed in Ref. 81.

The principal results[48,53–56,73] of the determination of the rate constants and other parameters of the elementary stages of the radiation polymerisation of VA and MMA on an aerosil and a methylated aerosil in the initial stage of the reaction can be considered.§ The kinetic parameters were determined using the usual equations of the theory of radical polymerisation which describe the stationary stage of the process:

$$\nu_{st} = \nu_i k_g [M] \tau$$

$$\nu_{t,sp} = 1/\tau;\ \nu_p = k_g [M] \tau;\ k_t = 1/\nu_i \tau^2 \qquad (2)$$

Here, ν_{st} is the stationary rate of polymerisation, $\nu_{t,sp}$ the specific (calculated for one growing chain) rate of termination, ν_p the length of the polymerisation kinetic chains, and k_t the rate constant for quadratic chain termination. The growth rate constants k_g were determined from Eqn. (2); here, the main difficulties are associated with the reliable measurement of the rates of polymerisation initiation ν_i and the lifetimes of the polymerisation kinetic chains τ.

1. Determination of the Rate of the Radiation Initiation of Polymerisation

As shown below, the initiation of radiation polymerisation on a surface when the concentrations of adsorbed monomers are not too high (up to 1–2 monolayers) is due chiefly to the active centres produced as a result of the absorption of the energy of the radiation by the solid. It should be noted that a sufficiently complete mechanism has not yet been reliably established for the radiolysis processes leading to the initiation of radical polymerisation on a surface, even for the most widely studied adsorbent silicon dioxide. It has been shown[35–38,84,85] by various methods (EPR, ultraviolet spectroscopy, etc.) that the γ-irradiation of finely dispersed silicon dioxide may lead to the production of hole, electronic, and radical centres on its surface. The hole centres may be localised on an oxygen atom of a hydroxide group or on an oxygen atom situated next to an impurity aluminium or boron atom.[36] Impurity atoms usually play an extremely important role in the localisation of electron or hole active centres and to a large extent determine the EPR and ultraviolet spectra of these centres. When an adsorbate is present on the surface of the irradiated specimens, transformation of these centres to radical-ions of the adsorbed molecules, or the formation of their donor–acceptor complexes with the adsorbate, is observed, depending on the relationship between the ionisation potential (or electron affinity) of the adsorbed molecules and the "depth" of the hole or electron traps. The radical-ions formed may take part in the initiation of surface ionic and radical reactions.

The initiation of radical reactions can also take place as a result of the transfer to the adsorbate molecules of the energy of recombination of the electron–hole pair, which is often sufficient for bond rupture in the adsorbed molecule. The energy of recombination of the ion pair may also bring about bond rupture in the surface silanol groups and the formation of $\geqslant SiO^{\bullet}$ and $\geqslant Si^{\bullet}$ radicals, and also the low-molecular-weight radicals $H^{\bullet}$ and $HO^{\bullet}$, which can also initiate radical reactions involving the adsorbate. It has been suggested[86,87] that an appreciable proportion of radical centres are formed by a homolytic mechanism.

The reliable determination of the rate of initiation of polymerisation ν_i on a surface is fairly complicated. The use of the usual methods for determining ν_i in the liquid phase, involving the measurement of the induction periods of inhibited polymerisation or the rate of consumption of radical acceptors,[89] in the case of polymerisation on a surface is complicated by the lowered diffusion mobility of the inhibitors and acceptors usually employed. As a result, their reactions with the active centres of the polymerisation are diffusion-controlled, and the efficiency of these reactions is lowered, making quantitative analysis of the results difficult.

Three different methods for determining ν_i, whose results show fairly good agreement with one another, have been developed and used: 1) the determination of the duration of the induction period of the polymerisation when an effective non-adsorbed inhibitor, namely gaseous oxygen, is used; 2) a kinetic method, based on the use of expressions, familiar from the theory of radical polymerisation, relating the average degree of polymerisation to the kinetic parameters of the process; and 3) a method based on the determination of the number of polymeric molecules formed in systems with a low effective constant for non-degenerate chain transfer. The characteristic features and limits of applicability of each method were discussed.[48]

Table 2 gives the values found by averaging the results obtained by different methods for ν_i and the radiation-chemical yields of the initiation calculated per unit of energy absorbed by the entire system G_i and by the adsorbed monomer G_i^* for the radiation polymerisation of MMA and VA on an aerosil. It is significant that the values of ν_i were found to be practically the same for the two monomers. Table 2 shows, in particular, that the values of G_i^* are anomalously high. This indicates directly that there is effective migration of the energy absorbed in the bulk of the aerosil particles to their surface. Table 2 also shows that the values of ν_i in the range of degrees of coverage from 0.4 to 1.5 monolayer depend little on the degree of coverage. In the temperature range studied, from −20 °C to +50 °C, the values of ν_i are practically independent of temperature.[48] The values of ν_i may differ significantly for a given monomer

on different adsorbents. For example, the values of ν_i for VA on AS/400 and on MAS are ~10^7 molecule cm^{-2} s^{-1} and ~6×10^7 molecule cm^{-2} s^{-1} respectively.

2. Determination of the Lifetimes and Rate Constants for the Growth of the Kinetic Chains

The lifetimes of the polymerisation kinetic chains τ have been determined from the measured durations of the initial non-stationary period of the polymerisation. Analysis of the relationship between τ and the extrapolated non-stationary time t_{ns} showed that for systems with linear termination of the kinetic chains $t_{ns} = \tau$,[56,83] and for systems with mixed termination $t_{ns} = z\tau$, where z lies in the range 0.7–1, depending on the ratio of the rates of linear and quadratic termination.[91] For systems with quadratic termination, $t_{ns} = \tau \ln 2$.[89] Thus in all cases, it is possible with sufficient accuracy to use the relationship $\tau \cong t_{ns}$.

The initial non-stationary stage of the polymerisation has been studied by two methods: vacuum gravimetry (VG) and adiabatic increase in temperature (AIT). The determination of t_{ns} by VG under real experimental conditions requires the introduction of a correction, associated chiefly with retardation in the diffusion transfer of the monomer in the specimen, and has a low accuracy.[56,73] The conclusion[83] that there is no diffusion retardation is apparently erroneous. The fact that the observed values of t_{ns} are independent of the thickness of the aerosil tablets on which the polymerisation was carried out, which provided the experimental basis for this conclusion, is probably related to the influence of the non-isothermal character of the specimen on the dynamics of the adsorption of the monomer.[56,73] Thus the values of k_g obtained in Ref.83 are several times too low.

The AIT method is more convenient for determining t_{ns}. The method involves essentially the measurement of the increase in the temperature of the specimen as a result of the heat liberated on polymerisation under pseudo-adiabatic conditions, when heat exchange between the specimen and the surrounding medium can be neglected. The measurements were made in a cell with an adiabaticity time from 5 min to 9 min; particular attention was paid to the analysis of the possible errors of the method.[56] The method used makes it possible to determine t_{ns} in the range 5 to 100 s with a relative error ≤30%. In Refs.53–56 the rate constants were calculated using the values of t_{ns} obtained by the AIT method.

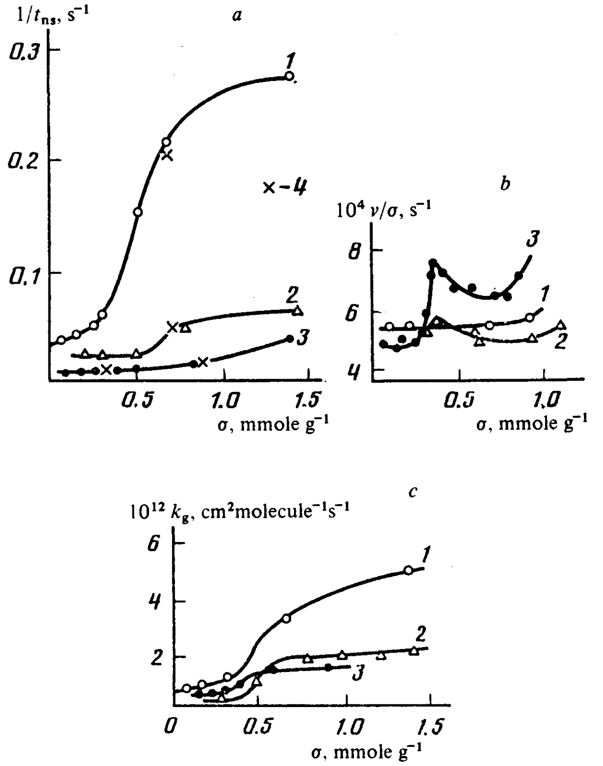

Figure 1. Dependence of $1/t_{ns}$ (*a*), the reduced stationary rate of polymerisation (*b*), and the chain growth rate constant (*c*) on the concentration of adsorbed monomer σ: *1*) VA on AS/400; *2*) MMA on AS/400; *3*) MMA on AS/200. Temperature 50 °C, dose rate 0.35 Gy s^{-1} (points *4* were obtained at 1.7 Gy s^{-1}).[9,55]

Fig.1*a* gives the results of the experimental determination of the values of $\nu_{t,sp} = 1/t_{ns}$ for various systems studied. The values of $\nu_{t,sp}$ are much lower than those for polymerisation in the liquid phase in the initial stages; these values increase with increase in the monomer concentration σ. These data, the values of ν_i given above, the values of ν_{st} given in Fig.1*b*, and Eqn.(2) were used to calculate the growth rate constants k_g for different values of σ. Fig.1*c* shows that the values of k_g are of the order of 10^{-12} cm^2 $molecule^{-1}$ s^{-1}, and that they increase with increase in σ. A significant feature is that k_g increases abruptly in the range of degrees of coverage corresponding to approximately half a monolayer (0.3–0.4 mmole g^{-1}), where an abrupt decrease in the heat of adsorption takes place (see section IV). Calculation shows that for VA molecules, which are adsorbed "more weakly" (filling the second half of an effective monolayer), the values of k_g on the average are ~4 times those for the monomer adsorbed "more strongly" (at degrees of covering of 0.2–0.3 monolayer).

Interesting results have been obtained in experiments on polymerisation in adsorbed solutions.[53,54] If two thirds of a monolayer of ethyl acetate (EA) are added to one third of a monolayer of VA, there is a sharp increase in the effective value of k_g (by a factor of ~4). It is suggested that this effect is related to the fact that in the presence of VA, whose adsorption properties on the aerosil are practically completely analogous to those of VA, an appreciable proportion of the VA molecules are displaced from strong to weak adsorption centres. When additives such as chloroform, which are adsorbed on the aerosil much more weakly than VA and EA, and which cannot displace the monomer from the strong centres, are introduced into the adsorption layer instead of EA, k_g remains practically unchanged.[54]

The question of whether the values of E_g are different for the monomer adsorbed on strong and weak centres are different is extremely important. Table 3 gives the results of a study of the temperature dependence of the rates of the overall process (E_{tot}), the termination reactions (E_t), and the growth (E_g) of the polymerisation chains of various monomers on AS/400 for different values of σ. As already noted, $E_i \cong 0$. It can be seen that E_g is much higher at low than at high degrees of covering. This difference corresponds approximately to the differences in k_g.

Table 3. Activation energies of the overall process (E_{tot}) and the reactions of chain growth (E_g) and termination (E_t) in the polymerisation of monomers on AS/400 (dose rate 0.35 Gy s^{-1}).[53,55]

Monomer	σ, mmole g^{-1}	Activation energies, kJ mole^{-1}		
		E_{tot}	E_t	E_g
VA	0.25	8.4	14.2	22.6
VA	0.7	6.3	10.9	17.2
MMA	0.25	28.5	9.7	38.2
MMA	0.65	21.8	9.7	31.5
MA	0.25	23.4	—	—
MA	0.7	10.5	—	—

Table 4. Kinetic parameters of the polymerisation of VA and MMA on an aerosil and on MAS (monolayer coverage, temperature 50 °C, dose rate 0.35 Gy s^{-1}).[9,55]

Parameter	VA-AS/400	VA-MAS	MMA-AS/400	MMA-AS/200
k_g, cm^{2}molecule^{-1}s^{-1}	$3.6\cdot10^{-12}$	$7.1\cdot10^{-13}$	$1.0\cdot10^{-12}$	$0.67\cdot10^{-12}$
k_t, cm^{2}molecule^{-1}s^{-1}	—	$2.4\cdot10^{-10}$	—	—
k_m, cm^{2}molecule^{-1}s^{-1}	$1.8\cdot10^{-15}$	—	$1.6\cdot10^{-17}$	$1.1\cdot10^{-17}$
10^{-8} n_{st}, cm^{-2}	0.72	4.9	3	8.4
10^{-3} $\bar{P}_n$	1.3	0.45	4	4.4
10^{-4} ν_p	0.44	1.2	0.5	0.8
τ, s	6	8.5	25	60

Notation: n_{st} is the stationary concentration of growing radicals; $\bar{P}_n$ the number-average degree of polymerisation; and k_m the rate constant for chain transfer to the monomer.

Table 4 gives the values of the principal kinetic parameters of polymerisation for some systems with weak bonding. Table 4 shows, in particular, that k_g for VA on MAS is ~2 times that on AS/400. This is apparently due to the weaker adsorption bonding of VA on the MAS surface.

3. Comparison of the Kinetic Parameters of Polymerisation on a Surface and in the Liquid Phase[9,55]

It is of considerable interest to compare the rate constants for the growth and termination of the chains in the polymerisation of monomers in the adsorbed state and in the liquid phase in the initial stages of the reaction (Table 5). The values of the surface constants were recalculated to the bulk values using a model in which the adsorbed monolayer is regarded as a reaction volume of thickness 4 Å, which is approximately equal to the gas-kinetic diameter of the monomer molecules. Table 5 shows, in particular, that the values of k_g, recalculated to bulk values, correlate well with the values of the specific rates of chain growth $\nu_{g,sp}$, which are independent of the concentration dimensions and are not related to the model adopted.¶ This indicates that the model adopted for the recalculation is correct.

Table 5. Kinetic parameters of the polymerisation of VA and MMA on the surface of AS/400 and MAS (monolayer coverage)[9,55] and in the liquid phase (in the bulk)[89,90] (temperature 50 °C).

Parameter	Vinyl acetate			Methyl methacrylate		
	on AS/400	on MAS	in the liquid phase	on AS/400	on AS/200	in the liquid phase
k_g, litre mole^{-1}s^{-1}	84	160	1500—2600	22	15.4	350—410
10^{19} k_g, cm^{3}molecule^{-1}s^{-1}	1.4	2.7	25—43	0.39	0.26	5.8—6.8
k_t, litre mole^{-1}s^{-1}	—	$5.4\cdot10^{3}$	$2{,}5\cdot10^{7}$	—	—	$2\cdot10^{7}$
10^{17} k_t, cm^{3}molecule^{-1}s^{-1}	—	0.9	$4.2\cdot10^{3}$	—	—	$3.3\cdot10^{3}$
$\nu_{g,st}$, s^{-1}	$0.73\cdot10^{3}$	$1.4\cdot10^{3}$	$(1.6—2.8)\cdot10^{4}$	$0.2\cdot10^{3}$	$0.15\cdot10^{3}$	$3.5\cdot10^{3}$
$\nu_{t,st}$, s^{-1}	0.16	0.12	—	0.04	0.017	1*

*For the radiation polymerisation of MMA in the bulk in the initial stage; dose rate 0.35 Gy s^{-1}.[32]

Table 5 shows that the rate constant of the quadratic termination k_t for the polymerisation of VA on MAS is lower by ~3.5 orders of magnitude than that in the liquid phase. This result is due to the diffusion character of k_t and the fact that the translational mobility of the macro-radicals on the surface is much lower than that in the liquid phase. The suppression of the quadratic termination of the chains on the surface is responsible for the low rates of termination and

---

¶Thus Table 5 shows that the ratio of the bulk and surface specific growth rates for each of the systems studied is close to the ratio of the bulk and surface growth rate constants.

for the fact that the lifetimes of the polymerisation kinetic chains are much longer than those in the liquid phase. The same factor increases the role of linear chain termination in polymerisation on a surface and the occurrence of systems with linear and mixed termination. An analysis of the initial non-stationary stage in systems with mixed termination kinetics has been carried out.[91]

The data in Table 5 also show that for the systems studied, the values of k_g in an adsorbed monolayer are 15–20 times lower than those in the liquid phase.

The possible influence of processes of molecular transport of the monomers on the surface on the observed values of k_g has been analysed.[92] The analysis was carried out using the concepts of the theory of diffusion processes in an adsorbed layer, and also the experimentally determined values of D_s and data on the equilibrium adsorption of monomers. The authors obtained mathematical expressions which give the conditions for replacement of the limiting stage of the chain growth process (and also any other bimolecular reaction) on a surface, that is the conditions corresponding to the change from kinetic to diffusion conditions, and which make it possible to calculate the values of the effective rate constants of polymerisation under purely diffusion conditions and under intermediate conditions. The analysis showed that for values $D_s \cong 10^{-5}$ cm^2 s^{-1}, appreciable deviations of the concentration of the reagent close to the reaction centre from the equilibrium concentration for a bimolecular reaction on a surface are possible only for values of the chemical rate constant of this reaction greater than 10^{-6} cm^2 molecule^{-1} s^{-1}. This value corresponds to a bulk rate constant of ~10^{-13} cm^3 molecule^{-1} s^{-1} or 10^8 litre mole^{-1} s^{-1}; it is greater by ~5 orders of magnitude than the experimental values of k_g for the radical polymerisation of monomers in the liquid phase. Such high values of k_g obviously cannot be realised for non-catalytic reactions of radical polymerisation on a surface. Thus in the systems with weak bonding studied, as in the polymerisation of monomers in the liquid phase in the initial stages, kinetic conditions of chain growth are established.

With allowance for this, it is possible to examine the nature of the observed differences in the values of k_g on a surface (k_g^{surf}) and in the bulk (k_g^{bulk}). When examining the reactions of the chain growth of VA or MMA in an adsorbed monolayer on an aerosil, it is necessary to bear in mind that, according to adsorption measurements,[82] the monolayer can be regarded as a "compact" monolayer, in which the average area corresponding to one monomer molecule is close to the corresponding value for the liquid monomer. On the other hand, it is necessary to take account of the probable difference in the number of monomer molecules close to the reaction centre, in the reaction "cage" (n_c). The value of n_c is apparently 2–3 times lower for polymerisation in an adsorption monolayer than for polymerisation in the bulk of the liquid monomer. With allowance for this essentially concentration factor, however, the values of k_g^{surf} for the systems studied are appreciably lower than those for polymerisation in the bulk, by a factor of 6–8 for monolayer coverage, and by a factor of ~20 for a coverage corresponding to one third of a monolayer. These differences are due to corresponding differences in the nature of the elementary act of chain growth, related to the characteristic features of the structure of the intermediate complex and the form of the potential surface. A definite role may be played by both the energy and the entropy factors.[9,32,55] In the polymerisation of MMA, the energy factor, associated with the need for a decrease in the strength of the adsorption bond of the monomer, predominates; in the polymerisation of VA, a greater role is played by the entropy factor.

4. Various Thermodynamic Characteristics of Polymerisation on a Surface

The enthalpy and entropy of adsorbed monomers and polymers formed on a surface usually differ considerably from the corresponding parameters in the liquid and gas phases. Thus polymerisation on a surface should show definite thermodynamic characteristics. A general analysis of this question[32] leads to the conclusion that in polymerisation on a surface at degrees of covering up to one monolayer, the heat of polymerisation Q_{pol} may be appreciably lower (by ~10–50 kJ mole^{-1}) than that for the polymerisation of the corresponding monomers in the liquid phase. The examination of this question in Ref.1, where the opposite conclusion was reached, is apparently not completely correct (see Ref.32).

Various problems of the thermodynamics of polymerisation on a surface have been studied experimentally.[80,81] According to the results of a calorimetric study of the polymerisation of a number of monomers (AN, MMA, tetrafluoroethylene) adsorbed on KSK-2 silica gel, the effective heats of polymerisation $Q_{\text{pol}}^{\text{surf}}$ at low degrees of covering of the surface by the monomer differ considerably from the values of Q_{pol} for the polymerisation of the same monomers in the liquid phase. In some systems (for example for MMA and AN) at coverages of a quarter of a monolayer, the values of $Q_{\text{pol}}^{\text{surf}}$ are only 5–10 kJ mole^{-1}. With increase in the degree of covering of the surface, $Q_{\text{pol}}^{\text{surf}}$ increases (extremely sharply in the systems indicated), and in the range near one monolayer it reaches values characteristic of the liquid phase.

Some approximate thermodynamic estimates have also been made[32] using the results of a study of the polymerisation of VA and MMA on an AS/400 surface by the adiabatic increase in temperature method. These estimates showed that for both monomers, $Q_{\text{pol}}^{\text{surf}}$ increase considerably with increase in the degree of coverage of the surface by the monomers up to a monolayer, but at a coverage corresponding to a monolayer they still remain slightly lower than the values for the liquid phase; in the range of degrees of coverage studied, $Q_{\text{pol}}^{\text{surf}}$ for MMA is appreciably lower than that for VA.

VI. POLYMERISATION IN ADSORPTION POLY-LAYERS

The main regular features of polymerisation on a surface at comparatively low concentrations of the adsorbed monomers (up to 1–2 monolayers) were examined above. From the practical viewpoint, the examination of the characteristic features of polymerisation at higher monomer concentratons is also of considerable interest. These characteristics have been examined[93] for the radiation polymerisation of MMA and VA on AS/400. Specimens containing 50 mass % monomer relative to the aerosil were taken as model specimens with a "thick" adsorption layer. The layer thickness was ~10 to 15 effective monolayers. In the thick layer the order of the polymerisation reaction with respect to the dose rate is 0.8–0.85, whereas it is 1 in a monolayer, and 0.5 in the liquid phase. Thus in a thick adsorption layer, a mixed mechanism of chain termination, with linear termination predominating, is observed. The predominantly linear termination of the chains is confirmed by the weak dependence of the molecular mass of the PMMA, formed in the "thick" layer, on the radiation dose rate.

The dependence of the reduced rate of polymerisation (v/σ) on σ has been studied.[93] For both monomers (VA and MMA) this dependence shows extremal character with a maximum in the range of coverage corresponding to 3–4 monolayers (Fig. 2). The dependence of the molecular mass of PMMA on σ is similar. This is probably due to a corresponding change in the effective rate constants of growth (k_g^{eff}) and termination (k_t^{eff}); k_g^{eff} increases more rapidly at coverages up to 3–4 monolayers, and k_t^{eff} increases more rapidly at higher concentrations. Moreover, the reduced rate of initiation ν_i/σ decreases with increase in σ. For polymerisation in a model "thick" layer, the value of E_g^{eff} is close to E_g for the liquid phase. It is suggested that the constant k_g^{eff} for the "thick" layer is close to k_g for the liquid phase. The reaction of chain termination is specific, however; quadratic termination is suppressed to a considerable extent, and linear termination predominates. In the initial stages the value of $\nu_{t,sp}$ is appreciably lower than in the liquid phase. This is confirmed, in particular, by the fact that the molecular mass of PMMA formed by polymerisation in a "thick" layer is 6 times that for polymerisation in the bulk under comparable conditions.[93]

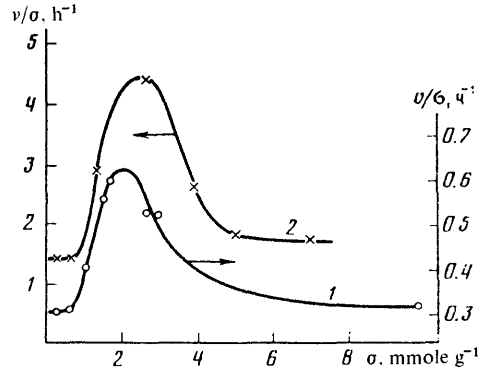

Figure 2. Dependence of the reduced rate of polymerisation ν/σ for VA (*1*) and MMA (*2*) on AS/400 on the concentration of adsorbed monomer σ. Temperature 50 °C, irradiation dose rate 0.1 Gy s^{-1} (*1*) and 0.35 Gy s^{-1} (*2*).[93]

The ratio of the rates of radiation polymerisation on a surface at different values of σ and in the bulk is illustrated by the data in Table 6 for MMA and n-butyl methacrylate (BMA) on an aerosil. Table 6 shows, in particular, that in the region of the maximum (at a coverage of ~4 monolayers), the reduced rate of polymerisation on the surface is 30 to 50 times that in the bulk under comparable conditions. An important feature is that this difference should increase with increase in the dose rate, because of the difference in the dependence of the reaction rate on the dose rate. These results are apparently typical of a fairly wide range of monomer–support systems. The main channels of this accelerating influence of the support on the polymerisation are: 1) increase in the rate of initiation of polymerisation, firstly because of the "maintenance" of the adsorption layer by the active centres formed by the energy of the radiation absorbed by the solid particles (this "maintenance" is particularly significant in those systems in which there is effective transfer of energy from the bulk to the surface of the particles), and secondly as a result of the increase in the radiation dose rate for the layer of monomer situated at the interface with the solid with a high electron density[88] (this effect is not very great for an aerosil, but it should be considerable for heavy metal oxides); 2) decrease in the probability of termination and increase in the lifetime of the polymerisation kinetic chains.

Table 6. Rates and radiation-chemical yields of the polymerisation and the molecular masses of the polymers of MMA and BMA, formed on an AS/400 surface and in the bulk (in the volume) [temperature 50° (MMA) and 25° (BMA), dose rate 0.35 Gy s^{-1}].[32,93]

Parameter	Monomer	Adsorbed state*			Liquid phase (in the bulk)
		1 monolayer	4 monolayers	"thick" layer

*Concentrations of adsorbed monomer for 1 monolayer, 4 monolayers, and the "thick" layer were 5 (? Ed. of trans.), 26, and 50 mass % respectively.

Various characteristics of radiation polymerisation in micron layers of monomers on solid surfaces† have been examined in general terms.[94] Attention is drawn to a possible change in the mechanism and rate of radiation-chemical transformations on a surface compared with polymerisation in the bulk. The "structure" of the monomer layer is examined with allowance for various characteristic features of the action of radiation on a heterogeneous system. In particular, a "range of molecular contact", which adjoins the support and in which higher rates of radiation polymerisation can be expected, is distinguished. The main factors responsible for this increase in the rate are considered[94] to be: 1) the increase in the dose rate in this range, due to the effect of radiation "reflected" from the solid; 2) the increased viscosity of the system, which hinders the termination of the growing radical chains; 3) the increase in the rate of chain growth, due to the ordered arrangement of the molecules relative to the substrate and one another. The effect of the first two factors appears indisputable. In the case of the last factor, however, the formation in the boundary layer on a solid surface of "prepared" monomer molecules whose relative arrangement would lead to an increase in the rate of polymerisation appears to be the exception rather than the rule. The formation of these "prepared" molecules requires at least strict complementarity between the support and the layer of adsorbed monomer.

---

†That is in extremely thick (thousands of monolayers) adsorption layers or thin liquid films of the monomers.

VII. POLYMERISATION IN SYSTEMS WITH STRONG BONDING

For a number of reasons, the study of polymerisation in systems with strong bonding is usually associated with considerable experimental difficulties. There are very few published papers on these systems.

Acrylic acid chemisorbed on an aminated aerosil undergoes practically no polymerisation. The monomer adsorbed physically above the chemisorbed layer is polymerised at an extremely high rate.[56,73]

The polymerisation of N-vinylpyrrolidone on Silochrome[9,96] takes place practically only at temperatures above 70 °C. The rate of polymerisation and the molecular mass of the polymer formed are low. The total activation energy of the process is 60–70 kJ mole^{-2}. The order for the dependence of the rate of polymerisation on the dose rate is $n_i \cong 1$. A study of the combined polymerisation on Silochrome of N-VP and the weakly-bonded monomer methacrylic acid gave an interesting result. At all compositions of the original mixtures studied, including mixtures containing 95 mole % N-VP, only pure polymethacrylic acid is formed, although the constants for the copolymerisation of these monomers in the liquid phase are similar. This shows that increase in the strength of the adsorption bonding decreases the effective reactivity of the monomer on the surface.

4-Vinylpyridine on AS/400 at 20–50 °C is polymerised at a rate which is 5–10 times lower than that for, for example, MMA under comparable experimental conditions. The molecular masses of the poly-4-VP formed are much lower.[9,73]

Thus the rates of polymerisation and the molecular masses of the polymers formed in typical systems with strong bonding are much lower than those in systems with weak bonding. These characteristic features are probably due chiefly to the much lower values of the effective growth rate constants. The values of k_g in systems with strong bonding are apparently 2–3 or more orders of magnitude lower than those for the polymerisation of the corresponding monomers in the liquid phase.

The polymerisation of 2-methyl-5-vinylpyridine on silica gel at high temperatures (90–150 °C) has been studied.[97] Under these conditions the rate of the process is fairly high. Judging from the kinetic data,[97] $G_{\text{pol}} \cong 10^4$ at 100 °C. At high temperatures this system apparently behaves like a typical system with weak bonding (see section IV).

---o0o---

Thus in recent years considerable progress has been made in the study of the mechanism and characteristic features of the elementary stages of radiation polymerisation on a surface, providing a basis for the development of the theory of these reactions. Nevertheless, many unresolved problems remain in this field, primarily those related to the mechanism of the elementary stages of these processes. In the case of the initiation stage, it is necessary to study the influence of the electronic character, the actual structure, and the particle size of the solid on the rate of initiation and to determine the mechanism of the basic radiation reactions leading to the formation of the initiating centres. The more accurate determination of the conditions under which the surface exerts stereochemical control over the acts of chain growth is of particular interest; in this connection it is appropriate to study the characteristic features of the micro-structure of the polymer chains obtained in systems with strong adsorption bonding. Finally, it is necessary to carry out additional studies of the detailed mechanisms of linear and quadratic chain termination in real systems, including adsorption layers of different thickness. The study of this question should give new results of fundamental importance, related to the properties of the macromolecules and their solutions on solid surfaces. It is also extremely important to extend the range of systems in which the kinetic parameters of polymerisation are determined, to make detailed studies of the processes of ionic radiation polymerisation on a surface, and to study the characteristic features of polymerisation on regular supports and of oriented and matrix polymerisation on a surface.

Halogenodeoxy-derivatives of Cellulose

R.G.Krylova

Halogenodeoxy-derivatives of cellulose are examined for the first time in terms of a wide range of their characteristics: synthesis, methods for the determination of structure, reactions, and properties. The replacement of some of the hydroxy-groups of cellulose by halogen atoms imparts to it a number of practically important properties, for example resistance to combustion and acid or enzyme hydrolysis. The reactive halogenodeoxy-derivatives of cellulose are used for the synthesis of a wide variety of cellulose derivatives with functional groups, frequently with properties of practical interest. The bibliography includes 70 references.

V. Practical applications 103

I. INTRODUCTION

Cellulose is a unique organic compound: it is available in large amounts and it is being continuously renewed. The introduction of a halogen into the glucopyranose unit of cellulose as well as the reactions of halogenodeoxycelluloses can be used to synthesise new materials with properties specified beforehand.

Halogenodeoxy-derivatives of cellulose have not been considered in the reviews devoted to the chemistry of halogenodeoxy-derivatives of monosaccharides.[1,2] In the monographs on cellulose chemistry, the derivatives of this class are either not considered[3,4] or their treatment is incomplete.[5,6]

Since the earlier review by the present author and Golova,[7] devoted to the synthesis and properties of various deoxycelluloses, including halogenodeoxy-derivatives, was written, methods of their synthesis known previously have been significantly developed, new methods have appeared, new procedures for the determination of their structure have been developed, and some of their properties have been investigated in greater depth.

II. METHODS OF SYNTHESIS

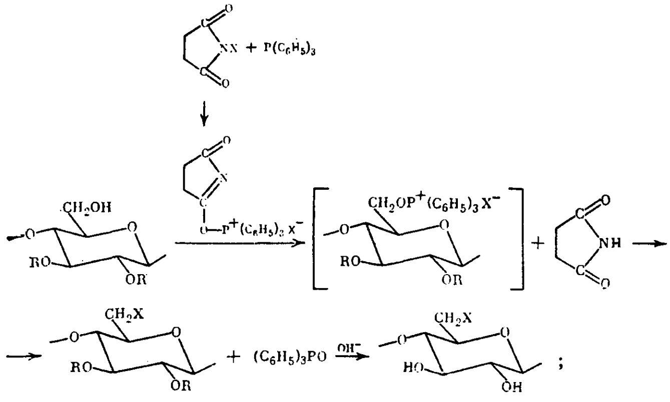
The studies in the synthesis of halogenodeoxycelluloses have developed in several directions, including procedures for the most complete substitution of all the hydroxy-groups of cellulose by halogen atoms,[8] the utilisation of the possibilities for the selective introduction of a halogen at specific carbon atoms of the glucopyranose unit of cellulose,[9-13] the development of methods for the introduction of a halogen into the cellulose macromolecule which are already known,[9,14,15] and the search for new cellulose halogenating agents, for example *N*-halogenosuccinimides,[9,10] SO_2Cl_2,[11,12] SF_4,[16-18] etc. Methods for the substitution of the relatively unreactive secondary hydroxy-groups of cellulose by a halogen are being developed[11,14,15] and a search is being prosecuted for reagents which would make it possible to introduce various halogens into the cellulose macromolecule under comparable conditions; the latter is associated with the fact that various halogenodeoxycelluloses, obtained under identical conditions, should have more similar physicochemical properties than the analogous derivatives obtained by different methods, which is extremely important for the subsequent comparative study of their properties.[9,10] The behaviour of a number of partly substituted cellulose derivatives under conditions where the free hydroxy-groups are substituted by a halogen is also being investigated;[19,20,38] in particular, the stability of various blocking groups, the removal of blocking groups in the presence of a halogen, and problems associated with the preparation (activation) of cellulose before halogenation reactions are being studied.[13,21] These and other problems have been solved to a greater or lesser extent in recent years. The principal reactions and reagents employed for the synthesis of halogenodeoxycelluloses are listed in Table 1.

Table 1. The reactions and reagents used to synthesise halogenodeoxycellulose.

Reaction, initial cellulose derivative, type of reagent	Reagent	Refs.
Nucleophilic substitution of a cellulose OH group on treatment with acid chlorides	SO_2Cl_2 $SOCl_2$ $POCl_3$ RSO_2Cl	[11, 12] [8.14, 19—25] [26] [13,27,28]
Nucleophilic substitution by means of metal halides of active functional groups introduced into cellulose beforehand	MX(X=Cl, Br, I, F)	[14,15,20, 29—34]
alkane- and arene-sulphonate	—	[34]
sulphate	—	[34—37]
nitrate	—	
phosphinite with alkyl halide	RCl	[38]
Nucleophilic substitution of a cellulose OH group by reaction with halogen-containing phosphorus compounds	 $NX+P(C_6N_5)_3$ X=Cl, Br, I	[9,10]
	$CH_3I\cdot P(OC_6H_5)_3$	[19,39,40]
	Cl_2 or Br_2+P	[41]
Nucleophilic substitution of cellulose OH groups by reaction with halogen-containing sulphur compounds	SF_4	[16—18]
Addition of hydrogen halide to 2,3-epoxy-derivative of cellulose	HCl	[42]
Addition of a halogen to 5,6-cellulosene	Cl_2, Br_2	[43]

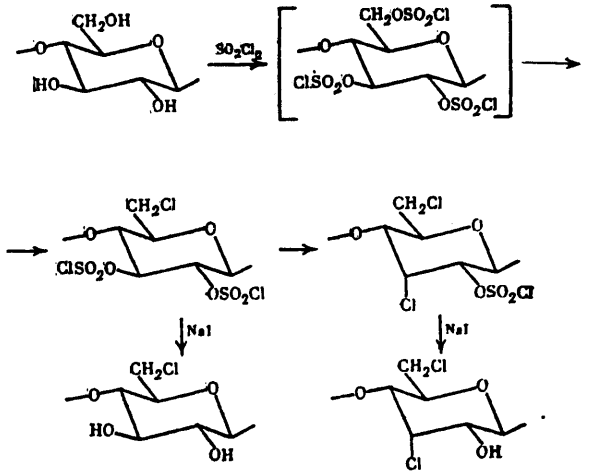
A new convenient method of synthesis of 6-chloro-, 6-bromo-, and 6-iodo-6-deoxycelluloses under comparable conditions involves the reaction of partly substituted

2,3-di-O-acetylcellulose with the *N*-halogenosuccinimide and triphenylphosphine with subsequent deacetylation.[9,10] 2,3-Di-O-acetylcellulose is initially dissolved in dimethylformamide (DMF) and is then treated with the reagent for 5 h at 50 °C with a glucopyranose unit : *N*-halogenosuccinimide : triphenylphosphine ratio of 1 : 2 : 2 in order to obtain the chloro- and bromo-derivatives and 1 : 6 : 6 in order to obtain iododeoxycellulose. Under identical conditions, *N*-iodosuccinimide proved to be the least reactive. There are virtually no side reactions in the case of *N*-chloro- and *N*-bromo-succinimides. After the first hour, the reaction slows down sharply and the degree of substitution (D.S.) reaches a limit corresponding to the substitution by the halogen of one (or approximately one) hydroxy-group in the glucopyranose unit. Under the reaction conditions, the acetyl groups are retained but can be fully removed from halogenodeoxycelluloses by treatment with a 0.25 *N* NaOH solution for 1 h. This results in the formation of 6-chloro- and 6-iodo-6-deoxycelluloses in 83–95% yield under mild conditions with D.S. = 1.0, 0.8, and 0.7 respectively.



R=H, Ac; X=Cl, Br, I .

The mildest and most effective reagent for the substitution of the hydroxy-groups of cellulose by chlorine is sulphuryl chloride.[11,12] A suspension of cellulose in chloroform is treated with sulphuryl chloride in the presence of pyridine using the molar ratios OH : SO_2Cl_2 : Py = 1 : 1.7–5 : 1–8 during a period ranging from 20 min to 3 h. The reaction takes place at room temperature and does not require the preliminary dissolution of cellulose. A chlorosulphate derivative of cellulose is apparently formed as an intermediate. The reaction product contains, together with the chlorodeoxy-groups, also the chlorosulphate groups, which are resistant to substitution by halogen and sulphate groups. The chlorosulphate groups can be removed quantitatively by treating the polymer with sodium iodide in aqueous methanol and the sulphate groups can be eliminated by successive treatment with a base and an acid. This results in the formation of chlorodeoxycellulose containing 12.4 to 30.4% of chlorine (D.S. up to 1.7) and 1.2–0.9% of sulphur. The primary hydroxy-groups are exchanged for chlorine in the first place and then the secondary hydroxy-groups are exchanged. The substitution of a secondary hydroxy-group by chlorine atoms is accompanied by the inversion of the configuration. A distinctive feature of the reagent is its high selectivity: among the secondary hydroxy-groups, only the hydroxy-group in the C(3)-position is substituted by chlorine. The hydroxy-group at C(2) remains unsubstituted.



Highly chlorinated cellulose with D.S. = 2.8 has been obtained by treating cellulose with thionyl chloride in solution.[8] Cellulose is dissolved in 50–100 parts of DMF in the presence of 10 parts of chloral at 40 °C for 15 h and is treated with 15–30 parts of thionyl chloride at 20 °C for 15 h or at 40° and 80 °C for 1 h. The product contains 46–47.3% of chlorine and 2% of sulphur.

$$C_6H_7O_2(OH)_3 \xrightarrow{CCl_3CHO} C_6H_7O_2[OCH(OH)CCl_3]_3 \xrightarrow{SOCl_2} C_6H_7O_2(OH)_{0,2}Cl_{2,8} .$$

The reaction of cellulose with thionyl chloride is one of the principal reactions used for the synthesis of chlorodeoxycellulose. It has frequently attracted the attention of investigators[8,14,19–25] and its conditions have been most thoroughly investigated compared with other reactions. The principal results are compiled in Table 2.

Table 2. Reactions of cellulose and its derivatives with thionyl chloride.

Reaction conditions			D.S.	Refs.
solvent	temperature, °C	time, h

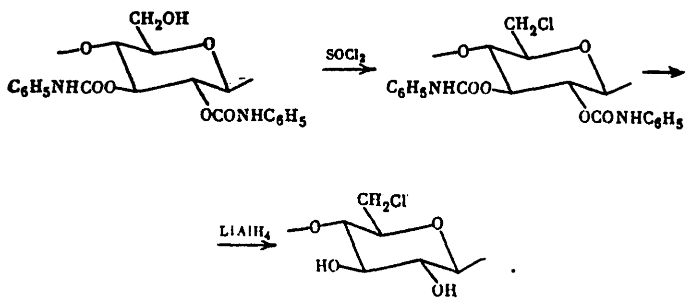
*On a cellulose derivative with a free primary OH group.
**On cellulose derivatives with free secondary OH groups.
***HMP = hexamethylphosphoramide.

In order to introduce chlorine in a specific position in the glucopyranose cellulose unit, thionyl chloride in DMF is allowed to react with partly substituted cellulose derivatives: 2,3-di-O-phenylcarbamoylcellulose, 6-O-trityl-2(3)-tosylcellulose, 2(3),6-di-O-tosylcellulose, and 6-O-phenylcarbamoyl-2(3)-tosylcellulose.[19,20] It has been shown that the primary hydroxy-group in 2,3-di-O-phenylcarbamoylcellulose is fully substituted by chlorine already in the course of the first

15 min of the reaction (70 °C, tenfold excess of the reagent).[19] The phenylcarbamate groups can be removed by treatment with lithium tetrahydroaluminate in tetrahydrofuran (THF) for 1 h at 70 °C with the preferential retention of chlorine.[20]



The free secondary hydroxy-groups in the partly substituted 6(2,3)-O-phenylcarbamoyl-2(3)-O-tosylcellulose are much less reactive. Under the same conditions, they are substituted to the extent of only 20% after 1.5 h of the reaction and, when the reaction time is raised from 1.5 to 6 h, the degree of substitution is 50%. The nitrogen and sulphur contents in the products indicate the retention of the blocking phenylcarbamate and tosylate groups under the reaction conditions. On increasing the reaction time to 12 h, partial removal of the phenylcarbamate groups is observed.[19]

The free hydroxy-groups in the tosylated cellulose 6(2,3)-phenylcarbamate can be fully substituted by chlorine on treatment with thionyl chloride using hexamethylphosphoramide (HMP) as the solvent.[14,20] After 1.5 h of the reaction in HMP, the hydroxy-groups are replaced by chlorine to the extent of 70% and after 3 h their substitution is complete. The contents of sulphur and nitrogen in the final product indicate the retention of the tosylate and phenylcarbamate groups under the reaction conditions: the degree of substitution is 1.55 for the $OCONHC_6H_5$ groups, 0.7 for the OTs groups, and 0.75 for Cl atoms. The use of HMP as the solvent increases the rate of reaction of the hydroxy-groups of cellulose with thionyl chloride and also the degree of their substitution by chlorine.[14]

The reaction involving the substitution of active functional groups (alkane- and arene-sulphonate groups, nitro-groups, etc.), introduced into cellulose beforehand, by a halogen atom by treatment with alkali metal halides constitutes a widely used method for the halogenation of cellulose:[14,15,20, 29–37]

$$C_6H_7O_2(OH)_{3-n}(OR)_n \xrightarrow{MX} C_6H_7O_2(OH)_{3-n}(OR)_{n-m}X_m$$
$$R{=}SO_2R',\ SO_2OH,\ NO_2;$$
$$R'{=}CH_3,\ C_2H_5,\ C_6H_5,\ C_7H_7,\ C_6H_4NO_2,\ C_6H_4Br;$$
$$X{=}Cl,\ Br,\ I,\ F\ .$$

The principal results of the use of this reaction for the halogenation of cellulose and its derivatives are presented in Table 3.

The possibility of substituting the secondary hydroxy-groups in cellulose by halogen atoms via the reactions of cellulose alkane- and arene-sulphonates with alkali metal halides has been investigated. The trityl ether of cellulose is esterified by the chlorides of methane-, ethane-, benzene-, toluene-, p-bromobenzene-, and p-nitrobenzene-sulphonic acids and is then treated with NaI at 100 °C for 10–100 h.[15] Tritylcellulose p-nitrobenzenesulphonate is the most reactive. When this ester, having D.S. = 0.91 with respect to the $OSO_2C_6H_4NO_2$ groups, is iodinated for 100 h at 120 °C, a product with D.S. = 0.52 with respect to I is obtained, while the remaining esters give rise to products with D.S. = 0.25 with respect to I.

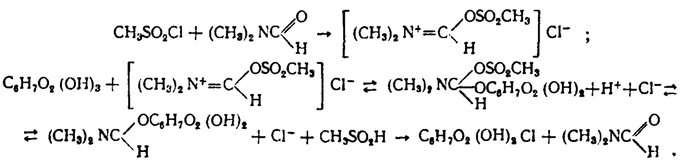
The use of HMP as the solvent makes it possible to substitute 60–80% of the secondary tosyloxy-groups in tritylcellulose tosylate on treatment with LiCl. The chlorine content in the final product corresonds to D.S. = 0.65–0.72.[14,20]

Table 3. The reactions of cellulose alkane- and arene-sulphonates, sulphates, and nitrates with alkali metal halides.

Reaction conditions			D.S.	Refs.
solvent	temperature, °C	time, h		
Acetone	100	2	0.2	[29]
Cyclohexanone	120	2	0.2	[30]
Acetylacetone	120	0.5—6	0.95—1.2	[31]
H_2O	—	—	—	[32]
DMF	97	24	0.9—1.22	[33]
H_2O	108—130	1—35	0.2—0.4	[34]
DMF	100—140	16—50	0.3—0.5*	[15]
HMP	97	10	0.65—0.72*	[14,20]

*Substitution of secondary arene- and alkane-sulphonyloxy-groups in 6-O-tritylcellulose esters.

The reaction with methanesulphonyl chloride has been proposed recently for the preparation of chlorodeoxycelluloses.[13,27] Chlorodeoxycellulose with D.S. = 0.58 is obtained by treating cotton cellulose activated with alkali or acetylcellulose in DMF with methanesulphonyl chloride.[27] The reaction mechanism involving the formation of an intermediate iminium derivative has been proposed[27] on the basis of the data of Edwards et al.:[44]



$$CH_3SO_2Cl + (CH_3)_2NC{\lesssim}^{O}_{H} \rightarrow \left[(CH_3)_2N^+{=}C{<}^{OSO_2CH_3}_{H}\right]Cl^- \ ;$$
$$C_6H_7O_2(OH)_3 + \left[(CH_3)_2N^+{=}C{<}^{OSO_2CH_3}_{H}\right]Cl^- \rightleftarrows (CH_3)_2NC{\overset{OSO_2CH_3}{\underset{H}{\leftarrow}}}OC_6H_7O_2(OH)_2 + H^+ + Cl^- \rightleftarrows$$
$$\rightleftarrows (CH_3)_2NC{<}^{OC_6H_7O_2(OH)_2}_{H} + Cl^- + CH_3SO_2H \rightarrow C_6H_7O_2(OH)_2Cl + (CH_3)_2NC{\lesssim}^{O}_{H}\ .$$

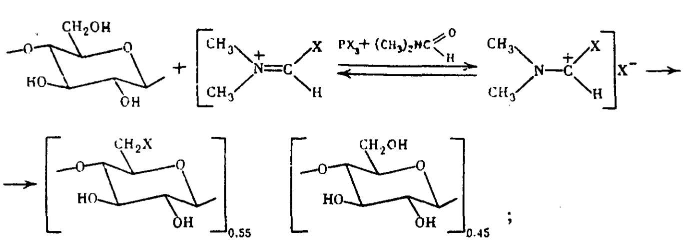
The higher D.S. = 0.83 in the reaction with methanesulphonyl chloride is attained when cellulose regenerated from its solution in cupriethylenediamine by precipitation in DMF is employed.[13] It has been noted that the effectiveness of the reaction is higher when it is carried out at 90 °C for a shorter time than at 60 °C for a longer time. A side reaction involving the introduction of formyl groups into cellulose is observed. They are removed by keeping the reaction product in an aqueous solution of sodium carbonate at room temperature.

Chlorodeoxycellulose with D.S. = 1.3 has been obtained by this reaction by dissolving cellulose in the DMF–chloral system (in the course of a week at room temperature) and subsequent treatment with methanesulphonyl chloride at 75 °C.[28] The chlorine content in cellulose reaches 16% after 1 h of the reaction and 24% after 48 h.

$$C_6H_7O_2(OH)_3 \xrightarrow{CCl_3CHO} C_6H_7O_2[OCH(OH)CCl_3]_3 \xrightarrow{CH_3SO_2Cl} C_6H_7O_2(OH)_{1,7}Cl_{1,3}\ .$$

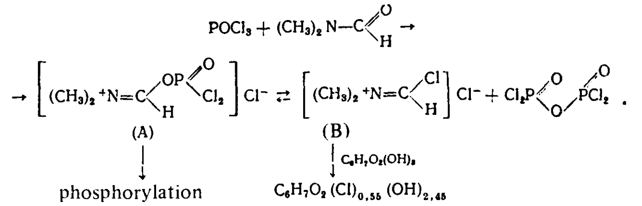
Extensive substitution of the secondary hydroxy-groups of cellulose by chlorine on interaction of tritylcellulose with alkane- and arene-sulphonyl chlorides, especially ethanesulphonyl chloride, has been reported.[15] With increase of reaction time from 24 to 72 h, the D.S. increases from 0.5 to 0.7.

Among other methods, mention should be made of the reaction of cellulose with halogen-containing phosphorus derivatives. Thus the hydroxy-groups of cellulose have been substituted by halogen on treatment with bromine or chlorine in the presence of phosphorus.[41] The reaction is carried out in DMF. The synthesis of bromodeoxycellulose by this reaction has been studied in greatest detail. A temperature of 50–70 °C and glucopyranose unit : phosphorous : bromine molar ratios of 1 : 1 : 30 are optimum for the maximum introduction of bromine. The bromodeoxycellulose obtained under these conditions contains 16% of bromine. The formation of cellulose phosphates in side reactions (phosphorus content 1.5%) and the appearance of carbonyl groups (an absorption band occurs in the IR spectrum at 1693 cm^{-1}) have been noted. When chlorine was passed through the reaction mixture under the same conditions at 60 °C for 6 h, chlorodeoxycellulose containing 10.2% of chlorine and 1.4% of phosphorus was obtained.



X = Cl, Br .

When cellulose is treated with phosphoryl chloride in DMF, chlorodeoxycellulose or phosphorylated cellulose is obtained depending on the reaction conditions.[26] The mode of reaction depends to a large extent on the reagent concentration and this dependence is maintained over a wide temperature range. It has been found that the following conditions are optimal for the synthesis of chlorodeoxycellulose: concentration of phosphoryl chloride in DMF 12%, temperature 75 °C, time 1 h. D.S. = 0.55 is attainable. On the basis of literature data,[45,46] the intermediate formation of active compounds (A) and (B)has been postulated:[26]



$$POCl_3 + (CH_3)_2N{-}CHO \rightarrow \left[(CH_3)_2{}^+N{=}CH{-}OP(O)Cl_2\right]Cl^- \rightleftarrows \left[(CH_3)_2{}^+N{=}CHCl\right]Cl^- + Cl_2P(O){-}O{-}P(O)Cl_2\ .$$

(A) → phosphorylation

(B) $\xrightarrow{C_6H_7O_2(OH)_3} C_6H_7O_2(Cl)_{0,55}(OH)_{2,45}$

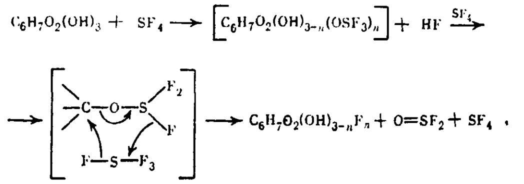
At a high phosphoryl chloride concentration, the interaction of cellulose with compound (B) leads to the formation of chlorodeoxycellulose. It had been shown earlier[47] that compound (B) plays an important role in the formation of chlorodeoxycellulose.

The reaction involving the substitution of the hydroxy-groups of cellulose by iodine on treatment of the following cellulose derivatives with triphenoxymethylphosphonium iodide has been investigated: tritylcellulose,[19,39,40] 2,3-di-*O*-phenylcarbamoylcellulose, and 2(3),6-di-*O*-tosylcellulose.[19,39] A possible reaction mechanism has been proposed.[48]

$$CH_3I + P(OC_6H_5)_3 \rightarrow [CH_3P^+(OC_6H_5)_3]\,I^- \xrightarrow{C_6H_7O_2(OR)_n(OH)_{3-n}}$$
$$\rightarrow \{C_6H_7O_2(OR)_n(OH)_{3-n-m}[OP^+(CH_3)(OC_6H_5)_2]_m\}\,I^- + C_6H_5OH \rightarrow$$
$$\rightarrow C_6H_7O_2(OR)_n(OH)_{3-n-m}I_m + CH_3PO(OC_6H_5)_2\ ;$$
$$R{=}OTr,\ OCONHPh\ .$$

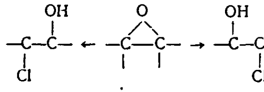
The products of the reaction with tritylcellulose were found to contain 15.2% of iodine after 3 h, 16.1% after 5 h, and 12.25% after 10 h.[19,39] It has been shown[40] that, when tritylcellulose is acted upon by the complex of triphenyl phosphite with an alkyl halide at a temperature below 60 °C, the substitution of hydroxy-groups by iodine is not observed. An increase of temperature from 60° to 120 °C leads to an appreciable increase of D.S. with respect to iodine (from 0.25 to 0.98). When the reaction of 2,3-di-*O*-phenylcarbamoylcellulose with triphenoxymethylphosphonium iodide is carried out in chloroform with a glucopyranose unit: halogenating complex molar ratio of 1 : 15 and a reaction time of 10–40 h at 60–120 °C, the maximum iodine content in the product is 11.6% (D.S. = 0.4).[19,39] Despite the fact that the reaction of 2(3),6-di-*O*-tosylcellulose with triphenoxymethylphosphonium iodide in chloroform takes place under homogeneous conditions, the D.S. with respect to iodine remains low (0.42). The reduced sulphur content indicates a decrease in the number of blocking tosylate groups under these conditions.[19,39]

Fluorodeoxycellulose with a high degree of substitution has been obtained by the reaction of cellulose with SF$_4$.[16,17,18] The degree of fluorination depends on the ratio of the initial components and the reaction time. With increase of the sulphur tetrafluoride: glucopyranose unit molar ratio, the rate of reaction and the content of the fluorine introduced into cellulose increase. The maximum amount of fluorine was introduced on treatment of the glucopyranose unit with a 30-fold molar excess of SF$_4$ for 6 h. The fluorodeoxycellulose with D.S. = 1.5 obtained was characterised by elemental analysis and IR spectra.[16–18] The substitution of hydroxy-groups by fluorine can take place without the inversion of configuration via the mechanism[49]



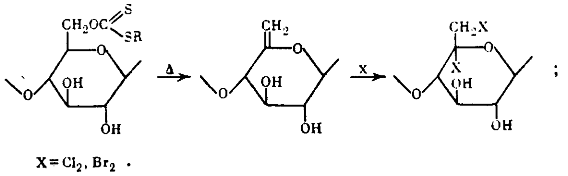
$$C_6H_7O_2(OH)_3 + SF_4 \longrightarrow \left[C_6H_7O_2(OH)_{3-n}(OSF_3)_n\right] + HF \xrightarrow{SF_4}$$
$$\longrightarrow [\ \ ] \longrightarrow C_6H_7O_2(OH)_{3-n}F_n + O{=}SF_2 + SF_4\ .$$

When the trityl group was split off from the 6-*O*-trityl-2,3-anhydro-derivative of cellulose with a solution of hydrochloric acid in methanol or chloroform for 24 h at room temperature, products with D.S. = 0.2–0.4 with respect to chlorine were obtained.[42] The authors suggested the formation of 2-chloro-2-deoxyglucose and 3-chloro-3-deoxyaltrose units:



$$-\underset{Cl}{C}-\overset{OH}{C}- \leftarrow -C\overset{O}{-}C- \rightarrow -\overset{OH}{C}-\underset{Cl}{C}-$$

The introduction of a halogen into the cellulose macromolecule can be achieved via a reaction involving the addition of the halogen to the double bonds in 5,6-cellulosene.[43] 5,6-Cellulosene is obtained by the pyrolysis of cellulose 6-(alkylxanthate) at 170 °C in a stream of argon. Cellulose derivatives containing 17.5% of bromine or 8.5% of chlorine have been obtained by treating a solution of 5,6-cellulosene in carbon tetrachloride with Br$_2$ and Cl$_2$ at room temperature for 3 h. The reaction products were characterised by elemental analysis and IR spectra:



X = Cl$_2$, Br$_2$.

III. METHODS FOR THE DETERMINATION OF STRUCTURE

The determination of the structure of halogeneodeoxycelluloses is essential for the solution of two interrelated problems: on the one hand, for the identification of a newly synthesised derivative and, on the other, for the elucidation of the transformations which cellulose undergoes under the conditions of a particular reaction. The question of the determination of the structure is the most complex: (1) on partial substitution of hydroxy-groups; (2) on non-selective substitution of three different hydroxy-groups of the glucopyranose unit of cellulose; (3) on inversion of the configuration in the reaction centre whereupon the secondary hydroxy-groups enter into the reaction; (4) when secondary reactions occur. The macromolecule of the cellulose derivative can contain in the general case, together with the unchanged glucopyranose units, also a series of glucopyranose units differing in the degree of substitution, the position of the substituent, and the stereochemistry of their reaction centres, as well as monosaccharide units formed as a result of side reactions. The determination of the structure of cellulose derivatives therefore involves the solution of two problems: (1) the determination of the monosaccharide composition, which entails the elucidation, in its turn, of problems such as that of the degree of substitution, the position of the substituent in the glucopyranose unit, and the configuration of the substituent; (2) the determination of the squence in which the monosaccharide residues are linked up in the macromolecule.

Until recently, there were no reliable methods for the investigation of the structure of halogenodeoxycelluloses. Due to the general development of the methods for the determination of the structure of carbohydrates and their derivatives and also in connection with the advances in the research into the reactions of halogenodeoxycelluloses, such methods have now been developed.

In order to establish the structure of halogenodeoxycelluloses, methods which both cause and do not cause the degradation of the polysaccharide chain are used. The former include acid hydrolysis in combination with paper—thin-layer—(TLC) or gas—liquid (GLC) chromatography together with chromatomass-spectrometric, and spectrophotometric methods for the investigation of the hydrolysates. Among the non-degradative methods, chemical methods based on selective reactions with the primary hydroxy-group (tosylation with subsequent iodination), and the glycol group (periodate oxidation), as well as spectroscopic methods (^{13}C NMR) are used for the determination of the structure of halogenodeoxycelluloses.

Quantitative analysis of the monosaccharide composition of 6-bromo- and 6-iodo-6-deoxy-celluloses has become possible since a procedure has been found for their quantitative reduction to 6-deoxycellulose.[9,10] In contrast to halogenodeoxycelluloses, the latter does not undergo side reactions during the hydrolysis of the polysaccharide, the tetrahydroborate reduction, and acetylation and can be investigated by the usual methods for the structural analysis of polysaccharides. The position of the halogen in the bromo- and iodo-deoxycelluloses obtained by reaction with *N*-halogenosuccinimide and triphenylphosphine has been rigorously demonstrated by this method.[9,10] The amount of 6-deoxyglucose found by GLC and spectrophotometric methods in the reduced specimens of bromo- and iodo-deoxycelluloses corresponds to the halogen content in the halogenodeoxycelluloses investigated. This demonstrates unambiguously that the entire bromine and iodine introduced into cellulose is located at the six carbon atom of the glucopyranose unit of cellulose.[9,10]

Chlorodeoxycellulose is only partly reduced by $NaBH_4$. Apart from 6-deoxyglucose and glucose, 6-chloro-6-deoxyglucose and 3,6-anhydroglucose were detected in the hydrolysis products after the reduction of chlorodeoxycellulose. Owing to the instability of these compounds under the hydrolysis conditions, it is impossible to carry out a complete quantitative analysis of the monosaccharide composition of the polymer using the hydrolytic and chromatographic methods.

A convenient procedure for the determination of the structure of chlorodeoxycelluloses is ^{13}C NMR.[12,50] The characteristics of the changes in the chemical shifts of the signals due to the carbon atoms on substitution of the hydroxy-groups by chlorine atoms in both the given and neighbouring monosaccharide units in the disaccharides investigated have been established for the model compounds β-methyl cellobioside, methyl 6,6′-dichloro-6,6′dideoxycellobioside, methyl (3′,6′-dichloro-3′,6′-dideoxyallopyranosyl)-6-chloro-6-deoxyglucopyranoside, and methyl (3′,6′dichloro-3′,6′-dideoxyallopyranosyl)-3,6-dichloro-3,6-dideoxyallopyranoside.[50] The chemical shifts of the C(1) signals have been calculated on the basis of the spectra of the test compounds for all the possible sequences in which the monosaccharide derivatives comprising unsubstituted D-glucose, 6-chloro-6-deoxy-D-glucopyranose, and 3,6-di-chloro-3,6-dideoxy-D-allopyranose are joined together. The spectra of model compounds and the chlorodeoxycelluloses investigated, obtained by the reaction of cellulose with sulphuryl chloride, are recorded in solution in deuterated dimethyl sulphoxide (DMSO-d_6). The agreement of the chemical shifts of the most intense signals both in the region of the anomeric carbon atoms and in the region of the C(2)—C(6) atoms with the signals of the carbon atoms of the corresponding model compounds showed that 6-chloro-6-deoxy-D-glucose units linked to one another predominate in chlorodeoxycellulose with D.S. = 0.7 and that unsubstituted D-glucose units and a certain number of 3,6-dichloro-3,6-dideoxy-D-allose residues are present. The 3,6-dichloro-3,6-dideoxy-D-allose residues linked to one another predominate in chlorodeoxycellulose with D.S. = 1.5 and there is a small amount of 6-chloro-6-deoxy-D-glucose and unsubstituted D-glucose units. Thus the method makes it possible to establish not only the monosaccharide composition of chlorodeoxycellulose but also the main sequence in which the sugar units forming part of the composition of the polysaccharide are linked together.[12,50]

Some information about the structure of chlorodeoxycellulose can be obtained by the periodate oxidation method.[12] Chlorodeoxycellulose with D.S. = 0.7, obtained by the reaction with sulphuryl chloride, absorbed ~1 mole of the oxidant per mole of the glucopyranose unit of cellulose, which indicates the retention of all the glycol groups of cellulose at the given stage of substitution. Chlorodeoxycellulose with D.S. = 1.5 absorbs 0.5 mole of IO_4 per monosaccharide residue, which means that, when cellulose is treated with sulphuryl chloride, initially the primary hydroxy-groups and then one of the secondary hydroxy-groups are substituted by chlorine atoms.

The method for the determination of unsubstituted primary hydroxy-groups, based on the successive application of reactions involving the tosylation of the hydroxyl-groups and the subsequent substitution of the primary tosyl groups by iodine on treatment with NaI, has been used[41] to determine the position of the halogen in the monosaccharide residues of halogenodeoxycelluloses obtained by the action of Br_2 or Cl_2 in the presence of phosphorus. The number of free primary hydroxy-groups in the halogenodeoxycellulose investigated and hence the amount of halogen attached to the primary carbon atoms are inferred from the amount of iodine introduced. However, such proof of the position of the halogen is not rigorous, since under the conditions governing the substitution of the tosyl group by iodine there is a possibility that the bromine atoms at a primary carbon atom are also substituted by iodine.

A number of workers have used hydrolysis and the study of the composition of the hydrolysate by chromatographic methods (paper and TLC, GLC, and chromatomass-spectrometry) for the determination of the structure of chlorodeoxycelluloses.[13,22,28] However, the incomplete hydrolysis of chlorodeoxycellulose[12,22,28,51] and also the occurrence of side reactions of the sugars with increase of the time during which chlorodeoxycellulose is kept in 72% sulphuric acid from 2 h in the standard method to 16 h [13] or 36 h [28] preclude the derivation of complete information.

IV. THE PROPERTIES OF HALOGENODEOXY-DERIVATIVES OF CELLULOSE

The data accumulated at the present time on various properties of halogenodeoxycelluloses, including those of practical importance such as the resistance to acid hydrolysis, combustion, and enzyme hydrolysis, are widely scattered. Only some workers[22] have published data obtained in a comparative study of the chemical properties as a function of the degree of substitution of halogenodeoxycellulose or the type of halogen introduced.

1. Physical, Physicochemical, and Mechanical Properties

There have been no systematic studies on the physical, physicochemical, and mechanical properties of halogenodeoxycelluloses.

Chlorodeoxycellulose obtained by reaction with $SOCl_2$ in pyridine from mercerised cotton linters is coloured;[21] according to Boechm,[22] the colour deepens with increase of reaction temperature. The replacement of pyridine by the more polar DMF as the solvent leads to the formation of less coloured products.[23] Colourless products are obtained in chloroform and carbon tetrachloride. Chlorodeoxycellulose obtained using methanesulphonyl chloride from soluble sulphide cellulose is slightly coloured after chlorination for more than 2 h.[28] According to Boechm,[22] chlorodeoxycellulose with D.S. = 0.29, 0.67, and 1.04 gives rise to low-viscosity solutions in copper–ammonia solution and only a small proportion of such cellulose can be precipitated from the solution. It has been reported[28] that chlorodeoxycellulose containing 16% of chlorine is soluble in water, while that containing 20% of chlorine is insoluble. Data on the molecular weight distribution of these two chlorodeoxycellulose specimens indicate the absence of the degradation of the polymer during chlorination with methanesulphonyl chloride up to a chlorine content of 16%; when a chlorine content of 20% is attained, the degree of degradation is slight. The molecular weight distribution has been established by gel chromatography using chlorodeoxycellulose nitrate. On chlorination with thionyl chloride, the loss of the fibrous structure of cellulose has been noted.[21] The tensile strength does not decrease on chlorination of methanesulphonylcellulose by alkali metal halides.[32]

2. Chemical Properties

The substitution of some of the hydroxy-groups of cellulose by chlorine hinders the acid hydrolysis of the glycoside linkages between the monosaccharide units in chlorodeoxycellulose.[12,22,28,51] According to Boechm's data,[22] an increase of the D.S. with respect to chlorine from 0.33 to 1.04 entails an increase of the fraction of unhydrolysable residue from 0 to 8.3% under the conditions of the standard two-stage hydrolysis of cellulose; incomplete hydrolysis products are present in the soluble part. 3,6-Dichloro-3,6-dideoxy-derivatives of cellulose with D.S. = 1.6 are almost stable under the conditions corresponding to the hydrolysis of cellulose: under standard hydrolsyis conditions, only 13–20% of the total sugars pass into solution (via the reaction with the phenol–H_2SO_4 reagent).[12] Chlorodeoxycellulose with D.S. = 2.8 is fully resistant to acid hydrolysis.[51] There are data indicating the resistance of the C–Cl bond in chlorodeoxycellulose to acid hydrolysis: when $AgNO_3$ is added to the chlorodeoxycellulose hydrolysate, only traces of AgCl are formed.[22]

The elimination of the halogen from chloro- and bromodeoxycelluloses on treatment with 1 *N* NaOH solution has been investigated as a function of temperature (20–100 °C) and reaction time (30–120 min).[41]

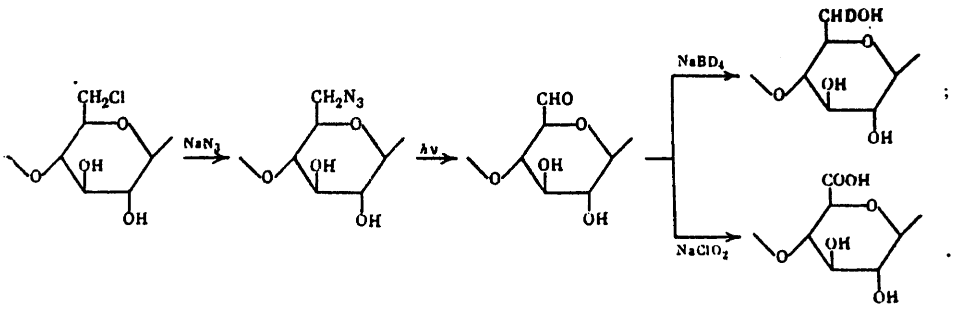
According to the data of a number of workers, the introduction of a halogen into cellulose increases its resistance to combustion. In terms of their resistance to inflammation, methanesulphonyliodo- and methanesulphonylbromo-deoxycelluloses are superior to the initial methanesulphonylcellulose and methanesulphonylchlorodeoxycellulose.[32] Judging from the length of the charred region, the area of charring, and the residence time of the ash in the hot state, chlorodeoxycellulose is much more resistant to burning than cellophane and is little inferior in this respect to poly(vinyl chloride).[8]

According to thermogravimetric data, chlorodeoxycellulose produces more water and carbon and less tar on decomposition than does cellulose.[52] The difference in the behaviour of cellulose and chlorodeoxycellulose has been explained by reactions involving the elimination of HCl from chlorodeoxycellulose. Chlorodeoxycellulose has been investigated by special methods and also by IR spectroscopy, X-ray diffraction, and thermogravimetric measurements. It has been established that the Cl atom bound chemically in chlorodeoxycellulose or added to cellulose in the form of chlorine-containing paraffins has little influence on the combustibility of the materials.[53] The combination of Cl atoms and added Sb_2O_3 effectively retards combustion (the introduction of Sb_2O_3 alone is ineffective). It has been suggested that the synergism in the action of the above agents is associated with the catalytic acceleration of the dehydration of chlorodeoxycellulose, which is accompanied by the formation of a thermostable polyene structure.[53]

The study of the morphology of the charring of chlorodeoxycellulose fibres by scanning electron microscopy has shown that their thickness appreciably diminishes under these conditions, in contrast to the fibres of cotton treated with fireproofing agents.[54]

Chlorodeoxycellulose obtained by the reaction with thionyl chloride, methanesulphonyl chloride, or phosphoryl chloride has been frequently used as the starting compound for the preparation of new deoxy-derivatives of cellulose by the nucleophilic substitution reactions with KSCN,[33] NH_3, NH_2NH_2, KCN,[23,55,56] $HSCH_2COOH$, RNH_2,[24] diethylenetriamine,[57] ethylenediamine, thiourea, thiosemicarbazide, thioacetamide,[58] and 1,6-diaminohexane.[59] Cellulose phosphonimidate has been synthesised by the reactions of chloro- and bromodeoxycelluloses with phosphoramidites.[60] Mercaptodeoxycellulose has been obtained from chlorodeoxycellulose.[61,62]

The nucleophilic substitution reaction between chlorodeoxycellulose and sodium azide has been studied in greatest detail.[13] Chlorodeoxycellulose with different D.S. (0.12, 0.37, and 0.67) was treated with sodium azide in DMF, water, and DMSO:



It was established that, when the reaction is carried out in DMF, the degree of polymerisation falls from 506 to 153, whereas in water the fall is to 448 and in DMSO to 463. Furthermore, in the presence of DMSO the greatest degree of conversion of the halogenodeoxy-groups into azidodeoxy-groups was noted. Further reactions of azidodeoxycellulose take place quantitatively and serve as proof of the structures of both azido deoxycellulose and the initial chlorodeoxycellulose.

Another reaction of halogenodeoxycelluloses which has been studied in detail is their reduction. The reduction of 6-halogeno-6-deoxycellulose by various reducing agents in order to obtain 6-deoxycellulose has been investigated by a number of workers.[9,10,20,63]

When 6-iodo-6-deoxy-2,3-di-*O*-tosylcellulose is reduced with zinc in methanol, the iodine content falls only from 28 to 22%, while on reduction with sodium in dioxan it diminishes from 34 to 6%.[63] The formation of C=C bonds in the reaction product was noted in the latter case, which indicates the simultaneous occurrence of the HI elimination reaction.

The reductive elimination of phenylcarbamate groups from 6-chloro-6-deoxy-2,3-di-*O*-phenylcarbamoylcellulose on treatment with $LiAlH_4$ in THF is accompanied by the elimination of chlorine: 25% of chlorine is eliminated after 1 h and the chlorine is lost entirely after 5 h. 6-Deoxyglucose and glucose were detected by paper chromatography in the reaction product after its hydrolysis.[20]

The reaction conditions and the structure of the products were investigated most completely in the reduction of 6-chloro-, 6-bromo-, and 6-iodo-6-deoxycelluloses with $NaBH_4$ in DMSO.[9,10] 6-Deoxycellulose with the highest content of 6-deoxyglucopyranose units (~80%) compared with the products obtained previously in other reactions was produced by the reduction of 6-bromo-6-deoxycellulose. The bromodeoxy- and iododeoxyglucopyranose units are then quantitatively converted into 6-deoxyglucopyranose units; apart from the 6-deoxyglucopyranose residues, the final product contains only the unchanged glucopyranose units.

Halogenodeoxycellulose has been frequently used to obtain 5,6-cellulosene by the reaction involving the elimination of a hydrogen halide molecule with alkali. When 6-iodo-6-deoxycellulose is treated with 9–10% alcoholic alkali for 1–2 days at 20–70 °C, a mixed cellulose derivative containing 5,6-glucosene, 3,6-anhydroglucopyranose, and glucopyranose residues is formed.[37,64,65] The use of potassium t-butoxide in DMSO makes it possible to achieve the quantitative conversion of chlorodeoxycellulose into 5,6-cellulosene.[27]

The photoinitiated grafting of methyl methacrylate on chlorodeoxycellulose has been achieved.[66]

3. Biochemical Properties

The enzyme hydrolysis of 6-chloro-, 6-bromo-, and 6-iodo-6-deoxycelluloses by the cellulases from *T.viride* and *A.niger* has been investigated and compared with that of 6-deoxycellulose and cellulose hydrate which are the starting materials in their synthesis.[67] From the accumulation of non-reducing and reducing sugars in the hydrolysates, it was established that, under conditions optimal for the enzyme hydrolysis of cellulose hydrate, the specimens of the modified celluloses are also cleaved by the *T.viride* cellulase. However, the hydrolysis is not complete. The obstacles to enzyme hydrolysis increase with increasing bulk of the substituent: H < Cl < Br < I. The reactions involving the formation of non-reducing sugars are hindered to a greater extent than the reactions resulting in the formation of reducing sugars. Among the soluble products of the enzyme hydrolysis of 6-chloro-, 6-bromo-, and 6-iodo-6-deoxycelluloses, there is no modified monosaccharide. The joint action of the *T.viride* and *A.niger* cellulases leads to the formation (according to paper chromatographic data) of a certain amount of modified monosaccharide from 6-chloro-6-deoxycellulose with D.S. = 0.3 and 0.9.

V. PRACTICAL APPLICATIONS

Although halogenodeoxycelluloses have properties important from the practical point of view such as resistance to inflammation and acid and enzyme hydrolysis, they have not themselves found applications as yet. It is noteworthy that their resistnace to acid and enzyme hydrolysis has been discovered comparatively recently, the possibility of using for their synthesis sulphuryl chloride—the most readily available, cheapest, and most effective halogenating agent. However, there exist many recommendations for the employment of halogenodeoxycelluloses in the synthesis of deoxy-derivatives of cellulose of practical importance.

In order to render cotton fabric creaseless, the latter is treated with phosphoryl chloride in DMF at 65–78 °C for 0.5–1 h.[68] The chlorodeoxycellulose formed is treated with a 1–10% solution of ethylenediamine hydrogen sulphite in ethylenediamine. The resulting cellulose, cross-linked by polysulphide linkages, has effective creaseless properties: the opening angle is 210–300°, while more than 65% of the strength is retained. However, owing to the appearance of a yellow colour in the fabric, this method has not found a practical application.

In order to obtain a cationic polyelectrolyte capable of adsorbing transition metal ions, particularly mercury and copper ions, microcrystalline cellulose is activated with a 20% NaOH solution and is treated with thionyl or methanesulphonyl chloride in DMF at 90–100 °C for 1.5–16 h.[69] The resulting deoxycellulose is acted upon by hydrazine hydrate at 70–110 °C for 1–60 h. It has been suggested that the resulting hydrazinodeoxycellulose be used for analytical (detection of traces of polyvalent metals) and technological (purification of sewage) purposes.[69]

Compounds useful as adsorbents have been obtained by the reaction of chlorodeoxycellulose with diethylenetriamine,[57] ethylenediamine, thiourea, thiosemicarbazide,[58] 1,6-diaminohexane,[59] and other compounds. 2,2'-Diaminodiethylaminodeoxycellulose, obtained by the method of Smits and van Grieken,[57] is characterised by an ion-exchange capacity of 2.4 μequiv.cm^{-2} in relation to variable-valence metals. The limiting concentrations of iron, zinc, and copper ions detectable in one litre of water with the aid of membranes prepared from the given derivative are 1.5×10^{-7}, 0.5×10^{-7}, and 0.2×10^{-7}% respectively. The cellulose derivatives obtained by the method of Tashiro and Shimura[58] remove mercury ions from aqueous $HgCl_2$ solutions (concentration 1×10^{-3}%) to an extent greater than 99%. The mercaptodeoxycellulose obtained from chlorodeoxycellulose is used to immobilise enzymes and also as carriers for chromatography.[62,70]

---oOo---

Analysis of the available data shows that the chemistry of halogenodeoxycelluloses has developed significantly in recent years.

A series of halogenating agents, new as regards cellulose, have found applications in the synthesis of halogenodeoxycelluloses. The possibility of using a readily available, cheap, and effective halogenating agent, namely sulphuryl chloride, for the synthesis of chlorodeoxycellulose with different D.S. has been demonstrated. A method has been developed for the introduction of any halogen (Cl, Br, or I) in the C(6)-position in the glucopyranose unit of cellulose under comparable conditions. Fluorodeoxycellulose with a high D.S. has been synthesised. Approaches have been outlined towards the selective substitution of the secondary hydroxy-groups in cellulose by halogen. The behaviour of a series of blocking functional groups in the reactions involving the substitution of the hydroxy-groups by a halogen and methods for their successive elimination in the presence of a halogen have been investigated.

New methods for the determination of the position of the halogen in the glucopyranose unit of halogenodeoxycellulose have appeared. A quantitative chemical procedure for the determination of the structures of 6-bromo- and 6-iodo-6-deoxycelluloses has been developed. A method has been devised for the establishment of the structure of chlorodeoxycellulose by ^{13}C NMR. Apart from the position of the halogen atom, the latter makes it possible to determine the stereochemistry of the process involving the substitution of the secondary hydroxy-groups by chlorine and the sequence in which the sugar residues, differing in the number, positions, and stereochemistry of halogen atoms, are linked to one another.

The physicochemical and other properties of halogenodeoxycelluloses have been little studied. The investigation of the biochemical properties, in particular the enzyme hydrolysis reactions, has only just begun.

A series of derivatives, which are difficult or are altogether impossible to obtain by other methods, have been synthesised from chlorodeoxycellulose. Some of them have found novel applications (for the immobilisation of enzymes and as adsorbents).

The Physical Chemistry of Energy-saturated Media

I.V.Tananaev, V.B.Fedorov, and E.G.Kalashnikov

The physicochemical properties of ultradispersed media, as a particular case of energy-saturated media, have been reviewed. The size dependence of the temperatures of fusion, polymorphic transformation, and sintering, the diffusion coefficients, and the chemical activity of ultra-small particles have been explained from a single viewpoint. Methods for obtaining ultradispersed powders, and methods for producing an ultradispersed structure in metals and alloys, have been described.
The bibliography contains 96 references.

I. INTRODUCTION

Energy-saturated media are media into which an excess of energy, comparable with the internal energy of the equilibrium condensed medium, has been introduced by some means. An energy-saturated medium can be produced by dispersal of the substance, plastic deformation of solids, quenching of a metastable structure or a supersaturated solution in alloys, irradiation of solids with a beam of neutrons or hard γ-radiation, etc.

In practice, a combination of these methods is most frequently used. Irrespective of the method used to obtain the dispersed system, its excess energy is determined either by the surface energy or by the formation of metastable solutions (in particular by an increase in the limiting solubility of inert gases in small particles). At the lower limit of the particle size of dispersed systems (<5 nm), that is in ultradispersed (UD) media, the contribution of these forms of energy is comparable with the internal energy, so that the definition of energy-saturated media is satisfied, in particular, by UD media.

Cooling a melt sufficiently rapidly (up to 10^6 K s^{-1}) makes it possible to fix metastable structures (phases), supersaturated solid solutions, and systems with dispersed phase components.

The deformation of metals and alloys leads to the appearance of dislocations, disclinations, and vacancies, and hence to saturation by an excess of energy if the relaxation time is sufficiently long.

The irradiation of a solid by neutrons, a beam of charged particles, or hard electromagnetic radiation produces radiation defects: vacancies and interstitial atoms, accumulations of vacancies, and impurity atoms (on neutral irradiation or as a result of ion implantation), again leading to energy saturation.

All states of this kind are non-equilibrium states. In some cases they are metastable states (when the system is at an intermediate energy minimum), and in other cases they are kinetically hindered states. The present review deals only with states for which the relaxation time is sufficiently long for local equilibrium to be established, and in a number of cases a thermodynamic approach can be used to discuss these systems. The chief characteristics of these media will be discussed for the case of UD media.

Ultradispersed media (UDM) represent unique states of condensed substances—macroscopic ensembles of ultra-small particles with dimensions reaching about 10 nm. The unusual properties of UD systems may be due both to the characteristic features of the individual ultra-small particles present in the ensemble and to their collective behaviour, determined by the nature of the interaction between them. In UDM, the surface states acquire particular importance, since in an ultra-small particle the number of atoms on the surface becomes comparable with the number of atoms in the bulk, so that the contribution of the surface energy to the total energy of the particle becomes comparable with that of the bulk energy. Thus for the liquid droplets of aluminium at 10^3 K, the proportion of excess (surface) energy relative to the bulk energy increases from 9% to 45% with decrease in the particle size from 10 nm to 20 nm.[1] The developed surface influences the lattice and electronic subsystems of the UDM, changing the spectra of various elementary excitations sensitive to change in the symmetry and the boundary conditions. The interaction of the particles in the system determines those physical properties of the UDM resulting from the correlation of the electronic and phonon states of the system. Finally, the presence of a large excess of energy in the ultra-small particles leads to an increase in their chemical activity, and this on the one hand must be taken into account in their preparation (the problem of "passivation") but on the other hand can be used in various technological processes.

A basis for the physical chemistry of UDM is provided by the theory of heterophase fluctuations,[2] the physicochemical mechanics of materials,[3] the thermodynamics of "small" systems,[4,5] and the fundamental postulates of thermodynamics and statistical physics.[6]

In the last 10 years, the properties of ultradispersed metal particles and powders (UDP) have been actively studied,[7–9] the properties of clusters in ultra-fine channels, in particular in the pores of zeolites, have been studied,[10] plasma-chemical methods for obtaining UDP[11–14] and methods for the thermal decomposition of solid substances[15] have been developed, new properties of ultradispersed carbon materials have been studied,[16,17] the thermodynamics of metastable states and methods for producing ultradispersed structures in compact solids under synthesis conditions and with plastic deformation,[17–21] and the technology of the production of heat-resistant amorphous alloys,[22] have been developed, and the physicochemical properties of materials with ultradispersed structures have been studied.[23]

An important methodological addition to the physicochemical analysis of metastable (ultradispersed) systems is the need to take account of not only the composition and physicochemical and mechanical properties but also the structural characteristics of the reaction products. An important structural characteristic of a material is its degree of dispersion. The three-term formula of classical physicochemical analysis, "composition–structure–property", can be supplemented by the additional term "degree of dispersion". This is particularly obvious for materials with degrees of dispersion at the lower limit of the size of the structural fragments. Thus in compact form the extended equation of physicochemical analysis[24] has the following form:

Composition	Structure	Degree of dispersion	Property
Atomic, molecular (mass) from 0 to 100%	Determined by X-ray diffraction or spectroscopy (infrared, NMR, Mössbauer, EPR, etc.), and also determination of structural defects (dislocations, defects, associations of defects)	From monoatomic or molecular to single crystals, including the colloidal state	All measurable properties (physics, thermodynamics, mechanics, resistance of materials)

The introduction of the degree of dispersion into the basic equation of physicochemical analysis requires firstly the accumulation of the appropriate experimental data. This is done using the methods of modern experimental physics: X-ray, electron, and neutron diffraction, Auger, photoelectron, and infrared spectroscopy, secondary ion mass spectrometry, nuclear and electronic magnetic resonance, and the methods of crystal chemistry.

The effects of size on physicochemical properties, clearly revealed in ultradispersed systems, are used in various practical technological processes. For example, the production of a system of ultrafine channels from powders makes it possible to use capillary effects in low-temperature soldering processes. Ultradispersed powders can provide a basis for the production of pastes for the permanent joining of materials of different kinds, and also for the development of composition materials with improved physicomechanical properties for the production of tungsten-free hard alloys and special optical and other materials. The use of UDM as additives in powder metallurgy (for example in sintering) decreases considerably the energy of the activation processes. Promising possibilities are provided by the electrophysical properties of powdered pure metals and their compounds (nitrides, carbides, borides, etc.), which can be used as superconducting and semiconducting materials and as getters, catalysts, and filters with improved properties. The products of a stable ultradispersed structure in compact materials leads to an increase in their strength up to the theoretical value and to increased values of the hardness and toughness.

The use of energy-saturated and in particular ultradispersed media is now one of the most important conditions for the development of the new technology in various branches of the national economy. The importance of this field is the reason for the development of intensive studies in the USSR and other countries (West Germany, Japan, the USA, France, Sweden, etc.).

The solution of the problems associated with the technological application of energy-saturated media, leading to direct "production of materials", is not a remote possibility. The comprehensive development of this field of study is therefore now necessary.

II. THE PHYSICOCHEMICAL PROPERTIES OF ENERGY-SATURATED MEDIA

1. The Thermodynamics of Small Systems. The Minimum Size of Particles with the Characteristics of the Phase

The thermodynamic and statistical-mechanical approaches to the study of the theory of UDM have developed fruitfully in recent years. In the thermodynamic approach, difficulties arise, associated with the limiting change to small systems. Classical thermodynamics and statistical physics no longer "operate" with decrease in the particle size to 1 nm.

When the degree of dispersion is introduced into the thermodynamic description, the energy of the system is no longer a linear homogeneous function of its variables;[5] an additional degree of freedom appears, namely the size of the particles in the ensemble, or in other words the degree of dispersion. According to the criteria adopted, this requires additional coordinates in the equilibrium diagrams. The physicochemical analysis of inorganic materials is therefore complicated considerably, particularly in the case of multi-component systems.

The non-additivity of the thermodynamic functions, due to the contribution of the phase interface, is taken into account in Gibbs thermodynamics by introducing the surface tension σ, related in definite fashion to the chosen interface surface, and leads to size effects of first order for the principal thermodynamic quantities. The extension of the thermodynamic approach to the range of small particle sizes (r < 5–7 nm), which is justified in the examination of ensembles of these particles, makes it necessary to take account of the size dependence $\sigma(r)$, and hence leads to second-order size effects for the principal thermodynamic quantities characterising the small system. It will be shown that σ decreases with decrease in r, leading to the lowered values of the Laplace pressure p_L, that is to a decrease in the proportion of the surface energy, which is characterised by p_L, relative to the bulk energy, compared with the result of the calculation for $\sigma = \text{const}$. Thus the first-order size effects are due to the basic non-additivity of the thermodynamic functions, whereas the second-order effects based on them are due to the elimination of this non-additivity and the approach of the bulk and surface states in a small particle. The second-order size effects represent the most characteristic feature of the physical chemistry of UDM. Their introduction makes it possible to extend considerably the range of applicability of the thermodynamic description to particles with small dimensions.

Using the thermodynamic approach, Tolman[25] obtained the following expression for $\sigma(r)$:

$$\ln\frac{\sigma(r)}{\sigma_s}=\int\limits_{\infty}^{r}\left\{\frac{2\sigma}{r^2}\left[1+\frac{\delta}{r}+\frac{1}{3}\left(\frac{\delta}{r}\right)^2\right]\right\}dr\Big/\left\{1+\frac{2\delta}{r}\left[1+\frac{\delta}{r}+\frac{1}{3}\left(\frac{\delta}{r}\right)^2\right]\right\} \tag{1}$$

where σ_s is the surface tension of the planar phase interface, and $\delta = r_e - r$ the difference between the radii of the equimolar surface and the tension surface. In the general case the $\delta(r)$ relationship is not known. The determination of the $\delta(r)$ relation requires the statistical-mechanical calculation of the profiles of the density and the pressures of the inter-phase region for a real spherical structure corresponding to the given supersaturation. These calculations are fairly complex, and require the selection of some "single equation of state", by means of which, given the supersaturation of the vapour, it is possible to calculate the parameters of the pressure of the macroscopic condensed phase in equilibrium with it at a given temperature, to determine the density profile of the spherical formation, and to find the position of the equimolar surface and, from the profile of the basic pressures, the position of the tension surface. In addition, in the statistical-mechanical calculation it is necessary to make various assumptions associated with the description of the inter-phase region.

The following method for the closure of Tolman's expression (1) has been proposed.[26] The difference between the equimolar volume $V_e = 4\pi r_e^3/3$ and the tension volume $V = 4\pi r^3/3$ is related to the dispersion of the equimolar volume:

$$(\overline{(\Delta V_e)^2})^{1/2}=(kT\varkappa_T V_e)^{1/2},\ \text{that is}\quad V_e-V=a\,(kT\varkappa_T V_e)^{1/2} \tag{2}$$

where a is a correction factor, and κ_T the isothermal compressibility. Expressing r_e from Eqn.(2) in terms of r gives a $\delta(r)$ relationship of the form:

$$\delta(r)=\frac{r_0}{6^{1/3}}\left\{1+\left[1+6\left(\frac{r}{r_0}\right)^3\right]^{1/2}\right\}^{2/3}-r,\quad r_0=\left(\frac{9kT\varkappa_T a^2}{8\pi}\right)^{1/3} \tag{3}$$

Integrating Eqn.(1) with allowance for Eqn.(3) gives the explicit form of the expression for $\sigma(r)$:

$$\frac{\sigma(r)}{\sigma_s}=\left(\sqrt{1+y}+\frac{\sqrt{y}}{3}\right)^{1/3}(\sqrt{1+y}-\sqrt{y});\quad y=\frac{1}{6}\left(\frac{r_0}{r}\right)^3 \tag{4}$$

In the range of small dimensions ($r \ll r_0$), Eqn.(4) gives a physically justified linear relationship $(\sigma(r)/\sigma_S) = r/r_0 + \ldots$, and the slope of the straight line is determined by the characteristic dimension r_0. At high $r \gg r_0$, the approach of σ to σ_S is described by the approximation

$$\frac{\sigma(r)}{\sigma_s}=1-\frac{2}{3}\left(\frac{2}{3}\frac{r_0}{r}\right)^{3/2}+\ldots$$

that is the influence of slight curvature on the surface tension is proportional to $r^{-3/2}$, in complete agreement with the results of statistical-mechanical calculations.[27]

Since Eqn.(2) contains the unknown factor a, the parameter r_0 can be found only by comparing the experimental $\sigma(r)$ relationship. These experimental data are not available, however. Another possibility is to consider data on the spinodals of the substance. This procedure[28] is based on the assumption that at the boundary of stability of the homogeneous original phase, that is on the spinodal defined by the condition $(\partial p_0/\partial v_0)_T = 0$, both the radius r of the tension surface of the critical nucleus of the new phase and the tension corresponding to this surface σ become zero. Here, ν_0 is the volume corresponding to one mole of the vapour.

The radius of the tension surface of the critical nucleus of the competing phase satisfies the equations

$$\begin{cases} p_1-p_0=\dfrac{2\sigma}{r} & (5)\\ \mu(p_1,T)=\mu_0(p_0,T) & (6)\end{cases}$$

where 1 and 0 are the indices of the parameters of the liquid and vapour respectively. On going deeper into the metastable range as $p_0 \to p_2$ (the pressure on the spinodal), the size of the critical nucleus $r \to 0$, but the decrease in $\sigma(r) \sim r$ leads to the final value of the left-hand side of Eqn.(5). The approximation of Eqn.(4) in the range of small dimensions gives the expression

$$(p_1-p_0)\big|_{p_0\to p_2}=\frac{2\sigma}{r}\bigg|_{r\to 0}=\frac{2\sigma_s}{r_0} \tag{7}$$

When $p_2(T)$ is known, the difference between the pressures in the left-hand side of Eqn.(7) can be determined from Eqn.(6). For two infinitely close states of equilibrium of the critical nucleus with the metastable vapour it is possible to write

$$d\mu_1(p_1,\ T)=d\mu_0(p_0,\ T)$$

or at constant temperature

$$\int\limits_{p_s}^{p}v_1dp_1=\int\limits_{p_s}^{p_0}v_0dp_0 \tag{8}$$

The index s relates to quantities on the binodal. Neglecting the compressibility of the liquid ($\nu_1 = \nu_{1S} = \text{const}$) and regarding the vapour as an ideal gas ($\nu_0 p_0 = p_S \nu_{0S}$), Eqn.(8) with allowance for Eqn.(5) yields:

$$\frac{2\sigma}{r}=\frac{p_s v_{0s}}{v_{1s}}\ln\frac{p_0}{p_s}-(p_0-p_s) \tag{9}$$

If in Eqn.(9) the last term is neglected and $p_S v_{0S}$ is replaced by kT, it is possible to obtain the familiar Kelvin equation: $\ln(p_0/p_S) = 2\sigma v_{1S}/kT$. The ideal-gas approximation is fairly crude in the metastable range, but the proposed[29] relation of the isotherm of an ideal gas not to the far range of the true isotherm, where they are in fact similar, but to the condensation point, reduces the error of the approximation considerably.

Equating p_0 in Eqn.(9) to p_2, and allowing for Eqn.(7), gives for the parameter $r_0(T)$ an expression of the form:

$$r_0 = 2\sigma_s \Big/ \left[\frac{p_s v_{0s}}{v_{1s}} \ln \frac{p_2}{p_s} - (p_2 - p_s) \right] \tag{10}$$

If in Eqn.(3) $r = 0$, then $\delta_0 = (2/3)^{1/3} r_0$.

Thus the fluctuation approach, supplemented by the spinodal procedure, makes possible not only the closed calculation of the $\sigma(r)$ relationship but also the estimation of the minimum spinodal diameter of the competing phase $2\delta_0$.

The problem of finding the minimum size of the nucleating phase is related to the fundamental problem of determining the size limit of applicability of the thermodynamic description of small systems. A rigorous definition of thermodynamic concepts is possible only in the limit $N, v \to \infty$, $N/v \to$ const, that is for a large system. The use of the thermodynamic concepts of small systems is justified only in the examination of not an individual small particle but an ensemble consisting of n identical particles. As $n \to \infty$, the ensemble becomes a macroscopic system, no matter how small its component subsystems, and the use of the thermodynamic approach becomes fully justified. The minimum size of the new formation and the deviation from homogeneity which would make it possible to speak of the appearance of a new phase can be considered. As already shown, the systematic extension of the Gibbs—Tolman ideas to the range of small dimensions leads to the boundary condition $\sigma = 0$ with the disappearance of the tension surface ($r = 0$). The radius of the equimolar surface is non-zero and equal to δ_0. Since this radius characterises most accurately the size of the physical inhomogeneity, it is natural to regard it as the minimum size, beyond which the separation of the system into different phases loses meaning. The condition of disappearance of the tension surface corresponds to the disappearance of the nucleus of the new formation, that is the entire small "particle" is an interphase particle, so that it is now not a particle of a new phase, but a cluster. The same condition can alternatively be called the spinodal limit of stability of the homogeneous phase with respect to the appearance in it of the nucleus of a competing phase, since the work of nucleus formation also becomes zero. A clear boundary is thus drawn between homogeneous and heterogeneous states.

2. Change in the Phonon Spectrum with Decrease in the Particle Size

It is natural to try to describe the properties of an ultra-small particle by the methods of statistical physics. If the atoms in a cluster can undergo vibrations about equilibrium positions, and the cluster as a whole can undergo rotations and translations, then the partition function can be represented as the product of the translational Z_{tr}, rotational Z_{rot}, and vibrational Z_{vib} partial partition functions:

$$Z(N, T) = Z_N^{rot}(T) Z_N^{tr}(T) Z_{vib}(N, T) e^{-U_0(N)/kT} \tag{11}$$

Here, $U_0(N)$ is the minimum value of the potential energy of the cluster. To calculate $Z_N^{tr}(T)$ it is necessary only to know the mass of the cluster; $Z_N^{rot}(T)$—the moment of inertia of the cluster (that is it is necessary to have an idea of the shape of the cluster); and $Z_{vib}(N, T)$—the frequencies ν_i of the normal vibrations of the system, which can be found from the expression for the potential energy of the system:

$$U(N) = \sum_i^N \sum_{j \neq i}^N U(r_{ij}) \tag{12}$$

where $U(r_{ij})$ is the potential of the interaction between the atoms, of the Lennard—Jones or Morse type.

By expanding $U(N)$ in a series with respect to powers of the Cartesian coordinates of small displacements of the atoms from their equilibrium positions and restricting to harmonic terms, it is possible to calculate the magnitude of the forces acting on the atoms and to write the equations of motion of the atoms. Changing from Cartesian to normal coordinates gives a system of $3N - 6$ independent equations, whose determinant gives the frequencies of the $3N - 6$ modes. A knowledge of the spectrum of the normal vibrations (the phonon spectrum) makes it possible to calculate $Z_{vib}(N, T)$, and hence the thermodynamic characteristics of the cluster.[30]

Direct mechanical methods (of molecular dynamics) of calculating the properties of the clusters are also used. In this case, for each atom, a system of ordinary equations of motion under the influence of the forces is written,

$$\overline{F}_i = -\sum_{j=1}^{N-1} \nabla U(r_{ij}),$$

where $U(r_{ij})$ is also the pair interaction potential. The magnitude of the calculation increases in avalanche fashion with increase in the number of particles, so that the possibilities of the method are determined by the possibilities of the computers used.[31] The machine methods also include the Monte Carlo method.[32]

The phonon spectrum of small particles show low-frequency modes which are not present in the spectrum of large crystals.[33–35] These "soft" modes are related to the surface vibrations, and change irregularly with change in the size of the cluster: the spectrum depends on the geometry of the equilibrium configuration. The thermodynamic characteristics also change irregularly. The "soft" surface modes lead to increased values of the heat capacity for small particles at low temperatures, as follows from the form of the vibrational part of the partition function

$$Z_{vib}(N, T) = \prod_{i=1}^{3N-6} \exp\left(-\frac{h\nu_i}{2kT}\right) [1 - \exp(-h\nu_i/kT)]^{-1} \tag{13}$$

The change in the low-frequency part of the phonon spectrum is due to the fact that the longest wavelength of elastic vibrations should not be greater than twice the maximum dimension of the crystal and is determined by the shape of the solid, the boundary conditions, and the wave velocities. The density of the frequency spectrum of a small cube with edge dimensions a can be written in the form:[30]

$$g(\nu) = 4\pi a^3 w^{-3} \nu^2 - a^2 w^{-2} \nu - 0{,}125 a w \tag{14}$$

where $w^{-3} = w_l^{-3} + 2w_t^{-3}$ is the average rate (defined in terms of the rates of the longitudinal w_l and transverse w_t vibrations), and the total number of these normal vibrations is

$$3N = \int_{\nu_{min}}^{\nu_{max}} g(\nu)\, d\nu.$$

For a large crystal, the second and third terms in $g(\nu)$ can be neglected, $\nu_{min} = 0$. Thus $\nu_{max}^3 = 9Nw^3/4\pi a^3$, and the Debye frequency $\theta = h\nu_{max}/k$. For a small particle it is necessary to take account of the low-frequency cut-off of the spectrum ($\nu_{\min} \neq 0$), and in this case the use of the familiar relationship

$$E = \int\limits_{\nu_{\min}}^{\nu_{\max}} h\nu g(\nu)\,[\exp(h\nu/kT) - 1]^{-1}\,d\nu \qquad (15)$$

gives the dependence of the heat capacity $C_V = (\partial E/\partial T)_V$ on size in terms of $\nu_{\min}$, and also, with change in the interatomic distances, in terms of $\nu_{\max}$. The Debye temperature θ for a small spherical particle depends on the radius R:[36]

$$\theta \approx \theta_\infty + \theta_\infty(2G\sigma\varkappa - 3w/16\nu_{\max})/R \qquad (16)$$

where $G = -\partial \ln \theta_\infty / \partial \ln \nu$ is the Gruneisen constant, κ the isothermal compressibility, and σ the surface tension. This description of the phenomena is naturally qualitative. For gold particles with $R = 10$ nm, $\theta = 0.966\theta_\infty$, and for $R = 1$ nm, $\theta = 0.92\theta_\infty$. The same trend is observed experimentally.[37]

3. Phase Transformations in Ultra-small Particles

If the size of the cluster exceeds the minimum spinodal diameter, a particle of a new phase is produced. The morphology of relatively large metal particles does not differ from Wolff polyhedra, but for very fine particles the deviations become appreciable. The particles of face-centred cubic metals with dimensions up to 20 nm have dodecahedral and icosahedral forms. A dodecahedral particle can be represented as a combination of five tetrahedra. Twenty tetrahedra with a common vertex give the other stable configuration, that is the icosahedron. The presence in these crystals of five-fold symmetry axes, not characteristic of the massive crystals, indicates that at a definite size of this repeatedly twinned particle, a polymorphic transformation should take place to give the structure characteristic of large particles of the given metal. Repeated twinning of tetrahedra cannot give a continuous "framework", and between some of the twins, gaps filled with an amorphous phase, or stresses distributed through the entire particle, will be produced. The stability of small metal particles with dimensions of 1.5–1.6 nm has been examined theoretically.[33] It was found, for example, that particles of gold, silver, and copper with a diameter smaller than 10.7, 7.6, and 6.8 nm respectively have an icosahedral structure, and that larger particles have the normal face-centred cubic structure. Aerosil particles of most substances with dimensions ≥ 20 nm in fact have the structure of the massive crystal.[30] Thus after the growing particle reaches a certain size, a phase transformation from the icosahedral to the usual structure takes place.

Calculations by the methods of molecular dynamics[38] of the temperature dependence of the total energy show that the temperature–energy diagram contains a section corresponding to heating, a horizontal plateau corresponding to a phase transformation, and a section corresponding to supercooled states of the liquid. This indicates that the concepts of "solid" and "liquid" are also applicable to very small particles. Measurements on UDP show that particles with $R \cong 5$ nm melt at 200–400 K.[37,39,40] This also applies to polymorphic transformations. An example is provided by the transition metals W, Mo, and Nb. The massive specimens have a body-centred lattice (β-phase), but thin films (and small particles) have a face-centred cubic structure (α-phase).[41]

An expression can be written for the chemical potentials of the melt (L) and the α- and β-phases with allowance for the dimensions of fragments of the corresponding phase of n atoms

$$\begin{gathered}
\mu_L = \mu_\beta^0 + \lambda\left(1 + \frac{T}{T^0_{\text{fusion}}}\right) + \frac{2}{3}\alpha_L\sigma_L v_L^{2/3} n^{-1/3} \\
\mu_\beta = \mu_\beta^0 + \frac{2}{3}\alpha_\beta\sigma_\beta v_\beta^{2/3} n^{-1/3} \\
\mu_\alpha = \mu_\beta^0 - \lambda_{\alpha\beta}\left(1 - \frac{T}{T^0_{\alpha\beta}}\right) + \frac{2}{3}\alpha_\alpha\sigma_\alpha v_\alpha^{2/3} n^{-1/3}
\end{gathered} \qquad (17)$$

Here, α_i ($i = L$, α, β) are the form coefficients, σ_i the surface energy, and ν_i the volume per atom in the melt and in the α- and β-phases respectively; λ and T^0_{fusion} the heat and temperature of fusion; and $\lambda_{\alpha\beta}$ and $T^0_{\alpha\beta}$ the heat and temperature of the α–β transformation of the massive specimen. Since μ_L and μ_β are equal on the equilibrium line, an expression is obtained for the dependence of the melting point of the particle on the size n, the shape α_β, and the density ρ_β:

$$\frac{T^0_{\text{fusion}} - T_n}{T^0_{\text{fusion}}} = \frac{2m_0^{2/3}}{3\lambda}\left(\frac{\alpha_\beta\sigma_\beta}{\rho_\beta^{2/3}} - \frac{\alpha_L\sigma_L}{\rho_L^{2/3}}\right) n^{-1/3} \qquad (18)$$

Here, m_0 is the mass of the atom, and T the melting point of a particle containing n atoms. Since $\rho_\beta \cong \rho_L$, $\sigma_\beta > \sigma_L$, and, usually, $\alpha_\beta > \alpha_L$ (faceting takes place), then $T_n < T^0_{\text{fusion}}$, that is the melting point of the ultra-small particles is lowered.

Similarly, since μ_β and μ_α are equal on the equilibrium line,

$$\frac{T^0_{\alpha\beta} - T_{\alpha\beta}}{T^0_{\alpha\beta}} = \frac{2m_0^{2/3}}{3\lambda_{\alpha\beta}}\left(\frac{\alpha_\alpha\sigma_\alpha}{\rho_\alpha^{2/3}} - \frac{\alpha_\beta\sigma_\beta}{\rho_\beta^{2/3}}\right) n^{-1/3} \qquad (19)$$

Since $\alpha_\alpha \cong \alpha_\beta$, $\sigma_\alpha \cong \sigma_\beta$, and $\rho_\beta < \rho_\alpha$, the difference in brackets is negative, and the temperature of the polymorphic transformation of the ultra-small particle $T_{\alpha\beta}$ is higher than $T^0_{\alpha\beta}$ for the massive specimen. From this it is clear that in a certain range of temperatures, as the film becomes thinner, the β-phase may be converted into the α-phase, metastable with respect to the massive equilibrium specimen, as observed in experiments with films of W, Mo, and Nb.[41]

As far as the mechanism of the fusion of the particles is concerned, Petrov,[30] for example, considers that the most acceptable model is the cluster model, according to which any single crystal, when heated to pre-fusion temperatures, breaks down into clusters separated by amorphous layers of atoms. With increase in temperature, the thickness of the amorphous layers increases, and at the moment of fusion, rupture of the bonds between the clusters takes place. X-Ray diffraction has shown[40] that lead particles with $r \cong 10$ nm on fusion break down to give clusters with an edge length approximately seven times the lattice parameter; with increase in the temperature of the melt by 300 K, the cluster dimensions decrease by a factor of only 1.5, and the structure of the gas is acquired only at the temperature of the liquid–vapour transformation.

The size dependence of diffusion in small particles has been studied.[42,43] A relationship has been established between the activation energy of diffusion θ and the melting point of the substance T_m: $\theta = \alpha T_m$.[44] If it is assumed that this relationship is preserved for a given substance in the UD state, that is that the relationship $\theta_r = \alpha T_r$ is also applicable for particles with radius r, then eliminating the factor α gives $\theta_r = \theta T_r/T_m = \theta - \theta\Delta T/T_m$, and the diffusion coefficient in a particle of radius r will be

$$D_r = A\exp\left(-\frac{\theta_r}{kT}\right) = A\exp\left(-\frac{\theta}{kT}\right)\exp\left(\frac{\theta}{kT}\frac{\Delta T}{T_m}\right) = D\exp\left(\frac{\theta}{kT}\frac{\Delta T}{T_m}\right)$$

The experimental values of the melting points of the particles should be substituted in this equation. Since $\Delta T = T_m - T_r$ increases with decrease in the particle size, D_r also increases, and for dimensions of 10 nm it differs from the diffusion coefficient D in the macro-phase by several orders of magnitude.[43]

4. The Energy Saturation and Reactivity of a Medium

A very important characteristic of UD media is their high chemical activity. This is also related to the high energy saturation of dispersed particles, in particular due to the contribution of the surface energy. Thus the equilibrium constant in a closed system is given by the expression[45] $K_e = \exp(-\Delta\Phi^0/RT)$, where the change in the Gibbs potential in the standard state is

$$\Delta\Phi^0 = \Phi_2^0 - \Phi_1^0 = \sum_j \nu_j^1\Phi_{Bj}^0 - \sum_i \nu_i\Phi_{Ai}^0$$

This equation is applicable for equilibrium with respect to the reaction

$$\sum_i \nu_i A_i \rightleftarrows \sum_j \nu_j^1 B_j$$

for given P and T. If the starting materials and products are dispersed, the change in the thermodynamic potential is:

$$\Delta\Phi = \Delta\Phi^0 + \sum_j \nu_j^1\Delta\Phi_j^1 - \sum_i \nu_i\Delta\Phi_i$$

where the summation is carried out over the dispersed reagents. Recalculation to one dispersed particle of n atoms gives $\delta\Phi = \alpha\sigma\nu^{2/3}n^{2/3}$. It is assumed that the reaction is forbidden under standard conditions ($\Phi_2^0 > \Phi_1^0$). If in the dispersed state

$$\Phi_2^0 + \sum_j \nu_j^1\Delta\Phi_j^1 < \Phi_1^0 + \sum_i \nu_i\Delta\Phi_i,$$

then the reaction becomes possible, and the equilibrium constant of the reaction can be calculated from the equation

$$K_e = K_e^{(\infty)}\exp\left[\left(\sum_i \nu_i\Delta\Phi_i - \sum_i \nu_j^1\Delta\Phi_j\right)/RT\right]$$

When the reaction products are more highly dispersed than the starting materials, the entropy factor will facilitate an increase in the displacement of the process towards the formation of the products, since $\Delta\Phi^0 = \Delta H^0 - T\Delta S^0$.

As a result of the extremely high reactivity of UDP, they react even with inert gases. On the freshly formed surfaces of finely divided solids[46] there is appreciable irreversible adsorption not only of oxygen, nitric oxide, and the products of the dissociation of the liquids in contact with it, but also of inert gases at ordinary pressure and temperature. The gas molecules form strong bonds with the surfaces of the solid particles; the bond energy, estimated from thermal data, is 2–4 kJ mole^{-1}.

The passivation of metals by inert gases is possible in the cold plasma of a glow discharge.[47] For example, the simultaneous bombardment of an aluminium surface by argon and hydrogen ions from the plasma leads to the irreversible penetration of the atoms of these gases not only into the surface layer (5–10 nm) but also into the bulk of the metal, with the formation of a metastable metal–inert gas substitutional solid solution. The concentration of absorbed argon may reach several percent.

It has been established experimentally that the limiting concentration of dissolved argon in aluminium c_0 is 0.3 at.% at 400 K. At a higher concentration, the metastable solution breaks down with the formation of gas-filled bubbles. The lattice parameter increases practically linearly with increase in the inert gas concentration from 0.40496 nm for pure Al to 0.40533 nm for Al containing 0.3 at.% Ar. If this macroscopic solution is described in the regular approximation and it is assumed that the free energy of argon in the solution is equal to that of the argon ions, then at $T = 400$ K and $c_0 = 0.003$ the energy of mixing ΔH is 1.5×10^6 J g-atom^{-1}.

If the solution is a system of small particles, the equilibrium concentration is increased. Using the Ostwald–Freundlich relationship and assuming that the concentration of Ar in the macroscopic solution is 0.003 at $T = 400$ K, and that the surface tension of the macroscopic solution–gas boundary is ~1 J m^{-2}, gives for particles with dimensions of 10, 3, and 2 nm, the argon concentration values 0.54, 2.20, and 6.10 at.% and the values of the excess energy of solution 0.76, 3.66, and 8.10 respectively in units of $\Delta H/\Delta H_m$, where $\Delta H_m = 10.68$ J mole^{-1} is the heat of fusion of aluminium. Thus the solution is formed with a huge expenditure of energy. On its relaxation (breakdown), this excess energy of mixing will be liberated, and at the lower limit of the UDM it may be appreciably greater than the heat of fusion of aluminium. In Ref.48, tablets (diameter 6 mm and height 1.2 mm) were compressed and heated at a rate of ~200 K min^{-1} in an inert gas atmosphere (under a pressure of 0.13 Pa) from powders obtained by the electrical explosion of wires ($r = 0.03$–1.3 μm). At 720–820 K the tablet of copper powder began to glow brightly, and its temperature rose to 1200 K. The temperature of the aluminium tablets increased spontaneously to 940 K, which corresponds to the melting point. Thus for powders with the degree of dispersion indicated, the excess energy is sufficient to maintain the self-propagating process of sintering and even fusion.

A whole series of papers describe the experimental observation of an increase in the chemical activity of energy-saturated media. It has been reported[49] that in two-layer oxide hetero-structures, reactions of the type

$$MgO + Nb_2O_5 \rightarrow MgNb_2O_6$$

take place spontaneously at temperatures 800–1000 K lower than the usual temperatures for the reactions in the massive state. Many examples from the work of Boldyrev and co-workers have demonstrated the activation of solid-phase reactions under the influence of mechanical subdivision,[50] a shock wave,[51], X-rays,[52] and a stream of protons.[53] Finally, recent studies have revealed the high biological activity of highly dispersed metal powders at all levels, from the general indices of the metabolism of the organism to the influence on the activity of individual biological systems and biomacromolecules.[54,55] The antimicrobial activity of various metal powders has been established. Progress in this field is being held up by the lack of satisfactory methods for introducing the metals into the organism. A possible solution is the introduction of the required metals into the organism as UD powders, particularly since their activity increases with decrease in size. This topic lies outside the scope of the present review, however, and will not be discussed in detail here.

III. METHODS FOR OBTAINING ULTRADISPERSED POWDERS OF METALS AND COMPOUNDS

1. Mechanical Methods of Dispersing Solid Metals

Ultradispersed powders can be obtained by the mechanical dispersal of solids, the decomposition, precipitation, and reduction of chemical compounds, and the condensation of metal vapours. A combination of these methods is often used.

In powder metallurgy, coarsely dispersed materials are often obtained by mechanical sub-division in ball, rod, or other mills or in disintegrators, [56] and also by electrohydraulic impact. When a certain degree of dispersion has been achieved, however, a dynamic equilibrium is established between the processes of dispersal and coagulation of the particles. To obtain particles with micron dimensions it is necessary to carry out the sub-division at very low temperatures, at which the material is more brittle, [57] to use ultrasonic dispersal, [58] or to add surface-active substances, which lower the surface energy and strength of the particles.

Sputtering of melts in liquid or gas streams, and ultrasonic [59] and other methods can also be used to obtain powders, but in these cases the products are coarsely dispersed.

The above methods can apparently be used only as an intermediate stage in the production of UD powders. Ultrasonic treatment can be applied to prepared UDP (to break down conglomerates, for mixing, and to produce more compact pressings).

There is however a form of mechanical treatment which creates conditions both for the synthesis of the desired products (diamond) and for their dispersal, namely the action of a shock wave. [60] Diamonds are obtained by the shock-wave treatment of mixtures of graphite and metals at 20–40 GPa and a shock-wave duration of 10–20 µs. The structure and composition of the resulting powders have been studied. [61] The average particle size of the diamonds was ~4 nm.

2. Physical Methods of Obtaining UD Powders Based on Volatilisation and Condensation Processes

The simplest and most natural method for obtaining UD metal powders is by volatilising the metals and condensing their vapours. This method was used to obtain UDP in early studies. [62] Assemblies using the volatilisation–condensation principle may differ in the method of introducing the material to be volatilised, the method of introducing the energy required to volatilise the metal, the nature of the working medium, the organisation of the condensation process, and the system for collecting the powder.

The metal is either volatilised from a crucible or fed to the heating system in the form of a powder, wire, or stream of liquid, through special devices.

Energy can be supplied to the metal to be volatilised through a conductor, [63] by high-frequency induction heating[64] or superhigh-frequency currents,[65] by electric-arc discharge in a plasma, [66] by a laser light flash, etc.

The processes of volatilisation and condensation may take place in a vacuum, in a stationary inert gas, or in a stream or gas (in particular in a plasma stream).

In the production of UD powders, the condensation process is the decisive stage. The physical principles of the theory of the condensation of metals is fairly well developed, [67,68] and methods have been proposed[67,69,70] for calculating the particle size distribution of metal aerosols. The numerical solution of the equations of the kinetics of bulk condensation for this model has been carried out: [70] the vapour–gas mixture in the condensation zone moved in a channel with a constant cross-section of 118.7 mm^2 at a constant velocity of 150 m s^{-1}, the axial temperature gradient due to cooling of the stream was 200 K min^{-1}, the pressure in the channel was constant and equal to atmospheric pressure, and the boundary layer was not taken into account; the argon consumption was 3.5 m^3 h^{-1} (6.24 kg h^{-1}), and the consumption of tungsten powder volatilised 2 kg h^{-1}. These values of the parameters correspond to those of a real assembly. The kinetic analysis showed that it is theoretically possible to obtain tungsten powder with an average particle size of 3–5 nm (without allowance for coagulation). The length of the coagulation zone (90 mm) is much less than the length of the nucleation zone (~4 mm); this makes it possible to protect the powder formed from coagulation, for example by removing it from the condensation zone.

Methods of condensation have been discussed in detail. [71] The vapour–gas mixture at a temperature of 5000–10 000 K can simply be passed into a chamber of large cross-section filled with a cooled inert gas, in which condensation takes place. In improved assemblies, two coaxial streams are passed into a channel; the inner axial stream contains the vapour–gas mixture, and the outer annular stream contains a cold inert gas. As a result of turbulent mixing, the temperature of the metal vapour is lowered, the supersaturation increases, and rapid condensation takes place. The width of the condensation zone in this assembly changes along the longitudinal coordinate, however, and this gives a broad particle size distribution function. Nevertheless, detailed analysis and allowance for the characteristic features of the turbulent mixing of non-isothermal coaxial streams in a channel[73] makes it possible to decrease considerably the thickness of the temperature layer and to obtain UDP with a narrow fractional composition. UDP of copper, aluminium, iron, nickel, and other metals have been obtained in this way in a laboratory assembly. [71] The average particle size of the powders obtained was 7–20 nm at a production rate of 40–50 g h^{-1}, depending on the material and the operating conditions.

If the vapour–gas mixture is directed into a channel with a cooled wall, hydrodynamic, temperature, and concentration boundary layers are established at the surface of the channel. Under turbulent conditions, the thickness of the boundary layer and hence of the condensation zone is proportional to the longitudinal coordinate to the power 0.2. [71] The resulting particles, under the influence of thermophoresis forces, are displaced across the boundary layer to the wall. The temperature gradient in the boundary layer (~10^5 K m^{-1}) is higher than in the layers of the stream, and this makes it possible to obtain particles with smaller dimensions (less than 1 µm). The particles settling out, however, accumulate on the wall surface and partly coagulate and cake to form agglomerates. The growth of the layer of particles on the wall of the channel increases the thermal resistance of the layer and the temperature of the outer layer, and this in turn leads to sintering of the particles with the formation of a crust and overgrowths. Special methods of cleaning the surface have to be used to prevent this phenomenon.

The most favourable conditions for the condensation of metal vapours (to obtain UD powders with a narrow particle size distribution) are apparently produced on adiabatic expansion in a Laval nozzle. [71,72] With sufficiently rapid expansion of the mixture, a temperature gradient of

$\sim 10^8$ K s^{-1} is created,[13] and the vapour of the metal (for example aluminium) condenses almost instantaneously to give UDP with an average particle size of 50–60 nm. The temperature of the walls of the nozzle should be greater than the melting point of the metal, to avoid the deposition of metal particles on the wall and the production of a metallic crust.

The UDP obtained are usually collected on special filters or by centrifugal deposition. In some assembles, the particles are either deposited on a rotating drum or endless belt, after which the surface is cleaned with a scraper, or trapped in a liquid film.

3. Chemical Methods for Obtaining UD Powders

Chemical methods include precipitation, the reduction of oxides and other compounds of the metals, and thermal decomposition. The chief condition for obtaining dispersed powders by chemical methods is that the reaction should take place at a distance from equilibrium, with a high rate of formation of the nuclei of the new phase, combined with a low rate of their growth. These conditions are ensured by selecting a temperature at which the chemical reaction takes place sufficiently intensively, but transfer through the gas phase is still retarded.

The deposition is carried out in a solution, a stream of gas, or a plasma. For example, titanium dioxide is obtained by precipitation as a result of the hydrolysis of titanyl sulphate with heating. The fresh precipitate is amorphous. Transformation to the rutile structure is achieved by subsequent heating to 1000–1300 K.[74] Methods for obtaining powdered iron, cobalt, nickel, and alloys of palladium have been described (see Ref.71 for bibliography). The particle size of these powders varies from 5 nm to 3 μm.

Oxides and halides are usually reduced using hydrogen or carbon monoxide. Powdered iron, vanadium, niobium, tantalum, chromium, molybdenum, and tungsten with an average particle size of 0.1 μm have been obtained by this method at 750–1600 K.[75]

Powdered nickel, iron, chromium, copper, etc. are obtained by the thermal decomposition of the carbonyls, formates, oxalates, and other compounds at 500–700 K. These methods have been reviewed in detail.[7,74]

General unsatisfactory features of methods for obtaining metal UDP by low-temperature processes are the formation of comparatively large particles (0.03–10 μm), a wide particle size distribution, a high concentration of impurities in the powder, and a complex, multi-stage, non-universal technology. In a number of cases, however, the large-scale production of powders can be organised using these processes.

A significant increase in the degree of dispersion of the powders can be achieved by carrying out the process at high temperatures, in particular in a low-temperature plasma generated by an arc or induction discharge. This method can be used to obtain practically all refractory carbides, nitrides, borides, oxides, etc., and also more complex compounds. UD titanium nitride powders with a particle size of <0.5 μm are obtained by reducing the chlorides with hydrogen in a flux of nitrogen plasma.

Thermodynamic calculations for the systems M–Cl–H–N, where M = Ti, Zr, or Hf, show that at the stoichiometric ratio of the original components of the reaction

$$2MCl_4+4H_2+N_2=2MN+8HCl$$

the equilibrium throughout the temperature range (400 to 3500 K) is characterised by the presence of chlorides, so that the degree of transformation of MCl_4 into MN is slight, but a combined excess of hydrogen and nitrogen ensures a nitride yield of 100% over a wide temperature range.[12] The combined reduction of $TiCl_4$ and thermal decomposition of hydrocarbons in a nitrogen plasma is used to obtain titanium carbide nitrides which in the composition range from $TiN_{0.98}$ to $TiC_{0.4}N_{0.6}$ form single phases and consist of a series of solid solutions of carbon in titanium nitride with the NaCl structure. The average particle size of these powders is ~50 nm.[76]

The carbides of titanium, zirconium, hafnium, vanadium, tungsten, and other metals with an average particle size of 0.01–0.1 μm have been obtained in the plasma of an arc discharge using the corresponding metal chlorides and hydrocarbons as starting materials.[77,78]

UD copper powder has been obtained[81] by reducing copper chloride with hydrogen in the stream of argon plasma of an electric-arc discharge. A thermodynamic calculation for the Cu–Cl–H system showed that it is possible to obtain copper in a yield close to 100% in the temperature range 500–1800 K with more than ten-fold dilution of the system with hydrogen, relative to the stoichiometric quantity. The assembly gave copper powder with a particle size <0.1 μm and a relatively narrow particle size distribution.

The reduction of nickel monoxide in a high-enthalpy stream of gas obtained by the complete oxidation of propane by air:

$$C_3H_6+1.5\,O_2+5.64\,N_2=3\,CO+4\,H_2+5.64\,N_2$$

has been studied.[82]

Thermodynamic analysis showed that in a 1.2-fold excess of the reducing agent in the temperature range 800–6000 K, complete reduction of the oxide to the metal is achieved. The experiments gave nickel powder with an average particle size of 0.1–0.4 μm, containing 0.2–3% carbon and 1.5–6% oxygen.

Silicon carbide powders can be obtained from quartz sand and a propane–butane mixture[79] or from a mixture of silanes and halogen derivatives of hydrocarbons in a hydrogen plasma at 2800–3800 K. The average particle size is 0.05 to 0.02 μm.

UDP of tungsten have been obtained by reducing tungsten trioxide in an argon–hydrogen plasma.[80]

An unsatisfactory feature of thermal decomposition and reduction methods is the low selectivity of the process; the reaction product usually consists of a mixture of the desired product and other compounds.[14]

Overall, however, assembles with a low-temperature plasma at present provide one of the most efficient, productive, and universal means of obtaining UDP of metals and compounds.

4. The Electrical Explosion of Wires

One version of the volatilisation–condensation method involves the production of UDP by the electrical explosion of wires. This method is dealt with separately because of its practical importance.

In the electrical explosion of wires (EEW), the materials of the wire breaks down under the influence of a powerful current pulse; part of the material of the wire may volatilise, while the rest is scattered as liquid droplets.[83] As a result of volatilisation at the expense of condensation in the stream of rapidly expanding vapour, particles with very small dimensions are formed, but the solidified droplets give larger particles. The ratio of these components depends on the nature of the breakdown of the wire, which is determined by the process used to introduce the energy into the wire.

The quantities characterising the electrical explosion of wires are functions of the parameters:[84]

$$E = CU_0^2 n^{-2} d^{-4} Z^{-1},\ \lambda = l n^{-1} d^{-2} Z^{-1},\ \nu = L^{1/2} C^{1/2} d^{-1}$$

where l is the length, d the diameter, and n the number of the exploding wires, Z the wave resistance, L the inductance, C the capacity of the circuit, and U_0 the initial voltage at the condenser. The parameters of the explosion are selected using these variables.

The results of the study of copper powders obtained at an inert gas pressure of 200 Pa have been described.[63] The size of the spherical copper particles depends to a significant extent on the density of the energy introduced and the rate of its introduction. It is possible to obtain a powder with a maximum size distribution in the region of 20 nm for copper exploded in air, or in the region of 50 nm for aluminium in argon.

5. Freeze Drying

Ultradispersed powders of metals and compounds can be obtained by freeze drying. The starting materials, in particular metal salts, are used to prepare a solution with the required composition, which is rapidly frozen by spraying into a chamber containing a cryogenic medium. The pressure of the gaseous medium above the frozen granules is then decreased until it is lower than the equilibrium pressure for the multi-component system formed on cooling, and the material is heated with continuous evacuation to sublime the solvent. The product consists of very fine porous granules with identical composition. Heating the granules in air gives the oxides, reduction gives the metal powders, and selective reduction gives a mixture of the oxides and the metals. The UD compositions Pb–10% MgO, W–S, W–25% Re, $Cu-ThO_2$, Cu–W, $NiZnFe_2O_4$, etc. with a particle size of 10–60 nm have been obtained in this way.[85,86]

The reduction of ammonium paratungstate in solution by hydrogen gives a finely dispersed tungsten powder with a particle size of 0.2–0.8 μm, and the product acquires a completely new structure.[87] Ammonium paratungstate has several crystalline hydrated forms, each of which gives a characteristic X-ray diffraction pattern. When the paratungstate obtained by freeze drying was examined by X-ray diffraction, however, no diffraction lines were observed.

Sub-micron nickel powders are obtained by this method from solutions of nickel chloride and nitride.

IV. ENERGY-SATURATED MEDIA AS MATERIALS OF PRESENT-DAY TECHNOLOGY

1. Materials with an Ultradispersed Structure—A Unique Form of Composite Material

Attempts to eliminate the gap between the requirements to be satisfied by constructional materials for present-day technology and the possibilities provided by the usual alloys of materials science are being made by developing and applying composite materials.[24] The complexity of this problem lies in the fact that elements of different kinds (for example metal and non-metal), combined in the same composite material, must function as a single whole. For a long time these difficulties could not be overcome, so that in the past, materials consisting of one substance were preferred.

Composite materials may be of three main types: metal + metal; ceramic + ceramic; and metal + ceramic. The components either do not react, or react with one another during use. In the first case the system is a purely mechanical system, whose behaviour under working conditions can be predicted from mechanical data with allowance for the scale factor. In the second case, the components of the composite materials react to form a new product at the interface. This practically always takes place, since during use the materials are subjected to high temperatures and pressures and other influences. For inorganic materials used at sufficiently high temperatures, the first case need not be considered.

The reaction "within" the composite material may give chemical compounds corresponding to the complete range of possible oxidation states of the metal, including sub-compounds, complex compounds, compounds formed by ceramic + ceramic and metal + metal (intermetallic compounds) combination, and also phases of variable composition of the solid solution type. Thus the "spectrum" of components of a composite material is complicated considerably when the corresponding material starts to be used at high temperatures. This makes it difficult to calculate accurately the behaviour and capacity of the material at different stages of its use, and its examination is usually restricted to the determination of the dependence of the properties, in particular the strength characteristics of the material, on the intensity of the reaction with time. These phenomenological data have now been collected for a whole range of composite materials, and their amount is increasing rapidly. The generalisation of this experience still lags behind practice. A tendency to move to the "molecular level" in the examination of the mechanisms of the reactions of the components of composite materials is gradually being observed, in spite of the considerable difficulty of these questions.

It should be noted, in particular, that the view that the composition of the products of the reaction in composite materials is determined by data from the corresponding equilibrium diagrams cannot be fully accepted, since composite materials are generally non-equilibrium systems. Thus kinetics must be added to present-day methods for their physicochemical analysis. Composite materials are "living" systems, and kinetic questions become fundamental in their study during use. The equilibrium diagrams in the case being considered are of major importance if they are constructed from data obtained in experimental studies with allowance for kinetics. The question of the importance of obtaining "kinetic" equilibrium diagrams is not new,[88] but it has not found extensive practical application. The possible reason may be that up to the present, physicochemical analysis has been applied chiefly to substances as such, when there has been no particular need to study the kinetics of the corresponding processes. Moreover, in the examination of composite materials it is necessary to take account of the degree of dispersion of the starting material and the products formed when the materials are used.

It is usually assumed that composite materials are artificial systems made up of the corresponding macro-components, namely the matrix, which is a compact material (metal or ceramic) of any dimensions, and the reinforcing material, in the form of fibres or filaments, ceramic or metallic, and best of all in the form of single crystals. Since a sharp boundary cannot be drawn between macro- and micro-states, the concept of composite material can apparently be extended to include in this category materials having components with atomic or molecular degrees of dispersion, placing arbitrary boundaries between individual groups.

It is appropriate to divide each of these three types of composite material into three groups, in which the components differ in their degree of dispersion.

1) Composite materials made up of two parts ("blocks") of any dimensions, each of which has independent functions. In this case the area of contact between the blocks is negligibly small compared with the blocks themselves, and at high working temperatures (not exceeding their melting points) the behaviour of the corresponding composite material can be regarded as a function of the behaviour of its component parts, and the "events" at the interface are of secondary importance, the interface functioning only as a means of holding the blocks together.

2) Composite materials in which the degree of dispersion of the reinforcing particles is relatively high: fine single-crystal filaments, short (1–5 mm) fibres, and fine crystals. Here, the components cannot behave independently, and the mass of the interphase formations may be comparable with that of the original components. The behaviour of this most widely encountered classical type of composite material ($Al + Al_2O_3$; $Mg + MgO$; etc.) must be examined in a known temperature range as a system which is the usual object of physicochemical analysis.

3) Composite materials at the level of mixing of components with atomic or molecular dimensions. These are ordinary chemical compounds of the type AB, AB_2, A_2B, etc., up to double salts and complex compounds, and also phases of variable composition. Materials with these components are not usually regarded as composite materials, but in principle this is not quite correct, since there may also be external factors influencing the material (for example radiation, defect-forming influences), when its component atoms or molecules behave "independently" and influence the working properties of the material.

The proposed classification may possibly be disputed, but it covers all types of composite material, if they are classified according to the particle size of the components. Moreover, account must be taken of the fact that at sufficiently high temperatures (for example close to the melting points of the components), their mutual diffusion will take place so rapidly that a composite material of type 2 begins to function as a composite material of type 3. It is always necessary to take into account the extent to which this transformation of one type of material into another is permissible from the viewpoint of the application of the composite material.

2. The Relationship Between the Energy Saturation, Structure, and Mechanical Properties of Materials

The characteristic feature of ultradispersed particles discussed in the previous sections also appear in compact materials with an ultradispersed structure. In this case the degree of dispersion is determined by the average dimensions of the defect-free regions (structural fragments) and the angles of disorientation between them. Here, the relationship between the ultradispersed structure and the physicomechanical properties of the materials is of the greatest importance.

In these materials it is possible to distinguish three levels of structural organisation:[21] granules with dimensions of 10^3–10^4 nm, angles of disorientation 1–90°; sub-granules with dimensions of 50–10^3 nm, angles of disorientation 5′–3°; and blocks with dimensions of 3–100 nm, angles 5′–5″. The energy saturation of a structure of this kind depends on the dimensions of the elements of the structure and the energy of the interfaces. The energy of the interfaces, calculated by the Shockley–Read method, for example for nickel, varies from 0.0014 J m^{-2} ($\theta = 30''$) to 1.1 J m^{-2} ($\theta = 57°$).[21]

Analogous calculations of the excess values of the chemical potential for gold show that for dimensions of the structural fragments of 4.5 nm and large-angle interfaces between them, the state of the structural fragments corresponds to the state of the macro-system at the melting point, and that for dimensions of ~10 nm and large-angle interfaces it corresponds to the state of the macro-system at a temperature of 0.6 T_{fusion}. Since at this temperature relaxation processes (of the crystallisation type) take place actively in metals, a dispersed system with these parameters will not apparently be stable.

For low-angle boundaries, an analogous state is reached at structural fragment dimensions of ~3 nm. It is evidently possible to speak of a limiting attainable level of dispersion of a polycrystalline system.

Accordingly to the familiar Oding diagram, the greatest strength is shown either by materials with a low density of dislocations (single crystals) or materials with a dislocation density of 10^{13}–10^{14} m^{-2}. The strength properties of metals are influenced not only by the density of dislocations, but also by the nature of their distribution in the volume. Distribution of the dislocations in the form of networks of block boundaries is thermodynamically favourable. Assuming that all the dislocations lie at the boundaries between the blocks, the size of the blocks L is related to the density of dislocations ρ by the expression:[89]

$$L = (a/\rho)^{1/2}$$

where a is a parameter of the order of 1, defining the degree of regularity of the distribution of the dislocations. For $\rho = 10^{15}\,m^{-2}$, the dimensions of the blocks lie in the range 4–5 nm.

The relationship between the structure and the strength characteristics is given qualitatively by the Hall–Petch relationship,[90] according to which the strength of a metal is proportional to $L^{-1/2}$, where L is the size of the granules for materials with a coarsely granular structure, and the size of the blocks for materials with highly developed fragmentation of the structure.

By changing the sub-structure of the materials (the size of the structural fragments and the angles of disorientation), it is possible to control their physicomechanical properties.[90,91] For example, the strength of U-8 steel increases from 1.4 GPa to 2.8–3.2 GPa with decrease in the size of the structural fragments from 30 nm to 10 nm. The yield point of TsM-6 molybdenum alloy increases from 400 MPa to 750 MPa with decrease in the particle size from 160 μm to 1 μm. With decrease in the size of the granules of the sub-structure, the impact strength also increases. Thus for 45 steel it changes from 0.62 kJ m^{-2} to 1.5 kJ m^{-2} with decrease in the size of the granules from 60 μm to 6 μm.

An important feature is that with the increase in strength, a sufficient reserve of plasticity is retained, since the temperature of cold brittleness is lowered. For example, for molybdenum it is lowered from 600 K to 415 K with decrease in the size of the granules from 7.3 μm to 1.2 μm.

The temperature of the transition from viscous to brittle breakdown (the temperature of cold brittleness) is a structure-sensitive property, and decreases with decrease in the size of the elements of the sub-structure.[23] The formation and growth of cracks of critical dimensions in an UD material is hindered because of the small size of the structural fragments and the presence of a large number of boundaries, so that the breakdown viscosity of the UD material is increased.

Lowering the temperature of cold brittleness and increasing the breakdown viscosity are important aims for most constructional materials, particularly refractory materials, intermetallic compounds, and metal–ceramics. The possibilities provided by traditional methods (metallurgical, thermal, thermomechanical) in this area have been practically exhausted. To solve the problems of improving further the physicomechanical properties of materials it is necessary to look for new methods of producing ultradispersed structures.

3. The Production of Highly Dispersed States in the Synthesis of Titanium Carbide Under Bulk Combustion Conditions

The mechanism of the formation of a dispersed structure in the synthesis of titanium carbide under non-isothermal conditions can be considered. It has been shown[17,91,94,95] for the Ni–C, Al–Si, and other systems that the presence of ultradispersed components in the original system gives metastable equilibrium diagrams. Thus the temperature of eutectic formation in the Zr–C system is lowered by 500 K when the form of carbon used is coke with an excess energy of about 8.4 kJ mole^{-1}.

The Ti–C system has been studied.[92] It contains an intermediate titanium carbide phase (subsequently denoted σ). The equilibrium diagram can be divided into two regions, Ti + σ and σ + C. The thermodynamic potentials in the left-hand and right-hand regions will have the form:

$$\Phi^{\mathrm{Ti}+\sigma}=(1-x)\Phi^0_{\mathrm{Ti}}+x\Phi^0_{\mathrm{C}}+(x/x_0)\Delta\Phi^\sigma,$$
$$\Phi^{\sigma+\mathrm{C}}=(1-x)\Phi^0_{\mathrm{Ti}}+x\Phi^0_{\mathrm{C}}+[(1-x)/(1-x_0)]\Delta\Phi^\sigma$$

The thermodynamic potential of the σ-phase can be estimated by the published method:[93]

$$\Delta\Phi^\sigma=x(1-x)W_0+(1-x)(1-2x)W_1+x(1-2x)W_2+$$
$$+RT\{A_1x+A_2x^2+(1-x)\ln[(1-x)/(1-2x)]-x\ln[x/(1-2x)]\}$$

where for titanium carbide $A_1 = 0.62$, $A_2 = -0.32$, $W_0 = -368 \times 10^6$ J kmole^{-1}, $W_1 = 117 \times 10^6$ J kmole^{-1}, $W_2 = 92 \times 10^6$ J kmole^{-1}. Substituting gives $\Delta\Phi^\sigma = (92 \times 10^3 - 1.9T)$ J kmole^{-1}.

The liquid phase can be described in the approximation of regular solutions

$$\Phi^L=(1-y)\Phi^L_{\mathrm{Ti}}+y\Phi^L_{\mathrm{C}}+RT[y\ln y+(1-y)\ln(1-y)]+y(1-y)\Delta L$$

where ΔL is the interaction parameter in the liquid solution,

$$\Phi^L_{\mathrm{Ti}}=\Phi^0_{\mathrm{Ti}}+\Delta H_{\mathrm{Ti}}(1-T/T_{\mathrm{Ti}}),\quad \Phi_{\mathrm{C}}{}^L=\Phi_{\mathrm{C}}{}^0+\Delta H_{\mathrm{C}}(1-T/T_{\mathrm{C}}),$$

and the temperatures and enthalpies of fusion of the components have the values $T_{\mathrm{Ti}} = 1940$ K, $T_{\mathrm{C}} = 4000$ K, $\Delta H_{\mathrm{Ti}} = 15.47 \times 10^6$ J kmole^{-1}, and $\Delta H_{\mathrm{C}} = 104.5 \times 10^6$ J kmole^{-1}.

For simplicity it will be assumed that the homogeneity range extends to a line around $x = 0.5$; the formation potential $\Delta\Phi^\sigma$ at the point of congruent fusion is related to $x = 0.5$; the range of solubility of titanium in carbon (α-solution) and the influence of pressure are neglected, and the data on the fusion of carbon are taken for $P = 10^7$ Pa.

Using the condition $\Phi^{\sigma+\mathrm{C}} = \Phi$ on the right-hand eutectic of the equilibrium diagram ($x = 0.643$, $x_0 = 0.5$, $T_e = 3049$ K) gives $\Delta L = -258.6 \times 10^6$ J kmole^{-1}. The lowering of the right-hand eutectic as a result of the dispersal of carbon can now be estimated. In this case it is necessary to add to the left-hand side of the condition $\Phi^{\sigma+\mathrm{C}} = \Phi^L$ the term $\Delta H_{\mathrm{excess}}(x - x_0)/(1 - x_0)$ reflecting the contribution of the excess energy. For $x - y$ this gives the equation

$$[(1-x)/(1-x_0)]\Delta\Phi^\sigma+[(x-x_0)/(1-x_0)]\Delta H_{\mathrm{excess}}=(1-x)\Delta H_{\mathrm{Ti}}(1-T/T_{\mathrm{Ti}})+$$
$$+x\Delta H_{\mathrm{C}}(1-T/T_{\mathrm{C}})+RT\{x\ln x+(1-x)\ln(1-x)\}+x(1-x)\Delta L$$

By specifying a series of values of $\Delta H_{\mathrm{excess}}$ and looking for the minimum $T = T(x)$ it is possible to find the positions of the eutectic for different carbon materials (CM). The estimates give downward temperature displacements of the right-hand eutectic of 540 K for coke, 1200 K for carbon black, and 1800 K for "amorphous" carbon, with a simultaneous displacement to the right along the concentration axis.

Since the carbide phase formed is also dispersed, it is also possible, by estimating the excess energy of the σ-phase and making use of the condition $\Phi^\sigma = \Phi^L$, to determine the decrease in the temperature of congruent fusion and then to construct the entire metastable equilibrium diagram, as described in Ref.91, including the left-hand side (with allowance for the degree of dispersion of titanium).

The characteristic features of the M–C diagram determine the mechanism of the reaction of fine-crystalline mixtures of a metal and CM. In the reaction of Ti with imperfect forms of carbon, nuclei of the carbide phase, which will give the titanium–carbide eutectic, are formed first at the Ti–C interface. Because of the dispersal of Ti and the carbide, the temperature of the titanium–carbide eutectic will be lowered. The metal, penetrating into the channels of the CM, accumulating in the micro-pores, and reacting with carbon, gives new TiC nuclei, and Ti and TiC give a metastable eutectic. The front of this eutectic is displaced towards the imperfect CM, leaving perfect forms behind it, that is "processing" of the CM takes place. When $T \geq T_e$ for the right-hand metastable eutectic is reached, as a result of spontaneous heating of the mixture, the same processing of the CM begins, but now with the carbide–carbon eutectic, with simultaneous precipitation of the carbide phase. This stage determines the yield of carbide. These processes are based on the phenomenon discovered by Elyutin and co-workers.[16] There are many reaction channels, but the system tends to lower its energy, so that the basic reaction is the processing of the imperfect forms of CM.

Since the new phase appears on the metastable equilibrium lines, it is strongly supercooled, as it were "self-quenching" takes place, and an ultradispersed structure is produced because of the retardation of the relaxation processes at low temperatures. This method can also be used to obtain UD structures in the non-equilibrium processes of the combustion of powdered exothermic mixtures in the synthesis of intermetallic compounds, carbides with metallic bonding, and other materials.[94,20]

4. The Production of an Ultradispersed Structure in the Plastic Deformation of Titanium Nickelide

One method for the intensive treatment of solids involves a combination of high pressure and shear deformation. Available data indicate that this leads to physical and chemical processes which cannot be initiated by other methods.

The fine structure of titanium nickelide formed by the action of high pressure and shear deformation, various physicomechanical properties of the intermetallic compound, and the stability of its structure when heated have been studied.[18,96] The original specimen was a TiNi strip with thickness 200 μm, annealed at 770 K for 1 h.

Analysis of the X-ray spectra shows that the diffraction reflections become broader and merge to give a single diffuse reflection on going from the centre to the periphery of the specimens; with increase in the angle of rotation of the anvils, these differences in the structure are less clearly defined. This is due to the increase in the degree of dispersion and defect character of the structure. The dimensions of the structure are approximately 3–1.5 nm.

Electron microscope studies showed that at low degrees of deformation the granular structure of the material is close to the original structure, that is deformation takes place within the structural fragments, and the distinct boundaries between them are retained. At high deformations, dispersal takes place and the range of coherent scattering of X-rays decreases.

With increase in the deformation and pressure, the microhardness of the specimens increases and reaches 9 GPa. which is almost ten times that of the material in the annealed state.

---o0o---

Energy-rich media have a number of valuable physicochemical properties, which determine the possible fields of their technological application.

Such properties of UD powders as the lowered temperatures of phase transformations, the increased coefficients of diffusion in the particles, the lowered sintering temperatures, etc. make them particularly attractive for the synthesis of materials with unique properties by sintering, reactive sintering, hot pressing, and hot isostatic pressing; for preparing pastes for low-temperature soldering and welding, etc.

The chemical activity of UDP, including biologically active materials, is finding a number of useful applications.

The properties of energy-saturated solids (metals and alloys) are equally valuable. These include increased strength, hardness, and toughness, and lowered cold brittleness threshold, for materials with an ultrafine fragmentation structure.

A number of technologies have been developed, and experience gained, in the construction and use of experimental assemblies for the production of UDP of metals and compounds. Experience has also been gained in the storage, transportation, mixing, and compaction of UDP.

All this makes the problem of the technological application of energy-saturated media in industry and the national economy of the greatest importance.

The Thermal Theory of the Ignition of Reacting Condensed Substances

I.S.Lyubchenko and G.N.Marchenko

The processes involved in the solid-phase ignition of reacting condensed substances, taking place in the absence of mass diffusion due to temperature or concentration gradients, have been examined using a single asymptotic method. An analytical criterion for the ignition of a substance has been formulated, and a basis obtained for a universal linearisation method, which makes it possible to express experimental results statistically in the form of a linear relationship in a special system of coordinates. The question of the range of existence of non-degenerate ignition conditions has been discussed in detail. Experimental data confirming the reliability of the thermal of ignition have been given.

The bibliography contains 97 references.

I. INTRODUCTION

The study of the processes involved in the ignition of reacting condensed substances has developed extensively throughout the world in recent decades, because of their practical importance. The development of the theory of ignition originates in classical studies of the theory of thermal explosion,[1-3] summarised in a monograph.[4] The simplest model of the surface ignition of a condensed substance was first studied in Refs.5–8, where numerical integration using a computer was used to solve the non-stationary problems of the heating of the surface of a substance with an exothermic reaction taking place in the solid phase and with the Arrhenius dependence of the reaction rate on temperature.

The non-stationary thermal model of ignition adopted in these studies provided a basis for subsequent theoretical and experimental work, which has been reviewed in Refs.9 and 10 and in a recent monograph.[11] Since then, a large number of studies have been carried out, and a new asymptotic method in the theory of ignition has been developed, leading to the further development of the thermal theory and its experimental justification. It has therefore become necessary to summarise the theoretical principles of the thermal theory of ignition from a single asymptotic viewpoint. Present-day asymptotic procedures, which provide a powerful analytical method for solving boundary problems for differential equations with partial and complete derivatives, are most fully described in Refs.12–16. In the solution of problems of mathematical physics of this type, represented by the problems of the thermal theory of ignition, the asymptotic method provides a well-founded and convenient instrument of study, since the numerical values of the activation energy E and the heat Q for the chemical reactions of the ignition and combustion of known substances are fairly large.

To solve these problems, extensive use is made of approximate methods, which can be divided into four groups: 1) the critical condition method,[17-21] 2) the method of breakdown into stages,[22-25] 3) the method of successive approximations,[26,27] and 4) the method of integral relationships.[28] All these approximate methods are based on physical and mathematical simplifying assumptions about the course of the process, and not on the rigorous analytical solution of the non-linear problems of the thermal theory of ignition. At the same time it should be noted that all approximate methods are based on the same general view that the ignition process takes place in two stages: inert warm-up of the substance and progressive chemical spontaneous warm-up, ending in a "temperature explosion" at the surface at the moment of ignition. These ignition conditions have been called non-degenerate,[10] in contrast to degenerate conditions, in which the ignition process cannot develop in the warm-up and spontaneous warm-up stages. Degenerate ignition conditions can obviously lead either to "superficial burning" of the substance, at high thermal fluxes from an external source, or to the production of transition conditions intermediate between ignition and spontaneous ignition, at extremely low thermal fluxes.

None of the studies mentioned above, carried out using approximate methods, gives an answer to the problem of the range of existence of non-degenerate ignition conditions. Moreover, up to the present there has been no single definition of the criterion of ignition. Since the experimental determination and the calculation of the ignition delay time depend on the choice of ignition criterion, the arbitrary nature of this choice naturally also influences the conclusions about the agreement between theory and experiment. The moment of ignition is determined experimentally by measuring either the temperature at the surface of the substance, or the intensity of radiation, or the pressure in the system, and also by recording the behaviour of the specimen after the external heat supply is stopped. Reliable ignition takes place when the total quantity of heat liberated in the chemical reactions is greater than the heat loss. It is usually assumed that ignition does not take place if stationary combustion conditions are not established after the abrupt removal of the external heat source.[3] It has been shown,[10] however, that the calculation of pulse ignition conditions using this criterion is not a rigorously justified procedure, since this criterion was obtained by solving the particular problem of the unsymmetrical combustion of a thin slab of the reacting substance.

It should also be noted that the principle of linear universalism, which makes it possible, within the ignition model adopted, to "plot" the experimental results statistically on a straight line in a special system of coordinates, and when necessary to solve the inverse problem of determining the thermokinetic constants, has not yet been sufficiently developed.

Before proceeding to the presentation of the asymptotic thermal theory of ignition, it may be noted that in the literature[9] there are three main groups of ignition model, differing in their representation of the place where the main chemical reactions take place: 1) the model of gas-phase ignition, 2) the model of heterogeneous ignition, and 3) the model of solid-phase ignition.

In the first group of models it is assumed that ignition takes place as a result of a chemical reaction between a gaseous oxidant and a fuel vapour. This reaction is a self-maintaining heat source. Studies of the gas-phase model of the ignition of solid rocket fuels have been reviewed.[9,29] A method for calculating the ignition delay time for the case where the warm-up time of the substance is greater than the excitation time of the chemical reaction in the gas phase has been described.[30,31]

In the heterogeneous ignition model, the reaction at the phase boundary between a solid fuel and a gaseous oxidant is regarded as decisive. In the analysis of the heterogeneous ignition process it is necessary to take account of diffusion and hydrodynamic phenomena. In the particular case when the rate of the process is determined by the kinetics of the heterogeneous reaction, however, a purely thermal approach is possible.[22,23,32-37]

The solid-phase (or thermal) theory of ignition is based on the simplest (from the physical viewpoint) model of the phenomenon, in which only the processes of heat liberation and propagation in the substance are taken into account, and diffusion factors and possible phase transformations are not considered. The characteristic features of this model have been formulated,[9,10] and it is now widely used in the analysis of the processes involved in the ignition of non-volatile systems and systems difficult to volatilise.

In the present review, only the solid-phase models of ignition are analysed, for different initiation conditions.

II. THE ASYMPTOTIC ASPECT OF THE THERMAL THEORY OF IGNITION AND THE INFLUENCE OF THE MECHANISM OF HEATING ON THE BASIC REGULAR FEATURES OF THE IGNITION PROCESS

The dimensionless numerical parameters $\varepsilon = RT_0/E$, $\gamma = cRT_0^2/QE$, where T_0 is the initial temperature of the substance, c the heat capatity, and R the universal gas constant, appear in the mathematical description of the thermal model of ignition;[38-40] when $\varepsilon = 0$, because of the Arrhenius temperature dependence of the reaction rate, the chemical sources of heat become degenerate, and when $\gamma = 0$ there is no combustion of the substance in the ignition delay period, which corresponds to a zeroth-order reaction.

A natural element of the asymptotic analysis of the problems of the thermal theory of ignition is the construction of a non-stationary space–time temperature field in the substance as $\varepsilon \to 0$ ($\varepsilon \neq 0$). For this purpose, use is made of a compound asymptotic expansion, which gives a uniform approximation to the exact solution of the ignition problems both in and outside the boundary layer. Since in this case non-linear equations of a parabolic type with an exponential source are being analysed, it follows that in cases where the highest temperature is reached at the surface of the substance there is a "temperature explosion" at the surface at the moment of ignition t_*, that is there exists only a local solution of the boundary problems in the range $0 < t < t_*$. For the specific thermal model of ignition, the relationship between the rates of supply of heat from an external source of energy and from chemical reactions at the moment of ignition is calculated unambiguously. This relationship, which can be taken as a criterion of ignition, is generally easily transformed into a linear equation in a special system of coordinates and can be used to calculate the thermokinetic constants of the reaction from experimental data. In contrast to the ignition criterion, which assumes that the rates of supply of heat from the reaction and from an external source of energy are equal at the moment of ignition,[10,18,19,26,41] the asymptotic criterion in principle does not specify this equality. Other criteria, adopted in Refs. 28 and 42–47, are not sufficiently well-founded, since they were not obtained from a rigorous analysis of the corresponding boundary problems of the thermal theory of ignition. They are applicable only in a restricted range of conditions of combustion initiation.

The asymptotic analysis, together with the ignition criterion, leads to two definite inequalities, fulfilment of which determines the range of existence of the asymptote or, in other words, the range of existence of non-degenerate ignition conditions. This question has not previously been discussed in the literature, although information on the range of existence of non-degenerate ignition conditions is very necessary for experimental workers in the correct organisation of experiments and choice of initial parameters and appropriate recording apparatus. The analytical apparatus of the method of compound asymptotic expansion exists in differential[40] and integral[48] versions. The influence of the mechanism of heating of a substance on the basic regular features of the ignition process is examined below for the case of the solution of the specific problems in the thermal theory of ignition, and simple equations are given for calculating the characteristics of ignition.

1. Dynamic Conditions of Ignition of a Non-transparent Condensed Substance

For a semi-infinite solid slab and a one-dimensional thermal flux, the mathematical formulation of the ignition problem has the form:[49]

$$\left.\begin{array}{l} T_t = \varkappa T_{xx} + Qk_0c^{-1}(1-\eta)\exp[-E/RT], \\ \eta_t = k_0(1-\eta)\exp[-E/RT] \\ t=0: T=T_0,\ \eta=0;\ x=\infty: T=T_0 \end{array}\right\} \qquad (1)$$

$$x=0: -\lambda T_x = q(t);\ q>0 \qquad (2)$$

Here, T is the current temperature of the substance, t the time, x the spatial coordinate, η the degree of transformation, q the density of the thermal flux from the external source, ρ, λ, and κ the density, coefficient of thermal conductivity, and temperature conductivity of the substance respectively, and k_0 the pre-exponential factor. The other symbols were given above.

The asymptotic study of the general problem (1) and (2) has been carried out.[48,49] The chief characteristics of the ignition for the particular case $q = At^n$, $A > 0$, $n > -0.5$ are calculated using the equations:[50]

$$t_* = \left[\left(\frac{\lambda T_0}{A}\right)^2 \frac{u_*}{\varkappa}\right]^{\frac{1}{2n+1}},\quad T_* = T_0\theta_*,\quad T_i = T_*\left(1 + \frac{\theta_*}{2}\varepsilon\ln(1/\varepsilon)\right),$$
$$Q_* = \frac{At_*^{n+1}}{n+1},\quad \eta_* = 1.48\gamma\varepsilon^{-1/2}\theta_*\left(\frac{d\theta_*}{du_*}\right)^{-1/2} \qquad (3)$$

Here, the dimensionless ignition delay time u_* is determined from the transcendental equation

$$A=\left[\frac{\varkappa}{u_*(\lambda T_0)^2}\right]^n\cdot\left[1.5385\,\varepsilon^{1/2}Q\rho k_0\lambda T_0\theta_*\left(\frac{d\theta_*}{du_*}\right)^{-1/2}\exp\left(-\frac{1}{\varepsilon\theta_*}\right)\right]^{n+1/2}\qquad(4)$$

and $\theta_* = \theta_*(u_*)$ is calculated from the equations

$$\theta_*=1+\frac{u_*^{1/2}}{\delta_n},\quad \delta_n=\frac{\Gamma(1.5+n)}{\Gamma(1+n)}\qquad(5)$$

In Eqns.(3), T_* is the scale temperature, T_i the ignition temperature, Q_* the minimum energy required for ignition, and η_* the extent of the combustion in the ignition delay period. The tabulated Euler gamma-function $\Gamma(z)$ is used in Eqns.(5). Eqn.(4) gives the relationship between the rates of supply of heat from the external source and from the chemical reactions at the moment of ignition. It can be written in the form

$$At_*^n=\sigma_n\left\{\lambda\rho Qk_0\frac{RT_*^2}{E}\exp\left(-\frac{E}{RT_*}\right)\right\}^{1/2}\qquad(6)$$

where

$$\sigma_n=\theta_0^{1/4}[2.1757\,\delta_n]^{1/2},\quad \theta_0=E(T_*-T_0)/RT_*^2$$

For $n = 0$ (constant thermal flux), the expression for σ_0 has the form $\sigma_0 = 1.39\,\theta_0^{1/4}$, and with increase in the parameter n the function σ_n increases, that is $\sigma_n > \sigma_0 \cong 2.9$–$3.1$. Eqn.(6) can be used as a criterion of ignition. At the same time, in Refs.10, 18, 41, and 51, the value of σ_n is assumed to be 1. The range of existence of non-degenerate ignition conditions is determined by the inequalities[50,52]

$$A^-(n,\ T_0)\leqslant A\leqslant A^+(n,\ T_0)\qquad(7)$$

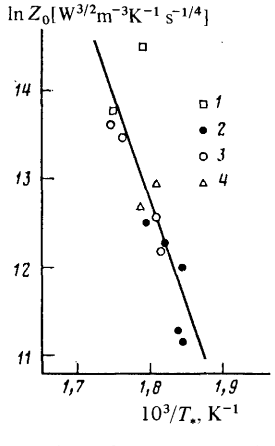

Figure 1. Determination of the thermokinetic constants of the ignition of nitrocellulose from experimental data;[50] continuous line—calculated by the least-squares method; the experimental points were obtained for the following values of n: *1*) 0.6; *2*) 1.0; *3*) 1.39; *4*) 2.8.

Eqn.(4) is readily transformed to the special form

$$\ln Z_0=\ln[2.1757\,\rho Qk_0\varkappa^{1/4}(R\lambda/E)^{1/2}]-\frac{E}{RT_*}\qquad(8)$$

where Z_0 and the scale temperature T_* are determined from the measured values of T_0, A, n, and t_* using the equations

$$Z_0=A^{3/2}T_*^{-1}t_*^{(6n-1)/4}\delta_n^{-1/2},\ T_*=T_0+At_*^{n+1/2}\cdot\delta_n^{-1}(c\rho\lambda)^{-1/2}\qquad(9)$$

Eqn.(8) is described graphically by a straight line in the coordinates $\{\ln Z_0,\ 10^3/T_*\}$. It is universal for any values of $\{A, n, T_0\}$ in the range of existence of non-degenerate conditions. By treating the experimental results by the least-squares method in the system of coordinates indicated, it is possible readily to calculate the thermokinetic constants E and Qk_0. Fig.1 gives experimental data on the ignition of nitrocellulose under dynamic conditions in a special light apparatus.[50] The least-squares method gave the values

$$\ln Z_0=56.3458-24.25\frac{10^3}{T_*},E=201\,760\ \text{J mole}^{-1},\ Qk_0=2.4932\times10^{25}\ \text{W kg}^{-1},$$

in good agreement with published data.[10]

To illustrate the effectiveness of the asymptotic method of calculating the characteristics of ignition, Table 1 compares the experimental[50] values of the ignition delay time of nitrocellulose at T_0 = 300 K with the values calculated using Eqns.(3). The agreement between these values of t_* is good. Finally, it may be noted that the influence of the relative uncertainty of the determination of σ_n on the accuracy of the estimation of t_* has been studied,[53] and it was concluded that this influence decreases with increase in n.

2. The Ignition of a Transparent Substance by a Constant Thermal Flux (n = 0, A = q)

This problem requires special consideration because of its considerable methodological importance, since in this case it is possible to compare results obtained by different authors. Eqns.(3)–(6) for n = 0 lead to calculation equations for determining the characteristics of ignition, and also ignition criteria, differing considerably from those adopted in the literature. This difference is illustrated by data on the value of σ_0 used in approximate methods (Table 2).

This variety of ignition criteria obtained is related to the fact that rigorous allowance was not made for the explosive character of the change in temperature at the surface of the substance at the moment of ignition. Only the method of compound asymptotic expansions[50,54] has made it possible to obtain a well-justified ratio of the rates of supply of heat from the reaction and from the external source at the moment of ignition, and also to find the relationship $\tau_* = (t_*/t_0) = 0.4065\ \theta_0^{3/2}$, where t_0 is the adiabatic induction period of the thermal explosion at a temperature T_*.

*Relationship obtained by the present authors using Eqn. (18) from Ref.10.

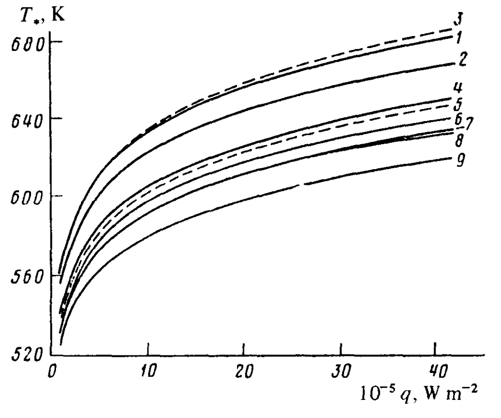

Figure 2. Dependence of the ignition temperature of nitrocellulose on q, calculated from various data: *1*) Refs.18, 19, 55, *2*) Ref.45, *3*) from Eqn.(3), *4*) Ref.7, *5*) from Eqn.(3), *6*) Ref.25, *7*) Ref.46, *8*) Ref.47, *9*) Refs.10 and 46.

To illustrate the influence of the value of σ_0 on the scale temperature T_*, calculated on the basis of the combustion criterion (6) for $n = 0$, Fig.2 gives the $T_*(q)$ relationships obtained from the data of different authors for $T_0 = 303$ K for nitrocellulose; the thermophysical and kinetic constants required for the calculation were taken from Ref.10. Since all the authors assume that $T_* = T_i$, Fig.2 gives the curve for the ignition temperature T_i (curve *3*), calculated using Eqn.(3). Curve *5*, obtained by the asymptotic method, is extremely close to curve *4*, obtained by numerical integration using a computer,[7] and curve *3* agrees fairly well with curve *1*.[18,19,55] On the whole, the discrepancy in the values of T_* obtained by different authors increases with increase in the density of the thermal flux, reaching 10%. A comparison of the values of t_* and T_* calculated by the asymptotic method with the results of the numerical solution of the problem using a computer[7] can be carried out for nitrocellulose at $T_0 = 303$ K on the basis of the data in Table 3. Good quantitative agreement is observed.

Table 3. Comparison of the results of the asymptotic and numerical solutions of the problems of ignition by a constant thermal flux.

$10^{-4} q$, W m^{-2}	8,38	41,9	83,8	209,5	419
T_*, K (Ref.7)	542	582	601	628	650
t_*, s (Ref.7)	1.564	0.0852	0.0243	0.00463	0.00132
T_*, K (Ref.54)	539	578	597	623	645
t_*, s (Ref.54)	1.522	0.0828	0.0236	0.00449	0.00128

Note. The values of T_* and t_* were obtained by numerical integration using a computer in Ref.7, and by the asymptotic method in Ref.54.

The results of the calculation of the ignition delay time using the asymptotic equations (3)–(5) and the equations obtained in Refs.28 and 56 can be compared. In Ref.56, the value of t_* was calculated using the interpolation equation

$$t_* = 0.699\ \frac{\lambda\rho c}{q^2}(T_* - T_0)^2,\quad T_* = \frac{E}{2R}\left[D - \ln D + \frac{\ln D}{D}\right]^{-1},\quad D = \frac{1}{2}\ln\left(\frac{\lambda\rho Qk_0E}{2Rq^2}\right) \tag{10}$$

In Ref.28, an equation obtained by the method of integral relationships

$$t_* = \frac{c\rho\lambda\ (T_* - T_0)^2}{q^2}[1 + \theta_0^{-1}\ln(2\theta_0)]^2,\quad \theta_0 = \frac{E\ (T_* - T_0)}{RT_*^2} \tag{11}$$

was used; the ignition criterion (6) with $\sigma_0 = 1$ was used to determine T_*.

Table 4 compares the values of t_* for nitrocellulose, calculated by the three methods indicated for different values of q and T_0. The appreciable difference between the results indicates that the approximate methods[28,56] are insufficiently rigorous. The range of existence of non-degenerate ignition conditions for a substance for q = const is given by Eqn.(7) with $n = 0$. Using the relationships which follow from Eqn.(9) for $n = 0$,

$$Z_0 = q^{3/2}t_*^{-1/4}T_*^{-1}\delta_0^{1/2},\quad T_* = T_0 + 2q\,[t_*(\pi\lambda\rho c)^{-1}]^{1/2}$$

Eqn.(8) can be transformed to

$$\ln\left[\frac{(T_* - T_0)^{3/2}}{T_*t_*}\right] = 2\ln[2.78(\pi c)^{-1/2}\cdot(Qk_0)^{1/2}\cdot(R/E)^{1/4}] - \frac{E}{RT_*} \tag{12}$$

and can be used to determine the thermokinetic constants from experimental data. Fig.3 gives the results of experiments on the ignition of "N" powder,[57] which lie on a straight line on the coordinates of Eqn.(12). The use of the thermophysical constants from Ref.42 and Eqn.(12) gives the values $E = 147.8$ kJ mole^{-1}, $Qk_0 = 4.97 \times 10^{20}$ W kg^{-1}.

Although the asymptotic approach developed in Ref.44 does not make it possible to establish the range of existence of non-degenerate ignition conditions, to determine the values of σ_0, T_i, and η_*, or to obtain a universal straight line (12), it nevertheless gives good agreement between the calculated principal characteristics of the ignition of a substance by a constant thermal flux, and the results obtained by numerical integration using a computer. This indicates the advantage of using asymptotic analysis to study the ignition process.

3. The Ignition of Non-transparent Condensed Substances

The simplest case of the ignition of a substance by a stream of hot gas having a constant temperature T_c ($T_c > T_0$) can be considered. In this case, the heat exchange at the surface of the substance ($x = 0$) can be described using Newton's law

$$-\lambda T_x = \alpha\,[T_c - T(0, t)] \tag{13}$$

where α is the coefficient of heat transfer from the gas to the substance (a constant quantity). This problem was previously analysed using the methods of the critical condition,[7,10,18,46,51] breakdown into stages,[24] and integral relationships.[28] These approximate methods do not give sufficient accuracy, however, since they do not use the analytical procedure of the method of compound asymptotic approximations.[40,48,58] As shown below, the latter makes it possible to establish the ignition criterion and the range of existence of non-degenerate ignition conditions, and also to calculate the principal characteristics of ignition and to construct a universal straight line for calculating the kinetic constants from experimental data.

The ignition criterion in this case has a form analogous to that of Eqn.(6)

$$\alpha\,(T_c - T_*) = \sigma\left\{\lambda\rho Q k_0 \frac{RT_*^2}{E}\exp\left(-\frac{E}{RT_*}\right)\right\}^{1/2} \tag{14}$$

where

$$\sigma = \frac{\theta_0^{1/4}}{(0.65)^{1/2}}\left(\frac{T_c - T_*}{T_* - T_0}\right)^{1/4} F^{1/4}(x_0),\quad x_0 = \varphi(y),\quad y = \frac{T_c - T_*}{T_c - T_0},$$

$$F(x_0) = \frac{y(x_0)}{(\pi x_0)^{-1/2} - y(x_0)},\quad y = \exp(x_0)\,\mathrm{erfc}\,[x_0^{1/2}]$$

The value of σ obtained differs considerably from other published values: $\sigma = 1$,[10,51] 4.2,[46] and $(0.1\,\pi\theta_0)^{1/2}$.[7] Eqn.(14) can be used to find the scale temperature T_* and then to calculate the quantity $x_0 = \phi(y)$ and the ignition delay time:

$$t_* = c\rho\lambda\alpha^{-2}x_0 \tag{15}$$

The ignition temperature T_i and the minimum energy of ignition Q_* are calculated using the equations:

$$T_i = T_*\left[1 + 0.5\frac{T_*}{T_0}\,\varepsilon\ln(1/\varepsilon)\right]$$

$$Q_* = c\rho\,(\lambda/\alpha)\,(T_c - T_0)\,[2\,(x_0/\pi)^{1/2} + \exp(x_0)\,\mathrm{erfc}\,[x_0^{1/2}] - 1]$$

Eqns.(14) and (15) can be used to compare the results of the calculation of the ignition delay time t_* by the asymptotic method and by the method used in Refs.10 and 51 (for $\sigma = 1$). Fig.4*a* compares the dependence of t_* on α for nitrocellulose, calculated for T_0 = 303 K, with the experimental data.[59] The relationship has the form $t_* \sim \alpha^{-m}$ noted earlier.[46] Fig.4*b* shows that the function $m = m(T_c)$ obtained by the asymptotic method practically coincides with the curve obtained by numerical integration using a computer and interpolation, with the form:[46]

$$m = 1.79 - 44\left[\frac{RT_0T_c}{E\,(T_c - T_0)}\right]^{1.67} \tag{16}$$

The experimental value $m = 1.64$ for T_c = 573 K[60] also lies satisfactorily on the calculated curve. The curves obtained by the method of Refs.10 and 51 differ considerably from the asymptotic relationships, indicating that the use of the ignition criterion with $\sigma = 1$ is not sufficiently correct.

The asymptotic approach also makes it possible to determine the kinetic parameters E and Qk_0 from experimental data on the ignition of a substance in a stream of hot gas. No accurate relationships for calculating E and Qk_0 have been published, and the method used in Refs.51 and 57, based on the use of the ignition criterion (14) with $\sigma = 1$, as noted above, leads to errors. The method proposed in Ref.60 also is not universal, although it enabled the authors of Ref.59 to carry out the treatment of experimental data on the ignition of a number of substances. The best-justified method for determining the kinetic constants from experimental data is that described in Ref.58. If in the experiment the conditions of heat exchange (T_c, α) are recorded, and the initial temperature of the substance T_0 and the ignition delay time t_* measured, then Eqns.(14) and (15) in the coordinates $\{\ln Z_0,\ 10^3/T_*\}$ can be used to obtain the equation of a universal straight line for determining the kinetic parameters

$$\ln Z_0 = \ln\left[(0.65)^{-1}\lambda\rho Qk_0 (R/E)^{1/2}\right] - \frac{E}{RT_*} \qquad (17)$$

where

$$Z_0 = \alpha^2 T_*^{-1}(T_c - T_*)(T_c - T_0)^{1/2}\left[(\pi x_0)^{-1/2} - y\right]^{1/2},$$
$$T_* = T_c - (T_c - T_0)\exp\left[\frac{\alpha^2 t_*}{c\rho\lambda}\right]\operatorname{erfc}\left[\left(\frac{\alpha^2 t_*}{c\rho\lambda}\right)^{1/2}\right]$$

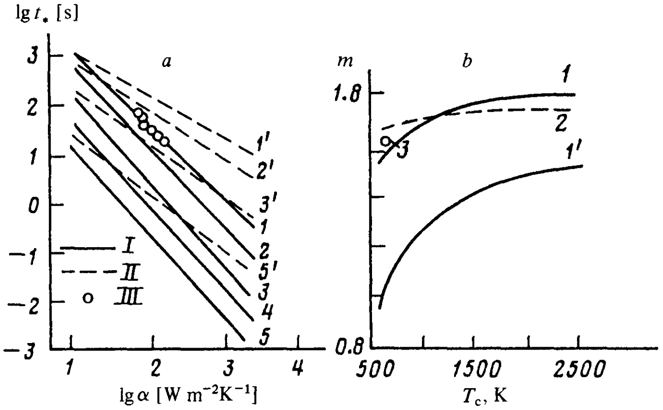

Figure 4. *a*) Dependence of the ignition delay time of nitrocellulose on the thermal properties of the external medium for T_c, K: *1, 1'*) 600; *2, 2'*) 700; *3, 3'*) 1000; *4*) 1800; *5, 5'*) 2500 (*I*—calculation using Eqns.(14) and (15); *II*—calculation by the method of Refs.10 and 51; *III*—experiment[59]); *b*) dependence of the parameter *m* on the temperature T_c: *1*) calculation using Eqns.(14) and (15), *1'*) calculation by the methods of Refs.10 and 51, *2*) calculation using Eqn.(16), *3*) experiment.[60]

As an illustration, *E* and Qk_0 can be calculated for nitrocellulose using published experimental data[60] for $T_0 = 298$ K and $T_c = 573$ K. The least-squares method and treatment of the experimental data on coordinates $\{\ln Z_0,\ 10^3/T_*\}$ gives the linear equation

$$\ln Z_0 = 61.7386 - 24.1843\,\frac{10^3}{T_*}$$

With allowance for Eqn.(17) this gives

$$E = 2.012 \times 10^5 \text{ J mole}^{-1};\quad Qk_0 = 3.475 \times 10^{26} \text{ W kg}^{-1}$$

The value of Qk_0 obtained is 19.5 times that previously calculated by other methods.[10] This is apparently due to the inadequacy of the mathematical model adopted for the calculations, and of the physical experiment,[60] where in addition to convective heat exchange between nitrocellulose and the gas stream, radiant heat exchange from the walls of the vessel also took place. According to the authors' estimates it amounted to ~30% of the total heat exchange.

The asymptotic approach also makes it possible to find the range of existence of non-degenerate ignition conditions

$$\alpha^-(T_0, T_c) \leqslant \alpha \leqslant \alpha^+(T_0, T_c) \qquad (18)$$

The corresponding data are given in Fig.5. The thermophysical and thermokinetic characteristics were taken from Ref.10. It can be seen that with increase in T_0 and decrease in the temperature of the hot gas T_c, the range of existence of non-degenerate ignition conditions becomes much narrower. This important feature must be taken into account when carrying out experiments.

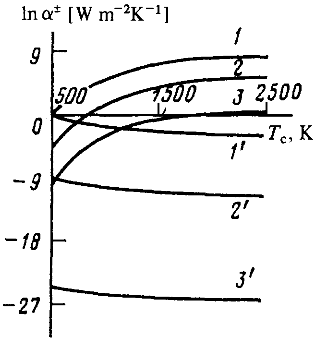

Figure 5. Ranges of existence of non-degnerate ignition conditions for nitrocellulose at T_0, K: *1, 1'*) 383, *2, 2'*) 303; *3, 3'*) 223; α^+—curves *1, 2*, and *3*; α^-—curves *1'*, *2'*, and *3'*.

The approximate equation $t_* \cong C\exp(E/RT_*)$ given in Ref.10, under the conditions of convective heating, makes it possible to calculate with an accuracy reaching 10% only the activation energy from the experimental values of t_*, T_c, α, and T_0, but gives no answer to the question of the magnitude of Qk_0. Calculations carried out by the asymptotic method for octogen, hexogen, nitrocellulose, and "N" powder confirmed this important conclusion and demonstrated again the practical applicability of Eqn.(17).

4. The Ignition of Non-transparent Condensed Substances Using a Heated Block

The simplest thermal model for the ignition of non-volatile condensed systems by a heated block assuming that a zeroth-order reaction takes place has been examined by many workers using various approximate analytical and numerical methods.[8,26–28,44,45,61–65] The lack of agreement between the results obtained, however, indicates that the approximate methods used are insufficiently accurate. Allowance for the combustion of the substance during the ignition delay time was made only in Ref.63, but the equation proposed in this study for calculating the conditional degeneration boundary gives results which are too high.

The present section gives the results of applying the asymptotic theory of the ignition of reacting substances; the examination is carried out for a boundary condition of the first kind without allowance for phase transformations and the large number of kinetic and physical stages, and also without allowance for the dispersal of the substance by the expanding gaseous reaction products. For ideal heat exchange between the substance and the heated block, the system of equations (1) is examined, and the conditions at the surface are written in the form $T(0,t) = T_b$, where T_b is the temperature of the heated block. In Refs.66 and 67, a complete asymptotic analysis of the problem was carried out, and its analytical solution given (in dimensionless units)

$$\left.\tau_* = \frac{\theta_0^2}{2\pi}[1 + 2\theta_0^{-1}\ln\theta_0],\ \tau_i = \frac{\theta_0^2}{2\pi}[1 + 2\theta_0^{-1}\ln\theta_0 + 7.545\theta_0^{-1}]\right\} \quad (19)$$

$$\left.\begin{array}{l}\Delta H = 2^{1/2}\pi^{-1}H_0\theta_0^2[1 + \theta_0^{-1}\ln\theta_0],\ H_0 = c\rho(\varkappa t_0)^{1/2}\cdot(RT_b^2/E),\\ \Delta Q = 2^{-1/2}\pi^{-1}H_0\theta_0^2\{[\theta_0^{-1}(1+\theta_0^{-1})]^{1/2} + 0.5(\arcsin(-1+2\theta_0^{-1}) - 0.5\pi]\},\\ \Delta R = \Delta H - \Delta Q, (\Delta R/H_0) = 0.297 - 0.372 \text{ for } \theta_0 = 10-30,\\ \eta_* = 1 - \exp(-\gamma\tau_*),\ \eta_i = 1 - \exp(-\gamma\tau_i)\end{array}\right\} \quad (20)$$

where

$$\tau = t/t_0,\ t_0 = \frac{cRT_b^2}{EQk_0}\exp\left(\frac{E}{RT_b}\right),\ \gamma = \frac{cRT_b^2}{QE} \quad (21)$$

Here, t is the current time, t_0 the adiabatic induction period of the thermal explosion at T_b, τ_* the dimensionless warm-up time of the specimen, τ_i the dimensionless ignition delay time, θ_0 the temperature head of the heating block ($\theta_0 \gg 1$), η_* the depth of combustion in the warm-up time, η_i the depth of combustion in the ignition delay time, and ΔH, ΔQ, and ΔR the stored energy, the energy supplied from outside, and the energy liberated in the reaction respectively.

Eqns.(19) and (20) were obtained neglecting the quantity $\beta = RT_b/E$ and with the condition that the warm-up of the substance is complete at the moment t_* when the temperature gradient at the surface becomes zero, and the ignition of the substance takes place at the moment t_i when the temperature gradient at the surface becomes infinite. For sufficiently small values of $\gamma\theta_0^2$, the equations for η_* and η_i are simplified and take the form

$$\eta_* = \gamma\tau_*,\ \eta_i = \gamma\tau_i \quad (22)$$

The conditional boundary of degeneration of normal ignition conditions can be determined from the inequalities $\eta_* \leqslant a$, $\eta_i \leq a$, where $a = 0.1-0.2$.[66] Eqn.(20) is then used to find the equation for calculating the limiting value of the parameter γ characterising the conditional boundary of degeneration

$$\gamma \leqslant \gamma_0 = \tau_i^{-1}\cdot\ln[1/(1-a)] \quad (23)$$

The equation proposed in Ref.63 has the form $\gamma_0 = 0.5\,\theta_0^{-1}$ and gives results which are 1–2 times higher than those given by Eqn.(23).

The accuracy of the asymptotic equations for calculating the basic characteristics of ignition is extremely high, as indicated by comparing with the results of numerical integration using a computer (Table 5). Fig.6 compares the results of the calculation of the warm-up periods of a reacting substance τ_* for $\beta = 0$ with the approximate equations used by a number of authors and also with Eqn.(19). The results of the calculation using Eqn.(19) practically coincide with those obtained[61] by computer calculation. Curves *2* and *3*, calculated using the data of Refs.27 and 63, are close to one another. The results obtained in Ref.26 (curve *1*) and in Ref.64 (curve *7*) are extremely far from the true values of the warm-up period. Most authors have tried to obtain simplified equations for calculating the warm-up time in the form of functions $\tau_* = A\theta_0^2$; the coefficient A has been assigned the values 0.21,[68] 0.207,[65] 0.25,[27,28] and 0.159.[45,62] This simplification, however, leads to marked deviations from the results obtained using Eqn.(19).

The asymptotic method has been used[44] to obtain more rigorous values of τ_*. Although the authors[44] did not use this method in complete form to solve the problem of the ignition of a substance by a heated block, they were able to estimate the lower and upper values of τ_* (denoted τ_*^- and τ_*^+ respectively). Table 6 gives the values of τ_*^- and τ_*^+ from Ref.44, and also compares the values of τ_* calculated using Eqn.(19) and obtained by numerical integration using a computer.[61] Good quantitative agreement is observed. As $\theta_0 \to \infty$, Eqns.(19) are simplified, and in the limit give the values obtained in Refs.45 and 62. This limit, however, is only the zeroth asymptotic approximation to the actual value of the warm-up period of the substance; this approximation does not give the required accuracy.

Table 5. Dimensionless characteristics of the ignition of a condensed substance by a heated block.

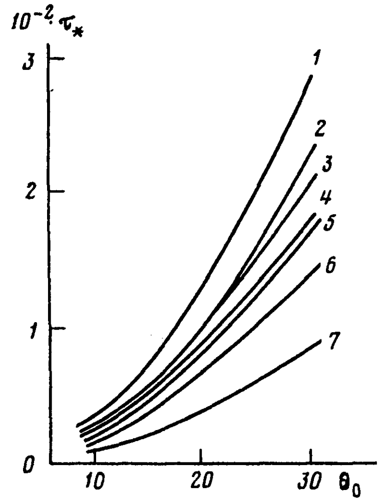

Figure 6. Dependence of the dimensionless warm-up time of a reacting substance τ_* on the parameter θ_0, calculated from various data: *1*) Ref.26, *2*) Ref.27, *3*) Ref.63, *4*) Ref.61, *5*) from Eqn.(19), *6*) Ref.45, *7*) Ref.64.

Fig.7 gives the results of the calculation, using Eqns.(20) and (22) for η_*, of the boundary conditions of the degeneration of the normal ignition conditions of nitrocellulose. Nondegenerate ignition conditions are produced at temperatures lying below the corresponding curves *1–3*, each of which corresponds to a definite value of the parameter a. Using Eqn.(21), Eqns.(19) can be represented in a form convenient for determining the kinetic constants, that is they can be linearised. For example, the following expression is obtained for the warm-up time

$$\ln\left[\frac{t_*}{T_b-T_0}\right]=\frac{E}{RT_b}+\ln\left\{\frac{c}{2\pi Qk_0}\left[\frac{E(T_b-T_0)}{RT_b^2}+2\ln\left(\frac{E(T_b-T_0)}{RT_b^2}\right)\right]\right\} \tag{24}$$

Table 6. Comparison of ignition delay times calculated by different methods.

Ignition characteristic	θ_0			Method of calculation	Refs.
	10	20	30		
τ_*	25.7	86.2	181.5	I	[61]
τ_*	23.2	82.7	175.7	II	[66, 67]
τ_*^-	20.9	74.6	160.7	III	[44]
τ_*^+	28.7	97.4	203.3	III	[44]

Note: I—numerical integration using a computer; II—calculation using the asymptotic equation (19); III—calculation by the asymptotic method.

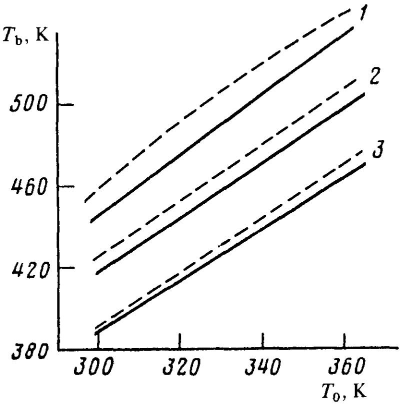

Figure 7. Conditional boundaries of the degeneration of the normal ignition conditions of nitrocellulose for values of the parameter a: 1) 0.2; 2) 0.15; 3) 0.1; continuous lines—calculation using Eqn.(20), broken line—calculation using Eqn.(22).

The results of an experimental study of the ignition of nitrocellulose by a heated block with a temperature T_b = 485–515 K at a temperature of the specimens T_0 = 293–298 K have been published.[69] Fig.8 gives these results, treated by the least-squares method on the coordinates of Eqn.(24). In the treatment of the experimental data, allowance was made for the fact that under the conditions of the experiment, the quantity $(T_b-T_0)/T_b^2$ varied within a range of 5%. Assuming that the average value of this quantity is 0.816×10^{-3} K^{-1}, treatment of the experimental data[69] using Eqn.(24) gives E = 200 kJ mole^{-1} and $Qk_0 = 1.08 \times 10^{26}$ W kg^{-1}. Treatment of the data of the same experiment using the equation for the delay time τ_i gives the value $Qk_0 = 7.45 \times 10^{26}$ W kg^{-1}.

Thus the ignition criterion in the problem with boundary conditions of the first kind is the "explosion" of the temperature gradient on the surface of the substance at the moment of ignition, whereas in problems with boundary conditions of the second and third kind the criterion is the "explosion" of the actual temperature at the surface of the substance.

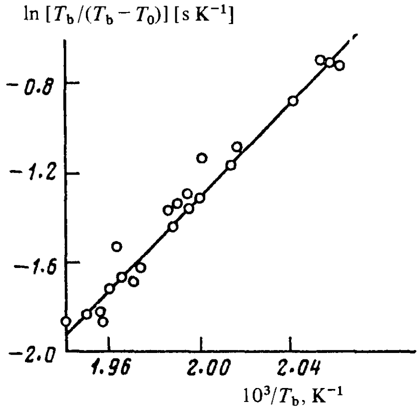

Figure 8. Determination of the thermokinetic parameters of the ignition of nitrocellulose from experimental data:[69] continuous line—calculation by the least-squares method, points—experiment.

5. The Ignition of a Semi-transparent Substance by a Beam of Radiant Energy

In the last ten years, studies of the combustibility of condensed systems using a CO_2 laser (wavelength 10.6 μm) have found extensive application in various branches of science and technology. They make it possible to carry out experiments at appreciable thermal flux densities and to take correct account of the bulk character of the absorption of light by the substance. The problem of the ignition of a semi-transparent substance by a beam of radiant energy has been studied by numerical and approximate analytical methods by many authors.[10,18,21,24,39,42,44,56,70,71] The works cited, however, give no single expression for the ignition criterion, do not indicate the ranges of existence of non-degenerate ignition conditions, and do not contain universal linear equations making it possible to solve the inverse problem of calculating the thermokinetic parameters from experimental data on the ignition of a substance by a beam of radiant energy.

The mathematical formulation of the problem with the notation given above has the form:[72]

$$\begin{gathered}T_t=\varkappa T_{xx}+Qk_0c^{-1}(1-\eta)\exp(-E/RT)+q\nu(c\rho)^{-1}\exp(-\nu x),\\ \eta_t=k_0(1-\eta)\exp(-E/RT);\ t=0:\ T=T_0,\ \eta=0;\\ x=0:\ T_x=0;\ x=\infty:\ T=T_0\end{gathered} \tag{25}$$

Here, q is the density of the beam of radiant energy, and ν the coefficient of bulk absorption of energy at a given wavelength.

The principal results obtained using the asymptotic theory of ignition described in Refs.72 and 73 will be given. The parameter $\nu_1 = \nu\lambda T_0 q^{-1}$ is introduced, representing the ratio of the thickness of the heated layer to the thickness of the absorption zone. In the case where $\nu_1 \gg 1$, the ignition criterion has a form analogous to that of Eqn.(6):

$$q=\sigma\left\{\lambda\rho Qk_0\frac{RT_*^2}{E}\exp\left(-\frac{E}{RT_*}\right)\right\}^{1/2},\ \sigma=\left[\frac{\Phi(\alpha)}{0.65}\right]^{1/2}\theta_0^{1/4}\left[(\theta_*-1)\frac{d\theta_*}{du_*}\right]^{-1/4} \quad (26)$$

where

$$\alpha=\nu_1\varepsilon\theta_*^2,\ \Phi(\alpha)=(\alpha)^{1/\alpha-1}\cdot\gamma\left(\frac{1}{\alpha},\frac{1}{\alpha}\right)\exp\left(\frac{1}{\alpha}\right),$$
$$\theta_*=1+2(u_*/\pi)^{1/2}-\frac{1}{\nu_1}+\frac{1}{\nu_1}\exp(\nu_1^2u_*)\,\mathrm{erfc}\,[(\nu_1^2u_*)^{1/2}], \quad (27)$$
$$\gamma(n,m)=\int_0^m t^{n-1}\exp(-t)\,dt$$

Eqn.(26), with allowance for Eqn.(27), can be used to calculate the dimensionless ignition delay time u_*, and hence the values of θ_* and $d\theta_*/du_*$. The dimensional characteristics of the ignition are calculated from the equations

$$t_*=\left(\frac{\lambda T_0}{q}\right)^2\frac{u_*}{\varkappa},\ T_*=T_0\theta_*,\ T_\mathrm{i}=T_*[1+0.5\theta_*\varepsilon\ln(1/\varepsilon)],$$
$$\eta_*=1.48\gamma\varepsilon^{-1/2}\cdot\theta_*\left(\frac{d\theta_*}{du_*}\right)^{-1/2}\cdot[\Phi(\alpha)]^{-1} \quad (28)$$

As $\nu_1\to\infty$, Eqns.(26) and (27) lead to the familiar result given in the section on the ignition of a non-transparent substance: $\sigma_0 = 1.39\,\theta_0^{1/4}$.

Eqn.(26) and the function θ_* are readily transformed to

$$\ln Z_0=\ln\left[\frac{\rho Qk_0}{0.65}\left(\frac{R\lambda}{E}\right)^{1/2}\right]-\frac{E}{RT_*} \quad (29)$$

$$Z_0=\frac{q^{3/2}[\nu y(t_*)]^{1/2}}{T_*\Phi(\alpha)},\ T_*=T_0+\frac{q}{\nu\lambda}\left[y(t_*)+2\left(\frac{\varkappa\nu^2t_*}{\pi}\right)^{1/2}-1\right],$$
$$y(t_*)=\exp[\varkappa\nu^2t_*]\,\mathrm{erfc}\,[(\varkappa\nu^2t_*)^{1/2}] \quad (30)$$

If the quantities T_0, q, ν, and t_* are measured experimentally Eqn.(30) can be used to calculate T_*, y, and Z_0, and, having expressed the experimentally obtained relationships on coordinates $\{\ln Z_0,\ 10^3/T_*\}$, Eqn.(29) can be used to calculate the thermokinetic constants E and Qk_0. The ignition characteristics of nitrocellulose t_* and T_* calculated from Eqns.(28) for T_0 = 293 K show good quantitative agreement with the same quantities obtained by the method used in Refs.10, 21, and 56.

For the case where $\nu_1 = 0$ (1), when the thicknesses of the heated layer and the absorption zone are commensurate, the function σ in the expression for the ignition criterion (26) has the form:

$$\sigma=\theta_0^{1/2}\left[(\theta_*-1)\frac{d\theta_*}{du_*}\right]^{-1/2}\exp\left[-\frac{C}{2}\bar{x}^m\right] \quad (31)$$

where

$$\bar{x}=\nu_1^2u_*=\varkappa\nu^2t_* \quad (32)$$

and the values of the constants C and m are given in Ref.72.

Eqn.(26) can be used to calculate the dimensionless delay time $\bar{x}$, and hence θ_* and $d\theta_*/du_*$ from Eqns.(27) and t_* from Eqn.(32). The temperatures T_* and T_i are then determined:

$$T_*=T_0\theta_*,\ T_\mathrm{i}=T_*[1+0.75\,\theta_*\varepsilon\ln(1/\varepsilon)] \quad (33)$$

Eqn.(26), in which σ is given by Eqn.(31), can also be represented in the form of the universal linear equation:

$$\ln[\nu q\exp(C\bar{x}^m+\bar{x})\,\mathrm{erfc}\,(\bar{x}^{1/2})]=\ln(\rho Qk_0)-\frac{E}{RT_*} \quad (34)$$

The value of T_* is calculated from the experimental values of $\{T_0,\ q,\ \nu,\ t_*\}$ using Eqn.(30), and the left-hand side of Eqn.(34) is calculated from the value of $\bar{x}$ using Eqn.(32). By treating the experimental results by the least-squares method and using Eqn.(34) it is possible to calculate E and Qk_0. Fig.9 gives experimental data[56] on the ignition of nitrocellulose ($\nu = 3\times10^4$ m^{-1}) and nitrocellulose containing 1% carbon ($\nu = 6\times10^4$ m^{-1}) for T_0 = 293 K. Treatment of these data on coordinates $\{\ln Z_0,\ 10^3/T_*\}$, where $\ln Z_0$ is the left-hand side of Eqn.(34), makes it possible to calculate the thermokinetic parameters

$$E = 192767\ \text{J mole}^{-1},\ Qk_0 = 2.1\times10^{25}\ \text{W kg}^{-1}$$

in good agreement with the values given in Ref.10.

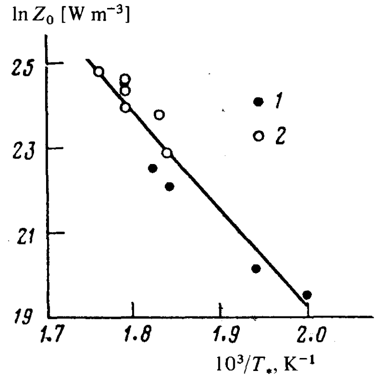

Figure 9. Determination of the thermokinetic constants of the ignition of nitrocellulose from experimental data;[56] continuous line—calculation by the least-squares method; *1, 2*) experimental points obtained for the following values of ν, m^{-1}: *1*) 3×10^4, *2*) 6×10^4.

Comparison of the results of the calculation of the ignition characteristics t_* and T_* by the asymptotic method (31)–(33) with the results in Refs.10, 21, and 56 on the whole shows good quantitative agreement and, which is particularly important, indicates that the "asymptotic" values practically coincide with the values obtained by numerical integration using a computer.[21] An exception is the method of Ref.56, where in the estimation of the scale temperature T_* no account is taken of the change in the value of ν, so that the values obtained are too high.

If the thickness of the heated layer is much less than the thickness of the absorption zone, that is for $\nu_1 \ll 1$, the absorption of energy in the zone of the chemical reaction is slight, and the substance heats up slowly. In this case the ignition process becomes degenerate and resembles the conditions of thermal explosion. The principal characteristics of ignition can be calculated using the equations

$$T_*=\frac{E}{R}\left[\ln\left(\frac{\rho Qk_0}{q\nu}\right)\right]^{-1},\quad t_*=\frac{c\rho}{\nu q}(T_*-T_0),\ \theta_*=\frac{T_*}{T_0},$$
$$T_\mathrm{i}=T_*[1+\theta_*\varepsilon\ln(1/\varepsilon)],\ \eta_*=\gamma\theta_*^2\ln(1/\varepsilon) \quad (35)$$

with the condition that

$$q>q_m=\rho Qk_0\nu^{-1}\exp(-E/RT_0)$$

Eqn.(35) readily gives the universal straight-line equation

$$\ln(q\nu/\rho)=\ln(Qk_0)-E/RT_*,\ T_*=T_0+\nu qt_*/c\rho \quad (36)$$

which makes it possible to treat experimental data in the range $\nu_1 \ll 1$ and to calculate the thermokinetic parameters for the values of T_0, q, ν, and t_* recorded in the experiment. Comparison of the results of the calculations using

Eqns.(35) and the methods of Refs.10, 21, and 56 shows that none of these methods gives satisfactory results in the range of variation in the parameter ν_1 examined. This is revealed by the excessively high value of T_*[10,21] and by the fact that T_* is completely insensitive to change in ν.[56] Only the asymptotic method[35] gives acceptable results in the range $0.009 \leq \nu_1 \leq 0.1$, confirming again the usefulness of its practical application.

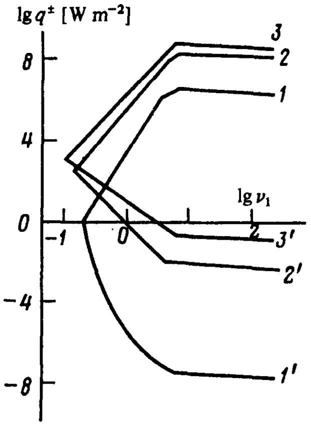

Figure 10. Ranges of existence of non-degenerate conditions for the ignition of nitrocellulose by laser radiation for T_0, K: *1, 1'*) 223; *2, 2'*) 293; *3, 3'*) 323; curves *1*–*3* correspond to q^+, and curves *1'*–*3'* correspond to q^-.

Fig.10 gives the ranges of existence of non-degenerate ignition conditions for nitrocellulose, calculated with allowance for the thermophysical and thermokinetic constants from Ref.10, for three values of the initial temperature T_0 for the cases $\nu_1 = 0$ (1) and $\nu_1 \gg 1$, when the thickness of the heated layer is much greater than or commensurate with the thickness of the absorption zone.[73] The ignition conditions are non-degenerate if the following condition is satisfied:

$$q^-(T_0, \nu_1) \leqslant q \leqslant q^+(T_0, \nu_1) \tag{37}$$

For $q \gg q^+$, the thickness of the heated layer is small, and "superficial burning" of the substance is observed, and for $q \ll q^-$, the thickness of the heated layer is appreciable and ignition does not take place. In neither case does the ignition process take place in two stages, since the warm-up of the substance is accompanied by spontaneous chemical heating with an appreciable energy contribution from the chemical reaction.

III. THE IGNITION OF NON-TRANSPARENT CONDENSED SYSTEMS ON THE PULSED INTRODUCTION OF HEAT, WITH HEAT LOSSES, AND ON UNSYMMETRICAL HEATING

1. Pulse Ignition Conditions

The development of a self-accelerating reaction in a reacting substance and the formation of a sufficiently wide heated layer requires the definite action of an external energy source on the substance. If the external source acts for a limited time, then under certain conditions, ignition of the substance may not take place. Pulse ignition conditions have been studied[7,9,10,17,43,68,74] by numerical and analytical methods using the Zel'dovich criterion,[3] applicable only to the problem of the unsymmetrical ignition of a thin slab of substance by a heated block. The aim of the works cited was to determine the critical ignition conditions. A more general problem, however, is the determination of the ranges of existence of non-degenerate ignition conditions, examined above for the problems of the thermal theory, in which the continuous supply of heat from the source is assumed.

The problem of the ignition of a substance with stepwise change in the density of the thermal flux at its surface ($x = 0$) is examined below:

$$-\lambda T_x = \begin{cases} q_1, & 0 < t < t_0 \\ q_2, & t > t_0 \end{cases} \qquad q_1 > q_2 > 0 \tag{38}$$

This problem has been studied[75] by the method of compound asymptotic expansions[48] without introducing any of the additional conditions used in Refs.10 and 74. The ignition criterion for the pulsed introduction of heat is given by the expression:

$$q_1 q_2 = 1.5385\varepsilon^{1/2} Q\rho k_0 \lambda T_0 \theta_* \left(\frac{d\theta_*}{du_*}\right)^{-1/2} \exp(-1/\varepsilon\theta_*) \tag{39}$$

where

$$\theta_* = 1 = 2\pi^{-1/2}[u_*^{1/2} - A_0(u_* - u_0)^{1/2}],\ A_0 = 1 - q_2/q_1,\ u_0 = \varkappa t_0(\lambda T_0/q_1)^{-2},$$
$$u_* = \varkappa t_*(\lambda T_0/q_1)^{-2},\ u_* > u_0 \tag{40}$$

The calculation of the dimensionless quantity u_* and hence the calculation of the quantities θ_* and $d\theta_*/du_*$ is carried out using Eqn.(39), and the dimensional characteristics of the ignition are calculated using the equations

$$t_* = \frac{u_*}{\varkappa}\left(\frac{\lambda T_0}{q_1}\right)^2,\ T_* = T_0\theta_*,\ T_i = T_*[1 + 0.5\theta_*\varepsilon \ln(1/\varepsilon)],$$

$$\eta_* = 1.48\gamma\varepsilon^{-1/2}\frac{q_2}{q_1}\theta_*\left(\frac{d\theta_*}{du_*}\right)^{-1/2},\quad Q_* = \frac{c\rho\lambda T_0^2}{q_1}\left[u_0 + \frac{q_2}{q_1}(u_* - u_0)\right] \tag{41}$$

In the limiting particular case $A_0 = 0$, $q_2 = q_1$, Eqns.(39)–(41) can be used to calculate all the characteristics of ignition for the continuous action of a source with a flux density q_1.

Eqn.(39) can be represented on coordinates $\{\ln Z_0, 10^3/T_*\}$ in the form of the universal straight-line equation

$$\ln Z_0 = \ln\{1.5385 Q\rho k_0 (\pi\varkappa)^{1/4}(R\lambda/E)^{1/2}\} - \frac{E}{RT_*} \tag{42}$$

where

$$Z_0 = \frac{q_1^{1/2} q_2 [(t_* - t_0)^{1/2} - A_0 t_*^{1/2}]^{1/2}}{T_*[t_*(t_* - t_0)]^{1/4}},\ T_* = T_0 + \frac{2q_1[t_*^{1/2} - A_0(t_* - t_0)^{1/2}]}{(\pi c\rho\lambda)^{1/2}} \tag{43}$$

If the quantities T_0, t_0, t_*, q_1, q_2 are recorded experimentally, it is possible using the least-squares method in the coordinates indicated to carry out the treatment of the experimental data and to calculate the parameters E and Qk_0. In the particular case $A_0 = 0$, $q_2 = q_1$, Eqns.(43) become

$$Z_0 = q_1^{3/2} T_*^{-1} t_*^{-1/4},\quad T_* = T_0 + 2q_1(t_*/\pi c\rho\lambda)^{1/2}$$

The range of existence of non-degenerate pulse ignition conditions is given by the inequalities[75]

$$t_0^-(q_1, q_2, T_0) < t_0 < t_0^+(q_1, q_2, T_0) \tag{44}$$

and the switch-over time t_0 is shorter than the ignition delay time $t_*(q_1)$ with continuous action of a source with an energy flux density q_1. Fig.11 illustrates the change in the ranges of the non-degenerate ignition conditions of nitrocellulose for $T = 300$ K in the range of values $q_1 = 10^4$–5×10^6 W m^{-2}, $A_0 = 0.1$–0.9 [75] (the values of the constants from Ref.10 were used).

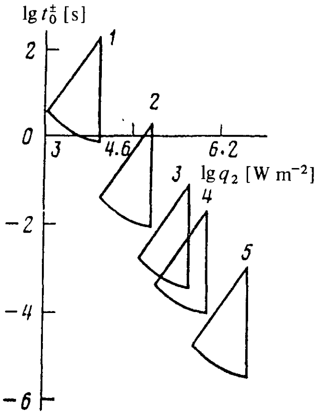

Figure 11. Ranges of existence of non-degenerate conditions for the pulse ignition of nitrocellulose for q_1, W m^{-2}: *1*) 10^4, *2*) 10^5, *3*) 5×10^5, *4*) 10^6, *5*) 5×10^6.

Analysis of the results of the calculation using Eqns.(39)–(41) shows that with decrease in the values of q_2 and t_0 from the range of existence of non-degenerate ignition conditions at a fixed value of the thermal flux density, the ignition delay time increases sharply. This corresponds to the physical picture of pulse ignition conditions.

2. The Ignition of Condensed Systems with Heat Loss from the Lateral Surface of the Specimen

The critical conditions for the ignition of non-transparent condensed substances have been studied by the thermal explosion and integral relationships methods, and approximate equations have been obtained for calculating the ignition delay time for a cylindrical specimen with heat loss from the lateral surface and boundary conditions of the second kind at the ends.[28,56,76] As shown below, however, the methods used[28,56,76] do not ensure sufficient accuracy of the determination of the ignition delay time, do not make it possible to formulate rigorously the ignition criterion, and leave open the questions of the range of existence of non-degenerate ignition conditions and the conversion of the experimental curves to straight lines in a special system of coordinates.

To solve these problems of the thermal theory of ignition, it is possible to examine the "two-dimensional" problem of the ignition of a semi-infinite cylindrical specimen of radius r_0 with heat loss into the surrounding medium, given by Newton's law

$$T_t = \varkappa\,[T_{xx} + r^{-1}(rT_r)_r^{\bullet}] + Qk_0c^{-1}(1-\eta)\exp(-E/RT),$$
$$\eta_t = k_0(1-\eta)\exp(-E/RT);\ t=0:\ T=T_0,\ \eta=0;$$
$$x=\infty:\ T=T_0;\ x=0:\ -\lambda T_x = q;\ r=r_0:\ -\lambda T_r = \alpha(T-T_0) \quad (45)$$

Here, x and r are the longitudinal and radial coordinates respectively, and α the coefficient of heat transfer (a constant quantity) from the lateral surface of the specimen to a surrounding medium with temperature T_0. The problem (45) was solved by averaging[77] with respect to the variable r, and the similarity criterion σ_α determined[78]

$$\sigma_\alpha = \beta\mu_0(\mathrm{Bi}),\ \beta = (\lambda T_0/qr_0)^2,\ \mathrm{Bi} = \alpha r_0/\lambda \quad (46)$$

where $\mu_0(\mathrm{Bi})$ is the function of the Biot criterion, defined and tabulated by Lykov.[79] The ignition criterion according to Ref.78 has the form

$$q = \{1.5385\varepsilon^{1/2}\rho Qk_0\lambda T_0\theta_*(\mathrm{d}\theta_*/\mathrm{d}u_*)^{-1/2}\exp(-1/\varepsilon\theta_*)\}^{1/2} \quad (47)$$

where

$$\theta_* = 1 + (\sigma_\alpha)^{-1/2}\operatorname{erf}[\tilde{x}^{1/2}],\ \frac{\mathrm{d}\theta_*}{\mathrm{d}u_*} = \left(\frac{\sigma_\alpha}{\pi\tilde{x}}\right)^{1/2}\exp(-\tilde{x}) \quad (48)$$

Solving Eqn.(47) gives the dimensionless ignition delay time $\tilde{x}$, and hence the quantities of Eqn.(48) at the moment of ignition. The dimensional characteristics of the ignition of the substance are calculated from the equations

$$T_* = T_0\theta_*,\ T_\mathrm{i} = T_*[1 + 0.5\theta_*\varepsilon\ln(1/\varepsilon)],\ t_* = \frac{\tilde{x}}{\varkappa\sigma_\alpha}\left(\frac{\lambda T_0}{q}\right)^2,$$
$$\eta_* = 1.48\gamma\varepsilon^{-1/2}\theta_*\left(\frac{\mathrm{d}\theta_*}{\mathrm{d}u_*}\right)^{-1/2},\ Q_* = qt_* \quad (49)$$

Eqn.(47) can also be written in the form

$$\ln Z_0 = \ln\left[\frac{\rho Qk_0}{0.65}\left(\frac{R\lambda}{E}\right)^{1/2}(\pi\varkappa)^{1/4}\right] - \frac{E}{RT_*} \quad (50)$$

where

$$\tilde{x} = \varkappa t_* r_0^{-2}\mu_0(\mathrm{Bi}),\ Z_0 = q^{1/2}(T_*t_*^{1/4})^{-1}\exp(-x/2),$$
$$T_* = T_0 + qr_0[\lambda\mu_0^{1/2}(\mathrm{Bi})]^{-1}\operatorname{erf}[\tilde{x}^{1/2}] \quad (51)$$

For $\alpha = 0$, the particular case of ignition without heat loss, examined in section II, is obtained. If the values of T_0, q, α, t_*, and r_0 are recorded experimentally, Eqns.(51) can be used to calculate the values of $\tilde{x}$, T_*, and Z_0, and the least squares method in the coordinates $\{\ln Z_0,\ 10^3/T_*\}$ can be used to determine the coefficients of the linear equation (50), and then the thermokinetic parameters E and Qk_0.

The range of existence of non-degenerate ignition conditions is given by the inequalities[52]

$$\theta_*\left(\frac{\mathrm{d}\theta_*}{\mathrm{d}u_*}\right)^{-1/2} \leqslant \frac{1}{3}\varepsilon^{-1/2},\quad \theta_*\left(\frac{\mathrm{d}\theta_*}{\mathrm{d}u_*}\right)^{1/2} \leqslant \frac{1}{3}\varepsilon^{-1/2}$$

Introducing the ignition criterion (47) gives:[78]

$$q^-(T_0,\sigma_\alpha) \leqslant q \leqslant q^+(T_0,\sigma_\alpha) \quad (52)$$

The ranges of existence of the non-degenerate conditions (52) for the ignition of nitrocellulose are given in Fig.12, and Fig.13 makes it possible to compare the results of the calculation of the ignition delay time t_* from Eqns.(47)–(49) and by the methods of Refs.28 and 76 for $T_0 = 300$ K, $q = 10^4$ W m^{-2}, and $0 < \sigma_\alpha < 2$.

The delay time with heat loss can be calculated using the equation[76]

$$t_* = t_*^0[1 - 1.78t_*^0/d]^{-1},\ d = c\rho\lambda T_0^2/q^2\sigma_\alpha \quad (53)$$

where t_*^0 (without allowance for heat loss) is given by Eqns.(10). In Ref.28 the time t_* was calculated from the equation

$$t_* = d\ln[(1 - t_*^0/d)(1 - 2t_*^0/d)^{-1}] \quad (54)$$

and t_*^0 was determined from Eqns.(11). Fig.13 shows that the methods of Refs.28 and 76 give an unjustifiably high value for the ignition delay time, compared with the asymptotic method (47)–(49). This is due to the insufficient accuracy of the determination of the quantity t_*^0 (see Table 4) and the critical conditions for ignition of the substance.

The problem (45) is readily generalised to the case where there is additional heat loss due to flow over the surface being ignited in the case of conductive and convective heat exchange mechanisms.

Thus the rigorous asymptotic approach also has an appreciable advantage over published approximate methods in the analysis of the ignition of substances with heat loss.

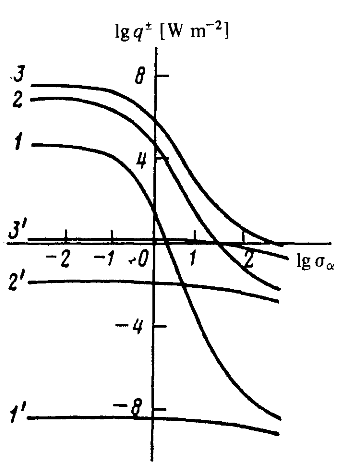

Figure 12. Ranges of existence of non-degenerate conditions for the ignition of nitrocellulose with heat loss for T_0, K: *1,1'*) 220; *2,2'*) 300; *3,3'*) 340; curves *1–3* and *1'–3'* correspond to q^+ and q^- respectively.

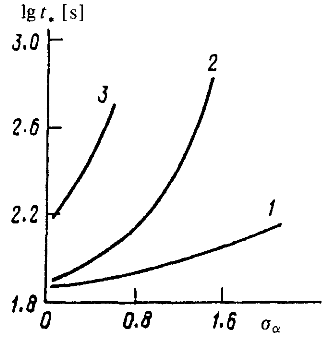

Figure 13. Calculated dependence of the ignition delay time of nitrocellulose on the parameter σ_α: *1*) calculation using Eqn.(49), *2*) calculation using the method of Ref.76, *3*) calculation using the method of Ref.28.

3. The Ignition of Substances with Unsymmetrical Heating

The theory of the ignition of a thin slab of condensed substance with thickness h, for which a constant high temperature T_1 is continuously maintained at one surface, and a low temperature T_2 at the other, has been examined.[3,61,80–82] In Refs.3 and 80, a stationary theory of ignition was developed, and an equation obtained for calculating the heat removed from the reaction zone under critical conditions. It was shown that if the heat removed is lower than a critical value, the slab ignites; otherwise, stationary heat liberation conditions are established. In Ref.61, numerical integration using a computer was used to study the dependence of the warm-up time and the ignition delay time on the parameters of the problem, and also the critical conditions of ignition. In Ref.82, the zeroth approximation of the asymptotic method was used to determine the warm-up time of a substance and to find the critical conditions for ignition. An asymptotic non-stationary theory of unsymmetrical ignition of a substance was developed in Ref.83, where the method of compound expansions was used to obtain equations for calculating the ignition delay time and the energy supplied to and stored by the substance in the warm-up period, and the critical conditions for ignition were found.

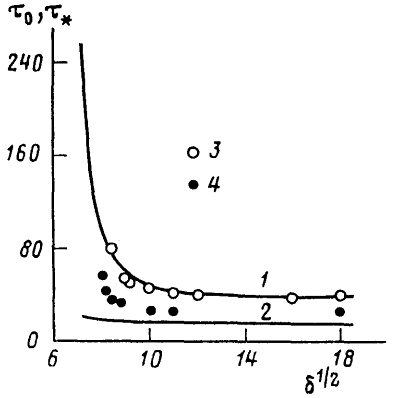

Figure 14. Calculated dependence of the dimensionless ignition delay time τ_* and the warm-up time τ_0 of a reacting substance on $\delta^{1/2}$ for unsymmetrical heating: *1*) τ_* calculated from Eqn.(55), *2*) τ_0 calculated by the method of Ref. 82; the open and black circles give the values of τ_* and τ_0 respectively, obtained by numerical integration.[61]

Fig.14 for $\varepsilon_0 = 0.1$ compares the results of the calculation of the dimensionless ignition delay time τ_* obtained in Refs. 61 and 82 with the results from Ref.83:

$$\tau_* = \delta \sum_{k=0}^{5} \varepsilon_0^{k/4} u_k(\mu), \quad \mu = \varepsilon_0 \delta^{1/4}, \quad u_1 \equiv 0,$$
$$\varepsilon_0 = \frac{RT_1^2}{E(T_1 - T_2)}, \qquad \delta = \frac{E}{RT_1^2} \frac{\rho Q k_0 h^2}{\lambda} \exp(-E/RT_1) \tag{55}$$

Curve *1*, calculated using Eqn.(55), shows good agreement with the results of the numerical integration.[61] At the same time, the values of τ_0, which were also found by numerical integration,[61] do not lie on curve *2*, obtained by the method of Ref.82. Non-degenerate ignition conditions are produced if the following condition is satisfied:[3,61,80,82,83]

$$h > h_* = \left[\frac{E}{2R}\left(\frac{T_1 - T_2}{T_1}\right)^2 \frac{\lambda}{\rho Q k_0} \exp\left(\frac{E}{RT_1}\right)\right]^{1/2} \tag{56}$$

which with allowance for stationary heat removal from the reaction zone gives the critical value of the density of the thermal flux

$$q_* = 2^{1/2}\left[\lambda \rho Q k_0 \frac{RT_1^2}{E} \exp\left(-\frac{E}{RT_1}\right)\right]^{1/2} \tag{57}$$

In the stationary case for $q < q_*$ the slab ignites, and when $q \geqq q_*$, ignition does not take place.

The coefficient $\sigma_0 = 2^{1/2}$ from Eqn.(57) has been used[43] find a criterion for the ignition of a semi-infinite slab by constant thermal flux. This approximation is not rigorous, noted above (section II).

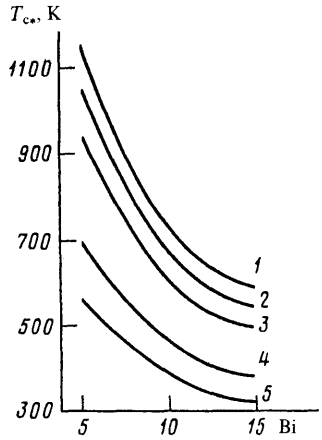

Figure 15. Ranges of existence of non-degenerate conditions for the ignition of spherical nitrocellulose particles in a stream of hot gas for T_0, K: *1*) 340, *2*) 320, *3*) 300, *4*) 250, *5*) 220.

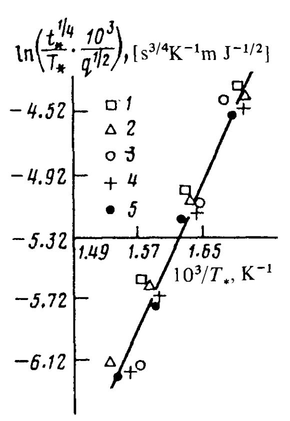

Figure 16. Determination of the thermokinetic constants for the ignition of a composite fuel from experimental data;[32] continuous straight line—calculation by the least-squares method;[87] the experimental points were obtained for T_0, K: *1*) 213, *2*) 243, *3*) 273, *4*) 303, *5*) 333.

V. THE IGNITION OF NON-TRANSPARENT SUBSTANCES N SYMMETRICAL HEATING, AND WHEN HETEROGENEOUS EACTIONS AND MULTI-STAGE CHEMICAL REACTIONS AKE PLACE

The asymptotic method of compound expansions makes it ossible to solve the important applied problem of the igni- on of lamellar, cylindrical, and spherical specimens of a substance in a stream of hot gas, to establish the ignition criterion and the range of existence of non-degenerate conditions, and to construct a universal straight line in a special system of coordinates.[84,85] Fig.15 gives the dependence of the critical temperature of the medium T_{c*} on the Biot criterion and the initial temperature of the substance T_0 for spherical particles of nitrocellulose. Ignition takes place in the regions lying above the curves with fixed values of T_0, when the temperature of the hot gas T_c is higher than the critical temperature T_{c*}(Bi). For $T_c < T_{c*}$, intermediate conditions between ignition and spontaneous ignition are produced.

An asymptotic solution has been described[86,87] for the problem of the heterogeneous-exchange ignition of a substance when a heterogeneous reaction of zeroth order takes place, and the results of studies[10,22,23,32-37] in which various approximate methods were used have been summarised. Experimental data[32] on the purely heterogeneous ignition of a composite fuel are given in Fig.16 in linearised form. The constants E and Qk_0 obtained differ considerably from those found in Ref.32.

The solution of the problem of the ignition of a substance when successive and parallel reactions take place in it is also of undoubted interest. The examination of this problem extends the theory of the influence of multi-stage chemical reactions on the regular features of the ignition process. An asymptotic analysis and analytical solution of these problems have been given.[88-90] The thermal theory of ignition has also been used to analyse the ignition of gas systems. In Ref.91, numerical integration using a computer was used to study the regular features of the ignition of gases by a heated surface when a single-stage reaction takes place and with allowance for diffusion and hydrodynamic phenomena. An asymptotic analysis made it possible to study this problem without allowance for hydrodynamic factors.[92] The most general asymptotic solution of the problem of the ignition of gases by a heated surface without allowance for hydrodynamic factors when successive two-stage and parallel N-stage reactions take place was obtained in Ref.93, which generalises the results of Ref.92 to the case of multi-stage reactions.

---o0o---

The aspects of the thermal theory of ignition examined in the present review do not exhaust existing problems of the ignition of condensed systems, particularly for the case of the diffusion and hydrodynamic phenomena accompanying a multi-stage chemical reaction. The actual ignition of solid fuels is generally extremely complex, and cannot be described within a single theory of gas-phase, heterogeneous, or solid-phase ignition. Attempts are therefore now being made to develop a single theory taking account of reactions in the gas and solid phases, and also at the surface of a solid fuel.[94,95] The constructive ideas of the intermediate asymptote of a non-stationary ignition process, described in Ref. 96, may prove extremely useful in the study of these questions.

The thermal theory of ignition, in which no account is taken of the gas phase, generally does not make it possible to predict the influence of the surrounding medium. In the ranges of existence of non-degenerate conditions and at low thermal flux densities and high concentrations of oxidant in the surrounding medium, however, the inert warm-up is appreciably greater than the time of diffusion and chemical reaction, so that good quantitative agreement is obtained between the ignition delay times determined experimentally and calculated from the thermal theory.[97] The method of compound asymptotic expansions has been used successfully for the practical solution of problems of the thermal theory of ignition. This makes possible an optimistic approach to the study of the more complex and promising problems of the ignition of condensed and gaseous reacting systems.

The Photochemistry and Photophysics of Spiropyrans

A.S.Kholmanskii and K.M.Dyumaev

The results of studies on the structure and nature of the electronic states of spiropyrans (SP) and the products of their photochromic reactions as well as the mechanism of the dissociation of the $C_{spiro}-O$ bond and the formation of a coloured form of the SP are surveyed and analysed. Also analysed are the mechanisms of the α-dissociation and predissociation of the bond, which make it possible to explain satisfactorily the dependence of the quantum yield of the photocolouring reaction on the structure of the SP, the nature of the matrix, and temperature. The prospects for the utilisation of the photochromic SP are discussed.

The bibliography includes 179 references.

IV. Prospects for the employment of photochromic spiropyrans in science and engineering 147

I. INTRODUCTION

The photochromic spiropyrans (SP) have continuously attracted the attention of investigators. By virtue of their unique properties, they have been finding increasing applications. This is also promoted by the fact that the photochromic properties of SP are manifested in virtually any matrix—in the pure compound (in the crystalline or amorphous state), in solutions, and in polymers, and the conditions under which these matrices exist can vary over a wide range of temperature, viscosity, external pressure, and electric and magnetic field strengths. This makes it possible to employ SP as test objects in the study of the properties of the medium and of the mechanisms of its influence on the intramolecular photophysical and photochemical processes.

Spiropyrans are already used to prepare reusable polymeric photochromic materials or variable density light filters,[1-9] but their application for these purposes is limited by the low light sensitivity of the photomaterials and because enough cyclic information recording and deletion processes cannot be achieved. Apparently in the future SP will also be applied in other equally important fields. For example, it has been reported that they can be used as photoregulators of the ionic conductivity of membranes,[10] as modulators of the intensity of the fluorescence of monolayers,[11,12] etc. Presumably in the near future they will be used as elements in electronic circuits acting at the molecular level.[13,14]

Since the publication of the authors' earlier review,[15] numerous communications concerning the study of the photochromic reactions of SP and their structure have appeared. The fairly large amount of the data which have accumulated and, what is most important, its significance for the understanding of the photochemistry and photophysics of SP urgently require a critical analysis and a survey of the entire set of the results available.

As before,[15] in the analysis of the results of the studies of the primary photochemical processes as a function of the structure of the SP and external conditions, the SP are regarded as representatives of a specific class of organic compounds containing heteroatoms and belonging to the ($\sigma\pi nl$) type in terms of the orbital classification of electronic states.[16-19]

Analysis of the experimental results has shown that the photochemical activity of SP and their luminescence characteristics are determined by the position of the energy levels and the orbital nature of the lowest electronically excited states. Furthermore, in order to understand the mechanism of the photodissociation of the bond in SP, it is essential to take into account the degree of involvement of the electrons of the heteroatoms in the configuration of the electronically excited states and also the interaction of the electronic orbitals of the mutually orthogonal heterocycles in both ground and excited states.

The SP photocolouring reaction can be represented schematically as follows in a general form:[6,15]

$$A \overset{h\nu}{\rightleftarrows} A^{*} \xrightarrow{\varphi_d} X \xrightarrow{\varphi} B\,, \tag{1}$$

where A is the colourless initial spiro-form of the SP, A^* its electronically excited state, X the *cis*-cisoid isomer of the coloured form arising after the dissociation of the bond and still preserving the orthogonality of the heterocycles, B the planar coloured form of the SP, ϕ the quantum yield in the formation reaction of the B form, and ϕ_d the quantum yield in the bond dissociation process. The recombination reactions of the photoproducts with transition to the initial state and also the possible pathway leading to the formation of the B form without the formation of the intermediate X isomer are not shown in Scheme (1).

The chemical structure of the SP considered in the review are presented in Tables 1 and 2. Table 1 also lists the known quantum yields of the SP colouring reaction under the influence of light with λ = 313 and 365 nm (ϕ_{313} and ϕ_{365} respectively). The yields ϕ were determined in weakly polar solvents at temperatures close to room temperature. The total number of SP investigated for which the values of ϕ are known is much greater;[6,9,15,20-35] Table 1 includes only some SP with characteristic structures and substituents. The yields ϕ in different matrices (for certain SP) are presented in Table 3.

II. THE NATURE OF THE ELECTRONIC STATES OF SPIROPYRANS AND THE PRODUCTS OF THEIR PHOTOCHROMIC REACTIONS

1. The Structure of Spiropyrans and Their Photoproducts

The structures of more than ten SP, including the strucures of the coloured forms,^{38} have now been investigated y X-ray diffraction (XD).$^{36-41}$ The XD data show that n almost all the SP investigated the angle between the heterocycles is 90°. However, the heterocycles themselves are non-planar—the angle of the bend in the planes of the indoline ring system along the C(3)–N(1) line is 23–30° and the angle in the bend in the benzopyran ring system along the C(3′)–O(1′) line is 11–17°,^{38} depending on the ring substituents.

Table 1. The structure of spiropyrans and the quantum yields of the photocolouring reactions.

SP	Structure of SP and substituents	Solvent	φ_{313}	φ_{365}	Refs.

*The activation energies E_a were determined in a matrix comprising the given compound—the melt or the amorphous vitreous state of the SP.

It is of interest to compare the length of the dissociating bond r with the activation energies E_a for the thermal bond dissociation in SP and the quantum yield in the photocolouring reaction (Tables 1 and 2). The values of E_a for all

SP with the exception of SP_{32} and SP_{33} are correlated with r: as a rule, E_a falls with increase of r. The introduction of substituents in the 7′-position stabilises the coloured form of the SP as well as the E_a as a result of the conjugation of the substituent orbitals with the π orbital of the central carbon atom.[7,35,38] The correlation between E_a and r is a consequence of the fact that the dissociation of the bond in the thermal reaction proceeds via the ground electronic state of the vibrationally excited SP.

Table 3. The quantum yields ϕ_{365} for spiropyrans in various media*.

*With the exception of specially noted cases, the temperature was close to room temperature. The yields ϕ_{365} were taken from Bertelson[6] for SP_{13}, from Reeves and Wilkinson[29] for SP_3 in PMMA at room temperature, and from Kholmanskii[22] and Kholmanskii and Tarasov[24] in the remaining cases.

**The dielectric constant ε is indicated in brackets.

***The quantum yield of the sensitised colouring reaction.

On the other hand, there is no correlation between ϕ and r. This shows in its turn that the photodissociation of the bond in the SP proceeds via the electronically excited state of the SP whose orbital nature determines the mechanism and the quantum yield ϕ of the SP photocolouring reaction. Therefore, in predicting the photochemical activity of the SP from XD data, it is essential to take into account the factors which can affect the orbital nature of the excited state, the intensity of the electronic transition, and also the effectiveness of the interaction of the electrons of various heterocycles in the excited state. Such factors are in the first place the orientation of the nitro-group relative to the plane of the benzene ring and other substituents, and the spatial orientation of the l orbitals of the heteroatom and the dissociating bond as well as the heterocycles themselves.

Since the pyran ring in the SP is nearly planar and the C–O–C angle is 119°,[36–38] presumably the valence orbitals of the oxygen heteroatom are sp^2-hybridised.

In the indoline ring of the SP, the nitrogen atom is somewhat displaced out of the plane drawn through the carbon atoms linked to it (in particular by 0.26 Å for SP_{11} [38]). The valence angles between the N–C bonds in SP_{11} are 121.4°, 119.9°, and 108.8°.[38] These data suggest the sp^2-hybridisation also of the atomic orbitals of nitrogen, although it is somewhat distorted by virtue of steric factors. This is also indicated by the comparison of the structural and luminescence-spectroscopic characteristics of SP and aromatic amines in which the nitrogen atom is sp^2-hybridised.[42]

Indeed the values λ_{max} = 375 nm and $\varepsilon_{375} = 1.8 \times 10^4$ litre mol^{-1} cm^{-1} [21,25] for the first absorption band in the spectrum of the SP having the nitro-group in the indoline ring (SP_{11}) are virtually identical with the corresponding values for p-nitroaniline and NN-dimethyl-p-nitroaniline (376 nm and 1.6×10^4 litre mol^{-1} cm^{-1} for the former and 388 nm and 1.8×10^4 litre mol^{-1} cm^{-1} for the latter[43]). We may note that the agreement between the spectra and phosphorescence decay times for SP_{11} and nitroaniline[44] also indicates the similarity of the electronic structures of the T_1 states of these compounds.

In order to determine the structure of the coloured form of the SP, IR spectroscopic,[7,45] Raman spectroscopic,[46] and photoelectron spectroscopic[47] methods were resorted to in addition to XD. Studies,[9,48–58] including, for example, polarisation measurements,[51–54] measurements of the dipole moments of the coloured molecules,[56,57] and quantum-chemical calculations,[58] have also been devoted to the investigation of the structure and properties of the coloured form and its isomers.

2. Luminescence-Spectroscopic Characteristics of Spiropyrans

The study of the orbital nature of the electronically excited states had as its primary aim the elucidation of the degree of involvement of the electrons of the heteroatoms in the electronic configuration of the lowest excited states of the ππ* type. The orbital nature of the lowest electronically excited states of SP and their energy are determined by investigating the absorption and luminescence spectra using the theory of solvatochromism.[59,60] Methods based on quantum-chemical calculations for SP or compounds modelling their fragments have also been resorted to in order to achieve a qualitative justification.[8,58,61–63] With the aid of these calculations and the theory of solvatochromism, the charges on the heteroatoms in the excited states were estimated. For this purpose, a study was also made of the deactivation of the triplet photochemically active (PCA) state of the SP by various quenching agents and in the first place by electron donors. The optical absorption spectra of certain characteristic SP have been published.[5,21,22,26,27,64–69]

The electronic transition of the π–π* type in SP without the nitro-group can be represented as a linear combination of one electron π–π* (in the aromatic system) and l–π* (electron transition from the heteroatom to the π* orbital of the aromatic system) transitions and can be designated by πl–π*.[15,18,19]

Calculations have been made for the electronic transitions and the distribution of the electron density in the S_0, S_1, and T_1 states of SP_1 has been evaluated by the CNDO method.[61] The calculated transition energies as well as the assignment of the first transition in the benzopyran ring to the π–π* type agree qualitatively with experimental data. The redistribution of electron density in the S_1 and T_1 states leads to the appearance of a positive charge on the oxygen (0.07), nitrogen (0.03), and spiro-carbon (0.017) atoms relative to the S_0 state. These results agree with the assignment of the lowest S_1 and T_2 states to the (πl, π*) type or, briefly, the L type.

On the basis of the results of theoretical calculations,[8,61,63] one can assume that the positive charge on the heteroatom of SP_1 in the S_1 and T_1 states is ~0.1. We may note that the contribution of the (l, π*) configuration to the excited state of the molecule is determined by the charge on the heteroatom.[63]

The introduction of an electron-donating substituent into the SP heterocycle leads to the appearance of an additional absorption band due to the transition involving charge transfer (CT) from the electron-donating substituent to the π^* orbital of the π-electron system.[22] The contribution of the l, π^*) configuration then diminishes and the positive charge on the oxygen heteroatom in the excited state is reduced as a result compared with the corresponding value for SP_1.[23,55]

The first transition in unsubstituted SP with the naphthopyran ring (SP_{21}, SP_{27}, and SP_{29}) is also of the $\pi l-\pi^*$ type;[22] this has been confirmed by solvatochromic studies and the presence in the absorption spectrum of bands due to stretching (1290–1350 cm^{-1}) and deformation (450–500 cm^{-1}) vibrations of the COC group.[22,64,65]

Since it is known from theoretical calculations[18,19,63] that the contribution of the (l, π^*) configuration to the excited state falls as the π-conjugation chain lengthens, presumably in the case of SP with the naphthopyran ring the positive charge on the oxygen heteroatom is smaller than for SP_1.

The introduction of a nitro-group into any of the SP fragments results in the appearance of a low-energy $\pi-\pi^*$ transition, which involves intramolecular charge transfer.[15,21,26,27,30,48,66-69] A spiropyran with the nitro-group in the benzopyran ring (A) can be designated by DSA, where D represents a heterocycle with a fairly low ionisation potential I (indoline, xanthene, benzothiazole, etc.) and C represents the spiro-carbon atom. It is known[70] that in molecules of the DSA type in which the D and A fragments are separated by three σ-bonds, apart from the local $\pi-\pi^*$ transition in the A fragment, hyperconjugation via the system of σ-bonds is responsible for the charge-transfer transition from the D to the A fragment:

$$\mathrm{DSA} \xrightarrow{h\nu} (\mathrm{D^+SA^-})^*. \qquad (2)$$

The positions and intensities of the absorption bands corresponding to the transitions in the A fragment and in process (2) are determined by the value of I for the D fragment and the electron affinity ε_A for the A fragment as well as the energy of the interaction of the (DSA*) and $(D^+SA^-)^*$ configurations.[70]

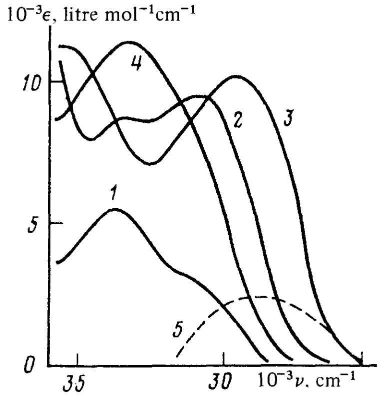

Figure 1. Absorption spectra of SP in isopentane: 1) SP_1; 2) SP_3; 3) SP_4; 4) SP_{34}; 5) difference between the absorption spectra of SP_4 and 8-methoxy-6-nitro-2*H*-chromene (MA).[68]

In SP the interaction with the π electrons of the D and A rings as a consequence of spiroconjugation[62] and the hyperconjugation of the n, σ, and π orbitals of the non-planar D and A rings in the ground state of the spiropyran can also lead to the appearance of a transition of type (2).[61]

Indeed comparison of the absorption spectra of SP having different D rings with the spectrum of the molecule modelling the A ring (MA), presented in two publications,[68,69] makes it possible to discover in the spectrum of the SP an additional absorption band whose position (ν_M^{DA}) depends on the structure of the D ring and which has an extinction coefficient ε a factor of 2–3 smaller than the band due to the transition in the A ring. The value of ν_M^{DA} for indoline SP is close to ν_M^A for the band due to the $\pi-\pi^*$ transition with charge transfer in the A ring, which is designated by $\pi l-\pi^*\pi_n^*$,[15,16,21,26] where π_n^* represents the orbital of the nitro-group and l the orbital of the heteroatom conjugated with the π system of the benzene ring[42] (Fig.1). The first absorption band in the spectra of these SP therefore constitutes a superposition of the absorption band due to the charge transfer transition in the A ring and the transition (2). Since I for the D ring in SP_{34} is greater than I for the D ring in SP_3,[70] the frequency ν_M^{DA} for SP_{34} should be greater than for SP_3. It is therefore evident that ν_M for the first absorption band of SP_{34} is greater than ν_M for SP_3 (Fig.1).

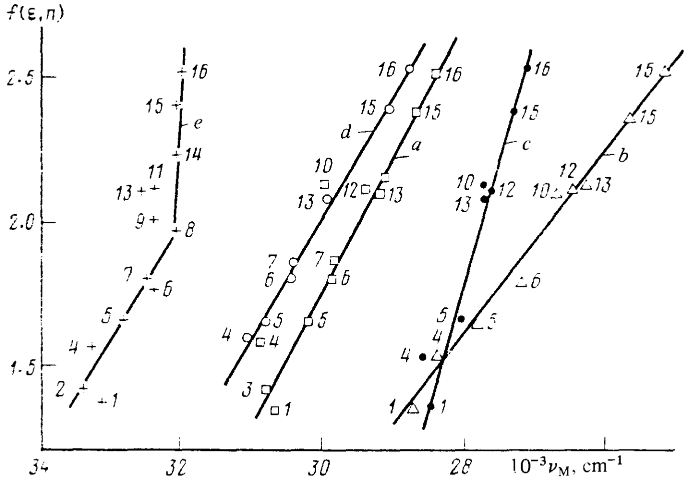

Figure 2. Dependence of the positions of the maxima of the first absorption bands of SP_3 (*a*), SP_{11} (*b*), SP_{24} (*c*), SP_{26} (*d*), and SP_{34} (*e*) on the universal interaction function $f(\varepsilon, n)$: 1) hexane; 2) isopentane; 3) cyclohexane; 4) heptane; 5) carbon tetrachloride; 6) benzene; 7) toluene; 8) chloroform; 9) tetrahydrofuran; 10) ethanol; 11) methanol; 12) acetone; 13) acetonitrile; 14) chlorobenzene; 15) dimethylformamide; 16) dimethyl sulphoxide.[66,67]

The energies of the (π, π^*) states (DSA*) and $(D^+SA^-)^*$ of spiropyran diminish as a result of general interaction with the solvent and to a greater extent than the energy of the ground state of SP.[59,60] If the molecule has no isolated orbitals, the dependence of ν_M on the dielectric constant and the refractive index is described in this case by the familiar[59] function of the general interactions $f(\varepsilon, n)$. This relation for characteristic SP is illustrated in Fig.2 (according to the data of Kholmanskii and co-workers[15,66,67]). The orbital nature of the electronic transition and the change in the dipole moment of the molecule in this transition can be determined from the qualitative and quantitative analysis of these relations. In particular, in the case of SP_{34} the presence of a break in the relation between ν_M and $f(\varepsilon, n)$ for $f \cong 2$ demonstrates the involvement of the electrons of the isolated *n* orbital of the oxygen in the oxaindan ring in the transition (2). The specific interactions of the highly polar and OH-containing solvent molecules with the *n* orbital of SP_{34} lower the ground level of this compound. As a result of the summation of the effects of the universal and specific interactions, ν_M hardly changes when $f > 2$, while under conditions where $f < 2$ the dependence of ν_M on $f(\varepsilon, n)$ for SP_{34} has almost the same slope as for SP_3, SP_4, SP_{26}, and MA (Fig.2 [69]). This indicates the similarity of the changes in the dipole moment of the SP on excitation of the transition in the A ring and in the transition (2).

However, the dipole moment changes appreciably when the oxygen heteroatom in the A ring is replaced by nitrogen (as in SP_{11}) and sulphur (as in SP_{24}) (Fig.2). Evidently, as a consequence of the changes in *I* for the D ring and ε_A for the A ring of SP_{11} and SP_{24}, the transition (2) in these SP has a significantly greater energy than the transition in the A ring.[68,70] On the basis of the dependence of ν_M on $f(\varepsilon, n)$, it is possible to estimate the charges on the heteroatoms in the DSA* states of the (π, π^*) type[21,66] which will be designated for brevity as states of the N type (Table 4).

Table 4. The orbital nature, the charges on the heteroatom (*q*), the lifetimes (τ_t), and the constants for the quenching by triphenylamine of the triplet states of spiropyrans (k_q^{TPA}) in toluene.[23,27,55,66]

SP	State	τ_t, s	k_q^{TPA}, litre $mol^{-1} s^{-1}$	*q*, *e*
SP_1	*L*	10^{-8}	$6 \cdot 10^8$	~ 0.1
SP_2	*L*	—	$< 6 \cdot 10^8$	< 0.1

SP_7	*N*	$6 \cdot 10^{-10}$	—	—
SP_{12}	*N*	$1.5 \cdot 10^{-8}$	$9 \cdot 10^8$	0.4
SP_{22}	*L*	$< 10^{-8}$	—	$\leqslant 0.1$
SP_{22}	$(\pi, \pi^* \pi_n^*)$	10^{-6}	$3 \cdot 10^7$	$\ll 0.1$
SP_{24}	—	—	—	0.2
SP_{26}	*N*	—	—	0.4
SP_{28}	*L*	$6 \cdot 10^{-9}$	$5 \cdot 10^5$	$\leqslant 0.1$
SP_{36}	$(\pi, \pi^* \pi_n^*)$	$1.5 \cdot 10^{-8}$	10^8	$\ll 0.1$
SP_{38}	$(\pi, \pi^* \pi_n^*)$	$2 \cdot 10^{-8}$	$6 \cdot 10^7$	$\leqslant 0.1$

In SP with the naphthopyran ring containing the nitro-group, the first electronic transition is of the $\pi - \pi^* \pi_n^*$ type.[27] The involvement of the *l* electron in excitation is improbable[18,27] and the charge on the nitro-group is transferred mainly from the naphthalene ring.

All the SP with the nitro-group phosphoresce at 77 K.[6,21,27,66] In addition, the fluorescence of SP_{19} in liquid solution at room temperature has been observed.[71] The phosphorescence spectrum of SP_3 has a vibrational structure. It follows from its analysis, carried out by Khamchukov et al.[72] and Gehrtz et al.,[73] that the stretching (symmetrical) and deformation vibrations of the nitro-group are manifested in the spectra. The frequencies of these vibrations differ appreciably for SP and MA.[68] The 0–0 transition frequency ν_{00} in the case of the phosphorescence of SP with the nitro-group in the benzopyran ring can be both greater and smaller than the ν_{00} for the phosphorescence of the corresponding nitrochromene, depending on the structure of the D ring.[68,69] For example, for SP of the type of SP_3 and SP_4, the frequency ν_{00} is greater by ~700 cm^{-1} than for the phosphorescence of the corresponding MA and the quantum yield ϕ_{ph} of the phosphorescence of the SP exceeds by a factor of three that for the MA.[69] These differences are apparently caused by the interaction of close levels of the (DSA*) and $(D^+SA^-)^*$ singlet and triplet states of the SP.

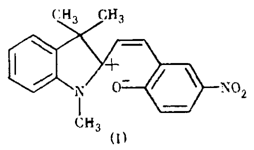
The position of the 0–0 band in the phosphorescence spectra of spiropyrans with the nitro-group is almost independent of the nature of the solvent.[6,29,48,72,73] On the other hand, in the case of SP_2 this band undergoes a hypsochromic shift by ~2000 cm^{-1} on replacement of the non-polar matrix by a polar one or by a hydroxylated matrix.[29,48] The phosphorescence lifetime of SP having the nitro-group and the corresponding nitrochromenes varies from ~0.03 to 0.3 s. The phosphorescence excitation spectrum of SP_3 coincides with the absorption spectrum within the limits of the first absorption band in solvents of the type of petroleum ether, propanol, and tetrahydrofuran (THF).[30,72] These results make it possible to assign the phosphorescence state of SP with the nitro-group in the benzopyran ring to the ^3N type and in the case of SP_2 to the ^3L type.

The high values of the intersystem inversion constant K_{ST} for SP with the nitro-group are due to the presence of intermediate $^{1,3}(n, \pi^*)$ levels of the nitro-group, at least one of which is located between the $^{1,3}N$ levels.[15,66,68,74,75] The constant K_{ST} can reach in this instance ~10^{11} s^{-1}.[16-18,74] It follows from the analysis of the experimental data for nitroanisoles, epoxynitroindalone, and nitronaphthalenes[76-78] and from theoretical calculations that the energy of the $^1(n, \pi^*)$ level for SP with the nitro-group is ~27500 cm^{-1} and that of the $^3(n, \pi^*)$ level is 23500 cm^{-1}–24500 cm^{-1}.

The fluorescence of the spironaphthopyrans SP_{22}, SP_{23}, and SP_{28} arises from the $^1(\pi, \pi\pi_n^*)$ state and the simultaneous presence of both fluorescence and phosphorescence shows that the $^{1,3}(n, \pi^*)$ levels of the nitro-group lie above the energy level of the $(\pi, \pi^*\pi_n^*)$ state.[27,79,80] The sharp differences between the fluorescence and phosphorescence intensities of SP_{22}, SP_{23}, and SP_{28} indicate different positions of the ^3L and $^3(\pi, \pi^*\pi_n^*)$ levels in these compounds and hence a different nature of the phosphorescent states.

Only fluorescence is observed for SP without the nitro-group (SP_1 and SP_{21}),[65,81,82] but one can postulate that the lowest triplet level of SP_1 has an energy close to that of the phosphorescent level of SP_2.

The following facts are known about the luminescence-spectroscopic characteristics of the SP photoproducts. The coloured form (*B*) exhibits only an intense fluoroescence.[6,7,15,30,49] In a study[73] of the photocolouring reaction of SP_3 at $T \leqq 4.2$ K, which stops at the state involving the formation of the *cis*-cisoid isomer *X*, the phosphorescence band of the *X* isomer has been discovered (at ~15000 cm^{-1} in trimethylpentane and n-hexane). The formation of this isomer has been confirmed by the method involving the optically detectable magnetic resonance, whose use together with theoretical calculations made it possible to investigate the structure of the *X* isomer and to represent it in the following form:



(I)

It has been established by studying the photocolouring reactions of SP at low temperatures and in the matrix comprising the compound itself that an absorption band whose frequency is close to the absorption band of the thermodynamically more stable *trans*-isomer of the *B* form corresponds to the *cis*-cisoid isomer of the *B* form of SP such as SP_3 or spironaphthopyrans with and without the nitro-group.[6,35,49,50,54,80]

. Spectrokinetic Studies on Photochromic Transformations f Spiropyrans

The spectrokinetic studies on photochromic reactions of SP, carried out under both photostationary conditions and with the aid of pulse (mainly laser) techniques proved fruitful for the elucidation of the orbital nature and the energy of the PCA state of the SP and for the determination of the photocolouring reaction mechanism. We shall not dwell on a large number of studies of the kinetics of the reactions of the coloured form of SP in which the influence of the structure of the SP and the nature of the matrix on the rate constant for the dark decolorisation of the *B* form[55,83–89] and the molecular association processes of the SP in both *A* and *B* forms were investigated.[74,83,90–97] The association effects significantly complicate the pattern of the photochromic reactions of the SP, particularly in aliphatic solvents and at high SP concentrations but do not influence appreciably the primary intermolecular photophysical and photochemical processes over a wide range of SP concentrations (10^{-6}–10^{-4} M)[97] in weakly polar solvents.

We shall analyse in the first place the results of the study of the quenching of the photocolouring reactions of SP by various quenching agents under photostationary conditions. These studies were performed to elucidate the question of the involvement of the triplet state of the SP in the photocolouring reaction and to determine its orbital nature.

The following results were obtained in experiments on the quenching of the photocolouring reaction by molecules with a low energy of the *T* state (anthracene, etc.) and electron donors. The reaction involving the photocolouring of SP having the nitro-group in the indoline and naphthopyran rings in weakly polar solvents proceeds 100% via the triplet state, while in SP with the nitro-group in the benzopyran ring it proceeds via this state to an extent not less than 70%.[23,27,29,98,99] The results of the estimation of the lifetimes of the lowest triplet states of SP (including PCA) are presented in Table 4. The quenching of the SP photocolouring reaction by electron donors is due to the deactivation of the triplet state as a result of electron transfer in a triplet exciplex between the SP and the electron donor.[23,99,100–102]

The quenching rate constant k_q depends on *I* for the electron donor and ε_A for the spiropyran in the excited state. For example, for tetramethyl-*p*-phenylenediamine (TMPP), it is close to the diffusion rate constant regardless of the SP structure.[23] Conclusions concerning the orbital nature of the deactivated triplet state of various SP have been reached from a comparison of the k_q for the same electron donor having a higher *I* than TMPP. These data for the case where the quenching agent was triphenylamine are listed in Table 4, from which it follows that k_q^{TPA} is correlated with q. The contribution of the (l, π^*) configuration to the *T* state of the SP of the corresponding type and the electron affinity ε_A are determined by the positive charge q on the heteroatom. The negative charge is in this case localised on the nitro-group and ensures, for example, the effective formation of hydrogen-bonded complexes between the proton-donating additive in the SP or another aromatic nitro-compound in the excited state.[6,76,103,104]

The low values of τ_T (Table 4) are due to the rapid intramolecular deactivation of the triplet state as a result of the reaction yielding the coloured form. This evidently also

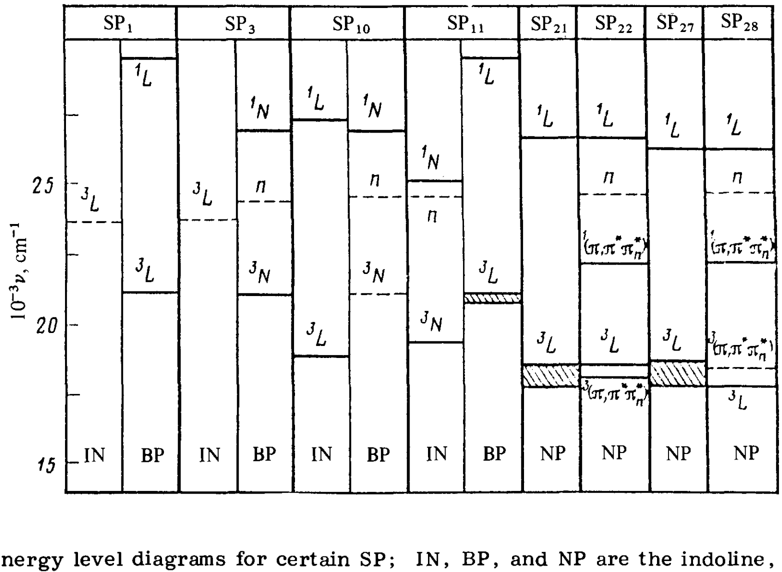


Figure 3. Energy level diagrams for certain SP; IN, BP, and NP are the indoline, benzopyran, and naphthopyran rings of the SP.[66]

accounts for the absence of an influence of added oxygen and cyclo-octatetraene[15,71] on ϕ at concentrations of additives of $\sim 10^{-3}$ and 10^{-2} M respectively. Such concentrations are insufficient for the observation of an appreciable influence by the quenching agent on the photocolouring reaction of the SP with the nitro-group in the benzopyran ring.[23,102]

Thus experimental studies have shown that both the singlet (for SP without the nitro-group) and triplet (for SP with the nitro-group) PCA states should include a definite contribution by the (l, π^*) configuration. This contribution determines the positive charge on the heteroatom in the D and A rings and, as will be shown below, the mechanism and the effectiveness of the dissociation of the C_{spiro}–O bond depend in their turn on the latter. The probability of the population of the levels of the PCA states depends significantly on the relative positions of the electronic levels of the SP. Data[15,22,27,29,68,105–107] concerning the disposition of the electronic levels of the various fragments of the SP molecule make it possible to construct a diagram of the lowest electronic levels for SP with certain characteristic structures and substituents (Fig. 3 [66]). The suggested disposition on the diagram of the levels which had not been observed experimentally is shown by dashed lines. Levels of the $^{1,3}(n\pi^*)$ type have been conventionally represented by a single level designated by n, and this also applies to the levels of the (DS*A) and $(D^+SA^-)^*$ states of SP_3, which are represented by a single N level.

III. THE MECHANISM OF THE PHOTOCOLOURING REACTION

The principal question concerning the mechanism of the photodissociation of the C_{spiro}–O bond and the formation of the B form is how the redistribution of electron density arising on excitation of the π-electron system of the SP ensures the weakening of the C_{spiro}–O σ-bond and what role the vibrational excitation of the SP molecule plays in the bond dissociation.

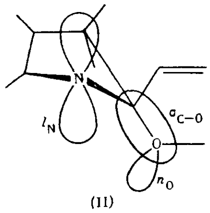
The intramolecular photophysical and photochemical processes are unambiguously determined by the orbital nature of the electronically excited state of the SP, which specifies the initial redistribution of electron density, regulating both the mechanism of the interaction of the electrons of the C_{spiro}–O σ-bond with other electrons of the molecule and the mechanism of the excitation of particular vibrations in the molecule. The orbital nature of the electronically excited state of the SP is determined in its turn by its molecular structure. For this reason, the elucidation of the mechanism of the bond photodissociation makes it possible to relate directly the effectiveness of the photocolouring of the SP to the structure, i.e. permits the specific synthesis of SP with particular photochromic properties.

1. The Mechanism of the α-Dissociation of the C_{spiro}–O Bond

The quantum yields of the photocolouring reaction of SP with the nitro-group in the indoline ring are fairly high and comparable to the ϕ for SP with the nitro-group in the benzopyran ring (Table 1). On the other hand, the energy of the electronic excitation of these SP on irradiation with light at the wavelength corresponding to the first absorption band is fully localised in the indoline fragment regardless of the type of substituent in the benzopyran ring (Fig. 3 [21,25]).

For SP with an analogous disposition of the levels but with a different orbital nature of the lowest triplet state, the values of ϕ are significantly smaller than for SP of the SP_3 type (cf. with SP_{10} in Fig. 3 and in Table 1). The principal difference between the orbital nature of the lowest triplet state of these SP consists in a much greater positive charge on the nitrogen heteroatom in the ^3N state of SP of the SP_{11} type than in the ^3L state of SP of the SP_{10} type.

On the basis of data for the structure of SP (see Section II), their central part can be represented as follows:



(II)

Here the axis of the l orbital of oxygen is perpendicular to the plane of the figure. It follows from XD data for SP that the solid angle between the l_N orbital and the σ_{C-O} bond is 10–30°. Bearing in mind their close proximity, one can postulate the interaction of the electrons of these orbitals. In the gound state of the SP, such interaction is referred to as the anomeric effect.[21,108] Its essential feature consists in the mixing of the l_N orbital and the unoccupied antibonding σ^*_{C-O} orbital. As a result of this interaction, the C_{spiro}–O bond is weakened even in the ground state.[36–41]

We shall now discuss the orbital nature of the N-type triplet PCA state of SP_{11}. It follows from Section II, that the luminescence-spectroscopic characteristics of SP with the nitro-group in the indoline ring virtually coincide with the corresponding characteristics of p-nitroanilines and are close to the characteristics of p-cyano-N,N′-dimethylaniniline.[109] For the latter compound it is known[110] that the dipole moments of the molecule in the ^1N state ("b") and in the biradical state with "twisted" configuration ("a") are virtually identical. This makes it possible to represent the structure of the precursor of the state "a", namely the Franck–Condon state "b", also in the form of a biradical in which the unpaired electrons are localised on the nitrogen atom of the CN group.

Taking into account these data and using the one-electron approximation, the N-type Franck–Condon state of SP_{11}, in which there is an appreciable positive charge on the nitrogen atom, can also be represented by a biradical. Consequently the l_N orbital in the $^{1,3}N$ states of SP_{11} has a radical character and this leads to the exchange interaction of the electrons of the l_N and σ_{C-O} orbitals, which constitutes the basis of the mechanism of the α-dissociation of the bonds (type 1 Norrish reaction[19,20,100]). The vibrationally excited radical-cations of amines and various carbonyl compounds dissociate according to this mechanism.[19,100,111–113] In SP of the SP_{11} type, the vibrational excitation of the spiro unit (II) is also essential for the dissociation of the C_{spiro}–O bond via the α-mechanism.[113] Under these conditions, the most effective are the low-energy deformation vibrations of one heterocycle relative to the other, in which the solid angle between the axes of the l_N and σ_{C-O} orbitals diminishes. The torsional vibrations of the heterocycle are less effective in this respect, although their excitation can increase sharply the probability of the non-radiative relaxation of the electronically excited state of the SP [114] with formation of the B form.

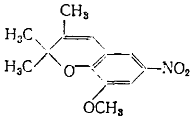
Together with the dissociation of the C–O bond, the dissociation of the C_{spiro}–C(3′) bond in SP with the nitro-group in the indoline ring can also dissociate via an analogous mechanism. Presumably this reaction ensures the irreversible decomposition of the given SP which has a lower photostability than SP with a nitro-group in the benzopyran ring.[115]

The effectiveness of the dissociation of the C_{spiro}–O bond via the α-mechanism is fully determined by the electronic structure of the indoline ring in the ^3N state. The introduction of various substituents into the benzopyran fragment of an SP containing the nitro-group in the indoline ring has virtually no effect on the yield ϕ.[21,25,102]

Since, like the nitro-group, the acetate group is an electron-accepting substituent, its introduction into the 5-position renders the lowest triplet state a highly polar CT state. It follows from the data of Gal'berstshtam and co-workers[9,89] that the disposition of the electronic levels of SP_{15} is analogous to that in SP_{11}. Taking into account these data, it is possible to postulate also for SP_{15} a mechanism for the α-dissociation of the C_{spiro}–O bond, which explains the fairly high value of ϕ_{365} for this SP (0.24) compared with ϕ_{365} for SP_{10} (Table 1).

Thus the α-dissociation mechanism, well known in the photochemistry of organic compounds, makes it possible to explain the high effectiveness of the cleavage of the C_{spiro}–O bond in the formation of the *B* form of SP with an electron-accepting substituent in the indoline ring.

We shall consider the mechanism of the photodissociation of the bond in indoline SP with the nitro-group in the benzopyran ring and SP with other D and A rings (xanthene, oxaindan, etc.). Before doing this, we may note that the mechanism of the bond cleavage in the MA



(III)

proceeds to the extent of 80% via *N*-type *T* state and the quantum yield of the *B* form of compound (III) is 0.7.[116] On this basis, one can assume that the (DS^3A^*) state of SP is likewise a PCA state. Furthermore, in the case of indoline SP with the nitro-group in the benzopyran ring, the positive charge is localised in the $(D^+SA^-)^*$ states on the nitrogen atom of the D ring,[28,117,118] while the negative charge is localised on the nitro-group.[103,118,119] Consequently the electronic structure of the given states ensures bond dissociation via the α-mechanism. Thus the high values of ϕ for the spiropyrans of SP_3 type are due to the fact that both lowest ^3N states of the (DSA^*) and $(D^+SA^-)^*$ types are PCA states and that the photocolouring reaction proceeds via the mechanism

$$\begin{tikzcd}
 & (DS^1A^*) \arrow[r] \arrow[dd] & (DS^3A^*) \arrow[dd] \arrow[dr] & \\
DSA \arrow[ur, "h\nu"] \arrow[dr] & & & B \\
 & {}^1(D^+SA^-)^* \arrow[r] & {}^3(D^+SA^-)^- \arrow[ur] &
\end{tikzcd} \qquad (3)$$

The probability of bond dissociation on excitation in the PCA states of SP is determined by the charge *q* on the oxygen and nitrogen atom. The latter depends in its turn on the change in the dipole moment of the molecule, which is correlated with the dipole moment of the transition |M| for transitions with intramolecular CT.[15]

The value of |M| is related to the experimental characteristics of the CT band:[120]

$$|M| = 0.0958\,(\Delta\nu_{1/2}\varepsilon_M\nu_M^{-1})^{1/2}, \qquad (4)$$

where $\Delta\nu_{1/2}$ is the half-width of the CT band. Assuming that ϕ is proportional to *q*, it is possible to obtain with the aid of Eqn.(4) the relation between ϕ and the intensity of the first absorption band of the SP with the nitro-group. Fig.4 presents the dependence of ϕ on $(\varepsilon_M\nu_M^{-1})^{1/2}$ for a series of SP. Its linearity demonstrates the validity of hypotheses[15,21,102] concerning the dependence of the mechanism of the photodissociation of the bond in SP on its structure.

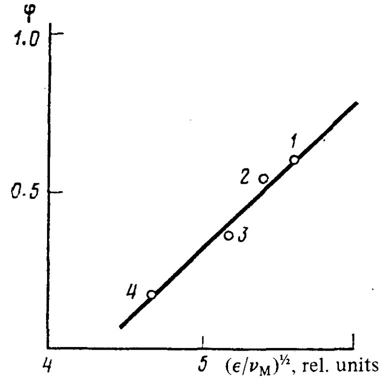


Figure 4. Dependence of ϕ on $(\varepsilon/\nu_M)^{1/2}$ for different SP: 1) SP_3; 2) SP_6; 3) SP_{33}; 4) SP_8 (the values of ε and ν_M have been taken from Kholmanskii et al.[15]).

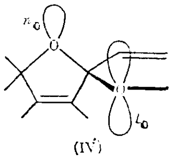
The occurrence of the transition (2) and the corresponding states $(D^+SA^-)^*$ in SP of the SP_3 type makes it possible to explain readily the dependence of the probability of the photoionisation of the SP on its structure in the presence of an external electron acceptor.[28,117,121,122] Scheme (3) can also be used successfully to account for the intra- and intermolecular photochemical processes occurring on UV irradiation of an SP_8 single crystal at 77 K,[123,124] since the key factor in these studies was the assumption of the formation of the $^3(D^+SA^-)^*$ states via the tunnel electron transition between the D and A rings in the (DSA^*) state of the SP. The orbital nature of the (DSA^*) state ensures, with the corresponding probability, the α-dissociation of the C_{spiro}–N bond, which may be the basis of the irreversible photodecomposition of SP of the SP_3 type.

On the basis of XD data for the structure of SP_{34}, its spiro-unit can be represented as follows:



(IV)

On excitation of the $(D^+SA^-)^*$ states in SP_{34}, the positive charge is localised on the oxygen atom of the oxaindan ring and its n_O orbital assumes a radical character (see Section II). Since the n_O orbital is almost orthogonal in relation to the σ orbital of the C_{spiro}–O bond [see structure (IV)], the exchange interaction between the electrons of these orbitals is unlikely. As a result, the $(D^+SA^-)^*$ states of SP_{34} are not PCA states. The lower yield ϕ for SP_{34} compared with SP_3 (Table 1) and the temperature dependence of ϕ for SP_{34} [33] show that the levels of the $^{1,3}(D^+SA^-)^*$ states are below the levels of the PCA states of the (DSA^*) type.

As in a study by the authors of the review,[27] the following scheme can be formulated for SP_{34}:

$$\begin{tikzcd}
& (DS^1A^*) \arrow[r] & (DS^3A^*) \arrow[r] \arrow[d, shift right] & B \arrow[d] \\
DSA \arrow[ur, "h\nu"] \arrow[dr] & & & \\
& {}^1(D^+SA^-)^* \arrow[r] & {}^3(D^+SA^-)^* \arrow[r] \arrow[u, shift right, "\overline{kT}"'] & DSA
\end{tikzcd} \qquad (5)$$

The energy difference ΔE between the (DS^3A^*) and ${}^3(D^+SA^-)^*$ states of SP_{34} is close to the activation energy E_a for the photocolouring reaction[27] and can be estimated by comparing the known values of E_a for other SP. E_a for SP_{34} is greater than for SP_3 (~0.04 eV) [29] but smaller than for SP_{22} and SP_{36} (~0.15 eV),[27] since $\phi = 0$ for SP_{34} at 77 K and does not change appreciably in the range 180–250 K.[33] Consequently an estimate in the range $0.04 < \Delta E < 0.15$ eV is valid for $\Delta E \cong E_a$. For such a low value of ΔE, the PCA state of the (DS^3A^*) type is effectively populated via a thermal mechanism.

The structure of the xanthone ring also fails to ensure conditions essential for bond dissociation via the α-mechanism in the $(D^+SA^-)^*$ states.[21,102] The more significant decrease of ϕ for SP_{26} compared with SP_3 (Table 1) is apparently caused by the increase of ΔE to such an extent that the thermal population of the PCA state of the (DS^3A^*) type becomes improbable and the state is almost completely deactivated owing to the transition $(DS^3A^*) \rightarrow {}^3(D^+DA^-)^* \rightarrow DSA$.

In SP of the SP_{24} type, the valence orbitals of the sulphur atom are sp^3-hybridised,[40] which diminishes the degree of their conjugation with the π-electron system of the benzene ring and the charge q in the ${}^1N$ state (Table 4). The values of I for the indoline and benzopyran rings are similar.[70] On the basis of these data, one can postulate that the levels of the $(D^+SA^-)^*$ states lie above the corresponding levels of the (DS^*A) states and that the α-dissociation of the C_{spiro}–S bond is unlikely; the photocolouring reaction of the given SP therefore proceeds with a fairly high value of ϕ via the (DS^1A^*) state[34,40] in accordance with the predissociation mechanism (see below). Thus, using the known[15,21,24,26,70,125,126] features of the changes in the intensity and energy of CT transitions (within the ring having the nitro-group and between the orthogonal rings) as a function of the structure of the SP and the nature of the matrix and also by invoking the α-dissociation mechanism, it is possible to explain successfully and to predict the photochemical activity of SP.

2. The Role of Vibrational Excitation and the Mechanism of Bond Predissociation in SP

Studies of the influence of the vibrational excitation of the electronically excited state on the kinetics of the photochemical reaction are of undoubted interest. For SP with the nitro-group, the photocolouring reactions proceed mainly via the formation of the triplet state: the vibrational excitation of the PCA state is essential to ensure the effective interaction of the orbitals of the orthogonal rings, which constitutes the basis of the α-dissociation mechanism. The energy of the electronic excitation, equal to the difference between the energies of the S_1 and T_1 states (5000–6000 cm^{-1}), may be expended on this vibrational excitation.[16,66] This excitation is also necessary to ensure that the atoms whose bond is ruptured can move apart to a sufficient distance to avoid recombination.[19]

SP with the naphthopyran heterocycle (SPN) are characterised, like their benzopyran analogues, by high yields ϕ (Table 1). However, the increase in the length of the π-electron system changes the disposition and orbital nature of the lowest electronically excited states of SPN (Table 3), as a result of which their photophysical and photochemical properties are also altered. In particular, the yields ϕ for SPN without the nitro-group depend only very slightly on th nature of the solvent and of the second heterocycle (Tables 1 and 3). This is a consequence of the photocolouring reaction of the given SP via a singlet state in accordance with a mechanism different from the α-dissociation mechanism.[22,24,27] It has been established[22] that the dissociation of the C_{spiro}–O bond in the ${}^1L$ state requires the excitation of the SPN at least to the first vibrational level of the given state. The vibrations whose nature is that of the vibrations of the COC group (see Section II) and their excitation promote the non-radiative transition $A^* \rightarrow X$ under these conditions. The same transition is evidently responsible for the decrease by a factor of two of the intensity of the fluoresence of SP_{21} on increase of the frequency of the exciting light from ν_{00} to $\nu = \nu_{00} + 500$ cm^{-1}.[65] In conformity with these features, the yield ϕ tends to zero on excitation of the SPN by light having a frequency ν close to ν_{00}.[22]

In the irradiation with light having $\lambda = 365$ nm ($\nu_{365} = 27\,400$ cm^{-1}) of the spiropyrans SP_{29}, SP_{35}, and SP_{37}, the energy of the light quantum is lower than the energy of the 0–0 transition ($h\nu_{00}$), whose frequency can be determined from the absorption spectra. For SP_{35}, SP_{29}, and SP_{37}, this frequency is 28750, 28640, and 28500 cm^{-1} respectively.[22,23] In this case the photocolouring reaction takes place because light with $\lambda = 365$ nm is absorbed by vibrationally and rotationally excited SPN molecules in the ground electronic state. Consequently ϕ_{365} for these SP should be proportional to the number $n^{\#}$ of such molecules, which is determined by the Boltzmann distribution $n^{\#} = n\exp[-\Delta\nu/kT)]$, where $\Delta\nu = \nu_{00} - \nu_{365}$.

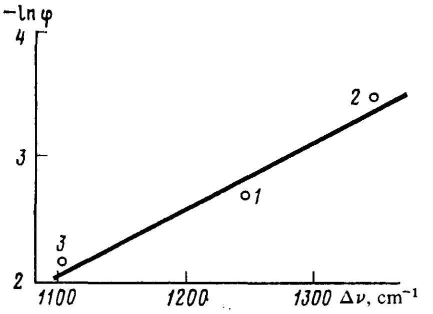


Figure 5. Dependence of $-\ln\phi$ on $\Delta\nu$ for SP: 1) SP_{29}; 2) SP_{35}; 3) SP_{37} (the values of ϕ and ν have been taken from Kholmanskii[22] and Kholmanskii and Lokshin[33]).

Thus $\ln\phi$ should be directly proportional to $\Delta\nu$. Fig.5 presents the dependence of $-\ln\phi$ on $\Delta\nu$ for a series of SPN, from the slope of which it is possible to determine T. It proved to be 250 ± 10 K, i.e. was virtually identical with the temperature at which ϕ_{365} had been determined for these SP.[22,33] The result constitutes additional confirmation that the photocolouring reaction of the SPN without the nitro-group proceeds via the ${}^1L$ state of the vibrationally excited SPN molecule. Under these conditions, light with $\lambda = 313$ nm excites either the higher vibrational levels of the S_1 state or the S_2 state is excited. The maximum value $\phi \cong 0.6$ (Table 1) is obtained in both cases. It follows from the temperature variation of ϕ for SPN with the nitro-group that E_a for the photocolouring reaction exceeds ΔE, which is equal to the difference between the energies of the ^3L-type PCA state and the lowest $^3(\pi, \pi^*\pi_n^*)$ state by ~600 cm^{-1} and is close to the frequency of the first vibrational quantum.[27]

These results suggested[22,35] that the bond dissociation in SPN proceeds via the predissociation mechanism. The role of the dissociative level is then assumed by the electronic level of the *cis*-cisoid isomer *X*, which intersects the level of the PCA state in the vicinity of its first vibrational level. The formation of the isomer *X* leads to the isomerisation mechanism for the degradation of the electronic excitation energy to vibrational energy.[6,127,128] On the basis of the results described and using the data[6,7,35] for the E_a for the forward and reverse thermal formation reactions of the coloured form of SP, it is possible to represent the path followed in the photochemical and thermal formation reactions of the isomer *X* in the *B* form by potential energy curves and the transitions between them can be illustrated (Fig.6).

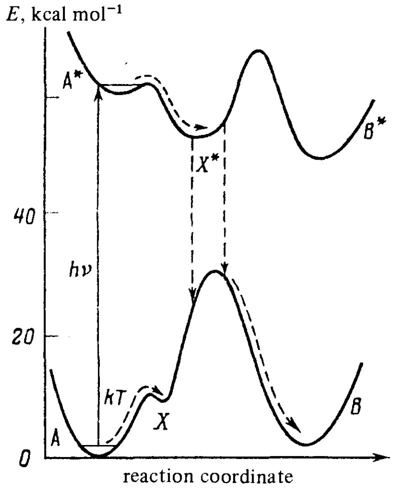

Figure 6. The potential energy surfaces for the ground and electronically excited states and the thermo- and photocolouring reaction pathways of SP [35].

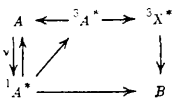
3. The Nature of the Short-Lived Products arising in the Flash Photolysis or Pulse Radiolysis of Spiropyrans. The Mechanism of the Photocolouring Reaction

Numerous studies have been made of reaction (1) by the method of kinetic pulse spectroscopy (especially laser spectroscopy).[55,74,90,99,116,128–141] The time resolution of pulse apparatus has been increased at the present time to the picosecond range.[74,97,132,140] The values of λ_{max} obtained in the above studies, characterising the absorption by short-lived products, and their lifetimes are listed in Table 5.

An especially large number of studies have been devoted to SP containing a nitro-group. It has been established for SP_1 and SP_{21} [15,55,81,91,128] that the photocolouring reaction proceeds via the ^1A state. Only the absorption bands of the coloured form but not of the short-lived products are observed in the spectra of the photoproducts at least in the time range $\geq 10^{-7}$ s. The T–T absorption spectrum of SP_1 has been obtained by means of the sensitised population of the T_1 level via the T–T energy transfer mechanism.[128]

The photocolouring reaction of the nitrochromene(III) and the 3,3-dimethylpiperidine SP with the benzopyran ring has been investigated by laser flash photolysis.[116,141] The following process scheme, analogous to scheme (1), has been proposed for compound (III):



(6)

The absorption spectra of the states ^3A, ^3X, and B are similar and can be distinguished only kinetically using the differences between their lifetimes, which are 80 ns, 400 ns, and 0.1 s respectively. The quantum yields in the formation of B via ^1A and ^3A are in the ratio 1 : 4, their sum amounting to 0.7, while the quantum yield of the state ^3A is 0.7.

Table 5. Spectrokinetic characteristics of the short-lived products of the photolysis and radiolysis of spiropyrans.

SP	Method of study	Δt, s	Matrix	λ_{max}, nm	τ, s	Refs.

SP_7	l.p.	10^{-8}	b	450	$5\cdot10^{-6}$	[135]
	l.p.	10^{-8}	ppg	450	$3\cdot10^{-5}$	[135]
	l.p.	10^{-8}	ms	450	$2\cdot10^{-6}$	[135]
SP_{16}	p.r.	10^{-8}	b	430	$2\cdot10^{-6}$	[139]
SP_{17}	l.p.	10^{-9}	t	440	10^{-6}	[97]
	l.p.	10^{-9}	an	440	10^{-8}; 10^{-5}	[97]
SP_{20}	l.p.	10^{-11}	b	440	10^{-8}	[140]
SP_{23}	l.p.	10^{-8}	b	470, 530	10^{-6}	[138]
Nitro-chromene (III)	l.p.	10^{-8}	t	330, 520	$8\cdot10^{-8}$; $4\cdot10^{-7}$	[116]

Notation: f.p. = flash photolysis, l.p. = laser photolysis, p.r. = pulse radiolysis, Δt = time resolution of the method, ch = cyclohexane, mch = methylcyclohexane, t = toluene, e = ethanol, ee = 2 : 1 ethano–ether mixture, b = benzene, an = acetonitrile, ppg = poly(propylene glycol), ms = micellar solutions, pmma = poly(methyl methacrylate).

Scheme (6) is also valid for the piperidine SP with the sole difference, that, owing to steric factors, the reaction stops at the stage involving the formation of the isomer X and not B.

The formation reaction of the coloured form of SP with the nitro-group by pulse radiolysis in benzene proceeds via mechanisms similar to that described by scheme (6) or more precisely via the "triplet channel":[55,139]

$$\begin{tikzcd} A \arrow[r, "^3C_6H_6"] & {}^3A \arrow[r] \arrow[dr] & {}^3X \arrow[r] \arrow[d, "O_2"] & A \\ & & B & \end{tikzcd} \qquad (7)$$

The lifetime of the state ^3A is $\leq 10^{-8}$ s, while that of ^3X is 2×10^{-6} s (in the absence of oxygen). The presence of atmospheric oxygen accelerates the reaction $^3X \rightarrow B$, increasing thereby the yield of B.

The influence of various quenching agents (oxygen, TMPP, and triphenylamine) on the kinetics of the decrease of the intensity of the short-lived absorption band of the SP_4 solution in toluene at 440 nm has been investigated[99] by flash photolysis using the results of a study of the quenching of the photocolouring reaction in photostationary experiments. This absorption disappeared with the rate constant $\geq 10^5$ s^{-1} and did not arise in the presence of O_2. The results obtained show that the photolysis of SP_4 proceeds via a mechanism analogous to mechanisms (6) and (7) and that the absorption band at 440 nm constitutes a superposition of the absorption bands of two SP photoproducts—^3A and ^3X.[99] Oxygen and the electron donor deactivate ^3X and ^3A respectively under these conditions.

Thus, on the basis of the results of a number of studies,[4,99,116,139,141] and taking into account the fact that in the photostationary colouring of SP with the nitro-group the reaction proceeds mainly via the triplet state, one can postulate that scheme (6) is valid for SP with the nitro-group, as for compound (III), with the sole difference that the deactivation of the ^3X state by oxygen in the case of SP leads to the formation of the B form, while in the case of compound (III) the initial form of the nitrochromene is regenerated.[116]

We shall analyse from this standpoint other studies of the photocolouring reaction by the laser flash photolysis method. The short-lived spectra of SP_3 and SP_{20} arise over a period of only $\sim 10^{-11}$ s [132,140] and the disappearance of the band at 580 and 440 nm in the initial instants proceeds in accordance with the same law with a characteristic time in the range 10^{-9}–10^{-8} s, depending on the solvent (toluene and ethanol). Hence it follows that these two bands belong to the same product. By analogy with other studies[130,137,142] and in view of the high rate of its appearance, Krysanov and Alfimov[132] assigned the 440 nm band to the $S_0 \rightarrow S_1^*$ absorption of the isomer X, assuming that it is formed from the ^1A state. Although this reaction can in fact make a definite contribution ($\lesssim 20\%$) to the formation of the isomer X and the B form,[97,116,141] nevertheless it is preferable to attribute the band to the overall absorption by the SP and the isomer X in the T states (^3A and ^3X respectively). This assignment makes it possible to explain the biexoponential kinetics of the decrease of the absorption by the short-lived products, noted in a number of investigations[132,137,140,142] and characterised by two times τ_1 and τ_2, and also the influence of the presence of oxygen on the latter. The rapid and slow components of the kinetics of the decrease of absorption can be reasonably assigned to absorption by the ^3A and ^3X states respectively. The time τ_1 for the ^3A state is then 10^{-9}–10^{-8} s, while τ_2 for the ^3X state is $\sim 10^{-7}$ s. The time τ_1 for the ^3A state agrees well with its existing estimates (see Table 4 and Refs.139, 143, 144). For such values of τ_1 and τ_2 and at a low O_2 concentration ($\sim 10^{-3}$ M), the quenching process, whose rate is determined by diffusion, can exert an appreciable influence only on the slow component of the decrease of the absorption by the short-lived products, i.e. on τ_2 for the ^3X state. Indeed it has been noted that τ_1 remains unchanged and τ_2 diminishes with the simultaneous increase of the yield of the B form in the presence of O_2.[137,139,142] The high rate of formation of ^3A is also not surprising, since K_{ST} for aromatic nitro-compounds is of the order of $\gtrsim 10^{11}$ s^{-1}. For example, the maximum intensity of the T–T absorption for nitroanisoles is attained after only $\sim 10^{-11}$ s.[76] This is also promoted by the high quantum yield (0.6–0.7) for the formation of the triplet states of aromatic nitro-compounds.[76,78,145]

Analysis of the absorption spectra of the short-lived products[131,132,140] permits the conclusion that in the case of SP, as for compounds (III), the extinction coefficients of the ^3A and ^3X states and the positions of the absorption bands are similar. In the range 570–610 nm the pattern of the variation of the short-lived spectrum may become complicated as a consequence of the superposition of the absorption band of the B form.

For SP_4 and SP_5, the assignment of the 440 nm band to the T–T absorption in PMMA [131] agrees with the results of a study[133] in which the identity of the lifetimes of the phosphorescence and of the short-lived absorption of SP_5 at 77 K was established. The character of the time variation of the spectrum of the short-lived product derived from SP_4 [131] permits the conclusion that the 420 nm band represents the superposition of the absorption bands of two products with appreciably different lifetimes—of the order of 10^{-8} and 10^{-6} s, which agrees qualitatively with the results of Kholmanskii et al.[99]

Biexponential kinetics of the decrease of the absorption at 440 nm have been observed for SP_{17} in acetonitrile;[97] the shorter-lived absorption was assigned by the authors to the S_0–S_1 absorption by the isomer X, since the decrease of the absorption intensity at 440 nm was not accpanied by an increase in the region corresponding to absorption by the B form (500–600 nm). However, as noted above, the constancy of the absorption intensity in the range 500–600 nm, which was observed also in other studies,[116,139,146] may be be due to the fact that the decrease of the ^3A absorption and hence also of the ^3X absorption is compensated by the increasing absorption by the B form.

It has been established[97] that the absorption of SP_{17} at $\lambda = 530$ nm increases with a characteristic time of 2.7×10^{-10} s (in methylcyclohexane) regardless of the initial SP concentration (the latter fact shows that the association of the SP molecules does not affect the primary photoprocesses in the molecule). This increase was attributed to the reaction $^1A \rightarrow B$ which may make a slight contribution to the formation of the B form in the case of SP with the nitro-group, as for compound (III).

Summing up the discussion of the results obtained with the aid of kinetic pulse spectroscopy, one may conclude that the formation of two products can be detected kinetically on apparatus with a time resolution $\leq 10^{-8}$ s and that the lifetime of the shorter-lived product is not appreciably influenced by oxygen. With laser pulse apparatus with a time resolution $\geq 10^{-7}$ s, a single short-lived product is detected as a rule, its lifetime depending on the presence of O_2. The identification of these products as the SP and the isomer X in the ^3A and ^3X states respectively appears to be most likely.

Thus, on the basis of the above analysis and taking into account the data in Section II and in the previous parts of the present Section, one can formulate the following general mechanism of the SP photocolouring reaction:

$$\begin{tikzcd} A \arrow[r, shift left, "h\nu"] & {}^1A^* \arrow[l, shift left] \arrow[r] \arrow[d] \arrow[drr] & {}^3A^* \arrow[r] \arrow[dr] & {}^3X^* \arrow[d] \\ & {}^1X^* \arrow[r] & X \arrow[r] & B \end{tikzcd} \quad (8)$$

The scheme does not show the recombination reaction of the excited states A^* and X^* to give A and also the transitions ${}^1X \rightarrow {}^3X$ and ${}^3X \rightarrow X$ and the reverse dark reaction $B \rightarrow A$ are entirely feasible.

The occurrence of the photocolouring reaction via a particular channel is determined by the structure of the SP and external conditions. For SP containing a nitro-group, the reaction takes place mainly via the triplet channel, while for SP without the nitro-group the singlet channel is involved. Bearing in mind that the bond dissociation reaction in the ${}^3A$ state of SP_3 has an activation barrier of 0.04 eV,[29] the photochemical reaction pathway for an SP of the type SP_3 can also be represented under these conditions by the transitions illustrated in Fig.6.

The results of the study of the kinetics of the reactions of the SP photoproducts and their lifetimes make it possible to estimate the rate constants for the transitions between them. The rate constant for the intersystem transition for SP with the nitro-group in a weakly polar solvent has values in the range $>10^{11}$ s^{-1} (transitions of the type ${}^1A \rightarrow {}^3A$ and apparently ${}^1X \rightarrow {}^3X$).[74] The rate constants for the transition ${}^3A \rightarrow {}^3X$ or B as well as the transition ${}^1A \rightarrow B$ are in the range 10^8–10^{10} s^{-1} [97] depending on the structure of the SP. The transition ${}^3X \rightarrow B(X)$ in the absence of oxygen is characterised by a rate constant of 10^5–10^7 s^{-1}. This applies to SP whose T state is photochemically active. If the T state is photochemically inactive, its lifetime increases to 10^{-6} s (SP_{22} and SP_{23}). The transitions between the isomers B, including the transition $X \rightarrow B(A)$, take place with a rate constant of ~10^7 s^{-1} at room temperature.[137] Since the transition $X \rightarrow A(B)$ can have activation barriers (Fig.6 and Refs.6 and 35), the photocolouring process can be arrested at the X-isomer formation stage as the temperature is reduced, which has in fact been observed.[35,40,73,80]

IV. PROSPECTS FOR THE EMPLOYMENT OF PHOTOCHROMIC SPIROPYRANS IN SCIENCE AND ENGINEERING

Photochromic SP have found the main application in the preparation of various recording media and in the treatment of optical information and also in the manufacture of filters with a variable optical density.[5,7,9] More than 20 light sensitive compositions of photographic materials in which SP play one role or another are patented annually in this field. Apart from their use as colour-generating components (in photochromic and free-radical photographic materials with a sensitivity up to 10^{-4} J cm^{-2},[4,147–149]), SP are also introduced as spectral sensitisers in diazotype, photopolymeric, and electrophotographic photomaterials.[7] Photochromic materials based on SP have a high resolving power (up to 10^4 mm^{-1}) and a capacity for recording and counting on a real time-scale; the light sensitivity of photochromic materials to UV light is 0.05 J cm^{-2} for a unit decrease in optical density while their sensitivity to IR irradiation is 1–2 J cm^{-2}.[4,5] The number of recording and deletion cycles on the photochromic material varies from tens to thousands depending on the optical density drop and the type of material.[5]

Photochromic materials based on SP are being improved by increasing the number of cycles which can be achieved and the light sensitivity and by creating multicolour photochromic systems and materials, which make it possible to regulate the storage time of the information recorded on them. In order to solve the latter problem, the influence of the polymer on the characteristics of the photochromic transformations and the possibility of stabilising the coloured form by selecting the appropriate polymer or the type of chemical binding of the SP to the latter are investigated[32,84,86,151–153] as is altering the structure of the SP to increase the activation barrier of the thermal decolorisation reaction.[150,151]

The light sensitivity of photographic materials based on SP, in which the image is recorded on the basis of the fluoresence of the coloured form of the SP, reaches 10^{-5} J cm^{-2}.[4,7] Materials of a similar type are nowadays being vigorously investigated and improved.

We shall consider in greater detail the use of SP as regulators of various physicochemical processes controlled with the aid of light. The principal property of SP which permits their use in this field is the sharp difference between the physicochemical characteristics of the coloured and colourless forms. The coloured form of the SP with the nitro-group is a highly polar merocyanine dye and hence it possesses the entire wide variety of properties characteristic of this class of dyes.

The possibility of the photocontrol of the potential difference on the surface of a membrane with the aid of SP has been investigated.[10,154] For this purpose, one uses the ability of the coloured form of the SP on the surface of the membrane to react effectively with a proton to form a positively charged product. The surface charge on the membrane and hence the potential difference is regulated in this way.

The possibility of using SP for the investigation of the photoregulation of ion transport through a biological membrane is extremely attractive,[154–156] particulaly the photocontrol with the aid of SP of the transport of metal salts (KCl and NaCl) and aminoacids through liquid membranes. By means of an SP, using the photochromic properties of its hydrochloride, it is possible to control the electrical conductivity of liquid solutions by means of light.[157]

The possibility of the photoregulation and investigation of the chemical reactivity of biological molecules by introducing SP into their compositions appears promising. Thus interesting studies have been made on the photocontrol of the chemical reactivity of the SP-modified α-amylase.[158–161] The mechanism of the influence of SP on the chemical reactivity of compounds is based on the change in the distribution of electron density in the molecule under the influence of the charges of the highly polar B form. The same property of the coloured form determines also the possibility of using SP as surfactants, capable of altering the surface tension at the interface between two liquids[162,163] and also of regulating with the aid of light the hydrophilicity of the polymer surface.[164–166]

The use of SP as light-sensitive additives in films and Langmuir–Blodgett monolayers is of special interest.[11,13,14,167–169] SP modified by introducing a long saturated hydrocarbon chain into the indoline or benzopyran fragment (as, for example, in SP_{18}) are used for such purposes.

Thus it is possible to modulate fluorescence by light and also to investigate the mechanism of the energy and electron transfer between layers, regulating the distance between them with the aid of intervening multilayers consisting of different numbers of monolayers but without admixtures (for example, the thickness of the cadmium arachidate layer was 25 Å [169]).

The high rates of the intermolecular reversible photochemical processes in SP (see Section III) give rise to the hope that the use of SP in multilayers of various structure in combination with the appropriate laser pulse technique will help to create interrupters or modulators of light or electric signals, which are triggered over a period of ~10^{-11} s.

Since SP exhibit photochromic properties when adsorbed on solid surfaces,[5-8] it is of undoubted interest to introduce them as light-sensitive admixtures into ordered monolayers prepared by the chemisorption of certain compounds on solid surfaces, including oriented polymers.[170-172]

The introduction of SP into liquid crystal materials and the synthesis of molecules with liquid-crystal properties on the basis of SP make it possible to expand the range of applications of the latter.[48,173-175] The preparation of photochromic compositions in the form of micellar solutions or the use of SP with amphiphilic properties makes it possible to render visible a stream of liquid to which the SP has been added[176,177] and to apply the method of flash photolysis to the study of various problems of the hydrodynamics of liquids.

It has been suggested[178,179] that SP be used as analytical reagents for the ions of a series of metals, because the latter react with the *B* form to produce intensely coloured chelate complexes.

The 1,3-Anionic Cycloaddition Reactions of αβ-Unsaturated Thiolates and Their Analogues

M.L.Petrov and A.A.Petrov

The reactions of αβ-unsaturated alkali metal thiolates and the analogous salts of selenols and tellurols involving the 1,3-anionic cycloaddition mechanism are examined. The principal factors determining the capacity of the unsaturated triad anions for 1,3-anionic cycloaddition are identified and surveyed, which makes it possible to predict the mode of the reactions of these compounds.

The bibliography includes 93 references.

V. Conclusion 160

I. INTRODUCTION

The reactions involving the cycloaddition of neutral 1,3-dipoles to unsaturated compounds have now been thoroughly investigated in relation to many examples. Huisgen formulated the main principles governing the structure of the 1,3-dipolar system and proposed a synchronous cycloaddition mechanism. As a result of these studies, 1,3-dipolar cycloaddition has become an important method of synthesis of heterocyclic compounds.[1]

The αβ-unsaturated compounds of sulphur and its analogues (selenium and tellurium) usually participate in 1,3-dipolar cycloaddition reactions as fairly reactive dipolarophiles and, due to the specific influence of the sulphur atom, the product is a regioisomer of the cyclic adduct different from that obtained in the case of αβ-unsaturated oxygen-containing compounds. However, the multiple bond remains the reaction site.[2]

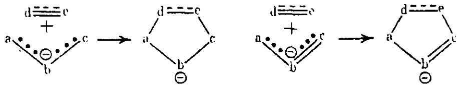
The reactions of αβ-unsaturated sulphur compounds in which they participate as 1,3-dipoles and not as dipolarophiles have also been discovered recently. Thus a group of Soviet and foreign chemists have been actively investigating the interaction of 1,2-dithiole-3-thiones, which are stable quasi-aromatic compounds, with dipolarophiles.[2,3] Drozd and co-workers extended the above reaction to allylic and propargyl derivatives of dithiocarboxylic acid esters.[4,5] In all these cases the cyclisation is accompanied by a sigmatropic shift.

Other instances of the 1,3-dipolar reactivity of sulphur compounds, for example, the adducts of carbon disulphide with phosphines or diamines, are also known.[2]

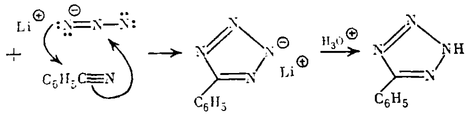
Nitrile sulphides, whose structure and reactivity are analogus to the classical 1,3-dipolar nitrile oxide systems, have been obtained recently.[6]

Thus the capacity for 1,3-dipolar cycloaddition, known previously only for oxygen and nitrogen compounds, has been recently demonstrated also for sulphur compounds.

Within the framework of the principle of the conservation of orbital symmetry in a chemical reaction, 1,3-dipolar cycloaddition is a special case of the symmetry-allowed $[_{\pi}4_s + _{\pi}2_s]$cycloaddition of allyl anions to unsaturated compounds.[7] For this reason, the allyl and propargyl anions have been used as the basis of the classification of the octet-stabilised 1,3-dipoles:[8]



The possibility of the involvement of such anions in cycloaddition reactions analogous to that of the "classical" 1,3-dipoles was predicted by Woodward and Hoffmann.[7] These reactions with participation of αβ-unsaturated anions have been called "1,3-anionic cycloaddition" (1,3-AC) on Kauffmann's suggestion.[9] The reactions involving the cycloaddition of inorganic azides (anionic 1,3-dipoles) to multiple bonds, known for a long time, can also be included among them:[1]

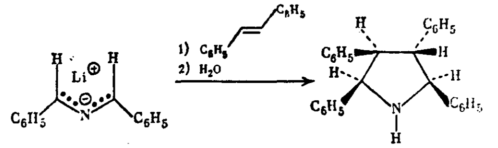


The 1,3-AC reaction of the unsubstituted allyl anion has not so far been achieved. However, allyl anions having substituents in the 2-position capable of stabilising the charge on the central atom of the triad do undergo the 1,3-AC reaction with activated alkenes. Thus 2-cyano-1,3-diphenylallyl-lithium reacts with *trans*-stilbene in a rigorously stereospecific manner with formation of the corresponding cyclopentantes. *cis*-Stilbene does not react with the salt, which confirms the concerted mechanism of the formation of new bonds.[10]

The participation of propargyl anions in 1,3-AC reactions has not been investigated, although it has been suggested that the dimerisation of 1,3-diphenylpropyne under the influence of lithium diisopropylamide proceeds via the 1,3-AC of the 1,3-diphenylpropargyl anion.[9]

The study of this key reaction, predicted by the theory, developed only after 1974 as a result of the studies by Kauffmann and co-workers devoted to the nitrogen-containing allyl anions.[9] This group of chemists demonstrated that 1,3-diphenyl-2-aza-allyl-lithium is the most reactive in 1,3-AC reactions with participation of a wide variety of unsaturated compounds ("anionophiles" according to Kauffmann's terminology).

The study of the 1,3-AC reactions of 2-aza-allyl-lithium compounds with simple alkenes demonstrated their great similarity to the reactions of 1,3-dipoles of the allylic type.[8] Thus simple unsubstituted alkenes do not react with 2-aza-allyl-lithium compounds, as in the case of the usual 1,3-dipoles. Only the introduction of phenyl substituents (styrene, stilbenes) into the dipolarophile or an increase in the strain in the multiple bond (norbornene, acenaphthylene) leads to 1,3-AC. Such reactions proceed exclusively regioselectively, as for the usual 1,3-dipoles. *trans*-Stilbene is more reactive in 1,3-AC reactions than *cis*-stilbene. In most cases the 1,3-AC proceeds stereospecifically: *trans*-stilbene reacts with *cis*-1,3-diphenyl-2-aza-allyl-lithium to form only one conformer of tetraphenylpyrrolidine:



These data indicate a concerted mechanism of 1,3-AC. Apart from the alkenes enumerated above, alkadienes and, as shown recently, arylallenes are fairly reactive in the 1,3-AC reactions with 2-aza-allyl-lithium compounds.[11] The introduction of organoelemental substituents, incorporating Group IV–VI elements in the Third and Fourth Periods such as sulphur, selenium, phosphorus, arsenic, silicon, and germanium, into alkenes favours the 1,3-AC reactions.[12]

The 1,3-AC reactions of 2-aza-allyl-lithium compounds with alkynes and nitriles frequently lead to heteroaromatic products, since they are accompanied by the elimination of hydrogen.

The nature of the multiple bond in the anionophile has a particularly pronounced influence on the 1,3-AC reactions. As in the reactions with the usual 1,3-dipoles, the oxygen-containing anionophiles are less reactive in cycloaddition to 2-aza-allyl-lithium anions than the sulphur and nitrogen compounds. Aldehydes, ketones, and carbon dioxide react with 2-aza-allyl-lithium compounds to form only linear adducts. Carbon disulphide is uniquely reactive in 1,3-AC reactions.[9]

Thus 1,3-AC reactions have been relatively thoroughly investigated only for nitrogen-containing allyl anions. The results of these studies have been summarised in a review[9] and have been included in a reference publication on general organic chemistry.[13]

Yet another type of 1,3-AC reactions involving sulphur compounds, namely αβ-unsaturated thiolates and their Group VIA analogues has been investigated in very recent years. These reactions make available new groups of sulphur-containing hereocycles and extended thereby greatly the scope of 1,3-AC in organic synthesis. The present review is devoted to a survey of the results of the authors of the review and other chemists in the study of the reactivities of αβ-unsaturated thiolates in 1,3-AC reactions.

αβ-Unsaturated thiolates are generally related to thioaldehydes, thioketones, and thioketens and the investigation of their reactivity therefore helps to extend the applications of various thiono-compounds in organic synthesis.

Ethylenic thiolates, which are salts of enethiols—a tautomeric form of thiono-compounds—have been known for a comparatively long time, while the salts of acetylenic thiols—the "enol" form of thioketens—were first obtained only in 1962.[14] The electrophilic substitution reactions of αβ-unsaturated thiolates have been most thoroughly investigated. In contrast to the enolates, which react both via the oxygen and carbon centres, unsaturated thiolates interact with electrophiles only via the thiol reaction centre.[15] Ethylenic selenolates and even more so the tellurolates were until recently difficult to obtain or were unknown owing to the instability of the initial $>C{=}Se$ and $>C{=}Te$ compounds.[16] As a result of studies mainly by Arens and his school,[14] the salts of αβ-acetylenic selenols and partly tellurols are readily available.

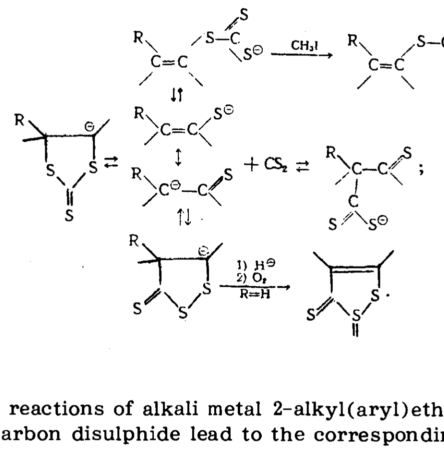
The nucleophilic character of the heteroatom in αβ-unsaturated thiolates and their analogues as well as the available data on the reactivity of 1,3-dipoles of the "allylic type"[8] have determined the choice, as objects of study, of anionophiles such as heterocumulenes and activated acetylenes, in the first place carbon disulphide, whose unique reactivity in 1,3-dipolar cycloaddition reactions is well known.[1] Furthermore, αβ-unsaturated thiolates can be successfully introduced into "mixed" dimerisation reactions with Huisgen's classical 1,3-dipoles. Such reactions have been fairly thoroughly investigated for the αβ-unsaturated compounds of tervalent phosphorus.[2] The latter are regarded as 1,3-dipolar systems with the negative charge on the phosphorus atom and the positive charge on the extreme carbon atom involved in the multiple bond.

II. INTERACTION WITH HETEROCUMULENES

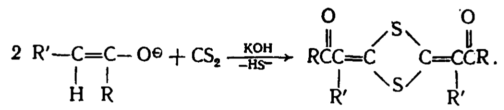
1. αβ-Ethylenic Thiolates

2-Alkyl(aryl)ethylenethiolates are usually obtained as mixtures of the *Z*- and *E*-isomers on treatment of the corresponding ethylthioethylenes with alkali metals in liquid ammonia.[17,18]

Despite the fact that carbon disulphide exhibits a unique reactivity in both 1,3-dipolar cycloaddition and 1,3-AC reactions, 2-alkyl(aryl)ethylenethiolates enter into the 1,3-AC reaction with the above anionophile with difficulty. The formation of cyclic adducts is not then the only reaction pathway. The unsubstituted ethylenethiolate does not form cyclic adducts with carbon disulphide, like the allyl anion:[19,20]



The reactions of alkali metal 2-alkyl(aryl)ethylenethiolates with carbon disulphide lead to the corresponding 1,2-dithiole-3-thione in a low yield after neutralisation and oxidation with atmospheric oxygen. The addition is preferentially to the thiol reaction centre. Treatment of the reaction mixture with methyl iodide results in the formation of methylalk-1-enyl trithiocarbonates. On the other hand, when iodine is added to the reaction mixture as the oxidant, only dialk-1-enyl disulphide is obtained.[20] In contrast to the thiolate anions, the enolate anions react with carbon disulphide to form *C*-adducts and not cyclic adducts:[21]



In order to elucidate the causes of this difference between the behaviour of enolates and αβ-unsaturated thiolates in the reaction with carbon disulphide, the charge distribution in the C(2)=C(1)–X (X = S or O) systems was estimated from ^{13}C NMR spectra and from quantum-chemical calculations.[22] It was established that the maximum negative charge is located in both cases on the heteroatom, but the nono-uniformity in charge distribution is more striking for enethiolates than enolates. In the case of enethiolates one may speak of the strong nucleophilic centre on sulphur and the weak centre on the C(2) atom, while in the enolate anion there are two nucleophilic centres of approximately equal strength [O and C(2)].

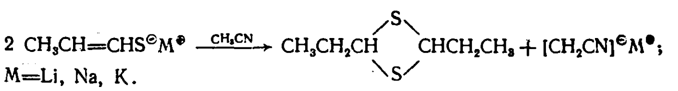
These data agree with the mode of nucleophilic addition of alkenethiolates to the electrophilic carbon atom of carbon disulphide. However, the question of the mode of addition of enolates and the mechanism of the [3 + 2]cycloaddition of alkenethiolates to carbon disulphide remains open.

The possibility that the reaction proceeds not only via the concerted mechanism but also via a stepwise mechanism is real for 1,3-AC reactions to an even greater extent than for 1,3-dipole cycloaddition.[8,9] One can assume accordingly that the reactions of an enolate with carbon disulphide belong, like the reactions of alkenethiolates, to the [$_{\pi}4_s$ + $_{\pi}2_s$] cycloaddition type, but the suggested cyclic adduct is unstable owing to the instability of the O–S bond. A similar hypothesis has been put forward in the literature for the reactions of enolates with carbonyl compounds.[23]

In order to confirm this hypothesis and to explain the causes of the observed high regioselectivity of the reaction, the results of quantum-chemical calculations for the enolate and enethiolate ions and carbon disulphide were analysed with the aid of the rules established by the molecular orbital perturbation theory in the 1,3-dipolar cycloaddition reaction.[22] Such analysis is entirely justified, since 1,3-AC also belongs to the class of [$_{\pi}4_s$ + $_{\pi}2_s$]cycloaddition reactions.

The calculations have shown that the distribution of the energy levels of the frontier orbitals in the reactions of both enethiolates and enolates with carbon disulphide belongs to Sustmann's type I. However, the estimation of the regiospecificity of the cycloaddition of enethiolates and enolates to carbon disulphide by the energy stabilisation method yields a different result for these interactions. The observed regioisomer of the cyclic anion (1,2-dithiole-3-thione and not 1,3-dithiole-2-thione) was accurately predicted in the case of enethiolates, while for the enolates the stabilisation energies of different regioisomers of the cyclic adduct are approximately the same. The reaction of the enolate with carbon disulphide is not cycloaddition. On the other hand, the same method predicts correctly the experimentally observed mode of nucleophilic addition of enethiolates and enoaltes to carbon disulphide.[22] Thus it has been suggested that the formation of 1,2-dithiole-3-thiones in the reactions of alkenethiolates with carbon disulphide proceeds via a concerted mechanism with the immediate formation of a cyclic anion and not the nucleophilic addition product, which cyclises under the influence of the oxidant after neutralisation.[20,22]

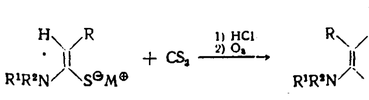
A mixture of the *Z*- and *E*-isomers of 2,4-diethyl-1,3-dithietan (the propenethiol dimer), whose formation is promoted by the presence of weak proton donors, has also been discovered in the products of the reaction of propene-1-thiolate with carbon disulphide:[19,20]



A similar dimerisation has been observed also for thioketones in the presence of bases.[24]

Heterosubstituted ethylenethiolates are much more reactive in the 1,3-AC reactions with carbon disulphide. In view of the fact that the capacity of the 1,3-dipole for cycloaddition reactions is directly related to the ability of substituents to destabilise the dipole and to stabilise the transition state,[8] the ease of the 1,3-AC should diminish in the following sequence of heteroatoms in the 1-position in the ethylenethiolate: N > O > S.

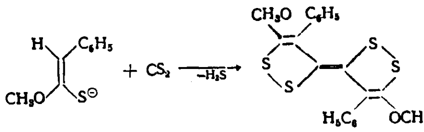
Substituted 1-aminoethylenethiolates do indeed react with carbon disulphide even at –55 °C to produce a high yield of only substituted 5-amino-1,2-dithiole-3-thiones:[25–27]



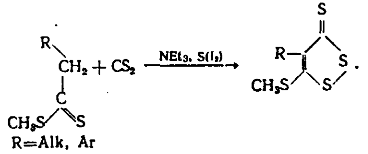
M=K, Na; R=H, Alk, Ar; R^1,R^2=Alk, Ar.

Here it is essential to note that substituted 1-aminoethylenethiolates, obtained by the reaction of thioamides with potassium or sodium amides in liquid ammonia, exist exclusively in the form of the *Z*-isomers.[28]

On the other hand, 1-methoxy-2-phenylethylenethiolate reacts with carbon disulphide only at room temperature, and more effectively on heating, the product of the oxidative dimerisation of the intermediate cyclic anion, namely 5,5'-dimethoxy-4,4'-diphenyl-1,1',2,2'-tetrathiofulvalene, being formed unexpectedly:[29]



The reactions of 1-methylthioethylenethiolates with carbon disulphide give rise to only traces of 1,2-dithiole-3-thiones. Cyclic adducts were obtained only by the reaction of the dithioesters with carbon disulphide in the presence of triethylamine and oxidants (S or I$_2$) in a solvating solvent:[25]



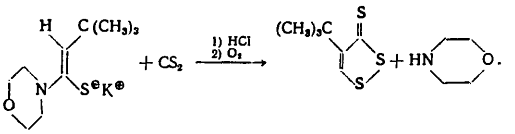
R=Alk, Ar

NN-Disubstituted 1-aminopropene-1-thiolates react vigorously with carbon disulphide regardless of the structure of the substituents at the nitrogen atom with formation of only the *NN*-disubstituted 5-amino-4-methyl-1,2-dithiole-3-thiones.[26]

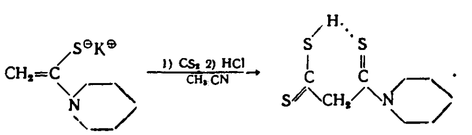
The nature of the substituent in the β-position in *N*-substituted α-aminoethylenethiolates has a much more significant influence on the reaction with carbon disulphide.[27]

Thus, in the absence of a β-substituent, the products of the competing oxidative dimerisation, namely substituted 5,5'-diamino-1,1'-2,2'-tetrathiafulvalene, are formed apart from the usual 1,3-AC products:[27,29]

The introduction of a bulky substituent in the β-position in ethylenethiolate results in the reaction with carbon disulphide being accompanied by the elimination of an amine molecule and the formation of 4-t-butyl-1,2-dithiole-3-thione:[27]

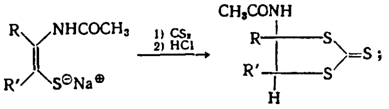


The cyclic structure of the intermediate is confirmed by the formation of a monopiperidide of trithiomalonic acid on interaction of potassium 1-piperidinoethylenethiolate with carbon disulphide in the presence of acetonitrile:



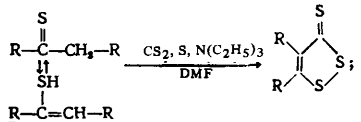
The compound isolated is not oxidised by atmospheric oxygen to the corresponding 1,2-dithiole-3-thione.[27]

Only one example of the formation of 1,3-dithiolan-2-thiones, and not 1,2-dithioles, in the reactions of alkene-1-thiolates with carbon disulphide is known in the literature, namely on interaction of 2-acetamidoethylenethiolate with carbon disulphide:[30]



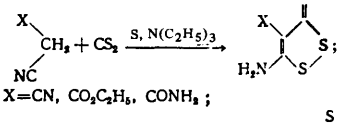
R, R'=H, CH₃

The formation of alkene-1-thiolates may be postulated as an intermediate stage in certain methods of synthesis of 1,2-dithiole-3-thiones, in the first place in the reaction of thioketones with carbon disulphide in the presence of a base (triethylamine) and an oxidant (sulphur):[24]

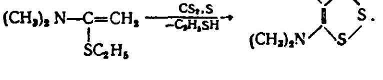


R = n-C₃H₇, iso-C₄H₉.

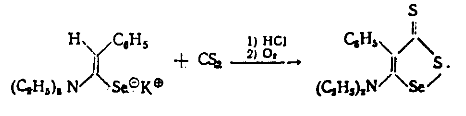
This can also occur on interaction of alkyl-substituted enamines with a mixture of sulphur and carbon disulphide[31] and also in the reactions of nitriles having mobile hydrogen atoms in the α-position with carbon disulphide and sulphur in the presence of bases[32,33] and in the exothermic reaction of keten *NS*-acetals with carbon disulphide and sulphur in dimethylformamide (DMF):[34]



X=CN, CO₂C₂H₅, CONH₂ ;



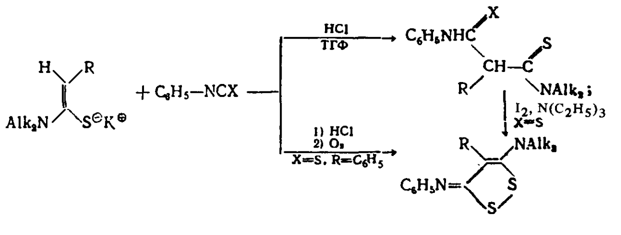
The αβ-ethylenic selenolates, which are isoelectronic analogues of alkene-1-thiolates having the amino-group in the α-position and which have been obtained recently, are also capable of entering into the 1,3-AC reaction:



The reaction is accompanied by the formation, together with a thiaselenole, also of compounds with the dithiole structure, because selenium is replaced by sulphur in the selenolate anion.[35]

Like carbon disulphide, phenyl isothiocyanate is an active dipolarophile and anionophile in 1,3-dipolar cycloaddition and 1,3-AC reactions.[1,9] In contrast to carbon disulphide, its molecule is asymmetric and, as shown in relation to the 1,3-dipolar cycloaddition reactions, it is capable of interacting via the C=S and C=N bonds.[1] However, in 1,3-AC reactions involving 2-aza-allyl anions, phenyl isothiocyanate reacts only via the C=N bonds.[9]

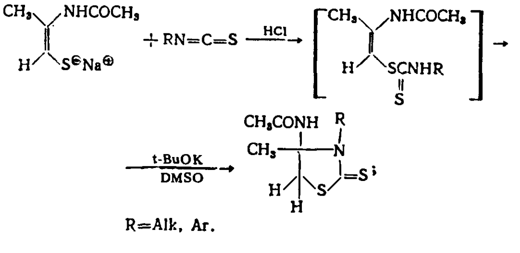
NN-Disubstituted 1-aminoethylenethiolates, which are the most reactive in the 1,3-AC reactions with carbon disulphide, combine with phenyl isothiocyanate and phenyl isocyanate via the carbon reaction centre with formation of derivatives of dithio- and mono-malonic acids respectively:[36]



R=Alk, Ar; X=O, S.

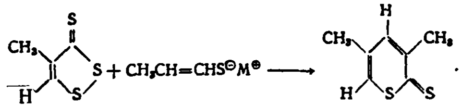
The products of the reactions of ethylenethiolates with phenyl isothiocyanates are oxidised by iodine to the corresponding 3-phenylimino-1,2-dithioles. The unusual site of nucleophilic addition (at the carbon centre of ethylene-1-thiolate) and the formation of a cyclic adduct in the reaction of 2-phenyl-1-piperidinoethylenethiolate with phenyl isothiocyanate suggest a concerted mechanism of the addition reaction. Derivatives of thiomalonic acid are formed as a consequence of the high instability of the corresponding cyclic anions. The phenyl substituent increases somewhat the stability of the cyclic anion, which is oxidised to a 1,2-dithiole after neutralisation.[28,36]

Sodium 2-acetamidoalkenethiolates react with isothiocyanates, forming, after neutralisation, linear nucleophilic addition products, which are tentatively identified as substituted dithiocarbamates. The latter cyclise to thiazolidine-2-thiones on heating in dimethyl sulphoxide (DMSO) in the presence of t-C₄H₉OK:[30]

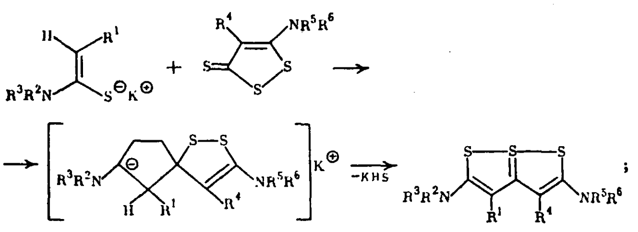


R=Alk, Ar.

Ethylenethiolates can react even with 1,2-dithiole-3-thiones. Thus the condensation of 4-methyl-1,2-dithiole-3-thione with sodium or potassium propene-1-thiolate results in the formation of 3,5-dimethylthiapyran-2-thione:[20]

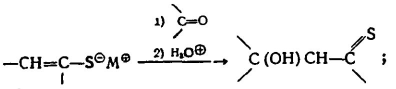


On the other hand, the interaction of *NN*-disubstituted 5-amino-1,2-dithiole-3-thiones with an excess of *NN*-disubstituted potassium 1-aminoethylenethiolate leads to derivatives of 1,6,6*a*-*S*(IV)-trithiapentalene:[37]



—R^1, R^4 = Alk, Ar, H; R^2, R^3, R^5, R^6 = Alk.

It has been shown for aza-allyl anions that the nature of the double bond involving a heteroatom has a marked influence on the 1,3-AC reaction. Thus aldehydes, ketones, and carbon dioxide react with 2-aza-allyl-lithium derivatives to form only linear products.[9] Alkene-1-thiolates react analogously with carbonyl compounds:[38-40]



$$-CH{=}\underset{|}{C}{-}S^{\ominus}M^{\oplus} \xrightarrow[2)\ H_3O^{\oplus}]{1)\ \gt C{=}O} \gt C(OH)CH{-}C(\!{=}S)\lt\ ;$$

$M^{\oplus}$=Li, Na, MgCl.

2. αβ-Acetylenic Thiolates

αβ-Acetylenic thiolates are isoelectronic analogues of 1,3-dipolar systems of the propargyl type such as nitrileimides, nitrileimines, and diazonium betaines.[8,41] Instead of the nitrogen atom, the role of the centre at which the charge is stabilised is assumed by the *sp*-hybridised carbon atom having a higher electronegativity than the sulphur atom.[42]

The cyclic anions formed on the 1,3-AC of αβ-acetylenic thiolates are more stable than in the case of αβ-ethylenic thiolates, since they have the character of the cyclopentenyl and cyclopentadienyl anions.[43] However, both the cyclopentadienyl anion and its hetero-analogues readily undergo cycloelimination for an "inexplicable" reason (in Huisgen's words[41]). Probably, the 1,3-AC reactions of αβ-acetylenic thiolates can take place only in the presence of stabilising substituents such as aromatic groups. The activating influence of such substituents has been noted for 2-aza-allyl anions[9] and for αβ-ethylenic thiolates.[19,20,25,27]

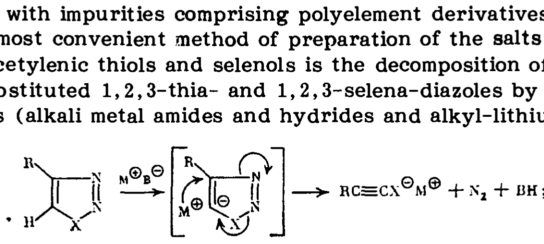
αβ-Acetylenic thiols and their analogues are unknown and are believed to be extremely unstable.[44] In the form of alkali metal salts, they are nevertheless readily available. The method of synthesis of αβ-acetylenic thiolates, selenolates, and tellurolates on interaction of acetylides with chalcogens in liquid ammonia was proposed as early as 1962:[45]

$$RC{\equiv}C^{\ominus}Na^{\oplus} + X_8 \rightarrow RC{\equiv}CXX_7^{\ominus}Na^{\oplus};$$

$$RC{\equiv}CXX_7^{\ominus}Na^{\oplus} + RC{\equiv}C^{\ominus}Na^{\oplus} \rightarrow RC{\equiv}CX^{\ominus}Na^{\oplus} + RC{\equiv}CXX_6^{\ominus}Na^{\oplus}\ \ldots\ \text{etc.};$$

R=Alk, Ar; X=S, Se, Te.

The main deficiency of this method is the synthesis of salts with impurities comprising polyelement derivatives. The most convenient method of preparation of the salts of αβ-acetylenic thiols and selenols is the decomposition of 4-substituted 1,2,3-thia- and 1,2,3-selena-diazoles by strong bases (alkali metal amides and hydrides and alkyl-lithium):[46-49]

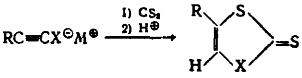


X = S, Se; R = Alk, Ar.

There also exists a convenient preparative version of the method of synthesis of an important group of thiolates and selenolates—potassium 2-arylethylenethiolates and 2-arylethyleneselenolates—by treating the corresponding thia- and selena-diazoles with KOH.[49,50]

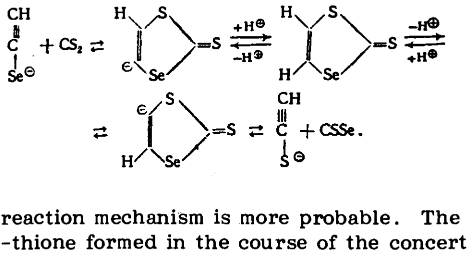
The synthesis of potassium 2-phenylethylenethiolates and 2-phenylethyleneselenolates in a pure form made it possible to investigate them by infrared and ^{13}C NMR spectroscopy. Analysis of the spectroscopic data and the results of quantum-chemical calculations demonstrated a significant non-uniformity in the charge distribution in the C≡C–X (X = S or Se) system. In the selenolate anion, this non-uniformity is more pronounced than in the thiolate anion.[51] The presence of a strong nucleophilic centre at the heteroatom in the molecules of αβ-acetylenic thiolates and selenolates agrees well with the mode of the alkylation and acylation reactions.[44,51] The non-uniformity in the charge distribution in these anions predetermines the possibility of their involvement in 1,3-AC reactions.

Compared with αβ-ethylenic thiolates, their acetylenic analogues react more vigorously with heterocumulenes containing the C=S bonds. Thus it has been established that both αβ-acetylenic thiolates[52-57] and the analogous selenolates[49,57-60] interact with carbon disulphide to form only 1,3-dithiole-2-thiones and 1,3-thiaselenole-2-thiones respectively:



M=Na, K; X=S, Se; R=H, Alk, Ar.

Some workers suggested an unusual nucleophilic addition mechanism for this reaction (the formation of a salt of trithiocarbonic acid) with subsequent intermolecular addition of the anion to the triple bond.[52] A similar reaction mechanism has been invoked to account for the results of the interaction of sodium acetylide in succession with selenium and carbon disulphide; in addition to the expected 1,3-thiaselenole-2-thione, 1,3-dithiole-2-thione, 1,3-dithiole-2-selenone, 1,3-thiaselenole-2-selenone, and 1,3-diselenole-2-thione are also formed:[60]

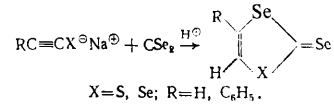


Anothe reaction mechanism is more probable. The 1,3-thiaselenole-2-thione formed in the course of the concerted 1,3-AC of ethyleneselenolate to carbon disulphide undergoes 1,3-anionic cycloelimination[61] to form ethylenthiolate and CSSe. The latter reacts further analogously to carbon disulphide.

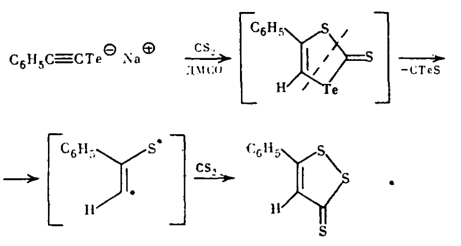
The introduction of substituents increasing the stability of the cyclic anion prevents the 1,3-anionic cycloelimination. For this reason, only 5-aryl-1,3-thiaselenole-2-thiones are formed in the 1,3-AC of 2-arylethyleneselenolates to carbon disulphide.[49,50]

The influence of substituents on the 1,3-AC has been investigated by the method of competing reactions in relation to the interaction of potassium 2-(*p*-R-phenyl)ethyleneselenolates with carbon disulphide. It has been observed that the introduction of electron-donating substituents promotes and that of the electron-accepting substituents hinders cycloaddition. As was to be expected, electron-accepting substituents stabilise the heteropropargyl system C≡CSe, while electron-donating substituents actually destabilise it.[49]

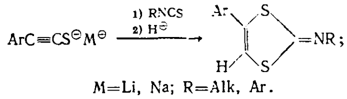
Acetylenic thiolates and their analogues react analogously also with CSe_2:[60,62]



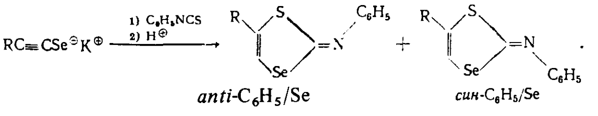
The interaction of sodium 2-phenylethylenetellurolate with carbon disulphide leads to the formation of 5-phenyl-1,2-dithiole-3-thione, which confirms the intial formation of 5-phenyl-1,3-thiatellurole-2-thione. 5-Phenyl-1,2-dithiole-3-thione could have been formed only from its decomposition products by interaction with a new carbon disulphide molecule:[63]



In contrast to αβ-ethylenic thiolates, the 1,3-AC reactions of αβ-acetylenic thiolates with isothiocyanates lead only to *N*-substituted 4-aryl-1,3-dithiole-2-imines:[64,65]

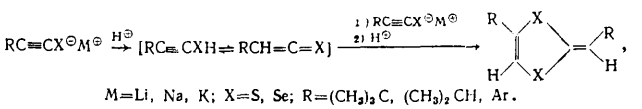


On reaction with phenyl isothiocyanate, potassium 2-aryl-(alkyl)ethyleneselenolates produce 5-aryl)alkyl)-1,3-thiaselenole-2-phenylimines in the form of mixtures of the *syn*- and *anti*-isomers, differing in the position of the benzene ring at the nitrogen atom relative to the selenium atom, in 60–80% yield:[49,64,66]

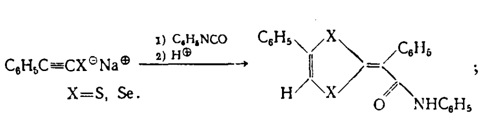


In the case of aryl-substituted selenolates, the *anti*-isomers are formed as the main product, while alkyl-substituted selenolates give rise to the *syn*-isomers.[49]

In the absence of heterocumulenes and when proton donors with pK_a < 18 (water, methanol, acids) are used, αβ-acetylenic thiolates and selenolates "dimerise" to *cis*-2,ω-diaryl-(alkyl-1,4-dithiafulvenes or their selenium analogues:[53,57,67–69]

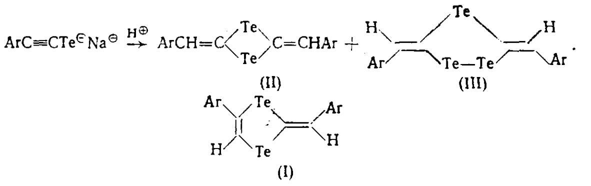


The stereoslectivity of this reaction[68,69] and its kinetics[70] confirm the occurrence of the concerted 1,3-AC of 2-aryl-substituted ethylenethiolates and ethyleneselenolates to the thio- or seleno-ketens formed from them as intermediates. This mechanism has also been confirmed by the unusual character of the interaction of sodium 2-phenylethylenethiolate or 2-phenylethyleneselenolate with phenyl isocyanate:[64]



The formation of "1,4-dichalcogenfulvenes" agrees well with the much greater reactivity of thiono-compounds compared with carbon compounds in 1,3-AC and 1,3-dipolar cycloaddition reactions.[1,9]

When the salts of 2-arylethylenetellurol are neutralised with an ethereal solution of HCl in DMSO and other similar solvents, they give rise to mixtures of *cis*- and *trans*-2,4-diarylidene-1,3-ditelluretans (II) in a satisfactory yield[63,71] and not to ditellurafulvenes (I), as expected by analogy with sulphur and selenium compounds:

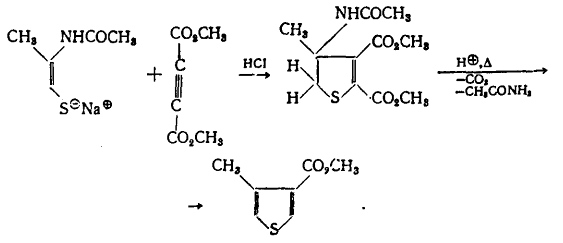


cis-3,5-Dibenzylidene-1,2,4-tritellurole (III) was isolated in an insignificant yield as an impurity.[72] The neutralisation of tellurolates with trifluoroacetic acid nevertheless leads to ditellurafulvenes (I).[73] The role of DMSO is extremely significant.[63] When diethyl ether is incompletely replaced by DMSO,[71–73] the yield of 1,3-ditelluretan (II) falls sharply.

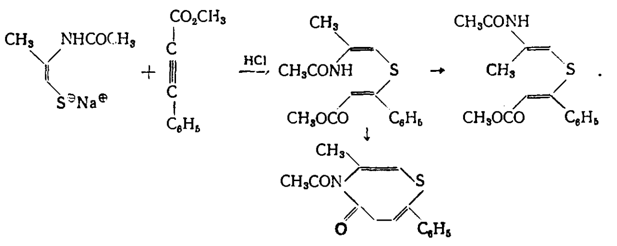
III. INTERACTION WITH ACETYLENIC COMPOUNDS

Like heterocumulenes, acetylenecarboxylate esters are active electron-accepting dipolarophiles or anionophiles in 1,3-dipolar cycloaddition or 1,3-AC reactions.[1,9] However, it has been shown that, under the conditions of the reaction of *N*-substituted 1-aminoethylenethiolates with acetylenecarboxylate esters, the latter polymerise readily.[74]

On the other hand, the interaction of sodium 2-acetamidopropene-1-thiolate with dimethyl acetylenedicarboxylate leads to a high yield of the cyclic [3 + 2]adduct—the dimethyl ester of 2-acetamido-4-methyl-4,5-dihydrothiophen-2,3-dicarboxylic acid and the product of its further reaction—methyl 4-methylthiophen-3-carboxylate:[75]

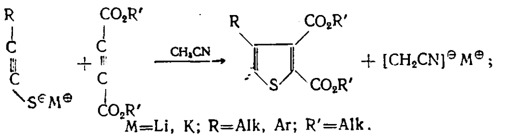


The study of the interaction of 2-acetamidopropene-1-thiolate with other anionophiles containing a triple bond (methyl ester or nitrile of phenylpropiolic acid) showed that only linear adducts—substituted divinyl sulphides—and also the products of their subsequent reaction are formed in both cases,[74] for example:



In contrast to αβ-ethylenic thiolates, the 1,3-AC reactions of αβ-acetylenic thiolates with a triple bond are energetically more favourable, since the charge redistribution takes place more readily: a more stable cyclic anion with a thiophen structure is formed.

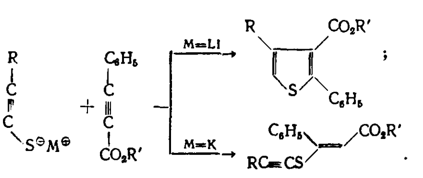
Thus it has been established that αβ-acetylenic thiolates react with acetylenedicarboxylate esters via the [3 + 2]-cycloaddition mechanism with formation of derivatives of thiophen-2,3-dicarboxylic acid:[50,67]



M=Li, K; R=Alk, Ar; R′=Alk.

The reaction proceeds most effectively in aprotic non-polar or weakly polar solvents (benzene, THF) in the presence of proton donors with pK_a = 20–25 (acetone, acetonitrile). Under these conditions, a solution of potassium 2-phenylethylenethiolate in a mixture of THF and acetonitrile contains only ion pairs, which has been demonstrated by the study of the electrical conductivities of these solutions.[77] The role of the solvents as the proton donor for the cyclic anion has been confirmed by carrying out the reaction of potassium 2-phenylethylenethiolate with dimethyl acetylenedicarboxylate in the presence of deuterioacetone. This resulted in the formation of dimethyl 4-phenyl-5-deuteriothiophen-2,3-dicarboxylate. When the reaction is carried out without a proton donor, or with proton donors having $pK_a < 18$, or in the presence of the "mild" proton donor $(CH_3)_3CBr$, the "dimerisation" of acetylenethiols to *cis*-2,ω-diaryl-1,4-dithiafulvenes takes place instead of cyclisation.[50]

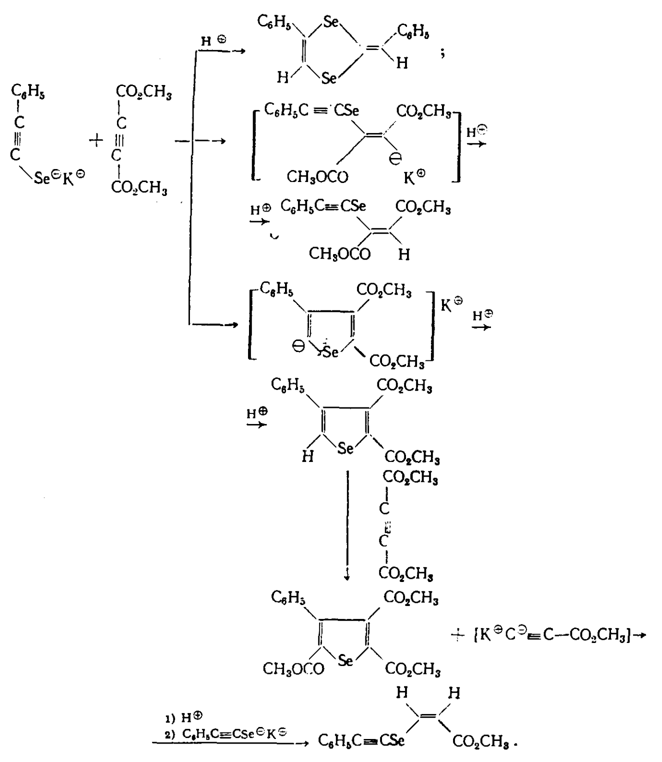
The study of the interaction of 2-arylethylenethiolates with asymmetric dipolarophiles—phenylpropiolic acid—demonstrated a significant dependence of the mode of reaction on the nature of the cation. Thus only one of the possible regioisomers of the cyclic adduct, namely alkyl 4-aryl-2-phenylthiophen-3-carboxylate, is formed in 65–82% yield from lithium 2-arylethylenethiolates. Under the same conditions, potassium 2-arylethylenethiolates gives rise to the *E*-isomers of the products of nucleophilic addition to the triple bond in phenylpropiolate esters and not to cyclic adducts:[78]



The absence of products of nucleophilic addition to acetylenedicarboxylate esters can be accounted for by the more effective stabilisation of the cyclic anion under the influence of two carboxy-groups.

In order to investigate the reactivity of acetylenic selenolates in 1,3-AC reactions wth acetylenic compounds and to determine the influence of the nature of the heteroatom, a study was made of the reactions of 2-phenylethyleneselenolate with an active anionophile—dimethyl acetylenedicarboxylate:[79]

Scheme



Careful analysis of the reaction products revealed the presence, together with the usual 1,3-AC products, namely dimethyl 4-phenylselenophen-2,3-dicarboxylate,[80,81] also of the nucleophilic addition product, i.e. dimethyl *Z*-(2-phenylethynylseleno)butenedioate, and trimethyl 4-phenylselenophen-2,3,5-tricarboxylate. The formation of derivatives of selenophentricarboxylic acid can be regarded as the result of the carboxymethylation of the selenophen anion by dimethyl acetylenedicarboxylate. The resulting methyl propiolate combines with the initial selenolate to form the ester of *Z*-3-(2-phenylethynylseleno)propenoic acid. As usual, 2,ω-diphenyl-1,4-diselenafulvene is formed as a side product.[53] The formation of these reaction products supports the intermediate existence of the anion of the substituted selenophen formed in the course of the concerted 1,3-AC reaction.

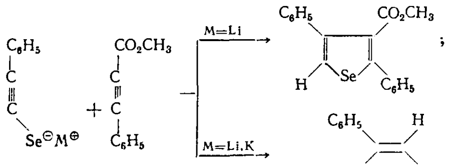
On passing from acetylenic thiolates to selenolates, the negative charge on the heteroatom increases,[51] which should promote nucleophilic addition to the heteroanion. Indeed, the products of nucleophilic addition to the triple bond of the ester were not detected in the reactions of acetylenic thiolates with dimethyl acetylenedicarboxylate.[50] Acetylenic selenolates give rise to small amounts of nucleophilic addition products, but 1,3-AC products are mainly produced.[79]

In order to investigate the influence of the cation on the selectivity of the 1,3-AC reactions of acetylenic selenolates, a study was made of the interaction of lithium 2-phenylethyleneselenolate with the same anionophile—the ester of acetylenedicarboxylic acid. The nucleophilic addition product was not then detected, the 1,3-AC product being formed with a significant increase of the yeild of the dimerisation product.[79]

All these data suggest that the influence of the cation on the mode of the reactions of selenolates with acetylenecarboxylic acid esters is due to the different states of the selenolate in the reaction medium, i.e. the different amounts of ionic character of the selenium–methyl bond.

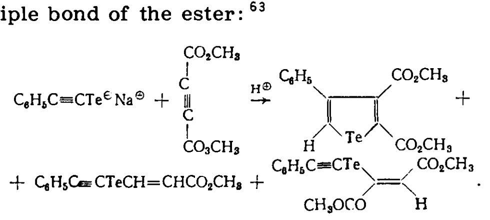
Since it is known that crown-ethers alter significantly the state of salts in solutions as a result of their coordination to the cation, the interaction of the potassium salt of 2-phenylethyleneselenol with the same anionophile was investigated in the presence of dibenzo-18-crown-6 ether. Only the cyclic adduct was then obtained in a satisfactory yield.[79]

The 1,3-dipolar cycloaddition reactions are usually highly regiospecific.[1] In order to determine the regiospecificity of the reactions investigated, a study was made of the interaction of 2-phenylethyleneselenolates with asymmetric anionophiles—phenylpropiolic acid esters.[79,82] It was then observed that the lithium salt produces only one of the possible regioisomers—methyl 2,4-diphenylselenophen-3-carboxylate, together with the product of the nucleophilic addition of the initial selenolate to the triple bond of the anionophile—methyl *Z*-3-(2-phenylethynylseleno)-3-phenylpropenoic acid:



On the other hand, the poassium salt of 2-phenylethyleneselenol (which is more nucleophilic than the lithium salt) reacts with the same anionophile to form only the nucleophilic addition product having the same *Z*-configuration.

The interaction of sodium 2-phenylethylenetellurolate with dimethyl acetylenedicarboxylate led to the dimethyl ester of 4-phenyltellurophen-2,3-dicarboxylic acid. As for selenolates, the cyclisation is accompanied by nucleophilic addition to the triple bond of the ester:[63]

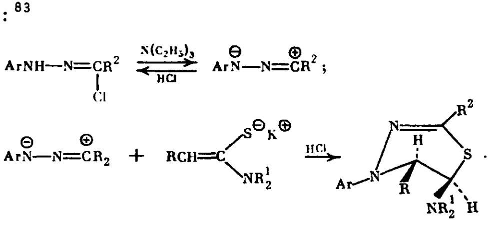


The yield of the tellurophen is appreciably lower than that of the thiophen[50] or selenophen[79] in the analogous reactions.

IV. "MIXED" DIMERISATION WITH HUISGEN'S 1,3-DIPOLES

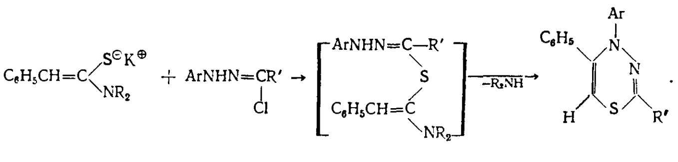
Ethylenethiolates enter into "mixed" dimerisation reactions[2] with 1,3-dipolar systems of the kind formed when HCl is eliminated on treatment with bases.[1] The hydrochloride of the base formed in the reaction reacts as a proton donor in the neutralisation of the cyclic anion.

Thus, when the *C*-chlorohydrazone is converted by treatment with triethylamine into a nitrileimine and the latter is made to react, without being isolated, with *N*-substituted 1-aminoalkenethiolates, then [3 + 3]cycloaddition products, namely 5,6-dihydro-4*H*-1,3,4-thiadiazines, are mainly obtained:[83]



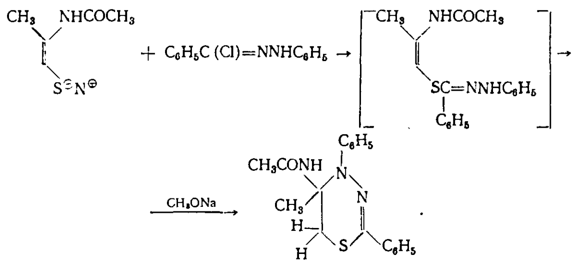
Although the formation of both "half-chair" and "half-boat" conformers with any relative disposition of the substituents is sterically feasible, nevertheless, judging from the ^1H NMR spectrum, only the "half-chair" conformer is actually formed.[83]

On the other hand, 1-*NN*-dialkylamino-2-phenylethylenethiolates react with *C*-chloro-*N*-phenylhydrazones under conditions which rule out the generation of nitrileimine, with formation of only 4*H*-1,3,4-thiadiazines,[83,84] i.e. the reaction is accompanied by the elimination of an amine:

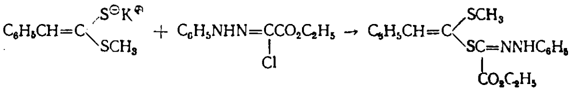


Under the reaction conditions, 5,6-dihydro-4*H*-1,3,4-thiadiazine is not converted into 4*H*-1,3,4-thiadiazine, but it does readily eliminate an amine molecule in the presence of an equimolar amount of acid or on the surface of silica gel.[83]

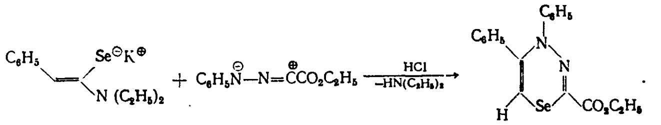
Sodium 2-acetoamidoethylenethiolate reacts with *N*-phenylmethylenehydrazonoyl chloride to form 5-acetamido-5,6-dihydro-1,3,4-thiadiazine. The product of the nucleophilic substitution of the halogen in the *C*-chlorohydrazone by the thiolate is suggested as an intermediate:[85]



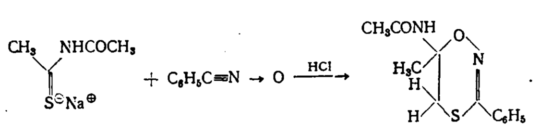
The less reactive potassium 1-methylthio-2-phenylethylenethiolate reacts with the *C*-chloro-*N*-phenylhydrazone of ethyl glyoxylate to form only the linear product of the nucleophilic substitution of chlorine:[83]



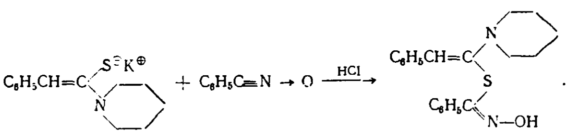
However, potassium 1-diethylamino-2-phenylethyleneselenolate readily enters into the [3 + 3]cycloaddition reaction with nitrileimines obtained from the same *C*-chlorohydrazones. forming 2-ethoxycarbonyl-4,5-diphenyl-4*H*-1,3,4-selenadiazine:[86]



Sodium 2-acetamidoethylenethiolates react also with another widely used 1,3-dipole—benzonitrile oxide,[1] forming 6-acetamido-5,6-dihydro-1,4,2-oxathiazines:

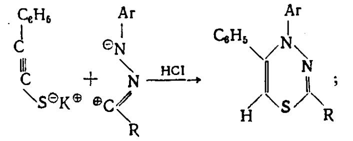


Here too it is assumed that the reaction proceeds via a two-stage mechanism.[85] On the other hand, the interaction of potassium 2-phenyl-1-piperidinoethylenethiolate with benzonitrile oxide yielded only benzohydroximoyl-2-phenyl-1-piperidinovinyl sulphide:[87]



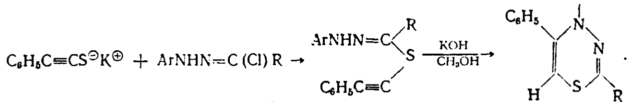
Acetylenic analogues of ethylenethiolates and ethyleneselenolates are also capable of undergoing the [3 + 3]cycloaddition reaction with the usual dipoles—nitrileimines.

Thus potassium 2-phenylacetylenethiolate reacts with nitrileimines, generated from *C*-chloro-*N*-arylhydrazones by treatment with bases, via the [3 + 3]cycloaddition mechanism with formation of 2,4,5-trisubstituted 4*H*-1,3,4-thiadiazines in a satisfactory yield:[88,89]



R=Ar, $CO_2C_2H_5$.

When the reaction of potassium 2-phenylacetylenethiolate with *C*-chloro-*N*-arylhydrazones is carried out in the absence of a base, the products of the nucleophilic substitution of the hydrogen atom—the corresponding (*C*-2-phenylethynyl sulphido)-*N*-arylhdrazones—are formed in a quantitative yield.[89] Their treatment with strong bases (KOH in methanol) results in their ready intramolecular cyclisation with quantitative formation of 4*H*-1,3,4-thiadiazines:[89]



(C-2-phenylethynyl mercapto)-N-arylhydrazones

However, under the influence of triethylamine the intramolecular cyclisation does not occur, which permits the unambiguous assumption that the interaction of 2-phenylacetylenethiolate with nitrileimine proceeds only via a two-stage mechanism.

V. CONCLUSION

Among the αβ-unsaturated heteroanions of Group VIa elements, only sulphur and selenium derivatives, in which the electronegativities of the heteroatom and the extreme C(2) atom of the anion are comparable, exhibit a distinct capacity for 1,3-AC. It has been shown for αβ-ethylenic thiolates that the introduction into the anion of substituents equalising the charge distribution and the *p*,π-electron density at C(2) and S has the greatest influence on the reactivity of unsaturated sulphur and selenium anions in cyclisation reactions.[21,28]

The influence of the heteroatom is no less significant. Thus the basicity of the heteroatom increases in the series of αβ-acetylenic thiolates, selenolates, and tellurolates, which promotes the occurrence of reactions involving the nucleophilic addition of the anion to the multiple bond of the anionophile.[50,63,79]

On the other hand, enolates have a fairly uniform charge and *p*,π-electron density distribution over the C(2) and O atoms of the triad,[21,28] but cyclic adducts are not formed. It may be that, as a consequence of the weak transmission properties of the oxygen bridge,[90] charge redistribution on formation of the cyclic anion is difficult.

The majority of the features of the 1,3-AC reactions investigated for αβ-unsaturated heteroanions can be readily accounted for from a standpoint of the concerted cycloaddition mechanism. The αβ-unsaturated heteroanions of the sulphur subgroup behave like Sustmann's type (I) 1,3-dipolar system or as electron-donating 1,3-dipoles.[21,28,51,74] The introduction of electron-donating substituents promotes and that of electron-accepting substituents hinders the 1,3-AC reactions of the anion, destabilising or stabilising its charge respectively. The stability of the intermediate cyclic anions, which increases under the influence of substituents, particularly aromatic substituents, plays an important role in 1,3-AC reactions.[40] The structure of the anionophile influences the reactivity of the unsaturated anions analogous to 1,3-dipolar cycloaddition reactions.[1] Only electron-accepting anionophiles with substituents capable of stabilising the charge give rise to stable cyclic adducts with αβ-unsaturated heteroanions.[51]

The accumulated data concerning the effect of the character and positions of substituents on the reactivity of heteropropargyl and heteroallyl anions and also the available literature data on the 1,3-AC reactions of aza-allyl anions[9] and allyl anions[10] make it possible to formulate general postulates on the basis of which a particular unsaturated triatomic anion can be assigned to systems capable of entering into 1,3-AC reactions.

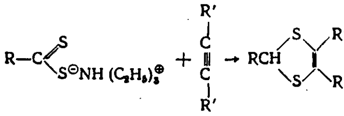
1. A uniform distribution of the *p*,π-electron density at the extreme atoms of the triad is necessary. It can be achieved either as a result of their approximately equal electronegativities or by introducing the appropriate substituents.

2. Since the reactions involving the 1,3-AC of αβ-unsaturated anions to anionophiles are accompanied by a cyclic charge shift on formation of the cyclic anion, the bonds and atoms entering into the composition of the αβ-unsaturated anions must have satisfactory transmission properties. The bonds both in the anion and in the anionophile must have high polarisabilities.

3. The cyclic anion formed as an intermediate must be stabilised either by the increased electronegativity of the central atom of the triad, or by conjugation with a substituent, or by the removal of the anionic group. Otherwise the reaction proceeds with formation of linear products of addition to the multiple bonds with retention of the same regioselectivity as in the cycloaddition.

Using these principles, it is possible to predict the reactivities in the 1,3-AC reactions of heteroallyl anions containing Group V and VI elements which have not been investigated in this respect. Thus the $R_2C{=}N{-}X^{\ominus}$ or $R{-}C\begin{smallmatrix}{\nearrow X}\\{\searrow X^{\ominus}}\end{smallmatrix}$ (X = S or Se) systems having substituents such as aryl, heteroaryl, CH=CHR, or C≡CR at the central atom should be reactive in 1,3-AC reactions.

Indeed it has been found recently that the trialkylammonium salts of aromatic and heteroaromatic dithiocarboxylic acid[91–93] interact with active anionophiles, forming the corresponding 1,3-dithioles:



R'=CO_2CH_3, CF_3.

1,3,2-Diheterophosphacyclanes Containing a Hexacoordinate Phosphorus Atom

R.A.Cherkasov and N.A.Polezhaeva

Data are presented on the methods of synthesis, structure, and physical and chemical properties of cyclic compounds of hexacoordinate phosphorus-λ^6-1,3,2-diheterophosphacyclanes, in which the phosphorus atom is incorporated in one, two, and three heterocycles containing P-O or P-N bonds. The dynamic stereochemistry and equilibrium dissociative as well as tautomeric processes involving them are described. The role of phosphorus(VI)† intermediates in the reactions of organophosphorus compounds with tricoordinate, tetracoordinate, and pentacoordinate phosphorus is analysed. The bibliography includes 140 references.

V. Cyclic compounds of hexacoordinate phosphorus as intermediates in the reactions of organophosphorus compounds 174

I. INTRODUCTION

Compounds of hexacoordinate phosphorus (phosphorates) began to be investigated vigorously only in the last decade, although the first description of substances of this type dates back to 1954 and is associated with the study of the adducts of PCl_5 with pyridine (see Dillon et al.[1,2] and the references quoted therein). Numerous inorganic "ate" complexes formed by compounds of pentacoordinate phosphorus and basic substances[3] as well as cyclic and acyclic organylhalogenophosphorates[4] are known. Cyclic phosphorates with six P–C bonds and aromatic substituents and finally λ^6-1,3,2-diheterophosphacyclanes with monocyclic, bicyclic, and tricyclic structures were later described. Individual aspects of the chemistry of compounds of hexacoordinate phosphorus have been dealt with in reviews.[5-8]

Numerous phosphorus(VI) compounds are now known and their number continues to grow, which undoubtedly indicates an appreciably greater role of these compounds in phosphorus chemistry than has been assumed hitherto. Hexacoordinate intermediates in the reactions of organophosphorus compounds containing a phosphorus atom with a lower coordination number are apparently important. Interesting data have been obtained on the steric structures of phosphorates and the equilibrium processes involving them.

Analysis of the literature data has shown that the stability of hexacoordinate phosphorus compounds increases sharply following the incorporation of the phosphorus atom in one or several rings, mainly five-membered rings. The acyclic alkoxyphosphorates known at the present time[9] are stable only in solution.

The first attempt has been made in the present review to give a systematic account of the available literature data on 1,3,2-diheterophosphoacyclanes containing a phosphorus(VI) atom entering into the composition of one, two, or three rings, mainly four- or five-membered rings, and bound to several heteroatoms (O, N). Data on the methods of synthesis, structure, physicochemical, and chemical properties of these compounds, the dynamic and equilibrium processes involving them, and the role of phosphorus(VI) compounds as intermediates in the chemical reactions of organophosphorus compounds (OPC) were used in the review.

The data on the compounds of hexacoordinate phosphorus with the 1,3,2-diheterophosphacyclane structure, summarised in the present review, supplement the available information about the reactivities of similar heterocyclic compounds containing tricoordinate,[10] tetracoordinate,[11] and pentacoordinate[12] phosphorus atoms and in our view they provide at the same time an integral picture of the chemistry of 1,3,2-diheterophosphacyclanes.

II. SYNTHESIS AND REACTIONS

Phosphorates of two types are known: those with salt (ionic) structures, in which the phosphorus atom is part of the composition of a phosphorus(VI) anion or (more rarely) a phosphorus(VI) cation, and neutral molecules, which exist in the form of dipolar ions with an anionoid phosphorus atom. A convenient analytical criterion whereby it can be demonstrated that the phosphorus atom has a coordination number of six is the marked shielding of the $^{31}P(VI)$ nucleus; it is manifested by the fact that the signals in the NMR spectra are displaced to very strong fields (between −70 and −300 p.p.m.). As already stated, the cyclisation of phosphorus(VI) compounds tends to increase their stability; the acyclic organylphosphorates $(MeO)_6P^-$ and $(EtO)_6P^-$ have been identified by ^{31}P NMR in solutions. They decompose when an attempt is made to isolate them from solution.[9]

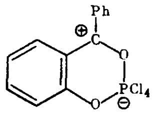
1. Monocyclic Phosphorates

The commonest method of synthesis of monocyclic phosphorates involves the reactions of phosphorus pentahalides with bifunctional nucleophiles in which one of the halogen atoms at the pentacoordinate phosphorus is substituted and

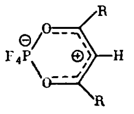
---

† [Roman numerals used in this way refer to coordination number and not to oxidation state in this review (Ed.of Translation)].

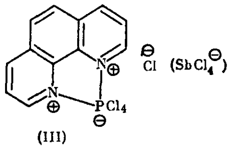
a sixth phosphorus–element bond is formed as a result of the donor–acceptor interaction of the electron-deficient P(V) atom with a second basic centre of the bidentate organic ligand. The reaction of *o*-hydroxybenzophenone with PCl_5 leads to a quantitative yield of the six-membered cyclic phosphorate (I), to which the structure of a dipolar ion has been attributed on the basis of the spectroscopic data and the high dipole moment (9.17 D):[13]



(I)



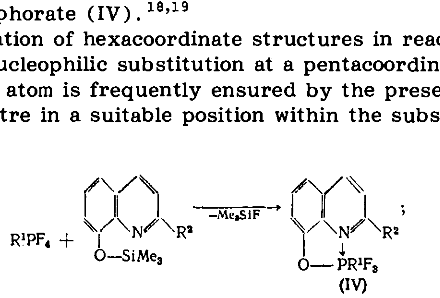
(II)



(III)

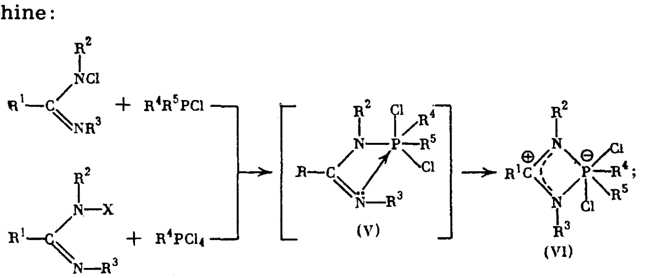
β-Dicarbonyl compounds evidently react in the enolic form, as in the formation of λ^6-1,3,2-dioxaphosphorinane (II).[14,15] Substitution by a neutral nitrogen-containing base is accompanied by the quaternisation of the donor centre [in structure(III)][16,17] and the strength of the donor–acceptor bond increases after the introduction of electron-accepting substituents at the phosphorus atom, for example, for R^1 = F in the phosphorate (IV).[18,19]

The formation of hexacoordinate structures in reactions involving nucleophilic substitution at a pentacoordinate phosphorus atom is frequently ensured by the presence of a donor centre in a suitable position within the substituting reagent:



R^1=F, Me, Et, Ph; R^2=H, Me.

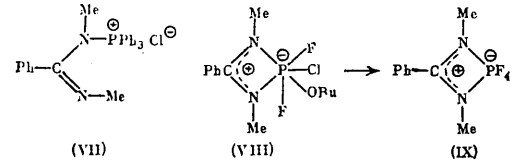
The intramolecular cyclisation of *NN'*-dialkyl-*N*-halogenophosphoranylamidines (V), formed in the reaction of *NN'*-disubstituted amidines with the chlorides of tricoordinate or pentacoordinate phosphorus made it possible to obtain a series of phosphorates (VI) containing the 1,3,2-diazaphosphetidine ring.[20–23] We may note that the reaction of *N*-chloroamidines constitutes in essence the 1,1-addition of the N–Cl fragment to the P(III) atom of the chlorophosphine:



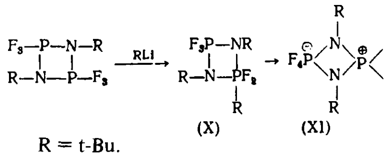
X = H, $SiMe_3$; R^1 = Ph, CCl_3, CF_3; R^2, R^3 = alkyl; R^4, R^5 = alkyl, aryl, halogen.

The reaction of *NN'*-dimethyl-*N*-trimethylsilylbenzamidine with bis(*o*-phenylenedioxy)chlorophosphorane results in the formation of tricyclic phosphorates.[20]

The stability of the four-membered monocyclic phosphorates (VI) depends greatly on the character of the substituents at the phosphorus atom and in the N–C–N triad. The benzamidinium derivative with four chlorine atoms at the phosphorus atom (VI, R^1 = Ph, R^2 = R^3 = Me, R^4 = R^5 = Cl) is the most stable. The replacement of the phenyl group at the amidinium carbon atom by the electron-accepting CCl_3 and CF_3 groups destabilises the P(VI) structure, inducing the reversible P → C migration of a chlorine atom[22] (see Section IV). An increase in the bulk of the substituent at the nitrogen atom and the introduction of two phenyl groups at the phosphorus atom lead to the same result. Three phenyl groups at the phosphorus atom stabilise only the phosphonium salt (VII),[23] while the butoxy-group induces the disproportionation of the alkoxyphosphorate (VIII) to the tetrafluoro-analogue (IX).[21]

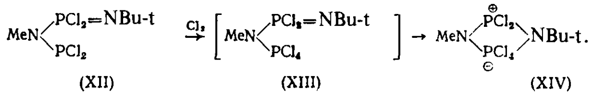


Hexacoordinate phosphorus compounds may prove to be more stable than the phosphoranes having the analogous structure. Thus the presence of bulky substituents in the diazadiphosphetidine ring induces the rearrangement of the phosphorane (X) to the corresponding phosphorate (XI):[24]

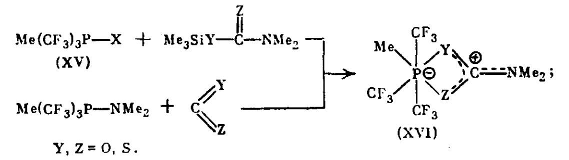


R = t-Bu.

The intramolecular addition of the nucleophilic imino-nitrogen to the P(V) atom, inducing the formation of stable phosphorates, can occur so readily that, for example, in the chlorination of the aminophosphimine (XII) the resulting phosphorane (XIII) rearranges immediately to the phosphorate (XIV):[25]



The reactions of halogenophosphoranes (XV) with silylcarbamates lead analogously to the phosphorate-carbamates (XVI) in a high yield.[26–28] The latter are also obtained when CO_2, COS, and CS_2 are inserted in the P–N bond in aminophosphoranes (XVII):

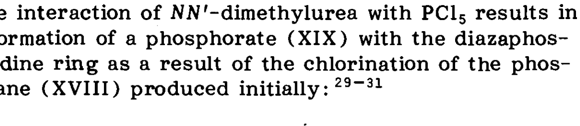


Y, Z = O, S.

The monothiocarbamates (XVI, Y = O, Z = S) are converted quantitatively into the dithio-derivatives on treatment with carbon disulphide. The resonance of the phosphorus atom in the phosphetidines (XVI) is characterised by a signal at very high field (between −251 and −298 p.p.m.).

Phosphorus(VI) compounds may be formed from phosphoranes also as a result of the addition to the electrophilic P(V) atom of "external" nucleophiles—the anions of proton-containing nucleophiles and neutral *n*-donor Lewis bases.

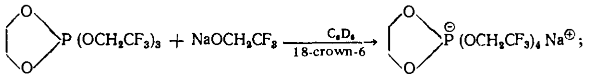
The interaction of *NN'*-dimethylurea with PCl_5 results in the formation of a phosphorate (XIX) with the diazaphosphetidine ring as a result of the chlorination of the phosphorane (XVIII) produced initially:[29-31]



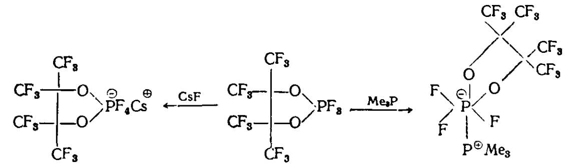
(XVIII) (XIX)

Further substitution of the chlorine atoms in compound (XIX) on treatment with dimethylurea leads to a phosphorate of the spiran type, which, however, cannot be isolated from solution.[32]

Monocyclic phosphoranes are characterised by a pronounced Lewis acidity and readily react with anions, being converted into stable phosphorates. Thus, in the presence of crown-ether, the phosphorane (XX) is converted by alkoxide into the corresponding sodium phosphorate,[33] while the perfluoropinacol trifluorophosphorane combines with both a fluoride anion and a neutral trimethylphosphine molecule, forming stable phosphorates with the characteristic chemical shifts of the P(VI) and P(IV) atoms in compound (XXI):[34,35]

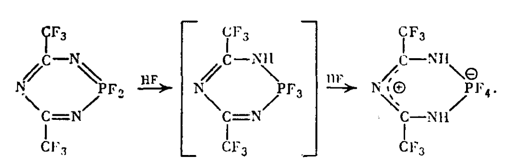


(XX) $\delta(^{31}P) = -128$ p.p.m.



$\delta(^{31}P) = -122.9$ p.p.m. (XXI) $\delta(^{31}P) = -130, +20$ p.p.m.

The formation of the six-membered monocyclic phosphorate (XXIII) as a result of the addition of hydrogen fluoride to the N–P=N triad of the cyclophosphazene (XXII) has been described:



(XXII) (XXIII)

The structure of the dipolar phosphorate (XXIII) was demonstrated by the IR, ^1H, ^{19}F, and ^{31}P NMR spectra [$\delta(^{31}P) = 162.7$ p.p.m.] and mass-spectrometrically.[36]

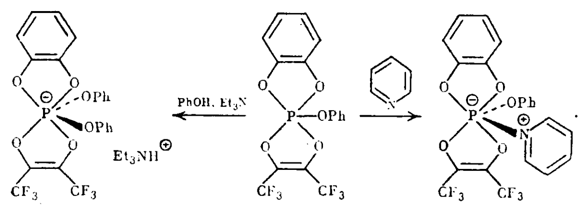
The thermal and hydrolytic stabilities of phosphorates are close to the corresponding properties of phosphoranes. Chlorine-containing phosphorates are usually very sensitive to moisture, while certain fluorine-containing compounds exhibit an appreciable hydrolytic stability.[37]

As already mentioned, the high-field position of the P(VI) signal in the ^{31}P NMR spectra, characteristic of phosphorates, can be convienently used for the identification of the latter. The values of $\delta(^{31}P)$ for monocyclic phosphorates are in the range −100–−200 p.p.m., while for acyclic P(VI) compounds the $\delta(^{31}P)$ reach −300 p.p.m.;[38,39] the phosphorus atom in fluorine-containing phosphorates usually resonates in somewhat weaker fields.[40] The shielding of the phosphorus nucleus as a rule diminishes when the P(VI) atom is incorporated in one or more five-membered rings (see Section III).

2. Bicyclic Phosphorates

The incorporation of a phosphorus atom in one or two heterocycles is known to stabilise hypervalent structures.[12] This is equally valid also for P(VI) compounds: the stability of phosphorates increases on passing from acyclic to monocyclic and bicyclic and further to tricyclic λ^6-phosphacyclanes.

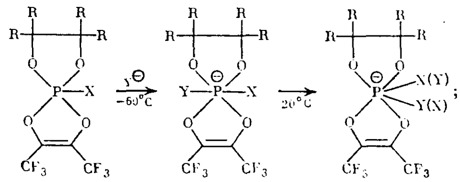
The commonest method of synthesis of bicyclic phosphorates involves the addition of ionic or neutral nucleophiles to the P(V) atom in the corresponding spirophosphoranes. The addition of the phenoxide ion or pyridine to the spirophosphorane (XXIV) leads to the spirophosphates (XXV) and (XXVI) respectively with two bidentate and two monodentate ligands:[41,42]



(XXV) (XXIV) (XXVI)

The ionic compound (XXV) is more stable than the dipolar ion (XXVI), which regenerates the initial phosphorane after prolonged heating.

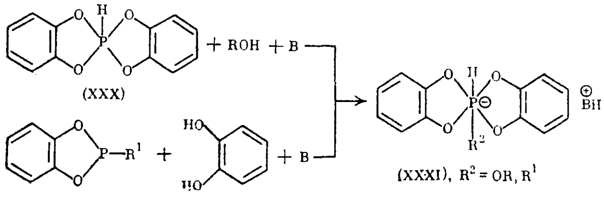
The addition of ionic nucleophiles to the phosphoranes (XXVII) results in the formation of the more stable *cis*-phosphorates (XXIX), which are the products of thermodynamically controlled reactions; under the conditions of kinetic control, the *trans*-isomers (XXVIII) arise and undergo the *trans–cis* isomerisation as the temperature is increased.[41,43-48]



(XXVII) (XXVIII) (XXIX)

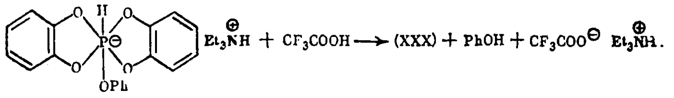
X, Y = F, OC_6H_4F-*p*.

Compounds with a P–H bond, namely hydrophosphorates, constitute an interesting group of phosphorates. They can be synthesised from the hydrophosphoranes (XXX) by treatment with alcohols in a basic medium[49-55] or by the reaction of monocyclic phosphonites with catechol under the same conditions:[49,56-60]



(XXX) (XXXI), R^2 = OR, R^1

The hydrophosphorates (XXXI, R^2 = OPh) regenerate phosphoranes in many instances on treatment with acids via a reaction which is the opposite to that of the formation reaction of the P(VI) compounds:[50]



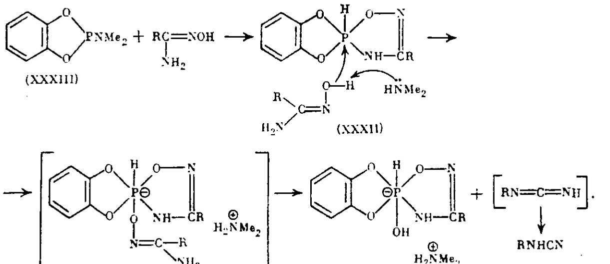
(XXXI)

Acetic acid does not induce this decomposition, i.e. the basicity of the phosphorate (XXXI) is intermediate between that of MeCOO$^-$ and CF$_3$COO$^-$.

The ease of formation of phosphoarates from spirophosphoranes and nucleophiles depends on the Lewis acidity of the P(V) atoms and increases as the cyclic substituents become more electron accepting.[54] The greatest tendency to be converted into P(VI) compounds is shown by spirophosphoranes containing 4,5-benzo-1,3,2-dioxaphospholan rings; spirophosphoranes with alkylenedioxy-substituents do not form hydrophosphorates on interaction with alcohols.[55]

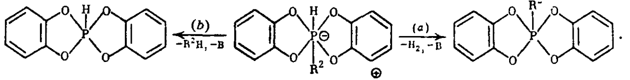
The spirophosphoranes (XXXII), which are derivatives of catechol and amidoximes, are sufficiently electrophilic to combine with the protic nucleophiles methanol, aminoalcohols, and amidoximes in non-polar solvents in the presence of bases, although the interaction with pyridine has not been observed under these conditions.[53] In polar solvents, phosphorates decompose to symmetrical phosphoranes.

The interaction of the phospholan (XXXIII) with amidoxime in solution in the benzene–ether mixture takes place in an unusual manner. Substitution of the dimethyl amino-group and subsequent reaction of the phosphorane (XXXII) with amidoxime proceed via the hydrophosphorate (XXXIV) stage, in which the N–O bond is broken. This leads to the phosphorate (XXXV), containing the P–OH and P–H groups, the first of the hydroxyphosphorates described:[53]



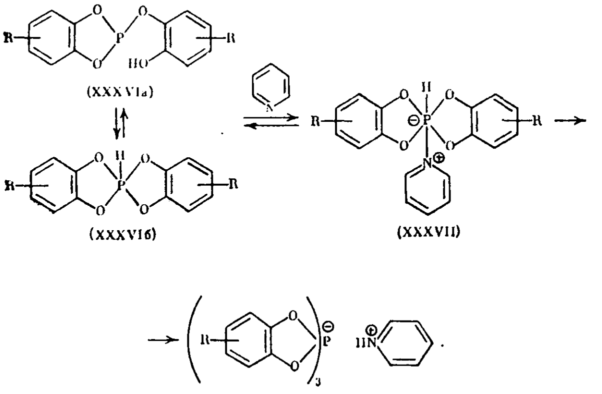
(XXXIII) (XXXII) (XXXIV)

At elevated temperatures, the hydrophosphorates (XXXI, B = Et$_3$N) decompose. The decomposition pathway depends on the nature of the exocyclic substituent R^2: for R^2 = Me, t-Bu, or Ph, hydrogen is evolved and alkyl(phenyl)spirophosphoranes are obtained (pathway *a*). The presence at the phosphorus atom of groups which can be eliminated more readily (R^2 = Ph or OMe) results in the regeneration of the amine and the hydrophosphorane (XXX) (pathway *b*):[56–60]



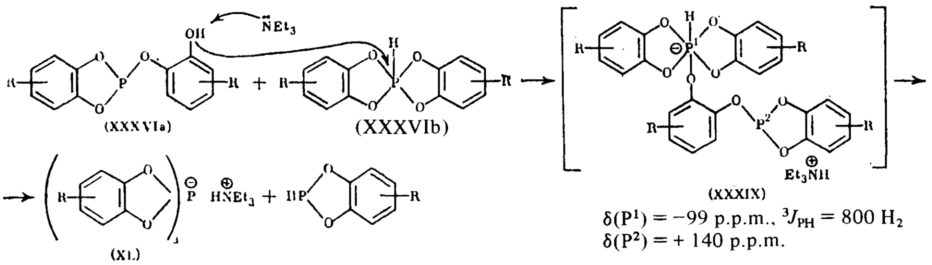
(XXX) (XXXI)

On dissolution in pyridine, the spirophosphoranes (XXXVI) interact with the solvent. The dynamics of this process has been investigated (see Section VI) and the very hygroscopic phosphorate (XXXVII) has been isolated.[42,61–63] In the course of 24 h, it is converted into the tricyclic phosphorate (XXXVIII):



(XXXVIa) (XXXVIb) (XXXVII) (XXXVIII)

In the presence of stronger bases (triethylamine, triethylenediamine, and di-isopropylamine), the reaction does not stop at the hydrophosphorate stage and a tricyclic phosphorate is formed immediately. It has been suggested[63] that stronger (harder) bases react with the tautomeric P(III) form of the hydrophosphorate (XXXVIa), which gives rise, with participation of the hydrophosphorane (XXXVIb) to the phosphite-phosphorate (XXXIX) and subsequently the phosphorate (XL):



(XXXVIa) (XXXVIb) (XXXIX) (XL)

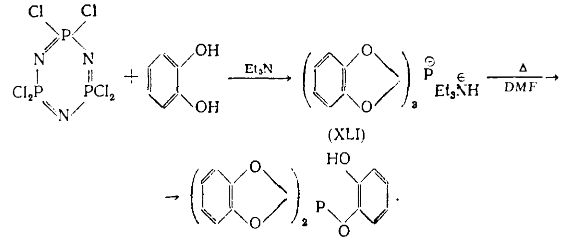
δ(P^1) = −99 p.p.m., $^3J_{PH}$ = 800 H$_2$
δ(P^2) = + 140 p.p.m.

An analogous process probably occurs also in the case of spirophosphoranes with a P–OH bond.[64]

3. Tricyclic Phosphorates

Among all the derivatives of hexacoordinate phosphorus known at the present time, tricyclic phosphorates together with halogenophosphorates constitute the most numerous group of compounds. The inclusion of the P(VI) atom in the octahedral structure of the spirotricyclophosphorate, especially one made up of three five-membered rings, increases sharply its thermodynamic stability (reduces the molecular energy). It is therefore not surprising that tricyclic phosphorates have been some of the first organic compounds with a hexacoordinate phosphorus atom to be synthesised and characterised.

The first tricyclophosphorate was obtained as a result of the unexpected and interesting reaction of hexachlorocyclotriphosphazene with catechol in the presence of triethylamine.[65–70] *o*-Aminophenol reacts analogously:

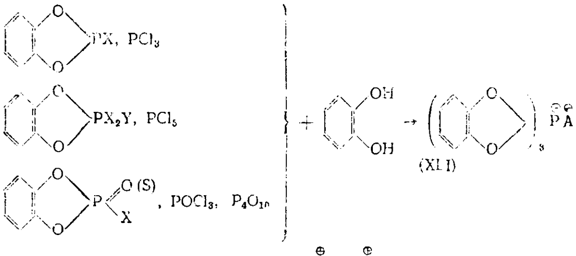


(XLI)

(XLII)

After the phosphorate (XLI) has been heated for a long time in anhydrous dimethylformamide (DMF), the phosphorate (XLII) is formed, while in the presence of moisture the product is tri(*o*-phenyl) phosphate. The latter is also obtained on hydrolysis of compound (XLI) with hot water and on acidolysis with inorganic acids.

The thermodynamic ease of formation of the tris(phenylenedioxy)phosphorate anion determines the course of many reactions of compounds of tricoordinate, tetracoordinate, and pentacoordinate phosphorus with catechol in the presence of bases[12,71–74] or with the dilithium salt of catechol:[75]



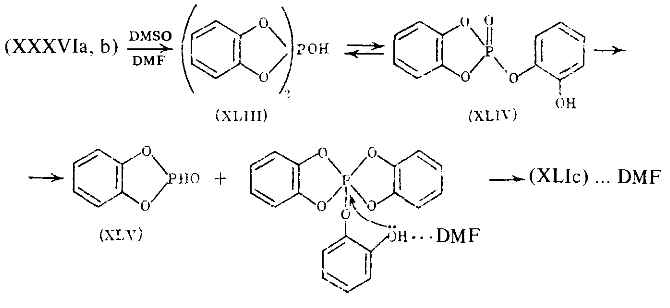
(XLI)

X, Y = halogen $\overset{\oplus}{A}$ = $Et_3\overset{\oplus}{N}H$ (a), Me_2NH_2 (b), H (c)

2,2′-Dihydroxybiphenyl reacts with PCl_5 to form a phosphorate with three seven-membered rings.[74]

The phosphorate (XLIc) is stable only in a basic medium (DMF, DMSO, amines) and apparently exists in solutions in the form of the free acid;[71] it has been suggested[64] that in weakly basic solvents this compound exists in the tautomeric P(V) form (XLII).

The tricyclophosphorate of type (XLIc) is formed as a result of the oxidation of the hydrophosphoranes (XXXVIa, b) with DMSO, sulphur, or iodine in DMF. The reaction evidently takes place via a stage involving the hydroxyphosphorane (XLIII), which interacts with its tautomeric phosphate form (XLIV), and is completed by the formation of the phosphite (XLV) and the phosphorates (XLIc) bound in a hydrogen-bonded complex with a solvent molecule:[64]

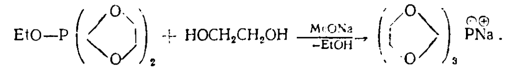


(XLIII) (XLIV)

(XLV)

Reactions involving the substitution of mobile ligands in phosphoranes by bifunctional compounds and reactions in which bidentate ligands add to tervalent phosphorus compounds have been fruitful for the purpose of the synthesis of phosphoranes.

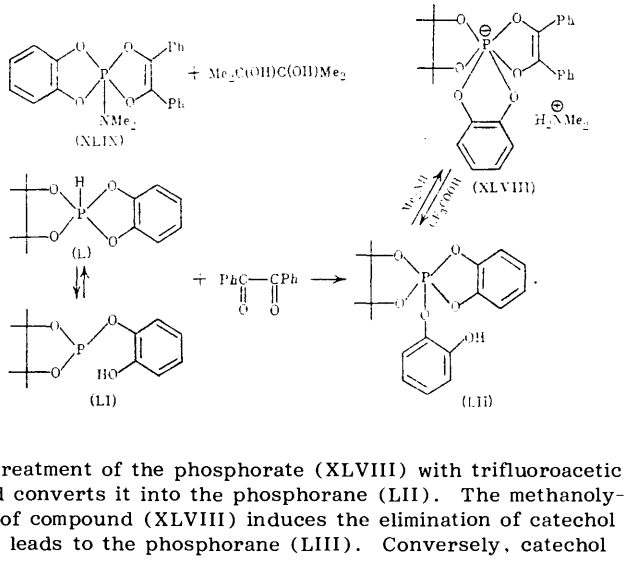
The first of these principles constituted the basis of the synthesis of the aliphatic tricyclic phosphorate (XLVII) by the reaction of ethylene glycol with the spirophosphorane (XLVI):[76]



(XLVI) (XLVII)

Compound (XLVII) does not melt before decomposition (300–310 °C). The attempts to obtain other aliphatic tricyclophosphoranes by this method were unsuccessful.

The phosphorate (XLVIII), made up of three different rings, arises analogously when the exocyclic dimethylamino-group in the spirophosphorane (XLIX) is substituted by a diol. The same λ^6-phosphacyclane (XLVIII) can be arrived at using the interaction of the hydrophosphorane (L) [which is apparently involved in the reaction in its tautomeric phosphite form (LI)] with benzil in the presence of dimethylamine:[77–82]

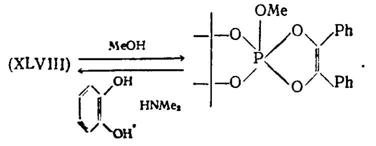


(XLIX) (XLVIII)

(L)

(LI) (LII)

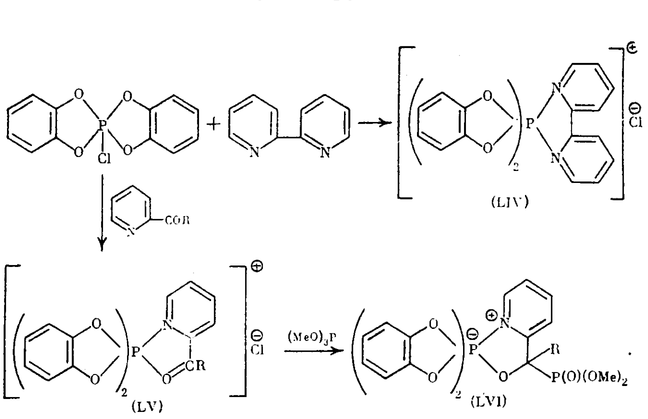
Treatment of the phosphorate (XLVIII) with trifluoroacetic acid converts it into the phosphorane (LII). The methanolysis of compound (XLVIII) induces the elimination of catechol and leads to the phosphorane (LIII). Conversely, catechol and dimethylamine readily convert the methoxyphospha(V)-cyclane (LIII) into the phosphorate (XLVIII) at room temperature:[78,81]



(LIII)

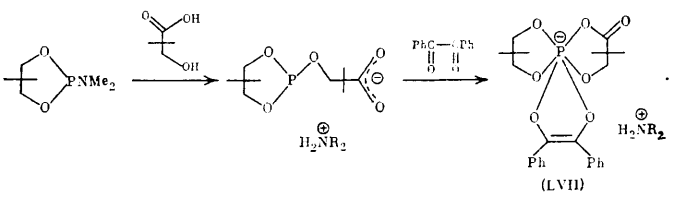
These reactions reflect the comparative ease of the interconversions P(V) ⇌ P(VI) in the presence of acids and bases (see Section IV).

Substitution with subsequent intramolecular cyclisation via the formation of the N → P donor–acceptor bond made it possible to synthesise cationic compounds with hexacoordinate phosphorus from bipyridyl and pyridyl ketone:[43,83,84]



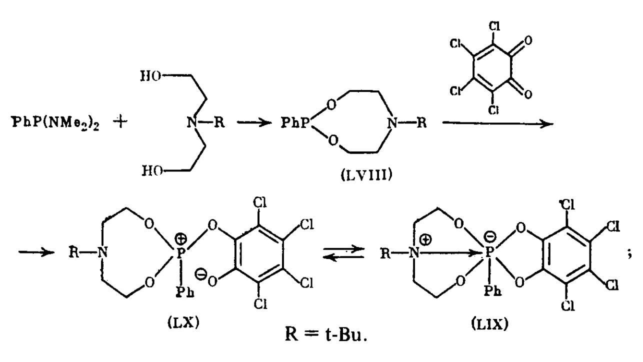
The anion exchange of the chlorine in the phosphorate (LIV) makes it possible to obtain other P(VI) compounds, including an exotic molecule in which the hexacoordinate phosphorus is present in both the anionic and cationic components.[43] The phosphorate (LV) enters into the Arbuzov reaction, forming the phosphonato-phosphorate (LVI) in the form of two spectroscopically different diastereoisomers[84] (see below).

The second principle governing the increase of the coordination number of the phosphorus atom to six with formation of tricyclic phosphorates involves the addition of bifunctional nucleophiles to the phosphorus atom in cyclic phosphites having in the exocyclic substituent a group capable of adding to the phosphorus centre.[85] Thus the reactions of cyclic phosphoramidites with hydroxy acids and further with α-diketones lead to the tricyclophosphorates (LVII):



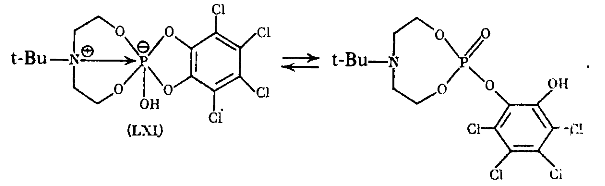
(LVII)

The phosphite (LI) is converted analogously into the phosphorate (XLVIII), while 1,3,6,2-dioxazaphosphocane (LVIII), obtained from a phosphonamidite and *N*-t-butyldiethanolamine, reacts with chloranil to form the phosphorate (LIX), in which the coordination number of phosphorus, equal to six, is determined by the formation of the transannular N → P bond:[86]



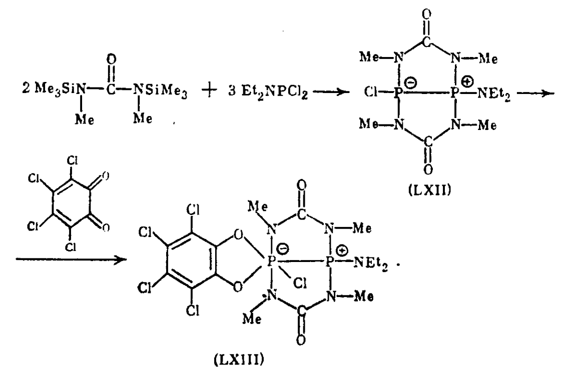
The authors[86] suggest that the equilibrium (LX) ⇌ (LIX) occurs in the system, as shown by the observation of two signals in the ^{31}P NMR spectra—at -14.5 p.p.m. for (LX) and at -96.2 p.p.m. for (LIX) in proportions of 2 : 3.

The interaction of *N*-t-butyldiethanolamine with the amide or chloride of phenylenephosphorous acid leads only to a phosphorate of type (LXI).[87] An equilibrium mixture of the phosphorate (LXI) with the P–OH fragment and the phosphate has been obtained in the reaction of phosphorous acid containing the 1,3,6,2-dioxazaphosphocane ring with tetrachloro-*o*-benzoquinone:[86]



(LXI)

In order to synthesise tricyclic phosphorates, dicarbonyl compounds have been made to interact not only with cyclic phosphites but also with cyclic phosphonium compounds. Thus the first phosphorate (LXIII) with a P–P bond has been obtained by adding chloranil to the anionoid phosphorus atom in the condensed bicyclic structure (LXII):

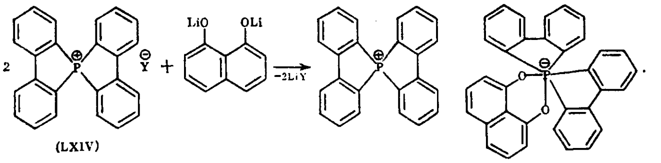


(LXII)

(LXIII)

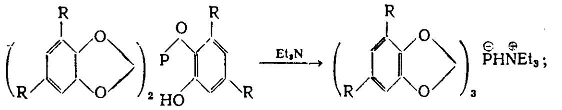
The chlorine atom at the phosphorus atom can be exchanged for fluorine by treatment with arsenic trifluoride (but not sodium fluoride).[88]

The spirocyclic phosphonium salt (LXIV) interacts with salts of catechol or naphthalene-1,8-diol, forming a phosphorate in which the P(VI) atom is part of two phospholan rings and one 1,3,2-dioxaphosphorinane ring:[75]



(LXIV)

The phosphorane (LXV) has been obtained by the reaction of 3,5-di(t-butyl)-o-quinone with white phosphorus in the presence of 3,5-di(butyl)catechol as the reductant.[89] The addition of triethylamine to compound (LXV) induces the precipitation of the phosphorate (LXVI), which is also formed in the reaction of phospha(III)adamantane with the same o-quinone:[90]



(LXV) (LXVI)

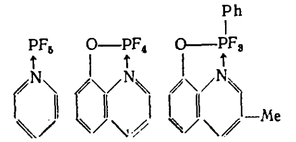
R=C(Me)$_3$.

The thermolysis of the dimer $(MeNPF_3)_2$, which results in the formation of complex polyhedral structures incorporating hexacoordinate phosphorus atoms, has been described.[91]

III. MOLECULAR STRUCTURE AND DYNAMIC STEREOCHEMISTRY

X-Ray diffraction analysis of acyclic,[92–94] monocyclic,[15,18,19,26–28,30,35] spirobicyclic,[45] and spirotricyclic[44,70] hexacoordinate phosphorus compounds made it possible to establish unambiguously their tetragonal-bipyramidal structure with a greater or smaller distortion of the octahedral skeleton, depending on the nature of the ligand bound to the central P(VI) atom.

The length of the N–P bond in the nitrogen-containing P(VI) complexes, formed via the intermolecular [as in compound (LXVII)] or intramolecular [as in compounds (LXVIII) and (IV)] binding of the nitrogen atom to phosphorus, is greater than the length of the usual single nitrogen–phosphorus bond (1.769 Å).[18,19,94]



(LXVII) (LXVIII) (IV)

An appreciable weakening of the N → P bond has been observed in the series of neutral P(VI) complexes (IV), (LXVII), and (LXVIII): 1.898 Å for (LXVII), 1.911 Å for (LXVIII), and 1.980 Å for (IV), owing to the decrease of the Lewis acidities of the groups in the sequence $PF_5 > POF_4 > POF_3Ph$. It is striking that the influence of other ligands is also reflected in the length of the P–F bond. Thus the length of the P–F bond in compound (LXVIII) diminishes with decrease of the electronegativity of the *trans*-ligand in the sequence F–P(F) > F–P(←N) > F–P(O).[18]

A significant distortion of the regular octahedral geometry, expressed by the deviation of the PF^1, PF^2, and PO bonds from the P–C bond, has been observed in the molecular structure (IV). This may be a consequence of the repulsion of the coplanar P–O and P–F bonds from the P–C bond, which is characterised by a high electron density in the latter.[19] A similar deviation of the fluorine atoms from the nitrogen atom has been observed in the complex (LXVII).[94]

An increase in the length of the phosphorus–nitrogen bonds (1.91 and 1.85 Å) compared with the single bond has been found also in the four-membered ring of the zwitterionic complex (XIX).[30] On the other hand, the C–N bonds are much shorter (1.34 and 1.19 Å) than the usual bond (1.48 Å) and this suggests the delocalisation of the positive charge in the N–C–N triad and the partial double bond character of the C–N bonds. One of the causes of the formation of the "long" P–N bonds in compound (XIX) may be the angular strain in the four-membered phosphorus-containing heterocycle.

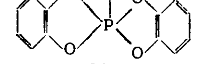
For the same reason, the P–O bonds in the complexes (XVI) are appreciably longer (1.82 and 1.89 Å) compared with the phosphorate (XLIa).[26,27] The electron density in these compounds is also delocalised in the carbamate unit, which is indicated by the smaller lengths of the C–O bonds (1.29 and 1.30 Å) compared with the usual bond (1.43 Å) and by the significant shortening of the C–N bond involving the bridgehead carbon atom (1.33 Å); the terminal C–N bonds are considerably longer (1.48 and 1.49 Å). The small difference between the lengths of the P–O bonds is associated with the *trans*-influence of the Me and CF_3 groups. The P–O bond in the *trans*-position with respect to the relatively small electron-accepting trifluoromethyl substituent is somewhat shorter than the O–P(Me) bond.

The fluorophosphorates $F_{4-n}(CF_3)_nPO_2CNMe_2$ have an analogous steric structure. The trifluorophosphorate ($n = 1$) has been isolated in the form of two structural isomers with "equatorial" and "axial" CF_3 groups. One isomer has been observed for each of the compounds with $n = 2$ and $n = 3$, X-ray diffraction of the monofluoroderivatives demonstrating the "equatorial" disposition of the fluorine atom; the carbamate ring, the fluorine and phosphorus atoms, and the carbon atom of one of the CF_3 groups are coplanar. The length of the P–O(F-*cis*) bond (1.832 Å) exceeds somewhat the length of the other bond, namely P–O(F-*trans*) (1.788 Å).[28]

The difference between the lengths of the P–O bonds (1.706 and 1.723 Å) in the five-membered phenylenedioxy-rings of the *tris*(*o*-phenylenedioxy)phosphorate anion (XLIa) reflects some distortion of the octahedral structure of the phosphorate. The endocyclic OPO angles (91.4°) are close to the right angle, indicating the absence of angular strain.[70]

At the same time the increase of the length of the endocyclic ether bonds compared with the exocyclic bonds is evidently in general characteristic of small rings incorporating a phosphorus atom and heteroatoms with an unshared electron pair.[45] Thus the exocyclic P–O bonds in the phosphorate (XXV) are appreciably shorter (1.656 Å) than the endocyclic bonds (1.711 Å). According to the authors,[45] this may indicate a greater degree of $(p-d)_\pi$ binding of the unshared electron pairs of the exocyclic oxygen atoms to the phosphorus atom compared with the endocyclic atoms. This effect, which has also been established in phosphorane molecules, is called "steric inhibition of $(p-d)_\pi$ bonding".[45] It has been suggested[45] that this may entail a decrease of the shielding of the phosphorus nuclei by the electrons, which is reflected in a shift of the ^{31}P signal in the NMR spectra towards weaker magnetic fields, observed when one or several five-membered rings are introduced into hydroxyphosphorane molecules:

$(PhO)_5P$



$\delta(^{31}P) = -88.7$ p.p.m. -30 p.p.m.

In phosphorate molecules a tendency has also been observed towards decreased shielding of phosphorus on passing from acyclic [$\delta(^{31}P) = -142$ p.p.m. for $(MeO)_6P^-K^+$ [9] and -147 p.p.m. for $(EtO)_6P^-K^+$ [9]] to monocyclic [-128 p.p.m. for (XXI) [33]], bicyclic [-109.5 p.p.m. for (XXV) [41] and -98 p.p.m. for (XXXI, R^2 = OPh) [50]], and tricyclic [-82 p.p.m. for (XLI, A = Na) [75] and -89 p.p.m. for (XLVII) [70]] phosphorates.

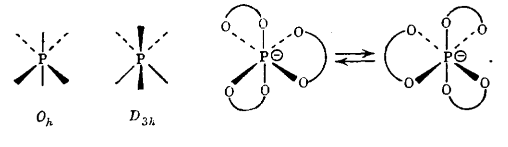
A distorted octahedral configuration has also been found in the cationic bipyridyl P(VI) complex (LIV).[44] The unusual features of its structure can be clearly revealed by comparing it with the structure of the phosphorate (XLI) and the hypothetical spirocyclic phosphonium cation (LXIX), from which compounds (XLI) and (LIV) can be produced formally by the addition of the bidentate phenylenedioxy- and bipyridyl ligands respectively:[44]

(LXIX)

The P–O bonds in the cation (LIV) are shorter by 0.045 Å and the endocyclic OPO angles are greater by 1.6° than in compound (XLI). The OPO axis, which is almost straight in compound (XLI), bends in compound (LIV) towards the bipyridyl ligand (172.7°). The imaginary addition of the phenylenedioxy-dianion to the tetrahedral phosphorus in the cation (LXIX) yields a P(VI) configuration which is close to the octahedral P(VI) configuration in compound (XLI). An analogous change in the geometry of the molecular skeleton should also occur in the transition (LXIX) → (LIV), but, since the bipyridyl ligand is a weaker electron donor than the catechol dianion, the features of the "tetrahedral" configuration are retained in the structure (LIV).[44]

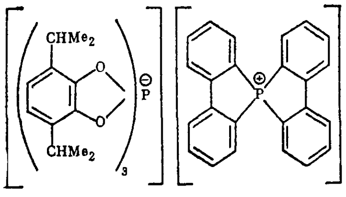
X-Ray diffraction data for the only cyclic six-membered λ^6-1,3,2-diheterophosphorinane investigated by this method, namely the acetylacetonate complex (II), indicate only small changes in the length of the P–O bond compared with those in compound (XLI), i.e. the P–O bonds in the dioxaphosphor(VI)inane ring are also of the σ-type. The ring has the boat conformation with the phosphorus and C(5) atoms deviating from the plane of the remaining atoms.[19]

Thus an octahedral O_h geometry is characteristic of phosphorate structures, as for many other molecules incorporating elements with a coordination number of six.[95] Recent calculations for the hypothetical PH_6^- molecule have shown[96] that this geometry is more stable than the alternative prismatic geometry with the D_{3h} symmetry:

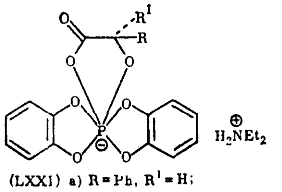


(1)

The tris-chelate hexacoordinate structures, including phosphorate anions, are chiral and exhibit the enantiomeric equilibrium (1) in solutions. The diastereotopic nature of the methyl groups in the isopropyl groups of compound (LXX) (two doublets with δ = 0.86 and 1.03 p.p.m., $^3J_{hh}$ = 7 Hz) confirms this postulate.[97] The study of the ^1H and ^{31}P spectra of the phosphorates (LXXI) led to an analogous conclusion:[98]



(LXX)



(LXXI) a) R = Ph, R^1 = H;
b) R = R^1 = Me.

The phosphorus atom in compound (LXXIa) gives rise to two signals in the region of -90 p.p.m. and the difference between the chemical shifts is 0.5 p.p.m. The proton of the aliphatic ligand resonates in the form of two doublets with $\delta(A)$ = 5.33 p.p.m. and $\delta(B)$ = 5.19 p.p.m. At the instant of the synthesis of compound (LXXIa) at room temperature, the isomer ratio (B) : (A) = 25 : 75, varying with time to 44 : 56. Coalescence of the doublet is observed at 120 °C.

The study of the kinetics of the epimerisation of the optically active P(VI) compounds by the polarimetric and NMR method made it possible to determine the free energies of activation for the unimolecular epimerisation process $\Delta G^\# = 20.5$ kcal mol^{-1} for (LXXIa) and 21.7 kcal mol^{-1} for (LXXIb), whose rate increases with increase of the concentration of the test substances.[98,99] The epimerisation of phosphorates is characterised by low activation entropies and, as noted for phosphorates of type (LXXI), is accelerated in the presence of acids.[100]

Two mechanisms of the enantiomeric isomerisation (and in general of polytopic processes) of octahedral structures has been discussed: the regular mechanism unaccompanied by the dissociation of the bond between the central atom and the ligand and the irregular mechanism which takes place with cleavage of the element–ligand bond. In the former case the ligand isomerisation process proceeds in accordance with the trigonal twist mechanism via a transition state having the pyramidal D_{3h} structure,[96,101] while in the second case the process proceeds via intermediates with a pentcoordinate central atom.

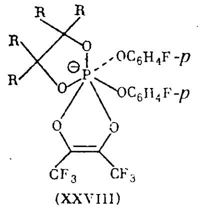
Calculation of the barriers to the topomerisation of simple molecules[95,96] demonstrated that the regular mechanism is energetically unfavourable. Thus the energy barriers to the trigonal twist E amount to -66 kcal mol^{-1} for PF_6^-, -56 kcal mol^{-1} for PCl_6^-, and -41 kcal mol^{-1} for PH_6^-, which indicates the stereochemical rigidity of the octahedral O_h structures for atoms of non-transition elements. It is difficult to say to what extent these calculated data are applicable to complex real systems containing oxygen and nitrogen atoms as well as chelated ligands, but one should note that the replacement of hydrogen atoms by more electronegative atoms or groups increases the activation barrier.[101]

The experimental results of the study of the kinetics of the epimerisation of phosphorates presented above led the authors[98–100] to the conclusion that the isomerisation has the irregular mechanism. The process proceeds with dissociation of one of the ether bonds in the aliphatic five-membered ring, pseudorotation in the phosphorane intermediate, and subsequent recyclisation leading to the formation of the second enantiomer. The free energies of epimerisation found fall within the range characteristic of ligand reorganisation processes involving phosphoranes (14–22 kcal mol^{-1}).[96,102] The low activation entropies agree with this conclusion and the concentration effects found are associated with the variation of the ionic strength of the solution, which influences the dissociation of the bonds and the charge separation.[98]

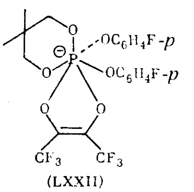
An analogous epimerisation mechanism has been proposed for neutral P(VI) chelates (LVI): the $\Delta G^{\#}$ for these processes fall within the range indicated above: 18.1 kcal mol^{-1} for (LVI, R = C_5H_4N) and 17.3 kcal mol^{-1} for (LVI, R = Ph).[47]

At the same time the irregular permutation process has been postulated for the *cis–trans* isomerisation of the phosphorates (XXVIII), investigated by ^{19}F NMR.[47] At room temperature these compounds are characterised by the energetically favourable *cis*-disposition of the aryloxy-ligands. However, at -101 °C the CF_3 groups in the phosphorate (XXVIIIb, R = Me) give rise to signals at -0.49 and -0.75 p.p.m., while p-FC_6H_4O generates signals at -60.2 and -61.7 p.p.m. The CF_3 signals coalesce reversibly at -77 °C ($\Delta G^{\#}$ = 9.7 kcal mol^{-1}), whereas for p-FC_6H_4O coalescence is observed at 34 °C ($\Delta G^{\#}$ = 14.5 kcal mol^{-1}). For the analogous *cis*-anion (XXVIIa, R = H), the free energy of activation determined from the coalescence of the signals of the trifluoromethyl group, is 17.2 kcal mol^{-1} (T_c = 80 °C). In the case of the 1,3,2-dioxaphosphor(VI)inane anion (LXXII), the signals of the CF_3 groups coalesce at 3 °C ($\Delta G^{\#}$ = 13.1 kcal mol^{-1}), whereas the signals of the p-FC_6H_4O groups remain separated up to 60 °C ($\Delta G^{\#}$ > 16 kcal mol^{-1}).

Thus the energy barriers to "equilibration" in the phosphorates (XXVIIIa, b) and (LXXII) are different for different magnetically non-equivalent groups—CF_3 and p-FC_6H_4O. This can be explained from the standpoint of the formation of different trigonally-prismatic intermediates in the above processes:

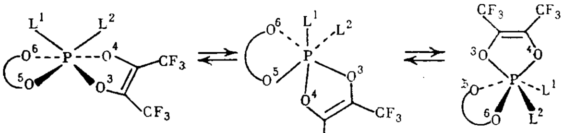


(XXVIII)
R = H (a); Me (b)



(LXXII)

Scheme 1

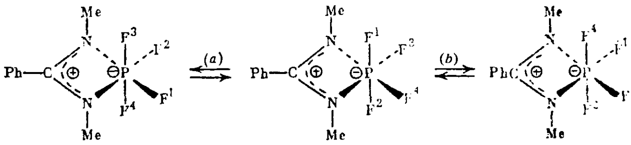


(LXXIV) (LXXIII) (LXXV)

In the structure (LXXIII, L = p-FC_6H_4O) the 60° clockwise rotation of the (2,4,3) trio relative to the (1,5,6) trio leads to the trigonal prism (LXXIV) in which the CF_3 groups are equivalent and there is no p-FC_6H_4O (Scheme 1). On the other hand, the 60° anticlockwise rotation of the (1,2,3) trio relative to the (4,5,6) trio generates the trigonal prism (LXXV) with the equivalent fluorophenoxy-groups and non-equivalent trifluoromethyl groups. Other possibilities involving a trigonal twist (there are eight in all—not shown in the Scheme) have an analogous effect on both types of F atoms. The observed experimental results are believed[47] to agree well with the regular permutation polymerisation process. The retention of the values of J_{PF} for structures (XXVIII) and (LXXII) confirms the intramolecular character of this topomerisation.

The permutation isomerisation of *NN*-dimethylbenzamidinium tetrafluorophosphorate (LXXVI), as a result of which the mutually non-equivalent F(1,2) and F(3,4) atoms change places in the tetragonal bipyramid according to ^{19}F NMR data, is also intramolecular.[103] This is indicated by the retention of the $^{31}P-^{19}F$ and $^{31}P-^{1}H$ spin–spin coupling and also by the absence of an influence of the concentration of the test substance in solution and by the nature of the solvent on the rate of isomerisation

Scheme 2



(LXXVIa) (LXXVI) (LXXVIb)

Two alternative isomerisation mechanisms were discussed in this instance also: irregular and regular. The irregular mechanism can in its turn include the dissociation of the phosphorus–nitrogen bond, which leads to structure (LXXVIa) (Scheme 2), in which all four fluorine atoms change places (pathway *a*) or the dissociation of the P–F bond with migration of, for example, the F^2 atom to the cationoid carbon. In this case (pathway *b*) the positions of three F atoms change and structure (LXXVIb) is formed (the intermediate structures are not shown in Scheme 2). For the regular mechanism, it is also possible to put forward several versions of the trigonal twist, but the exchange of all fluorine atoms is preferred to the greatest extent [pathway *a* leading to (LXXVIa)].

The fairly high free energy of activation for the permutation isomerisation of compound (LXXVI) (23.6 kcal mol^{-1} at 170 °C) exceeds the values characteristic of the polytopic rearrangements of phosphorates. In view of this and also the independence of the rate of isomerisation of the nature of the solvent the authors are inclined[103] to select the regular mechanism via pathway *a* (LXXVI) → (LXXVIa), although the available data are as yet insufficient for an unambiguous conclusion.

Thus one may decide that, on the basis of what are so far still few instances of the study of polytopic rearrangements of P(VI) compounds, it is impossible to arrive at reliable conclusions about their mechanism. However, one cannot rule out the possibility that the character of the ligand reorganisation in phospha(VI)cyclanes can depend greatly on their structure—the nature of the atoms attached to phosphorus and the number, size, and compositions of the phosphorus-containing heterocycles. One can only note that the irregular mechanism is believed to be preferred for spirotricyclic phosphorates, while the regular mechanism is preferred for spirobicyclic and monocyclic phosphorates.

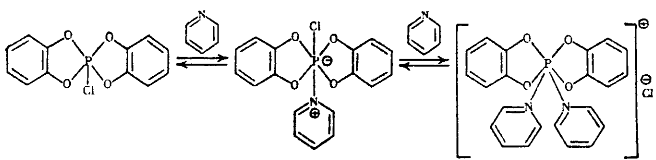
IV. P(VI) ⇌ P(V) EQUILIBRIUM PROCESSES

The capacity for the rupture of one of the P(VI)–ligand bonds, which is responsible for the possibility of the intramolecular or intermolecular P(V) ⇌ P(VI) equilibrium processes, is characteristic of certain hexacoordinate phosphorus compounds.

When the tautomeric mixture (XXXVIa, b) interacts with pyridine, a successive decrease of the intensity of the low-field NMR signal of the P(III) atom in the form (XXXVIa) and an increase of the peak intensity in strong fields, reflecting the content of the P(V) form (XXXVIb) and the P(VI) form (XXXVII), are observed as the mole fraction of the base increases and the temperature is reduced. An appreciable excess of the base at room temperature shifts the resonance peak to the "phosphorate" region (-93 p.p.m. for 8 moles of pyridine).[42,61,62]

The position of the P(III) ⇌ P(V) ⇌ P(VI) equilibrium is significantly affected also by the basicity of the amine. The weak base diphenylamine does not induce appreciable changes in the ^{31}P NMR spectrum, while in the presence of tertiary and secondary aliphatic amines the signals due to the P(III) and P(V) forms disappear and high-field doublets appear at −110 p.p.m. (J_{PH} = 800 Hz).[63]

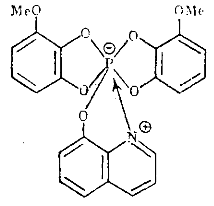
The addition of pyridine to the chlorophosphorane (LXXVII) is also accompanied by a shift of the (LXXVII) signal (−9.5 p.p.m.) to a strong field (−84.5 p.p.m.):



(LXXVII) (LXXVIII) (LXXIX)

It has been suggested[43] that the reversible addition of the base molecule [(LXXVII) ⇌ (LXXVIII)] takes place without a significant reorganisation of the (LXXVII) molecular skeleton and requires only a low activation barrier to be overcome. This is responsible for the lability of the above equilibrium and for this reason the average signal of both forms, (LXXVII) and (LXXVIII), is observed. However, after the addition of even the first portions of pyridine, the (LXXIX) signal is observed at −100 p.p.m., together with the −84.5 p.p.m. peak, its intensity increasing with increase of the mole fraction of pyridine on reaching a maximum in the presence of a twofold excess of the base. The (LXXVIII) → (LXXIX) transition represents a substitution reaction and requires a higher activation barrier to be overcome. In the presence of an excess of pyridine the cationic P(VI) compound (LXXIX) crystallises quantitatively.

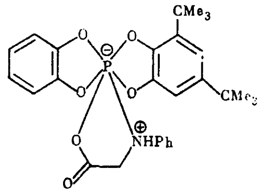
The capacity of phosphoranes to be converted into phosphorate structures is manifested most distinctly in the formation of the intramolecular P–N bond. Compound (LXXX) exist in the P(VI) form even at room temperature [δ(^{31}P) = 78 p.p.m.].[62]



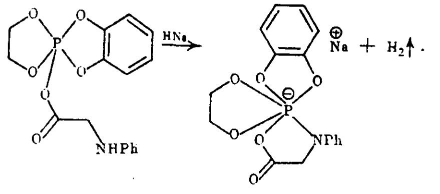
(LXXX)

The study of factors determining the capacity for intramolecular N → P complex formation in systems of type (LXXX) has demonstrated a strong influence of the nature of the ligands on the tendency towards the formation of phosphorates. The electron-accepting properties of the substituents at the phosphorus atom play a decisive role in this connection. Thus, when one fluorine atom is replaced by an alkyl group in the molecule of compound (IV), the N–P bond is not formed and the difluoro-derivative exists exclusively in the form of the difluorophosphorane, while tri- and tetrafluoro-analogues exist only in the P(VI) form.[18]

Two arylenedioxy-substituents have a strong positive influence on the phosphorus atom, so that compound (LXXXI) is characterised by a high-field signal [δ(^{31}P) = 89 p.p.m.]. The introduction of the aliphatic ethylenedioxy-group instead of the phenylenedioxy-ligand results in the existence of only the P(V) form—the phosphorus atom in the structure (LXXXII) is pentacoordinated. However, when compound (LXXXII) is acted upon by sodium hydride, it is converted into the phosphorate (LXXXIII).

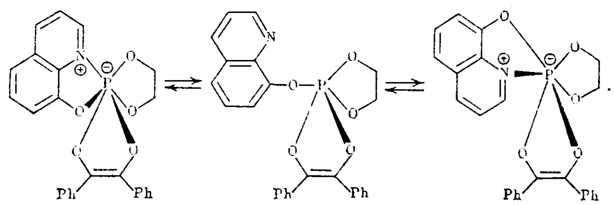


(LXXXI)



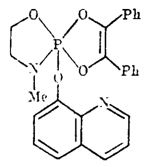
(LXXXII) δ(^{31}P) = −28 p.p.m. (LXXXIII) δ(^{31}P) = −83 p.p.m.

The high-field signal can reflect the P(V) ⇌ P(VI) equilibrium, which is as a rule established rapidly on the NMR time scale and for this reason both forms are manifested by a single average signal, whose increasingly upfield shift implies an increase in the content of the P(VI) compound in the equilibrium mixture. Thus the resonance peak for compound (LXXXIV) in the region of −85 p.p.m., recorded at 20 °C, is observed in weak fields (−75 p.p.m.) at 150 °C and, conversely, on reducing the temperature to −70 °C, the signal undergoes an upfield shift to −88.7 p.p.m., while at −90 °C an additional resonance line appears at −90.6 p.p.m. It has been suggested[85] that a decrease of temperature shifts the equilibrium towards the P(VI) isomer, which exists in the two diastereoisomeric forms (LXXXIVa) and (LXXXIVb), with corresponding doubling of the signal at −90 °C.

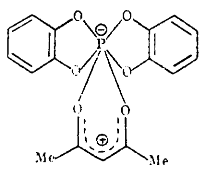


(LXXXIVa) (LXXXIV) (LXXXIVb)

It is striking that replacement of the endocyclic oxygen atom in the ethylenedioxy-fragment of compound (LXXXIV) by the more electron-donating NMe group lowers the Lewis acidity of the phosphorus atom and the oxazaphospha(VI)-cyclane (LXXXV) is a phosphorane [δ(^{31}P) = −43.7 p.p.m.]



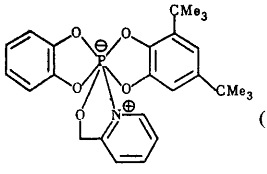
(LXXXV)



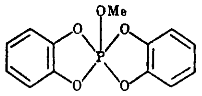
(LXXXVI)

Comparison of the structures of compounds (LXXXII) and (LXXXIV) also indicates the importance of the effects of electron delocalisation in the stabilisation of hexacoordinate structures. The π-electron system of the hydroxyquinoline ligand, which promotes the delocalisation of electron density, favours the P(VI) form more than does the aliphatic structure of *N*-phenylglycine. The relative instability of the P(VI) acetylacetonate compound (LXXXVI) is explained by the fact that the delocalisation of electron density is restricted to the region within the non-polar 1,3,2-dioxaphospholan ring.[85]

The influence of the entropy factor on the position of the P(V) $\rightleftharpoons$ P(VI) equilibrium, which is more significant for intermolecular complex formation ($\Delta S_0 = -30$ e.u.) than for intramolecular complex formation (−10 e.u.), has been noted.[85] In particular, as a result of this complex formation is not observed in the pyridine–phosphorane (LXXXVIII) system if compound (LXXXVII) exists mainly in the P(VI) form.



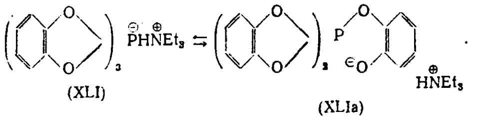
(LXXXVII) $\delta(^{31}P) = -86$ p.p.m.



(LXXXVIII) $\delta(^{31}P) = -26$ p.p.m. (pyridine)

Finally, mention must be made of the role of steric effects of the substituents in the ligand. Thus the introduction of a methyl substituent in the 2-position in the hydroxyquinoline fragment in compound (LXXX) shifts the equilibrium towards the P(V) form, which has been explained by the repulsion of the methyl group and one of the oxygen atoms of the benzodioxaphospholan rings. This hinders the closure of the oxazaphospholan ring (the formation of an N → P bond).[85]

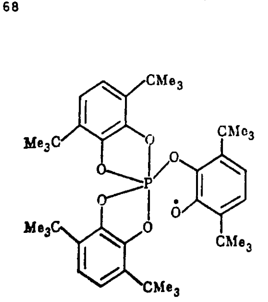
It has been suggested that the P(V) $\rightleftharpoons$ P(VI) equilibrium obtains also in the tri(phenylenedioxy)phosphorate anion (XLI) and is displaced towards the phosphorane (XLIa) in solution and towards the phosphorate in the crystalline phase:[66]



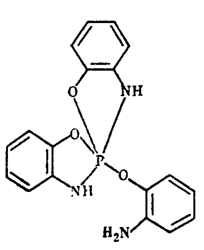
(XLI) (XLIa)

A sextuply degenerate rearrangement with "random wandering" of the charge over the aromatic ligands obtains in this instance.[95,104] However, the rate of such "random wandering" is low on the NMR time scale, so that the single average chemical shift due to the P(V) and P(VI) nuclei as well as the protons of the aromatic ring is observed in the spectra.

Such intramolecular degenerate tautomerism, associated with the "random wandering" of the free valence over the aromatic fragments, has been observed for the stable radicals having the octahedral P(VI) structures (LXXXIX).[104] On the other hand, the nitrogen compound (XC), having a analogous structure, exists in the phosphorane form, although the authors do not reject the possibility of formation of the corresponding phosphorates in the crystalline state.[68]



(LXXXIX)

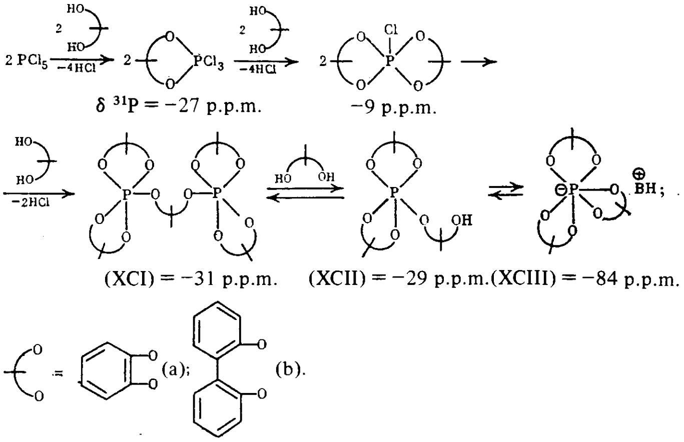


(XC) $\delta(^{31}P) = -46.3$ p.p.m.

It has been established in many instances that the conjugate acid (XCIIa) of the anion (XCIa) and its analogues are intermediates in the synthesis of phosphorates from the corresponding phosphoranes and diols, usually catechol (see Section II). The transition (XCII) → phosphorate (XCIII) is a prototropic process associated with the intermolecular proton transfer to an "external" base, as in ring closure in hydroxyalkyl (aryl) phosphates.[12]

The study of the interaction of PCl_5 with catechol and 2,2′-dihydroxybiphenyl established the occurrence of the stepwise substitution of the chlorine atoms including the prototropic equilibrium P(V) $\rightleftharpoons$ P(VI)[74] (Scheme 3)

Scheme 3



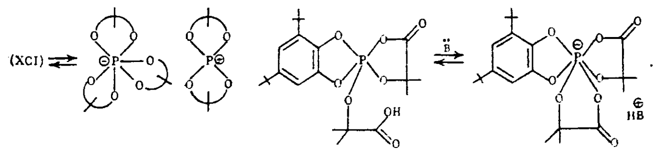
δ ^{31}P = −27 p.p.m. −9 p.p.m.

(XCI) = −31 p.p.m. (XCII) = −29 p.p.m.(XCIII) = −84 p.p.m.

(a); (b).

When the PCl_5 : catechol ratio is 1 : 2.5, the deposition of a crystalline deposit of compound (XCI) is observed. The latter is redissolved by an excess of catechol. The existence of the equilibrium (XCI) $\rightleftharpoons$ (XCII) (the ratio of the compounds involved was 8 : 2 in benzene) has been established by NMR. The addition of DMF to this mixture induces a gradual shift of the signal of compound (XCII) (−29 p.p.m.) to the region of −84 p.p.m. of compound (XCIII) and a decrease of intensity followed by the disappearance of the −31 p.p.m. signal of the compound (XCI). This corresponds to the process (XCI) $\rightleftharpoons$ (XCII) $\rightleftharpoons$ (XCIII), in which the equilibrium between the last two compounds is attained rapidly on the NMR time scale.

Koenig et al.[74] also did not rule out the existence in solutions of an equilibrium between compound (XCI) and the ion pair (XCIa), which has been confirmed by the ebullioscopic determination of the molecular weight of this compound:



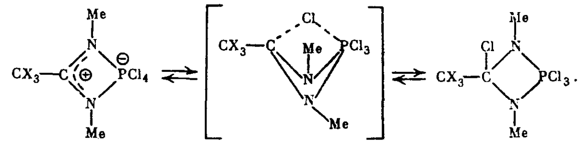
(XCIa) (XCIV) (XCV)

The conversion of the ω-hydroxyalkylphosphorane into a phosphorate has been observed in systems constructed with the aid of hydroxyacid ligands. In toluene the equilibrium (XCIV) $\rightleftharpoons$ (XCV) is fully displaced towards the phosphorane (XCIV), while in DMF and DMSO it is displaced towards the spirophosphorate (XCV).[105]

The action of strong bases on the (XCI) $\rightleftharpoons$ (XCII) equilibrium mixture leads to the formation of the insoluble phosphorates (XCIII). The use of the chiral base (−)-brucine in this reaction[74] made it possible to observe the signals of two diastereoisomeric brucinium phosphorates (−84.4 and

and −84.5 p.p.m.), which are in equilibrium. A kinetic study of the epimerisation of these diastereoisomers led the authors[74] to the conclusion that the P(VI) anion is obtained in the synthesis in a non-racemic form and that the P(V) → (VI) transformation is therefore stereospecific. The results obtained[74] agree well with the concept of the occurrence of degenerate tautomeric processes with participation of spirobicyclic and tricyclic anions of type (XLI).

The first example of chlorotropic tautomerism with participation of pentacoordinate and hexacoordinate phosphorus compounds has been described recently:[22]

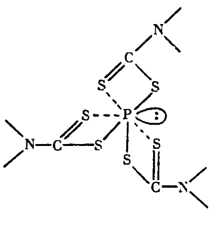


(XCVI) X = Cl (a); F (b) (XCVII)

The equilibrium (XCVIa) ⇌ (XCVIIa) is attained fairly slowly on the NMR time scale: the signals of both forms can be detected in the spectra. As the CX_3 group becomes more electron accepting (CF_3 > CCl_3), the solvent polarity decreases, the temperature rises, and the equilibrium is displaced towards phosphoranes. Thus at 30 °C the content of the P(V) form (XCVIIa) is 60% in CD_3CN, 84% in $C_6H_4Cl_2$-o, 87% in C_6H_6, and 97% in C_6D_{12}; at 50 °C the content of the P(V) tautomer in CD_3CN increases to 66%. The signals of the methyl protons coalesce at 120 °C. The independence of the rate of interconversion of the tautomeric forms of concentration indicates the intramolecular character of the tautomerism and suggests a structure with a bridging chlorine atom and a hexacoordinate phosphorus atom as the transition state or the intermediate.

The equilibrium processes with participation of pentacoordinate and hexacoordinate forms of organophosphorus molecules examined here model satisfactorily the first stage of the associative nucleophilic substitution of the pentacoordinate phosphorus, which presupposes the addition of the nucleophile to the P(V) atom of the substrate with formation of hexacoordinate intermediates and/or transition states.[12]

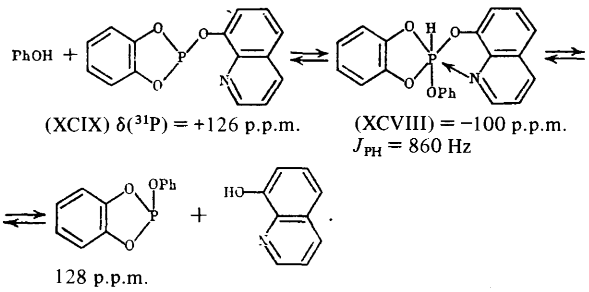
The question of the character of the intermediates or transition states in nucleophilic substitution reactions at a hexacoordinate phosphorus atom is therefore intriguing. The substitution of chlorine in compound (LXXVII) by a pyridine molecule with formation of the dipyridine P(VI) cation (LXXIX)[43] is one of the few examples of such reactions. The process is most likely to proceed via a dissociative mechanism with the preliminary elimination of the chloride anion. The associative mechanism appears unlikely: not a single example of the existence of structures with a phosphorus atom surrounded by seven ligands has so far been discovered. In the tris(dithiocarbamato)phosphines,[106,107] trisdithioacylates, and phosphinodithioyl derivatives of other group VB elements[108–110] described hitherto, a coordination number of seven of the central atom is attained by the formation of three sulphur–element coordinate bonds by virtue of the presence of a stereochemically active unshared electron pair of the element.



V. CYCLIC COMPOUNDS OF HEXACOORDINATE PHOSPHORUS AS INTERMEDIATES IN THE REACTIONS OF ORGANOPHOSPHORUS COMPOUNDS

It has been suggested and in many cases demonstrated that λ^6-1,3,2-diheterophosphacyclanes can be intermediate in reactions of organophosphorus compounds containing the atoms of tricoordinate, tetracoordinate, or pentacoordinate phosphorus. The involvement of P(VI) intermediates in the reactions of tervalent phosphorus compounds has been demonstrated only in some instances and is more likely to be an exception rather than the rule.[10] The intermediate formation of hexacoordinate phosphorus compounds occurs only in specific cases—in reactions of bifunctional or polyfunctional reactants or substrates.

The formation of the intramolecular P(VI) complex (XCVIII) in the transesterification of the phosphite (XCIX) with phenol has been detected from ^{31}P NMR spectra: the signal of compound (XCVIII) with $\delta(^{31}P) = -100$ p.p.m. and $J_{PH} = 860$ Hz, whose intensity is high at the beginning of the reaction and decreases as the latter is completed, has been detected at −70 °C in methylene chloride:[111]

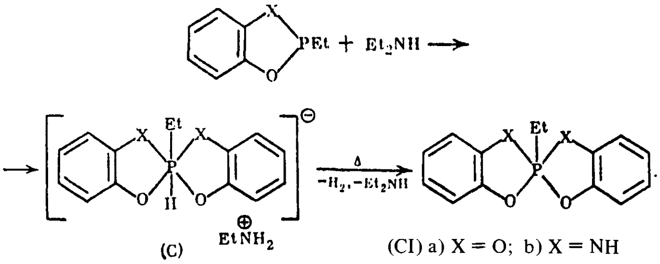


(XCIX) $\delta(^{31}P) = +126$ p.p.m. (XCVIII) = −100 p.p.m. $J_{PH} = 860$ Hz

128 p.p.m.

The stabilisation of compound (XCVIII) is achieved as a result of the presence of the 1,3,2-benzodioxaphospholan ring and the possibility of the formation of intramolecular P → N bonds.

The spirobicyclic phosphorate (Ca) has been isolated in 15% yield in the reaction of 2-ethyl-4,5-benzo-1,3,2-dioxaphospholane with diethylamine.[60] On heating, the salt (Ca) evolves a hydrogen molecule and is converted into the phosphorane (CIa). The same result has been obtained in the reaction of catechol with ethylphosphonous bis(diethylamide):



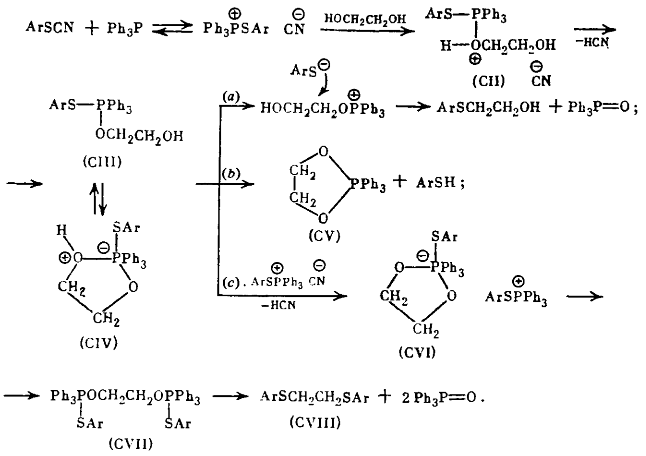
(C) (CI) a) X = O; b) X = NH

The interaction of o-aminophenol, leading to the phosphorane (CIb), can take place via the same pathway. However, the corresponding aminophosphorate could not be isolated owing to its smaller stability [see structure (XC)].

The results of the reactions of aryl thiocyanates with alcohols and diols in the presence of triphenylphosphine has been explained by the involvement of pentacoordinate and hexacoordinate phosphorus intermediates. The interaction of phenyl thiocyanate with triphenylphosphine and ethylene glycol takes place via pathway a (Scheme 4) and leads to 2-phenylthioethanol and triphenylphosphine oxide.[112]

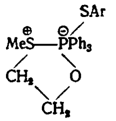
Aliphatic alcohols react analogously with formation of alkyl aryl sulphides.[113] On the other hand, another pathway (pathway *b*), leading to the isolation of *p*-methoxybenzenethiol and the cyclic phosphorane (CV), is also followed in the reaction with participation of *p*-methoxyphenyl thiocyanate. It has been suggested[112] that the oxonium–phosphorane adduct (CII) is a key intermediate in these processes.

Scheme 4



Its deprotonation by the cyanide ion affords the phosphorane (CIII); the decomposition of compounds of type (CIII) via pathway *a* is responsible for the formation of sulphides in the reactions of alcohols and of 2-phenylthioethanol in the reaction of ethylene glycol. The *p*-methoxyphenylthio-group is difficult to eliminate compared with the phenylthio-substituent and for this reason the attack by the terminal hydroxy-group on the pentacoordinate phosphorus atom competes with elimination of the arylthio-group from the phosphorane (CIII, Ar = p-MeOC$_6$H$_4$) (pathway *a*). This leads to the cyclic dipolar phosphorate (CIV); the fragmentation of the latter leads to the *p*-methoxybenzenethiol and the cyclic phosphorane (CV) (pathway *b*).

The possibility of the formation of the phosphorate (CIV) in these processes has been confirmed by the synthesis of aryl methyl sulphide in the reaction of *p*-methoxyphenyl thiocyanate with 2-methylthioethanol ($MeSCH_2CH_2OH$), which proceeds via the intermediate (CIX), which is analogous to the intermediate (CIV):



(CIX)

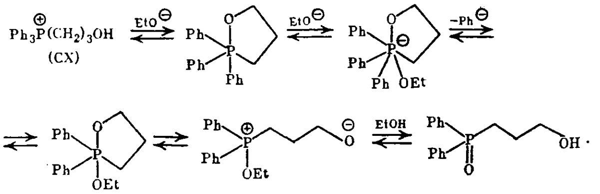
The involvement of *p*-nitrophenyl thiocyanate in this reaction does not lead to the formation of the sulphide, because the nucleophilicity of the arylthio-group is in this case insufficient for the demethylation of compound (CIX, Ar = p-NO$_2$C$_6$H$_4$) and the process proceeds in the "normal" way via pathway *a* to the bis-sulphide $MeSCH_2CH_2SC_6H_4NO_2$-*p*.

An essential condition for the formation of the phosphorate intermediate (CIV) from compound (CIII) is the presence of a free hydroxy-group, since glycol monoethers react only via pathway *a*, like primary alcohols.[112]

The *p*-nitro-substituent in the aryl group stabilises the negative charge on the phosphorus atom in the phosphorate (CIV) and the possibility of yet another competing pathway (pathway *c*) arises in this case; it is associated with the deprotonation of the phosphorate (CIV) by cyanide ion and the appearance of the ion pair (CVI). The interaction of the ions of the pair (CVI) leads to the bis-sulphide (CVIII) via the bisphosphorane (CVII) stage.

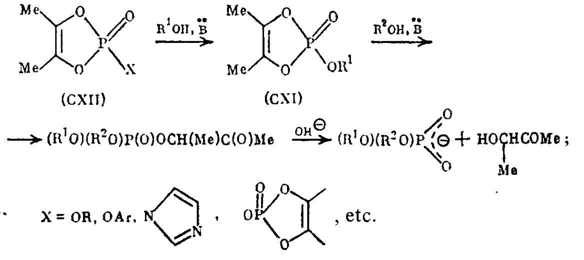
When the nitro-group is introduced in the *o*-position in the benzene ring, the formation of compound (CIV) is hindered for steric reasons and the process is therefore wholly directed via pathway *a*. The same results have been observed when 1,3- and 1,4-diols were used. Evidently the formation of phosphorates with a greater ring size than in compound (CIV) is energetically unfavourable.

An analogous intermediate formation of a five-membered ring in the P(V) and P(VI) intermediates ensures a sharp acceleration, induced by alkoxide ions, of the decomposition of 3-hydroxypropylphosphonium chloride (CX) (the rate constant at 60 °C is 7.3 litre mol^{-2} min^{-1}), compared with triphenyl-n-propylphosphonium chloride (the rate constant at 60 °C is 0.003 litre mol^{-2} min^{-1}):[114,115]



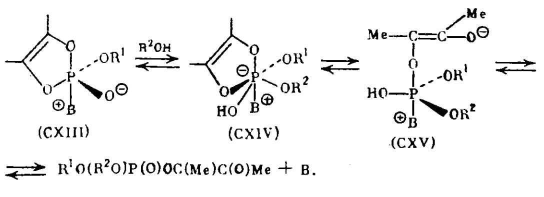
It has been suggested that tetracoordinate phosphorus compounds can give rise to P(VI) intermediates in chemical reactions involving base-catalysed nucleophilic substitution at a tetrahedral phosphorus atom.

In the presence of bases, the cyclic enediol phosphates (CXI) readily phosphorylate alcohols to form asymmetric diesters of phosphoric acid.[41,116] Effective catalysis by bases (amines,[117,118] phenoxides,[119,120] and the acetate ion[121]), which increases the rate of reaction by tens and hundreds of times, takes place in these reactions:



The mechanism of the catalytic action of bases is associated with the formation in the first stage of the hydroxyphosphorane (CXIII), which is obtained either by the reaction of the full phosphates (CXII, X = OR) with the catalyst or as a result of the addition of the alcohol to the enediol phosphate with a P–N bond (CXII, X=N, Netc.).[116]

The interaction with the substrate leads to an increase of the coordination number of the phosphorus atom in the rapidly formed intermediate phosphorate (CXIV):



The removal of one of the ligands in the intermediate (CXIV) converts the latter into the phosphorane (CXV) and then into the reaction products.

The essential feature of the catalytic action of bases apparently consists in increasing the rate of addition of nucleophiles to a phosphorane intermediate of type (CXIII) compared with the rate of reaction with the initial phosphate.

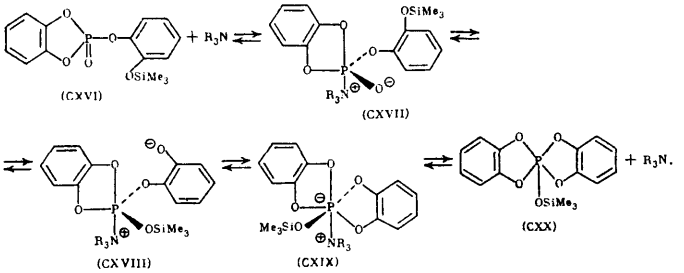
The phosphorylation of enediol phosphates by amide derivatives is accompanied by autocatalysis, because the interaction of, for example, the phosphimidazole (CXII, X = imidazolyl) with alcohol in the first stage is associated with the liberation of imidazole, which ensures effective catalysis of the phosphorylation reaction.[116–118,122]

The duration of the reaction of phosphoric acid triesters in the presence of imidazole is 2–30 min, while in its absence it is 8–12 h.[117] Triethylamine is just as effective in the reactions of primary alcohols and hardly affects the rate of phosphorylation of secondary alcohols. This is caused by the high steric requirements by the tertiary amine under the conditions involving the formation of a hexacoordinate intermediate. A definite role is also played by the basicity of the amine. Thus, in the base-catalysed opening of the ring in enediol phosphates by alcohols, the effectiveness of the catalysis is correlated with the basicity of the amines.[123]

The catalytic action of the *p*-nitrophenoxide ion in the trans-esterification of *p*-nitrophenyl diphenyl phosphate by alcohols has been explained by the formation of acyclic P(VI) intermediates.[116,124]

It has been noted[117,119] that the mechanism discussed here probably operates in the action of enzymes catalysing the reactions of phosphates and pyrophosphates in biological systems, because the presence of tyrosine, lysine, arginine, and histidine facilitates the addition of nucleophiles to a tetracoordinate phosphorus atom.

The base-catalysed cyclisation reactions of tetracoordinate phosphorus compounds containing an ω-hydroxyalkyl, *o*-hydroxy, or *o*-siloxyphenyl group [11,12] also take place with participation of P(VI) intermediates. Thus silyl transfer, which is responsible for the occurrence of the phosphate–phosphorane equilibrium (CXVI) (CXX), is accelerated by amines, the effectiveness of such catalysts diminishing as the steric requirements of the amines become more stringent.[125] The process includes the addition of the amine to the phosphate with formation of the monocyclic phosphorane (CXVII), in which the trimethylsilyl group is transferred from the phenoxy-oxygen to the equatorial oxy-anionic centre, so that the intermediate phosphorane (CXVIII) is produced. The addition of the anion to the phosphorane centre leads to the spirobicyclic zwitter-ionic phosphorate (CXIX), whose decomposition to the amine and siloxyphosphorane completes the isomerisation process:



The examples of the base catalysis of nucleophilic reactions of tetracoordinate phosphorus compounds presuppose the occurrence of two successive stages involving the addition of nucleophilic species to the tetrahedral phosphorus atom of the substrate and the phosphorane centre of the intermediate, which necessitates the participation of intermediates with the phosphorate structure in these processes. In this connection we may note that the formation of P(VI) intermediates, which may arise by the reaction of two hydroxide ions with the phosphoryl centre, has not been ruled out in the hydrolysis of five-membered cyclic phosphates either.[126,127] This hypothesis has been based on the experimental observation of a second-order dependence on hydroxide ion at high pH (in excess of 10) on the hydrolytic reaction.

However, the attempts to demonstrate the formation of phosphorate intermediates in the hydrolysis of ethyl ethylene phosphate using an isotope label and ^{31}P NMR (190.3 MHz) were not successful.[128] Nevertheless, the experimental data presented in this section make it necessary to consider the possibility of the formation of P(VI) structures and processes involving the interaction of tetracoordinate and even more so pentacoordinate phosphorus compounds with nucleophilies.[129] Furthermore, the data obtained in recent years leave no doubt that intermediates containing a P(VI) atom do in fact to a large extent determine the kinetic and synthetic results in many reactions of phosphoranes.[12]

It is known[12] that nucleophilic substitution at a pentacoordinate phosphorus atom can proceed via one or two mechanisms—dissociative, presupposing the unimolecular decomposition of the phosphorane to a phosphonium intermediate, and associative, in which nucleophilic species are added to or eliminated from the P(V) atom of the substrate. the formation of P(VI) intermediates in the second case has been established experimentally by isolating the products of the addition of ionic or neutral nucleophiles to phosphoranes.

Theoretical calculation for the minimum reaction energy pathway (MREP) in nucleophilic substitution at the P(V) involving the simple model reactions (2)–(4), i.e.

$$H^{\ominus} + PH_5 \rightleftarrows (PH_6)^{\ominus} \rightleftarrows PH_5 + H^{\ominus}, \tag{2}$$

$$H^{\ominus} + PH_4Me \rightleftarrows (PH_5Me)^{\ominus} \rightleftarrows PH_4Me + H^{\ominus}, \tag{3}$$

$$H^{\ominus} + PH_3Me_2 \rightleftarrows (PH_4Me_2)^{\ominus} \rightleftarrows PH_3Me_2 + H^{\ominus}, \tag{4}$$

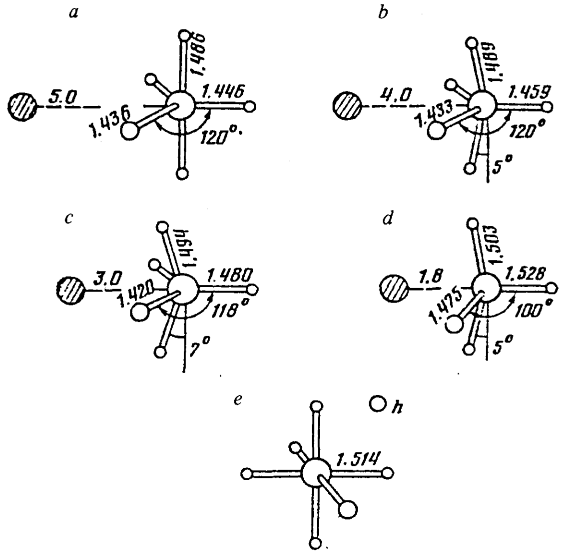
demonstrated that the attack by the hydride ion takes place rigorously in the equatorial plane of the trigonal bipyramid of the substrate.[95] The interaction leads to an octahedral intermediate and the main geometrical rearrangement of the system takes place in the reaction zone ($R \cong 2.0–2.2$ Å) with a gradual decrease of the total energy (see Figure). The *trans*-equatorial ligand begins to "sense" the approach of the nucleophile even over long distances and the *trans*-P–H bond gradually lengthens and, when the interaction is completed, reaches its equilibrium value. The lengths of the *cis*-P–H bonds increase monotonically.

Calculations for the less symmetrical RR^1PH_3 molecules have shown that the energetically most favourable direction of attack of a nucleophile involves movement along the bisector of the RPR^1 angle.

According to the data of Minaev and Minkin,[95] the addition of the nucleophile to the P(V) atom results in the preferential *cis*-disposition of the most electronegative group and the removal of the electronegative group being substituted takes place in the *cis*-conformation. #

The view has been expressed recently that equatorial attack by the nucleophile in the trigonal bipyramid of the phosphorane intermediate[130] and not only axial attack, as had been believed previously,[11] is possible also in reactions involving nucleophilic substitution at a tetrahedral phosphorus atom proceeding with retention of configuration.

At the same time, it has been shown[46,48] that, when the formation of P(VI) anions is subject to kinetic control, the addition of ionic nucleophiles to spirophosphoranes results in the initial formation of *trans*-phosphorates, which isomerise on raising the temperature to the thermodynamically favourable *cis*-phosphorates[12] (see also Section IV).



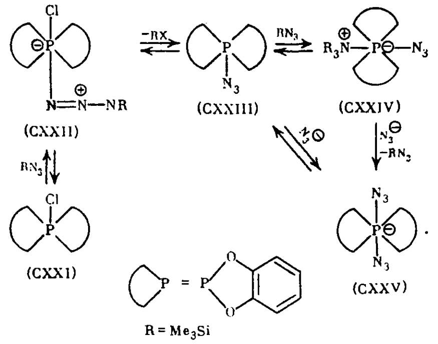
The minimum energy pathway in reaction (2);[95] the heats of formation of the supermolecule (ΔH_f, kcal mol^{-1}) are quoted for different distances R between the hydride ion and the attacked molecule: *a*) 120.5; *b*) 118.4; *c*) 115.4; *d*) 88.9; *e*) 78.6.

The formation of phosphorate intermediates in nucleophilic substitution at a pentacoordinate phosphorus atom has been detected in many instances by NMR.[12]

In the reaction of the chlorophosphorane (CXXI) with trimethylsilyl azide at −100 °C, the main product is the zwitter-ionic adduct (CXXII), which eliminates chlorotrimethylsilane at −60 °C and is converted into the azidophosphorane (CXXIII). However, the use of a twofold excess of the silyl azide yields as the main component of the reaction mixture the phosphorate (CXXIV), which is subsequently converted into compound (CXXV) (Scheme 5).

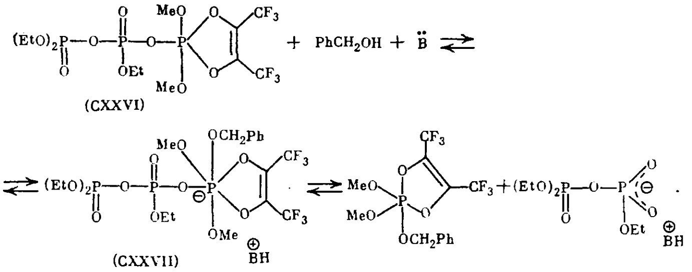
The equilibria (CXXIII) $\rightleftharpoons$ (CXXIV) and (CXXIV) $\rightleftharpoons$ (CXXV) are characteristic of the interaction of phosphoranes with nitrogen-containing nucleophiles (see Section IV). Phenylenedioxytrichlorophosphorane also combines with the azide molecule in the first stage and then exchanges in succession all the chlorine atoms for the azido-ligands

Scheme 5

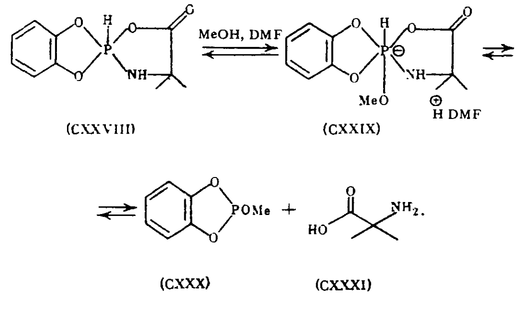


Thus reactions involving the nucleophilic substitution of chlorine atoms by azide ions proceed via a series of consecutively formed individual phosphorate intermediates.[131]

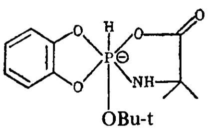
The interaction of hydroxyphosphoranes with alcohols, which takes place via transesterification[41,132,133] or alcoholysis[55] mechanisms, also involves the intermediate formation of phosphorates. Thus in the presence of γ-collidine, benzyl alcohol substitutes the pyrophosphate ligand in the phosphorane (CXXVI) in a relatively rapid and reversible reaction proceeding via the monocyclic phosphorate (CXXVII). The coordination of the phosphorus atoms is preserved in the reaction products.[41]



However, in alcoholysis reactions leading to products with a reduced coordination number of the phosphorus atom, the formation of phosphorate intermediates can be established spectroscopically in many instances.[55] The methanolysis of the hydrophosphorane (CXXVIII) in DMF leads to the cyclic phosphite (CXXX) and the aminoacid (CXXXI). At −60 °C a high-field signal [δ(^{31}P) = 110 p.p.m., $J_{\rm PH}$ = 760 Hz] was recorded in the NMR spectrum of the reaction mixture:



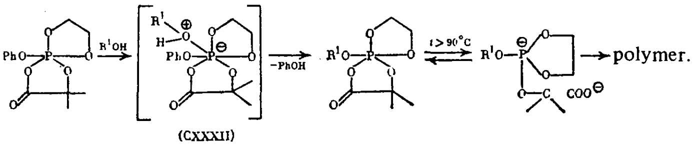
The signal was assigned to the intermediate (CXXIX) on the basis of a comparison with the similar spectroscopic characteristics of the phosphorate (CXXXII) obtained from compound (CXXVIII) and t-BuOK.



(CXXII) δ(^{31}P) = −112 p.p.m., J_{PH} = 740 Hz

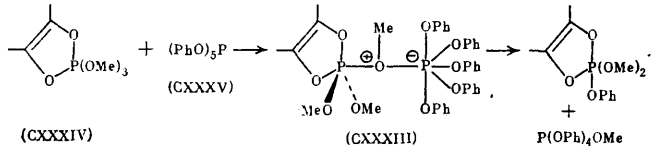
It is striking that the attack by the nucleophile is directed not to the alternative electrophilic centre of the molecule of compound (CXXVIII), namely the carbonyl carbon atom, but to the phosphorane phosphorus atom, which is known[12] to be characterised by a pronounced Lewis acidity. The replacement of the phenylenedioxy-substituent in compound (CXXVIII) by the less electron accepting ethylenedioxy-group precludes the detection of the P(VI) intermediate in the course of alcoholysis.[55]

It has been suggested that the transesterification of spirophosphoranes in neutral media and their subsequent polymerisation at an elevated temperature (>90 °C) proceed via a stage in which bicyclophosphorates (CXXXII) are formed:[134]



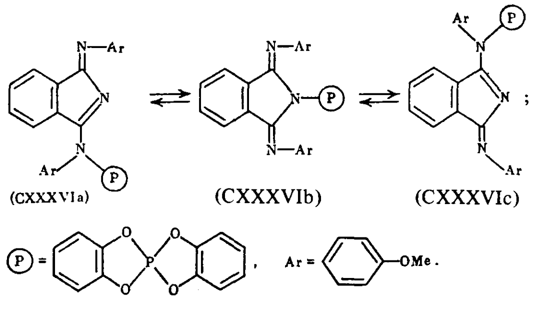
(CXXXII)

The formation of the oxonia-phosphorate intermediate (CXXXIII) probably ensures[135] intermolecular ligand exchange between the cyclic and acyclic phosphoranes (CXXXIV) and (CXXXV):



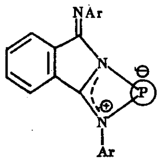
(CXXXIV) (CXXXIII)

Systems in which phosphotropic tautomerism occurs with participation of the phosphoranyl group have been discovered recently.[136] Two equal intensity singlets, at 3.63 p.p.m. (1) and 3.94 p.p.m. (2), as well as a singlet at 3.75 p.p.m. (3) with the intensity ratio (1 + 2) : (3) = 0.45 : 0.55, have been observed in the ^{1}H NMR spectrum of a solution of the phosphorane (CXXXVI) in o-dichlorobenzene at 25 ° C. The ^{31}P NMR spectra also contain two singlets with δ(^{31}P) = −26.8 and −36.7 p.p.m. and the same intensity ratio. The proton signals coalesce at 120 °C. This spectral pattern was explained by the existence of a dynamic equilibrium between the forms (CXXXVIa), (CXXXVIb), and (CXXXVIc) owing to two consecutive 1,3-migrations of the phosphoranyl group in the N=C–N=C–N pentad of compound (CXXXVI):



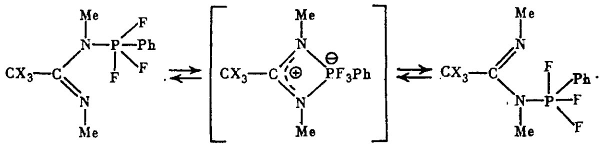
(CXXXVIa) (CXXXVIb) (CXXXVIc)

The free energy of activation for the process is 16.9 kcal mol^{-1}. The rate of these migrations is independent of concentration, which indicates an intramolecular mechanism of this phosphotropic process, involving the formation of the intermediate (CXXXVII) with a hexacoordinate phosphorus atom, which is short-lived on the NMR time scale and cannot therefore be detected spectroscopically.

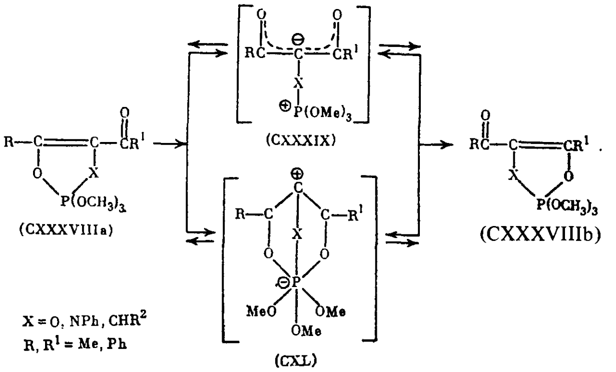


(CXXXVII)

A degenerate triad phosphotropism, associated with the migration of the PF_3Ph group, occurs in the phosphorane derivatives of trihalogenoacetamidinium. The intermediate phosphorate intermediate cannot be detected, because it is destabilised by the electron-accepting group at the cationoid carbon atom and the phenyl group at the phosphorate phosphorus atom:[137]



One cannot rule out the possibility that the phosphorotropic tautomerism (CXXXVIIIa) ⇌ (CXXXVIIIb), observed in monocyclic phosphoranes containing an acyl group at an endocyclic carbon atom,[138-140] can involve not only a dissociative mechanism via a betain intermediate (CXXXIX) with the phosphonium atom, but also via an associative mechanism with participation of a hexacoordinate intermediate or transition state (CXL). However, the experimental data are insufficient to make a choice between these variants.



(CXXXVIIIa) (CXXXIX) (CXXXVIIIb) (CXL)

X = O, NPh, CHR^2
R, R^1 = Me, Ph

The present paper completes a series of reviews[10-12] devoted to the chemistry, mainly reactivity, of 1,3,2-diheterophosphacyclanes containing a phosphorus atom with different coordination numbers. Summarising briefly the literature data of the last decade, one must note that all the main current trends in the development of organophosphorus chemistry have been reflected in the chemistry of these phosphorus-containing heterocycles. The endeavour by investigators to establish a relation between the structure and reactivity of OPC and to express it quantitatively whenever possible must be included among them in the first place. Much attention has been devoted to the study of the fine details of the reaction mechanisms and through their understanding to the development of new methods of synthesis of OPC, including those which are practically useful. The discovery of the character and role of the intermediates in the reactions of OPC is important for the development of the chemistry of phosphorus compounds at the present stage. It has led investigators to recognising the fact of the relative ease with which the coordination number of the phosphorus atom can change and to new views on the character of the driving forces in the reactions of OPC and has strongly stimulated progress in the chemistry of hypervalent compounds of phosphorus and other non-transition elements.

At the same time, many problems in the chemistry of 1,3,2-diheterophosphacyclanes, such as the character of the intramolecular electronic interactions, the manifestation of the stereochemistry of the phosphorus-containing heterocycle in the reactivity of OPC of this type, the quantitative characteristics of the electronic and steric effects of the alkylene(phenylene)dihetero-substituent or the entire phosphacyclane fragment, and many others still require a more far-reaching development. We are confident that studies in the near future will be marked by new successes in this rapidly developing field of organophosphorus chemistry.

The Resonance Raman Light Scattering in Studies of the Structures and Functions of Flavins and Flavoproteins

T.M.Ivanova

The application of the spontaneous and non-linear resonance Raman spectroscopic methods in studies on flavins and flavoproteins is examined. The biological functions of flavin systems are briefly surveyed and the parameters of the resonance Raman spectra and their relation with the electronic structure of the isoalloxazine ring in various oxidation states are described. The possibilities of identifying the flavin chromophore in a protein environment, in charge-transfer complexes, and in modified systems are discussed.

The bibliography includes 115 references.

I. THE LINEAR AND NON-LINEAR RESONANCE RAMAN SPECTROSCOPIC METHODS

Resonance Raman light scattering (RRS) was observed in the 1950's before the appearance of universal Raman scattering (RS) excitation sources—lasers. "Resonance" implies in this sense the coincidence of the frequency of the exciting light with one of the frequencies of the electronic transition in the molecule. This term was first applied to the description of the large increase in the intensities of certain Raman lines of aromatic nitro-compounds on excitation in the long-wavelength absorption band region.[1] All the characteristic features of RRS were described in subsequent studies:[2-4] high intensity coefficients exceeding by a factor of 10^3-10^9 the intensity of the usual RS; selective intensification of only certain normal vibrations among those actually applicable to the given electronic absorption band; the appearance in certain cases in the Raman spectrum of progressions of intense overtones; relations between the RRS line intensities and the parameters of the electronically excited state. These properties made it possible to expand greatly our ideas about the interaction of light with matter and to obtain new information about molecular structure and have led to analytical possibilities unavailable in the traditional RS methods. The invention and theoretical application towards the end of the 1960's of lasers led to a vigorous growth of the applications of RS, in particular RRS, in the solution of a wide variety of problems in physics, chemistry, and biology.[5,6] At the same time numerous non-linear effects, arising in matter under the influence of coherent laser beams, were observed and foundations were laid for a new field—non-linear optics and one of its branches, namely non-linear scattering spectroscopy.

In contrast to the traditional spontaneous RS, arising from fluctuation (thermal) vibrations, in non-linear scattering spectroscopy one considers the interactions with forced intramolecular vibrations which are excited under certain conditions by the powerful light fields of lasers in a large volume of matter. It is important to emphasise that the coincidence of the phases (phase synchronisation) of the forced vibrations plays the main role in these processes, whereas their amplitudes in the strongest light field remain smaller by 2–3 orders of magnitude than the fluctuation (spontaneous) changes in the normal nuclear coordinates. The first of these phenomena observed was forced Raman scattering (FRS).[7] Although the spectroscopic possibilities of this method are extremely limited, it served as the physical foundation of a whole series of non-linear Raman spectroscopic methods developed in the subsequent decade[8] and based on measurements of the amplitude, polarisation and phase of coherent waves "scattered" by forced vibrations.[9,10] Although many of these processes are not scattering in the traditional sense of the word, their interpretation may be based on classical ideas about the modulation of polarisability by normal nuclear vibrations, which are widely used in spontaneous Raman spectroscopy and which only arose at the time of the publication of Placzek's book,[11] while the parameters of the non-linear scattering—the intensities, forms, half-widths, and positions of the signal—may be compared with spontaneous RS data.

The rapid progress in the technology of lasers with tunable frequencies resulted in what were initially unique measurements becoming routine measurements.[12] Two non-linear Raman spectroscopic methods, which have found most practical applications and whose variants analogous to spontaneous RRS have also been investigated, are briefly described below.

The Coherent Anti-Stokes (Stokes) Light Scattering (CALS and CSLS) Spectroscopy. Two coherent beams with the frequencies ω_1 and ω_2 such that their difference $\omega_1-\omega_2$ coincides with one of the intramolecular vibration frequencies ω_r can be excited and phase-synchronised against the background of the vibration with the frequency ω_r; a third (trial) wave then interacts with forced vibrations, is scattered, and gives rise to intense coherent components in the anti-Stokes and Stokes regions:[8]

$$\omega_{a,\,c}=\omega\pm(\omega_1-\omega_2)\quad .$$

The most widely used version of this method is one where one of the pumping waves is used as the trial wave ($\omega = \omega_1$):

$$\omega_a=2\omega_1-\omega_2\quad ,$$

Evidently, by varying the difference $\omega_1-\omega_2$, it is possible to obtain all the frequencies corresponding to the spontaneous Raman spectrum of the molecule. The abbreviations CALS and CSLS widely used nowadays in the foreign literature were introduced by Byer et al;[13] however, even earlier Akhmanov and co-workers[10] proposed for this process the term "active RS spectroscopy (ARSS) which we shall also use subsequently.

The analogue of spontaneous RRS, where the coherent pumping frequency ω_1 is close to the frequency of the electronic (one-photon) transition in the molecule ω_e, is nowadays vigorously investigated in the CALS spectroscopy. On decrease of the difference $\omega_1-\omega_e$, a sharp increase in the intensity of the coherent signal was observed in the CALS spectra.[14,15] In the region of the one-photon resonance, the CALS and CSLS lines have extremely complex contours due to the interference of several contributions—electronic and vibrational (see, for example, Refs.9 and 10). This factor initially led to an erroneous interpretation of the observed phenomenon as inverse RS[15] (see below). Theoretical analysis within the framework of quantum-mechanical ideas has shown[16] that, when ω_1 is scanned in the region of a broad electronic absorption band, the contour of the anti-Stokes line can vary from positive Lorentzian through dispersion to negative Lorentzian, depending on the ratio of the parameters: the frequencies ω_1, ω_e, and ω_r and the decay constants Γ_e and Γ_r of the electronic and vibrational oscillators. For identical values of $\omega_1-\omega_e$, the CALS and CSLS signals have different forms (Fig.1). This has been observed experimentally for cytochrome c,[15] vitamin B_{12},[15] β-carotene,[17] and certain other biologically active substances.[9]

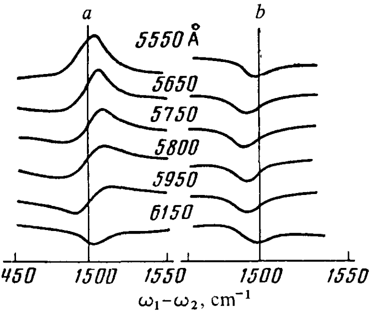

Figure 1. A model calculation of the CALS (*a*) and CSLS (*b*) band contours on resonance excitation;[16] the values of the parameters simulate the case of vitamin B_{12}; ω_e = 18,000 cm^{-1}, ω_r = 1500 cm^{-1}, Γ_e = 500, and Γ_r = 10.

Inverse Raman Spectroscopy. CALS and CSLS are four-photon processes. A lower-order non-linear process, namely a two-photon process, was also observed in the 1960's. When two coherent beams with the frequencies ω_1 (intense pumping) and ω_2 (weaker trial wave) were allowed to interact with the medium, Jones and Stoicheff[18] observed a weakening of the intensity of the trial wave, while the frequency difference $\omega_2-\omega_1$ coincided with the vibrational transition frequency ω_r:

$$\omega_2-\omega_1\simeq\omega_r;\quad \omega_1<\omega_2$$

This phenomenon was called the inverse Raman effect.[18] Instead of the weakening of the trial high-frequency wave in the field of powerful low-frequency pumping, one can employ another scheme and observe an intensification of the trial low-frequency ω_2 wave under the influence of the intense high-frequency ω_1 pumping.[19] The corresponding terms have been proposed in the Soviet literature: forced RS (FRS) in intensification and inverse RS (IRS) in attenuation.[10] These methods are sometimes referred to as modulation methods bearing in mind the change in the optical properties of the medium at the frequency of the trial wave.[10]

The case of "double resonance", vibrational and electronic (one-photon), has also been investigated in inverse Raman spectroscopy. This method has a number of advantages, among which the absence of an intense permanent background, associated with the non-resonance electronic susceptibility and generating a serious interference in the CALS and CSLS spectra (under conditions remote from one-photon resonance), is important.[9,10] It has also been suggested that, in contrast to ARSS, in the intensification–attenuation scheme it is possible to obtain spectra fully corresponding to spontaneous RS, including the form of the signal.[19,20] In the first experiment on resonance inverse RS, direct measurements were made of the absorption.[21] Subsequently various modulation schemes were proposed[22,23] permitting a significant improvement of the detection limits.[24] The experiments on the excitation of inverse RS in the region of broad electronic absorption bands showed that[24] the form of the signal changes as a function of the ratios of ω_1, ω_e, and Γ_e. The results of a model parametric calculation of the resonance inverse RS line contour are presented in Fig.2.

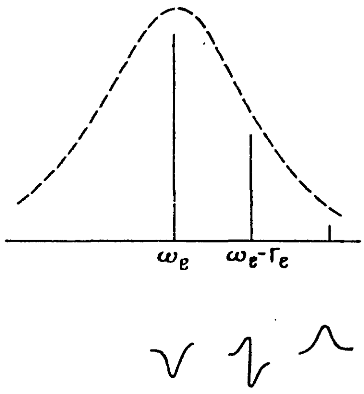

Figure 2. The contours of the inverse Raman signal (below) on excitation in the region of the absorption band (shown dashed); model calculation.[24]

The advantages of coherent Raman spectroscopy in the study of rarefied gases and in the diagnostics of plasma, rapid combustion processes, etc. have been frequently noted.[8,10,12] In comparing the possibilities of spontaneous RRS and its coherent analogues in studies of the structures of complex molecules in condensed phases, one should note in the first place the difficulties associated with the extraction of information from coherent Raman spectra in the region of one-photon resonance; the treatment of spontaneous RRS data is in this case much simpler. The ARSS and inverse Raman spectra have been calculated on a computer by adjusting parameters. At the same time, the complexity of the form of the coherent signal and the changes in the latter in the resonance region due to the interference by several contributions make it possible to obtain, with the aid of parametric analysis, a series of additional data—in particular one can estimate the decay constants for the electronic and vibrational oscillators, determine the frequencies in the excited state of the molecule, and refine the position of the 0–0 transition. However, all these processes have so far been inadequately studied.

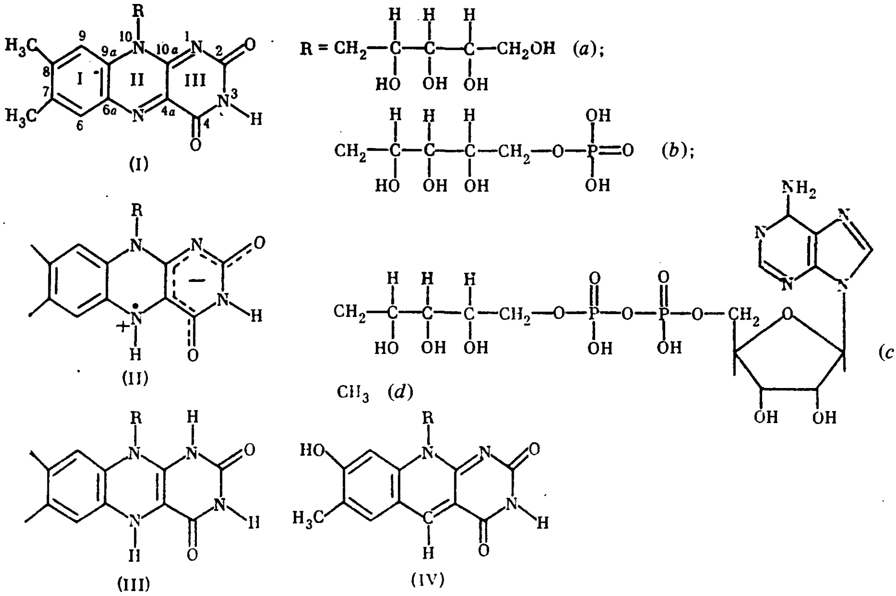

Figure 3. The prosthetic flavin groups and the numbering of the atoms in the isoalloxazine ring (I): *a*) riboflavin; *b*) flavin mononucleotide; *c*) flavin adenine dinucleotide; *d*) lumiflavin; II) semiquinone form; III) fully reduced form; IV) 5-deaza-8-hydroxyflavin.

The excitation in the region of resonance of complex and especially biological molecules is known to entail frequently the appearance of an intense fluorescence, which fully rules out the observation of spontaneous RRS. Since the CALS and inverse Raman signals are located in the anti-Stokes region and the fluorescence occurs in the Stokes region, they provide a unique possibility for recording Raman spectra in the presence of fluorescence. We may also note that the average level of the intensity of the irradiation of the specimen in the coherent spectroscopy is lower by 1–2 orders of magnitude than in the recording of spontaneous Raman spectra, which is important for photolabile substances.

Thus non-linear Raman spectroscopic methods significantly supplement the spontaneous spectroscopic method and sometimes constitute the only means of observing the Raman spectra. Yet another field, associated with studies on non-stationary processes and the determination of the dynamic characteristics of short-lived intermediate states, which is extremely important for biology, has developed rapidly during the last decade within the framework of non-linear spectroscopy (see, for example, Akhmanov and Koroteev,[10] Chapter 5). Progress in the technique of the generation of short and ultrashort [picosecond (10^{-12} s)] pulses and the creation of adequate recording methods[25–27] permitted the study of rapid biological processes, including the conformational rearrangements in the active centres of haemoproteins[28] and in visual pigments.[29]

The scale reached by studies with the aid of linear and non-linear resonance Raman spectroscopy in biology can be inferred from the appearance of the term "resonance Raman spectroscopy of haemoproteins",[30] "resonance Raman spectroscopy of visual pigments",[31] etc. The comparatively new rapidly developing field of flavoproteins has been least thoroughly investigated in this sense.[32–34] This review discusses resonance Raman spectroscopic data obtained for flavin and flavoproteins in connection with their structures and functions; the latest ideas concerning the role of flavoproteins in living nature and certain mechanisms of their action are also briefly surveyed.

II. THE STRUCTURES AND FUNCTIONS OF FLAVOPROTEINS

Flavins and Flavoproteins. This important class of natural products has been little investigated partly because of historical reasons† as well as a number of other factors: the great complexity of the molecules, the difficulty of isolation, the low content in natural objects, and, which is most important, the unusual wide variety of the functions of flavin-containing compounds in nature: in higher animal and plant organisms as well as micro-organisms. Flavoproteins are in most cases enzymes with a prosthetic group containing a substituted isoalloxazine ring (Fig.3), usually in the form of flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), or riboflavin. The highly conjugated tricyclic isoalloxazine system, in which there are comprehensive possibilities for electronic rearrangement by virtue of the presence of four nitrogen atoms and fragments analogous to the amide group, constitutes the centre of numerous biochemical reactions. The flavin system incorporated in a wide variety of protein environments—from comparatively short polypeptide chains (flavodoxins, ~130–170 aminoacid residues[35]) to enormous dimeric molecules (glutathione reductase, ~480 residues in each subunit[36,37])—affects the enzyme catalysis of the oxidation-reduction reactions of an enormous number of substrates, including amines, alcohols, amino- and hydroxy-acids, dithiols, etc.[34] The reactions of flavoproteins with molecular oxygen are no less varied. In certain oxidative processes, one oxygen atom of the O_2 molecule is transferred to the substrate, while the other is incorporated in a water molecule; in other reactions, molecular oxygen is reduced with formation of the superoxide O_2^-.

---

†The first natural flavin compound, namely riboflavin, was identified in 1935, while the most important prosthetic group, flavin adenine dinucleotide, was not identified until 1954.

Apart from its life supporting functions in organisms and plants, flavin enzymes play an enormous role in the turnover of the elements in nature effected by micro-organisms, in particular in the global turnover of carbon.[38] In the course of evolution, soil bacteria developed a wide variety of enzymes (monoxidases) catalysing the decomposition of residues from higher plants, mainly lignin, which is a stable natural polymer.[38] The function of flavin enzymes is just as important in the metabolism of nitrogen and especially sulphur, whose biological circulation effected by bacteria has been estimated[39] as amounting to 75% of the total content of sulphur on earth.

The applications of these compounds have extensive biomedical aspects. In the organisms of higher animals, the most important agent supporting the normal level of flavoproteins is riboflavin, which is ingested with food and is then transferred by special transfer proteins to the tissues, where it is bound in the form of FMN and FAD cofactors to other proteins.[40] One can apparently expect that in the immediate future it may be possible to approach an understanding of certain molecular aspects of diseases (including certain hereditary afflictions of the brain and the peripheral nervous system) associated with the deficiency of flavoproteins and the disturbance of their metabolism in the organism.[41] This is also indicated by the development of the medicinal antihypertensive agents and psychotropic preparations (derivatives of phenothiazine and tricyclic antidepressants), whose structure is close to that of riboflavin; their activity is apparently based on the inhibition of the conversion of riboflavin into FMN and FAD in the organism.[42] The functions of flavoproteins determining the occurrence of various detoxification processes, involving a wide variety of aromatic compounds, sulphur-containing derivatives, and mercury, have also been elucidated.

The multiplicity of functions of flavin enzymes has become evident only recently. On the basis of mainly biochemical data which have now accumulated, Massey and Hemmerich[43] suggested that five main classes of flavoprotein can be distinguished in accordance with the characteristic features of their catalytic cycles.

The field of flavins and flavoproteins is developing rapidly. Unusual flavin enzyme systems containing a modified isoalloxazine ring, including flavins with "double modification" of the ring—the 5-deaza-8-hydroxy-derivative (Fig.3), the so-called F-420 cofactor of methane bacteria, have been discovered and investigated.[44,45] In contrast to haemoproteins, the flavin group does not form covalent bonds with the protein in most cases and is retained in the active centre mainly with the aid of strong hydrogen bonds, favourable electrostatic interactions, etc. However, whole series of flavoproteins have now been identified in which the isoalloxazine ring proved to be covalently bound to the apoprotein, usually in the C(8)-position via a CH_2 group to histidine, cysteine, or tyrosine residues.[46]

Nevertheless, despite the undoubted progress made, the field of flavoproteins has so far been developing mainly via the extensive accumulation of new data, leaving many problems unsolved. The true natural substrates are unknown for a whole series of flavoproteins distributed in animal and plant tissues; the biological functions of many flavoproteins, including one of the first compounds identified—"the old yellow enzyme", have not been elucidated either. The biological role of the covalent bond between the isoalloxazine chromophore and the protein in covalently bound flavoproteins is unknown. All the biological oxidation-reduction chains contain at least one flavoprotein, which transforms two-electron transport into one-electron transport to a "one-electron" acceptor (cytochrome or sulphur-containing protein). The unique mechanism on this $2e^-/1e^-$ switch still remains obscure.

Protein plays an enormous role in the functioning of flavin enzymes. The immediate protein environment of the isoalloxazine ring actually determines ultimately its specific function in the enzyme. However, our information about this field is still very limited and the structure (even the primary structure) of many vitally important flavoproteins remains unknown. X-Ray diffraction data have now been obtained for representatives of only three classes of flavoproteins: flavodoxins,[47] glutathione reductases,[36] and p-hydroxybenzoate hydroxylases.[48] Furthermore, it is evident that only knowledge of the details of the steric structure of the active centre (in certain cases even the static [resting-state] structure) would make it possible to reach well-founded conclusions about the mechanism of the catalysis and the character of the intermediate stages. The example of glutathione reductase is instructive from this point of view; according to X-ray diffraction data,[36,37] the immediate environment of FAD in this enzyme predetermines its functions as a two-electron transferring agent and blocks the structures necessary for the transfer of one electron. However, this example is exceptional and most of the proposed mechanisms of the biochemical reactions of flavoproteins remain extremely speculative. In order to account for the mechanism and to identify the intermediate stages, traditional biochemical methods are resorted to, in particular methods using the formation of artificial complexes of the enzyme with the inhibitors. Another procedure for the "probing" of the active centre is based on the ease of the separation of the flavin chromophore from the aproprotein,[49] which can then be joined to isoalloxazine chemically modified at points tentatively assumed to be of "key" importance for the kinetic and thermodynamic parameters of the catalysis. In order to deduce the environment of the isoalloxazine chromophore in the protein, indirect physical information is also used. For example, it is known that the intense fluorescence characteristic of flavins is quenched following addition to certain proteins. It has been suggested that this can occur only when the isoalloxazine ring interacts with the tyrosine and tryptophan in the active centres of the protein which are close to it in space.[35]

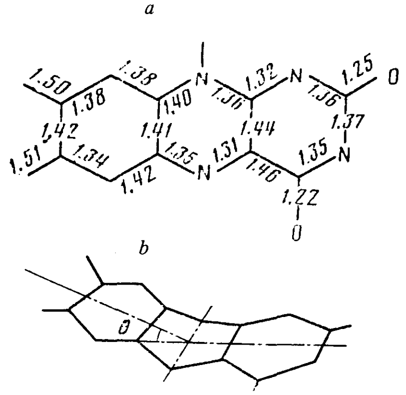

Figure 4. The bond lengths in the oxidised planar structure of the isoalloxazine ring (*a*) and the "butterfly" conformation of the fully reduced form (*b*); the energy minimum corresponds to the angle θ ≅ 15°.[50]

Electronic Absorption Spectra and Structural Parameters of the Isoalloxazine Ring. Three main biological functions of the isoalloxazine chromophore, namely (de)hydrogenation (only 2e$^-$), activation of molecular oxygen (2e$^-$ or 1e$^-$), and "pure" electron transport (1e$^-$), are possible by virtue of electronic rearrangements of three stable forms (Fig.3): oxidised, half-reduced (semiquinone; radical), and fully reduced. In addition various ionisation and protonation states are possible for the last two forms.

The structural parameters of the isoalloxazine ring are indicated in Fig.4. The conformational possibilities in the conjugated flavin system are extremely limited; according to X-ray diffraction data, the fully oxidised isoalloxazine ring in all the flavin systems investigated experimentally has a planar structure in conformity with the predictions of quantum-chemical calculations (see Dixon et al.[50] and the references quoted therein).

The "butterfly" conformation with a dihedral "folding" angle θ relative to the N(5)–N(10) axis of approximately 10° has been predicted for the fully reduced form by MO SCF calculations (in the INDO version—incomplete neglect of differential overlap)[50] (Fig.4). The experimental values of θ for this form in model systems vary in the range 30–8°, whereas in proteins the angle θ can apparently be even smaller.[51] Calculation has shown[50] that the variation of the angle θ in the range 20–0° can be achieved for an energy expenditure of approximately 3.5 kcal mol^{-1}, which corresponds to slight conformational rearrangements of the aminoacid residues in the protein surrounding the flavin. For this reason, a planar structure is apparently preferable for the semiquinone form in the protein environment.[52]

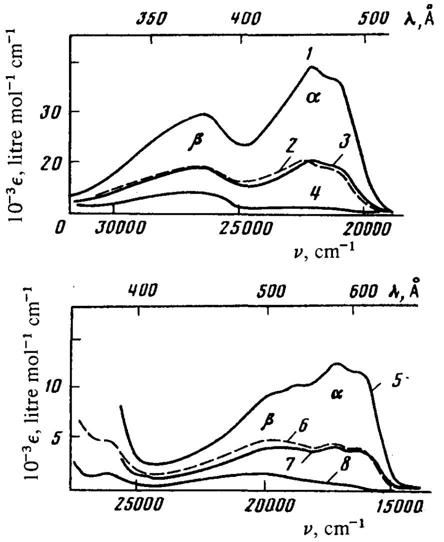

Figure 5. The electronic absorption spectra of an FMN-containing protein—flavodoxin from *Clostridium MP;* *a*) oxidised form; *b*) semiquinone form; the polarisation spectra of single crystals with $E \parallel$ crystal *c* axis (curves *1* and *5*) and $E_\perp$ crystal *c* axis (curves *4* and *8*) as well as the spectra of the solutions (curves *2* and *6*) are shown; curves *3* and *7* represent the calculated isotropic spectra of the crystals.[55]

The flavin chromophore has intense absorption bands in the long-wavelength part of the spectrum: one band at 20000–25000 cm^{-1} and another with centre at approximately 26400 cm^{-1},[53] which are due to the two lowest $\pi \rightarrow \pi^*$ transitions[54] and which will henceforth be designated as the α- and β-bands (Fig.5).[55] Polarisation measurements of the absorption in crystals[55] and earlier studies on oriented films and the polarisation of the fluorescence of model flavins showed that the corresponding transitions are linearly polarised in the plane of the flavin ring in the direction close to the axis parallel to the plane of the ring and perpendicular to the N(5)–N(10) axis.[55]

III. THE RESONANCE RAMAN SPECTROSCOPY OF FLAVINS AND FLAVOPROTEINS

The Non-Linear and Spontaneous Resonance Raman Spectroscopy of Flavins. The resonance Raman spectroscopy of flavin systems, like that of certain proteins of other classes, constitutes in essence the only (with the exception of X-ray diffraction analysis) source of the most detailed information about the structure of the active centre. Indeed, until recently, the electronic rearrangements of the isoalloxazine ring in the functioning of the flavoprotein could be inferred from only one parameter—the change in the positions and intensities of the long-wavelength $\pi \rightarrow \pi^*$ transitions.[43] Apart from the usual limitations, the application of NMR is in this case complicated also by the fact that, in addition to the protons of the two methyl groups in the 7- and 8-positions and the CH bonds in the 6- and 9-positions, whose signals contain little information, the isoalloxazine ring contains a single proton at the N(3) atom; the low relative content of the flavin fragment in proteins hinders the application of ^{13}C NMR. The NMR data obtained hitherto refer mainly to the ribityl fragment of FMN and FAD.[56]

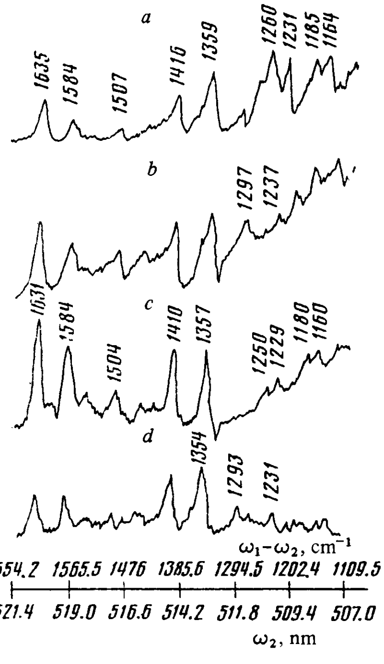

Figure 6. The resonance CALS spectra of flavin adenine dinucleotide [*a*) in H_2O; *b*) in D_2O] and riboflavin-binding protein [*c*) in H_2O; *d*) in D_2O]; pH 7; ω_1 = 480 nm.[58]

In a free state the flavin chromophore (FMN, riboflavin) exhibits a very intense fluorescence, its intensity exceeding by several orders of magnitude (by a factor of $\sim 10^4$) that of the Raman lines. The first resonance Raman spectra of FAD and FAD-containing protein (glucose oxidases) were obtained by means of the "spatial" separation of the scattering and fluorescence in the anti-Stokes ARSS (CALS) method with excitation in the region of the α-band.[57] The frequency $\omega_1 \cong 480.0$ nm, tentatively coinciding with that of the 0–0 transition (ω_{00}), was used as the pumping frequency.[54] Further improvement of the experimental technique (the introduction of a second monochromator into the optical path of the signal) made it possible to reduce the background in the vicinity of the pumping frequency and to obtain CALS resonance spectra for FAD and two FAD-containing proteins, glucose oxidase and riboflavin-binding protein (Fig.6), starting from 300 cm^{-1} in certain cases.[58]

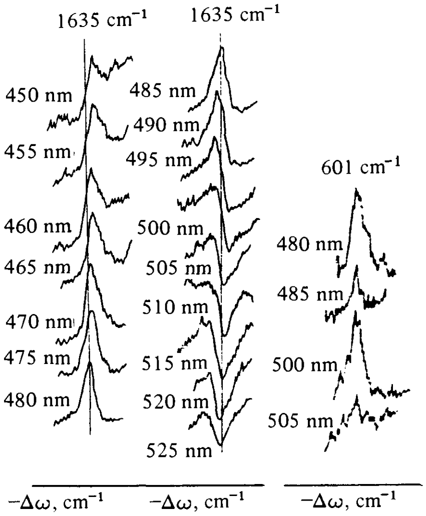

Figure 7. The $\omega_r \cong 1635$ and 601 cm^{-1} band contours in the resonance CALS spectra; the frequencies ω_1 are indicated in the Figure.[59]

As already mentioned, the major difficulties in the resonance excitation in the CALS are associated with the variation of the signal contour as a function of the ratios of ω_1, ω_e, ω_r, and a number of other parameters.[16] The FAD line contour ($\omega_r \cong 1635$ cm^{-1}) is illustrated in Fig.7 as a function of the varying ω_1 in the region of the α-band.[59] It is seen from these data that approximate estimates based on the semiclassical model[16,60] agree with experiment fairly satisfactorily (see also Fig.1). A positive Lorentzian contour is observed at $\omega_1 \cong \omega_0$; for higher and lower energies ($\omega_1 \cong \omega_{00} \pm \omega_{r/2}$), the signal becomes of the dispersion type and has a negative Lorentzian contour at $\omega_1 \cong \omega_{00} - \omega_r$.. We may note that, under the same excitation conditions, only a positive Lorentzian contour was observed for the $\omega_r \cong 601$ cm^{-1} lines, which the authors attributed to a large contribution of Franck–Condon factors.[59] In conformity with model calculations,[16] only dispersion line contours were observed for a coherent Stokes signal. Thus the exact determination of the frequency in the resonance CALS spectra may be difficult. The only practical procedure remaining so far is one involving the recording of a series of spectra at different pumping frequencies in order to discover the purely dispersion or purely Lorentzian contour.

Almost simultaneously with these studies, reports concerning the spontaneous resonance Raman spectra of flavins appeared. A group of Japanese workers[61]# used the ability, noted a long time ago, of the protein matrix to weaken greatly the fluorescence of the isoalloxazine chromophore and obtained the spectra of two riboflavin-binding proteins: from chicken egg yolk and white, and also of the 3-CH_3-, 2-CH_2COOH-, and 7,8-Cl-derivatives of riboflavin attached to the upper end of the apoprotein. Subsequently the resonance Raman spectra of several other flavoproteins and of the FMN and FAD prosthetic groups themselves were obtained; in order to eliminate the interfering fluorescent background, various procedures were employed; excitation by lines at longer wavelengths (600 nm; in the preresonance region)[63] or at shorter wavelengths (λ = 363.8, 351.1, 337.1, and 257.3 nm, in the region of high-energy electronic transitions of the chromophore), and also by adding quenching agents, mainly KI.[64,65]

In the first investigations,[57,58] it was already noted that only vibrations localised in the isoalloxazine ring are intensified by resonance and that, as might have been supposed, the vibrations associated with the substituents at N(10), namely ribose (in riboflavin), phosphoribose (in FMN), or adenosine diphosphate-ribose (in FAD), are not intensified. Typical FAD spectra are illustrated in Fig.6. We may note that some of the frequencies in the above study differ from those obtained subsequently in spontaneous Raman spectra (Table 1). Bearing in mind that positive CALS line contours are obtained at the pumping frequency $\omega_1 \cong 480$ nm[58] while negative contours are obtained at the frequency $\omega_1 \cong 495$ nm[66] the agreement between the frequencies in Table 1 can be regarded as satisfactory. It was shown subsequently that, under identical excitation conditions, the resonance Raman spectra of riboflavin, FMN, and FAD are almost identical in the region above 1100 cm^{-1} (for which reliable data are available) with the exception of small differences as regards the intensities of a number of bands.[64]

The Assignment of the Vibration Frequencies. In the very first studies, attempts were made to compare the resonance Raman frequencies with the structural elements of the isoalloxazine ring. The correlations were based initially on a single experiment involving isotope substitution [the replacement of the exchanging N(3)H proton by deuterium[58,61,63]] and also on data for 7,8-Cl-substituted derivatives[61] and intuitive guesses. However, a fundamental study by Kitagawa et al.,[67] who obtained the resonance Raman spectra for the N(3) and N(3)D forms of the isotope-substituted [2-^{13}C]-, [4a-^{13}C]-, [10a-^{13}C]-, [2,4,4a,10a-^{13}C]-, [5-^{15}N][1,3-^{15}N]- and [1,3,5-^{15}N]-riboflavins was soon published. In order to eliminate fluorescence, the authors used the ability of certain proteins, noted above, to exhibit a "quenching" effect on the fluorescence of isoalloxazine and the ease of the formation of its complexes with the apoprotein; the complexes of all the above derivatives with the riboflavin-binding protein from chicken egg protein were obtained in this way. The study of Kitagawa et al.[67] prepared a basis for a reliable calculation of the normal vibration frequencies of the flavin system, but these extremely rich data have remained virtually unused. The only calculation of the vibration spectrum of 10-methylisoalloxazine (lumiflavin) carried out hitherto[68] can be regarded as only preliminary.

#The observation of a single isoalloxazine line on excitation with a UV laser had been reported in an earlier study.[62]

[a] CALS, $\omega_1 = 480$ nm. [b] Spontaneous RS, $\lambda = 600$ nm. [c] pH 8.5 with added 5 M KI; spontaneous RS, $\lambda = 488$ nm. [d] In H_2O, CALS, $\omega_1 = 495$ nm. [e] In H_2O with added 6 M KI; spontaneous RS, $\lambda = 514.5$ nm. s = strong (intense), vs = very strong, m = moderate, and w = weak.

The force constants of the valence bonds and angles and also the interaction constants were in the main transferred in the above study from benzene, pyrimidine, and uracil molecules, taking into account the bond length—force constant correlations (see the references in the paper of Bowman and Spiro[68]). At first sight, the force field generated in this way could in principle reflect the specific features of the flavin system; the large bond interaction constants (up to 15% of the diagonal force constant) are characteristic of molecules with a high degree of delocalisation of the electron density. Nevertheless, almost all the frequencies calculated in terms of this approximation differ appreciably from the experimental values and in certain cases the differences for the most intensive bands reach 80–100 cm^{-1}. However, it is more significant that the calculated data do not reproduce the line shifts on isotope substitution.[67] This is particularly clear for the ~1250 and 1160 cm^{-1} bands, which undergo the greatest shifts on deuteriation, and in certain isotope-substituted specimens. Among the reasons for the failure of the calculation, one of the main ones consists apparently in the incorrect initial assignment of certain frequencies. The selection of the force field, in which certain important interactions, for example, those of the N(5)–C(4*a*) and C(10*a*)–N(1) bonds, were altogether disregarded, was also relatively unsuccessful (Fig.3). We may note that the initial approximation chosen by the authors proved to be relatively unsuitable also for uracil, where the calculation likewise reproduced unsatisfactorily the increase of the frequencies in the region of 1250 cm^{-1} on deuteriation.[69] Thus only preliminary conclusions may be made so far concerning the nature of the individual resonance Raman bands of flavins, mainly on the basis of isotope substitution data.[61,64,67]

Band I. The highest-frequency 1630 cm^{-1} band has been assigned in most investigations to vibrations with the predominant involvement of the benzene ring, mainly on the basis of the appreciable decrease of this frequency following substitution by halogen atoms in the 7- and 8-positions.[61,70] This Raman line proved to be almost insensitive to isotope substitution in the 2-, 4*a*-, 5, 1, and 3-positions;[67] it hardly shifts for the 1,3- and 5-deaza-derivatives[71] and is not intensified on resonance excitation at the frequency corresponding to the long-wavelength (α) absorption band. All the data obtained hitherto show that the symmetrical (ν_s) and anti-symmetrical (ν_{as}) vibrations of the C(2)=O and C(4)=O carbonyl groups are not manifested in the resonance Raman spectrum.

Band II (1548 cm^{-1}). This band changes appreciably on substitution of the N(5), C(4*a*), and C(10*a*) atoms in ring II[67] and disappears in 5-deaza-FMN.[71] However, the appreciable involvement of other coordinates is indicated by the shift of this band in the *N*(3)-substituted derivatives.[71] On resonance excitation at the frequency of the β-band (370 nm), it was possible to observe only this line.[62]

Table 2. The shifts of the resonance Raman lines of the N(3)H forms of the isotope-substituted riboflavin specimens.[67]

[a] The frequencies for the N(3)D form are given in brackets.

Band III. Large isotope shifts (21 cm^{-1} in the 2,4,4*a*,10*a*-^{13}C-substituted derivatives (Table 2) have been observed for the low-intensity 1548 cm^{-1} line.

Bands IV, V, and VI. The weak bands at 1500 cm^{-1} (IV) and 1462 cm^{-1} (V) and the intense 1407 cm^{-1} band (VI) are approximately equally sensitive to isotope substitution. The 1407 cm^{-1} vibration is appreciably delocalised; the shifts of this band are large on ^{13}C and ^{15}N isotope substitution in ring (III) and amount to approximately 10 cm^{-1} in the 7,8-dichloro-derivatives.[61]

Band VII. The 1355 cm^{-1} band is one of the most intense in the resonance Raman spectrum. It has been noted that it is intensified on resonance with the electronic absorption α-band (450 nm) and is the most intense on excitation in the pre-resonance region.[63] Table 2 shows that the corresponding vibration is very sensitive to ^{13}C substitution and is relatively insensitive to ^{15}N substitution. However, this finding is not in any "conflict" with the decrease of the frequency of this line in the deaza-derivatives,[71] since a different system of conjugated bonds is formed on replacement of the N(1) and N(5) atoms by carbon atoms.

Bands VIII and IX. The very weak lines at 1302 cm^{-1} (VIII) and 1282 cm^{-1} (IX) are almost insensitive to isotope substitution.

Bands X, XI, XII, and XIII (1255, 1228, 1182, and 1160 cm^{-1}). The greatest changes occur in this group of bands on replacement of the N(3)H proton by deuterium and were noted in the very early studies;[58] not only the line frequencies but also the relative line intensities change significantly under these conditions (Fig.6). Evidently the $\nu = 1295$ cm^{-1} band is the analogue of the intense 1255 cm^{-1} band in the spectrum of the deuteriated specimen. The increase of the frequency by more than 40 cm^{-1} is usually explained, after Kitagawa,[61] by the breakdown of the "resonance" interaction of the C–N stretching vibration (tentatively at 1290 cm^{-1}) with the in-plane NH deformation vibration, which reduces this frequency in the non-deuteriated specimen.§ However, we may note that the idea of "resonance" in interactions of the vibrations is altogether unnecessary for the explanation of the observed changes. Evidently, the frequency considered can increase even as a result of a slight involvement of the fairly rigid N–D bond when the amplitude of the stretching vibration of the deuterium atom is large. If this hypothesis is correct, then the replacement of the N(3)H hydrogen by the methyl-group should entail an increase in frequency, which has been observed experimentally for *N*(3)-methyl-lumiflavin.[70] It is evident from these ideas that the change in the 1255 cm^{-1} frequency can serve as a criterion of the strength of the hydrogen bonding of the N(3)H group of flavin with the solvent or the aminoacid residues in the active centre of the protein; the frequency should increase as a result of the increase of the effective rigidity of the C–N(3)–H angle as a consequence of the additional binding of the hydrogen atom (see below).

Among the remaining bands of this group, the 1179 cm^{-1} band partly corresponds to the most "delocalised" vibration. The 1179/1160 cm^{-1} band pair undergoes an appreciable change in the relative intensities on isotope substitution[67] also in *N*(3)-derivatives[61] and also on substitution by heavy atoms in the 7- and 8-positions.[61] Evidently any kind of reliable assignments in this region are impossible without a reliable calculation of the normal vibration frequencies; there appears to be little justification for the scheme of frequency shifts on deuteriation proposed by Schmidt et al.[64] (with the exception of the 1255 → 1290 cm^{-1} shift discussed above). Data for the region below 1100 cm^{-1} have also been obtained;[67] the greatest isotope shifts are apparently localised in ring II and have been observed for the 834 cm^{-1} band, while the greatest shifts on deuteriation are those of the 789 and 496 cm^{-1} frequencies.

The Hydrogen Bonds Involving the Isoalloxazine Ring in the Active Centres. Since the prosthetic flavin group does not in most cases form a covalent bond with apoprotein, hydrogen bonding is important for the stabilisation of the structure. The change in the distribution of electron density in the isoalloxazine ring on formation of hydrogen bonds is evident from the changes in the electronic absorption spectra in model systems (see Yagi and co-workers[73,74] and the references in the latter communication). As already mentioned, the frequencies and intensities of the bands in the range 1160–1300 cm^{-1} are sensitive to hydrogen bonds in the resonance Raman spectra. The hydrogen bonding of flavins has been studied experimentally by Schmidt et al.,[64] who compared the spectra of model flavins in H_2O (a powerful hydrogen bond donor and acceptor), dimethyl sulphoxide (DMSO) (a polar solvent which is a weaker acceptor than H_2O), and acetonitrile (a polar solvent). Potassium iodide was added to suppress fluorescence. On passing from aqueous solutions to DMSO, a change in the relative intensities of bands II and X and a decrease of the frequency of band X were noted. In the subsequent discussion the weak 1281 cm^{-1} band was used as an "indicator" of hydrogen bonding; however, it has been shown[67] that the corresponding vibration is insensitive to any kind of isotope substitution in rings III and II, i.e. at the sites where the hydrogen bonds are localised.

On the basis of these model studies, the authors attempted to examine the hydrogen bonds in the active centres of three FAD-containing flavoproteins of different classes and reached the following conclusions: (1) the acyl-CoA-dependent general aliphatic acid dehydrogenase is characterised by a "somewhat reduced" hydrogen bonding compared with FAD in H_2O; (2) acyl-CoA-oxidase does not form at all or forms only weak hydrogen bonds in all the potential N(1), N(5), C(2)=O, C(4)=O, and N(3) hydrogen bonding centres; (3) glutathione reductase is bound to the same extent as the free FAD group in water.

However, examination of the data of Schmidt et al.[64] (Fig.8) shows that the real situation is much more complex than the above simplified picture. In the case of acyl-CoA-dehydrogenase, the 1253 cm^{-1} band has an unusually high intensity, which may be a result of strong hydrogen bonding. X-Ray diffraction data have not as yet been obtained for acyl-CoA-oxidase, but the paradoxical conclusion that there is no hydrogen bonding in flavins of this class conflicts both with the entire experience gained in the steric studies on flavoproteins[34] and with the UV spectroscopic data.[74] An attempt has been made[74] to estimate the influence of hydrogen bonding on the electronic transition energies and absorption band intensities by modelling the hydrogen bond involving the heteroatom in the isoalloxazine ring (O or N) in the MO SCF calculation by variations in the ionisation potential of the valence state. The authors carried out calculations in this way for all the possible variants of hydrogen bonding; in the light of these results, the experimental electronic spectroscopic data for oxidases should correspond to a strong hydrogen bond at N(5).[74] The resonance Raman spectrum of glutathione reductase in the region 1300–1200 cm^{-1} has a complex contour made up of four incompletely resolved bands,[64] which differs completely from the picture for free FAD in aqueous solution. The resonance Raman

---

§ As already mentioned, this shift has an analogy with that observed in the Raman spectrum of uracil;[72] however, the increase of the frequency in the latter on deuteriation is only by 16 cm^{-1}.

spectroscopic data refer to glutathione reductase from yeast; the three-dimensional structure of the glutathione reductase from erythrocytes has been determined recently with a high resolution;[36,37] in this complex protein the isoalloxazine ring brings the subunits into contact by means of hydrogen bonding between the N(3)H proton of the FAD in one subunit and the histidine residue in the main chain of another subunit; the N(1) and N(5) atoms form strong hydrogen bonds with the aminoacid residues of the active centre. Since glutathione reductase contains two FAD domains, it is quite possible that the complex contour of the resonance Raman spectrum can be accounted for by certain differences in the orientation and strength of the hydrogen bonds of the two isoalloxazine rings.

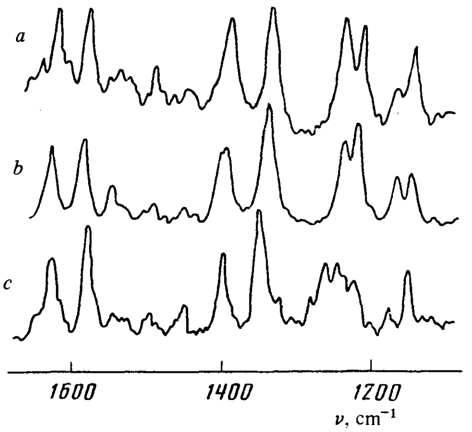

Figure 8. The resonance Raman spectra of aqueous solutions of certain flavoproteins:[64] *a*) acyl-CoA-dependent general aliphatic acid dehydrogenase (pH 8.4; λ = 488 nm); *b*) aliphatic acid acyl-CoA-oxidase (pH 8.0; λ = 488.0 nm); *c*) yeast glutathione reductase (pH 7.6; λ = 514.5 nm).

Flavodoxins. Flavodoxins are the smallest of the FMN-containing proteins; both long (~170 aminoacid residues)[75] and "short" (138 [35] and 148 [76] residues) flavodoxins fulfil identical biological functions; they transport one electron to other flavin systems, proteins with Fe/S centres, or haemoproteins. The two one-electron oxidation-reduction potentials of these molecules differ significantly, which makes it possible to characterise three forms; the oxidised form, the semiquinone (radical), and a reduced form, which makes the flavodoxins convenient model compounds. The resonance CALS spectra with excitation frequency of the long-wavelength absorption band have been obtained[66,78] for representatives of two classes of flavodoxins isolated from the bacteria *Clostridium* and *Desulfovibrio*, which differ in the aminoacid sequences, electronic spectra, and ability to bind riboflavin.[77]

High-resolution X-ray diffraction data are available for the same proteins,[35,76,79] which permits a comparison with the possible interactions with the resonance Raman spectroscopic parameters. It has been shown for flavodoxins of both types that the ribityl component "immersed" in the protein environment forms strong hydrogen bonds with the latter. The planar isoalloxazine ring is disposed nearer to the surface of the globule, but its contacts with the solvent or with an electron donor are strictly limited by the protein environment, which "closes" the pyrimidine and central pyrazine windows, so that only the dimethylbenzene component is accessible to external contacts. Fig. 9 illustrates the system of hydrogen bonds postulated for FMN in the active centre of the *Desulfovibrio vulgaris* flavodoxin.[76] Evidently, with the exception of N(1), all the donor and acceptor atoms are hydrogen-bonded, i.e. the situation in this instance is analogous to FMN in an aqueous environment. Nevertheless, on comparing the CALS spectrum (Table 3) of this flavodoxin with the spectrum of FMN in H_2O, the authors[66] noted a change in frequencies (cm^{-1}): 1629 (free)–1624 (bound); 1582–1573; 1412–1407; 1261–1251; 1233–1227; 1192–1185. The intensity of certain bands changes even more appreciably than the frequency, which is particularly notable in the region 1100–1300 cm^{-1}. As already mentioned, the low frequency (1251 cm^{-1}) and the low intensity of this line

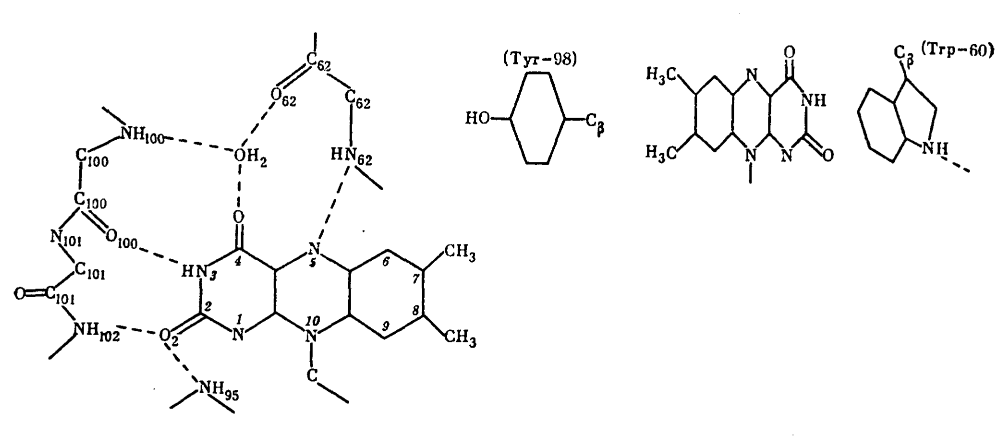

Figure 9. A tentative system of hydrogen bonds of the isoalloxazine ring in the active centre of the flavodoxin of *Desulfovibrio vulgaris*;[76] the numerals represent the numbering of the aminoacid residues in the protein chains; slight rotation of the residue 62 permits the formation of a hydrogen bond with the N(5) atom; the orientation of the flavin relative to the tryptophan and tyrosine residues is shown above.

most probably indicate a decrease of hydrogen bonding along the section C(2)O–N(3)–C(4)O. Among the remaining differences, the decrease of the frequency and intensity of the 1571 cm^{-1} band are the most significant; bearing in mind the sensitivity of the corresponding vibration to isotope substitution,[67] one can postulate a change in electron density in ring II as a result of the binding of N(5). However, there is also another possibility; the isoalloxazine ring in the active centre of flavodoxin is sterically close to the indole ring of the tryptophan-60 residue and the aromatic ring of tyrosine-98 (Fig.9). It is known that the intense fluorescence of the FMN in flavodoxins is entirely quenched; a stacking interaction of the isoalloxazine ring with tryptophan has been suggested as the quenching mechanism.[79] One cannot rule out the possibility that the change in the intensity of the 1573 cm^{-1} band is associated with an interaction of this type. However, we may note that the flavin and indole rings are in this case non-coplanar and make an angle of 45°, which renders the charge-transfer interaction problematical.

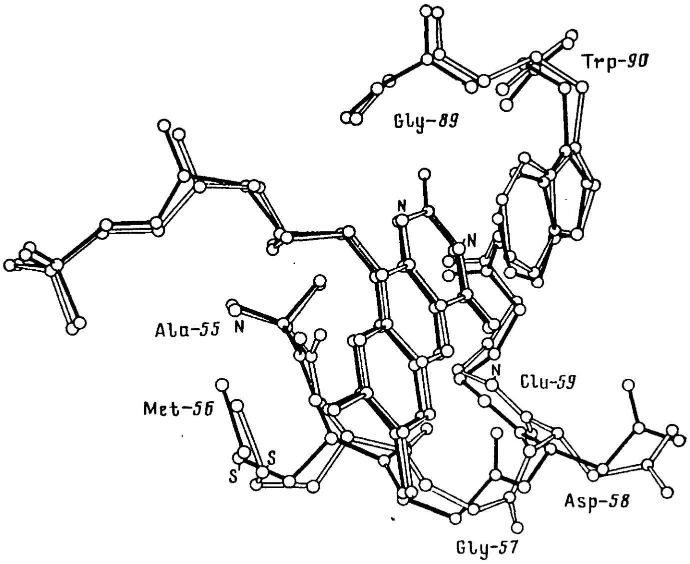

Figure 10. The orientation of the aminoacid residues 55–59 and 89–90 relative to the isoalloxazine ring in the active centre of the oxidised (light lines) and semiquinone (dark lines) form of the flavodoxin of *Clostridium MP.*[35]

Another flavodoxin from a *Desulfovibrio* of the same class (*Desulfovibrio gigas*), whose three-dimensional structure is unknown, has also been investigated by resonance Raman spectroscopy.[66] While the aminoacid compositions of the *gigas* and *vulgaris* flavodoxins are similar, their abilities to bind FMN were found to be different.[75] The CALS spectra demonstrate unambiguously that the immediate environment of the FMN in the active centres of the two proteins considered should be completely identical.[66]

A representative of another class of flavodoxins (from *Clostridium*), fulfilling analogous biological functions, differs significantly in many details of the environment of the isoalloxazine ring, whilst there is an overall homology of the three-dimensional structure with those of the proteins of the *Desulfovibrio* type examined above and the binding of the ribityl phosphate component is very similar.[35,79] However, despite the differences in the chemical sequences, in the active centres of proteins of these classes there is a considerable analogy of the steric structures, which apparently in fact plays a decisive role in their functioning. In the *Clostridium* flavodoxin the pyrimidine and pyrazine rings are likewise "close", the typtophan-90 residue is close to the pyrimidine component (at an angle of 27°), and the orientation of the Gly-57 residue, the interaction with which is tentatively believed to stabilise the semiquinone form (see below), is equivalent to the orientation of Gly-61 in the *Desulfovibrio* flavodoxin.[76] The CALS spectrum of the *Clostridium* flavodoxin[78] is in general similar to the spectra of the *Desulfovibrio* proteins obtained under the same excitation conditions (ω_1 = 480 nm[66]); a decrease of the frequency and intensity of the 1577 cm^{-1} line (tentatively assigned to the flavin–tryptophan interaction) is observed in this case also, but the changes in the relative intensities of the bands in the range 1100–1300 cm^{-1} indicate a different character of the hydrogen bonding in the active centre of the *Clostridium* flavodoxin. The high quality of the CALS spectrum,[78] for which the authors were able to obtain reliable data in the region below 1000 cm^{-1}, is noteworthy. The character of the low-frequency section of the spectrum proved to be significantly different than for free FMN.[63] There is no doubt that analysis of the low frequencies made it possible to obtain subsequently additional information about the electronic rearrangements and interactions of the prosthetic flavin group in the active centres of the proteins.

The Semiquinone Form. A key property of flavoproteins, as one-electron transferring agents, is the thermodynamic stabilisation¶ of the intermediate radical state—the so-called

---

¶ See, for example, the references in the paper of Smith et al.[35] concerning the association of the semiquinone form with the particular protein compared with the oxidised form on energy grounds.

semiquinone form (Fig.3). The electronic absorption spectra of model systems and flavoproteins with a stabilised semiquinone form contain intense bands due to the $\pi \rightarrow \pi^*$ transitions in the range 500–600 nm (Fig.5),[55] which indicates the retention by the isoalloxazine ring of the planar structure characteristic of the oxidised form; this is also demonstrated by the electronic nuclear double resonance (ENDOR) spectra.[80] These conclusions have been fully confirmed by X-ray diffraction data.[35]† It follows from Fig.10, where the disposition of the aminoacid residues closest to the flavin in the active centre is illustrated for the oxidised and semiquinone states of the flavodoxin, that the formation of the semiquinone form is unaccompanied by any radical changes in the orientation of the isoalloxazine ring in the active centre. At the same time the conformational rearrangements of certain aminoacid residues, particularly along the Gly-57–Asp-58 section, are apparently decisive for the stabilisation of the semiquinone. A special role has been attributed[35] to the change in the orientation of the Gly-57 residue by approximately 180°; as a result, conditions are created in the semiquinone for the formation of the N(5)...O (Gly-57) hydrogen bond and the dissociation of the O(4)...NH (Asp-58) hydrogen bond, which may exist in the oxidised form. According to Smith et al.,[35] the N(5)...O (Gly-57) binding is a decisive stabilising factor;# the shift of the atoms of the other residues in the active centre (with the exception of Asp-58) is on average 0.5 Å; the orientation of the tryptophan residue relative to the plane of the isoalloxazine ring also changes somewhat. We may note that these conformational rearrangements fully correspond to 3.4 kcal mol^{-1}—the preferential energy of the association of the semiquinone form relative to the oxidised form. A study[55] of the polarisation absorption spectra of flavodoxin crystals showed that the electronic α- and β-transitions in the oxidised and semiquinone forms (in terms of the author's notation[55]) are linearly polarised in the plane of the flavin ring with the direction of the transition moment closer to the N(5)–N(10) axis (Fig.6) for both the α- and β-bands. The most interesting conclusion reached by the above investigators[55] is that, in the electronic spectra of the semiquinone structure, both low-energy $\pi \rightarrow \pi^*$ transitions take place between orbitals of the same type as in oxidised FMN. This hypothesis is apparently confirmed by the following experimental observations:[55] (1) similar band polarisation ratios; (2) similar β-band contours and similar frequencies observed in the diffuse vibrational structure of the α-band (the 0–0 and 0–1 transitions respectively at 21000 and 22000 cm^{-1}) for the oxidised form and at 1620 and approximately 17300 cm^{-1} for the semiquinone form; (3) similar correspondingly normalised intensities. The identical signs for the α- and β-bands observed in the circular dichroism spectra of both forms and the similar anisotropies of the transitions may also serve to support the above hypothesis.[81] Thus if the hypothesis is valid, the formation of the semiquinone structure should be represented by the addition of one electron to the unoccupied π orbital of the oxidised form without a significant redistribution of electron density.

Apart from the information about the change in electron density in the semiquinone, the identification of this structure on the basis of Raman spectroscopic data may prove to be especially useful also because the manifestations of the semiquinone form in the electronic spectra of flavoproteins are frequently similar to those observed on formation of charge-transfer complexes (see, for example, Massey and Hemmerich[43] and the references quoted therein). The resonance Raman spectra have now been obtained for the semiquinone forms of two proteins, namely flavodoxin[78] and the riboflavin-binding protein,[82] and also for the semiquinone forms of FMN and FAD stabilised by the methylation of the N(5) atom.[83] As might have been supposed, the change in bond orders in ring II led to changes in almost all the vibration frequencies of the flavin system (Table 4). On excitation in the region of the β-transition of the semiquinone (λ = 514.5 nm; Fig.11), the 1611 cm^{-1} band predominates in the spectrum;[83] as the α-transition is approached, its intensity diminishes[82] and, after excitation at the frequency corresponding to the long-wavelength slope of the absorption α-band, the band at approximately 1340–1370 cm^{-1} becomes most intense.[83] It has been suggested[78,83] that the intense 1611 cm^{-1} line of the semiquinone is an analogue of the 1580 cm^{-1} line of the oxidised form and that the corresponding vibration is localised mainly in ring II. However, bearing in mind the reduced bond orders in ring II and also the displacement of the unshared electron pair of the N(5) atom from the conjugation system on formation of the semiquinone structure, a decrease (and a fairly large one) of the corresponding frequency might

†The "folding" angle relative to the N(5)–N(10) axis (Fig.5) is 2.5° in the semiquinone.[35]

#In the flavodoxins of the *Desulfovibrio class*,[76] this role is fulfilled by the Gly-61 residue; the H(62)–O(4) bond is possible in the oxidised form of the protein.

have been expected. Furthermore, the 1611 cm^{-1} line is almost insensitive to either methylation of the N(5) atom[83] or to the deuteriation of the semiquinone structures in which an exchangeable proton is present at the N(5) atom.[78,82] Thus the resonance Raman spectra can be used as a reliable criterion in the identification of the semiquinone structure, which has in fact been done[84] in studies on the NADP complex with adrenodoxin reductase. However, the Raman resonance spectroscopic data obtained hitherto cannot be used to either confirm[78,83] or reject Eaton's hypothesis.[55] In order to solve this problem, detailed studies of the dependence of the resonance Raman lines on the exciting frequency (the excitation spectra) in the region of the α- and β-electronic transitions of the semiquinone are necessary. On the other hand, the proposed correlations of the resonance Raman frequencies of the semiquinone and oxidised structures[83] can be reliably established only on the basis of data for isotope-substituted specimens.

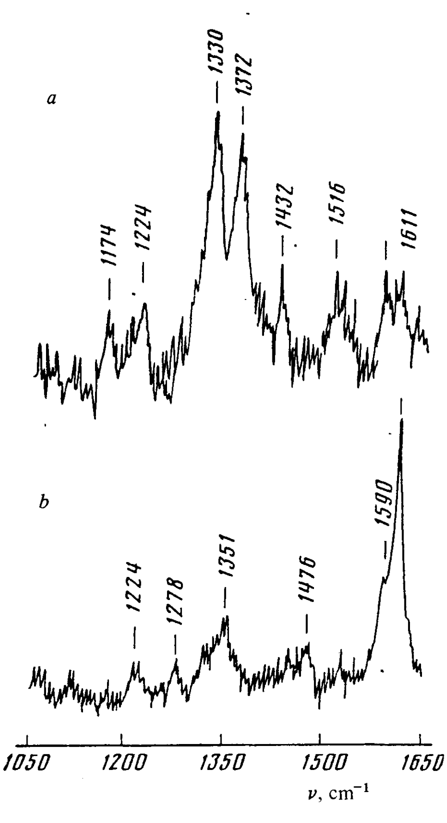

Figure 11. The spectra of *N*(5)-methyl-FAD in the semiquinone form; spontaneous RRS; excitation wavelengths (nm): *a*) 647.1; *b*) 514.5.[83]

Reduced Flavins. The fully reduced isoalloxazine ring undergoes electronic transitions at shorter wavelengths than the oxidised and semiquinone forms (Fig.12), a factor making difficulties in the measurement of the resonance Raman spectra. The latter have been obtained comparatively recently only for structures where the reduced form gives rise to a charge-transfer complex. The so-called "purple complexes", formed at the intermediate stages of the reaction of D-aminoacid oxidase (DAO) with D-alanine and D-proline, have been investigated.[85-88] These complexes have a characteristic long-wavelength absorption extending to approximately 750 nm. On excitation with light at wavelengths in the region of the long-wavelength band, a resonance intensification of the lines of both the substrate (alanine and proline) and of the active centre of the enzyme (FAD) was observed. Using numerous verions of isotope substitution in the isoalloxazine ring and in the substrate molecules, the authors[85-88] assigned the frequencies with exceptional reliability and demonstrated that, (1) the isoalloxazine ring in the purple complex exists in the fully reduced form, (2) the ~1605 cm^{-1} vibration of the flavin, which intensifies more than others on excitation at wavelengths corresponding to the charge-transfer band, is localised in the C(10*a*)–C(4*a*)–C(4) = 0 fragment, and (3) the 1692 cm^{-1} band in the complex with D-alanine and the 1658 cm^{-1} band in the complex with D-proline refer to the C=N§ stretching vibrations of aminoacids, which are thus involved in the imino-form in the complex formation reaction. An interesting and hitherto unexplained feature of the complexes with D-alanine is the sensitivity of the ~1540 cm^{-1} line to isotopic substitution in both the substrate molecule and in FAD.[88]

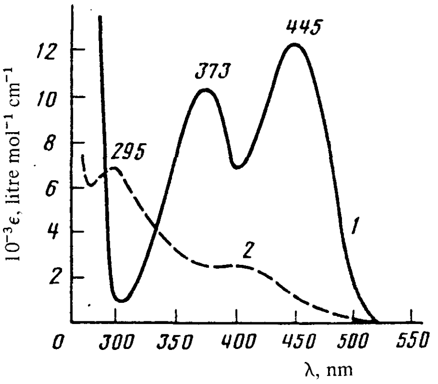

Figure 12. The electronic absorption spectra of the fully oxidised (curve *1*) and fully reduced (curve *2*) forms of FMN.[43]

The resonance Raman data obtained provide direct evidence that the C(10*a*)–C(4*a*)–C(4)=O fragment of reduced FAD in the purple complex is in close contact with the HN = C–COO⁻ plane of the substrate, ensuring an interaction of the charge-transfer type.

Charge-Transfer Complexes. One of the most important features which is apparently essential for the functioning of many flavin systems is their ability to form charge-transfer complexes (CTC); such complexes are formed by almost all flavoenzymes containing pyridine nucleotide.[89] Data obtained recently on the three-dimensional structure of glutathione reductase[36,37] confirmed that the NADP ring in the active centre is indeed located above the isoalloxazine ring in a conformation favourable for the formation of a

---

§ The changes in these frequencies in the deuteriated specimens indicate an appreciable involvement of δ(NH) in the vibration.

charge-transfer complex. Certain flavo-proteins are known to be capable of undergoing charge-transfer interactions also with other substrates, in particular with benzene derivatives.[89] The mechanisms of the formation of such complexes, their structure, and their catalytic value are still in many respects obscure. The formation of CTC of flavins is usually inferred from the appearance of a long-wavelength absorption in the range 500–700 nm, which is accompanied as a rule by a decrease of the intensity of the α- and β-bands, but these changes, as already stated, are extremely similar to those observed for semiquinone flavin structures. Resonance Raman spectroscopic data have been obtained recently for a series of model CTC of flavoproteins: it is now already evident that the resonance Raman spectra make it possible to identify reliably the CTC of flavins and can yield, in principle, unique information about the structure and about the site of the charge transfer.

The first model for the study of the CTC of flavins was the so-called old yellow enzyme (OYE) containing the FMN prosthetic group. In nature, this protein exists in the "green" form—a complex with *p*-hydroxybenzaldehyde;[90] it is also capable of forming artificial complexes with a wide variety of aromatic and heteroaromatic derivatives containing hydroxy-groups.[43,90] Japanese workers[91,92] investigated the resonance Raman spectra of the products of the interaction of OYE with a set of substituted phenols on excitation at the wavelength corresponding to the long-wavelength absorption band. Analysis of the data obtained shows in the first place that, in the complexes investigated, the flavin is present in the oxidised state; the 1628, 1585, 1548, 1415, 1356, 1260, and 1160 cm^{-1} bands present in the spectra of all the specimens have virtually the same frequencies as in the spectra of FMN and riboflavin. At the same time a resonance intensification of the bands (especially in the low-frequency section), specific to the substituted substrate, is observed in the resonance Raman spectra at 477, 390, 475, 386, and 547 cm^{-1} respectively for *p*-CH_3, *p*-Cl, *p*-F, *p*-NO_2, and other substituted phenols respectively. In the high-frequency region, it is also possible to identify bands referring to the phenolic component, which is especially apparent for complexes with pentachloro- and pentafluorophenols.[92] Studies on the frequency dependence of certain resonance Raman lines in the charge-transfer band[92] have shown that the 1588 cm^{-1} frequency of isoalloxazine and the 1475 and 454 cm^{-1} frequencies of phenol make the greatest contribution to the vibrational structure of the long-wavelength electronic absorption band (Fig.13).

In this case the spectra do not exhibit frequencies referring directly to the C–OH fragment of phenol, which is characteristic of, for example, the complexes of the phenoxide anion with metals, but the interaction takes place locally via the phenolic oxygen atom. The character of the dependence of the intensity on the excitation frequency $I(\nu)$ for the 1588 cm^{-1} line[92] yields direct evidence for charge transfer to the flavin ring. Since the corresponding vibration is associated predominantly with the N(5)–C(4*a*)–C(10*a*) fragment, these data make it possible to infer the location of the charge transfer. The occurrence of such interaction requires a sandwich conformation with parallel isoalloxazine and phenol rings. The constancy of the frequency of the 1588 cm^{-1} band (as for the remaining frequencies of the isoalloxazine ring) shows that all the changes in electron density refer exclusively to the excited state of the molecules. The greatest charge transfer occurs in the complex with *p*-nitrophenol, which can be inferred from the change in the distribution of intensities in the resonance Raman spectrum.

The same characteristic features have been noted in the resonance Raman spectra of the charge-transfer complexes of other flavoenzymes obtained at present. In the study of the complexes of the CoA-dependent aliphatic acid dehydrogenase (containing FAD) with acetoacetyl-coenzyme A, the authors observed a resonance intensification of the 1586 and 1550 cm^{-1} lines,[94] confirming thereby the fact that the electron transfer in the interaction with the most varied donors is directed to the N(5) and C(4*a*) centres of the isoalloxazine ring, in agreement with quantum-chemical calculations.[95] Artificial complexes of D-aminoacid oxidase with amino- and hydroxy-benzoates have also been studied:[96] the latter are known to be effective inhibitors of the enzyme. On excitation at the frequency corresponding to the long-wavelength absorption band (λ = 632.8 nm) of the complex of DAO with *o*-aminobenzoate, the 1583 cm^{-1} (isoalloxazine ring) and 568 cm^{-1} (*o*-aminobenzoate) lines were observed. It is of interest that resonance intensification has not been observed for the *meta*- and *para*-aminobenzoates, which indicates severe conformational limitations in the formation of the CTC.

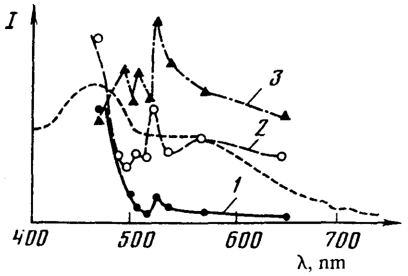

Figure 13. Dependence of the intensity of certain spontaneous resonance Raman lines of the complex of old yellow enzyme with pentachlorophenol on the frequency of the exciting light; the intensification of the lines of the flavin component [*1*) 1628 cm^{-1}; *2*) 1588 cm^{-1}] and the ligand [*3*) 1475 cm^{-1}] can be seen; the contour of the absorption band is shown by a dashed line.[92]

In the reaction of pig liver DAO with β-cyano-D-alanine, the intermediate stages also consist of CTC of the oxidised flavin according to resonance Raman spectroscopic data.[97] We may note that, in the spectra of all the DAO complexes investigated, the "hydrogen bond indicator" band is at 1240 cm^{-1},¶ [96,97] i.e. is appreciably displaced towards lower frequencies compared with other flavins, which indicates extremely specific interactions of FAD with the DAO apoprotein. Charge-transfer complexes have been identified also in the intermediate stages of the anaerobic reduction of adrenodoxin reductase by the NADP coenzyme.[98]

Metal Complexes. The problem of the interaction of flavins with metals is important for the understanding of the mechanisms of the functioning of flavoproteins containing Fe/S centres and also molybdenum.[99] The model complexes of FMN with silver and ruthenium[100] and the complexes of the riboflavin-binding protein (RBP) and 10-methylisoalloxazine with ruthenium(II) have been investigated.[100,101] The electronic absorption spectra of the silver(I) complex of FMN contain a weak shoulder at approximately 530 nm on the

---

¶ The assignment of this band in the spectra of the DAO complexes has been confirmed by the 1242 → 1284 cm^{-1} shift on deuteriation.

long-wavelength slope of the α-band, while an intense band at ~630 nm appears in the spectra of the complexes $(NH_3)_4Ru^{II}$ (Fig.14).

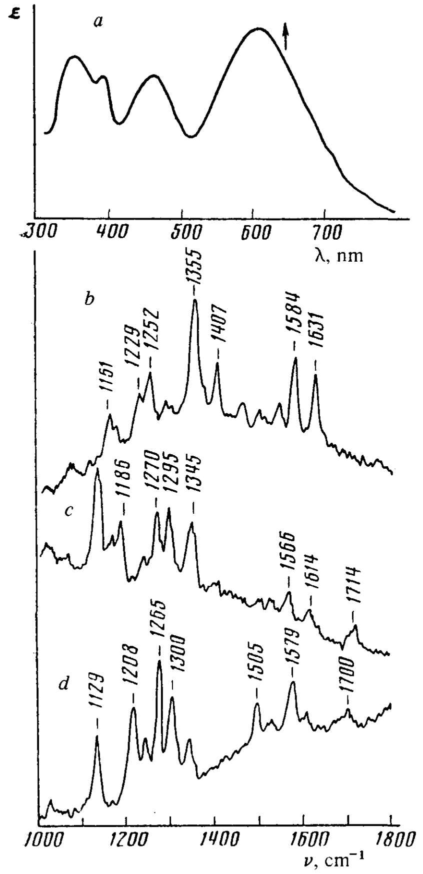

Figure 14. The electronic absorption spectrum of the complex of the riboflavin-binding protein with $Ru^{II}(NH_3)_4$ (*a*) and the spontaneous resonance Raman spectra: *c*) the RBP–$Ru^{II}(NH_3)_4$ complex; *d*) the complex of $Ru^{II}(NH_3)_4$ with 10-methylisoalloxazine; excitation at $\lambda = 647$ nm (indicated by an arrow on the absorption spectrum) was used in both cases; *b*) the spectrum of RBP ($\lambda = 488.0$ nm) is presented for comparison.[101]

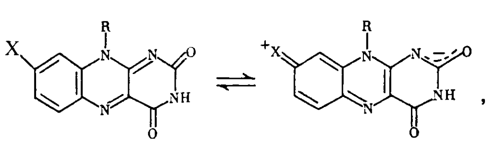
The resonance Raman spectroscopic data may permit the conclusion that the interaction in the Ag^+ FMN complex is of the charge transfer type. Apart from the N(5) atom (whose involvement can be inferred from the increase of the intensity of the 1580 and 1540 cm^{-1} lines), the oxygen atom closest to N(5) apparently also participates in the reduction; this is indicated by the changes in the symmetric and antisymmetric vibrations of the carbonyl groups in the infrared spectrum of the complex Ag^+ FMN.[100] On formation of the complex of $Ru^{II}(NH_3)_4$ with RBP,[101] the frequencies and relative intensities of almost all the lines in the resonance Raman spectrum are altered. The frequencies and particularly the distribution of the intensities on excitation at 647.1 nm (Fig.14) resemble most closely those observed for the semiquinone form (Section 5). However, this hypothesis requires further tests. It is of interest that bands at ~1700–1710 cm^{-1}, referring to the carbonyl groups, are manifested in the resonance Raman spectrum of Ru^{II}RBP as well as in the spectrum of the model ruthenium(II) complex of 10-methylisoalloxazine.[101]

The data obtained for the model metal complexes established[102] that there is no direct electron transfer between the Fe/S cluster and the flavin in the ETF hydrogenase,† an FAD-containing flavoprotein, which incorporates Fe/S centres and functions in the electron transport chain, although such transfer might have been postulated on the basis of the EPR spectra (see the references in the paper of Schmidt et al.[102]).

Modified Flavins. As already mentioned, in many cases the prosthetic group of the flavin can be readily separated from the protein without its denaturation, modified by the introduction of substituents, and then rejoined to the apoprotein. Such modifications have been widely used to obtain information about the interaction of the flavin with the protein, mainly from kinetic data—the binding constants, the changes in catalytic activity, and the changes in the electronic and circular dichroism spectra. The 1- and 5-deaza-derivatives or substitution of the methyl groups in the 7- and 8-positions are most often used for such purposes.# Evidently the results obtained cannot as a rule be interpreted unambiguously, since several factors can change simultaneously in the modified compound: the conformations of several aminoacid residues in the active centres (and hence the character of the interactions with the prosthetic group), the steric conditions for the approach of the substrate, and finally, the electronic structure of the isoalloxazine ring itself. Extensive data have been obtained recently on the resonance Raman spectra of modified flavins, both free and bound to different proteins,[65,70,71,103,104] which makes it possible, in principle, to differentiate these factors. It follows from resonance Raman spectroscopic data that the presence of halogen atoms in the 7- and 8-positions changes little the distribution of electron density in the isoalloxazine ring; the changes in the resonance Raman spectra[70] can be accounted for in this instance by the mass effect. However, the introduction of groups containing unshared electron pairs (the hydroxy-, amino-, or mercapto-groups) in these positions leads to radical changes in the resonance Raman spectroscopic parameters (Fig.15). It had been suggested earlier on the basis of UV spectroscopic data (see Massey and Hemmerich[43] and the references quoted therein) that tautomeric (sic) transformations of the type



(I) (II)

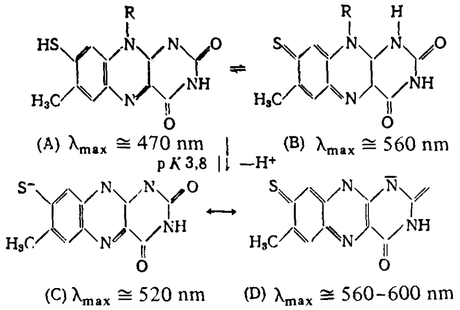
i.e. equilibrium between the benzenoid (I) and quinonoid (II) forms, are possible for compounds of this kind. In all cases the bathochromic shift and an increase of the intensity of the long-wavelength absorption band were noted for the suggested quinonoid structure.

---

†ETF = electron-transporting flavoprotein.

#In the flavoproteins with known structures,[35,36] the isoalloxazine ring is oriented in such a way that the benzene component and the 7- and 8-methylgroups are on the "surface" and are least in contact with the aminoacid residues of the active centre. This apparently actually accounts for the ease of the binding of the 7,8-modified analogues to the protein.

A large decrease of the frequencies of bands II and III (by 30–40 cm^{-1}), changes in the range 1400–1200 cm^{-1}, and the appearance of a whole series of new bands in the range 1100–1000 cm^{-1} are characteristic of the resonance Raman spectra of these derivatives (Table 5). The changes are especially large in the resonance Raman spectra of 8-mercaptoflavins exhibiting a long-wavelength absorption (λ_{max} = 500–600 nm), greatly exceeding in intensity the absorption by other derivatives (Fig.16). In conformity with UV spectroscopic data, the following tautomeric structures have been proposed for 8-mercaptoflavins as a function of the environment and the ionisation potential:[43]



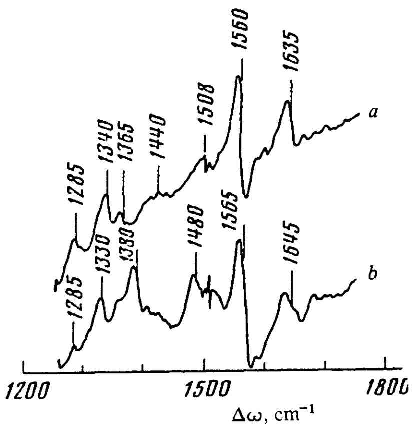


Figure 15. The inverse spectra (resonance excitation) of 8-aminoriboflavin (*a*) and 8-hydroxyriboflavin (*b*) at pH 7.3.[65]

The resonance Raman spectra of mercaptoriboflavin in various states have been obtained.[103] It follows from these data that the frequencies of lines I and II for the protonated form (pH 2) are reduced (by 9 and 14 cm^{-1} respectively relative to the riboflavin), but the constancy of the positions of the remaining lines and, what is more significant, of the distribution of the band intensities indicate the retention of the "benzenoid" character of the electron density, as in the halogeno-derivatives.[70,104] According to resonance Raman data, 8-mercaptoriboflavin[103] and 8-methylmercaptoriboflavin[104] add precisely in this form to the riboflavin-binding protein. The transition to conditions for the formation of the anionic (thiolate) form (C) (accompanied by a bathochromic shift of the absorption band) leads to radical changes in the resonance Raman spectrum, in which the 1616 and 1545 cm^{-1} bands are dominant; the latter band is usually regarded as an analogue of the 1584 cm^{-1} band of the oxidised form, the corresponding vibration being localised in the N(5)–C(4*a*)–C(10*a*) section[67] and it is therefore regarded as an indicator of the double bond character of this fragment.[65,103] The large decrease of the frequency of line II has been interpreted in all investigations as evidence for the decrease of the order of the π-bonds in this section of the isoalloxazine ring and as decisive evidence in support of the quinonoid structures (B) and (D). The study of the variation of the frequency of the 1545 cm^{-1} band[103] has shown that the corresponding normal vibration does indeed contribute to the long-wavelength electronic transition. However, we may note that no convincing evidence has been obtained so far in support of the fact that this vibration is localised in the same fragment as the 1584 cm^{-1} vibration of the oxidised form.

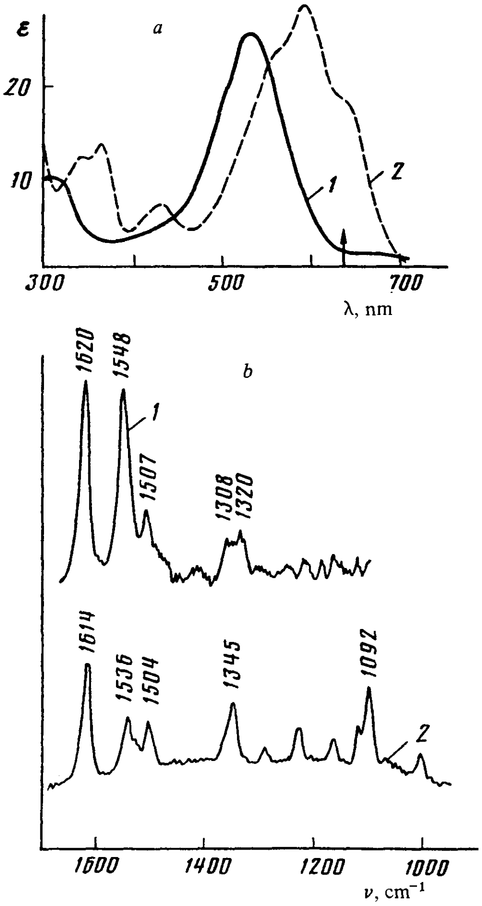

Figure 16. *a*) The electronic absorption spectra of modified flavoproteins: *1*) 8-mercaptoflavodoxin; *2*) D-aminoacid 8-mercapto-oxidase;[43] *b*) the spontaneous resonance Raman spectra: *1*) 8-mercaptoriboflavin (pH 8.4; λ = 514.5 nm); *2*) lactate 8-mercapto-FMN-oxidase (pH 7; λ = 632.8 nm).[65]

It had been noted earlier that the binding of 8-mercapto-FMN by certain proteins does not entail significant changes in the colour of the "red thiolate" form (flavodoxin),[105] while the addition of the modified prosthetic group to lactate oxidase, glucose oxidase, *D*-aminoacid oxidase, and old yellow enzyme results in a change of the red colour to a deep blue colour (Fig.16).[105] Since all the flavoproteins enumerated belong to the class of oxidases, it has been suggested that oxidases stabilise the "blue benzoquinone" structure (D) and that the presence of the aminoacid residue, stabilising the negative charge on the N(1)–O(2) section of isoalloxazine, in the active enzyme centre of the oxidase is essential:

Note. RF = riboflavin; RBP = riboflavin-binding protein.
[a] The discrepancies with the data of Nishina et al.[70] for RBP do not exceed ~2 cm^{-1}. [b] The data of Dutta et al.[71] are given in brackets.

The resonance Raman spectra of the "blue benzoquinone" structures have been obtained by Schopfer et al.[65] (Table 6). The spectrum of 8-mercapto-FMN lactate oxidase excited at λ = 632 nm (denoted by an arrow) is illustrated in Fig.16; the data for glucose oxidase and old yellow enzyme are presented in Table 6. These results demonstrate that the same electronic structure of the 8-mercaptoflavin prosthetic group, differing appreciably from the traditional hydroxy-form of riboflavin, FMN, and FAD, is characteristic of all the proteins enumerated. Certain changes in the frequencies of the principal bands within the limits of each spectrum evidently reflect the specific features of definite protein–flavin interactions in the active centre of the enzyme. In the literature these spectra have been interpreted as referring to the "fully quinonoid" structure (D),[65] while the spectra of derivatives of 8-hydroxy, 8-amino-, 8-mercapto-,[65] 8-methylamino-,[71] 8-methoxy-,[70] and 8-methylthio-riboflavins[104] are thought to be "intermediate" between those corresponding to the typical quinonoid and benzenoid structures with "greater" or "lesser" quinonoid character.[65] Apart from a number of discrepancies (the differences between the resonance Raman spectra of derivatives for which identical "contributions" by the quinonoid structure have been predicted on the basis of electronic spectra,[43,65] a significantly "benzenoid" distribution of intensities in the case of the 8-methoxy- and 8-methylthio-derivatives accompanied by major shifts of band II in the latter case, etc.), the very concept of describing the electronic states as mixtures of resonance structures and of the resonance Raman line shift as a result of a particular "percentage content" of the quinonoid form is unproductive and cannot yield any specific information either about the distribution of electron density in the isoalloxazine ring or about the interactions of the latter with the protein. The correlations of the positions of certain resonance Raman bands with the Hammett constants,[65,104] disregarding the influence of the masses and kinematic interactions on the vibration frequencies (see, for example, the correlations for band I in the study of Schopfer and Morris[104]), are also of little use. Despite the very unique nature of the resonance Raman spectra obtained for modified flavins, they have been scarcely used. The interpretation of these results requires additional experiments with isotope-substituted specimens, which would permit reliable assignments of the vibration frequencies, and also quantum–mechanical calculations of the electron density in the modified flavins.

Stacking Interactions of Flavins. It has been frequently suggested in the literature that the free FMN and FAD groups in solutions exist under certain conditions in the form of stacking complexes. In particular, the changes in the fluorescence properties of flavins have been attributed to interactions of this type. It is known that the fluorescence of FAD in aqueous solution is appreciably quenched compared with an aqueous solution of FMN at the same concentration; it has been suggested[106] that one of the probable causes of the quenching may be the stacking interaction of the isoalloxazine and adenine rings. The possibility of the formation of intramolecular stacked structures from the isoalloxazine and adenine rings in the FAD molecule has been discussed.[107] When 30% of DMSO is added to the solvent, such interaction is significantly weakened and the FAD fluorescence is intensified by a factor of 40, approaching that of FMN. Attempts have been made to detect stacking interactions with the aid of resonance Raman spectra. Comparison of the frequencies in the spectra of aqueous FMN solutions at a concentration of approximately 60 mM,[63] where the FMN molecules should be fully dimerised, with the CALS spectra of dilute aqueous solutions and solutions in the H_2O–DMSO mixture[66] failed to reveal any significant differences. One should note however that these results are difficult to compare, because the data of Nishimura and Tsuboi[63] refer to spontaneous RRS under conditions of virtually non-resonance excitation (λ = 600 nm), while the data of Irvin et al.[66] refer to the excitation of the anti-Stokes ARSS (ω_1 = 495 nm), which gives rise to a negative Lorentzian contour. On comparing the CALS spectra of FAD in water and aqueous DMSO, the authors noted small changes in certain frequencies.[66] However, it was subsequently confirmed that the FMN spectra in solutions at high concentrations, ensuring stacking interactions (> 50 mM), do not differ from the spectra of dilute solutions (< 2 mM).[64]

Flavocytochromes. These compounds, which function in electron transport chains, contain two centres for oxidation-reduction reactions: flavin and cytochrome (haem group). The mechanism of the functioning of flavocytochromes is in many respects still obscure;[108] little is known also about an interesting feature of these compounds—the postulated intramolecular tunnelling from flavin (electron donor) to cytochrome (electron acceptor). Furthermore, the study of this interaction is of general importance for many-centre enzymes.

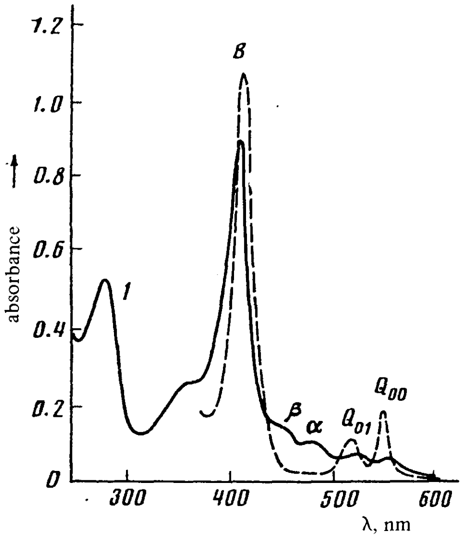

Figure 17. The electronic absorption spectra of flavocytochrome c_{552} in the oxidised (curve *1*) and reduced (curve *2*) forms; the symbols *B*, Q_{01}, and Q_{00} denote the absorption bands of haem c and α and β denote the absorption bands of the flavin component.[113]

Flavocytochrome c present in purple and green phototropic bacteria, which play an important role in the biological reduction of sulphates and in the general sulphur turnover on Earth, has been most thoroughly investigated in the class of cytochromes.[39] Flavocytochrome c_{552}, isolated from *Chromatium vinosium*, consists of two non-equivalent subunits, one of which (M_r = 21 000) contains two haem *c* groups, while the other (M_r = 46 000) contains one FAD group.[109] The isoalloxazine ring is in this case covalently bound to the protein by a sulphide linkage in the 8-position.[110] According to EPR data,[111] the two haem c groups are non-equivalent; the immediate environment of one of these groups (apparently consisting of the ligands) varies with the pH.

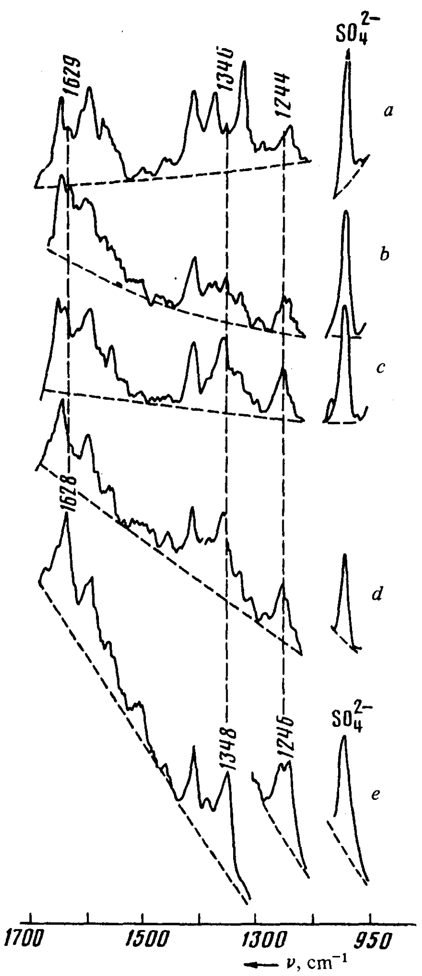

Figure 18. The resonance Raman spectra of flavocytochrome c_{552} (pH 6.5) on excitation with light corresponding to the 514.5 (*a*), 501.7 (*b*), 496.5 (*c*), 488.0 (*d*), and 476.5 nm (*e*) lines; internal standard—SO_4^{2-} ion (ν = 983 cm^{-1}); the vertical dashed lines indicate the positions of the resonance Raman lines of flavin.[113]

Flavocytochrome c_{552} has been investigated by the resonance Raman method simultaneously by two groups of investigators.[112,113] Owing to the unsuccessful choice of the exciting frequencies in the study of Ondrias et al.,[112] it was not possible to identify the resonance Raman lines which could be assigned to the isoalloxazine rings. The electronic absorption spectrum of the enzyme (Fig.17) consists of a superposition of the intense absorption by haem [the *B* bands (Soret bands) Q_{00} and Q_{01}] and less intense bands at approximately 450 and 480 nm referring to the flavin fragment. By altering the frequency of the exciting line, the authors[113] isolated the 1629, 1346, and 1244 cm^{-1} lines of the isoalloxazine ring together with the intense resonance Raman lines of the cytochrome at 1645, 1566, and 1366 cm^{-1}, which are close to the frequencies observed for horse ferricytochrome c (1637, 1563, and 1316 cm^{-1} respectively[114]). The intensity of the isoalloxazine lines is highest on excitation at λ = 476.5 nm, in the region of the bands due to the electronic transitions of flavin (Fig.18).

The resonance Raman spectrum of the reduced (ferro) form of flavocytochrome c_{552} contains lines referring exclusively to the haem groups;[113] their number, polarisation, and frequencies are virtually the same as for other ferrocytochromes c.[115] Judging from the symmetrical contours of the sharp 1588 and 1316 cm^{-1} lines, both haem groups in the ferrocytochrome c_{552} molecule should be identical. The absence of bands due to the isoalloxazine ring shows that the flavin exists in this case in the fully reduced form and not in the semiquinone form.[113]

The photoreduction of the entire enzyme and its constituent cytochrome- and flavin-containing submits separately as well as the interaction with strong inhibitors (sulphite and cyanide) have been investigated with the aid of RRS.[113] The changes in the intensities of the resonance Raman bands in the spectra of the complexes with cyanide and sulphite suggest that both adducts are formed as a result of the addition to the N(5) atom of the isoalloxazine ring, which is the cause of the inhibition of the enzyme. It has been shown[113] that in the photoreduction, which in this case proceeds exclusively in the presence of ethylenediaminetetra-acetic acid, the first prosthetic group to be reduced is the flavin system, while the haem groups cannot be reduced in the absence of flavin. These experiments constitute the first direct evidence for the occurrence of intramolecular transfer from the flavin group to the cytochrome in this class of enzymes.

---o0o---

Thus extensive data have now been obtained on the resonance Raman spectra of flavins. Evidently the method can be used successfully for the identification of the isoalloxazine ring and the derivation of information about its structure in all possible oxidation and ionisation states. Under conditions where the scope of NMR is extremely limited, resonance Raman spectroscopy remains in essence the only method potentially capable of yielding extensive information about the ground and excited states of flavin systems. Nevertheless, these data have so far been used to a small extent. Compared with the novel methods of isolation and synthesis of, for example, the modified specimens and with the exceptionally sophisticated experimental spontaneous and non-linear resonance Raman spectroscopic technique, the results of the interpretation appear to be modest. This situation is caused mainly by the inadequate development of the theoretical basis of the analysis of the normal vibrations and quantum-mechanical calculations of the electron density in model flavin systems. Evidently the description of the changes in the electronic states of the isoalloxazine ring in terms of the percentage contents of the resonance structures cannot promote the discovery of the real situation. Despite the abundance of data available on isotope-substituted specimens and modified systems, there has been so far no adequate calculation for the normal vibrations of flavin. In view of the quantum-chemical and vibrational spectroscopic methods which have now been developed and the present level of computational techniques, such theoretical data could be readily obtained after the correct choice of model. All the information about the frequencies, intensities, and polarisations of the resonance Raman lines could be fully employed on this basis in order to deduce the state of the isoalloxazine ring and its interactions with the protein environment.

Progress in the Polymer Chemistry of Borates

B.P.Tarasevich and E.V.Kuznetsov

Using a combined approach based on the symbiosis of macromolecular and colloid chemistry of polymers with inorganic chemistry, data on the low- and high-molecular-weight anionic metal oxoborates in the crystalline, amorphous, and vitreous states, in solution, in the melt, and in the gas phase are surveyed. An attempt is made on this basis to present an adequately logical and well-founded picture of their structure, to indicate a new method of study, and to facilitate the prediction of the properties of technical materials and the improvement of the technology of their manufacture. The entire wide variety of borates and many of their properties can be accounted for by the variation of the configurations and conformations of the macroanions in response to changes in external influences as a result of the flexibility of the B-O-B bonds by virtue of the O atoms being in a state intermediate between sp^2- and sp-hybridisation involving B atoms. The necessity to develop the polymer chemistry of compounds with the E-O-E linkages (E = B, Si, P, Al, etc.) is emphasised. It is noted that the chemistry of macroanions is in the forefront in this respect.

The bibliography includes 265 references.

I. INTRODUCTION

The unity of the nature of organic, organoelemental, and inorganic polymers and the differences between them have already been discussed in a review,[1] where the inadequate development of this problem in relation to polymers of the last type was noted. The number of new publications on this topic can be literally measured in single figures.[2,3] This is clearly inconsistent with the abundance and importance of inorganic polymers in nature and technology.[4–8] The ideas developed in a monograph by Korshak et al.[9] stimulated at an earlier stage the consideration of certain aspects of the macromolecular physics and chemistry of boron oxides and hydrogen oxoborates.[1] This review is devoted to polymeric metal oxoborates[†] (henceforth referred to simply as borates).

[†] The fluoro-, peroxo-, and other borate systems as well as inorganic polymers with B—O—E linkages in the macroanions (E = Si, Al, P, etc.), i.e. the corresponding boroelementoxanes,[10] will not be considered here. We note only that the use of the principles of macromolecular chemistry will permit an approach to the synthesis of such polymers and materials based on them.[11–16]

The characteristic features of the electronic structure of boron are responsible for the presence of the BO_3 and BO_4 sp^2- and sp^3-hybrids in the structures of borates and also for the possibility of their interconversions.[17] This complicates the structure of borates compared with, for example, phosphates[18] or silicates.[19] The elucidation of the structures of many borates has been scarcely reflected in their terminology, particularly in the trivial names of natural compounds. Although stereoregular crystalline linear (chain and cyclochain) borate polyanions can be fully described, according to IUPAC recommendations,[20] with the aid of stereochemical definitions and designations adopted by IUPAC for polymers,[21] in practice such terminology is not being used. Since the existing nomenclature for polymers[20–22] refers solely to linear single-stranded and quasi-single-stranded structures, the present review has retained mainly the traditional terminology of the chemistry of borates, in particular, the prefixed "phyllo" and "tekto" are used to designate two- and three-dimensional structures respectively.[23] Since the term "polyanion" has a dual significance in the chemistry of borates—it is frequently used to designate both intrinsically polymeric (chain, layer, and network) and isolated ("island") anions with a low degree of polymerisation, in the present review the latter are referred to as oligoanions[24] and the former as macroanions. The macroanions are in their turn subdivided into linear (poly-), layer (phyllo-), and network (tekto-). Instead of terms of the type "basic structural blocks",[25] "basic structural units",[26] etc., the term "constitutional repeat units" (CRU) [27] (it is also referred to as the elementary unit[28]), taken from the chemistry of macromolecular compounds, is used. The symbol "∞" has been replaced by the designation "n" used in the chemistry of macromolecular compounds.

The oligoanions are subdivided, as usual, into triborate, tetraborate, pentaborate, etc. anions. In order to reflect their wide variety, caused by the different combinations of BO_3 and BO_4 for the same number of boron atoms, it is most convenient to employ the nomenclature of complex compounds.[29] The review includes data on oxoborates published up to 1985, including data on new oligoanions with $n = 12$ [30] and $n = 16$,[31] on the heptaborate CRU,[32] etc., for example, the structure $CaO.2B_2O_3.0.5H_2O$,[33] which have not been included in any of the previous reviews.[34] Data on anhydrous crystalline[26] and vitreous[7,35] borates, etc. have also been supplemented.

II. HYDRATED BORATES

1. Crystalline Compounds

The fundamental principles governing the formation of structures[25] are described below taking into account the postulates of the chemistry of macromolecular compounds:

1. The simplest groups in the structures are BO_3 and BO_4.
2. The monomeric and dimeric anions are made up only of BO_3 groups or only BO_4 groups.
3. As a result of oligocondensation, the monomeric anions tend to form reactive anionic preoligomers, in which the degree of polymerisation of the simplest groups BO_3 (BO_4), functioning as structural fragments (subunits[20]) of the oligoanions, is $n \geq 3$.
4. The oligoanions specified in paragraph 3 can be modified by grafting to them side branches consisting of boron–oxygen and other element–oxygen groups.
5. Both monomeric and oligomeric anions (including modified anions) can polymerise via polycondensation (sometimes with ring opening) to macroanions functioning at the given stage of structural organisation as the CRU of the macroanions.#
6. In the structures of hydrated borates there is a possibility of the coexistence of the macroanions with mono-, di-, and oligo-anions.
7. In the hydrated borates, the oxygen atoms capable of being protonated are usually (but not always) protonated in the following sequence: initially the terminal oxygen ions (with formation of hydroxy-groups), next the oxygen atoms of the BO_4 sp^3-hybrid, then the oxygen atoms of the BO_3 sp^2-hybrid, and finally the hydroxy-group (with formation of water molecules).

The water in the crystalline hydrated borates can be present both in the molecular form (five classes of such water are distinguished)[36] and in the form of protons and hydroxyls, the hydrogen bonds playing an important role in the formation of the structures under these conditions. As the water content diminishes, the degree of polycondensation and the degree of cross-linking of the boron–oxygen anions increase.[36]

Fig.1 presents the known varieties of the borate mono-, di-, and oligo-anions in the fully hydrated form. Partly dehydrated forms have also been detected in real borates. Some of the oligomers illustrated in Fig.1 (*D*, *a*; *G*; *H*) have so far been detected in a modified form and as CRU of the macroanions. Examples of similar modified CRU are presented in Fig.2.

Fig.3 illustrates the "pentamer trimer" (i.e. a tripentaborate—not a pentadecaborate), found in the structure of natural ammonioborite,[37] and also the oligoanion $[B_{16}O_{24}.(OH)_{10}]^{10-}$ in which there are two heptaborate anions held by the BO_3 triangles.[31] The last example can also be regarded as an exception to the 7th of the principles quoted above; in the presence of water molecules, non-protonated oxygen bound to boron is present in the structure.

Starting with triborates ($1BO_3 + 2BO_4$), stereoisomers begin to appear. The triborate ring is a component of almost all oligoanions [the central O atom in the structure of the hexamers is coordinated to three B atoms at once and the charge of the hexamers is not equal to the number of B(IV) atoms as in other oligoanions, where it is smaller by unity]. One of the varieties of the tetraborate compounds is an exception.

The stereochemical similarity of borates to organic compounds has already attracted the attention of investigators[38] and Fig.3*b* demonstrates their ability to form "chelate" complexes which constitute the basis of many coordination polymers.[39]

Examples of borates in the macroanions of which the residues of mono- and oligo-anions behave as CRU are given in Tables 1 and 2. Figs.4 and 5 represent the fragments of certain macroanions included in the above Tables.

The set of data presented reveals the wide variety of macroanions, the origins of which are discussed in Section IV. In the light of ideas about the functionality of monomers in polycondensation,[76] the tendency towards the formation of predominantly heterocyclochain and layer polyboroxane macroanions, the possibility of their successive cross-linking, and also the possibility of the formation of

---

#The macroanions are capable of forming still higher forms of supermolecular (more precisely, "superionic") structural organisation, for example, formations of the spherulite type.

statistical and block-copolymers with B—O—E linkages (E = Si, Al, P, etc.) were already considered previously.[1] The possibility of the modification of the structures illustrated in Fig.1 by the grafting of various side branches and the formation of the CRU shown in Fig.2 also follows from the same pre-conditions. This type of transformation occurs likewise in the case where the polycondensation of the oligoanions is accompanied by the opening of the ring, as happens, for example, in the conversion of borax into kernite in accordance with the scheme shown in Fig.6.[25]

It is noteworthy that polyborates [for example, hydroboracite (III) and colemanite (IV) in Table 1] frequently give rise to superionic formations of the type of spherulites,[77] despite the views of Frenkel'.[6]

Since boron absorbs effectively slow neutrons and hydrogen absorbs fast neutrons,[78] hydrated borates and binding compositions based on them[79,80] are promising as materials for protection against neutron radiation. The mechanical indices (density, hardness, etc.) increase almost linearly on passing from the monoanionic to the di- and oligo-anionic structures and further to polymers, reaching a maximum for network macroanions.[81] The latter also contain the maximum amount of boron but the hydrogen content is then reduced to a minimum. This means that chain or layer macroanions have the optimum properties. An idea about the necessary ratio of the components can be gained from the data in Tables 1 and 2. On the other hand, the conditions in the synthesis of the binding materials must be close to those in the synthesis of single crystals (see the original communications quoted in the Tables). Clearly polycrystalline and even amorphous polymers, formed by borates at 323—523 K,[17] are suitable for the preparation of technical binders, phylloanions being usually produced under hydrothermal conditions.[82] It is useful to employ for this purpose

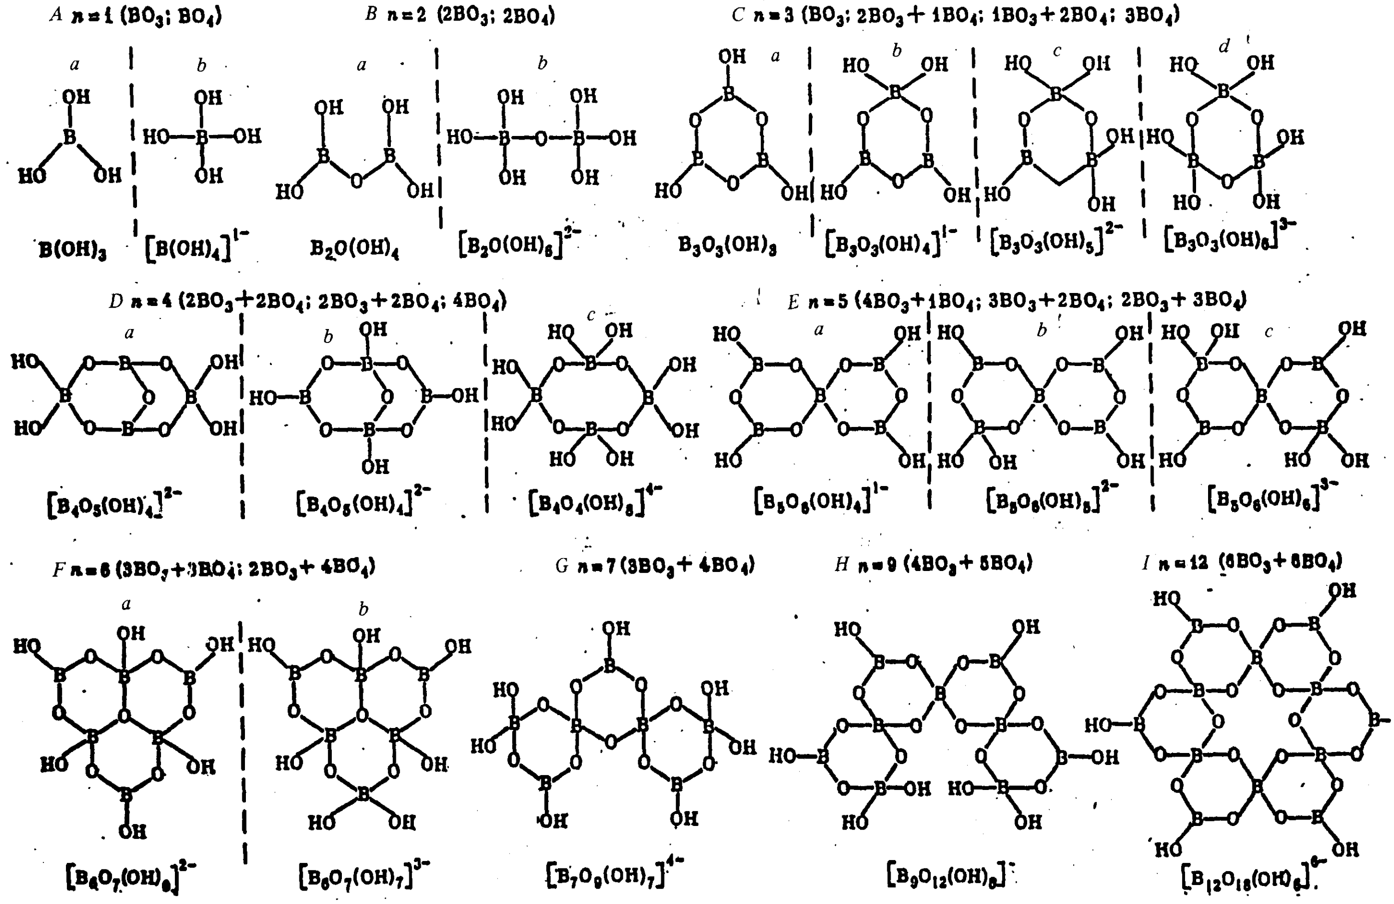

Figure 1. Borate monomers, dimers, and preoligomers with $n \geq 3$ in the fully hydrated form; their residues occur as the "usual" CRU of macroanions (Table 1) and subunits of modified (combined) CRU (Fig.2).

the experience gained in the chemistry of macromolecular compounds in carrying out the polycondensation reactions[83] and to invoke the mechanochemical reactions[84] which are already employed in the practical synthesis of borates.[85]

Hydrated borates, for example calcium borates, are manufactured on an industrial scale.[86] The B_2O_3 content in the polymeric borates is higher than in the monomeric and oligomeric borates and for this reason, in the manufacture of calcium borates, the half-finished product $CaO.B_2O_3.6H_2O$ with the monoanion $[B(OH)_4]^-$ [34] is nowadays subjected to polycondensation in the course of the so called "drying" (Ref.86, p.115) and is converted into the commercial product $CaO.B_2O_3.2H_2O$ (43% B_2O_3). Commercial preparations with a higher B_2O_3 content can be obtained under conditions where the degree of polymerisation of the boron–oxygen anions is increased further.

Figure 2. Examples of modified CRU in the macroanions of hydrated borates (the numerals correspond to those adopted in Table 2 for specific compounds); the arrows indicate the sites of grating of subunits; the connecting oxygen atoms shared with neighbouring CRU are indicated by dashed lines (see the footnote to Table 2).

The adhesive, binding, and film-forming properties of borates,[87, 88] which are characteristic of polymers and are considered in the next Section, are also of practical interest.

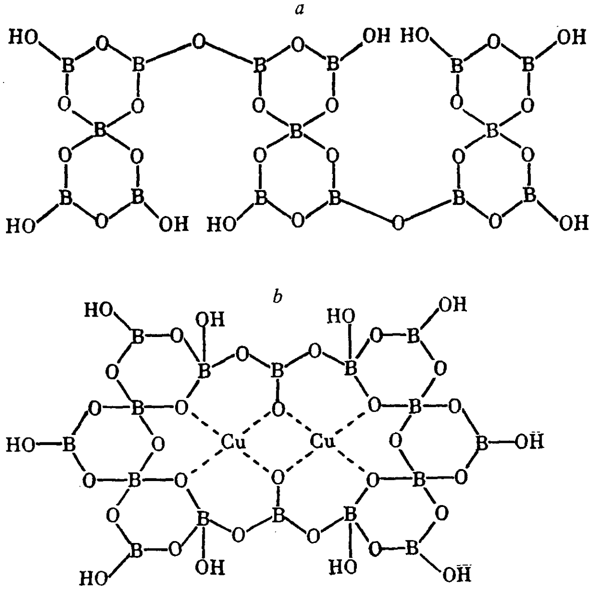

Figure 3. The tripentaborate oligoanion (*a*) in natural ammonioborite $(NH_4)_3[B_{15}O_{20}(OH)_8]\cdot 4H_2O$ and the oligoanion with $n = 16$ (*b*) as part of the "chelate" oligoanion in synthetic $Na_6\{Cu_2[B_{16}O_{24}(OH)_{10}]\}\cdot 12H_2O$.

2. Solutions of Oxoborates

The water-soluble borates of Group Ia s elements have been most thoroughly investigated. On dissolution in water, their macroanions are degraded as far as the formation of mono-, di-, and oligo-anions with $n = 3$–5.[1] The regions in which some of them predominate in solution are shown in Fig.7.[34,82]

It is striking that the structures made up wholly of BO_4 tetrahedra (for example, the network HBO_2-I macromolecules[1]) hydrolyse very slowly, in contrast to structures containing also the BO_3 triangles (for example, the cyclo-chain HBO_2-II macromolecules[1]), which makes it possible to isolate them from the mixture.[89] Consequently the resistance of borate macroanions to hydrolysis can be increased by filling with electrons the unoccupied *p* orbitals of the BO_3 sp^2-hybrids by their interaction with electron density donors, for example, with phosphates,[7,15] or by exposing them to UV [13] or ionising [90] radiation and by similar procedures.

Highly concentrated solutions in the M_xO_y–B_2O_3–H_2O systems (M = metal),[87,88] obtained on heating or hydrothermal treatment, exhibit adhesive, binding, and film forming properties. Concentrated solutions in the M_2O–B_2O_3–SiO_2–H_2O system have the same properties.[91] In the latter case even a very small content of boron compounds in compositions made up of oxygen compounds induces qualitative changes in the structures and properties of the statistical and block-copolymers formed.[91]

As already mentioned,[1] true solutions of borate polymers can be most readily obtained in non-aqueous solvents—either organic such as nitrobenzene in which they swell [92] or in "water removing" inorganic solvents of the type of H_2SO_4.[93] It has been suggested that in the latter case dissolution is

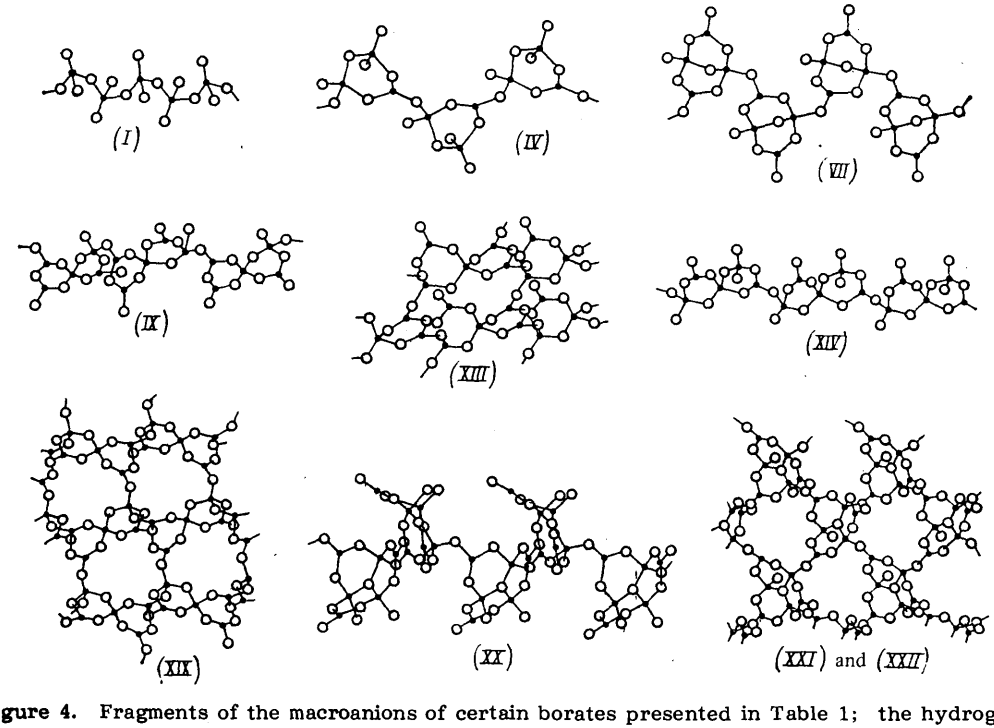

Figure 4. Fragments of the macroanions of certain borates presented in Table 1; the hydrogen atoms in the hydroxy-groups have been omitted for simplicity; here and henceforth the small filled circles denote boron and the larger open circles denote oxygen.

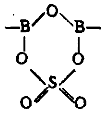
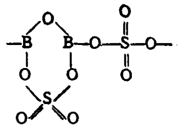
accompanied either by complex formation[94] or by polymer-analogue transformations with formation of CRU of the type[95]



or



The formation of a complex between $B(OH)_3$ and iron salts in solutions has also been noted.[96]

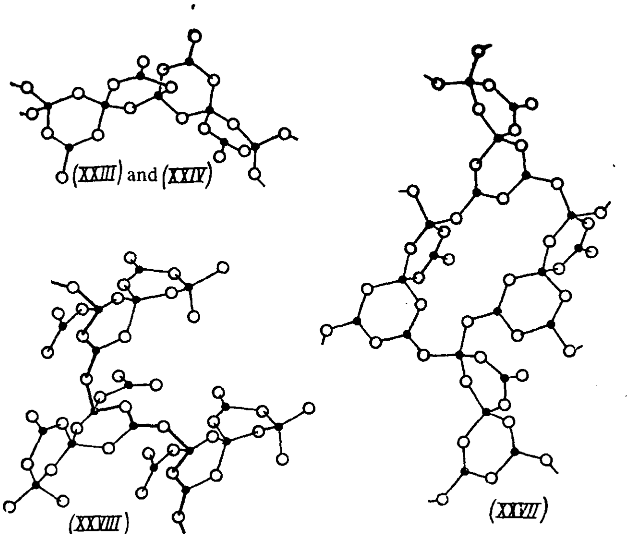


Figure 5. Fragments of the macroanions of certain borates presented in Table 2.

The set of data presented above provides a key to the understanding of the genesis of natural borate ores and the determination of the necessary conditions for the preparation of their synthetic analogues.

In nature at $T < 323$ K, mono-, di-, and oligo-borates are produced in the primary sedimentation period, undergoing various kinds of changes in the subsequent post-sedimentation period. As a result of polycondensation in accordance with the scheme[38]

$$[B_xO_y(OH)_z]^{(2y+z-3x)-} \xrightarrow[-qHOH]{t^\circ} [B_xO_{y+1}(OH)_{z-2}]_{q+1}^{(2y+z-3x)-} ,$$

accompanied under suitable conditions by ring opening (Fig.6), the grafting of side groups, and similar processes, the primary sedimentation borates are usually converted into secondary, post-sedimentation borates, as a rule chain or layer borates, following a change in thermodynamic conditions in deep layers.[82]

In order to obtain a synthetic borate with a particular structure, it must be deposited from a solution containing definite mono- or oligo-anions. On the other hand, as can be seen from the data in Fig.7, each of them exists predominantly within narrow temperature, pH, and concentration ranges, in the presence (see Section IV) of particular metal cations, and, finally, within a limited time interval (on "ageing" of the solutions). This greatly complicates the separation of borate homologues, which requires the application of many sophisticated technological methods and special procedures.[34,86,97–99] On the other hand, if the solution contains borate homologues of several varieties at once, then non-crystalline variable-composition amorphous borates are deposited from such a solution.

3. Amorphous Systems—Behaviour on Heating

Apart from the procedure noted above, amorphous borates are also formed in the course of the dehydration of crystalline hydrated borates (at a temperature ensuring the removal of the most strongly bound OH groups from the structures), yielding the so called amorphous powders.[77] The conversion of the amorphous borates into crystalline anhydrous compounds on further heating is accompanied by an effect which has been called the "borate rearrangement" (BR).[77]

In contrast to the usual crystallisation, whose rate is limited by the rate of removal of energy from the system, BR has an explosive (chain) exothermic character and occurs always at a reproducible temperature specific to each borate

Table 1. Examples of polymeric hydrated crystalline borates with the "usual" CRU (see also Figs.1 and 4).

CRU[a] of macroanions	Initial monomer or preoligomer	Form and formula of macroanions	Examples of specific compounds (the trivial names are also quoted for the natural borates)	Refs.	Designation
Monoborate	$[B(OH)_4]^{1-}$	Chain $[B^{IV}O(OH)_2]_n^{n-}$	Wimsite $Ca[BO(OH)_2]_{2n}=CaO\cdot B_2O_3\cdot 2H_2O$	[40]	(I)

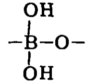
---

[a] The CRU of the macroanions[27] may not be identical with the stereorepeating unit.[21] Thus the CRU in wimsite I is



$-\overset{\overset{OH}{|}}{\underset{\underset{OH}{|}}{B}}-O-$

, while the stereorepeating unit is in essence a diborate unit consisting of two BO_4 tetrahedra.[40]

[b] See also Table 2 [(XXIII) and (XXXIV)].

[c] The monomeric $B(OH)_3$ groups in gowerite are located in each layer, while in p- and A-witchites they are located in alternate layers. In the structures of the latter the two-layer arrangements made up of identical phylloanions differ only by their relative dispositions; whereas the first layers are identical, the second in A-witchite is a mirror image of the second layer of p-witchite in the plane perpendicular to the c axis.[62]

[d] Although compounds (XV) and (XVI) have the same initial preoligomer $[B_5O_6(OH)_6]^{3-}$, its polycondensation can occur with participation of different OH groups, so that ultimately the end groups in compound (XV) consist of two different triangles with one OH group in each, while those in compound (XVI) consist of two OH groups in one of the tetrahedra.

[e] The synthesis under a pressure of about 100 MPa results in the formation of $Li_3[B_5O_8(OH)_2]$-I (tetragonal), in the anionic network of which it is possible to distinguish helical strips made up of triborate rings ($1BO_3 + 2BO_4$).[63] Sections through the deformation electron density of this borate[64] indicate the covalent character of the boron–oxygen bonds in the BO_3 and BO_4 groups and also in the B–O–B bridges, whereas the Li–O bonds are significantly ionic.

[f] The tektoanion is anhydrous and contains no functional OH groups, being a product of a later stage of the three-dimensional polycondensation of the preoligomer $[B_5O_6(OH)_6]^{3-}$. The zeolite-like boron–oxygen skeleton formed has large cavities in which water molecules are accommodated and in the case of compound (XVIII) also chlorine, so that the borates (XVIII) and (XIX) constitute, as it were, an intermediate stage on the way to the fully anhydrous systems—see (LXII) and (LXIII) in Table 3. Having the same CRU, the macroanions of (XVIII) and (XIX) nevertheless consist of different stereorepeating units: in compound (XVIII) the identity period along the boron–oxygen chains in the network is 0.63 nm, while in compound (XIX) it is 1.12 nm, i.e. corresponds to 2CRU.

[g] The triclinic modification of hilgardite has the same tektoanion.[65]

(somewhat below melting point T_m), and is accompanied by a marked contraction, an increase in the density and hardness of the substance, so that, on the basis of physical properties, it is difficult to put forward the hypothesis that before and after BR one is dealing with a substance having the same chemical composition.[77] It has been established[100–103] that, above the temperature of the BR exothermic effect, the specimens consist as a rule of a mixture of two borates, for one of which the modulus $m = B_2O_3/M_xO_y$ is higher and for the other lower than for the initial borate—in the limit it is made up of B_2O_3 ($m = \infty$) and monomeric (dimeric) borates with a minimum modulus if the newly formed borates are thermodynamically unstable. From the standpoint of the chemistry of macromolecular compounds, this resembles very closely the solid-phase polycondensation[104] or polymerisation[105] reactions. Both reactions proceed at an appreciable rate over a narrow temperature range below T_m, are autocatalytic, their rate has a high temperature coefficient, and their activation energy is also high. Bearing in mind that at the instant of the occurrence of the BR amorphous borates already lack the OH functional groups[100–103]§ (although the isolation of low-molecular-weight anionic products in the chemistry of silicates is also attributed to polycondensation processes as an alternative to ionic polymerisation[107]), it is more likely that the BR represents a kind of unusual solid-phase polymerisation process. It is noteworthy that, in the course of the BR, a fundamental change in the structures of the CRU of the macroanions frequently takes place. For example, colemanite, (IV) in Table 1, is converted after the BR into a mixture of $Ca[(BO_2)_2]_n$, (XXXV) in Table 3, and $Ca_2[B_6O_{14}]_{nnn}$, (LXXVI) in Table 4,[102] while hydroboracite, (III) in Table 1, is converted into a mixture of $Ca[(BO_2)_2]_n$

---

§ Certain iron borates are exceptions.[106]

[a] In order to maintain a unified treatment, on passing to the CRU of the anhydrous borates (see Section III), the subunits in the CRU and the CRU in the macroanions are distinguished in Fig.2 with respect to the connecting oxygen atoms[35] and not the boron–oxygen bonds.[25,34] For this reason, whereas the formulae of the CRU are identical, those of the subunits differ somewhat from those adopted in the literature.[25,34]

[b] The initial preoligomer is illustrated in Fig.1 (*D, b*); the formation of the polyanion is illustrated schematically in Fig.6.

[c] A characteristic feature of the phylloanion of this borate is the grafting of side branches ($2BO_3$ + $1BO_4$) to the main chain of the hydroboracite type—see (III) and (IV) in Table 1, as well as the cross-linking of these chains into layers via B–OH–B bridges[69] and not B–O–B bridges as is usually the case. Since two oxygen atoms (at the sites corresponding to grafting and cross-linking) are tricoordinate (with 2B and 1 H), the charge of the CRU does not agree with the number of B^{IV} atoms in it and is in fact equal to only −1 and not −3 [cf.also with (XX)–(XXII) in Table 1 and (XXIX)–(XXXI) in the present Table].

[d] The initial preoligomer is illustrated in Fig.1 (*D, a*).

[e] The CRU of the polyanion of the given borate can be regarded also as the dimer of the CRU of compound (XXIV) in the present Table.

and $Mg_2\{[B_4O_7]_{nnn}\}_2$, (XLIX) in Table 3,[101] and preobrazhenskite, (XXXIII) in Table 2, is converted into a mixture of $Mg_2\{[B_4O_7]_{nnn}\}_2$ and $Mg_2B_2O_5$ with a dimeric anion (on further heating, the former melts incongruently decomposing into the same compound $Mg_2B_2O_5$ and B_2O_5, which are in fact the final products of the thermal transformation of preobrazhenskite[103]). In the polymer chemistry of phosphates, this type of opening and transformation of the rings is attributed to heterolytic cleavage and the formation of zwitter-ions, the polymerisation proceeding subsequently in accordance with an ionic mechanism (Ref.5, p.91). As regards borates, it is known only (in relation to the so called calcium "octaborates". which are in fact tetraborates[108]), that although neither they themselves nor their dehydration products are electrically conducting, nevertheless electrical conductivity appears at the temperature of the BR [109] despite the fact that T_m is higher by 100 °C. However, electrical conductivity can be manifested also on homolytic cleavage of the rings accompanied by the appearance of radicals. EPR studies on the BR as well as its initiation by different methods might throw light on this question. Hitherto BR has been initiated mainly thermally, although in the chemistry of macromolecular compounds the radiation, mechanochemical, and other methods are used for the initiation of solid-phase polymerisation.[105]¶

The examples presented demonstrate differences in the structures of hydrated and anhydrous borates even when these contain the same cations and show that it is useful to consider separately these genetically interrelated compounds.

¶ Phenomena analogous to the BR effect are not a unique feature of borates. They occur also in the thermal transformations of aluminosilicates, for example, kaolinite (which consists of alternating polysiloxane and polyaluminoxane phylloanions[4] and is a component of natural clays), into mullite and silicon dioxide.[110] The latter are ingredients in the compositions of ceramic materials whose polymer-colloidal nature and composition are complex.[6,111]

III. ANHYDROUS OXOBORATES

1. Crystalline Compounds

The main methods for the preparation of crystalline anhydrous oxoborates are the BR considered above (for amorphous powders), synthesis from solutions or melts under normal and increased pressures, and also heat treatment of vitreous borates below T_m. In the last case, the process resembles the BR as regards its chain character (induction period, autoacceleration) the physical properties (density and hardness) of the crystals obtained from the amorphous powders and vitreous systems being identical.[77]

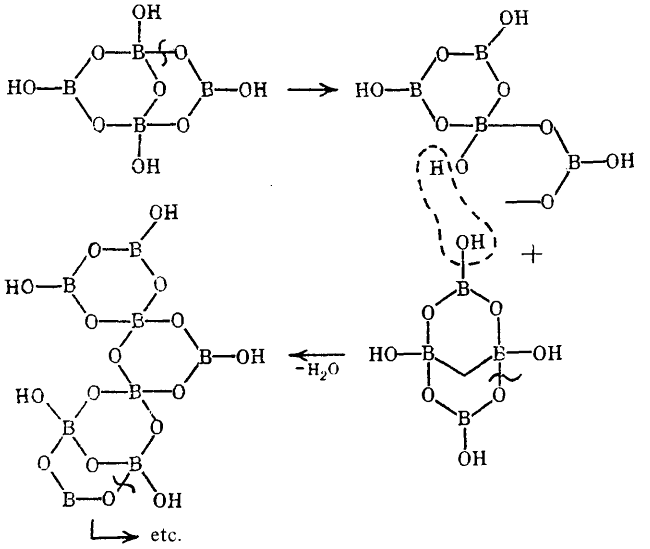

Figure 6. Schematic representation of the polymerisation reaction of borax to give kernite.[25]

The main principles governing the formation of the structures[26] are described below taking into account the postulates of the chemistry of macromolecular compounds.

1. The simplest groups in the structures are BO_3 and BO_4.
2. The monomeric and dimeric anions are made up only of BO_3 or only BO_4.
3. The simplest groups (subunits) can function as the CRU of the macroanions, which are usually formed as a result of the linking of the vertices of the BO_3 triangles and BO_4 tetrahedra via the p-bridges $>B{-}O{-}B<$, $>B{-}O{-}\overset{|}{\underset{|}{B}}{-}$, or $-\overset{|}{\underset{|}{B}}{-}O{-}\overset{|}{\underset{|}{B}}{-}$.†
4. Oligoanions with $n \geq 3$ can exist in the structures of anhydrous borates, but such oligoanions are more common as the CRU of the macroanions with a structure specific to anhydrous borates.
5. A decrease of M_xO_y/B_2O_3 (i.e. an increase of the modulus m) and an increase of the size of the metal cations (to a lesser extent) lead to an increase of the degree of polymerisation and of the density of the cross-linking of the macroanions (and also of the ratio BO_3/BO_4 for $M_xO_y/B_2O_3 \leq 1$), while an increase of the charge of the cations M^{y-} induces the opposite tendency.
6. Each O atom is usually linked to two B atoms (the ratio $BO_3/BO_4 = m-1$ is valid for such compounds having the composition $nM_xO_y.mB_2O_3$ when $m > 1$), but terminal (non-bridging) oxygen ions and transitional (bridging) oxygen atoms with hybrid coordinations with respect to boron of 3 and even 4 can be encountered.#
7. The phyllo- and tekto-anions of the anhydrous M^+ and M^{2+} borates exhibit a tendency towards twinning, frequently with formation of interpenetrating polymer networks (IPN).

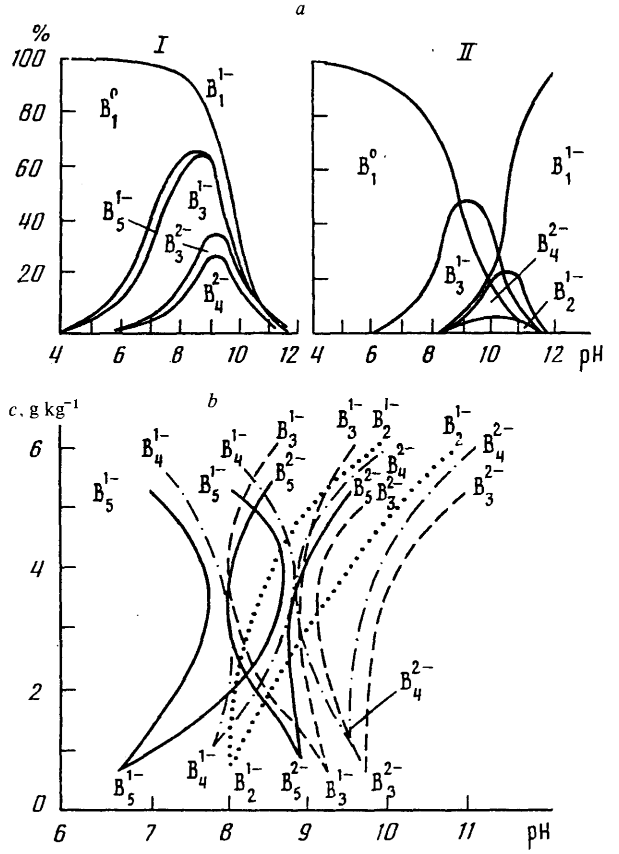

Figure 7. Borate homologues in aqueous solutions (B_n^{m-} is an abbreviated designation of the corresponding borates presented in Fig. 1): a) the fraction of the corresponding borate as a function of the pH of the solution at a boron concentration c = 0.4 M and T = 298 K (I) and also at c = 0.6 M and T = 393 K; the regions where they predominate as a function of the pH and the boron concentration c in the range 1–6 g kg^{-1} according to the data of Farmer[34] and Ozol[82]).

---

†An instance of the polymerisation of the BO_4 tetrahedra via  bridges is known—see (XCIX) in Table 4 and the corresponding remark in the same Table.

#See Figs. 9–12.

Fig. 8 presents the known varieties of the mono-, di-, and oligo-anions in the fully ionised (cationic) form. Specific examples of such borates are not considered here, as for hydrated borates in Section II. We shall only note that the pentaborate (Fig. 8, *D*), which is not mentioned in the monograph of Leonyuk and Leonyuk,[26] has been discovered in the structure $Bi_3O[B_5O_{11}] = 3Bi_2O_3.5B_2O_3$,[112] while the oligomer (Fig. 8, *E*) has been found in the structure $Pb_6.[B_{10}O_{21}] = 6PbO.5B_2O_3$.[113] The latter is not in fact a decaborate and consists of a modified (combined) oligoanion (two tetraborates grafted to one another via two BO_3 triangles).

Fig. 9 presents examples of the "usual" CRU in the macroanions of anhydrous crystalline borates and Table 3 lists the corresponding specific compounds.

Fig. 10 presents modified (combined) CRU and Table 4 the corresponding borates.

The fragments of the macroanions of certain borates quoted in Tables 3 and 4 are illustrated in Figs. 11 and 12. Fig. 13 demonstrates the formation of IPN.

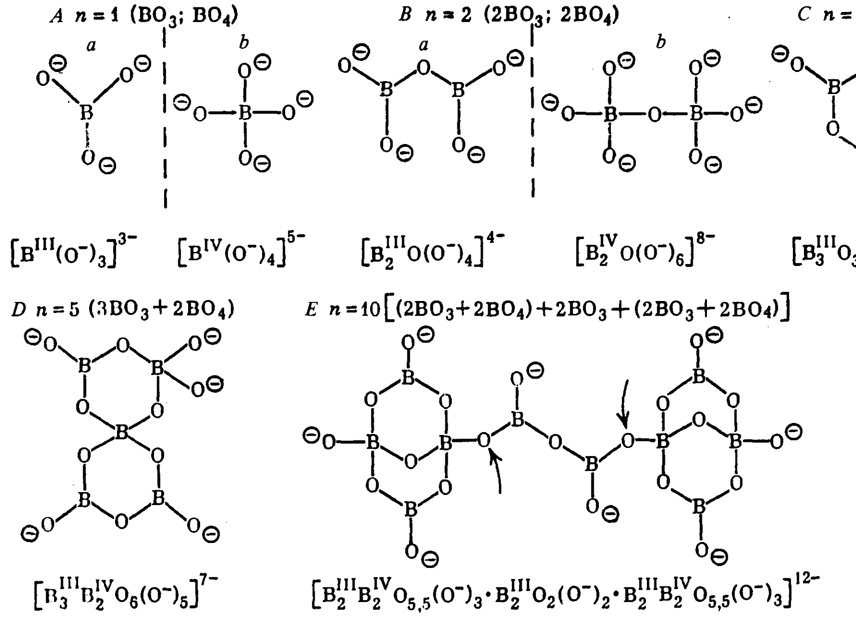

Figure 8. The monoanions, dianions, and oligoanions of anhydrous crystalline borates in the fully ionised (cationic) form.

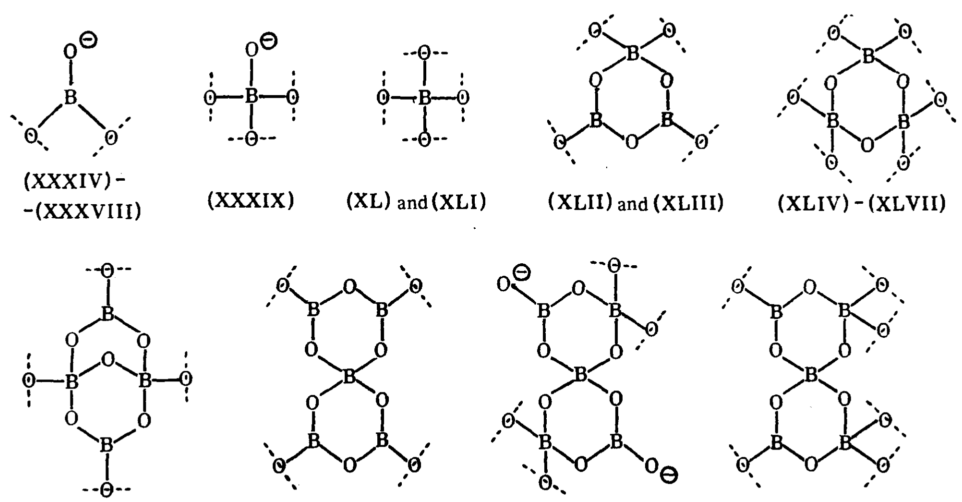

Figure 9. Examples of the "usual" CRU in the macroanions of anhydrous crystalline borates (the Roman numerals correspond to those adopted in Table 3 for specific compounds).

From the standpoint of the chemistry of macromolecular compounds, it is evident that, when the individual BO_3 (or BO_4) groups are linked predominantly by covalent bonds to other elementoxane groups (SiO_4, PO_4, AlO_4, etc.), forming the corresponding macroanions with the linkages B–O–E (for example, in the chain polyanions of calcium[175] or strontium[176] aluminoborates), then they are no longer isolated[26] and enter, in the form of subunits of a new kind, into the composition of the corresponding CRU in inorganic polyborelementoxanes, which are not considered here. Conversely, compounds of the type $La_2O_3.B_2O_3.2MoO_3$ and $La_2O_3.B_2O_3.2WO_3$ [compounds (XXXVII) and (XXXVIII) in Table 3], in the structure of which discrete MoO_4 and WO_4 tetrahedra are not in contact either with one another or with the chain polyboroxane polyanion, are not copolymers (inorganic polyboroelementoxanes) from the standpoint of the chemistry of macromolecular compounds, i.e. are not boromolybdates and borotungstates,[26] since the polyanions contain only B–O–B linkages. These compounds should be regarded rather as mixtures of a polyborate with a monomolybdate or

---

[a] The CRU of the macroanions[27] may not be identical with the stereorepeating units; for example, the stereorepeating units in compounds (XXXIV)–(XXXVIII) are made up of two BO_3 triangles.

[b] When the tetrahedra are joined together into chains, the stereorepeating unit is $2BO_4$, when the chains are joined up to form a layer, rings consisting of six BO_4 are produced, and when the layers alternate, the $\gt B-O^-$ terminal bonds in the layers are alternately directed to one side or another of the layer, so that overall a structure similar to micas is formed.[4]

[c] The tetrahedra in the tektoanion of this borate are linked in such a way that a "Chinese lantern" with six "windows" (rings made up of $4BO_4$) and eight "windows" (rings made up of $6BO_4$) is produced.

[d] Although the borates (XLIV) and (XLV) have identical CRU, they differ from compounds (XLVI) and (XLVIII) in the way that the CRU are joined together in space.

[e] As in Section II, the "kernite-like" CRU have been classified as modified units—see compounds (LXX) and (LXXI) in Table 4.

[f] Although the borate (XLVIII) has the same CRU, it differs from compounds (XLIX)–(LIII) in the stereorepeating units.

[g] The borates (LIV) and (LV) differ in the disposition of the CRU relative to the double rotational axes (in one case the axes pass near the ends of the pentaborate groups and in the other they pass virtually through their centres).

tungstate just as compounds (XII) and (XIII) in Table 1 are mixtures of phylloborates with monoborate.

It is seen from the data presented that the macroanions of anhydrous crystalline borates are more complex and varied than the hydrated macroanions (see also, Section IV). Modified CRU, distinguished by a great variety, are encountered among them more frequently. The macroanions themselves have a three-dimensional structure and more rarely two- and mono-dimensional structures. Network macroanions then tend to form IPN. All these factors prevent a stereoregular packing of the macroanions, greatly hindering the formation of polymeric single crystals of anhydrous borates. This requires the maintenance of a series of special conditions, including prolonged isothermal treatment, the introduction of seeds, etc.[26] When polymeric borate melts are cooled in the usual way, they pass to a vitreous state.

2. Vitreous Oxoborates

Many borates, including the borates of all the Group IA and IIA elements, zinc and cadmium (Group IIB), thallium (Group IIIA), lanthanum (IIIB), lead (Group IVA), and bismuth (Group VA),[7] tellurium (Group VIA),[177] and other elements, let alone binary and more complex borates, have been obtained in a vitreous state. In contrast to the crystalline borates, the vitreous borates are non-equilibrium systems, i.e. in any specific borate glass one of the many structures characteristic of melts having the same composition is fixed.

Table 5 makes it possible to compare the boundaries of the glass formation regions in certain borate systems[177,178] with data concerning the crystalline compounds existing in these regions.[179] It is easily seen that all the compounds with known structures are in this instance the polymers listed

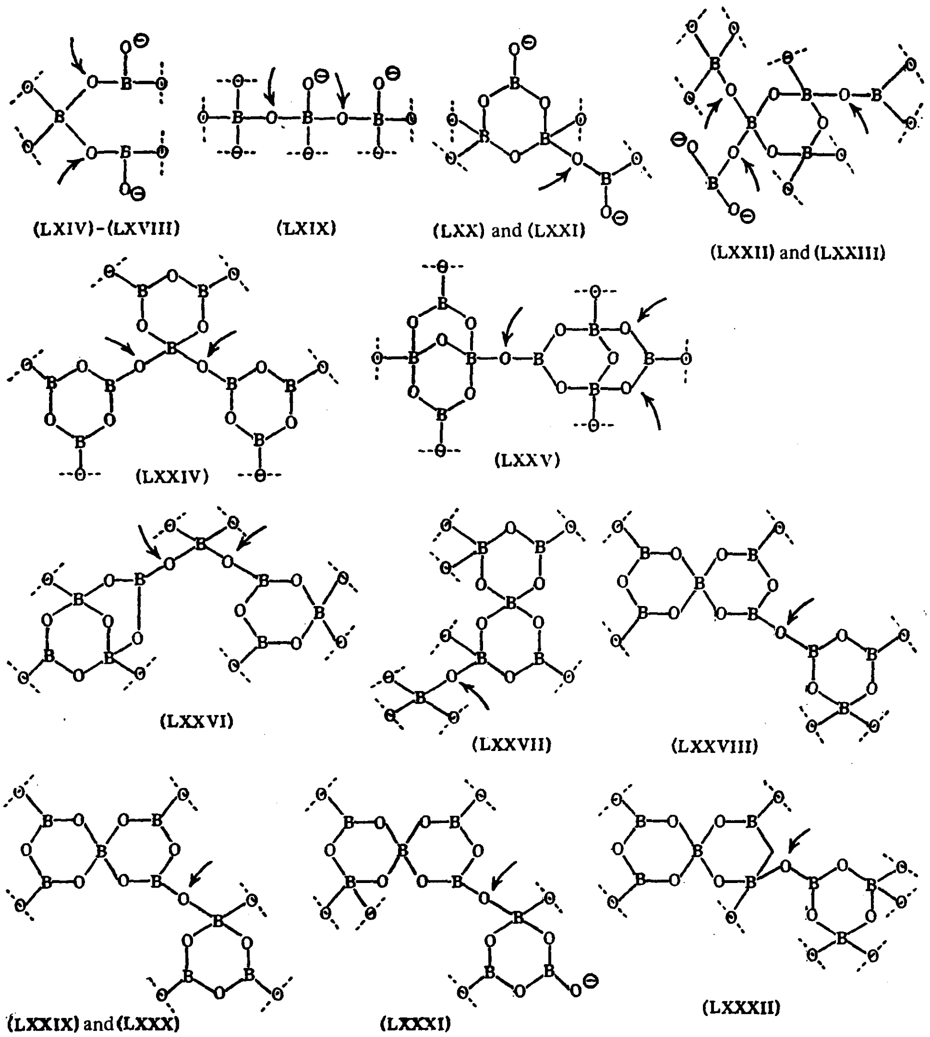

Figure 10. Examples of modified (combined) CRU in the macroanions of anhydrous crystalline borates in Table 4 (the notation is analogous to that adopted in Figs. 2 and 9); for the CRU of the macroanions (XCVI)–(XCVIII), the numerals opposite the connecting oxygen atoms sp^2-hybridised with respect to boron represent the fraction of such atoms contributed by neighbouring CRU.

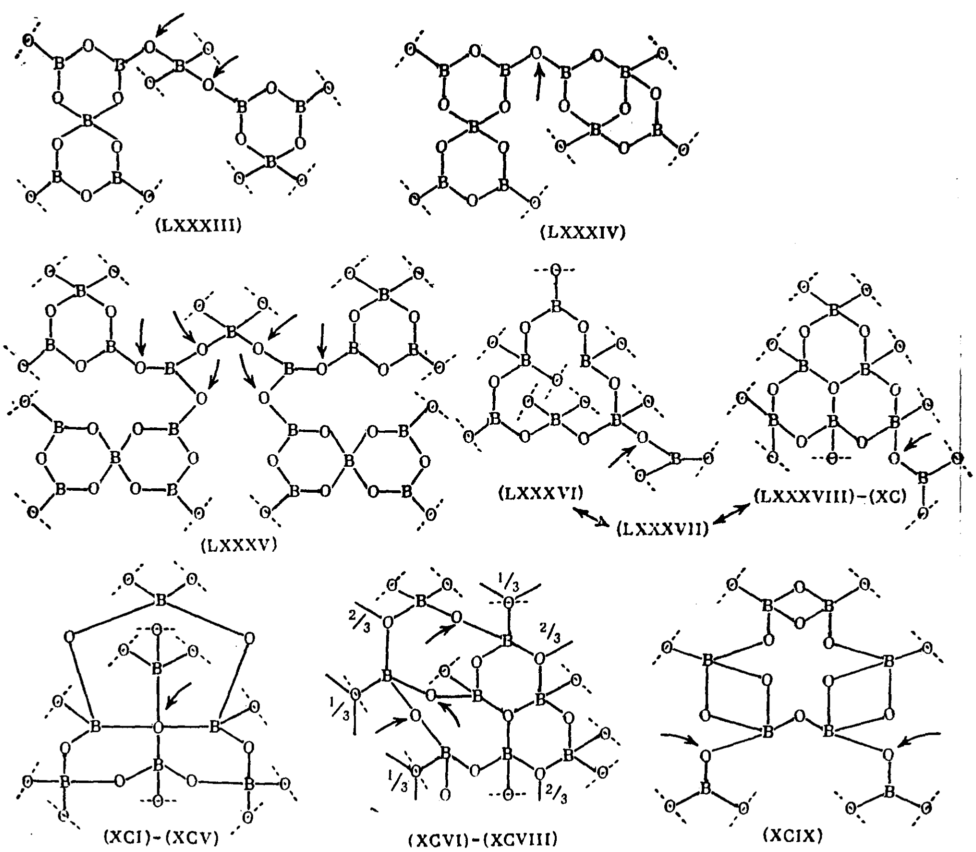

Figure 10 (contd.).

in Tables 3 and 4. This suggests that the structures which have not so far been elucidated also have a polymeric structure (or at least an oligomeric structure with $n \geq 5$).

The glass formation regions are usually bounded by compositions forming optically homogeneous glasses (these boundaries depend on the experimental conditions—the volume of the melt and the rate of its cooling). Polymeric borates can also form optically inhomogeneous glasses. In one case these are liquating glasses,[181,182] the appearance of which is a consequence of the immiscibility, with phase inversion, characteristic of colloidal polymer systems.[183] In another these are partly crystallising glasses, whose formation may be caused by the crystallisation of chain polyanions with a simple configuration or by the formation of rigid networks of the type of boracites. In the latter case, the fraction of flexible B–O–B bonds diminishes as the transitional O atoms undergo a change from a state involving sp-hybridisation to states involving sp^2- and sp^3-hybridisation with B atoms (the –O– bridges are replaced by $\overset{|}{\underset{/\ \backslash}{O}}$ and even $-\overset{|}{\underset{|}{O}}-$), i.e. the configurational-conformational statistics of the polymers is impoverished. However, the low-molecular-weight anionic fraction, especially monomeric borates, crystallises most readily, even under conditions where the melts are subjected to intense cooling. In other words, the tendency of a particular substance towards glass formation is determined not only and not so much by kinetic as by structural factors.[184] Among them, the leading role is due to the presence in the structure of atoms or groups of atoms connected by directional bonds[184]§ and such structures should possess fairly pronounced flexibility, ensuring a definite set of conformations and configurations (see Section IV).

---

§The latter agrees with all the criteria of the polymeric structure of matter.[1,185]

The fact that glasses are formed in boron oxide–zinc oxide (cadmium, lead, and bismuth oxide) systems when the B_2O_3 content is less than 50 mole % suggests that the above elements are incorporated into the macroanionic network of the glass with formation of B–O–E linkages.[7] In particular, this has been confirmed for the $PbO–B_2O_3$ system by NMR data[7] and for the $ZnO–B_2O_3$ system by the results of the EPR study of the mechanodegradation of the corresponding

$6BO_4+2BO_3$	Layer[i] $[B_6^{IV}O_{12}\cdot 2B^{III}O_{1.5}]_{nn}^{6nn-}$	$Na_2Zn_2MnB_{4.67}O_{11}=3Na_2O\cdot 6ZnO\cdot 3MnO\cdot 7B_2O_3^{k}$	[172]	(XCIX)

---

[a] When two CRU are joined together, a modified tetraborate ring is formed in the chain—see Fig.12 (LXIV)–(LXVII).

[b] When the CRU are joined together, "windows" consisting of rings made up of ($4BO_3$ + $4BO_4$) are produced in the layer.

[c] When the CRU are joined together, two forms of "windows" consisting of rings made up of $4BO_4$ and $6BO_4$ are produced in the layer.

[d] "Kernite-like" CRU—see also (XXIII) and (XXIV) in Table 2.

[e] As can be seen from Fig.10, compound (LXXVIII) differs from compounds (LXXIX) and LXXX) by the different ways in which the triborate subunit is joined to the pentaborate subunit in the CRU.

[f] Two layers are cross-linked by oxygen bridges (between the pentaborate subunits of the CRU and the BO_4 tetrahedra).

[g] Thus the metastable low-temperature β-form, having the same overall composition as the α-form, undergoes changes both in the steric structure of the macroanions and in the structure of the CRU subunits.

[h] The borate (LXXXVII) has a structure transitional between those of (LXXXVI) and (LXXXVIII). Whereas in compound (LXXXVI) the site of the 13th oxygen atom (at the centre of the ring) is unoccupied, in compound (LXXXVIII) it is fully occupied, while in compound (LXXXVII) it is partially occupied.

[i] If subsequent refinement confirms the interpretation of Bondareva et al.[172], it will be necessary to recognise the possibility of the anion polymerisation not only via B–O–B bridges but also via  bridges. In this connection one should note that the initial interpretation of the structure of the borate (XCVII) also assumed such a possibility,[173] but subsequently it was regarded as incorrect.[26,171] However, there is no fundamental prohibition of such polymerisation (see also Section IV). For example, the so called "fibrous" W-form of silicon dioxide, polymerising from the gas phase and having the chain structure[174] , i.e. the SiO_4 tetrahedra are in this case also joined together via their edges, is known in the chemistry of silicates. However, this product is unstable and after isothermal treatment is gradually transformed into the usual three-dimensional varieties of silicon dioxide (initially, at 473–1073 K, into tridymite and at higher temperatures into cristobalite), where the tetrahedra in the network are joined together in the usual way—via vertices (Si–O–Si) bridges—although different CRU are in fact produced.

[j] Boron is not present solely as part of the composition of the purely borate macroanion and part of it participates in the form of BO_3 triangles together with the ZnO_4 tetrahedra in the construction of the "cationic" part of the structure.[172]

glasses.[186] In the latter case the mechanodegradation of the macroanions involves precisely the B–O–Zn linkages, which are weaker¶ than the B–O–B linkages:[186]

As already mentioned, consideration of such copolymers is outside the framework of this review. The above results[186] have attracted attention primarily because of the very fact of the detection of radicals in the mechanical breakdown of borate glasses, since in low-molecular-weight compounds the dissociation of chemical bonds with formation of radicals does not occur under such an influence,[84] i.e. the phenomenon of mechanodegradation is characteristic of polymers alone.[84] Together with polymer-analogue transformations, the

¶ In the terminology of the chemistry of glass,[187] zinc behaves in this instance as a modifier-intermediate.

exchange interaction of the macromolecules, etc. it is a specific chemical property of macromolecular compounds. The macromolecular nature of the substance is also manifested in a series of specific physical properties. These include the capacity for fibre and film formation, adhesion (binding) properties, orientation effects in electric, magnetic, and mechanical fields (in the last case up to crystallisation on stretching), and the ability to pass to the highly elastic state (non-Newtonian flow of melts and solutions, dissolution with preliminary swelling, immiscibility in the plastic state, characteristic features of the change in heat capacity at a low temperature, the presence of a spectrum of relaxation times, etc.$^{188-190}$ A number of similar properties have also been shown by vitreous borates.$^{1,7,184,191-193}$ The effect associated with the orientation of the structure of the sodium borate glass on vitrification in weak (0.07 and 0.8 T) magnetic fields may serve as one of the new examples of this kind.^{194} Similar effects have been observed for organic polymers and diamagnetic liquid crystals and, when the number of elementary units in molecules of such substances is of the order of 10^6–10^8, orientation is already achieved at a magnetic induction $B \approx 0.1$ T.^{194}

Overall, the concept of the presence in the structure of a covalently bound element–oxygen "network" is nowadays virtually generally accepted for borate (and other oxides) glasses,$^{1,7,35,184,187,191-193}$ etc. In this case the term "network" includes the concept of macroionic element–oxygen chains or segments of these chains (including highly branched chains), two-dimensional layers, and also intrinsically three-dimensional networks and their fragments. Although the discussion concerning the structure of the last features is still continuing,^{195,196} as regards vitreous borates,^{35} there are numerous experimental data demonstrating the presence in such a "network" of CRU analogous to those shown in Figs.9 and 10 together with the corresponding metal cation clusters. However, for thermodynamic and kinetic reasons, these CRU are frequently different for crystals and glasses of the same composition, for example,

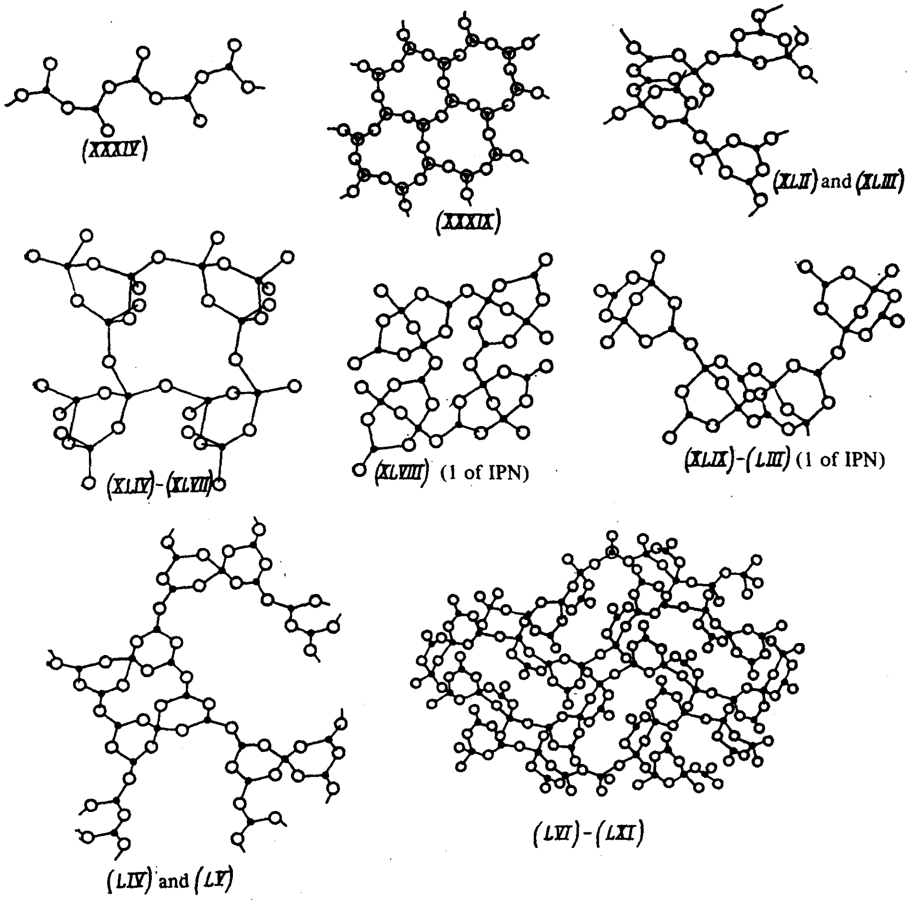

Figure 11. Fragments of the macroanions of certain borates in Table 3.

the $SrO.2B_2O_3$ CRU are not the same in the crystalline and vitreous states.[35] At the same time, the presence in the "network" of borate glasses of CRU analogous to (XXXIV) to (XXXVIII), (XLII) and (XLIII), (XLVIII)–(LIII), and (LIV) and (LV) in Fig. 9 and (LXXVIII) and (LXXXI) in Fig. 10, as well as the CRU subunits (LXXIV) and (LXXV) in the same figure can now be regarded as established.[35] Evidently, BO_3 and BO_4 can also function as independent CRU of the network and its fragments. The idea of a covalently-bound macroionic network in vitreous borates would be incomplete if one disregarded the possibility of its further differentiation already at the polymer–colloidal level of structural organisation (see the next Section).[181–183]

In contrast to the abbreviations Δ and *T* (or *t*) adopted for BO_3 and BO_4 in the crystal chemistry of borates,[25,26] in the chemistry of vitreous borates[35] a more far-reaching

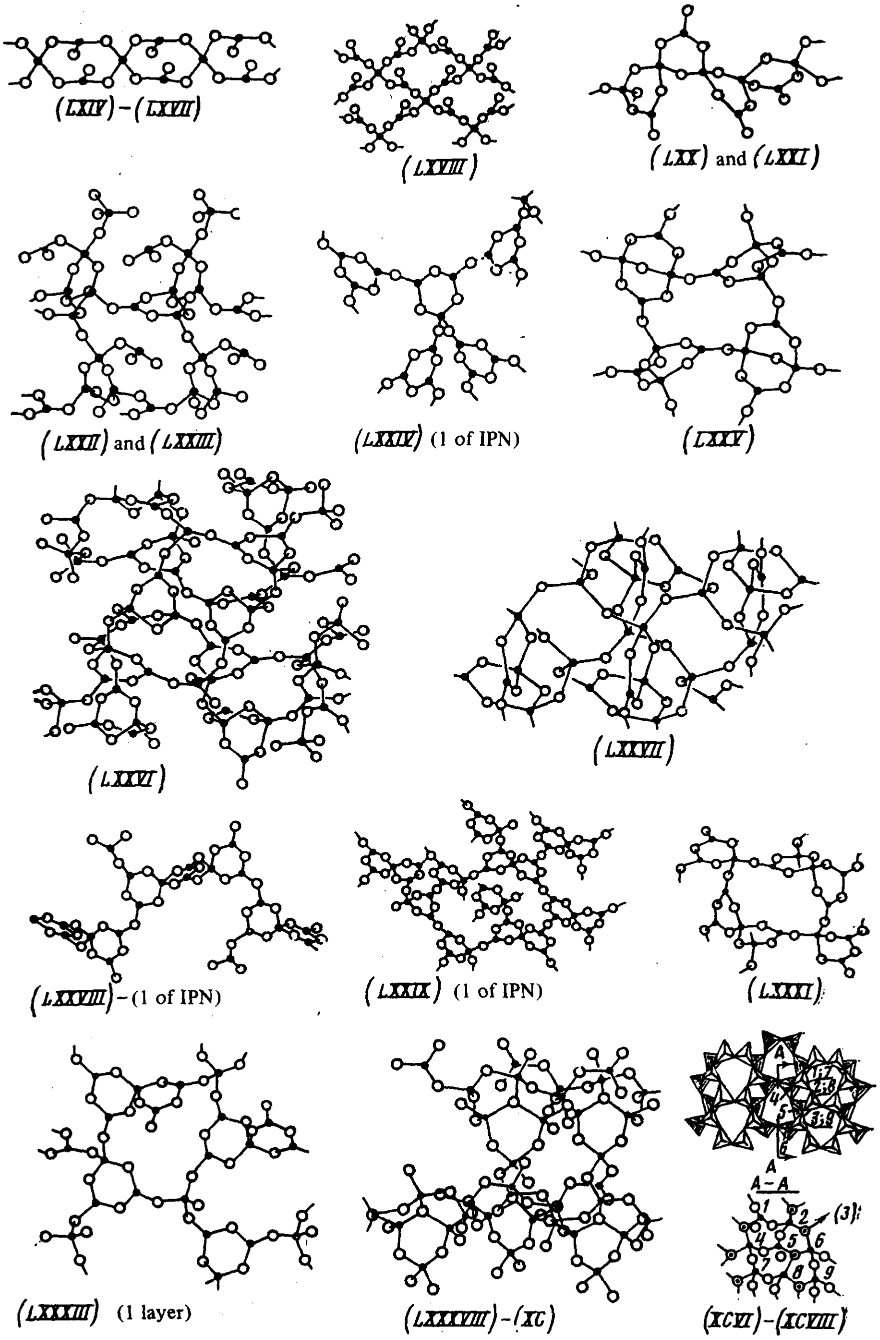

Figure 12. Fragments of the macroanions of certain borates in Table 4 [the A–A view for the clinographic (XCVI)–(XCVIII) projection—cf. with the planar representation of the corresponding CRU in Fig. 10].

gradation has been adopted in the abbreviations for borate groups together with a terminology based on chemical composition and not structure (Table 6). Here it is easy to put $BO_3 = a$, $BO'_3 = b$, $BO''_3 = b''$, $BO'''_3 = b'''$, $BO_4 = c$, etc. At the same time the term "diborate" for what is actually a tetraborate CRU and the term "tetraborate" for the modified CRU (LXXVIII) in Fig. 10 are unjustified. The use of double Greek prefixea to designate heterochain CRU with identical n ("di-triborate", "di-pentaborate") is also not entirely apt—it implies the dimerisation of the CRU.

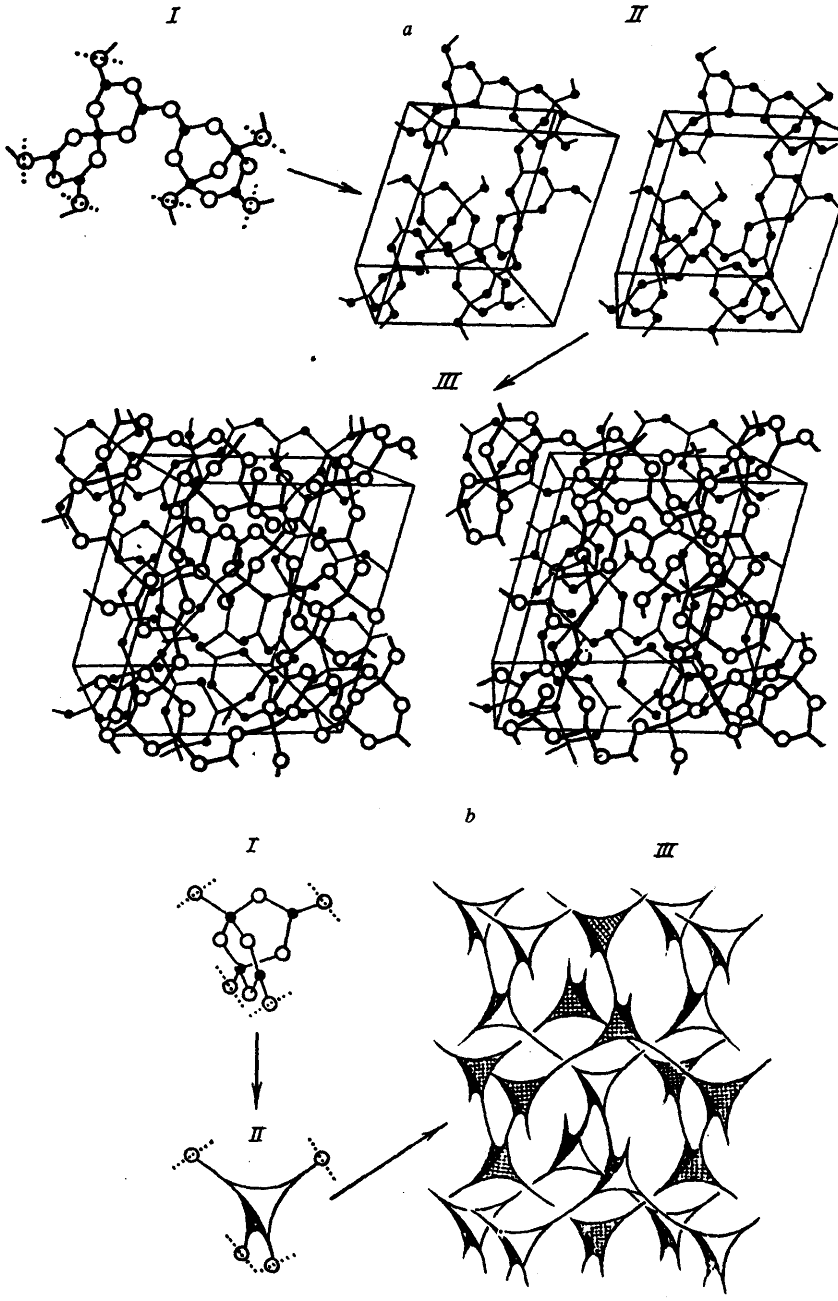

Figure 13. Examples of the formation of the IPN from the macroanions of anhydrous borates: *a*) for the borate (LXXXIV) in Table 4 [stereopairs based on "spherical" models were used: *I*) CRU; *II*) network made up of CRU *I*; *III*) IPN made up of two networks *II*]; *b*) for the borate (XLIX) in Table 3 [a simplified clear model was used: *I*) CRU; *II*) its conventional representation; *III*) IPN made up of two networks *II*].

Here it will be more convenient to invoke ordinal Latin prefixes or, even better, the nomenclature of complex compounds.[29]

In considering vitreous borates, one cannot bypass the question of the so called "borate anomaly" (BA)—the changes in the properties of borates which are non-additive in terms of composition.[35,197] The extrema and inflections in the "composition–property" relations are located predominantly in the regions corresponding to the compositions $2M_2O.5B_2O_3$ and $M_2O.5B_2O_3$ (28.6 and 16.7 mole % M_2O) and for certain properties also when the M_2O content is 4 to 5 mole.[197] Among the different models of the structural

[a] The macroanions listed in Tables 3 and 4; the literature references are given to the monoanions and oligoanions; ?—the compound is known but its structure has not been elucidated; dash—there is no information about the formation of compounds; α-, β-, and γ- as well as phase I, II—the compound exists in different polymorphic modifications.

[b] Compounds belonging to the Li_2O–LiCl–B_2O_3 system are also present in the glass formation region; see compounds (LXXXVI) and (LXXXVII) in Table 4.

[c] The Na_2O–B_2O_3–CO_2 system (effect involving the retention of CO_2 in the structure of borate glasses containing more than 67 mole % Na_2O [180]).

[d] It is appropriate to make a comparison with the structure of caesium borate of the same composition—see compound (LXXIV) in Table 4.

[e] The MgO–$MgCl_2$–B_2O_3 system.

[f] Isostructural with $CaO.B_2O_3$-I according to some data.[26]

[g] The La_2O_3–B_2O_3–MoO_3 and La_2O_3–B_2O_3–WO_3 systems.

[h] For the last four systems, there is a possibility of the incorporation of Zn, Cd, Pb, and Bi into the structure of macroanions in the vitreous state, i.e. the formation of the corresponding copolymers.[7]

[i] The CdO–CdS–B_2O_3 system.

[j] The compound $6PbO.5B_2O_3$, consisting of oligoanions with $n = 10$, is also present in the glass formation region[113] (see Fig.8, E).

changes occurring under these conditions, Tarasov's model[184,199] with certain modifications, illustrated in Fig.14 (here N_4 is the fraction of BO_4 according to NMR data), is thought to be outstanding.[198]

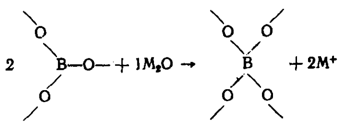
Table 6. The system of notation adopted in the chemistry of vitreous borates.[35]

Borate groups			Names of groups	Symbolic representation[a]
Fig.8	Fig.9	Fig.10		
A, a	—	—	Orthoborate	b'''
B, a	—	—	Pyroborate	b''_2
C	—	—	Cyclic metaborate	b_3
—	(XXXIV)—(XXXVIII)	—	Chain metaborate	b_∞
—	—	Subunit (LXXIV)	Boroxole ring[b]	a_3
—	(XLII) и (XLIII)	—	Triborate	a_2c
—	—	Subunit (LXXXI)	Triborate with one cyclic (non-bridging) oxygen ion	abc
—	—	Subunit (LXXV)	Di-triborate	ac_2
—	(XLVIII)—(LIII)	—	Diborate	a_2c_2
—	(LIV) и (LV)		Pentaborate	a_4c
—	—	Subunit (LXXXI)	Di-pentaborate	a_3c_2
—	—	(LXXVIII)	Tetraborate	a_6c_2

[a] Here a represents the BO_3 triangle with all the bridging (connecting) oxygen atoms, b, b'', and b''' represent similar triangles with one, two, and three terminal (non-bridging) oxygen ions, and c is the BO_4 tetrahedron with all the bridging (connecting) oxygen atoms [as in the CRU (XL) and (XLI) in Fig.9]. For example, the CRU (XLII) and (XLIII) in Fig.9 can be represented by the abbreviated formula a_2C.

[b] This is also the CRU in the layer network of vitreous B_2O_3 [1,35] (although it has been suggested[204] that the model in Fig.15c agrees best with experimental data in this case).

According to this model, as the M_2O/B_2O_3 ratio increases, the (B_2O_3) macromolecules, which are initially of the parquet type (Fig.14a), are cross-linked to form a three-dimensional network (Fig.14b) via the reaction[35]



$$2\ \geq B{-}O{-} + 1M_2O \rightarrow\ >B< \ + 2M^+$$

Next follows the accumulation in the network of non-connecting BO'_4 groups, i.e. the terminal $\geq B{-}O^-M^+$ groups (Fig.14c) with retention of the maximum density of cross-links attained in the region of x = 25 mole % M_2O. After this, the completion of the "accumulation" of BO'_4 is accompanied simultaneously by the degradation of the cross-links between the layers (Fig.14d). The latter then involves bonds between cyclochains in the layer, including the termination of the cyclochains themselves (Fig.14e). Finally, in the composition $M_2O.B_2O_3$, the small Li^+ ions are distributed freely at the terminal O atoms after the degradation of the polyboroxane layers into strips and chains and the capacity for their formation is retained (Fig.14f'). Under these conditions, as in the case of B_2O_3,[1] the CRU in the $Li_2O.B_2O_3$ chains in the vitreous and crystalline states are not identical, since in the former state N_4 = 33.3% while in the latter N_4 = 0. The larger Na^+ and K^+ ions break up the chain into segments as far as the formation of the corresponding cyclic trimers. The capacity for glass formation is then lost (Fig.14f''). Tarasov's model agrees with NMR data and explains satisfactorily a number of the changes in the properties of the vitreous borates.[7,184,200–202] At the same time it can be supplemented by taking into account the idea that some of the boroxole rings in the $B_2O_3)_C$ structure are opened,[1,203] particularly on passing to melts (Fig.15).[204] This is the reason for the larger set of CRU in the network and in the fractions of low-molecular-weight anionic groups in borate glasses.[35,200,205]

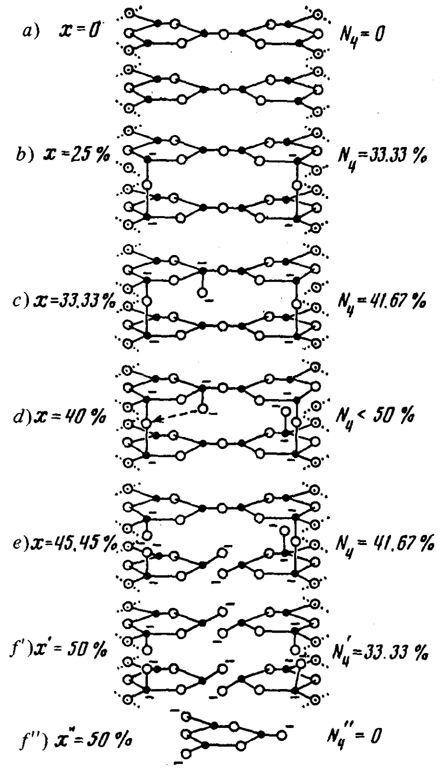


Figure 14. Tarasov's model for the cross-linking-degradation reactions of a network of borate glasses with M_2O contents in the range x = 0–50 mole % (according to Tarasov[184,199]).

This type of model does not exhaust the entire wide variety of mechanisms of the change in the long-range polymeric order in borate glasses (and the BA effect associated with it). For example, the interconversions of the one-, two-, and three-dimensional macroanions and their CRU can change as a result of hydrolysis (the properties of the glasses synthesised *in vacuo* and in air differ[197]). The fraction of the $\geq B{-}OH$ end groups (the changes in N_4 are not recorded by NMR) corresponding to 20% mole % M_2O can amount to only 0.002–0.004,[206] but this is not small, because even 0.01–0.1% of cross-linking (destructuring) agents are capable of influencing the course of macromolecular reactions.[189] Since vitreous borates are polyelectrolytes,[207] certain extrema (for example the solubility minimum) can be induced by passage through the isoelectric point (p*I*).[208] Since acid–base interactions are a fundamental concept in the chemistry of glass,[209] it is to be expected that additional structure-forming oxygen can be introduced into the glass network not only with M_2O (see Fig.14) but also directly from the atmosphere as N_4 is varied.[210,211] From the standpoint of the chemistry of macromolecular compounds, it is also not immaterial in what way the glass network has been formed: (a) by the fusion (congruent or incongruent) of the polymeric single crystal; (b) by the introduction of M_2O into the polymer $(B_2O_3)_c$ (Fig.14); (c) by synthesis from a charge containing monomeric $B(OH)_3$. In the latter case a series of macroanionic reactions, including polycondensation, BR effects (Section II), etc. take place. For example, a mixture of $Li_2O.B_2O_3$, $Li_2O.2B_2O_3$, and $Li_2O.4B_2O_3$ is formed at 873–1173 K from a mixture of H_3BO_3 and Li_2CO_3.[212] Although the exchange interaction[15] can lead to the formation of an equilibrium melt, it remains probable that different conformations of the macroanions, a distribution of their molecular weights, etc. will be observed under different cooling conditions in glasses with identical overall compositions.† Finally, changes in the structural organisation already at the polymeric-colloidal level can exert an appreciable influence on the properties of glasses,[181–183] as will be shown in the next Section.

Table 7. The phase separation regions and parameters in certain borate glass forming systems.[181]

M_xO_y in the M_xO_y–B_2O_3 system	Critical temperature, K	Critical composition (c_c), mole % M_xO_y	Liquidus temperature at c_c, K	Minimum temperature[a] T_{min}, K	Concentration range[b] for liquation at T_{min}, mole % M_xO_y

[a] In the range investigated.

[b] Like the boundaries of the glass formation regions (Table 5), these boundaries depend on the method of observation and can differ from the data quoted here.[213] In particular, the electron paramagnetic probe method,[214] for example, EPR for Cu^{2+} and other ions,[215] reveals the presence in the optically transparent borate glasses of the region of the so called "EPR immiscibility".[216] In order to eliminate the latter, for example, in the K_2O–BaO–B_2O_3 system, the K_2O content should be ten times greater than that required for the elimination of opalescence.[216]

[c] A "pseudophase" structure,[224,225] resembling structures of the phason type, known in the colloid chemistry of polymers[183] and intermediate between the classical one- and two-phase structures, has been discovered in alkali metal borate systems with Na_2O and K_2O.

[d] The system has two critical points—the upper point in the region of stable liquation and lower point in the region of metastable liquation.

[e] The temperature at which the region of liquating compositions is widest.

3. Oxoborate Melts

Melts of low-molecular-weight anionic borates are typical ionic liquids: they expand with increase of temperature and their viscosity falls, while on cooling they readily crystallise without passing to a vitreous state. On the other hand, monophase and multiphase glasses, polycrystalline sitalls, and polymeric single crystals can be obtained from melts of macroanionic borates (i.e. glass-forming melts) when the composition and conditions are varied.

Table 7 indicates the regions and parameters of phase separation in certain borate glass forming systems.[181] The table shows that phase separation is manifested for low contents of M_xO_y in B_2O_3. The latter does not exhibit microheterogeneities other than thermal density fluctuations.[217]# The characteristic LAX [220] and light scattering[221] "flash" on passing to a melt is gradually abolished and the state usual for thermal density fluctuations obtains. The content of M_xO_y less than 25 mole % in the melt is apparently insufficient for the formation of the structure, illustrated in Fig.14b, throughout the bulk of the melt. New CRU, stabilised by the metal cations, arise in the B_2O_3 matrix (Fig.15). These CRU form individual blocks in the B_2O_3 matrix (this is indicated by the low-frequency branch of the Raman spectra[200,222]) connected to the CRU of the matrix via B–O–B linkages. Ultimately the "network" is found to be made up of CRU blocks of different chemical nature. In the colloid chemistry of polymers[183] such systems (of the type of network polyblock polymers or IPN)§ are treated as multicomponent polymer mixtures as regards phase separation. Phase separation in such mixtures proceeds via binodal (nucleation and growth) and spinodal mechanisms. The phase decomposition mechanism is known[183] to influence the morphology of the polymeric-colloidal structures formed.

The nucleation and growth mechanism	Spinodal mechanism
1. The composition of the second phase remains constant and invariant in time (equilibrium phase).	1. Before the attainment of equilibrium, there is a continuous change in composition.
2. The interface between the growing phase and the matrix is sharp.	2. The interface is diffuse and only gradually becomes sharp.
3. There is a distinct tendency towards a statistical distribution of the sizes and positions of the particles of the equilibrium phases.	3. A definite regularity arises in the sizes and distribution of the segregated phases.
4. The particles of the segregated phases tend to become spherical and only weakly interconnected.	4. The separated phases are usually non-spherical and are highly interconnected.

---

† Effects similar to BA (as well as BR) are not a unique feature of borates and are manifested also in phosphate, inverted silicate, and other oxide glasses.[197]

We have in mind a preparation obtained from an evacuated melt. The presence of H_2O entails, according to low-angle X-ray diffraction (LAX) data,[217] the appearance of 25–30 nm heterogeneities, which is correlated with electron-microscope observations[218] and is reflected in a change of the rheological properties[219] (the appearance of a yield point and a decrease of viscosity). A decrease of viscosity is characteristic of only low (<0.3 mole %) H_2O contents, while an increase of the water content to >0.5 mole % inhibits such decrease.

§ A characteristic feature of macromolecular networks is the presence of rings in the latter and also a globular supermolecular organisation.[223] This is probably valid also for macroanionic networks.

The rheological, electrical, optical, diffusion, and chemical properties of borate melts and glasses, their glass points, densities, thermal expansion coefficients, capacity for crystallisation, etc. depend in their turn on the character of the phase distribution.[181,182] Hence the importance of taking into account the polymeric-colloidal aspect in synthesising vitreous materials with specified properties becomes clear.

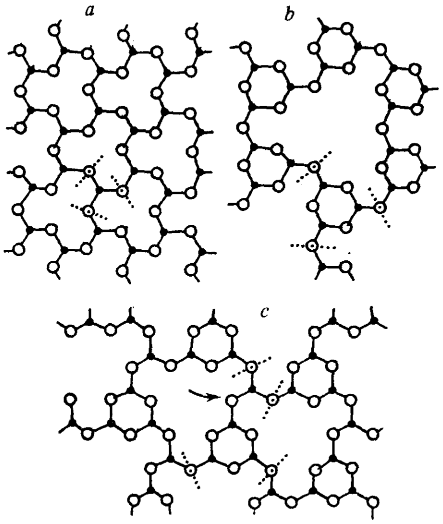

Figure 15. Quasi-crystalline models for the B_2O_3 melt:[204] a) $[BO_{1.5}]_{nn}$; b) $[B_3O_{4.5}]_{nn}$; c) $[B_3O_{4.5}\cdot BO_{1.5}]_{nn} = [B_4O_6]_{nn}$; the last model agrees best with the experimental data.

Together with features which they have in common with polymer mixtures, systems of the type of network polyblock polymers and IPN are also characterised by features such as the presence of chemical and real spinodal curves. For systems with an upper consolute point (UCP), the latter passes below the chemical spinodal curve, so that the region of unstable states under the real spinodal curve can be altogether inaccessible.[183] In the region between the chemical and real spinodal curves lie dissipative systems of the phason type, which are intermediate between the classical one- and two-phase systems. These apparently include also the so called "pseudophases" [224] and "modulated structures" [225] observed in borate melts and glasses. On ultracentrifugation of the melts,[182,226] the compositions of the separated phases correspond to those expected on the basis of the phase diagrams. Numerous examples of the practical applications of phase separation in glasses, including the so called precondition for the formation of sitalls,[228] are known.[227] The heat treatment of borate glasses designed to convert them into sitalls is carried out at 1023–1173 K (Ref.228, p.410). If polycrystalline sitalls are obtained in the presence of not less than 10^{12} prenuclear centres in 1 cm^3 of the volume, then the synthesis of polymeric single crystals requires the directional growth of one or several nuclei (see the original communications quoted in Tables 3 and 4). In general, the rate of growth changes from 2 [$PbO.2B_2O_3$—(XCVIII) in Table 4] to approximately 3000 μm s^{-1} [$Li_2O.2B_2O_3$—(XLVIII) in Table 3 [229]].

4. Oxoborates in the Gas Phase

Above the UCP, the glass-forming melts are homogenised evidently as a consequence of the decrease of the molecular weight and of the degree of polymerisation with increase of temperature. The presence of M_xO_y [230,231] as well as H_2O [1,232] in the B_2O_3 melt promotes its thermal degradation with transfer to the gas phase of low-molecular-weight anionic metal oxoborates[233–239] or of the low-molecular-weight fraction of hydrogen oxoborates.[1] Graft copolymerisation of the latter with various oxide substrates[11–13] makes it possible to achieve the chemical moulding of joints and coatings,[240–243] which has an advantage over the traditional technology in that it is possible to avoid laborious operations involving the processing of a macroanionic substance, since the synthesis of the polymer is combined with its moulding. As a consequence of the heterodiffusional character of the polymer formation reaction,[244] reactions of this type made it possible to achieve a gradient anisotropy of properties (refractive index, coefficient of thermal expansion, etc.) with respect to thickness. Special procedures for the formation of boron–oxygen monomers in the gas phase are also used in establishing a refractive index gradient in the manufacture of articles for fibre and integrated optics.[245,246]

IV. CONCLUSION

The question arises how one can account for the wide variety of borate macroanions which can be different for borates having identical chemical compositions. It is known that the unique nature of the macroanions and macromolecules is determined by the following criteria: (1) chains (layers, networks) of atoms or groups of atoms (CRU) linked by directional, predominantly covalent,¶ bonds can be discovered in their structure by one method or another;[1,185] the capacity for the formation of such chains (layers, networks) is determined by the structure of the electron shells of the corresponding atoms, i.e. by their position in the Periodic System of the Elements;[6,184] (2) the set of their properties does not change appreciably with decrease (increase) in the size of the chain (layer, network) by one or several CRU.[1,27] Such chains (layers, networks) are to some extent flexible due to the retention of the rotational degrees of freedom of the constituent units,[248] which is achieved in polyelementoxane macroanions as a result of a

---

¶It has been suggested[247] that a given chain (layer, network) is polymeric provided that the degree of covalence of the bonds between the atoms in it is not less than 50% (52, 65, 68, 71% respectively for Al–O, Si–O, B–O, and P–O) or in the case of magnesium–oxygen polymers it can even be as low as 43%. Apart from electronegativity, the decrease of the entropy of a particular element with increase of the degree of polymerisation, i.e. of the number of covalently bound atoms, can serve as a measure of the degree of covalence of bonds.[247]

change in the bond length and valence angles in the E–O–E p-bridges (E = Si, B, P, Al, etc.).[184,191] This ensures a fairly large set of conformations in the given macroanions (a physical change in the steric form) and configurations (a change in form accompanied by a chemical reaction, i.e. by at least one transposition of bonds or valence angles). Hence one can understand not only the ability of the macroanions to pass to the vitreous (and for linear and layer macroanions also the highly elastic) state[184,191] but also their ability, familiar in crystal chemistry,[249] to "become adjusted" to the cationic component of the structure, i.e. their ability to alter, as the nature of the cations is altered [or, for the same cation, when the conditions of synthesis are changed—see, for example, (LXXXIII) and (LXXXIV) in Table 4], their configuration at all levels of the structural hierarchy—from CRU (including the formation of the "bow-shaped" configurations  and bridges of the type  [249]) to a superanionic organisation (the formation of IPN). In anhydrous compounds the requirements for the flexibility of the macroanion are enhanced, as increase in degree of hydration entails the appearance of the possible coordination of the cations not only to the $>\!E{-}O^-$ end groups or the connecting $-\overset{|}{\underset{|}{E}}{}^{-}-$ groups but also to the oxygen of water with subsequent damping [?bonding (Ed.of Translation)] via hydrogen bonds to the anion.[36,250]

As a result of the non-directional nature of the ionic bond, the cations always tend to become surrounded by the maximum number of counter-ions. For this reason, in the structural† sense, cationic constructions constitute a conservative, rigid base of substances with element–oxygen macroanions.[249] On the other hand, the macroanions are a component of the structure of such substances, which is variable and responds to a change in the nature of the cation and external conditions. Their configurational and conformation statistics are determined by O atoms in a state intermediate between the sp^2- and sp-hybridisations with atoms of other elements[251] and ultimately determines both the wide variety of borates, silicates, phosphates, and similar compounds and many of their properties.

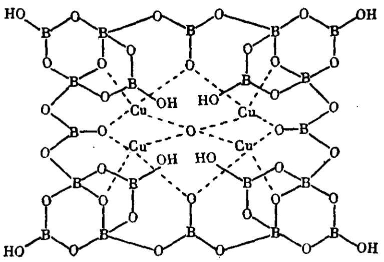
This justifies the assumption that the development of the chemistry of these substances, which are widely distributed in nature and are used in technology, will be determined by the advances in their polymer chemistry. The *chemistry of macroanions*, which, in contrast to the macromolecular chemistry of carboatomic compounds, is still an inadequately developed albeit a promising field of polymer chemistry, comes to the fore for such substances. For the development of this field, it appears useful to employ a combined approach the necessity for which has been noted at the XXIInd Conference on the Chemistry and Macromolecular Compounds.[252] Its essential feature is as follows: since the unity of the material world is manifested in inorganic polymers, in order to reflect it adequately it is essential to achieve the symbiosis of various chemical disciplines, in the first place the macromolecular and colloid chemistry of polymers with inorganic chemistry. In this sense the present review (as well as the previous review[1]) should be regarded as an attempt at a practical realisation of this type of approach to borates and an attempt to present on this basis a sufficiently logical and well-founded picture of their structure, to demonstrate new ways of study, and to facilitate the prediction of the properties of technical materials and the improvement of the technology of their manufacture.

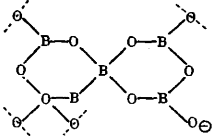
---oOo---

During the preparation of the manuscript for the press, a new monograph, devoted to inorganic polymers, was published.[253] Other publications[254,255] and the Russian translation of the IUPAC recommendations concerning the nomenclature of single-stranded and quasi-single-stranded inorganic polymers[256] attract attention in this connection. The choice of oxygen as a basis for the chemistry of non-carbon polymers has been justified[254] and a classification of the elements of the Periodic Systems in terms of their contributions to the structures of heteroatomic polymers has been developed.

During the same period, the family of oligoborates has been supplemented by a new representative $K_5H\{Cu_4O[B_{20}O_{32}.(OH)_8]\}.33H_2O$,[257] where n = 20. Ghose[258] examined the stereoisomers of the hilgardite network [(XVIII) in Table 1] with stereorepeating units made up of 1-, 3-, and 4-CRU.

Fig.9 may be supplemented by an example of a new pentaborate CRU ($3BO_3$ + $2BO_4$) with a single terminal (non-bridging) O atom:





while Table 3 may be supplemented by the corresponding example of a layer macroanion $[B_3^{III}B_2^{IV}O_8(O^-)]_{nn}^{3nn-}$, whose presence in the $CaNa[B_5O_9]_{nn}$ has been established,[259] and by yet another representative of phylloborates belonging to the $LnCo[B_5O_{10}]_{nn}$ group, where Ln = Yb.[260] Table 4 should be supplemented by new examples of boracites: $Fe_3Cl[B_7O_{13}]_{nnn}$ [261] and $Cu_3I[B_7O_{13}]_{nnn}$.[262]

Thermodynamic calculations have been carried out on the regions corresponding to the existence of various boron–oxygen monomers in the B_2O_3–H_2O vapour–gas phase at T = 300–1500 K at atmospheric pressure.[263]

The section on vitreous borates can be supplemented by data from a new review.[264] Detailed data on alkaline earth metal borates are described in a new monograph.[265]

The Isomorphism and Catalytic Properties of Silicates with the Zeolite Structure

K.G.Ione and L.A.Vostrikova

The properties of a new group of catalysts based on crystalline silicates with the zeolite structure[†], containing the multicharged Be^{2+}, B^{3+}, Cr^{3+}, Fe^{3+}, Mn^{2+}, Cu^{2+}, Zn^{2+}, Mo^{6+}, Se^{6+}, etc. cations occluded in the hydrothermal crystallisation process, are described. The state of the multicharged cations in the silicates has been characterised by physical methods (NMR, EPR, and X-ray diffraction). The selectivity and catalytic activity of such silicates in the formation and other reactions of hydrocarbons and hydrocarbon mixtures are examined.

The bibliography includes 174 references.

I. INTRODUCTION

According to Pauling's theory[1] and Tanabe's later revised versions,[2] the acid–base properties of binary oxides are determined by the incomplete compensation of the charges of the corresponding ions by the oxygen atoms in the environment. Any isomorphous heterocharge substitution of Si^{4+} cations in the silicon–oxygen skeleton of silicates by other cations of the type $Si^{4+} \rightleftharpoons M^{n+}$, where $n \neq 4$, should then impart to silicates a capacity for acid–base catalytic activity. Crystalline silicon oxides, including silicalite,[3] with an extensive system of pores are indeed adsorbents, but they do not possess catalytic properties. The catalytic properties of aluminosilicates, including zeolites, are determined by the fixation of aluminium cations in isomorphous positions in the silicon–oxygen skeleton as a result of the exchange $SiO_4^{4-} \rightleftharpoons AlO_4^{5-}$.

The idea that the above isomorphous heterocharge substitution takes place in zeolites, constituting a precondition for the formation of catalytically active centres, has been confirmed by a large number of data. For example, a dependence of the unit cell constant on the aluminium content in the zeolite crystals has been established.[4,5] It has been shown by ^{27}Al NMR that the vast majority of aluminium atoms in zeolites are in a tetrahedral oxygen environment.[6,7] It has been observed by ^{29}Si NMR [8-10] that the second coordination sphere of the Si^{4+} ion in the silicon–oxygen skeleton may contain between 1 and 4 aluminium atoms in groups of the type $[Si(OAl)_n]^{n-}$. A statistical model has been developed for the distribution of such groups with respect to the quantity n as a function of the overall aluminium content in the zeolite.[11] It was later suggested[7,12-15] that the change in the conditions of hydrothermal synthesis and in the subsequent treatment of zeolites can induce a deviation of this distribution from the statistical average in one direction or another.

It has been established that, as cations are eliminated[15,16] and also as a result of treatment of the specimens with acids,[17,18] $SiCl_4$,[19,20] and water vapour,[21,22] a signal with $\delta = -3-0$ p.p.m., assigned to Al atoms in an octahedral oxygen environment, i.e. outside the skeleton, appears in the ^{27}Al NMR spectra of zeolites together with a signal having the chemical shift $\delta = 55-61$ p.p.m. (which corresponds to Al^{3+} in a tetrahedral coordination with oxygen ions, i.e. in the silicon–oxygen skeleton. The solid-phase reactions

$$\underset{(I)}{[Si(OAl)_n]^{n-}} \rightarrow \underset{(II)}{Si[(OAl)_{n-1}]^{(n-1)-}} \frac{(n-1)}{3} Al^{3+},$$

leading to the appearance of the centres (II), probably occur during the cation elimination process ["decationation"] and in the course of thermochemical treatment. A group of type (II) can be regarded as a conjugate acid and base, capable of two-centre interaction with the reactant molecule. According to the literature,[12,15] the selectivity and stability of the catalytic action of zeolites depend both on the distribution of the groups $[Si(OAl)_n]$ with respect to n and on the concentration of groups of type (II).

Zeolites have found applications as catalysts in petroleum processing and in petrochemical processes. Different questions concerning their synthesis, investigation, and application have been considered in many reviews and monographs.[23-25] A series of studies devoted to new generation zeolites, of the ZSM type or pentasils, have been published during the last decade.[26,27] However, any zeolites constitute merely a special case of the manifestation of isomorphism, because they are all silicates with the same type of isomorphous substitution: $SiO_4^{4-} \rightleftharpoons AlO_4^{5-}$ or $Si^{4+} \rightleftharpoons Al^{3+}Na^+$.

A series of studies have been made in which silicates with the zeolite structure have been synthesised without adding sources of aluminium but in the presence of multicharged cations or Group I–VIII elements (M^{n+}), which created preconditions for the isomorphous substitutions $Si^{4+} \rightleftharpoons M^{n+}$ in the silicate skeleton formed.[23,28-30] This method of synthesis of silicates differs significantly from the methods of preparation of zeolites, in which multicharged cations are introduced by ion exchange. A zeolite behaves in ion exchange as a polyacid salt in which the chemical composition of the macroanion does not change and only the chemical nature of the cation, compensating for the negative charge

---

[†] We shall henceforth refer to crystalline silicates with the zeolite structure, obtained under hydrothermal conditions from mixtures to which aluminium compounds had not been added before hydrothermal synthesis, as elementosilicates or ez-silicates.

of the skeleton, is altered:

$$[\mathrm{Si(OAl)}_n]^{n-}M_1^{n+} \xrightarrow[-M_1A^-]{+M_2A^-} [\mathrm{Si(OAl)}_n]^{n-}M_2^{n+}.$$

The state of the cations fixed in zeolites in this way has been characterised in a large number of studies[31-33] (see also the relevant reviews[25,34]).

The introduction of multicharged cations M^{n+} into the initial silica gel before its hydrothermal crystallisation leads to the possibility of altering the chemical composition of the anionic part of the silicon–oxygen skeleton:

$$[\mathrm{Si(OM)}_n]^{n-} \text{ and } [\mathrm{Si(OM)}_{n-1}]^{(n-1)-}\ \frac{n-1}{n}M^{n+}.$$

The uncompensated charge of the anionic component of the silicate and hence also the strength of the centres with acid–base properties should depend on the nature of the cation M^{n+}.

II. GENERAL RULES GOVERNING THE LIMITATION OF THE DEGREE OF ISOMORPHOUS SUBSTITUTION

The ideas about isomorphism are widely used in geochemistry and crystal chemistry. According to definitions,[35,36] isomorphism is a result of the capture of impurities in the course of the crystallisation of the system with substitution of some of the atoms by the impurity atom without change in the type of crystal structure of the original state. Approximate relations between the thermodynamic parameters of the system and the degree of isomorphous substitution have been examined in a review.[37] The principal postulates which must be taken into account in estimating the probability of isomorphous substitution reduce to the following:

1. By virtue of the existence of a definite relation between the enthalpy of formation of the system with isomorphous substitution and the ratio of the radii (R) of the interacting ions A and B, the limits of the mutual substitution are smaller the greater the difference between the values of R. It has been suggested[38] that the isomorphous exchange A $\rightleftharpoons$ B is possible provided that $\Delta R/R \leq 0.15$.
2. The ions A with larger R substitute the ions B with smaller R more readily than in the case where substitution is accompanied by a decrease in the coordination number of the ion A and, conversely, the substitution is more difficult if it is accompanied by an increase in the coordination number of the ion A.[38]
3. The limits of isomorphous substitution depend on the ratio of the electronegativities χ and ionisation potentials of the interacting ions.
4. In the isomorphous substitution A $\rightleftharpoons$ B there is a possibility of a shift of the central atoms with retention of the symmetry of the environment in the main system. The minimum in the free energy of the system is attained when the atoms A and B shift by $(0.025-0.03)R$.
5. Since the exchange A $\rightleftharpoons$ B does not alter the long-range electrostatic interaction, a long-range order in the disposition of A and B may be absent, but a short-range order should exist as a condition for the attainment of the energy minimum.[39]
6. The substitution A $\rightleftharpoons$ B can occur when the charges differ by 1, 2, and 3 units. The compensation of the excess charges generated can be non-local (via the formation of electronic and hole centres) and local, when a species with a balancing charge is located in the immediate vicinity to the excess charge. Local defects can have uncompensated magnetic moments and can interact with an external magnetic field, which leads to the possibility of their investigation by EPR.
7. The distribution of ions in the crystal lattice can be statistically uniform or non-uniform.[40,41]
8. The mutually substituting cations should be chemically inert in relation to one another.

Examples of pairs of cations whose mutual substitution can take place with a high probability have been published:[35] the substitution of Si^{4+} by the Ge^{4+}, Al^{3+}, Be^{2+}, Fe^{3+}, Ga^{3+}, P^{3+}, and Ti^{4+} ions is most probable for the $Si^{4+} \rightleftharpoons M^{n+}$ system.

The parameter ρ, introduced by Pauling,[1] can also be used as a criterion for the selection of cations capable of mutual substitution. By definition,[1] ρ is a criterion of the stability of the state of the cation in the given coordination environment and is a function of the attractive and repulsive forces of the ions in the first coordination sphere. To a rough approximation, ρ can be set equal to the ratio of the radii of the cation and anion. The critical values of the parameter ρ for oxides (ρ_c) outside the limits of which the coordination environment of the cation should change, calculated in accordance with Pauling's approximations, are listed in Table 1. The table also includes the values of ρ for different cations. [The ionic radii R taken from Bokii [42] and $R_{O^{2-}} = 1.36$ Å [43] were used in the calculation of ρ.)

Table 1. The parameter ρ for the M^{n+} cations.[1]

Group 1 ($\rho_c = 0.732$; C.N. = 8)		Group 2 ($\rho_c = 0.414$; C.N. = 6)		Group 3 ($\rho_c = 0.225$; C.N. = 4)		Group 4 ($\rho_c = 0.147$; C.N. = 3)	
M^{n+}	ρ	M^{n+}	ρ	M^{n+}	ρ	M^{n+}	ρ
Pb^{2+}	0.926	In^{3+}	0.676	Al^{3+}	0.419	B^{3+}	0.147
Sn^{2+}	0.750	Mn^{2+}	0.669	Mn^{4+}	0.382		
Tl^{3+}	0.772	Zn^{2+}	0.610	Ge^{4+}	0.323		
Nd^{3+}	0.73	Hf^{4+}	0.603	V^{5+}	0.294		
Eu^{3+}	0.71	Cu^{2+}	0.589	Si^{4+}	0.287		
		Sn^{4+}	0.492	Cr^{6+}	0.257		
		Fe^{3+}	0.492	P^{5+}	0.257		
		Mo^{6+}	0.478	Se^{6+}	0.257		
		Ti^{4+}	0.470	Be^{2+}	0.250		
		Pt^{4+}	0.470				
		Cr^{3+}	0.470				
		Sb^{3+}	0.470				
		Ga^{3+}	0.456				
		Sb^{5+}	0.456				
		V^{4+}	0.449				

According to Pauling's criterion,[1] only cations comprising Group 3 in Table 1 should be fixed in a stable tetrahedral environment. Vernadskii's isomorphous series, within the limits of which cations in natural formations are believed to be capable of isomorphous mutual substitution, is widely known: Si^{4+}, Al^{3+}, Ga^{3+}, Fe^{3+}, Cr^{3+}, V^{4+}, Mn^{2+}, Mg^{2+}, Ti^{4+}.[35] It is assumed[35] that, within a narrow range of concentrations of the substituting ion (less than 1 at.%), isomorphism is possible in virtually all inorganic compounds.

III. HYDROTHERMAL SYNTHESIS

The principal procedures in the synthesis of zeolites and ez-silicates are the same. The initial mixtures contain in both cases a source of silicon, alkali, and salts of multicharged cations but in the synthesis of elementosilicates a source of aluminium is not added. There is a possibility of synthesising elementosilicates incorporating simultaneously several types of cations, with the substitution $Si^{4+} \rightleftharpoons M_1^{n+} + M_2^{n+}$.

In the preparation of elementosilicates with the structure of zeolites of the pentasil or ZSM type, organic surfactants, namely quaternary ammonium bases, polyamines, aminoalcohols, alcohol, etc., are also introduced into the initial mixture. An aqueous silica sol, water glass, and silica gel are used as sources of silicon. A mixture consisting of a source of silicon, a source of M^{n+}, organic additives, alkali, and, sometimes, a seed is homogenised and then placed in an autoclave, where it is kept under hydrothermal conditions for 1–30 days at 80–200 °C. After the completion of crystallisation, the deposit is filtered off, washed, and dried. Before catalytic tests, the solid product is annealed at 520–550 °C in order to eliminate organic inclusions and cations are removed by treatment with $NH_4OH + NH_4Cl$ solutions or solutions of inorganic acid.

We shall consider briefly the characteristics of the chemical behaviour of the SiO_2–H_2O and SiO_2–M_nO_m–H_2O systems in hydrothermal treatment. It is known[44] that $Si(OH)_4$ coagulates in the range $6 < pH < 8$, dissolution and depolymerisation begin at $pH \geq 9$, while at $pH > 10.5$ complete depolymerisation of $(SiO_2)_n$ is observed. In the pH range from 12 to 13.56, the system contains predominantly disilicate ions of the type $[Si_2(OH)_{10}]^{2-}$ whereas at $pH \geq 13.83$ the monosilicate ions $[Si(OH)_5 2H_2O]^-$ predominate.

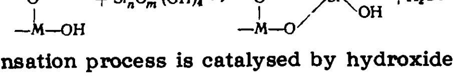
Thus polymerised silicon-containing ions of the type $[Si_nO_m(OH)_p]$, in which the coordination number of Si^{4+} is 4, predominate in aqueous media in the range $6 < pH < 10$. As a result of the surface reactions $[Si_nO_m(OH)_p] + 2OH^- \rightarrow [Si_nO_m(OH)_pO]^= + H_2O$, such species require a negative charge.

The polymerisation condensation of silicate ions includes reactions proceeding via an ionic mechanism with participation of OH^-. The condensation leads to the formation of siloxane linkages and the probability of the synthesis of cyclic structures is therefore high.

As a result of polymerisation condensation processes, silicate ions incorporating individual elements or individual structural blocks comprising crystalline varieties of silicates may be formed in an aqueous medium. Such structural blocks may be four- and six-membered rings of tetrahedra. The six-membered rings can be combined to form secondary structural blocks: an individual six-membered ring (beryl) and one-dimensional (amphiboles), two-dimensional (pyroxenes), and three-dimensional (elements of ultramarine, α-quartz, tridymite, and cristobalite) chains of rings.

The multicharged ions hydrolyse in aqueous solutions with formation of positively charged species and liberation of a proton to the outer sphere of the complex. The pK for the acid hydrolysis of multicharged cations have been published.[45,46] In alkaline media the hydroxides of Zn^{2+} and Si^{4+} are more basic than $Si(OH)_4$, while the hydroxides of the cations listed below are more acid, their acidity decreasing in the sequence $Ti^{4+} > Fe^{2+} \cong Fe^{3+} \cong Ga^{3+} > Th^{4+} > Al^{3+} > B^{3+} > In^{3+} > Si^{4+}$. The multicharged B, Ge, Tl, Cr, Mo, W, and V ions can hydrolyse with formation of negatively charged species. There is also a possibility of the polymerisation of hydroxides with formation of dinuclear and polynuclear complexes.[47]

The addition of metal salts facilitates the coagulation and polymerisation of silicate ions. In the presence of multicharged hydrolysed M^{n+} ions, the solubility of silicate ions falls in the first place owing to heteropolymerisation reactions:



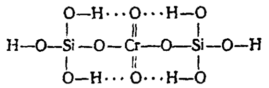
The condensation process is catalysed by hydroxide ions in this case also. The higher the charge of the ion, the greater its capacity for coagulation in relation to silica sol.

The Al^{3+} cation interacts most effectively with the monomeric silicate ion at pH 9. In the pH range 5–7, there is a possibility of the formation of the $[Al(OH)_2]^+$ and $[Al_2(OH)_5]^+$ ions. The complexes $NaAl_{13}(OH)_{32}(SO_4)_4(H_2O)_x$ are formed in the presence of SO_4^{2-}. The cation $[Al(OH)_4]^-$ is formed at pH 9–11.[47]

The interaction of Fe^{3+} with the surface Si–OH groups proceeds via heteropolymerisation processes, which has been demonstrated by the fact that at pH 6–8 the precipitation of $Fe(OH)_3$ on the macrosilicate ions is not observed in an SiO_2 containing system.[44]

As regards the character of its interaction with $(SiO_2)_n$, the cation Cr^{3+} differs greatly from Al^{3+}. The reason is that the chromite ion is not formed as readily as AlO_2^-; furthermore, Cr^{3+} is much larger than Al^{3+} and cannot be incorporated in the SiO_2 lattice with formation of stable anions.

The chromate ion, containing Cr^{6+}, retards the polymerisation of $Si(OH)_4$ at pH 0.5–3.0. It has been suggested[44] that the silicate ions dimerise in the presence of Cr^{6+} with formation of species of the type



The chemical properties of the Be^{2+} cation resemble those of Al^{3+}; solutions of beryllates, like those of aluminates, contain polymeric anions of the type $Be_2O_3^{2-}$ and oxo- and hydroxo-complexes. The hydrolysed Be^{2+} ion is capable of being strongly adsorbed on silica.[44]

The rate of interaction of silicic acid polymers with molybdic acid is higher the lower the molecular weight of the polymer. The interaction is preceded by the successive dissociation of the silicate ions to the monomer, which results in the formation of molybdosilicic acid.[44] The reaction of the silicate ion with H_3PO_4 represents condensation without the participation of water.[44] The Si–O–P and Si–O–B linkages hydrolyse in aqueous solutions. The precipitation of zinc salts by sodium silicate entails the mutual coagulation of zinc hydroxide and silica without the subsequent crystallisation of an amorphous deposit.[48,49]

Table 2. Conditions in the synthesis of beryllosilicates with the zeolite structure.

Type of structure	Source of Be^{2+}	Source of Si^{4+}	t, °C	τ, days	SiO_2/BeO*	Refs.
D, orthorhombic	$Be(NO_3)_2 + NaAlO_2$	32% SiO_2 sol	175	2	12—60	[50]

TRS-27, -41, -42	$Be(NO_3)_2$ in alcohol***	TEOS**, SiO_2 sol	155—200	0.5—1.0	12—100	[56]

*Molar ratio in solid product.

**TEOS = tetraethyl orthosilicate.

***Organic additives—tetrapropylammonium hydroxide and triethanolamine.

Thus, when the precipitation process is carried out in the range of mixture compositions and pH in which zeolites are formed, the sources of Si^{4+} and M^{n+} enter into the composition of polymeric blocks. The heteropolymerisation takes place via the interaction of polymers. The direction of this interaction depends on (a) the ratio of the basicities of the polymers containing Si^{4+} and M^{n+}, (b) the sign and charges on the species, and (c) the degree of polymerisation and dehydration of the monocationic polymers in the initial mixture for hydrothermal synthesis.

On the basis of general considerations, one can assume that the synthesis of the crystalline silicate should be preceded by the following stages: (1) the hydrolysis of the source of M^{n+} and the formation of monocationic polymers containing the Si^{4+} or M^{n+} ions; (2) the heteropolymerisation of the monocationic polymers; (3) their depolymerisation; (4) the oriented fixation of the polymeric blocks accompanied by the establishment of long-range order in the arrangement of ions in the skeleton.

The rate of crystallisation of the silicate system should depend on the ratios of the rates of processes involving the aggregation of the polymeric species, on the one hand, and their depolymerisation and orientation, on the other. The depolymerisation and reorientation stages require a definite activation energy and their rate should therefore increase with increase in the temperature of the hydrothermal treatment and should also depend on the presence of an initiator and, what is especially important, on the nature of the ion-transferring component. The rate of reorientation of the blocks is higher the larger the polar species of the deposit

Table 3. Conditions for the synthesis of borosilicates with the zeolite structures.

or the larger the charge of the elementary blocks.[48] The nature and concentration of the sources of the multicharged ions as well as the nature of the organic additives playing the role of ion-transferring agents therefore influences strongly the crystallisation of silicates with a particular structure.

The conditions for the synthesis of silicates described in the literature are described systematically in Tables 2–6. In the synthesis of beryllosilicates (Table 2), the source of beryllium employed is its nitrate or sodium beryllate, while the source of silicon is silica sol or sodium silicate. The reactant ratio and the crystallisation temperature influence the type of crystal structure of the final product. The crystalline zeolite-like orthorhombic silicate with a SiO_2/BeO ratio of 12–60 has been obtained by the hydrothermal treatment of a mixture consisting of sodium aluminate, beryllium nitrate, and an aqueous solution of silica sol for 24 h at 175 °C.[50] Silicates with structures of type A, X, and Y zeolites have been obtained by the crystallisation of mixtures of definite composition at 70–130 °C.[51–55] A zeolite, designated by TRS, with the ratio $SiO_2/BeO > 12$ in the solid product (of the ZSM type), has been obtained from a mixture of beryllium nitrate and tetraethyl orthosilicate in the presence of tetrapropylammonium hydroxide in an alcoholic medium over a period of 12–17 h at 155–200 °C.[56]

Table 3 presents the conditions for the synthesis of borosilicates, the composition of the solid phase synthesised, and also the reactions in which silicates have been investigated. A borosilicate of the type of a zeolite with the ratio $SiO_2/B_2O_3 = 1.78$ has been obtained from sodium silicate and borate at 45–170 °C.[57–59] A zeolite of the faujasite type has been synthesised from a mixture of borosilicate, boron oxide, kaolin, and quartz after it had been sintered at 1110 °C.[60–62] High-silica borosilicates with the structure of pentasils[63–78] have been obtained by the crystallisation at 150–170 °C of mixtures incorporating a source of boron (H_3BO_3), freshly prepared aluminium hydroxide, aerosil, and organic amines. The use of monoethanolamine[66] and hexamethylenediamine as the organic compound together with borosilicate[67,68] glass or soluble glass enabled the authors to obtain zeolites of the ZSM-5 type.

The main conditions for the synthesis of silicates with the zeolite structure, containing Group III, IV, V, and VI elements, are presented in Table 4. Numerous phosphorus-containing silicates with the analcime, chabazite, phillipsite, sodalite (HS) and type A, X, Y, P, and L zeolite structures have been synthesised.[79–81] The crystallisation was carried out from the gel at 80–200 °C using reactive phosphorus-containing compounds as the sources of phosphorus, usually orthophosphoric acid. The presence of an organic compound [tripropylamine (TPA)] in the crystallising system promoted the crystallisation of a silicate with the type ZSM zeolite structure.[82,83] A sulphur-containing zeolite has been obtained by introducing sulphuric acid into the crystallising mixture instead of phosphoric acid.[82] Silicates with the ZSM structure have also been obtained from systems incorporating silica sol, TPABr, hexamethylenediamine (HMDA), and also arsenic, tin, indium, or tellurium salts.[83,85–88] A zeolite-like silicate, whose composition incorporates iron and arsenic cations, is formed in an acid medium at 220 °C.[84]

Gallo- and germano-silicates (Table 5) were synthesised for the first time from aqueous solutions of sodium gallate and germanate and silica sol at 100 °C.[90] The silicates obtained proved to have the same structures as zeolites X, A, and P and thomsonite, which was demonstrated by X-ray diffraction. It was noted that zeolite A crystallises only from sodium aluminogermanate gels, while zeolite X crystallises from a mixture of sodium gallogermanate and sodium aluminogermanate. Zeolite P is formed on recrystallisation of zeolite A in an alkaline solution.[90] An analogue of zeolite X has been obtained from sodium metasilicate and $GaCl_3$ in an alkaline solution.[91,93–95] The zeolite chabazite has been synthesised from the potassium galloaluminosilicate system, while phillipsite has been obtained from the sodium gallosilicate system.[96,97]

The crystallisation of $HGaCl_4$ and sodium silicate for different periods at 200 °C is accompanied by the formation of several types of zeolites.[92] Analogues of faujasite having the aluminosilicate composition have been obtained in an alkaline medium from sodium and potassium germanates at temperatures not above 100 °C,[93–95,98–100] Zeolites of the

The data in Table 6, where the conditions in the synthesis of silicates crystallising in the presence of transition metal cations and platinum group elements are presented,[104–128] permit the following conclusions. The crystallisation of a silicate system, into the composition of which the above cations have been introduced together with quaternary ammonium compounds, leads to the formation of systems isostructural with type ZSM zeolites in alkaline media at 100 °C and above. The sources of cations are their salts and oxides and acids based on them. The sources of silicon and organic ions are the reagents indicated in Tables 2–5.

The characteristic features of the crystallisation of silicates in the presence of multicharged cations have been studied systematically as a function of the nature and content of the latter.[129–137] The influence of the temperature, crystallisation time, component ratio, and the nature of the modifying cation on the content of the zeolite-like silicate phase has been investigated. For the ratios $OH/SiO_2 = 0.1–0.2$, $TBABr/SiO_2 = 0.11–0.15$, and $H_2O/SiO_2 = 20–50$ and temperatures in the range 140–200 °C, the silica sol crystallises predominantly with formation of a product having the X-ray diffraction parameters of a type ZSM-11 zeolite regardless of the nature of the source of M^{n+}. In many cases the solid product may contain α-quartz or an amorphous phase depending on the temperature, crystallisation time, and the type of cation. With increase of crystallisation temperature from 140° to 200 °C for the same crystallisation time, the constant of the crystalline zeolite phase (CZP) passes through a maximum in the range 140–150 °C in many cases (Fig.1). As the CZP crystallisation temperature increases further, the content of α-quartz diminishes and increases. This result confirms the available data showing that the zeolite phase is formed as an intermediate in the hydrothermal treatment of the $SiO_2–H_2O–M(OH)_m$ system; after a time, it recrystallises and denser and thermodynamically more stable structures, including α-quartz, are formed.[23]

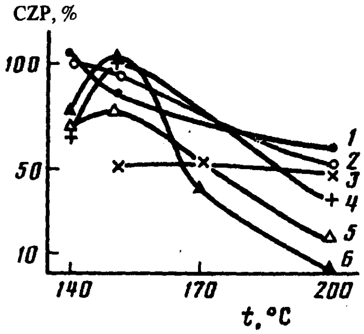

Figure 1. The influence of the temperature of the hydrothermal treatment (t, °C) of silica sol on the content of the ZSM-11 phase in the solid product obtained after the introduction of various cations M^{n+}: *1*) Mn; *2*) Cr; *3*) Eu; *4*) Fe; *5*) Cu; *6*) Zn.[133]

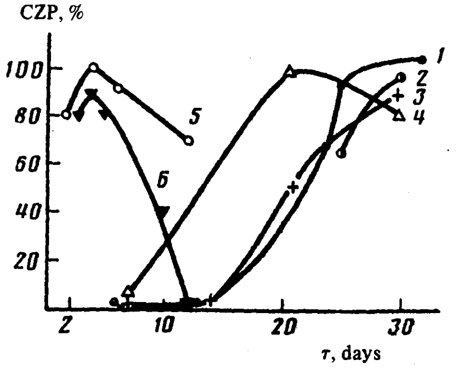

Figure 2. The influence of the duration of the hydrothermal treatment (τ, days) on the content of the ZSM-11 phase in the solid product obtained after the introduction of various cations M^{n+}: *1*) Ti; *2*) Cr; *3*) Cu; *4*) Zn; *5*) B; *6*) Eu.[137]

Changes in the CZP content of the same character are observed after an increase in the duration of the hydrothermal treatment of silica sol, keeping the temperature and the composition of the initial mixture unchanged (Fig.2): the content of the ZSM phase usually increases during the first 2–5 days and then gradually diminishes.[133]

A common feature is the decrease of the content of the ZSM phase with increase of the amount of M^{n+} in the initial mixture (Fig.3); this means that the crystallisation reactions of silicate ions are retarded in the presence of M^{n+}.[44] The cause of this phenomenon has not been investigated in detail. However, presumably in the presence of the M^{n+} hydrolysis product either the solubility of the silicate increases or the degree of coagulation diminishes and the stability of the silica sol increases as a result of the adsorption of the $[M_nO_m(OH)p]$ groups on the surface of the polymeric species of the silicate system. The adsorbed polymeric ions containing M^{n+} can prevent the establishment of long-range order in the silicate system.

According to Pauling's criterion, stabilisation in an eight-membered oxygen environment is most likely for the cations in groups 1 (Table 1). It has been shown[137] that most of

the group 1 cations contained in the initial silica sol are not entrained by the solid phase on crystallisation; the solid product obtained after filtration, washing, and the elimination of cations contains 3–20 times less of M^{n+} than the amount introduced into the initial silica sol. A mainly amorphous phase is obtained in the presence of Tl^{3+} and Sn^{2+}.

*The content of the zeolite phase of the ZSM-11 type was considered in relation to a standard, for which silicalite was used.

Six-membered coordination by oxygen is stable for group 2 cations (Table 1). Only traces of these cations have been detected in the solid products of the crystallisation of mixtures containing Ti^{4+}, Mn^{2+}, Zr^{4+}, and Mo^{6+} (Table 7).[137] For systems with the Fe^{3+}, Cr^{3+}, Cu^{2+}, Co^{2+}, Ga^{3+}, B^{3+}, Be^{2+} cations, the ratios Si/M^{n+} in the initial gel and its solid crystallisation product are similar. In these systems, the presence of M^{n+} does not prevent the crystallisation of silica sol and the M^{n+} cations are mostly occluded by the crystalline phase formed. The probability of occlusion depends on the size of the cation. Indeed the cations enumerated have the smallest values of ρ among the group 2 cations.

Regardless of the value of ρ, cations with the 4+, 5+, and 6+ charges are not retained by the silicate in any of the groups. Thus the Se^{6+}, Pt^{4+}, Mo^{6+}, and Zr^{4+} cations are present in the crystalline product in trace amounts, which are much smaller than in the initial silica sol. When the alkalinity of the system is the same as under conditions where the silicate crystallises, the cations forming part of the composition of the anion $[NaM_nO_m]^-$ are probably present in a dissolved state.

A high degree of crystallinity of the solid products and similar Si^{4+}/M^{n+} ratios in the initial mixture and in the crystalline phase have been observed for systems with group 3 and 4 cations.[137] Mixtures containing the highly charged V^{4+} and Se^{6+} cations, which are removed from the solid deposit already in the filtration and washing stages, constitute an exception in this instance. Owing to the high alkalinity of the system, vanadate and selenate ions are probably formed and remain in the liquid phase on crystallisation. The presence of compounds containing V^{4+} and Se^{6+} for Si^{4+}/M^{n+} ratios ranging from 15 to 30 hinders the zeolite formation process.[132]

IV. THE STATE OF THE MULTICHARGED CATIONS IN SILICATES WITH THE ZEOLITE STRUCTURE

The state of the multicharged M^{n+} ions in the product of the crystallisation of the $SiO_2–M_nO_m–H_2O$ system can be various and depends both on the composition of the initial mixture and on the nature of M^{n+}. Thus, apart from the fixation of M^{n+} in the silicon–oxygen skeleton in positions isomorphous with Si^{4+}, there is a possibility of occlusion of M^{n+} in salts or oxides within silicate channels or on the outer surface of the crystals and also of their localisation near groups incorporating oxygen ions with an uncompensated charge (in cationic positions). Various methods have been used to investigate the state of the M^{n+} ions: (1) X-ray diffraction (the incorporation of M^{n+} in the skeleton is inferred from the change in the crystal lattice parameters[50,51,54,58–61,64,71]); (2) high-resolution NMR which makes it possible to determine the symmetry of the coordination environment and the composition of the second coordination sphere of the silicon atoms;[132,133,135–138] (3) EPR and Mössbauer spectroscopy (when paramagnetic cations are introduced into the composition of the silicates[131,134,139]). The principal results of these studies are considered below.

1. The State of Mn^{2+}

The state of the Mn^{2+} cations in the elementosilicates obtained from silica gel with added $MnCl_2$ has been investigated by EPR.[134] EPR spectra with an isotropic *g*-factor of ~2.00 have been recorded for all the manganese-containing silicates with the structure of the type ZSM zeolite. The spectrum of the Mn^{2+}-containing elementosilicate at 77 K (Fig.4) can be represented by a superposition of two signals with a Lorentzian shape and a width of 1250 and 450 G and a 6-component spectrum in which the splitting between the third and fourth components is 93 G. Their relative contributions to the overall intensity are 91, 8.5, and 0.5% respectively. The Mn^{2+} cations, to which the signals of the first two types correspond, are probably present in a state with a weak interaction. In the EPR spectra of cations of the third type the splitting between the hyperfine structure components is 90–98 G; the splitting increases as the temperature of the recording is reduced and on passing to the Q-range. This spectrum can be attributed to Mn^{2+} cations in an octahedral oxygen environment. In this case, as in type X and Y zeolites,[138] the width of the EPR line is determined by the relaxation due to the periodic modulation of the crystal field caused by the distortion of the solvation shell of the ion and the anisotropic movement of the solvated ion.

The Mn^{2+} ions responsible for the hyperfine structure (HFS) in the EPR spectrum are apparently not "built into" the zeolite skeleton and are separated from the oxygen atoms of the skeleton by the solvation shell. An additional confirmation of this conclusion has been obtained in a study of the EPR spectra of specimens of elementosilicates heated at 500 °C and a pressure of 10^{-5} mmHg for 2 h. Instead of the superposition of several signals, single lines were observed in the EPR spectra of these specimens, whose width depended on the amounts of water and oxygen adsorbed after the activation of the specimen. On the basis of the form of the EPR spectra, one may claim that there are no Mn^{2+} ions in the test specimen in a tetrahedral environment of oxygen atoms. We may note that the EPR method by no means permits the detection of all the manganese ions introduced into the specimens.[134]

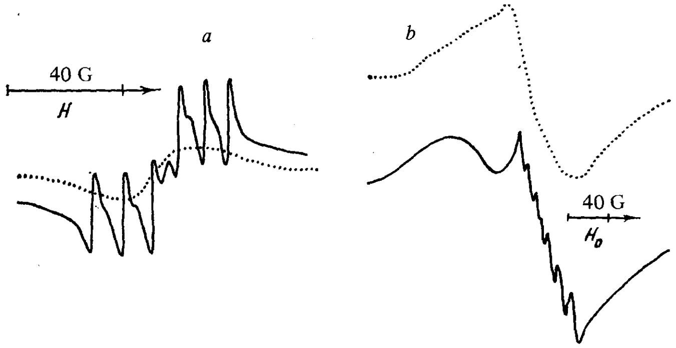

Figure 4. The EPR spectrum of the Mn^{2+} cations of a manganese-containing silicate recorded in the X-range (a) and Q-range (b) at 20 °C (dashed lines) and –110 °C (continuous lines).[134]

2. The State of Cr^{3+}

The EPR spectra of specimens of elementosilicates containing chromium exhibit a symmetrical signal with $g = 1.98$ and $\Delta H = 600$ G,[131] which may be assigned to the disperse chromium hydroxide $[Cr(OH)_3.nH_2O]$. After heating the specimens at 300 °C and above, the intensity of this signal diminishes together with an increase in its width. This may be caused by the dehydration of the hydroxide with formation of the antiferromagnetic Cr_2O_3, or, which is most probable, the oxidation of the Cr^{3+} ions in the chromium oxide particles. The latter hypothesis has been confirmed by the appearance of a signal due to the Cr^{5+} ions, whose intensity increases with increase of the heat treatment temperature. The distribution of the chromium ions detected by EPR on the surface of silicate crystals is indicated by the change in the spectra of the Cr^{5+} ions following the adsorption of pyridine.

3. The State of Cu^{2+}

Signals of mainly two types (I and II) are observed in the EPR spectra of specimens of elementosilicates[131,139] synthesised in the presence of Cu^{2+} ions:

$$g_{\parallel}^{\mathrm{I}}=2.30 \quad A_{\parallel}^{\mathrm{I}}=160\ \mathrm{G} \quad g_{\perp}^{\mathrm{I}}=2.055 \quad A_{\perp}^{\mathrm{I}}=25\ \mathrm{G}$$
$$g_{\parallel}^{\mathrm{II}}=2.32 \quad A_{\parallel}^{\mathrm{II}}=157\ \mathrm{G} \quad g_{\perp}^{\mathrm{II}}=2.058 \quad A_{\perp}^{\mathrm{II}}=26.5\ \mathrm{G}$$

The parameters of these signals correspond to Cu^{2+} ions fixed in an octahedral oxygen environment. The difference between the parameters of the ions of types I and II is probably determined by the existence of tetrahedral distortions for the type II Cu^{2+} ions. After the specimens have been heated at 250 °C and above, the intensity of the EPR signals of the Cu^{2+} ions is found to increase. It is noteworthy that some of the detected Cu^{2+} ions are inaccessible to the adsorbed molecules, which is indicated by the absence of changes in the EPR spectrum after the adsorption of pyridine. The copper ions interacting with pyridine give rise to an EPR spectrum with the $g_{\parallel} = 2.26$, $A_{\parallel} = 1.86$ G and $g_{\perp} = 2.08$, $A_{\perp} = 40$ G signals, which is due to the formation of pyridinates.[131]

Overall, the hydrothermal synthesis of elementosilicates from silica gel containing copper compounds results in the stabilisation of the bulk of the copper (~90%) in a state undetectable by EPR, probably in the form of an oxide phase. A small proportion of the copper (~10%) is stabilised in the form of isolated ions and, after treatment with thionyl, in a specific form with antiferrodistortion order.[139]

The crystal lattice parameters of the copper-containing zeolite do not differ from those of the unmodified zeolite, which provides additional grounds for the assumption that the isomorphous substitution of silicon atoms by copper atoms with tetrahedral coordination does not occur. It is more likely that the copper cations are localised in the channels of the zeolite structure and that the exchange interaction between them takes place via silicon–oxygen bridges or via oxygen atoms which do not belong to the zeolite skeleton.

4. The State of V^{4+}

The character of the X-ray diffraction patterns of specimens of vanadium-containing elementosilicates shows that the systems synthesised are mixtures of three phases: silicalite (crystalline SiO_2 with the zeolite structure), α-quartz, and an admixture of amorphous SiO_2. With increase in the amount of VO_2^- introduced into the initial sol, the content of the crystalline silicate phase in the specimen diminishes, as a result of which the actual SiO_2/V_2O_5 ratio in the solid phase is smaller by a factor of 4–10 than in the initial gel.

Low values of the HFS constant for the parallel orientation as well as the dependence of the character of the EPR spectrum on the temperature of the measurement are to be expected for a V^{4+} ion in a tetrahedral coordination.[140]

The EPR spectrum of vanadium-containing silicates obtained by hydrothermal synthesis is characteristic of V^{4+} ions in an octahedral coordination with tetragonal distortion ($g_{\parallel} = 1.93$, $A_{\parallel} = 1.95$ G and $g_{\perp} = 1.96$, $A_{\perp} = 56$ G) in the isolated (as part of the composition of VO_2^-) and exchange-linked states. Since the intensity of the EPR signal of V^{4+} proved to be many times smaller than might have been expected from chemical analysis, it was concluded that the main bulk of the V^{4+} ions present in the silicate are bound by a strong exchange interaction and are present in the composition of polymers. The EPR spectrum of the V^{4+} ions in this state has not been observed.[141]

Thus there are no grounds for the assumption that the V^{4+} cation is "built into" the silicon–oxygen skeleton in tetrahedral positions in the course of the hydrothermal synthesis of silicates with a zeolite structure.

5. The State of Fe^{3+}

The incorporation of Fe^{3+} ions into the composition of type A, X, and Y zeolites in the hydrothermal synthesis of the latter has been frequently established.[142–147] The source of Fe^{3+} consists of the admixture of iron compounds present in the components of the initial mixture. Thus it has been shown[142] that 0.01% of Fe^{3+} cations are occluded in type Y zeolites obtained by hydrothermal synthesis. Three signals, with $g = 4.27$, 2.4, and 2.0, have been observed in the EPR spectra. The signal with $g = 2.4$, whose width was 1600 G and which diminished with increase of temperature, was assigned to magnetite Fe_3O_4, which has ferromagnetic properties. The Curie point, determined from the magnetic susceptibility, was at 572 °C and was attributed to the highly defective nature of the phase produced. The EPR spectrum of Fe^{3+} occluded in the zeolite NH_4Y and mordenite was found to contain three signals:[143] with $g = 4.3$ (narrow), 2.3, and 2.0 (both broad). The first was assigned to Fe^{3+} fixed in a tetrahedral oxygen environment with pronounced orthorhombic distortion. The signal at $g = 2.0$ was assigned to all the cations in the octahedral environment incorporating three oxygen atoms and three OH groups at cationic sites.

The EPR spectra of the Fe^{3+} ions forming part of the composition of a type Y zeolite[144–146] have been interpreted in the same way: the signals with $g = 2.2–2.3$ were explained by the presence of an amorphous oxide phase[143] and an occluded salt,[145] in which the Fe^{3+} cations are in a state with strong exchange interaction. The fraction of Fe^{3+} cations in a tetrahedral environment ($g = 4.3$) was ~4% of the total Fe_3O_4 content in the zeolite. The part of Fe^{3+} forming part of the composition of the phase giving rise to the signal with $g = 2.2–2.3$ was most readily extracted.

A zeolite of the ZSM-5 type, in which the Fe^{3+} cations were introduced before the hydrothermal crystallisation of silica gel, has been synthesised[146] in the presence of hexamethylenetetramine. The general character of the EPR spectrum resembles that described above.[142–145] After the reductive treatment of the specimen, the intensity of the signal with $g = 2.02$ diminished markedly, while the intensity of that with $g = 4.28$ remained almost unchanged.

A characteristic signal with $g = 4.3$ (Fig.5*a*), which can be assigned to isolated Fe^{3+} ions, was observed[131] in the EPR spectra of iron-containing elementosilicates with the ZSM structure. The transitions near $g = 4.3$ in the low-field part of the spectrum refer to Fe^{3+} ions whose ligand environment is appreciably distorted (type I). The main transitions noted in Fig.5 can be assigned to Fe^{3+} ions stabilised in a weakly distorted octahedral environment (type II) ($D, E \leq h\nu$). Analogous spectra have been observed for Fe^{3+} ions in the hexa-aquo-complexes formed on dissolution of iron salts in water at low concentrations. The absence of a significant temperature dependence of the EPR of type II Fe^{3+} ions also indicates the fixation of the iron cations predominantly in the form of isolated ions. A symmetrical line in the vicinity of $g = 2.00$ (type III), characteristic of exchange-bound Fe^{3+} ions, can be observed in the EPR spectrum of the specimens obtained at 200 °C.

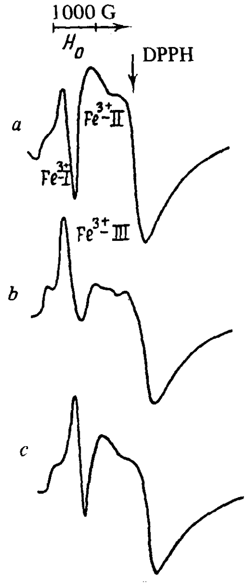

Figure 5. The EPR spectrum of the Fe^{3+} cations of an iron-containing silicate: *a*) initial specimen; *b*) after dehydration at 400 °C; *c*) after the adsorption of pyridine on the specimen and subsequent dehydration at 400 °C.[131]

The assignment of the signal with $g = 4.23$ in the Fe^{3+} EPR spectra to Fe^{3+} ions in a tetrahedral coordination does not alone justify the claim that the corresponding Fe^{3+} ions are fixed in the silicon–oxygen skeleton at sites isomorphous with those of Si^{4+}. Indeed the iron oxide compounds can incorporate Fe^{2+} and Fe^{3+} cations fixed in tetrahedral cavities.[140] Some evidence for the view that the Fe^{3+} cation giving rise to the EPR signal with $g = 4.23–4.3$ enters into the composition of the silicon–oxygen skeleton of a type ZSM zeolite has been obtained.[147]

The intensity of the signal with $g = 4.27$ in the EPR spectrum of the products of crystallisation of the $Na_2O.nFe_2O_3.SiO_2.mH_2O$ mixture increased almost in proportion to the content of the zeolite phase (Fig.6), but diminished after ion exchange. On the other hand, the intensity of the signal with $g = 2.0$ was independent of the degree of crystallinity of the specimen but increased with increasing Fe_2O_3 content for the well crystallised specimens. In the studies enumerated above, it was shown that the intensity of the signal of the type I ions is very low. In one study[145] it corresponded to 4% of the total amount of the Fe_2O_3 present in the type Y zeolite. In another study[147] the signal intensity ratio $I_{4.27}/I_{2.0}$ was 20–30.

Thus the literature data permit the conclusion that a small proportion of Fe^{3+} ions are built into the silicon–oxygen skeleton of the elementosilicate in the course of hydrothermal synthesis; most of the ions remain in the iron oxide phase or in cationic sites. These data indicate the possibility of the formation of the $[Si(OFe)_n]^{n-}Fe^{3+}$ groups in the skeleton.

After the removal of cations by acid or NH_4OH solutions, there is a possibility of the rupture of both Si–O–Fe–O–Si and Si–O–Al–O–Si linkages as a result of hydrolysis.

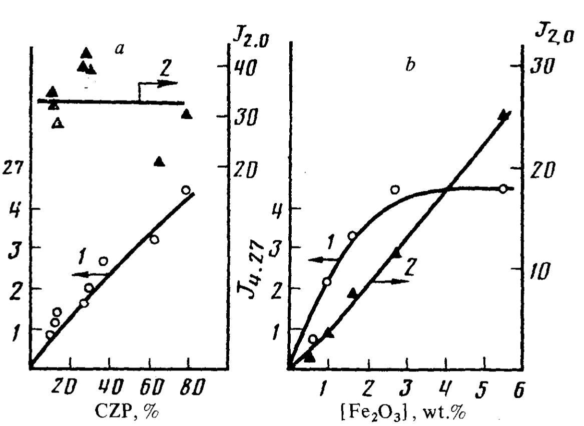

Figure 6. The relative intensities of the EPR signals of the Fe^{3+} cations with $g = 4.27$ (curves *1*) and $g = 2.0$ (curves 2) for a silicate occluding Fe^{3+} ions during hydrothermal treatment as a function of the content of the crystalline phase (*a*) and the content of Fe_2O_3 in the crystallisation product (*b*).[137]

The state of Fe^{3+} at various sites in the silicon–oxygen skeleton of faujasite[148] for Si/Al = 1 has been calculated by the semiempirical LCAO-MO SCF method in the CNDO/2 valence approximation. The authors[148] concluded that the Fe^{3+} cations must be bound to the oxygen atoms in the zeolite skeleton by strong donor–acceptor bonds whose strength is comparable to that of the bonds involving Al^{3+}. Comparison of the charge density and Wiberg indices of the $FeSi_5O_6.(OH)_{12}Na$ and $AlSi_5O_6(OH)_{12}Na$ clusters formed on isomorphous substitution of Si^{4+} in the six-membered silicon–oxygen ring showed that the Al^{3+} and Fe^{3+} ions have identical effects on the properties of the skeleton; the Fe–O bond is stronger than the Al–O bond.

6. The State of Be^{2+}

The isomorphous substitution of the atoms of the silicate skeleton by Be^{2+} ions has been observed in natural minerals: in helvin $Mn_4Be_3O_{12}S$, whose structure is similar to that of sodalite $Na_4Al_3Si_3O_{12}Cl$, with a three-dimensional skeleton formed by the linkage of silicon–oxygen tetrahedra, and in tugtupite,[149] where the isomorphous substitution is of the type $2Al^{3+} \rightleftharpoons Be^{2+}Si^{4+}$. Beryllosilicates with the analcime structure have been synthesised[150,151] at 150–400 °C in the course of 1–3 weeks from gels having the composition $NaBe_{1.5}Si_2O_6$ and $Na_3Be_{1.5}.Si_{4.5}O_{12}.NaCl$. The formula $Na_{16}Be_8Si_{40}O_{96}(H_2O)_{16}$ has been proposed for the final product. Its derivatograms showed an exothermic peak at 150–500 °C. The authors attributed its appearance to the removal of zeolitic water.

It has been noted[151] that the size of the unit cell and the refractive index of the products formed decrease linearly with increasing degree of isomorphous substitution $2Al^{3+} \rightleftharpoons Be^{2+}Si^{4+}$. These facts are regarded as proof of the occurrence of isomorphous substitution. Thus the unit cell of $Na_3Al_{2x}Be_{1.5-x}Si_{5-x}O_{13(4-2x)}$, synthesised under condtions with $0 \leq x \leq 1.5$, varies from 13.72 Å for the zeolite without Be^{2+} cations to 13.36 for beryllosilicate, while the refractive index varies correspondingly from 1.48 to 1.519.

The state of the Be^{2+} cations in the solid state can be investigated by NMR. The interpretation of the ^9Be NMR spectra is made difficult by the high sensitivity of the spin–lattice relaxation, which requires an exact determination of the strengths of the pulse for each specimen analysed, and by the low intensity of the signal obtained. The $[Be(H_2O)_4]^{2+}$ ion gives rise to a narrow resonance line at 50 and 1000 Hz, which indicates a symmetrical tetrahedral environment with quadrupolar interaction whose extent is close to zero.

It has been concluded[152] that a Be^{2+} ion in a tetrahedral environment gives rise to an NMR signal in a stronger field than the same ion in the tricoordinate state. A Be^{2+} ion in a three-membered environment gives rise to a ^9Be NMR signal with a chemical shift δ, relative to $[Be(H_2O)_4]^{2+}(NO_3)_2$, ranging from −21 to −11 p.p.m., while the same ion in a tetrahedral environment gives rise to a signal ranging from −12 to +1 p.p.m. The substitution of the negative ions of the environment by ions with a higher negative charge leads to a downfield shift of the signal. The introduction of strong bases into the environment of Be^{2+} causes an upfield shift of the signal. For example, the substitution of CH_3^- by Cl^- in the first coordination sphere of the Be^{2+} cation results in a shift of the NMR line from −4.2 to −5.5 p.p.m. The ^9Be NMR spectra of $BeCl_2$ in dimethyl sulphoxide, diethyl ether, and ammonia have $\delta = -5.5$, −3.1, and −1.7 p.p.m. respectively.

The state of Be^{2+} in beryllosilicates with the zeolite ZSM structure was investigated by the ^9Be NMR method for the first time by Ione and co-workers.[132,133,137] The spectra consisted of a single signal, whose chemical shift relative to that of ^9Be in the spectrum of sodium beryllate was −5.8 p.p.m. (Fig. 7*a*). The character of the spectrum differs also from that of beryllium oxide. The intensity of the ^9Be NMR signal is proportional to the amount of beryllium determined by chemical analysis. Comparison of the ^9Be NMR signal intensity and the Be^{2+} content determined by chemical analysis showed that most of the Be^{2+} ions in the silicate synthesised are fixed in the crystalline silicon–oxygen skeleton.[153]

7. The State of P^{5+}

Like Si^{4+}, the P^{5+} cation can have a tetrahedral oxygen environment and can form a three-dimensional phosphorus–oxygen skeleton. Bearing in mind the similarity of the radii of the above cations, one may expect the occurrence of the isomorphous substitution $PO_4^{3-} \rightleftharpoons SiO_4^{4-}$. In nature, this phenomenon has been observed in the mineral viséite, which is a structural analogue of analcime.[24]

Phosphorus-containing crystalline silicate with the analcime, chabazite, phillipsite-harmotome, and type A, L, and B(P) zeolite structures, containing 5–25% [of phosphorus? (Ed.of Translation)], have been synthesised.[154] It has been established that the lattice constant diminishes with increasing P_2O_5 content in the type Y zeolite (thus $a = 12.249$ Å in the presence of 5.2% of P_2O_5 and $a = 12.232$ Å in the presence of 10% of P_2O_5). The increase of the cell parameter is caused by the fact that the length of the P–O bond (1.54 Å) is smaller than those of the Si–O (1.61 Å) and Al–O (1.75 Å) bonds. With increase of the P_2O_5 content in the type A zeolite, the intensity of the refraction also changes almost linearly. These data enabled the authors[154] to conclude that the $Si^{4+} \rightleftharpoons P^{5+}$ isomorphism occurs in the type A zeolite synthesised.

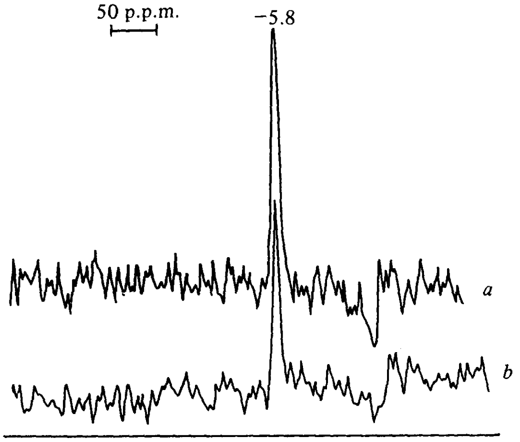

Figure 7. The ^9Be NMR spectrum of crystalline beryllosilicates; SiO_2/BeO_2 ratio in initial hydrogel: *a*) 60; *b*) 30.[137]

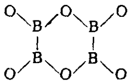
8. The State of B^{3+}

It has been established that B^{3+} cations in a tetrahedral coordination are present in the BF_4^-, BH_4^-, $[HB(OR)_3]^-$, and $[B(C_6H_5)_4]^-$ anions. In compounds with oxygen, boron forms either a planar structural BO_3^- unit with angles of 120° between the bonds or boron–oxygen tetrahedra (in glasses). In solutions, $B(OH)_3$ polymerises with formation of cyclic polymers, whose presence has been established also in crystalline borates. The latter include both BO_3^- groups and BO_4^- groups and consist of six-membered rings of the type



This has been demonstrated by ^{11}B NMR.

The boron phosphate BPO_4, obtained by the interaction of boric and phosphoric acids, includes a tetracoordinate boron atom; the phosphate contains B–O–P linkages.[140]

Borosilicates and aluminoborates with zeolite structures have been synthesised in many studies. The substitution of Si^{4+} by B^{3+} cations in the zeolite skeleton was not demonstrated by Barrer and Marchilly.[155] It has been suggested[156] that boron cations are occluded in the zeolite cavities in the compound $NaBO_2$ or $NaB(OH)_4$. These conclusions conflict with data[157] according to which all the unit cell parameters of borosilicates decrease almost linearly with increase of their B_2O_3 content (Table 8). The B_2O_3 content was determined from the amount of the carbon-containing precursors of borosilicates. Simultaneously with increase of the ratio B/(B + Si), a transition from the monoclinic to the orthorhombic system was observed.

The state of the B^{3+} ions in a silicate isostructural with the zeolite ZSM-11 has been studied systematically as a function of the conditions of their synthesis;[132,133,135,136] the elementosilicates were synthesised by the method of Ione et al.[130] Two lines were observed in the ^{11}B NMR spectra of borosilicates—a symmetrical narrow line with a width of ~1.7 kHz and a chemical shift of −23.3 p.p.m. (signal I) and a broad line with $\delta = -17 - 64$ p.p.m. (signal II).[135]

Table 8. The unit cell parameters as a function of the ratio B/(B + Si) in borosilicates with the zeolite structure.[157]

B/(B + Si)	*a*, Å	*b*, Å	*c*, Å	*d*, Å	*v*, Å^3
0	20.117	19.874	13.371	90.62	5345.5
0,007	20.087	19,852	13.364	90.46	5329.3
0.016	20.050	19,822	13.372	90.00	5314,3
0.022	20.022	19.816	13,340	90.00	5292.6
0.041	20.002	19.805	13,334	90.90	5282.1
0.049	19.974	19.774	13.306	90.90	5255.9
0.109	19.934	19,716	13,269	90.00	5215,0

The NMR spectra of the glasses usually show two types of lines due to the boron atoms in different coordination environments.[158] At a frequency of 30 MHz, a second-order quadrupolar splitting of ~15 kHz occurs for boron atoms in ternary coordination, which corresponds to a quadrupolar interaction constant of ~2 MHz. For tetracoordinate boron atoms, the quadrupolar interaction constant is much smaller. As a result of the latter, the spectrum of boron in a tetrahedral oxygen environment does not exhibit second-order splitting even at low frequencies; the line due to boron atoms in a tetrahedral environment is comparatively narrow and symmetrical. As a result of this, the narrow symmetrical line I, observed in the NMR spectra of borosilicates, can be assigned to boron atoms in a tetrahedral oxygen environment.

With increase of the ratio OH/SiO_2 in the initial borosilica sol, the chemical shift of the ^{11}B NMR signal in the spectra of the resulting borosilicates did not change, but the intensity of the main spectral line with $\delta = -23.3$ p.p.m. (signal I)[135] diminished. The degrees of crystallinity of the corresponding borosilicate change in the same sequence (NaB-0.1 > NaB-0.2 > NaB-0.3) with virtually identical total B_2O_3 contents in these substances (Table 9). The increase of the crystallisation time from 48 to 144 h (NaB-0.1 specimens) led to a comparatively small decrease of the intensity of signal I without change in the chemical shift and line width. The degree of crystallinity of the corresponding specimens (NaB-0.1 series) hardly changed under these conditions, but their B_2O_3 content diminished somewhat. With decrease of the B_2O_3 concentration in the specimens (from 4 to 0.7%), the intensity of signal I in the ^{11}B NMR spectra also fell.

Comparison of all the data enabled the authors[135,137] to postulate that signal I with $\delta = -23.3$ p.p.m. corresponds to boron atoms fixed in the crystalline part of the borosilicate synthesised as part of the composition of the silicate skeleton. Significant differences have been observed between the ^{11}B NMR spectra of freshly prepared specimens and the same specimens after a test in the catalytic conversion of methanol and after subsequent regeneration by annealing in air at 520 °C. The intensity of signal I in the

^{11}B NMR spectra decreases sharply, while the intensity of the broad band increases. In the course of the treatment of borosilicates at elevated temperatures in the presence of water vapour, the Si–O–B linkages are probably hydrolysed with the accompanying displacement of the B^{3+} cations from sites with a tetrahedral oxygen environment.[137]

Table 9. The influence of the ratio OH/SiO_2 in the initial mixture and of the crystallisation time τ on the content of the borosilicate phase isostructural with the ZSM-11 zeolite (crystallisation temperature 150 °C, SiO_2/B_2O_3 = 60).[135]

Specimen	OH/SiO_2	τ, h	$[B_2O_3]$, wt.%	S, m^2g^{-1}	CZP, %	I_{rel}
NaB-0.1	0.1	48	1.6	570	90	1.0
	0.1	78	1.5	580	100	0.9
	0.1	120	1.4	530	95	0.8
	0.1	144	1.2	540	90	0.7

	0.3	48	2.1	180	20	0.2

Notation: $[B_2O_3]$ = B_2O_3 concentration in the silicate and I_{rel} = relative intensity of signal I in the ^{11}B NMR spectrum.

9. The State of Ga^{3+}

The structure and properties of the oxygen-containing Ga^{3+} compounds are similar to those of aluminium oxides.[140] Gallium trioxide ε-Ga_2O_3 as well as gallate ions contain both tetracoordinate and octacoordinate Ga^{3+} ions.

Chabazite and phillipsite have been synthesised[159] in the presence of Ga^{3+} cations, but evidence for the isomorphous substitution of Si^{4+} by Ga^{3+} was not published. A type X zeolite has been synthesised[160] in the presence of Ga^{3+} cations and a change in the unit cell parameters was observed. Sodalite with the ratio $SiO_2/(Ga_2O_3 + Al_2O_3)$ = 1.28 and Na-GaX (1.14), Na-GaX (1.42), and Na-GaY (2.17) faujasites have been obtained[16] by the hydrothermal method. The Al_2O_3 content in these silicates was ~1% of the amount of Ga_2O_3 introduced. The state of the Si^{4+} and Ga^{3+} ions in the zeolite was investigated by ^{29}Si and ^{71}Ga NMR respectively and it was shown that the intensity of the NMR signal depends on the Si/Ga_2O_3 ratio, which was determined by chemical analysis.[160,161]

Comparison of the chemical shifts of the ^{29}Si NMR signals of zeolites having the silicon–oxygen composition and their gallium analogues[160,161] showed that the introduction of Ga instead of Al diminishes somewhat the shift of the peaks corresponding to the Si–$(OM)_n$ groups, where M = Ga or Al. The intensity of the peaks corresponding to the Si–OM and Si–$(OM)_2$ groups in the case of Ga-sodalite is smaller than for the Al–Ga-zeolites.

A ^{29}Si NMR signal, whose chemical shift is also smaller than in the case of the aluminium-containing analogues, is characteristic of type X and Y gallium-containing zeolites. The relative intensities of the peaks in the ^{29}Si NMR spectra of Ga- and Al-faujasites are similar, which indicates the identical character of the distribution of the corresponding elements in both cases.

The ^{71}Ga NMR signal of the zeolite Ga-Y, obtained by Thomas et al.[161], is broad and its chemical shift relative to $Ga(NO_3)_3$ is −182.5 p.p.m. The ^{29}Si NMR signal with $\delta = -75.5$ p.p.m. has been assigned to Si–$(OGa)_4$ and that with $\delta = -81.5$ p.p.m. has been assigned to Si–$(OGa)_3$. The ^{29}Si NMR spectrum of Ga-thomsonite includes signals with $\delta = -82.9$ and −83.5 p.p.m. The MAS ^{71}Ga NMR spectrum has been measured[132,137] for a gallosilicate with the ZSM-11 structure, obtained by the method of Ione et al.[130], and was found to contain one broad band with a chemical shift relative to $Ga(NO_3)_3$ of 154–155 p.p.m. (Fig.8).

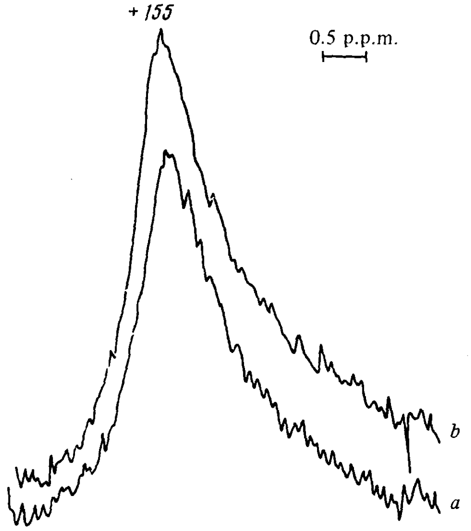

Figure 8. The ^{71}Ga NMR spectrum of crystalline gallosilicates with the ZSM-11 structure; SiO_2/Ga_2O_3 ratio in the initial silica sol: *a*) 60; *b*) 30.[137]

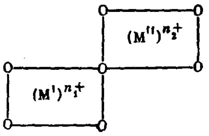
The set of data obtained by the ^{29}Si and ^{71}Ga methods justifies the assumption that the degree of isomorphous substitution and the character of the distribution of the Ga^{3+} ions in the silicon–oxygen skeleton are similar to the corresponding parameters for Al^{3+}.

Thus, depending on the type of the cation and the conditions in the hydrothermal treatment of the initial gel in the thermochemical treatment of the finished products, the modifying element M^{n+} can be fixed (1) in the composition of the individual (oxide or hydroxide) phase within cavities or outside the silicate crystals with the corresponding octahedral (for transition metal cations) and ternary (for boron) coordination, (2) in cationic sites in the form of species neutralising the negative charge of the skeleton, and (3) in the silicon–oxygen skeleton with a tetrahedral symmetry of the environment comprising oxygen atoms at sites isomorphous with respect to those of the Si^{4+} cations. The catalytic properties of the silicates should depend significantly on the state and the degree of coordination of the M^{n+} cations. Thus in the first case the individual phase can behave under the reaction conditions as an inert additive or can exhibit catalytic activity in oxidation-reduction reactions. The conversion of methanol on silicates with such additives can proceed with decomposition to CO and H_2. The M^{n+} cations fixed in silicates in accordance with types 2 and 3 should influence the acid–base properties of the latter.

V. CATALYTIC PROPERTIES

Crystalline silicates with zeolite structures (elementosilicates) are binary oxide systems like zeolites themselves. According to general ideas developed by Pauling[1] and Tanabe,[1,2] the acid–base properties of the binary oxides are determined by the incomplete compensation of the charges of the oxygen ions in polyhedra differing in the charges of their cations. Thus an uncompensated charge Z is generated on the oxygen atoms of the two polyhedra $M'O_4$ and $M''O_4$



with $n_1 \neq n_2$. According to Pauling's second rule,[162] the charge of the anion must be equal to the sum of the electrostatic forces of the bonds between the anion and the surrounding cations. The electrostatic strength of the bond is defined by Pauling as the ratio of the charge of the cation (en_i) to its coordination number (c). Hence the following formula is obtained for oxygen atoms in binary oxides:

$$Z=\frac{en_1}{c}+\frac{en_2}{c}.$$

The formation of a proton-donating centre on a polyhedron with an excess charge takes place (a) on substitution of the cation, compensating for the excess charge of the polyhedron, by a proton; for example, we have for silicates with a tetrahedral coordination of the cation

$$[(OSi)_n(OM)_{4-n}]^{(4-n)-}\cdot Na^+ \xrightarrow[-Na^+]{+H^+} [(OSi)_n(OM)_{4-n}]^{(4-n)-}\cdot H^+.$$

(b) In the heterolytic dissociation of water molecules in the field of the oxygen atoms of the polyhedron and the cation compensating for the charge:

$$[(SiO)_n(MO)_{4-n}]^{(4-n)-}\cdot H^+ + \ldots OH^- — M^{n+}.$$

The energy of the $\rangle$O...H bond in the $\overset{M}{\underset{Si}{\rangle}}$O...H group should diminish in a series of polyhedra with the cations $M^+ > M^{2+} > M^{3+}$, because the excess charge on the oxygen atoms decreases in the same sequence. For this reason, if the mobility of the proton in the $[(SiO)_n(MO)_{4-n}]^{(4-n)-}H^+$ group is adopted as a measure of its proton-donating activity, then the mobility should decrease in the sequence $M^{3+} > M^{2+} > M^+$.

Thus the proton-donating activity of silicates incorporating triply charged ions at sites isomorphous with those of Si^{4+} should be greater in the presence of doubly and singly charged cations.

Evidently the strength of the acid centres of silicates incorporating M^{n+} cations with identical charges should depend on the radius of the cations. The strength of the acid centres has been compared[163] with the difference between the electrostatic potentials (ΔV) of the BO_x and AO_y polyhedra at the sites of the B → A substitution:

$$\Delta V=\sum_i (q_i/r_i)_{BO}-\sum_i (q_i/r_i)_{AO},$$

where q_i is the charge of the ion at a distance r_i from the site A in the $BO_x.nAO_y$ matrix.

If one begins with the fact that the degree of polarisation of the O–H bond in the $[(SiO)_n(OM)_{4-n}]^{(4-n)-}H^+$ group depends on the electrostatic potential e/r in the field of the cation M and if the M–O bond length in the silicate is the same as in the oxide of M, then the acidity of the OH group in silicates incorporating triply charged cations should diminish in the sequence $B^{3+} > Al^{3+} > Ga^{3+} > Fe^{3+} > In^{3+}$ with decrease of e/r for these cations. However, this approximation has little predictive power, because the assumption of the equality of the M–O bond lengths in the silicate and the oxide has not been confirmed experimentally.

No studies have been published hitherto in which the variation of the strength of the acid centres of silicates was estimated as a function of the nature of the cation M^{n+} substituting Si^{4+} isomorphously in the silicate skeleton. So far there have been few studies in which the strength of the acid centres of such systems has been determined experimentally. Their comprehensive investigation is only beginning. The ^1H NMR method has been applied[164] in a comparative determination of the proton-donating strength of the OH groups in the zeolite ZSM-5 and borosilicate (H-borolite). The authors based their conclusions on the assumption that the chemical shift of the ^1H NMR signal reflects the degree of shielding of the proton nuclear spin by electrons and can serve as a measure of acidity. The authors observed that the ^1H NMR spectra of the two specimens each contain two signals—with δ = 6 and 2 p.p.m. (ZSM-5) and 3.5 and 2 p.p.m. (H-borolite). The signal at δ = 2 p.p.m. was assigned to the Si–OH groups, that with δ = 3.5 p.p.m. to the Si–O–B groups, and that with δ = 6 p.p.m. to the Si–O(H)–Al groups. The authors[164] concluded that the acidity of the OH group also increases in this sequence.

The catalytic activity of the solid surface is known to depend not only on the strength but also on the concentration of the active centres present on it. It has been established[165] on the basis of the relative intensities of the ^{11}B NMR signals of the boron cations having tetrahedral and ternary coordination in borosilicates with zeolite structures that only 5–10% of the total number of the B^{3+} detected in the specimens by chemical analysis is fixed in the former state.

It has been demonstrated[147] by ^{11}B and ^{71}Ga NMR that not more than 10–20% of the total amount of the elements which were determined by chemical analysis in the hydrothermal crystallisation product are present in a tetrahedral oxygen environment in zeolites with the erionite structure synthesised in the presence of the B^{3+} and Ga^{3+} cations.

Thus the true concentration of the cations substituting isomorphously the silicon atom in the silicon–oxygen skeleton and hence also the number of the catalytically active centres can be much less than the total content of the given element in the silicate. The latter factor hinders the determination of correlations between the nature of the M^{n+} cations fixed at isomorphous sites and the catalytic properties of the silicates. Nevertheless the data considered above show that the hydrothermal synthesis of the sources of SiO_2 in the presence of sources of multicharged M^{n+} cations leads to the formation of silicates with the zeolite structure, whose catalytic properties differ from those of aluminosilicate zeolites.

1. Germanium-containing Elementosilicates

The catalytic properties of the NaGe-X faujasite, synthesised from the Al–Ge gel and having the composition $Na_{75.8}(NH_4)_{20.2}(AlO_2)_{96}(GeO_2)_{96}$ have been investigated[166] in the isomerisation reaction of n-butenes at 150–350 °C. Comparison of the properties of the faujasites based on Al_2O_3–SiO_2 (HX and HY) and Al_2O_3–GeO_2 (HGeX) led to the following findings.

1. For high degrees of ion exchange, significant breakdown of the crystal lattice of the germanosilicate is observed as a consequence of the lower stability of the germanium–oxygen zeolite skeleton compared with that of the silicon–oxygen skeleton having an analogous structure.
2. In the presence of HGeX specimens, the isomerisation of n-butenes proceeds in accordance with a first-order equation without change in the kinetic parameters for 3.5 h, while in the presence of HX and HY the first order of the reaction is maintained only in the first 6 min after the start of the experiment. The catalytic activity of the zeolite HY falls during 1.5 h by a factor of 7, while the activity of HGeX does not change during this period.
3. The activation energy and selectivity of the process are close to those observed for HX and HY when the reaction is carried out in the presence of HGeX.
4. The rate of reaction, referred to a single active centre, and the average acidity of the OH groups diminish with increase of the Si, Ge/Al ratio in the zeolite HGeX. The process proceeds, as for the HY and HX catalysts, with participation of Brønsted acid centres.

2. Boron-containing Elementosilicates

Boron-containing faujasites have been investigated in the cracking of cumene[39] and it has been shown that their catalytic properties resemble those of the Al, Si-faujasites.

Data[55,58] concerning the catalytic properties of boron-containing silicates (borolites) in the synthesis of t-butyl methyl ether (TBME) from methanol and isobutene are of great interest. It has been shown that at 150–170 °C it is possible to attain a high degree of conversion of the initial reactant and that the yield of TBME in the presence of type B, C, and D borolites is 96–99.3%. The borolites proved to be highly selective and stable catalysts of the decomposition of TBME to isobutene and methanol over a wide temperature range; they ensure a selectivity of 99.8% and do not induce the subsequent conversion of isobutene and methanol. In contrast to this, in the presence of aluminosilicate zeolites methanol can be dehydrated with subsequent redistribution of hydrogen in the resulting olefins. The type C borolite acts as a catalyst of the alkylation of benzene by ethylene at 450 °C, a space velocity of 4 h^{-1}, and for the ratio benzene/ethylene = 5.[69,70]

According to the data in Ref.71, borolites are catalytically inactive in the synthesis of hydrocarbons from methanol. Bragin et al.[67] arrived at the opposite conclusion having established that borolites with the zeolite structure exhibit a high activity and selectivity in this reaction. The catalytic properties of borosilicates in the synthesis of hydrocarbons from methanol have been investigated[129–137] as a function of the state of the boron atoms in the silicate skeleton and of the content of the Al^{3+} admixture in them. Under the same conditions, the highest degree of conversion was attained in the presence of boron-containing aluminosilicates with SiO_2/Al_2O_3 ratios of 126 and 220 (Table 10, specimens 1 and 2). The catalytic properties of these specimens are typical for type ZSM zeolites with the same SiO_2/Al_2O_3 ratio. At 380 °C the degree of conversion of methanol is close to 100% and the fraction of C_5 and higher hydrocarbons is 57 to 60% of all the hydrocarbon reaction products and includes 16–27% of aromatic compounds.[136]

The borosilicates in which the Al_2O_3 content is very low (SiO_2/Al_2O_3 > 1000) and the SiO_2/B_2O_3 ratio is 25 and 46 have sharply different catalytic properties from those of aluminosilicates (Table 10): at 380 °C the main reaction product is dimethyl ether and C_2–C_7 olefins. The content of aromatic hydrocarbons in the reaction products is less than 2%.[135] With increase of the reaction temperature from 380° to 500 °C, the content of dimethyl ether in the reaction product falls (from 54 to 56% for specimens with SiO_2/B_2O_3 = 30), while that of aromatic and aliphatic hydrocarbons increases sharply (from 1.2 to 13.6 and from 32.5 to 67.8% respectively). However, after the reaction–regeneration cycle, the selectivity of the action of the catalysts changes: the selectivity diminishes with respect to the higher hydrocarbons and increases with respect to dimethyl ether.

Table 10. The degree of conversion of methanol and the composition of the reaction products in the presence of boron-containing silicates* with the ZSM-11 structure.[36]

Silicate	Chemical composition of silicate			α**, %	Composition of carbon-containing reactions products, %

***Dimethyl ether.

Cyclic compounds were not detected in the reaction products for specimens with SiO_2/B_2O_3 = 135 and silicalite (Table 10). These results show that the high catalytic activity of boron-containing zeolites in reactions involving the synthesis of aliphatic and aromatic hydrocarbons from methanol, observed in some investigations, is due to admixtures of aluminium. Nevertheless, there is a relation between the content of B_2O_3 in borosilicates and the degree of conversion of methanol, which supports the hypothesis that the B^{3+} cations enter into the composition of the active centres. However, as shown above, a considerable proportion of the boron cations are displaced from the silicate skeleton on elimination of cations and in the reaction–regeneration cycles. The boron atoms remaining in the tetrahedral coordination at sites isomorphous with those of silicon (or aluminium) atoms apparently constitute a significant proportion of the entire B_2O_3 introduced.

It has been established in a number of studies[167–171] that borosilicates with the structure of type ZSM zeolites are highly selective catalysts of the synthesis of olefins from methanol. The content of aromatic hydrocarbons in the reaction products obtained[168] at 500 °C and for a 100% degree of conversion of methanol in the presence of borosilicates was 5.4–13.8% and the selectivity with respect to the sum of the C_2–C_4 olefins was 56–70.9%. After treating the borosilicate having the ratio SiO_2/B_2O_3 = 35 with hydrochloric and hydrofluoric acids, its selectivity with respect to olefins increased to 78.9%. The same result was obtained in other investigations[169,170] at a reaction temperature of 550 °C. It is known that the content of olefins in the products obtained in the presence of aluminosilicate zeolites with the same structure (pentasil) and under the same conditions is not more than 20–30%, while the content of aromatic hydrocarbons in C_5 and higher fractions is up to 60–80%.

The appreciably lower catalytic activity of borosilicates compared with aluminosilicates containing approximately the same amount of B_2O_3 has been attributed[135,137,171] to two causes: (1) the catalytic activity of the Si–$(OB)_n$ groups of the silicate skeleton in reactions involving an acid–base mechanism is appreciably lower than that of the Si–$(OAl)_n$ groups; (2) the actual content of boron cations in the silicon–oxygen skeleton at isomorphously substituted sites is extremely low.

3. Elementosilicates with Transition Metal Cations

The catalytic properties of silicates where the Cr^{3+}, Pt^{4+}, V^{4+}, Mo^{6+}, and Zn^{2+} cations were introduced into the initial mixture before hydrothermal synthesis have been investigated[82] in the disproportionation of toluene. The disproportionation was carried out in an atmosphere of hydrogen at a pressure of 400 N cm^{-2}, for the ratio H_2/hydrocarbons = 2, and at temperatures in the range 455–593 °C. The degree of conversion of toluene reached 14–31.8%. The same catalysts were tested in the hydrocracking of the petroleum fraction with T_{nb} = 107–185 °C at a pressure of 70 N cm^{-2}, for the ratio H_2/hydrocarbons = 3, and at temperatures in the range 480–540 °C.[106]

Silicates with the ZSM-5 structure, synthesised in the presence of Cr^{3+}, have been investigated in the alkylation of toluene by methanol. It has been established that the chromosilicates (Cr–ZSM) with SiO_2/Cr_2O_3 ratios of 107 and 38.5 differ in the selectivity of their action from aluminosilicates with the same type of crystal structure (Al–ZSM). For a degree of conversion of methanol of 21–23%, the selectivity with respect to the total xylenes in the presence of chromosilicates was 94–99.2%. The content of *p*-xylene among all the xylene isomers then reached 90.9–58.2%, which is much higher than the equilibrium content (25%). For the chromosilicate impregnated with boric acid, the content of xylenes in the reaction products at 450° and for a degree of conversion of toluene of 20.13% was 86.28% and the content of *p*-xylene among all the xylenes was 74.55% under these conditions. At 500 °C and for a degree of conversion of toluene of 24.1%, these values were respectively 92.36 and 72.7%. The authors[172] suggest that the high *para*-selectivity of the chromosilicates is due to several causes: the influence of diffusion-dependent limitations, a higher concentration of strong acid centres than in aluminosilicates, etc. The ferrosilicates with the crystal structure of zeolites of the pentasil group have been tested as catalysts of the isomerisation of xylenes.[173] The content of *p*-xylene in a mixture of aromatic hydrocarbons containing xylenes and ethylbenzene increased as a result of the isomerisation reactions in the presence of ferrosilicates at 340 °C and atmospheric pressure from 7.4 to 14.5% (to 14.4% in the presence of aluminosilicate), while the content of *m*-xylene diminished from 55 to 40.1%.

The conversion of methanol has been investigated in the presence of a phosphorus-containing silicate with the ZSM structure.[82] The reaction was carried out in an atmosphere of H_2 at a pressure of 3.5 atm, with the ratio H_2/hydrocarbons = 2, and at temperatures of 372° and 400 °C. The specificity of the action of this catalyst compared with aluminosilicate zeolites is difficult to judge on the basis of the data presented,[82] because the content of aluminium in each specimen is not indicated. This precludes the estimation of the influence of the modifying element on the catalytic properties of the silicates synthesised.

Aluminosilicate zeolites with the chabazite and erionite–offretite structures have been synthesised[151] from gels containing sources of boron, titanium, gallium, and zironium. Catalytic data are presented for lanthanum-containing chabazite and erionite. The selectivity in the synthesis of olefins from methanol proved to be higher by 1–2% (82 to 83%) in the presence of these catalysts than in the presence of the H-form of chabazite not containing lanthanum (81%). It was demonstrated in the same studies that the selectivity of the action of type ZSM-5 zeolites, synthesised in the presence of sources of Zr^{4+} and Ti^{4+}, in the synthesis of olefins from methanol is higher by 8–9% (64–65%) than for the usual ZSM-5 zeolite (56%). However data concerning the content of Al_2O_3 in the test specimens and the state of the titanium and zirconium cations are not presented in the above communication.

A detailed study has been made of the catalytic properties of silicates with the structure of ZSM zeolites, synthesised in the presence of transition metal cations but without the addition of sources of aluminium, in reactions involving the synthesis of hydrocarbons from methanol.[129–137] The catalytic properties of the silicates synthesised were compared with those of crystalline silicon oxides having the structure of the ZSM-11 zeolite (silicalite) with the composition $0.02Na_2O.Al_2O_3.1000\ SiO_2$ and obtained by a method analogous to that of Ione et al.[130] At 380 °C methanol is converted to an extent not more than 50% in the presence of silicalite and the main reaction product is dimethyl ether (88–99%); hydrocarbons were also formed in trace amounts. The activity of silicalite was accounted for by the presence of the Al^{3+} admixture at sites isomorphous with respect to those of the Si^{4+} cation. A similar low activity and selectivity with respect to C_2–C_{10} hydrocarbons and a high selectivity with respect to dimethyl ether was shown by silicates containing the V^{4+}, Cr^{3+}, Mn^{2+}, Cu^{2+}, Eu^{3+}, and In^{3+} cations.

According to the data of Vostrikova et al.[134], the degree of conversion of methanol in the presence of manganese-containing silicates was 2–5% and the main reaction product was dimethyl ether. The low catalytic activity was observed both for the specimen where 90% of the manganese (according to EPR data) was in the state of Mn^{2+} ions and for the specimen in which 90% of the manganese introduced was not detected by EPR.

The silicates of the triply charged Ga^{3+} and Fe^{3+} ions as well as beryllium silicates manifested a high catalytic activity in the conversion of methanol into hydrocarbons.[132,133] The selectivity with respect to C_2–C_{10} hydrocarbons at 410–450 °C was 60–98% (Table 11). In the presence of type ZSM-5 and ZSM-11 zeolites, the degree of conversion of methanol under the conditions investigated was not less than 95–98%. The reaction products contained 22–38% of light C_1–C_4 hydrocarbons and 60–70% of liquid hydrocarbons. Mainly propane and butane were detected in the C_1–C_4 fraction, while the C_5 and higher fractions were found to contain aliphatic aromatic alkyl-substituted compounds. The overall content of products agreed on the whole with that quoted in a review.[26] The amount of aromatic hydrocarbons in the reaction product increased with decrease of the ratio SiO_2/Al_2O_3 in the catalyst. Thus, it amounted to 46% for SiO_2/Al_2O_3 = 38 and to only 22% for SiO_2/Al_2O_3 = 280.[137]

A series of studies have been carried out in which the combined substitution of the Si^{4+} cations by aluminium atoms and another cation (Cu–Al, Al–Fe, etc.) was achieved.[174] The introduction of copper or iron ions into the aluminosilicate at the hydrothermal synthesis stage altered the selectivity of their action. Thus, for the same Al_2O_3 content, the amount of aromatic hydrocarbons in the reaction products, obtained from methanol, was less in the presence of aluminoferro- and aluminocupro-silicates and greater in the presence of aluminosilicates. A sharp change in the selectivity of the action of silicates was attained after the complete replacement of Al^{3+} by Fe^{3+} in the latter. Thus the amount of aromatic reaction products did not exceed 10% in the presence of iron silicates whose Al_2O_3 content is at the level of impurities (less than 0.1%) and the Fe_2O_3 content is not less than 1.5%. On the whole, the fraction of aromatic hydrocarbons in the product obtained under the same conditions in the presence of catalysts with identical Al_2O_3 or Fe_2O_3 contents (Fig. 9) diminished in the sequence $SiO_2-Al_2O_3 > SiO_2-Al_2O_3-CuO > SiO_2-Al_2O_3-Fe_2O_3 > SiO_2-Fe_2O_3$.

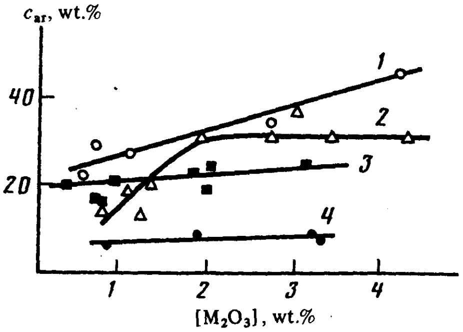

Figure 9. The content of aromatic compounds (c_{ar}) in the hydrocarbon methanol conversion products as a function of the M_2O_3 content in the crystalline silicate with the ZSM-11 structure (for reaction at 380 °C); rate of supply of liquid methanol 1 h^{-1}; composition of silicate: *1*) $SiO_2-Al_2O_3$; *2*) $SiO_2-Al_2O_3-CuO$; *3*) $SiO_2-Al_2O_3-Fe_2O_3$; *4*) $SiO_2-Fe_2O_3$.[174]

Thus, for the same M_2O_3 content in the silicate, the aromatisation reactions proceed at the lowest rate in the presence of iron-containing silicates and at the highest rate in the presence of aluminosilicates. Analysis of the aliphatic component of the hydrocarbons formed demonstrated that the fraction of hydrocarbons with a chain length of C_5 and above diminishes in the same sequence owing to the increase of the fraction of the light C_3–C_4 paraffins and, in the presence of the $SiO_2-Fe_2O_3$ system, also the C_3–C_4 olefins.[174]

A dependence of the rate of conversion of methanol (*k*), referred to one mole of M_2O_3 in a silicate with triply charged cations, on the quantity *e*/*r*, where *e* is the formal charge and *r* the radius of the cation, has been established[137] (Fig. 10). The character of the variation of lg *k* as a function of *e*/*r* does not change when the reaction temperature is raised from 380° to 450 °C: in both cases the curve passes through a maximum. At 380 °C the maximum corresponds to gallium silicate and at 450 °C to aluminium silicate (zeolite). The lowest values of lg *k* were obtained for indium and boron silicates. The maximum content of the C_2–C_{10} hydrocarbons, including olefins and aromatic compounds, in the reaction products was observed for aluminium and gallium silicates; the maximum yield of dimethyl ether was noted in those cases where the amount of hydrocarbons in the reaction products was lowest.

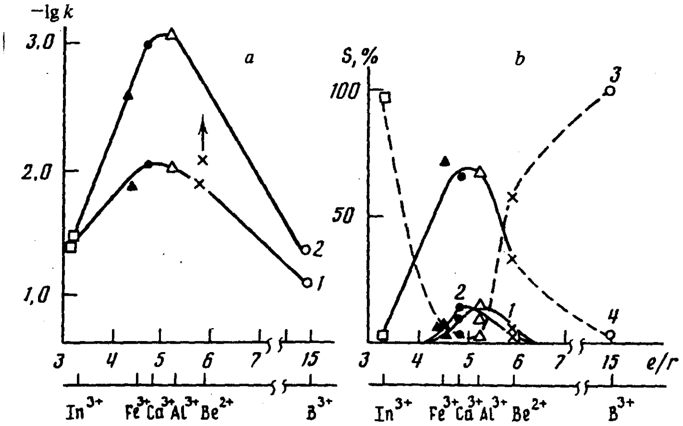

Figure 10. *a*) Dependence of the relative rate of conversion of methanol in the presence of various silicates on *e*/*r* at 380 °C (curve *1*) and 450 °C (curve *2*); *b*) dependence of the selectivity *S* in the formation of various methanol conversion products in the presence of silicates on *e*/*r* at 380 °C: *1*) aromatic hydrocarbons; *2*) isoparaffins; *3*) dimethyl ether; *4*) C_2–C_7 olefins.[137]

VI. CONCLUSION

The results presented in the present review show that silicates with the zeolite structure containing cations of only one type (Si^{4+}) exhibit no catalytic activity in reactions involving an acid–base mechanism. Thus hydrocarbons are not formed from methanol in the presence of silicalite. Silicates with the structure of zeolites, whose multicharged cations are fixed predominantly in an octahedral environment (V^{4+}, Cr^{3+}, Mn^{2+}, Cu^{2+}) and do not therefore enter into the composition of the silicon–oxygen skeleton, do not differ from silicalite as regards the selectivity of their action with respect to aliphatic reaction products. At 450 °C and above, methanol decomposition reactions with the predominant formation of CO and CH_4 (up to 60–90% of all reaction products) take place in the presence of these silicates, which can be due to the catalytic action of the phase comprising the oxides of the corresponding cations.

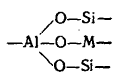
Aromatic hydrocarbons, paraffins, and olefins are formed from methanol in the presence of silicates in which at least some of the cations Fe^{3+}, Ga^{3+}, Al^{3+}, Be^{2+}, or B^{3+} are in a tetrahedral oxygen environment. The EPR and NMR data suggest that the introduction of these cations into the initial gel before the hydrothermal synthesis leads to the formation of active centres having the composition $[Si(OM)_n(SiO)_{4-n}]^{(4-n)-}$.

The dependence of the activity and selectivity of these silicates on the quantity e/r for the cations introduced is not linear, passing through an extremum. The character of the catalytic action is determined by the fact that not only the strength but also the concentration of the active centres depends on the nature of the cation in the silicon–oxygen skeleton. If the length of the M–O bond differs in one direction or another from that of the Si–O bond, then major structural distortions of the silicon–oxygen skeleton should occur. Since the bond length varies in the sequence B–O < Be–O < Si–O < Al–O < Ga–O < Fe–O < In–O, then the greatest distortions in the skeleton are to be expected for the B-, In-, and Fe-containing silicates.

The concentration of the M^{n+} cations in the silicon–oxygen skeleton of silicates should depend on the thermodynamic probability of their fixation in a tetrahedral oxygen environment relative to another, higher, or lower coordination. The energy of the stabilisation of the V^{4+}, Cr^{3+}, Mn^{2+}, and Cu^{2+} ions in an octahedral coordination is very high and the incorporation of these cations in the silicate skeleton in a tetrahedral environment has not been demonstrated. The B^{3+} cations can be fixed in a ternary coordination with a high degree of probability.

The fact that mainly olefins or dimethyl ether are formed from methanol in the presence of silicates containing the B^{3+}, Be^{2+}, and Fe^{3+} cations indicates the slow subsequent conversion of these products into aromatic hydrocarbons and paraffins. Consequently centres having the composition $[Si(OM)_n(SiO)_{4-n}]^{(4-n)-}$, where $M \neq Al$, are much less active in the hydrogen redistribution reactions in unsaturated compounds than the $[Si(OAl)(SiO)_{4-n}]^{(4-n)-}$ groups.

Bonds of the type



may be formed in the synthesis of zeolites (aluminosilicates) in the presence of multicharged cations M^{n+} introduced into the initial silica-alumina gel. For the same Al_2O_3 content, silicates without additives have a higher concentration of the $[Si(OAl)_n(SiO)_{4-n}]^{(4-n)-}$ centres with high values of n than the silicates incorporating the M^{n+} cations.

The introduction of multicharged cations, capable of substituting the Si^{4+} and Al^{3+} cations isomorphously, into aluminosilicates (zeolites) should therefore diminish the number of aluminium atoms in a single active centre and hence the ability of the latter to accelerate the hydrogen redistribution reactions in unsaturated compounds.

Study of Converse Problems in Chemical Kinetics as a Method for the Investigation of the Mechanisms of Complex Reactions

E.F.Brin

The application of mathematical modelling methods to the determination of the mechanisms of complex chemical reactions is considered. On the basis of the analysis of the present state of the mathematical modelling of chemical kinetic processes, it is shown that the study of converse problems constitutes an extension of the traditional kinetic approach to the construction of models. A classification of the direct and converse problems in chemical kinetics is proposed. It is shown that converse problems are of greatest interest at the present time in the identification of the chemical type of the reaction mechanism. The bibliography includes 133 references.

I. INTRODUCTION

The determination of the mechanisms of chemical processes is a complex physicochemical problem, whose solution is based on the fundamental postulates of theoretical chemical kinetics and on experimental studies.[1-3] The development of computer techniques and progress in the mathematical methods used in chemistry have altered qualitatively the role of mathematical modelling in the solution of this problem, having converted it into a method for the investigation of the mechanisms of chemical reactions just as legitimate as other procedures.[4-6] However, in most studies on the application of mathematical modelling in chemical kinetics,[7-15] mainly probability-statistical and computational aspects of the problem of the construction of models are considered and due attention is not paid to the kinetic aspect. The present review is devoted to the analysis of the present state of precisely this, kinetic aspect.

II. STUDY OF CONVERSE PROBLEMS IN CHEMICAL KINETICS AS A DEVELOPMENT OF THE KINETIC APPROACH TO THE CONSTRUCTION OF MODELS

One of the main ways of investigating the mechanisms of chemical reactions involves the kinetic approach.[16,17] The term reaction mechanism has usually come to be understood as the set of chemical stages making up the process.[5,18] In a broader sense, the word mechanism includes fundamental kinetic characteristics of the process such as the determination of the active species in the reaction, the ratios of the rates of the individual stages, etc.[4,13,19-22] (to make the treatment concrete, this type of mechanism has been called[22] the kinetic type of reaction mechanism).

The modelling method in the kinetic approach is based, on the one hand, on the kinetics of reactions of different classes and, on the other, on experimental design, which makes it possible to isolate and investigate quantitatively certain small fragments of the overall kinetic scheme.[4,17] A logical application of this approach permits the determination of the mechanism of the entire process, including the kinetic parameters of the stages. Indeed the majority of the mechanisms known at the present time have been deduced in precisely this way.[8-10,17,23] The success of this method has been to a large extent associated with the development of ideas about radical chain reactions.[1,24,25]

The modelling procedure in the kinetic approach includes three main stages:[4,5,17,22,26] (1) the purposeful collection of information, including the establishment of a tentative kinetic scheme process; (2) the selection of experimental methods on the basis of data obtained in the first stage and the design and carrying out of the experiment; (3) the kinetic-mathematical analysis. The application of the methods of computational mathematics and of the qualitative theory of differential equations in all the three stages of the modelling process[9] made it possible to isolate as the object of study a kinetic model of the process (i.e. a system of differential chemical kinetic equations).[17,27] The problems involved in the construction of such models reduce to problems involving the recovery of the right-hand sides in the systems of differential equations, which have come to be called the converse problems in mathematical physics.[28-30] Thus the converse problems in chemical kinetics are, in a broad sense of the term, problems involved in the determination of the reaction mechanism.[9,17,31] In essence, the converse problems involve the extension of the kinetic approach to processes whose models cannot be investigated without using computer techniques.

The specific content of each stage in the study of the mechanism is determined in the first place by the aim of the mathematical model.[5] Accordingly, it is possible to distinguish two large classes of converse problems;[32] the first class includes the converse problems whose study is used as a method for the investigation of the mechanisms of complex chemical reactions and the second includes converse problems in which mathematical models are a means for the solution of practically important problems of control, optimisation, prediction, etc. (target converse problems).

The traditional formulation of the converse problems in chemical kinetics[4,17,18,32,33] assigns primary importance to the rate constants for elementary reactions. It is assumed that, provided that the values of all the constants are known, the mathematical model of the process is defined and can be used for the solution of the target problems. For reactions of simple types, such formulation of the problem[18,35] is correct and the problems involved in setting up mathematical models, in the determination of their adequacy, and in the estimation of the parameters are in essence solved simultaneously.

However, one should not apply mechanically such formulation of the converse problem in the consideration of reactions of complex types (chain, autocatalytic, and such processes) also because, in relation to complex processes, the converse problems are solved as a rule under conditions of an acute deficiency of experimental data, as a result of which the solutions obtained are ambiguous.[4,17–22,33–36] This ambiguity has in fact led at one time to a natural lack of confidence by experimenters in the results obtained from the solution of converse problems.[33,35] Evidently the ambiguity of the solution obtained can be eliminated by improving only the experimental technique and not the numerical method.[30] Thus some modification of the formulation of the converse problems is essential.[30]

In the first place, we may note that the formulation of the converse problem for reactions of complex types should vary depending on the aim in constructing the model and on the amount of *a priori* information about the process mechanism. Thus, for processes whose kinetics are known beforehand (i.e. with a known kinetic type of reaction mechanism[22]), the aim of the investigation is the determination of the unknown rate constants. In this case special kinetic experiments are used to solve the problem.[4,18,23,33,37–40] As a rule, the use of such problems is correct when the amount of experimental data is sufficient. The necessity to develop special experimental techniques for virtually each specific problem, their uniqueness, and high cost led to their comparatively rare employment when the aim of the study is to obtain a mathematical model of the process reflecting adequately the main kinetic features. In this case experimental methods are used to solve the problems whereby one can record the kinetics of the changes in the concentrations of comparatively stable reaction components[4,18] or to measure the steady-state reaction rates.[4,8,10–14] In this situation the mathematical model of the process is not determined by the rate constants themselves but by certain combinations of the latter,[9,10,17–23,41–46] whose determination can sometimes be the aim of the solution of the converse problem—the identification of parameters.[42]

The main deficiency of the kinetic approach when such experimental information is available consists in the fact that the measurements refer to the rates of slow stages and do not yield information about the rates and presence of faster stages,[48] i.e. about the kinetics of conversion of the active components of the reaction. Evidently, in the absence of *a priori* information about these kinetic features, the formulation of the problem of the parametric identification becomes pointless and the problem of the identification of the mechanism (more precisely the kinetic type of mechanism) of the reaction comes to the fore. Indeed, the kinetic scheme of the process contains no information about the reactivity of the reaction components and about the relative contributions of the stages to the overall process. In the absence of such information, it is impossible to isolate beforehand the combinations of constants determining the course of the process. Accordingly, there is also a change in the specific aim of the study, which consists in this instance in the determination of the kinetics, i.e. of the possible reaction mechanism.[13,21,26]

The most obvious way of obtaining information necessary for the determination of the possible mechanism consists in a direct experimental measurement of the varying concentrations of the intermediate reactive reaction components. However, as already stated, the high cost and complexity of the methods limits significantly the applicability of this approach.[4,17,23,37,49] The availability of experimental methods whereby the kinetics of the conversion of the "slow" reaction components or the steady-rates of the stages can be recorded has made such an experiment the main procedure for the determination of the possible reaction mechanism. The dependence of the initial or steady-state rates, induction periods, and other macrokinetic parameters under experimental conditions, for example, on the initial concentrations, does indeed frequently permit the determination of the reaction mechanism[8–15,23] on the basis of which it is possible to set up an adequate mathematical model.

The converse problems in chemical kinetics, which result from the natural extension of the kinetic approach, possess not only all the advantages but also all the disadvantages of the latter. Within this framework, it is impossible to demonstrate that the true reaction mechanism has been established[48] and one can only speak of the lack of contradiction between the mathematical model, corresponding to the mechanism obtained, and the existing experimental data,[4,19] i.e. of the possibility that such a mechanism can occur. The term "identification" should also be understood in precisely this sense.

The mathematical and computational aspects of the problem have been described fairly completely in the literature and here we shall specify only certain problems of a mathematical character, whose solution determines the real possibility of formulating the converse problems of chemical kinetics: (1) experimental design;[13,30,42,49,50] (2) the choice of the functional determining the similarity between the experimental and calculated values of the observed variables;[26,42,50–54] (3) the selection of a method for the integration of the system of potential chemical kinetic equations;[4,13,17,20,26,55–63] (4) the selection of a method for the minimisation of the functional.[4,11,13,19–21,42,50,52–55,63–74]

III. DIRECT PROBLEMS IN CHEMICAL KINETICS

In chemical kinetics the course of the process is determined by the time variation of the concentrations of the reactants. This dependence constitutes the information obtained from the study of the chemical process. The derivation of this information by the mathematical modelling of the chemical process is understood as the direct problem.[18] To make the treatment concrete, we shall consider processes for which the variation of the concentrations of the reactants (x) is specified unambiguously by the Cauchy problem:

$$\frac{dx}{dt}=f(x);\ x(0)=x^0. \tag{1}$$

This system[6,17,27] constitutes a kinetic model of the chemical process. The form of the right-hand side of Eqns.(1) is determined by a set of kinetic postulates,[17,75] which can be formulated in the following manner for the processes involved in isothermal equilibrium chemical kinetics in closed systems and which are mainly considered in this review.

1. The chemical process can be represented by a set of elementary stages:

$$\sum_{i=1}^{N}\nu_{ij}^{+}A_i\to\sum_{i=1}^{N}\nu_{ij}^{-}A_i;\quad j=1,2,\ldots,M, \tag{2}$$

where A_1, A_2, ..., A_N are the components participating in the reaction and ν is the stoichiometric matrix ($\nu_{ij}=\nu_{ij}^{+}-\nu_{ij}^{-}$; the plus and minus signs correspond to the stoichiometric coefficients of the reactant entering into the jth reaction and formed in it).

2. The relation between the rate of the elementary stage w_j and the concentrations of the reactants involved in it, $x_i = [A_i]$, is determined by the Law of Mass Action:

$$w_j = k_j \prod_{i=1}^{N} x_i^{\overset{+}{\nu}_{ij}} , \qquad (3)$$

where k_j is the rate constant for the jth stage.

3. The overall rate of conversion of the ith reactant is determined by the principle of the independence of the occurrence of the elementary stages:

$$\frac{dx_i}{dt} = \sum_{j=1}^{M} \nu_{ij} w_j \qquad (4)$$

Thus, for the situation considered, the kinetic model of the process is specified by (1) the stoichiometric matrix ν and (2) by the initial concentrations and the rate constants.

The kinetic model should reflect the asymptotic character of the chemical process (the rapid attainment of steady-stage regimes with respect to the concentrations of the active reactants and the negligible contribution by the rates of certain stages to the rates of change in the concentrations of the reactants). We shall put Eqn.(1) in the following form:

$$\tau_i \frac{dx_i}{dt} = \varphi_i(x, k); \; i = 1, 2, \ldots, N; \qquad (5)$$
$$x(0) = x^0 ,$$

where

$$\varphi_i(x, k) = \sum_{j=1}^{M} H_{ij} \nu_{ij} w_j . \qquad (6)$$

Here $k = (k_1, k_2, \ldots, k_M)$ is the rate constant vector and τ_i and H_{ij} are parameters. We may note that Eqn.(1) is a special case of Eqn.(5) when $\tau_i = 1$ for all i and the elements of the matrix H_{ij} are determined for non-zero ν_{ij} and are unity.

We shall define the kinetic model as a special model in relation to Eqn.(1), provided that there exist parameters τ and H in Eqn.(5) such that, when $\tau_s \to 0$ ($s = p + 1, \ldots, N$) and $H_{mn} \to 0$, the system of Eqn.(1) is converted into a system

$$\frac{dx_i}{dt} = \varphi_i(x, k); \quad i = 1, 2, \ldots, p , \qquad (7)$$
$$0 = \varphi_i(x, k); \quad i = p + 1, \ldots, N$$

such that, over a certain time interval $t \in (t_1, t_2)$ and in a certain range of initial concentrations $x^0 \in X$, the following inequality holds:

$$|x(t) - \tilde{x}(z)| < \varepsilon , \qquad (8)$$

where $\tilde{x}(t)$ is the solution of Eqns.(7) and ε is a certain specified accuracy [for example the accuracy of the numerical integration of Eqn.(1)]. For convenience, we assume that the method of steady-state concentrations is applicable to the last $N-p$ reactants. The parameters H_{mn} will be set equal to zero, provided that the rate of the nth stage in the mth equation can be neglected.

We set up[32,42] a correspondence between the observations vector $\eta(t)$, in which account is taken of both the incompleteness and errors of the measurement, and the vector $x(t)$, which is a solution of Eqns.(1) or (7):

$$E(\eta(t)) = Rx(t) , \qquad (9)$$

where E is the symbol of the mathematical expectation of a random quantity and R a square matrix. In the general case, for example, in spectrometric measurements, the matrix R can be non-diagonal and can include spectral parameters. However, the matrix R is fairly often diagonal, i.e. measurements are made of the concentrations themselves and the diagonal elements of R are identical with the parameters of the vector τ or rank$(R) < N - p$. This situation will in fact be mainly analysed in the present review.

The procedure where the vector $\eta(t)$ is brought into correspondence with the vector-function $f(x, k)$ set up on the basis of Eqns.(1) will be referred to as the general direct problem and will be regarded as complete if rank$(R) = N$; otherwise it will be regarded as truncated.[32] The procedure in which the vector $\eta(t)$ is brought into correspondence with the vector-function $\phi(x, k)$ set up on the basis of Eqns.(7) will be referred to as the special direct problem.

Thus each direct problem is determined by the rules governing the construction of the right-hand sides of the equations, the stoichiometric matrix, the kinetic parameters and the law (R) relating the exact solution $x(t)$ to the observations vector $\eta(t)$.[32] For special direct problems, an essential intermediate link between the rules governing the construction of the right-hand sides, including the specification of the stoichiometric matrix, and the rules determining the kinetic parameters and the law (R) is the rule according to which the transition to the system of differential-algebraic Eqns.(7) is effected.

Evidently, depending on the values of the rate constants, the selected time interval, and the initial concentration range, different special problems correspond to the solution of the general problem [in the sense of the fulfillment of inequality (8)]. For this reason, before formulating the converse problem, we shall consider the classification of special kinetic models.

IV. SPECIAL KINETIC MODELS

We shall divide the kinetic models into two large classes. For models of class 1 (referred to by convention as the "chain" class), there are no linearly dependent equations among the algebraic components of Eqns.(7). For models of class 2 (the "catalytic" class), certain algebraic equations in the system (7) are linearly dependent. From the standpoint of kinetics, this means that a stationary regime with respect to the concentrations of the initial reactants is not established in "chain" processes, while in "catalytic" processes there is a possibility of the attainment of a stationary regime with respect to the concentration of the catalyst, which is a starting material. For "catalytic" processes, we eliminate from Eqns.(7) the linearly dependent equations and supplement the system by the material balance equations. Bearing in mind that certain concentrations involved in the material balance can be negligible, we introduce the parameters $\tilde{h}$ into the material balance equation. For example, in the case where the system contains one equation which is a linear combination of the remaining equations, we have

$$\sum_{i=p+1}^{N} \tilde{h}_i x_i = c^0 , \qquad (10)$$

where $\tilde{h}_i = 0$ provided that the concentration of the ith reactant in Eqn.(10) can be neglected, whilst otherwise $\tilde{h} = 1$ and c^0 is the initial concentration of the catalyst.

Evidently the selection of the elements of the vector τ and of the matrix H is not arbitrary in the general case. Thus τ_i can be zero only for intermediate reactants or the catalyst. Under these conditions, the choice of $\tau_i = 0$ determines to a large extent the choice of the elements of the matrix H. Indeed, in order that stationary conditions should hold with respect to all the intermediate reactions, it is essential that the following system be soluble:[18]

$$\sum_{j=1}^{M} \nu_{lj}\mu_j = 0 \quad , \tag{11}$$

where l are the numbers of the intermediate reactants (suppose that $l = p_1 + 1, \ldots, N$, where $p_1 < p$) and μ_j are the stoichiometric numbers of the stages.

The sum of the stages, taken with the corresponding stoichiometric numbers which are selected so that the overall stoichiometric reaction equation does not include intermediate species (for a stationary regime, the active intermediate species), is referred to as the reaction pathway[76-79] and determines a certain general kinetic model with lower dimensions:

$$\frac{dy}{dt} = \psi(y, \varkappa); \quad y(0) = y^0; \quad y = (y_1, y_2, \ldots, y_{p_1}) , \tag{12}$$

where $y_i = x_i$ for $i = 1, 2, \ldots, p_1$.

Evidently the choice of the stochiometric numbers must ensure that Eqn.(11) holds for $l = p + 1, \ldots, N$ and does not hold for $l = p_1 + 1, \ldots, p$. Here the elements of the matrix H must be unity, provided that the corresponding $\mu_j \neq 0$ and must be zero in the opposite case. The elements of H not entering into the algebraic component of Eqns.(7) are selected arbitrarily.

We shall illustrate this procedure in relation to a catalytic reaction:[18]

	Stages	Pathways		
		I	II	III
(1)	$E + S \rightarrow ES$	1	1	2
(−1)	$ES \rightarrow E + S$	1	0	1
(2)	$ES \rightarrow E + P$	0	1	1

Here S is the substrate, E the catalyst, and P the reaction product. On the assumption of the stationary character of the reaction, the equation determining the stationary condition is

$$\mu_1 - \mu_{-1} - \mu_2 = 0 \tag{13}$$

By choosing the smallest positive integral solutions of this equation, we find that three pathways (I–III) can be realised in the given system and that each pair of pathways is linearly independent.

We shall consider the balance equation

$$\tilde{h}_1[E] + \tilde{h}_2[ES] = [E]^0 . \tag{14}$$

Evidently, three ways of selecting the parameters $\tilde{h}_i$ in Eqn.(14) are possible: (1) $\tilde{h}_1 = \tilde{h}_2 = 1$; (2) $\tilde{h}_1 = 1$, $\tilde{h}_2 = 0$; (3) $\tilde{h}_1 = 0$, $\tilde{h}_2 = 1$. Thus, in the given system nine special models will formally correspond to the single general kinetic model. For example, for the second pathway, the following special model exists:

$$\frac{dx_1}{dt} = -k_1x_1x_3 \ ,$$
$$\frac{dx_2}{dt} = k_2x_4 \ ,$$
$$k_1x_1x_3 - k_2x_4 = 0 \ ,$$
$$x_4 = x_3^0 \ ,$$

where $x_1 = [S]$, $x_2 = [P]$, $x_3 = [E]$, and $x_4 = [ES]$. The general kinetic model with lower dimensions corresponding to this special model then has the following form:

$$\frac{dx_1}{dt} = -k_2x_3^0 \ ,$$
$$\frac{dx_2}{dt} = k_2x_3^0 \ .$$

We may note that the determination of the general kinetic model with lower dimensions is possible only if the algebraic component of Eqns.(7) is soluble in an explicit form in terms of the concentrations of the reactants with respect to which a stationary regime is established.[19] However, the asymptotic character of the behaviour of kinetic systems increases significantly the probability of obtaining an explicit form of such models. For example, this has been achieved for extremely complex processes involving the joint oxidation of hydrocarbons.[80,81]

A definite asymptotic form of Eqns.(1) or a definite kinetic feature of the reaction corresponds to each set of numbers τ_i, H_{ij}, and $\tilde{h}_i$. A definite reaction regime has been brought into correspondence[80] with each asymptotic type of this kind. When the range in which the initial concentrations are specified or the degree of conversion is altered, the regime can change. The set of regimes which can be realised in the system for the specified rate constants determines the kinetic type of the reaction mechanism.[22] Evidently a certain region in the rate constant space, in which specific asymptotic properties of Eqns.(1) are manifested, corresponds to each kinetic type of reaction mechanism. This region has been defined[22] only for "chain" processes (in the form of the ratio of the rates of elementary stages).

The solution of the direct problems in chemical kinetics is comparatively rarely the aim in itself; these problems [like the mathematical problem of integrating Eqns.(1) or (7)] are usually a component of the converse problems. One can indicate only one important feature associated intrinsically with their solution: the elucidation of the question of which special kinetic models correspond to the general model [in the sense of the fulfillment of inequality (8)] when the rate constants are known or within a certain range of rate constants and for specified ranges of the initial concentrations and a specified time interval.[4,17,26,63,82,83]

In other words, this problem consists in determining the kinetic type of the reaction mechanism. For example, in the solution of the problem for the methane oxidation reaction, it has been shown[26,63] that, up to 1600–1700 K, the course of the process is determined by the chain reaction regime, while at higher temperatures it is determined by the free radical reaction regimes; for the ethane oxidation reaction,[84] the kinetic type of the reaction mechanism is determined by the regime in which degenerate branching is associated with the decomposition of performic acid or of the superperoxy-radical and not with the reaction $CH_2O^{\bullet} + O_2 \rightarrow HCO^{\bullet} + HO_2^{\bullet}$, as had been assumed earlier. Gontkovskaya et al.[85] considered five reaction regimes and Dimitrov[17] considered six reaction regimes in the combustion of hydrogen as a function of conditions. The reaction regimes in the liquid-phase oxidation of hydrocarbons have been investigated.[4,81,86] The direct problem has been solved[87,88] in order to test the correspondence between the approximate formula for the calculation of the inhibition period in the inhibited oxidation hydrocarbons, obtained on the basis of a special kinetic model, and the exact values of this quantity obtained by solving the general direct problem.

V. CLASSIFICATION OF THE CONVERSE PROBLEMS IN CHEMICAL KINETICS

If the direct problems are considered as problems of discovering one realisation $\eta(t)$ of a certain structure, determined by the rules governing the construction of Eqns.(1), (9) or (7), (9), then the converse problems can be naturally interpreted as the recovery of the elements of this structure from the set of observations $\eta(t)$.[32] The rules governing the construction of the realisation $\eta(t)$ are regarded as statistical hypotheses.

We shall consider these hypotheses for isothermal chemical kinetic processes in which it is assumed that the following parameters are known: Π_1—the matrix for ν_{ij}; Π_2—the law relating the rate of the elementary stage to the concentrations, for example, Eqns.(3); Π_3—the expression for the total rate of conversion of all the reactants, for example Eqn.(4); Π_4—the limiting transition to which corresponds the the solution of the partial direct problem, or the absence of such a transition; Π_5—the kinetic parameters.

The system of hypotheses Π_1–Π_5 determines the general kinetic model and its corresponding special models. We shall supplement this system by hypotheses C, defining the model of observations, in which the following parameters are assumed to be known: C_1—the matrix R; C_2—the form of the distribution of experimental errors (with an accuracy to within the values of the parameters); C_3—the parameters of the distribution.

This system makes it possible to construct a hypothetical solution to the direct problem and to compare it with the existing set of experimental data $\eta(t)$. It is natural to consider the converse problems in chemical kinetics as problems of the recovery of the unknown hypotheses in this system from the known set of $\eta(t)$. The converse problems associated with the recovery of the hypotheses C_2–C_3 are outside the framework of this review. Their recovery requires as a rule the formulation of special statistical experiments.

The form of the matrix R is in most cases not known exactly. When different spectrometric measurements are performed, the matrix R frequently includes unknown parameters (for example, the absorption coefficients in spectrophotometric measurements[72]), which also have to be recovered in the solution of the converse problems. However, for simplicity, we shall assume that the matrix R is fully defined.

It is easy to note that, in the formulation of the direct problem, a hierarchy of hypotheses Π_l arises and consists in the fact that a definite content cannot be attributed to the hypothesis Π_s if the hypothesis Π_{s-1} has not been formulated. The pointlessness of formulating the converse problem as the problem of recovering the hypothesis Π_s when the hypothesis Π_{s-1} is unknown follows from the hierarchy of hypotheses. It is evident that, for example, the formulation of the problem of finding the rate constants has no significance if it is not known *a priori* whether the Law of Mass Action holds.

As a rule, having at ones disposal a set of observations, it is possible to state beforehand whether we are dealing with a complete [rank(R) = N] or truncated [rank(R) < N] solution of the direct problem. The situation is different as regards the question whether the above set of observations is a result of the solution of the general or special direct problems. In fact, in a real situation we are always dealing with a solution of the general problem and the limiting transition to the special problem is merely a mathematical reflection of the characteristic features of the chemical reaction.

We shall refer to the converse problem as general if it is known that there is no limiting transition in which it is impossible to distinguish the solutions of the general and special direct problems for a specified experimental accuracy. Otherwise we shall refer to it as a special converse problem.

The asymptotic character of the behaviour of chemical processes and the difficulty of the experimental measurement of the changes in the concentrations of all the reactants are due to the same physicochemical causes. The times during which the process begins to be determined by the special kinetic model amounts to millionths of a second (and less). This creates experimental difficulties in the study of the kinetics before the attainment of a stationary regime. Furthermore, in view of the high reactivity of the "fast" reactants, their concentrations are low (down to 10^{-12} M) and their experimental determination also gives rise to difficulties at the present time. Thus the deficiency of experimental data at the disposal of investigators in the solution of converse problems with deep physicochemical roots and the success of the solution are in many respects determined by the availability of *a priori* data on the process investigated.[22]

The extent to which the chemical process has been studied, i.e. the availability of information about Π_1–Π_5, determines the level of the converse problem.[32] The zero level corresponds to the case where all the factors constituting the direct problem, including the parameters, are known. The converse problem at this level consists in testing the consistency of the general or special kinetic model with the available set of experimental data. The converse problems at this level have been solved, for example, by Emanuel' and co-workers.[89–91] Evidently, whatever the level of the converse problem, the question of consistency is the first to which it is essential to obtain an answer in the course of its solution.

The usual formulation of converse problems as problems involving the determination of unknown kinetic parameters[5,14,17–22,26,35,41–45] on the assumption that information about Π_1–Π_4 is known beforehand belongs to the first level. A systematic approach[92] has been made[42] to the consideration of mathematical models of chemical kinetics. The term model is understood as a rule governing the transformation of the input variables into output variables, established by the analysis of causal-consequential relations:[93]

$$\eta(x(t)) = B\{t, \varepsilon, \theta\}\,, \qquad (15)$$

where $B\{.\}$ is an operator transforming the variables t, ε, and θ (where t is the time, ε are random factors, and θ are unknown parameters) into the observed variables η. Following the terminology proposed by Gorskii,[42] we shall define the converse first level problem as the problem of parametric identification arising in the case where the structure of the model, expressed by the operator $B\{.\}$, is known *a priori*. Otherwise, problems of structural identification arise—the converse problem at higher levels. The second level problems are associated with the recovery of hypothesis Π_4 for specified Π_1–Π_3, i.e. with the establishment of the kinetic type of the reaction mechanism.

The third and fourth level problems are associated with the recovery of the principal postulates of the chemical kinetics. In fairly numerous instances, for example, when reactions occurring under the conditions of a high density of the external energy flux (shock tubes, molecular beams, plasmachemical processes, etc. are considered), one cannot use the usual Arrhenius kinetics.[26,40,63] For a correct formulation of the kinetic postulates, it is essential to find the distribution of the excited species with respect to states. Thus the given problems refer to the generalised non-equilibrium chemical kinetics[94] and extend far outside the framework of the present review. Analysis of studies concerning non-equilibrium chemical kinetics has shown that, as a rule, the mathematical models for such processes are obtained within the framework of a physicochemical and not a kinetic approach.[17]

The fifth level problems are associated with the selection of one of several versions of the kinetic schemes for the process. If each such version (hypothesis) does not necessitate the reformulation of the fundamental postulates of chemical kinetics, a definite special kinetic model corresponds to it.

Thus in the case of equilibrium Arrhenius chemical kinetics, the second and fifth level problems actually refer to the same level.

1. Converse First Level Problems

When problems are considered at this level, account must be taken of the degree of completion and generality of the formulation of the direct problem with the aid of the solution of which a set of η_{ij} is believed to be obtainable. If a complete solution of the general direct problem is available, i.e. the kinetics of the variation of the concentrations of all the reactants in the time interval $t \in [0, T]$ have been determined experimentally, the problem has been correctly formulated.[34,36,45] The question of the validity of the formulation of the converse problem for the case where a truncated solution of the general direct problem is available (measurements are not made for all the reactants) or for the complete solution of the special problem (measurements are made for all the reactants in the stationary regime) can be elucidated for each specific problem. In the general case (truncated solution of the special problem), the formulation of the problem is as a rule incorrect.[4,17,18,20–22,33–36,41–45,95] From the physicochemical standpoint, such formulation is equivalent to an attempt to extract more information from experimental data than the latter contain.[4,19] Indeed the solution of the special truncated direct problem agrees in this case [in the sense that Eqn.(8) holds] with the solution obtained by the integration of the general kinetic model with lower dimensions [Eqn.(12)].

Thus the attempt to find all the rate constants reduces to the recovery of the concentration dependences for the "rapid" reactants which do not enter into Eqn.(12) at all.[41] From the mathematical standpoint, the causes precluding the solution of the problem in terms of the traditional formulation are as follows:[54] (1) the inadequate information extractable from the measurements; (2) a significant non-linearity of the kinetic models in terms of the constants being solved; (3) different sequences in the initial set of experimental data; (4) the lack of information about the fundamental statistical characteristics of the measurement. These causes are a consequence of the physicochemical characteristic of the processes (the asymptotic character of their behaviour), which were considered above.

Thus the solution of the problem of finding the rate constants gives rise to difficulties not as a result of any mathematical causes but by virtue of the complexity and the considerable labour involved in the extraction of sufficient experimental information.[19,20]

Regardless of the purpose for which the model has been constructed, the converse problem at the first level consists of two components:[20,21] the first significant component includes the test of the consistency of the proposed kinetic model with the available set η_{ij} of experimental data; the second, target component involves the extraction from the experiment of information about the process mechanism which is essential for the construction of the model. The fact that in the observation range the process is described by a special kinetic model and an umambiguous determination of the rate constants is therefore impossible clearly indicates a way of modifying the formulation of the converse problem. The first component of the problem then consists in finding a function from the class defined by Eqns.(1) which agrees [in the sense of Eqn.(8)] with the function from the specified class (7) providing the best description of the experimental data. The possibility of passing to a general model with low dimensions [Eqn.(12)] makes it possible in many instances to formulate the problem as one involving the finding of a function from the class defined by Eqn.(12). However, having solved this problem, it is essential to test whether rate constants having a physical significance, for which Eqn.(8) holds, do exist. Thus the first part of the converse first level problem can be formulated as follows: do parameters k or κ such that the kinetic model is not rejected for the given level of significance, actually exist? Hence follows the most frequently encountered formulation:[14,17,26] the aim is to find the parameters k or κ ensuring a maximum in the probability function.

Having solved the first part of the problem, it is possible, on the basis of the purpose for which the model has been constructed, to formulate the second part, which may consist in finding the unknown rate constant k or the unknown combinations of constants κ or the aim may be to reach a conclusion about the behaviour of the process.

2. Problems of Parametric Identification

The problem of finding unknown rate constants arises as a rule when a large amount of *a priori* information is available about the process, i.e. when many rate constants and some of their ratios are known. Special experimental kinetic studies are then performed,[37–39] which make it possible to estimate or revise a comparatively small number of constants. The vast majority of the values of the rate constants for elementary reaction known at present[35,96] have been obtained as a result of this approach.

For example, the aim of the study of the interaction of fluorine with halogens near the self-inflammation limit was the revision of the rate constants for the branching and energy chain termination reactions.[72] The experiments were performed under the conditions in the development of the branching-chain process, whose mechanism and the majority of rate constants were known.[97] The problem proved to be correctly formulated and the required parameters were estimated on a computer. An analogous investigation of the hydrogen combustion reaction[52] made it possible to revise four of the ten rate constants on the basis of the dependence of the maximum concentration of the radicals on the initial conditions. The solution of these converse problems does not give rise to fundamental difficulties. The methods developed[10,20,26,52,53,61,83,98] (see also the studies quoted by Gorskii[42]) have been applied successfully with this aim also in the study of reactions of simple types.[18,99,100]

The practically important properties of the process are often determined by the kinetics of the variation of the concentrations of the "slow" reactants. In this case the system of Eqns.(12) constitutes a model of the process and both parts of the converse first level problem can be combined in a single problem of the identification of the parameters κ. In many instances the parameters κ themselves determine the practically important properties of the process investigated and their determination is the aim of the solution of the converse problem, for example in tests.[101,102] This formulation of the converse problem also generally proves to be correct. Combinations of the rate constants have been estimated, for example, for the pyrolytic reactions of ethane,[20,61] the joint oxidation of hydrocarbons,[10,81,103] and the liquid-phase oxidation of tetralin [104] and in the study of the decomposition of hydroperoxides,[105] the initiated oxidation of hydrocarbons in the presence of inhibitors,[101,102] etc.

The formulation of the converse problem is used especially frequently in the study of heterogeneous-catalytic reactions. Thus the parameters κ have been estimated for the n-butene dehydrogenation reactions,[106] the interaction of ethane with water vapour,[107] the hydrogenation of oxo-synthesis aldehydes,[108] the isomerisation of higher olefinic hydrocarbons,[109] the dehydrogenation of n-butane,[110] the hydrogenation of phenol[13] and benzene,[11] the oxidation of carbon monoxide,[111] etc. A more detailed bibliography on the solution of the converse problems in the study of heterogeneous-catalytic processes can be found in a number of other communications.[5–15,26,27,50]

The combinations of rate constants obtained can be used to revise the intrinsic rate constants using the results of the corresponding experiment or using *a priori* information about certain rate constants.[103]

3. Target Converse Problems

The situation where both parts of the converse problem are solved simultaneously[21,62] was considered in the previous subsection. The validity of the formulation of this problem ensures the uniqueness of the solution of the parametric identification problem. The availability of such solutions makes it possible to test the hypothesis about the adequacy of the process model. In the general case the transition to a general kinetic model with lower dimensions is not always justified: any set of constants satisfying the physical significance (or the specified form) of the special kinetic model and ensuring an adequate description defines a mathematical model which can be used to solve target problems.

As examples of the solution of the first part of the converse problem, we may point to studies on the modelling of the oxidation of tetralin,[104] the radiation-initiated isotope exchange of deuterium with the hydroxy-groups of silica gel,[26] the oxidation of methylacrolein,[112] the oxidation of ethylbenzene in the presence of aromatic amines and bivalent copper compounds,[113] the coupled oxidation of hydrocarbons,[114] the oxidation of coconut oil,[115] the sulphonation of secondary alcohols,[116] the catalytic oxidative dehydrogenation of n-butene,[117] the oxidative regeneration of aluminosilicate cracking catalysts,[118] the cyclooligomerisation of butadiene,[119] the oxidation of methanol,[120] the photochemical oxidation of polyolefins,[121] the oxidation of anthrahydroquinone,[122] the liquid-phase oxidation of *p*- and *m*-di-isopropylbenzenes,[123] the oxidation of carbon monoxide,[124] the hydrochlorination of acetylene,[125] etc. In these studies the rate constants were used solely as a means for the parametric test of the hypothesis of the adequacy of the corresponding mathematical models.

When the problem of adequacy has been solved positively and solution (1) has been found, one can proceed to the solution of a particular problem for which the mathematical model has been constructed. Formulation of such target problems will be considered in relation to kinetic prediction problems.[3,126] Suppose that one needs to test the truth of the claim that the target function $\phi[x(k)]$ belongs to the region u. For this problem, there may be three solutions: (1) "yes", i.e. $\phi \in u$ and the probability of the error is less than β, (2) "no", i.e. $\phi \notin u$ and the probability of error is less than α, and (3) the amount of experimental data for a well-founded answer for the specified α and β is small. Here α and β are respectively errors of the first and second kind.

4. Allowance for the *a priori* Information in the Solution of Converse First Level Problems

Evidently first level problems arise when sufficient *a priori* information is available about the process mechanism: the mechanism must satisfy a whole series of various requirements, which make it possible to formulate the hypotheses Π_1–Π_4. The need to take into account the *a priori* information in the formulation of converse problems has already been pointed out.[14,17,20,22,26] The range of parameters among which the solution has to be found is limited to certain control requirements from which the general control requirements, valid for any chemical reaction, and special requirements determined from the analysis of the available experimental data and *a priori* kinetic information, have been isolated. The general control requirements are believed to include[17] the Law of Conservation of Matter, the Law of Conservation of Energy, and the requirement that the concentration of any reactant at any instant is non-negative. In essence, these requirements constitute a test of the validity of the formulation of the kinetic scheme and the validity of the integration of Eqns. (1). In conformity with the terminology developed in the present review, we shall refer to the control requirements as general if they differentiate a certain class of special kinetic models, within the framework of which the "true" model is located, and we shall call them special if they differentiate one special model from this class.

The general control requirements are formulated on the basis of data obtained or available outside the formal kinetic approach to the construction of mathematical models and qualitative information about the process investigated which the investigator usually processes. We shall consider, for example, the consecutive chemical reaction[127]

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C\,.$$

Suppose that the variation of the concentration of substance C, corresponding to the solution of special direct problems, is determined experimentally:

$$[C](t,\ k) = [A]^0[1 - \exp(-k_{\text{eff}}t)]. \tag{16}$$

In the absence of *a priori* information about the process mechanism, two special direct problems, defined by special control requirements, correspond to this solution: (1) $k_1 > k_2$ and (2) $k_1 \ll k_2$; accordingly, we have $k_{\text{eff}} = k_2$ or $k_{\text{eff}} = k_1$. The problem is formally outside the framework of the first level. In an informal consideration of A and B, the latter are real chemical substances and the possibility of the realisation of a particular special direct problem is determined in essence by the strength of the chemical bond in the corresponding molecules. Thus *a priori* information about the bond strength in the molecules of substances A and B makes it possible to formulate general control requirements within the framework of which the solution to the problem must be sought. For example, if the bond strength is greater in the molecule of substance A, then the general control requirement has the form $k_1 \ll k_2$. Analysis of semiquantitative data for the concentration of the intermediate B, which is not measured, leads to an analogous result. For example, when $\text{Max}[B](t) \ll [A]^0$, we obtain $k_1 \ll k_2$ and $k_{\text{eff}} = k_1$. The regions corresponding to the existence of different kinetic types of mechanisms of the liquid-phase oxidation reaction of hydrocarbons in the oxidation of hydrocarbons inhibited by phenol have been related[128,129] to the R–H bond strength and temperature. For these classes of reactions, it is possible to isolate, on the basis of the bond energy and temperature, the general control requirements within the framework of which the converse problem should be solved.

Qualitative information about the process investigated may include at least two kinds of data:[22] (1) semiquantitative data on the yield of particular reaction products or the concentrations of intermediate reactants; (2) data concerning any effect observed in the system, for example, critical phenomena, the effect of inhibiting or initiating additives, etc. Formal mathematical treatment of such data makes it possible to differentiate a system of general control requirements.

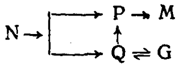
The question of the formal treatment of the control requirements ensuring the limitation of the region in which the converse problem is to be solved has been examined[14,22,26] but it is outside the framework of the present review. We shall only note that the control requirements must determine unambiguously the region in the rate constant space where the given special catalytic model of the process is realised.

Evidently the general control requirements unambiguously define the special kinetic model only for thoroughly investigated processes when a large amount of *a priori* physicochemical information is available. For example, such information has been obtained in the determination of the kinetics of the catalytic action of trinuclear clusters of the oxoacetates of the iron–chromium series in the model reaction involving the oxidation of ascorbic acid by hydrogen peroxide.[130] However the determination of such information is frequently associated, for example, in the study of pharmacokinetic reactions,[49] with serious experimental difficulties even for the example of consecutive chemical reactions considered above. Thus the problem of the identification of the kinetic type of the reaction mechanism—a converse second level problem—then comes to the fore.

VI. IDENTIFICATION OF THE REACTION MECHANISM

The ambiguity of the solution of the converse problem in terms of the traditional formulation is expressed, on the one hand, by the degeneracy of the minimum in the functional reflecting the similarity between the experimental and theoretical values of the observed variables, and, on the other hand, by the appearance of local minima in this functional. In both cases the ambiguity is caused by the deficiency of the experimental data, manifested in the asymptotic character of the system of differential Eqns.(1). Hitherto the formulation of the problem subject to the condition that the minimum in the functional is degenerate has been considered; we shall now deal with the formulation of problems involving the presence of local minima in the functional. The formulation of the converse problem as the problem of selecting the versions of the mechanisms agreeing well with the amount of experimental data arose as the natural response by investigators in the field of kinetics to the lack of validity of the traditional formulation.[33]

In the early studies the versions of the mechanism (the hypothesis about the mechanism) were special cases of a certain general kinetic scheme including all the process stages considered in the alternative versions of the mechanism.[13–15,26,57,101,102,131] For example, Peterson[131] considered eight alternative mechanisms of the oxidation of naphthalene and later Bard and Lapidus[50] considered thirteen such mechanisms, which are special cases of the general mechanism



where N is naphthalene, P phthalic anhydride, M maleic anhydride, Q naphthoquinone, and G gaseous products.

The need to formulate the problem by selecting the possible mechanism was dictated by the experimentally demonstrated lack of validity of the traditional formulation of the problem.[20,26] Indeed, if the formulation had been correct, then rate constants close to zero would have been obtained for stages which "do not occur" (the reactions take place at negligible rates) in the solution of the converse problems. However, even in the case of model problems[26] this was not found to be the case.

The presence of local minima in the functional in the case of mechanisms from which one cannot exclude any one stage necessitated an increase in the complexity of the concept of "version of the mechanism". Thus the ratios of the rates of individual stages[13,22] and different hypotheses concerning the reactivity of the intermediate reactants[20,22] have been included in this concept. It has been shown[22] that all these hypotheses are special cases of the description of experimental data by an asymptotic form of the complete system of differential Eqns.(1).

The need for the structural identification of kinetic models arises in the formal approach[20] to the study of any fairly complex process. Thus the model reaction involving the initiated chain consumption of a substance M with quadratic destruction of the active centre R, determined by the following kinetic scheme, has been considered:[22]

Stages	Pathways						
	I	II	III	IV	V	VI	VII
(1) $\xrightarrow{w_1} R$	1	2	0	1	2	0	0
(2) $M \rightarrow R$	1	0	2	1	0	2	0
(3) $R + M \rightarrow R + \Pi$	0	0	0	1	1	1	1
(4) $2R \rightarrow$ chain termination	1	1	1	1	1	1	0

If the experimental relation $[M]^{\exp}(t)$ is determined by a solution of the general direct problem with smaller dimensions, i.e.

$$\frac{d[M]}{dt} = -k_{eff}[M]; \quad [M](0) = [M]^0 ,$$

then the experimental data will be described by a kinetic model corresponding to pathway III:

$$\frac{d[M]}{dt} = -k_2[M]$$

and the model corresponding to cyclic pathway VII, where the concentration of active centres is determined by pathway II:

$$\frac{d[M]}{dt} = -\varkappa[M] ,$$

where $\kappa = k_3(w_1/k_4)^{1/2}$.

An analogous situation has already been considered above for the case of a consecutive chemical reaction.[127] The existence of several special kinetic models, describing equally well the experimental data, has been demonstrated, for example, in two investigations,[26,114] while the existence of local minima in the functionals, in which the quality of the description of the experimental data is different, has been described in other studies.[20,115,132]. Thus the need arises for a procedure whereby the local minima could be sorted and which would make it possible to find a unique solution to the problem of the identification of the reaction mechanism or which would demonstrate the non-unique nature of the solution.

As can be seen from the examples presented, local minima arise in the region of the rate constants space corresponding to different special kinetic models.[21] The hypothesis that, in the region where a particular kinetic type of reaction mechanism applies, local minima can exist enabled Pavlov and Brin[22] to reduce the problem of sorting the local minima to the problem of dividing the rate constant space into sections in which the system (1) has specific asymptotic properties. This creates the possibility of extending the approach, used in the selection of the possible process scheme,[13–15,26,50,102,131] to the problem of the identification of the kinetic type of reaction mechanism.[22,80] Thus the solution of the problem at this level (when the hypotheses Π_1–Π_3 are known) is determined by the following procedure:[80]

(1) The formal treatment of the qualitative data concerning the process in the form of a system of control requirements common to all the alternative hypothetical mechanisms.

(2) The formulation of hypotheses and specification of a system of special control requirements distinguishing one hypothesis from another (taking into account the possible change in the reaction regime).

(3) The selection for each hypothesis of the initial values of the rate constant ensuring the satisfaction of the control requirements (general and special) and a parametric test of the adequacy of the corresponding mathematical models.

(4) Statistical analysis of the results of tests of each hypothesis.

(5) Logical design of a discriminating experiment.

(6) The representation of the results of the solution of the problem.

Fairly extensive experience has now accumulated in the solution of problems in terms of such formulation. For example, this procedure has been used to select the most probable mechanism of the radiation-initiated isotope exchange between deuterium and the hydroxy-groups of silica gel,[26] to investigate the mechanism of the formation of methane in the pyrolysis of ethane,[133] to establish a possible mechanism of the oxidation of anthrahydroquinone by molecular oxygen,[122] to study the catalytic hydrogenation of phenol and the conversion of methane,[13] to model the kinetics of the liquid-phase oxidation of tetralin,[104] to identify the mechanism of the inhibited liquid-phase oxidation of hydrocarbons,[101,102] etc. In the main, hypothetical mechanisms differing in the set of elementary stages were considered in these investigations and the limiting transitions to systems of differential-algebraic equations were assumed to be known *a priori*.

The abundance of kinetic types of reaction mechanisms, which can be formally realised within the framework of a complex scheme, and the sometimes extremely large expenditure of computer time on the test of each hypothetical mechanism limit the scope of the approach. We shall list certain procedures which make it possible to overcome these difficulties and to facilitate and accelerate the solution.[22,80] Firstly, *a priori* information can be used to reduce the number of hypotheses considered. Secondly, it is possible to design and carry out an experiment whose aim is to compare qualitatively the principal observed kinetic features with the features obtained using various special kinetic models. For example, comparison of the experimental ratio of the initial rates of consumption of methylacrolein and the accumulation of methacrylic acid with the same ratio arising from different hypotheses about the reaction mechanism made it possible to eliminate a series of hypothesis from consideration.[80] Thirdly, one can design and carry out an experiment which makes possible the successive refining of the mechanism with increase of the amount of experimental material available. For example, this approach made it possible to analyse at each stage of the treatment not more than three hypothetical kinetic types of reaction mechanisms.[115]

---o0o---

Thus, the study of converse problems can be recommended to experimenters as a method facilitating the complex procedure whereby one establishes the mechanisms of chemical reactions. By regarding the study of converse problems as a generalised kinetic approach to the construction of mathematical models, one can use such studies as a method for the investigation of the mechanisms of complex reactions.

Application of the Spin Trapping Method in Kinetic Measurements

R.G.Gasanov and R.Kh.Freidlina (deceased)

The results obtained in recent years by the spin trapping method in the solution of a number of kinetic problems are analysed and a systematic account is given of the rate constants for the addition of alkyl, polychloroalkyl and hetero-radicals as well as certain others to nitroso-compounds and nitrones; the kinetic data obtained by the spin trapping method in the study of the isomerisation, fragmentation, elimination, substitution and addition reactions are surveyed.
The bibliography includes 127 references.

I. INTRODUCTION

The spin trapping (ST) method is used widely and successfully in the study of the mechanisms of reactions involving radicals.[1-16] Its essential feature consists in the fact that the short-lived radicals formed in the reaction add to the ST agent (STA) specially introduced into the reaction mixture, which leads to the formation of stable radicals capable of being identified by EPR.

The range of compounds which can be used as STA is fairly large. The present review includes the results obtained using nitroso-compounds and nitrones as STA.[1-10] When radicals are captured by these compounds, the products are mainly nitroxy-radicals, whose physicochemical properties have been thoroughly investigated.[17-19] The large set of such STA,[1-7] their selectivity,[5,20-23] and their other features[24-28] make it possible to identify radicals of different nature by EPR.

In order to identify the radicals formed during the reaction, it is essential to know the rate constants for their addition to the STA. These data are also required for the quantitative estimation of the rates of individual stages of complex chemical processes. The rate constants for the addition of a wide range of radicals to STA have now been determined and kinetic data characterising different stages of important processes in radical chemistry have been obtained. The present review is devoted to a survey of these results and an analysis of the scope of the ST method in the study of the reaction kinetics.

II. THE SPIN TRAPPING METHOD IN KINETICS

The radicals $\dot{R}_1$ formed in the reaction interact with the STA, giving rise to nitroxy-radicals—spin adducts (SA):

$$\dot{R}_1 + STA \xrightarrow{k_1} R_1R\dot{N}O \ . \qquad (1)$$

The radicals can participate in the following reactions:

(a) addition

$$\dot{R}_1 + M \xrightarrow{k_2} \dot{R}_2 \ , \qquad (2)$$

where M is the monomer,

(b) isomerisation

$$\dot{R}_1 \xrightarrow{k_3} \dot{R}_3 \ , \qquad (3)$$

(c) fragmentation or elimination

$$\dot{R}_1 \xrightarrow{k_4} X + \dot{R}_4 \ , \qquad (4)$$

(d) substitution

$$XR_5 + \dot{R}_1 \xrightarrow{k_5} \dot{R}_5 + R_1X \ . \qquad (5)$$

These reactions compete with the main reaction (1) if their rates are comparable to that of the latter.

The radicals $\dot{R}_i$, where i = 1–5, can recombine or disproportionate:

$$\dot{R}_i + \dot{R}_i \xrightarrow{k_6} \text{non-radical products.} \qquad (6)$$

The use of the ST method implies that the rate of capture of the radicals obtained in reactions (1)–(5) by the STA is higher than the rate of their conversion into non-radical products. The rate constants for the recombination and disproportionation of short-lived radicals are of the order of $k_6 \cong 10^6–10^{10}$ litre mol^{-1} s^{-1}.[29-35] If the concentration of the short-lived radicals $\dot{R}_i$, which depends on the rate of initiation of the reaction, does not exceed $10^{-7}–10^{-8}$ M and $[RNO]_0 \cong 10^{-2}–10^{-3}$ M (the STA concentrations most frequently used in experiments[1,5]), then it follows from the condition $k_i[RNO]_0 \gg 10^8–10^{10}\ [\dot{R}_i]$ that, when

$$k_i \gg 10^2 \div 10^6 \text{ litre mol}^{-1}\,\text{s}^{-1}, \qquad (7)$$

stage (6) can be neglected (k_i is the rate constant for the addition of the radicals $\dot{R}_i$ to the STA). Consequently if $[STA]_0 \cong 10^{-2}–10^{-3}$ M and condition (7) holds, it is possible to disregard stage (6). For example, it has been shown[30] that the recombination of alkyl radicals may be neglected when the solution contains 2×10^{-2} M 2,4,6-tri-t-butylnitrosobenzene.

Thus the knowledge of the rate constants for the addition of the radicals $\dot{R}_i$ to STA makes it possible to select initial STA concentrations and to create necessary experimental conditions such that it is possible to disregard the recombination and disproportionation of radicals and hence to simplify appreciably the reaction mechanism in kinetic studies.

The rate constants for the addition of the radicals $\dot{R}_i$ to STA (k_1) have been determined mainly using the methods of competition kinetics. Under these conditions, reactions (2) to (5), for which the rate constants k_i (i = 2–5) have been measured, were used as the reactions competing with the addition of the radicals $\dot{R}_1$ to STA. The rate constants k_1 have been determined using the methods of non-stationary kinetics $\{d[R_1R\dot{N}O]/dt \neq 0\}$ and quasi-stationary concentrations $\{d[R_iR\dot{N}O]/dt = 0\}$.

The difference between the ST method and the direct detection of the short-lived radicals in the liquid phase by EPR consists in the fact that the time required to obtain a stationary concentration of the nitroxy-radicals amounts in many cases to many minutes, which permits the measurement of the rate of formation of these radicals. Such experimental conditions are reached when STA effective in relation to the given radical at low rates of initiation are used. It has been demonstrated,[36] in particular, that, for a rate of initiation of 3×10^{-8} mol litre^{-1} s^{-1}, the times taken to attain a stationary concentration of the spin adducts (SA) of the $Cl_3\dot{C}$ radicals with 2-methyl-2-nitrosopropane (MNP) at $[MNP]_0 = 3.73 \times 10^{-3}$ M, nitrosodurene (ND) at $[ND]_0 = 3.27 \times 10^{-3}$ M, and α-phenyl-N-t-butylnitrone (PBN) at $[PBN]_0 = 2.15 \times 10^{-2}$ M are 7.5, 54, and 4 min respectively.

The formation of the nitroxy-radicals A and B is described by Scheme I when reaction (2) is used as one competing with the addition of the radicals $\dot{R}_1$ to the STA:

Scheme 1

$$\dot{R}_1 + RNO \xrightarrow{k_1} \underset{(A)}{R_1RN\dot{O}} \ ,$$

$$\dot{R}_1 + M \xrightarrow{k_2} \dot{R}_2 \ ,$$

$$\dot{R}_2 + RNO \xrightarrow{k_2'} \underset{(B)}{R_2RN\dot{O}} \ .$$

The rate constant k_1 is in this case determined by the expression

$$\frac{d[A]/dt}{d[B]/dt} = \frac{k_1[NRO]_0}{k_2[M]_0} = \frac{[A]}{[B]} \ , \tag{8}$$

where [A] and [B] are the concentrations of the STA radicals $\dot{R}_1$ and $\dot{R}_2$ before the attainment of their stationary values.

A method has been proposed[37] for the determination of k_1 on the basis of the measurements of the rate of formation of the radicals $R_1RN\dot{O}$ in the absence and presence of substances with which the radicals $\dot{R}_1$ can interact, for example, by adding to M via reaction (2). The constant k_1 is calculated from the formula

$$\frac{d[A]_{abs}}{d[A]_{pr}} = 1 + \frac{k_2[M]_0}{k_1[RNO]_0} \ , \tag{9}$$

where $d[A]_{abs}$ and $d[A]_{pr}$ are the increments of the concentrations of the SA of the radicals $\dot{R}_1$ with RNO in the absence and presence of M.

Eqns.(8) and (9) are valid under conditions where $d[\dot{R}_2]/dt = 0$ and $d[\dot{R}_1]/dt = 0$, which hold for short-lived radicals over a fairly short interval (see, for example, Denisov[38]). The choice of the STA is fairly wide. If the rate constant for the addition of the radical to one STA is known, then, by using the method of non-stationary kinetics, it is possible to determine the corresponding constants for other STA from the expression

$$\frac{[A]}{[B]} = \frac{k_1[RNO]_0}{k'[R'NO]_0} \ . \tag{10}$$

Eqn.(10) is valid for the reactions

$$\dot{R}_1 + RNO \xrightarrow{k_1} \underset{(A)}{R_1RN\dot{O}} \ ,$$

$$\dot{R}_1 + R'NO \xrightarrow{k'} \underset{(C)}{R_1R'N\dot{O}} \ .$$

When Eqns.(8) and (10) are employed, it is essential to know the relative stabilities of the nitroxy-radicals. It is known[17-19,35] that the stability of these radicals is determined by many factors. However, the relative stabilities of the radicals A and B or A and C, identified by EPR, can be estimated directly in the course of the study of the reaction. For this purpose, it is necessary to follow over a time interval the variation of the ratio of the concentrations of the radicals detected by EPR, and then to extrapolate this ratio to the start of the reaction.[39,40]

The nitroxy-radicals formed in the course of the reaction reach stationary concentrations in many instances after a short time interval. For this reason, the measurement of the rate of their formation involves considerable experimental difficulties. In the study of such reactions, the rate constants for the addition of the radicals $\dot{R}_1$ to the STA are determined by the method of quasi-stationary concentrations. The necessary and sufficient conditions for the determination of this constant after the attainment of stationary concentrations by the nitroxy-radicals will be examined in relation to the systems where reaction (2) competes with reaction (1). Such processes can be described by Scheme I supplemented by the recombination and disproportionation stages:

$$\left.\begin{array}{l} A + \dot{R}_1 \\ B + \dot{R}_1 \end{array}\right\} \xrightarrow{k_{11}} \text{non-radical products;} \tag{11}$$

$$\left.\begin{array}{l} A + \dot{R}_2 \\ B + \dot{R}_2 \end{array}\right\} \xrightarrow{k_{12}} \text{non-radical products;} \tag{12}$$

$$\left.\begin{array}{l} A + B \\ A + A \\ B + B \end{array}\right\} \xrightarrow{k_{13}} \text{non-radical products.} \tag{13}$$

If the conditions

$$k_{11}[\dot{R}_1],\ k_{12}[\dot{R}_2] \gg k_{13}([A]_{st} + [B]_{st}), \tag{14}$$

where $[A]_{st}$ and $[B]_{st}$ are the stationary concentrations of A and B, are satisfied, then the addition of the radicals $\dot{R}_1$ to M in the presence of RNO can be described by Scheme I and by reactions (11) and (12) (the methods of calculation of k_{11}, k_{12}, and k_{13} are described below).

At $\dot{R}_1$ and $\dot{R}_2$ concentrations of 10^{-8}–10^{-9} M and for $[A]_{st} + [B]_{st} < 10^{-5}$ M, conditions (14) for certain short-lived radicals are fulfilled, because it is known[41-44] that k_{11} and k_{12} are greater than k_{13} by 5–7 orders of magnitude.

When account is taken of stages (11) and (12), it follows from Scheme I that

$$\frac{[A]}{[B]} = \frac{k_1[\dot{R}_1]}{k_2'[\dot{R}_2]} \ . \tag{15}$$

On substituting the stationary concentration

$$[\dot{R}_2] = \frac{k_2[M]_0[\dot{R}_1]}{k_2'[RNO]_0 + k_{12}([A] + [B]} \ , \tag{16}$$

in Eqn.(15), we obtain

$$\frac{[A]}{[B]} = \frac{k_1[RNO]_0}{k_2[M]_0} + \frac{k_{12}([A] + [B])\,k_1}{k_2k_2'[M]_0} \tag{17}$$

or

$$k_1 = \frac{k_2k_2'[M]_0}{k_2'[RNO]_0 + k_{12}([A] + [B]))} \cdot \frac{[A]}{[B]} \ . \tag{18}$$

It follows from Eqn.(18) that, in order to determine the k_1 for the chemical reactions described by Scheme I and stages (11) and (12), it is essential not only to identify the nitroxy-radicals A and B by EPR but also to know k_{12} and the rate constants for the addition of the radicals $\dot{R}_1$ and $\dot{R}_2$ to the STA. Eqns.(17) and (18) are the most general for the calculation of the rate constants for the addition of the radicals $\dot{R}_1$ to the STA in the case of chemical processes described by Scheme I and stages (11) and (12) when the radicals A and B have attained stationary concentrations. It follows from Eqn.(18) that, when $k_2'[RNO]_0 \gg k_{12}\{[A] + [B]\}$, then a simple expression can be used to calculate k_1:

$$k_1 = k_2 \frac{[M]_0}{[RNO]_0} \cdot \frac{[A]}{[B]} \ . \qquad (19)$$

Eqn.(17) is valid also under the condition where $k_1 \gg k_2'$ and $k_1[RNO]_0 \gg k_{11}\{[A] + [B]\}$ (or $k_1 \gtrsim 10^7-10^8$ litre mol^{-1} s^{-1}), i.e. when the radicals $\dot{R}_1$ are much more reactive than the radicals $\dot{R}_2$ in the interaction with the STA. It is desirable that the condition $[A]/[B] \cong 1$ (taking into account the multiplicity of the signals in the EPR spectra of the spin-adducts of the radicals $\dot{R}_1$ and $\dot{R}_2$, on the one hand, and STA, on the other) should hold, although the content of the nitroxy-radicals in the reaction mixture can be determined over a fairly wide range of $[A]/[B]$ ratios by means of standard computer programs for the simulation of EPR spectra.[45] Using Eqns.(17) with known values of k_1, k_2, and k_2' and having determined the dependence of the ratio $[A]/[B]$ on $[RNO]_0/[M]_0$,[46] it is possible to calculate k_{12}.

Application of the method of quasi-stationary concentrations[31] to the radicals formed in the processes described by Scheme I and stages (11) and (12) yields

$$[A] + [B] = \frac{k_1[\dot{R}_1] + k_2'[\dot{R}_2]}{k_{11}[\dot{R}_1] + k_{12}[\dot{R}_2]}[RNO]_0 \ . \qquad (20)$$

When the conditions

$$k_1 = k_2' \text{ and } k_{11} = k_{12} \qquad (21)$$

hold, it follows from Eqn.(20) that

$$[A] + [B] = \frac{k_1}{k_{12}}[RNO]_0 \ . \qquad (22)$$

Taking into account Eqns.(21) and (22), we obtain from Eqn.(18)

$$k_1 = \frac{k_2[M]_0}{2[RNO]_0} \cdot \frac{[A]}{[B]} \ . \qquad (23)$$

Thus, when conditions (21) hold, Eqn.(23) can be used to calculate k_1.

Eqns.(8), (9), (17)–(19), and (23) have been obtained for examples where the reaction competing with reaction (1) involves the addition of $\dot{R}_1$ to M. Other expressions for the calculation of k_1 can be obtained by similar procedures having selected reactions (3)–(5) as the reactions competing with the addition of $\dot{R}_1$ to the STA. Joint examination of reactions (1) and (3) or (4) yields an expression for the calculation of k_1 similar to Eqns.(8), (9), (17)–(19) and (23) in which $[M]_0 = 1$, $k_2 = k_3$, or $k_2 = k_4$ $[B] = [R_3R\dot{N}O]$, or $[B] = [R_3RN\dot{O}]$ respectively. Similarly, when reactions (1) and (5) are considered jointly, one must replace $[M]_0$ by $[X\dot{R}_5]$ in the above expressions and $k_2 = k_5$ and $[B] = [R_5RN\dot{O}]$ must be adopted.

Thus the identification by EPR of the spin-adducts of the radicals $\dot{R}_1$ and $\dot{R}_i$ (where $i = 2-5$) with the STA and the knowledge of the constants k_i are necessary for the determination of the rate constant for the addition of the radicals $\dot{R}_1$ to the STA using the methods of non-stationary kinetics and quasi-stationary concentrations. If Eqn.(9) is used, then it is sufficient to identify the SA of the radicals $\dot{R}_1$ with the STA in order to determine k_1. Another feature which makes this method convenient is the fact that it can be applied also in cases where the radicals $\dot{R}_i$ ($i = 2-5$), formed as a result of the involvement of $\dot{R}_1$ in secondary reactions [see reactions (2)–(5)], are not trapped by the STA.

For reactions described by Scheme II, i.e.

Scheme II

$$\text{initiator} \xrightarrow{v_i} \dot{R}_1 \ ,$$
$$\dot{R}_1 + RNO \xrightarrow{k_1} R_1RN\dot{O} \ ,$$
$$\dot{R}_1 + R_1RN\dot{O} \xrightarrow{k_{11}} \text{non-radical products,}$$
$$2R_1RN\dot{O} \xrightarrow{k_{13}} \text{non-radical products,}$$

the following expression is valid:

$$\frac{k_1[RNO]_0 - k_{11}[R_1RN\dot{O}]_{st}}{k_1[RNO]_0 + k_{11}[R_1RN\dot{O}]_{st}} = \frac{k_{13}}{v_i}[R_1RN\dot{O}]^2_{st} . \qquad (24)$$

It has been suggested[42] that the following expressions be employed to determine k_1, k_{11}, and k_{13}:

$$\left(\frac{d[R_1RN\dot{O}]_{st}}{d[RNO]}\right)_{[RNO]\to 0} = \frac{k_1}{k_{11}} \ , \qquad (25)$$

$$([R_1RN\dot{O}])_{[RNO]\to\infty} = (v_i/k_{13})^{0.5} \ . \qquad (26)$$

The rate of initiation is determined by the method of measurement of the initial rate of formation of $R_1RN\dot{O}$.[42,47] Having determined k_1 by Eqn.(25), it is possible to calculate k_{11}. The knowledge of the constants k_{11} and k_{13} and v_i makes it possible, in its turn, to establish the limits of validity of condition (14) and $k_1[RNO]_0 \gg k_{13}[R_1RN\dot{O}]_{st}$ and hence the limits of the applicability of Eqn.(18) or (19) in the calculation of k_1. Since k_{11} may be determined also by other physicochemical methods,[48–51] the agreement between their values calculated by two independent methods can serve as a criterion of the correctness of the rate constants found for the addition of the radicals to the STA.

There exists a fairly wide range of methods for the determination of the rate constants for the addition of short-lived radicals to the STA, which may supplement one another in one form or other.

III. THE RATE CONSTANTS FOR THE ADDITION OF RADICALS TO SPIN TRAPPING AGENTS

1. The Rate Constants for the Addition of Carbon-Centred Radicals

Primary, secondary, and tertiary alkyl radicals are trapped by a large number of STA.[1,4–6,52,53] It is noteworthy that, when 2,4,6-$(Me_3C)_3C_6H_2NO$ (BNB) is used as the STA, the secondary radicals add both to the nitrogen atom, giving rise to nitroxy-radicals, and to the oxygen atom with formation of anilino-radicals.[54,55] Tertiary alkyl radicals add exclusively to the oxygen atom of the NO group in BNB.

Ingold and co-workers[41–43] determined the rate constants for the addition of primary and secondary alkyl radicals to a large number of STA using the cyclisation of $H_2C{=}CH(CH_2)_3\dot{C}H_2$ (I) to the radicals $\dot{C}H_2{-}\overline{CH(CH_2)_3C}H_2$ (II) and of $H_2C{=}CH(CH_2)_3\dot{C}HMe$ (III) to the radicals $\dot{C}H_2{-}\overline{CH(CH_2)_3C}HMe$ (IV). The authors[42,43] chose cyclisation as the reaction competing with the addition reaction in the determination of the rate constants for the addition of the radicals (I) and (III) to the STA. The rate constants for the cyclisation of the radicals (I) and (III) had been calculated earlier from the EPR spectra.[43,56] The rate constants determined in the above investigations[42,43] for the addition of the radicals to the STA are listed in Table 1, which also includes the rate constants for the addition of the radicals $Ph\dot{C}Me_2$ and $\dot{C}Me_3$ to STA, obtained by Doba et al.[37] and Maeda and Ingold.[43] Table 2 summarises the data on the rate constants for the addition of carbon-centred radicals with functional substituents. It follows from Tables 1 and 2 [cf., for example, No.4 in Table 2 with the data for the radicals (III) in Table 1] the replacement of the alkyl group or hydrogen at the C_β atom by other substituents does not entail an appreciable alteration of the rate constants for the addition of the secondary radicals to the STA.

2. The Rate Constants for the Addition of $\dot{C}Cl_3$ to Other α-Chloro-radicals

The range of STA which may be used for the identification of $\dot{C}Cl_3$ and other α-chlororadicals is limited.[5,21,65,66] The rate constants for the addition of chloro-radicals to the STA used most frequently for their trapping have been determined[36,67,68] (Table 3).

3. The Rate Constants for the Addition of Hetero-radicals

Table 4 presents the rate constants for the addition of hetero- and other radicals to the STA and also the rate constants for the addition of hydrogen and a hydrated electron.

*For the significance of the notation, see the footnote to Table 1.
**The temperature (in °C) at which k_1 has been determined is given in brackets.

The radicals $Et_3\dot{S}i$ (V) are widely used for the generation of other radicals as a result of the abstraction of a halogen:

$$Et_3\dot{S}i + RHal \xrightarrow{k_{27}} Et_3SiHal + \dot{R}\ . \qquad (27)$$

The constants k_{27} for many halogen-containing compounds have been determined.[81] Various STA are used for the EPR identification of the radicals (V).[54,55,82,83] In the case of BNB, anilino-radicals are produced, while the reaction with PBN gives rise to nitroxy-radicals. The radicals (V) add at high rates to the carbonyl group in ketones:[82]

$$(V) + R'RCO \xrightarrow{k_{28}} R'R\dot{C}OSiEt_3\ . \qquad (28)$$

The constants k_{28} have been determined for certain ketones and the rate constants for the addition of the radicals (V) to BNB and PBN have also been determined[71,72] (see Table 4, Nos. 5 and 6). Reactions (27) and (28) have been adopted as the stages competing with the addition of the radicals (V) to the STA.

Table 5 lists the rate constants for the addition of the radicals $H\dot{O}$, $HO\dot{O}$, $\dot{C}H_2O$, $Me\dot{C}HOH$, $Me_2\dot{C}OH$, and $MeCH_2$.$\dot{C}HOH$ to substituted PBN.

It is seen from the data in Tables 1–5 that the rate constants for the addition to the most frequently used STA have been determined for a large number of radicals. Although these constants have been obtained in relation to different STA for some of the radicals, nevertheless by employing Eqn.(10) it is also possible to determine the rate constants for the addition of the radicals to other STA. The rate constants for the addition of the radicals to STA vary over a range of several orders of magnitude depending on the STA used. This property of the STA makes it possible to choose a suitable STA permitting the use of simpler expressions, for example Eqn.(19), for the determination of the rate constants for reactions (2)–(5).

It follows from Tables 1–3 that nitroso-compounds are more effective STA for the trapping of aliphatic carbon-centred and phenol radicals than nitrones. Among nitroso-compounds, aromatic compounds are more reactive than alkyl nitroxy-radicals, provided that there is no appreciable steric hindrance. The highest rate constants for the addition of radicals have been obtained for nitrosodurene (Tables 1 and 3, Nos.1–3). However, it does not follow from this that nitrosodurene is also the most reactive STA for other radicals, because the efficiency of the STA depends on many factors, for example on the stability of the SA formed,[84,85] on the thermal and photochemical stabilities of the STA, and other causes.

The high rate constants for the addition of carbon-centred radicals to aromatic sterically unhindered nitroso-compounds can be accounted for by the stabilisation of the SA as a result of the delocalisation of the unpaired electron over the aromatic ring,[86] so that aromatic alkyl hydroxy-radicals should be more stable than dialkyl nitroxy-radicals. However, comparison of the rate constants for the addition of thiyl radicals to NB, PMNB, and MNP (cf.Nos.9–11 in Table 4 and Nos.1, 4, and 5 in Table 1) shows that the efficiency of the STA can also involve factors other than the delocalisation of the unpaired electron in the SA.

In contrast to nitroso-compounds, aliphatic nitrones are more reactive than aromatic nitrones (Table 1, Nos.7–13; in addition, cf.No.14 in Table 4 with Nos.1–3, 5, and 6 in Table 5). It is believed[42] that this is associated, apart from other causes, with the steric factor, because aliphatic nitrones are less sterically hindered than aromatic nitrones. Comparison of the rate constants for the addition of certain radicals to substituted and unsubstituted nitroso-compounds and nitrones shows that the steric structure of the substituents influences significantly the reactivity of the STA (cf. Nos.2–4, 7, 8, and 13 in Table 1, Nos.14–18 in Table 4, and Nos.1–3, 5, and 6 in Table 5).

*According to the data of Janzen and Evans;[75] the solvent was benzene, while in all the remaining cases it was water.

It follows from the data in Tables 4 and 5 that nitroso-compounds and nitrones are just as effective for the identification of oxygen-centred radicals. As for alkyl radicals, aliphatic nitrones are more reactive than aromatic nitrones (cf.No.14 and Table 1 and No.1 in Table 5). Furthermore, the polarity (Table 5) and steric properties (Nos.8–13 in Table 1 and Nos.15–18 in Table 4) influence appreciably the effectiveness of nitrones, as happens for aromatic nitroso-compounds (Table 1, Nos.2–4).

The causes of the differences between the activities of the STA in relation to different radicals are so far not altogether clear. For example, MNP is a relatively ineffective STA, compared with NB and PMNB, in the trapping of the Me_3C radicals (see Table 1, Nos.1, 4, and 5). However, it is seen from the comparison of the rate constants for the addition of thiyl radicals of MNP, NB, and PMNB (Table 4, Nos.9–11) that the difference between the effectiveness of these STA and that of thiyl radicals is insignificant. The strength of the bond between the radicals and the STA apparently has a significant influence on the effectiveness of the STA. Thus the rate constants for the addition of silicon-centred radicals to nitrones are somewhat higher (Table 4, No.5) than the corresponding rate constants for carbon-centred radicals (No.8 in Table 1 and No.4 in Table 3). On the other hand, the rate constants for the addition of silicon-centred radicals to BNB with formation of a silicon–carbon bond are greater by approximately two orders of magnitude than the rate constants for the addition of the same radicals to PBN (Table 4, Nos.5 and 6).

The rate constants for the addition of alkyl radicals of various types to the most effective STA have similar values (Table 1, Nos. 1–3 and 5; Table 2, Nos. 3 and 4). The radicals containing the HO group at the α-carbon atom are an exception (Table 5), which may be associated, apart from other causes, also with the fact that all these radicals have a planar or nearly planar structure[87,88] and the steric structure of the radicals identified does not therefore play a significant role.

The rate constants for chlorine-containing radicals depend appreciably on the nature of the radical. For example, the rate constants for the addition of the $Cl_3\dot{C}$ radicals to nitroso-compounds are approximately an order of magnitude greater than the corresponding rate constants for the $R\dot{C}Cl_2$ and $R\dot{C}HCl$ radicals (Table 3). This is probably associated with the geometry of the radicals, because it is known[87] that the $Cl_3\dot{C}$ radicals have a more pronounced pyramidal structure than the $R\dot{C}Cl_2$ or $R\dot{C}HCl$ radicals.

According to Ingold and co-workers,[42,43] the relative error in the determination of k_1 for aliphatic carbon-centred radicals is 30%. The error is determined mainly by the difficulty of measuring the relative stabilities of the radicals detected by EPR, because, during the initial period of the reaction, the signal to noise ratio precludes a more accurate determination of the relative SA concentration and the extrapolation of the ratio to zero time owing to the low concentration of the radicals. The absolute values of k_1 listed in Tables 1–5 can differ by a factor of 2–5,[42,43,59,77] which is associated with the accuracy of the determination of the rate constants k_i [i = 2–5, see reactions (2)–(5)] for other reactions competing with the addition of the radicals to the STA, because the k_i enter into the expressions for the determination of k_1 (see Section II).

Table 6 lists the activation energies and pre-exponential factors for the addition of n-alkyl radicals. It follows from these data that the pre-exponential factors are in the range characteristic of the addition of radicals to the double bond within the limits of the accuracy of their determination,[29,31,89,90] while the activation energy for this reaction is low.

Table 6. Parameters of the Arrhenius equation for the reaction involving the addition of radicals to STA.

IV. THE USE OF THE SPIN TRAPPING METHOD FOR THE DETERMINATION OF THE KINETIC PARAMETERS OF ISOMERISATION, FRAGMENTATION, ELIMINATION, SUBSTITUTION, AND ADDITION REACTIONS

Section III listed the rate constants for the addition of short-lived radicals to STA. These constants were determined for cases where the reactions selected to compete with addition of the radicals $\dot{R}_1$ to the STA were cyclisation, substitution, or addition reactions whose rate constants were known. Certain data on the rate constants for the isomerisation, fragmentation, elimination, addition, and substitution of the radicals $\dot{R}_1$, obtained by the ST method, are compiled below. On the other hand, the addition of the radicals $\dot{R}_1$ to the STA for which the rate constant has been measured were selected as the reaction competing with the above reactions.

It has been shown in Section II that, in order to be able to determine the rate constants for reactions (2)–(5) by the ST method, it is essential to detect simultaneously by EPR the SA of the radicals $\dot{R}_1$ and $\dot{R}_i$ (i = 2–5) [except in the cases where it is possible to employ Eqn. (9)]. Evidently the STA whose SA with the radicals $\dot{R}_1$ and $\dot{R}_i$ have the simplest EPR spectrum are the most suitable for these purposes. Many nitrones satisfy this condition. On interaction of radicals with these compounds, fairly simple spectra are obtained, and the nitroxy-radicals formed are extremely stable. However, the spectra of the SA of many radicals with nitrones have similar hyperfine interaction (HFI) constants[24,91] and the lines due to individual radicals can therefore frequently overlap. Nevertheless, the large set of the possible nitrones[52,91,92] allows the elimination of these difficulties in many instances. As regards nitroso-compounds, their selection as the STA depends on many factors and therefore requires special study in the investigation of a particular reaction. Nitroso-compounds are known to be selective (see, for example, Freidlina et al.[5]) with respect to individual radicals. For this reason, it is not always possible to detect simultaneously the SA of the radicals $\dot{R}_1$ and $\dot{R}_i$ with the aid of nitroso-compounds. In such cases one can use Eqn. (9) to determine the rate constants for reactions (2)–(5).

When Eqns. (8), (9), (19), and (23) are used to determine k_2, it is necessary to know only the values of k_1. However, the application of these expressions requires that certain conditions be maintained. If these conditions are not fulfilled, then more complex expressions, for example Eqn. (17), may be used to determine k_2, which requires the knowledge of the rate constants for the addition of the radicals $\dot{R}_1$ and $\dot{R}_2$ to the STA. It follows from the data in Tables 1–5 that much information is now available about the rate constants for the addition of short-lived radicals to STA. The main difficulty with which the use of Eqn. (17) for the calculation of k_2 is associated consists in the comparatively small amount of data available for the rate constant k_{12}. However, on the basis of Eqns. (24)–(26), it is possible not only to determine k_{12} but also to establish the validity of condition (14).

1. Determination of the Rate Constants for the Isomerisation Reaction

The present development of the chemistry of radical processes has shown that the chemical processes involving the rearrangement of radicals in the liquid phase [see reaction (3)] are general and can be regarded as one of the principal types of radical reaction together with the fragmentation, elimination, substitution, and addition reactions.[35,90]

The rearrangements of radicals with 1,2-migration of the chlorine atom[93,94] and sulphur-containing groups[95] as well as different types of isomerisation with migration of hydrogen to a more remote radical centre[93,96] occupy an important place in the series of known rearrangements of short-lived radicals. Such rearrangements have been investigated by methods of preparative chemistry,[93–96], EPR,[21,66,67,97–101] and other physicochemical methods.[93,96,102,103]

The STA more effective in relation to the radicals $\dot{R}_1$ and $\dot{R}_2$ investigated, namely MNP and ND, have been used to determine the isomerisation rate constants k_3 (Nos.1 and 2 in Table 1 and Nos.7–10 in Table 3). The rate constants k_3 were determined with the aid of the expression

$$k_3 = k_1 [\mathrm{RNO}]_0 \frac{[\mathrm{R_3RN\dot{O}}]}{[\mathrm{R_1RN\dot{O}}]}$$

[see Eqn.(19)], which has been shown in Section II to be valid subject to the condition $k_3[\mathrm{RNO}]_0 \gg k\{[\mathrm{R_3RN\dot{O}}] + [\mathrm{R_1RN\dot{O}}]\}$, where k is the rate constant for the interaction of the radicals $\dot{R}_3$ with $\mathrm{R_1RN\dot{O}}$ and $\mathrm{R_3RN\dot{O}}$ [see reaction (12)].

(*a*) *Determination of the rate constant for the isomerisation of polyhalogeno-radicals with 1,2-migration of chlorine.* The attempts to determine the rate constant for the rearrangement of the radicals $\mathrm{CCl_3\dot{C}H_2}$ to $\mathrm{\dot{C}Cl_2CH_2Cl}$ with 1,2-migration of chlorine by the EPR method have been unsuccessful, because it has not been possible to observe signals due to the non-rearranged radicals even at −140 °C.[97,98] On the basis of the results obtained,[98] it has been suggested that these reactions are characterised by low activation energies and that the rate constant for the isomerisation of the primary radicals $\mathrm{CCl_3\dot{C}H_2}$ to $\mathrm{\dot{C}Cl_2CH_2Cl}$ is apparently $k_{is} \approx 10^{10}$ s^{-1} at 50 °C.[87,98]

Using the selectivity of nitroso-compounds, Freidlina et al.[5] detected the SA of the radical $\mathrm{CCl_3\dot{C}H_2}$ with $\mathrm{Me_2C(COMe)NO}$. The rearranged $\mathrm{\dot{C}Cl_2CH_2Cl}$ radicals have been detected with the aid of ND as the STA. In subsequent studies,[62,66,67] it was possible to detect simultaneously the SA of the non-rearranged and rearranged radicals in other reactions. These results made it possible to find an approach to the determination of the rate constants for the rearrangement of polyhalogeno-radicals with 1,2-migration of chlorine by the ST method.

The authors[62,66,67] used MNP as the STA for the determination of the rate constant for the isomerisation of polyhalogenoradicals with 1,2-migration of chlorine, because, with the aid of this compound, it is possible to establish the equivalence or non-equivalence of the two β-chlorine atoms in the SA of these radicals with the STA[66,104,105] and thereby assign unambiguously the spectra of the non-rearranged and rearranged radicals when these are present simultaneously in the reaction mixture (Table 7).

Table 7. Parameters of the Arrhenius equation for the reaction involving the isomerisation of the radicals $\dot{R}_1$ to $\dot{R}_3$.[39,60,62,66,67]

*At 20 °C; in the remaining cases the data refer to 40 °C.

The rate constants for the isomerisation of certain polyhalogeno-radicals with 1,2-migration of chlorine determined in the above studies[62,66,67] and the parameters of the Arrhenius equation characterising these reactions are summarised in Table 7 (Nos.1–5). The knowledge of the isomerisation rate constants leads to the possibility of predicting a whole group of isotypical telomerisation, polymerisation, addition, and substitution reactions in which the intermediate radicals may rearrange with 1,2-migration of chlorine. In particular, the study of the polymerisation of $\mathrm{H_2C{=}CHCCl_2X}$, where X = Cl or F,[106] showed that the polymer formed consists mainly of the rearranged—$\mathrm{(CH_2.CHClCClX)}_n$—units. Since the rate of isomerisation of the secondary radicals is at least an order of magnitude higher than the rate of their addition to the monomer, the radicals $\mathrm{RCH_2\dot{C}HCCl_2X}$ formed have sufficient time to isomerise.

(*b*) *Determination of the rate constant for the isomerisation of the radicals $\mathrm{PhC(SPh)_2\dot{C}H_2}$ to $\mathrm{Ph\dot{C}(SPh)CH_2SPh}$ with 1,2-migration of the SPh group.* The rate constant for the rearrangement of the radicals $\mathrm{PhC(SPh)_2\dot{C}H_2}$ to $\mathrm{Ph\dot{C}(SPh).CH_2SPh}$ has been determined[39] in the temperature range 10–70 °C (Table 7, No.6). These radicals are obtained on thermal or photochemical isomerisation of acetophenone diphenylmercaptal to 1,2-di(phenylthio)ethylbenzene.[107] The activation energy and the pre-exponential factor obtained proved to be closer to the parameters characteristic of radical isomerisation[62,108,109] than to the parameters of the elimination[31,110] or addition[31] reactions. These results enabled the authors[39] to assume that the isomerisation of the radicals $\mathrm{PhC(SPh)_2\dot{C}H_2}$ to $\mathrm{Ph\dot{C}(SPh)CH_2SPh}$ with 1,2-migration of the thiyl group proceeds via an intramolecular mechanism.

(*c*) *Determination of the rate constant for the isomerisation of radicals with migration of hydrogen.* The SA of the initial $\mathrm{\dot{C}H_2(CH_2)_nCH_2CO_2R}$ and the rearranged $\mathrm{Me(CH_2)_n\dot{C}HCO_2R}$ radicals with ND have been identified by EPR.[60,101] The non-rearranged radicals were generated by abstracting bromine from $\mathrm{BrCH_2(CH_2)_nCH_2CO_2R}$ by triethylsilyl radicals.[101] The radicals $\mathrm{Me(CH_2)_n\dot{C}HCO_2R}$ are formed as a result of the rearrangement of the radicals $\mathrm{\dot{C}H_2(CH_2)_nCH_2.CO_2R}$ with 1,4-migration ($n = 2$), 1,5-migration ($n = 3$), and 1,6-migration ($n = 4$) of a hydrogen atom.

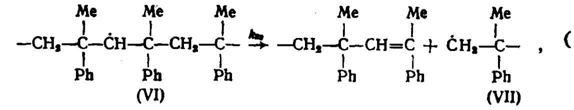
Table 7 (Nos.7–9) presents the temperature variation of the rate constants for the isomerisation of the radicals $\mathrm{\dot{C}H_2(CH_2)_nCH_2CO_2R}$ to $\mathrm{Me(CH_2)_n\dot{C}HCO_2R}$. These results were obtained over a narrow temperature range ($\Delta T = 30$ to 40 °C) and for a small number of experimental points.[101] Nevertheless it follows from the above data that 1,5-migration is preferred on both kinetic and thermodynamic grounds in reactions where there is a possibility of the rearrangement of the intermediate radicals with migration of hydrogen.

The use of the ST method yielded the kinetic and thermodynamic parameters for the isomerisation of short-lived radicals with migration of chlorine, the thiyl group, and hydrogen. The error in the measurement of the isomerisation rate constants, especially in the rearrangement of radicals with 1,2-migration of chlorine, is apparently half an order of magnitude and is associated with the inaccuracy in the determination of the rate constant for the addition of the non-rearranged radicals to the STA. Nevertheless the results obtained make it possible to take into account the role of the rearrangement stage in complex chemical reactions.

2. Determination of the Rate Constants for the Fragmentation Reaction

The rate constants for the fragmentation of the radicals $\mathrm{R\dot{C}O}$ (R = isopropyl, t-butyl, 1-adamentyl, tetra-allyl, and cumenyl) have been measured[57,77] using MNP as the STA.

The fragmentation of polymeric radicals via the mechanism



$$-CH_2-\underset{Ph}{\overset{Me}{C}}-\dot{C}H-\underset{Ph}{\overset{Me}{C}}-CH_2-\underset{Ph}{\overset{Me}{C}}- \xrightarrow{h\nu} -CH_2-\underset{Ph}{\overset{Me}{C}}-CH{=}\underset{Ph}{\overset{Me}{C}} + \dot{C}H_2-\underset{Ph}{\overset{Me}{C}}- , \quad (29)$$

(VI) (VII)

has also been studied.[111] Having determined the stationary concentrations (2g) of the SA of the radicals (VI) and (VII) with MNP and having adopted values in the range 3.3×10^6 to 9×10^6 litre mol^{-1} s^{-1} for the rate constants for the addition of the radicals (VI) to MNP, the authors[111] obtained $k_{29} = 5 \times 10^3 - 4.1 \times 10^4$ s^{-1} at 25 °C.

3. Determination of the Rate Constant for the Abstraction of a Chlorine Atom from CCl_4 by the Telomeric Radicals $CCl_3 . (CH_2CHX)_n^{\bullet}$ ($n = 1-3$; $X = H$, Me, or Cl) and Their Addition to Olefins

The telomerisation of the olefins $H_2C{=}CHX$ ($X = H$, Me, or Cl) with CCl_4 takes place at a fairly high concentration of the telogen via a radical chain mechanism:[112-114]

Scheme III

$$\text{initiator} \rightarrow \dot{R} \ ,$$

$$\dot{R} + CCl_4 \rightarrow RCl + \dot{C}Cl_3 \ ,$$

$$\dot{C}Cl_3 + H_2C{=}CHX \rightarrow CCl_3CH_2\dot{C}HX \ ,$$

$$CCl_3CH_2\dot{C}HX + H_2C{=}CHX \xrightarrow[(a)]{k_p^1} CCl_3CH_2CHXCH_2\dot{C}HX \ ,$$

$$CCl_3CH_2\dot{C}HX + CCl_4 \xleftrightarrow[(b)]{k'_{tr}} \underset{(T_1)}{CCl_3CH_2CHXCl} + \dot{C}Cl_3 \ ,$$

. . . .

$$CCl_3(CH_2CHX)_n^{\bullet} + H_2C{=}CHX \xrightarrow[(c)]{k_p^n} CCl_3(CH_2CHX)_{n+1}^{\bullet} \ ,$$

$$CCl_3(CH_2CHX)_n^{\bullet} + CCl_4 \xrightarrow[(d)]{k_{tr}^n} \underset{(T_n)}{CCl_3(CH_2CHX)_nCl} + \dot{C}Cl_3 \ ,$$

$$2\dot{C}Cl_3 \xrightarrow{k_9} \text{products} \ .$$

It is seen from this scheme that the relative yield of the telomer-homologue T_n is determined solely by the competition between the stages involving the substitution and addition of the radicals $CCl_3(CH_2CHX)_n^{\bullet}$ [stages (*a*)–(*d*)]. The methods of competitive kinetics made it possible to investigate the reactivity of the radicals. The determination of the partial chain transfer constants $C_n = k_{tr}^n/k_p^n$ is a widely used method for such estimates. An appreciable difference between C_1 and C_n ($n \geq 2$) has been observed in the telomerisation of styrene,[115] ethylene, propene, and vinyl chloride[116] with CCl_4. In order to elucidate the causes of the changes in the quantities C_n, it is essential to calculate k_{tr}^n or k_p^n and to establish thereby the contribution of stages (*c*) and (*d*) to the telomerisation of CCl_4 with olefins.

The rate constants for the abstraction of chlorine from CCl_4 by the radicals $CCl_3(CH_2CHX)_n^{\bullet}$ (where X = H, Me, or Cl) have been determined[61,68,117] by the ST method. The telomeric radicals were generated by the photochemical decomposition of $CCl_3(CH_2CHX)_nI$ in the presence of $Hg(m\text{-}C_2H_2B_{10}H_9\text{-}9)_2$.[118] In the determination of the rate constant $k_5 = k_{tr}^n$ for the abstraction of chlorine from CCl_4 by the radicals $CCl_3(CH_2CHX)_n^{\bullet}$, the authors[61,68,117] used ND as the STA, which is most effective in relation to these radicals, and also the expression†

$$k_{tr}^n = k_5 = k_1 \frac{[ND]_0 [CCl_3N(\dot{O})Ar]}{[CCl_4]_0 [CCl_3(CH_2CHX)_n N(\dot{O})Ar]} \ .$$

In particular, it has been shown[68] that, when a more general expression is used [see Eqn.(18)] to determine k_{tr}^n, the same values of k_{tr}^n are obtained as in the case where the above formula was used. This is associated with the fact that, as numerous results show,[36,41,42,61,68,117] the rates of addition of the radicals $CCl_3(CH_2CHX)_n^{\bullet}$ to ND are much higher than the rate of reaction of these radicals with the SA. The values of k_{tr}^n determined in a number of studies[61,68,117] are listed in Table 8.

Table 8. The chain transfer (k_{tr}, litre mol^{-1} s^{-1}) and propagation (k_p, litre mol^{-1} s^{-1}) rate constants for telomeric radicals at 40 °C.

No.	Radical	$10^{-4}\,k_{tr}$	$10^{-3}\,k_p$	Refs.
1	$CCl_3CH_2\dot{C}H_2$	0,39	45	[117]
2	$CCl_3(CH_2CH_2)_2^{\bullet}$	9,0	30	[117]
3	$CCl_3(CH_2CH_2)_3^{\bullet}$	14.0	19	[117]
4	$CCl_3CH_2\dot{C}HMe$	1.4	8.8	[61]
5	$CCl_3(CH_2\dot{C}HMe)_2^{\bullet}$	20.8	4.2	[61]
6	$CCl_3CH_2\dot{C}HCl$	0.045	168	[68]
7	$CCl_3(CH_2CHCl)_2^{\bullet}$	0.176	98	[68[

Table 9. The rate constants k_5 for the abstraction of hydrogen by the radicals $\dot{P}h$ [122] and $Me\dot{O}$ [123] at 20 °C.

Reaction	$10^{-5}\,k_5$, litre mol^{-1} s^{-1}	Reaction	$10^{-5}\,k_5$, litre mol^{-1} s^{-1}
$\dot{P}h + MeOH$	1.4	$Me\dot{O}$ + glycerol	13
$\dot{P}h + MeCHOH$	2.3±0.1	$Me\dot{O} + MeOCH_2OMe$	19
$\dot{P}h + Me_2CHOH$	4.1±0.1	$Me\dot{O} + HCOOMe$	48
$Me\dot{O} + MeCH_2OH$	5.0	$Me\dot{O} + MeOCH_2OH$	34
$Me\dot{O}$ + ethylene glycol	6.2	$Me\dot{O}$ + n-pentane	1

Freidlina and co-workers[61,68,117] determined the chain propagation rate constant k_p^n [see Scheme III, stages (*a*) and (*c*)] listed in Table 8 from the values of k_{tr}^n obtained and the partial constants C_n for chain transfer in the telomerisation reactions of propene and vinyl chloride.[116,119-121] It follows from the data in Table 8 that (1) the reactivity of the radicals $CCl_3(CH_2CHX)_n^{\bullet}$ (X = H, Me, or Cl) in reactions with CCl_4 depends significantly on the position of the CCl_3 group relative to the radical centre and on the nature of the substituents at the α-carbon atom, (2) the differences between the values of C_n for the telomerisation of ethylene and propene with CCl_4 are associated mainly with the differences between the rate constants for the abstraction of chlorine from CCl_4 by the radicals $CCl_3CH_2\dot{C}HX$ and $CCl_3(CH_2CHX)_n^{\bullet}$, where $n \geq 2$ and X = Me or H, and (3) the changes in the C_n for the telomerisation of vinyl chloride with CCl_4 are associated with changes in both k_{tr}^n and k_p^n.

---

†This expression is analogous to Eqn.(19) with $k_5 = k_2$; $[M]_0 = [CCl_4]_0$, $[A] = CCl_3(CH_2CHX)_nN(\dot{O})Ar$, and $[B] = CCl_3N(\dot{O})Ar$, where Ar = 2,3,5,6-Me_4C_6H.

4. Determination of the Rate Constants for the Abstraction of Hydrogen by the Radicals $\dot{Ph}$ and $Me\dot{O}$

The rate constants in the abstraction of hydrogen from methanol, ethanol, and isopropyl alcohol by phenyl radicals have been determined[122] using PBN as the STA (Table 9). Table 9 presents also the rate constants for the abstraction of hydrogen from various compounds by the radicals $Me\dot{O}$. These data were obtained on the assumption that the rate constant for the addition of the radicals $Me\dot{O}$ to PBN is 1.2×10^8 litre mol^{-1} s^{-1}.

5. Determination of the Rate Constants for the Addition of Radicals to Compounds Containing the $S{=}C\langle$ Groups

It is known[12,15,124,125] that compounds containing the $S{=}C\langle$ linkages can be used as STA. The stability of the radicals formed then depends significantly on a series of factors (for further details, see Scaiano and Ingold[12]). Using MNP and $(Me_3C)_2C=S$ as the STA, Scaiano and Ingold determined the rate constants for the addition of methyl radicals to $(Me_3C)_2C=S$. The SA of the radicals $\dot{Me}$ with MNP and $(Me_3C)C=S$ have been identified by EPR at −40 °C:

$$\dot{Me} + MNP \xrightarrow{k_{30}} \underset{(VIII)}{MeN(\dot{O})CMe_3}\,, \tag{30}$$

$$\dot{Me} + (Me_3C)_2C{=}S \xrightarrow{k_{31}} \underset{(IX)}{MeS\dot{C}(CMe_3)_2}\,. \tag{31}$$

The value $k_{30} = 1.5 \times 10^5$ litre mol^{-1} s^{-1} was adopted for the rate constant for the addition of the radicals $\dot{Me}$ to MNP at −40 °C on the basis of the data of Perkins and Roberts.[59,77] The rate constant $k_{31} = 1.1 \times 10^6$ litre mol^{-1} s^{-1} was determined by comparing the rates of formation of the SA of methyl radicals with MNP and $(Me_3)_2C=S$ using the known value of k_{30}. The results obtained showed that alkyl radicals add to compounds containing the $S=C\langle$ linkage at high rates. Thus the interaction of the radicals $\dot{Ph}$ with $S = C(OPh)CH_2Ph$ and $S = C(OPh)CHPh_2$ yields in addition to the radicals $PhS\dot{C}(OPh)CH_2Ph$ and $PhS\dot{C}(OPh)CHPh_2$, i.e.

$$\dot{Ph} + S{=}C(OPh)CH_2Ph \xrightarrow{k_{32}} PhS\dot{C}(OPh)CH_2Ph\,, \tag{32}$$

$$\dot{Ph} + S{=}C(OPh)CHPh_2 \xrightarrow{k_{33}} PhS\dot{C}(OPh)CHPh_2\,, \tag{33}$$

the radicals $S = C(OPh)\dot{C}HPh$ and $S = C(OPh)\dot{C}Ph_2$:

$$\dot{Ph} + S{=}C(OPh)CH_2Ph \xrightarrow{k_{34}} S{=}C(OPh)\dot{C}HPh\,, \tag{34}$$

$$\dot{Ph} + S{=}C(OPh)CHPh_2 \xrightarrow{k_{35}} S{=}C(OPh)\dot{C}Ph_2\,. \tag{35}$$

With $k_{34} = k_{35} = 5 \times 10^6$ litre mol^{-1} s^{-1}, the rate constants for the addition of phenyl radicals to $S = C(OPh)CH_2Ph$ and $S = C(OPh)CHPh_2$ at 45 °C were found[15] to be $k_{32} = 2.3 \times 10^6$ and $k_{33} = 2.7 \times 10^6$ litre mol^{-1} s^{-1} respectively. It is noteworthy that the values of k_{32} and k_{33} determined by the ST method are virtually identical with the corresponding constants calculated on the basis of the direct identification of the radicals $PhS\dot{C}(OPh)CH_2Ph$ and $PhS\dot{C}(OPh)CHPh_2$ by EPR.[15]

The phenylation of benzene has been investigated[63] by the ST method. Having adopted the value of 1.2×10^7 litre mol^{-1} s^{-1} for the rate constant for the addition of phenyl radicals to PBN at 25 °C in methanol, the authors[63] obtained the constant $k_{add} \approx 10^5$ litre mol^{-1} s^{-1} for the addition of phenyl radicals to benzene, which agrees well with the results of the phenylation of benzene by phenyl radicals obtained by Levy et al.[126] and Scaiano and Stewart[127] using other methods.

---o0o---

Thus the experimental results considered in this review demonstrate the probable usefulness of the application of the ST method in the determination of kinetic data for individual stages of complex chemical reactions of various types. Although the amount of such data is at present small, nevertheless one may hope that further accumulation of experimental rate constants for the addition of radicals to STA as well as the analysis of the dependence of the rate constants for the addition reaction on the steric and polar properties of the radicals and on the nature of the STA will permit a considerable extension of the range of reactions for which kinetic data may be obtained.

The Conformations of Polymethine Dyes

A.M.Kolesnikov and F.A.Mikhailenko

The conformational features of polymethine dyes and related compounds are examined and the principal factors controlled by the conformational equilibrium are identified. The methods for the determination of the geometrical structures of polymethines are discussed. Special attention is devoted to a new method for the determination of their conformations—from the absorption spectra of dyes with two chromophores.

The bibliography includes 140 references.

CONTENTS

I. Introduction 275
II. Rotational isomerism of compounds related to polymethines 275
III. Conformations of various polymethine dyes 276
IV. Absorption spectroscopic study of the conformational features of polymethine dyes with two chromorphores 282

I. INTRODUCTION

Polymethine dyes are a special class of organic compounds: they possess the unique ability to sensitise to visible light light-sensitive materials based on silver halides. The capacity of polymethine dyes for aggregation and adsorption on silver halides depends greatly on the steric structure of the cations of the dye itself.[1-3] In particular *cis–trans* isomerism has a pronounced and a by no means unambiguous influence on the effectiveness of the sensitisation.

Yet another field in which polymethine dyes are applied has been established in recent years—laser technology. Lasers based on these compounds generate radiation in the range 500–1250 nm. It has been established that the isomerisation of polymethine dyes plays an important role in the degradation of the photoexcitation energy, which ultimately affects the luminescence and generation properties of these dyes.[4,5]

Finally, polymethine dyes are a convenient model for the theory of the colour of organic compounds. Systematic investigation of the dependence of the colour of polymethines on their structure has made it possible to test a number of important postulates of this theory: the influence of the electronic symmetry of the chromophores, the intermolecular steric hindrance, and the presence of neutral solvents (solvatochromism) on the colour.[6] Furthermore, it has been shown that certain spectral anomalies of polymethine dyes are caused by the *cis–trans* isomerism.

However, despite the fact that the study of the conformational features of polymethine dyes is of both theoretical and practical importance, special reviews on this topic have not so far been published. Isolated non-systematic data may be found in the review of Sturmer and Heseltine.[1] X-Ray diffraction data for a series of cyanines are presented in Smith's review[7] and their photoisomerisation is considered in Kuz'min's review.[4]

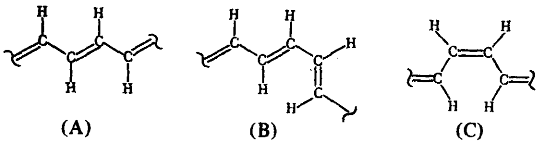
The aim of the present review is comparison of new and old spectroscopic data on the geometrical structure of polymethines and the elucidation of the factors on which it depends. Particular attention has been devoted to a new method for the determination of the conformations of polymethines—from the absorption spectra of dyes with two chromophores.

II. ROTATIONAL ISOMERISM OF COMPOUNDS RELATED TO POLYMETHINES

It is known that the ease of interconversion of atomic groups in the molecule depends on the order of the bond connecting these groups. For example, the barriers to the rotation of various substituted ethane derivatives are in the range 12–75 kJ mol^{-1}, while the barriers to rotation around significantly double bonds are extremely large (120–200 kJ mol^{-1}).[8] Hence, in contrast to the conformers of paraffins, the geometrical isomers of olefins are stable and can be isolated in a pure state. However, olefins tend to undergo photoisomerisation and the ratio of the products in the reaction mixture depends on the extinction coefficient of each isomer at the irradiation wavelength.[9]

The geometrical isomerism of polyenes can involve both double and single bonds. The planar *trans*-configuration (A) or the planar *s-cis*-configuration (B) and the *cis*-configuration (C) of the polyene chain are most energetically favoured; these configurations ensure the maximum interaction of neighbouring π-bonds, which can be represented by the following set of resonance forms:

$$-CH{=}CH-CH{=}CH- \longleftrightarrow -\overset{+}{C}H-CH{=}CH-\overset{-}{C}H- \longleftrightarrow -\overset{-}{C}H-CH{=}CH-\overset{+}{C}H-$$



(A) (B) (C)

Since the contribution of ionic resonance structures should be small, polyenes are characterised by an appreciable alternation of bond orders. Even a slight shift of electron density is sufficient to increase the barrier to rotation about the central bond from 7.3 kJ mol^{-1} in but-1-ene[10] to 20.5 kJ mol^{-1} in butadiene.[8,10] One should also note that the *trans*-form of butadiene is more stable by 9.6 kJ mol^{-1} than the *s-cis*-form and that at room temperature butadiene exists in the most extended *trans*-form.

As a rule, the absorption bands in the UV spectra of *cis*-polyenes and the cyclised *s-cis*-dienes are less intense than the bands of the fully *trans*-isomers.[9,11] Yet another characteristic feature of the electronic spectra of *cis*-polyenes is the appreciable short-wavelength absorption—the so called "*cis*-peak".[9] The latter is completely absent from the spectra of *trans*-polyenes owing to the mutual cancellation of the components of the second transition moment, which are equal in magnitude, have opposite directions, and are oriented along the long chain of the molecule.[12] In order to account for the spectroscopic characteristics, it has also been suggested that the model involving the interaction of bound chromophores be used.[13,14] For this purpose, the polyene molecule is divided into two parts relative to the bond involved in the isomerism and each component is regarded as an autonomous chromophore. According to the theory of the interaction of bound chromophores,[13,15] any deviation of the torsional angle from 180° relative to the bond connecting the two chromophores removes the prohibition of the short-wavelength absorption.

Like olefins, polyenes undergo reversible *cis–trans* transitions under the influence of light.[9] Thus the *cis–trans* photoisomerisation constitutes the basis of the transformations of retinal, which play an important role in the visual process.[16]

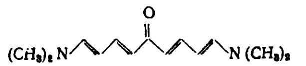
Amides, thioamides, amidines, and their vinylene homologues can serve as examples of compounds with bonds more delocalised than those in polyenes. The electronic structure of these compounds is characterised by an appreciable contribution of the resonance dipolar structure (B):

$$-\underset{|}{N}-(CH{=}CH)_n-CH{=}X \longleftrightarrow -\underset{|}{\overset{+}{N}}{=}(CH{-}CH)_n{=}CH{-}X^-.$$

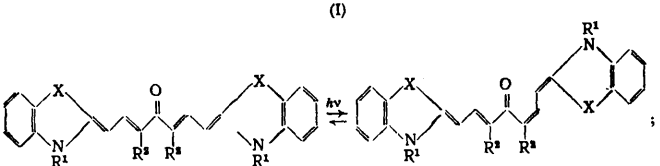
(A) (B)

Depending on the nature of the heteroatom X, the ease of the *s-cis–trans* isomerisation decreases in the sequence NR > O > S, which can be explained by the increased contribution of the structures (B) in the thione. The opposite variation has been found for the rotation about the remaining formally double bonds. For the vast majority of compounds of this kind (for $n > 0$), the isomerisation activation energy is in the range 38–96 kJ mol^{-1} and the acidity of the medium and the steric and the electronic structures of the substituents play a significant role. The relative thermodynamic stabilities of the conformers depend on the nature of the substituents and the dielectric properties of the medium.[8,17]

The ketocyanines (I) and (IIa), whose nature is similar to that of aminopolyvinyl ketones, have the fully *trans*-(*EEEEEEEE*)-structure:[18,19]†



(I)

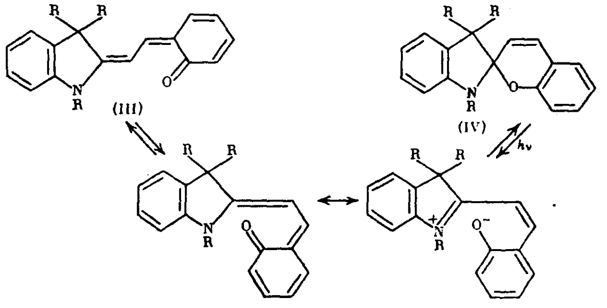


(IIa) (IIb)

$X{=}S,\ R^1{=}C_2H_5,\ R^2{=}(CH_2)_3;\ X{=}C(CH_3)_2,\ R^1{=}CH_3,\ R^2{=}H,\ (CH_2)_2,\ (CH_2)_3.$

In non-polar solvents the ketocyanines (IIa) undergo photoisomerisation with respect to a bond with a high order, the photoisomer (IIb) being stable and having a deeper but less intense colour compared with the initial form. The activation energy for the reverse reaction depends on the structure of the ketocyanine and also on the strength of the acid used as the catalytic additive and is in the range 41–71 kJ mol^{-1}.[20]

The merocyanines of type (III), formed as a result of the photoinitiated opening of the pyran ring of the spiropyran (IV), are a kind of analogue of aminopolyvinyl ketones:[21]



One of the stages in this reversible process is the *cis–trans* isomerisation with respect to the central bond, this stage determining the experimentally observed rate of the dark decolorisation.[22]

III. CONFORMATIONS OF VARIOUS POLYMETHINE DYES

1. Conformations of Streptocyanines

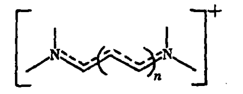
The protonation or alkylation of aminopolyvinylamines leads to the cationic conjugated systems (V)—streptocyanines, which possess "polymethine properties" i.e. their π bonds are fully delocalised and the charges on the atoms of the polymethine chain alternate.[23] The anionic systems (VI), namely oxanines, are also in the "polymethine state". The aminopolyvinyl ketones (thiones) in which the contribution by the dipolar limiting structure is comparable to that of the uncharged structure, i.e. merocyanines, are also close to the "polymethine state":

$$\left[{}^{R^1}_{R^2}\!\!>\!N{\,\overset{...}{=}\,}CH{\,\overset{...}{=}\,}(CH{\,\overset{...}{=}\,}CH)_n{\,\overset{...}{=}\,}N\!<^{R^1}_{R^2}\right]^+ \qquad [O{\,\overset{...}{=}\,}CH{\,\overset{...}{=}\,}(CH{\,\overset{...}{=}\,}CH)_n{\,\overset{...}{=}\,}O]^-.$$

(V) (VI)

Polymethine compounds are characterised by relatively narrow and intense principal absorption bands, which indicates a comparatively small change in bond lengths on excitation. A second maximum is usually observed on the short-wavelength side of these bands, being separated from the main maximum by 1200–1400 cm^{-1}. It is associated with the vibrational 0–1 transition polarised, like the 0–0 transition, along the axis of the polymethine chain.[24,25]

X-Ray diffraction data have shown that, regardless of the length of the unsubstituted polymethine chain and the presence of substituents at the nitrogen atoms, the cations of the streptocyanines have the fully *trans*-(E_{2n})-conformation with the equalisation of bond lengths characteristic of the "polymethine state" and a slight alternation of the valence angles formed by the sp^2-hybridised carbon atoms:[26–31]



The cations of the streptocyanines investigated are almost planar, which ensures the maximum interaction of the π-electrons and their delocalisation.

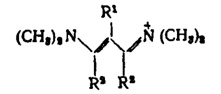
---

† Since different names are used to designate the same conformers of polymethines and related compounds, whenever necessary in the present review the two most frequently employed terms are used for them.

The ^{1}H NMR spectra[32-36] also support the fully *trans*-conformations of compounds (V) and (VI) in solution: the spin–spin coupling constants of the protons of the polymethine chain (12–14 Hz) do not change significantly also after the introduction of the bulky methyl group in the *meso*-position in the polymethine chain of the streptocyanine (V, n = 2), which rules out the formation of the *EZEE*-confirmation as a means of eliminating the steric hindrance which has arisen.

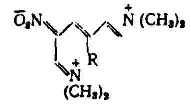
A narrow singlet in the ^{1}H NMR spectrum of compound (V, $n = 2$, $R^1 = CH_3$, $R^2 = C_6H_5$), due to aromatic protons, shows that the phenyl groups are arranged at right angles to the plane of the polymethine chain.[33]

The steric structure of the streptocyanines (VIIa, b) has been investigated with the aid of the nuclear Overhauser effect.[37] It has been shown that α,α′-di- and β-mono-alkylated trimethine streptocyanines exist in the fully *trans*-(*EE*)-conformation. Compared with the unsubstituted cation, there is some change in the valence angles, which is greater the greater the bulk of the substituent. The distortions of the angles and the deviation of the components of the cation from planarity for equal bulk of the substituent are greater in the α-derivatives (VIIa):



(VII)

$R^1 = H$, $R^2 = H, CH_3, C_2H_5$, iso-C_3H_7 (a); $R^1 = CH_3, C_2H_5$, iso-C_3H_7, t-C_4H_9, $R^2 = H$ (b)



(VIII)

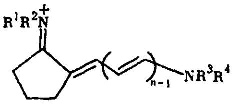
R=H (a); R=NO_2 (b)

Alkyl groups manifest weak electron-donating properties and their influence on the geometrical structure of the polymethines can be explained primarily by steric causes. Substituents such as the nitro-group are capable of being included in the conjugation chain, forming new chromophores and altering therby the conformation of the cation [compounds (VIIIa, b)].[38]

The ^{1}H NMR spectra of the streptocyanines (V, $R^1 = R^2 = CH_3$, n = 1, 2) exhibit two signals due to the protons of the methyl group at room temperature and for n = 3 also at a reduced temperature. The magnetic non-equivalence of these protons is caused by the hindered rotation of the methyl groups about the $\text{C}\cdots\text{N(CH}_3)_2$ bonds. With increase of the length of the polymethine chain, the barrier to rotation diminishes from 70 kJ mol^{-1} (n = 1) to 47 kJ mol^{-1} (n = 3). An increase in the acidity of the medium reduces the activation energy for the first compound to 36 kJ mol^{-1}. Experimental results[39,40] agree with data obtained by the *ab initio* calculation of the activation energies for the rotation of the amino-groups.[41]

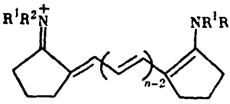
The electronic spectra of streptocyanines (V) cannot serve as a reliable criterion of their conformational homogeneity at room temperature, because instances of the overlap of the bands of isomers absorbing at close wavelengths are possible. A decrease of temperature as a rule causes a narrowing of the absorption bands as a result of the decrease of the amplitudes of low-frequency vibrations.[42] The appearance of inflections on the long-wavelength slopes of the principal bands was noted under these conditions [compounds (V), n = 2, 2, $R^1 = R^2 = (CH_2)_{3-5}$].[43] The authors[43] attribute such local maxima to the thermodynamically less stable mono-*cis*-conformers. The absorption bands of streptocyanines with shorter (n = 0, 1) chains do not inhibit such splitting. Apart from the principal long-wavelength band, the spectrum of compound (V, n = 3) shows yet another specific band in the region of shorter wavelengths, whose intensity increases on heating. By analogy with the short-wavelength absorption of *cis*-polyenes, this band has been called the "*cis*-peak" and has been assigned to absorption by the unstable *cis*-conformers, whose concentration in the equilibrium mixture increases with increase of temperature.

The fixation of the polymethine chain of streptocyanines in the mono-*cis*-($ZE_{2n-2}E$)-configuration (IX) and the di-*cis*-($ZE_{2n-2}Z$)-configuration (X) also leads to a bathochromic shift of the principal absorption band. Although the electronic influence of the substituent (the cyclic trimethylene group) also contributes to the magnitude of this shift, it is believed[44] that the contribution amounts to only half of the overall shift. The oscillator strength of the principal absorption band decreases in the sequence *trans* > *cis* > di-*cis*. The experimental results have been confirmed by LCAO-MO calculations.[44] Unfortunately the authors[44] did not pay attention to the short-wavelength part of the spectrum, where the appearance of "*cis*-peaks" on passing from the *trans*- to the *cis*-form might have been expected:



(IX)

$R^1, R^2 = CH_3, (CH_2)_4$; $R^3, R^4 = CH_3, C_6H_5, (CH_2)_4$



(X)

$R^1, R^2 = CH_3, (CH_2)_4$

Characteristic changes in the absorption spectra of streptocyanines occur when their solutions are irradiated at the wavelength of the absorption maxima.[43,45-49] It has been established that this entails the appearance of a new band, which is displaced to longer wavelengths relative to the first and is characterised by a smaller oscillator strength. In many instances the appearance and increase of the intensity of the new band are accompanied also by the appearance and increase of the intensity of the bands of the "*cis*-peaks" polarised at right angles to the principal band.[43,45] The photochemical reaction is reversible and the rate of the dark reaction increases with increase of temperature and depends on the viscosity of the solvent. The process activation energies are in the range 58–67 kJ mol^{-1}. An increase of the acidity of the medium lowers this energy to 42 kJ mol^{-1}.[48] These spectroscopic data can be readily interpreted within the framework of the *cis*–*trans* isomerisation of streptocyanines, although the formation of the excimers of these compounds on excitation has been postulated.[43] However, photoisomerisation is supported by the activation energy, which is intermediate between the barriers to rotation about the double and single bonds, which corresponds to a bond order of 1.5 in the "polymethine state".

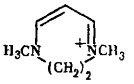
The phototropic mono-*cis*-(*EZ*)-form (XI) of the streptocyanine (V, $n = 1$, $R^1 = R^2 = CH_3$) has been compared with the di-*cis*-(*ZZ*)-form (XII), which is known to be stereohomogeneous.[43,46]

(V)

$\nu_{max} = 31750$ cm^{-1}
$f = 0.63$

(XI)

$\nu_{max} = 29400$ cm^{-1}
$f = 0.47$



(XII)

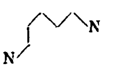
$\nu_{max} = 28400$ cm^{-1}
$f = 0.27$

A distinct bathochromic shift and a decrease of the oscillator strength are observed on passing from the *trans*- to the di-*cis*-form.

The same behaviour is reflected qualitatively by the results of the LCAO-MO calculation for certain conformers of pentamethine streptocyanine.[50] According to the calculated data, the energy of the ground state of the conformer increases in the sequence (A)–(F) and the bathochromic shift of the absorption band should take place in approximately the same order:

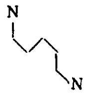
(A), fully *trans*-

(B), mono-*cis*-

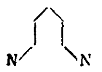


(C), mono-*cis*-

(D), di-*cis*-



(E), di-*cis*-

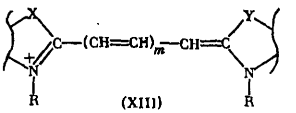


(F), di-*cis*-

Calculation has also shown that the rotation around the central bonds of pentamethine streptocyanine requires the expenditure of 61 kJ mol^{-1}, while the rotation about the remaining C$\overset{\cdots\cdots}{-\!-\!-}$C bonds requires 58 kJ mol^{-1},[43] which is in fair agreement with experimental data.

2. Conformations of Monomethine Cyanines

True cyanines of type (XIII) differ from streptocyanines by the fact that the terminal nitrogen atoms, adjoining the polymethine chain, are at the same time components of heterocyclic nuclei.



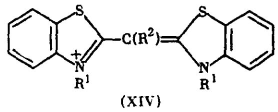
(XIII)

X, Y = O, S, $C(CH_3)_2$, CH=CH, NR; R = H, Alk, Ar

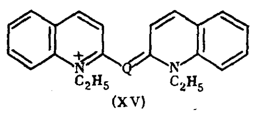
The closest methine group is also incorporated in the heterocyclic ring, so that the cyanine with m vinyl group corresponds to the streptocyanine with $n = m + 1$ vinyl groups.

On passing from simple cyanines to compound (XIII), i.e. on replacement of a hydrogen atom by a bulky group X or Y, the steric interaction of the cation intensifies in the first place and the possibility of twisting about the C$\overset{\cdots\cdots}{-\!-\!-}$N bond vanishes in the second place. Furthermore, in asymmetric cyanines (X ≠ Y) the "polymethine state" differs from the ideal state, namely an alternation of bond orders arises and is more pronounced the greater the difference between the basicities of the terminal heterocycles.[51] The latter factor merits attention because a decrease of the order of a bond facilitates rotation about the latter.

The steric interaction of the heterocyclic nuclei with one another is especially characteristic of monomethine cyanines (XIII, $m = 0$). According to X-ray diffraction data, the steric structure of the cations of monomethine cyanines depends primarily on the effective bulk of the groups X and Y in the terminal heterocycles and also on the presence of a substituent at the carbon atom linking these groups.[52-58] Thus the chromophores of monomethine cyanines (XIV, $R^1 = CH_3$, C_2H_5, $R^2 = H$) have the almost planar fully *trans*-(*EE*)-structure.[52,53] The same conformation obtains in the cation (XV, Q = CH), but, owing to the steric interaction of the hydrogen atoms in the 3 and 3′-positions, the planar structure is distorted (the central torsional angle increases to 50°). The angles between the planes of the heterocyclic rings and the C(2)C(9)C(2′) plane are the same.[54] On the other hand, the angles of rotation of the heterocyclic nuclei relative to the C(2)PC(2′) plane in the phosphorus-containing analogue (XV, Q = P), which also has the *trans*-(*EE*)-structure, are 40° and 24°, which means that the positive charge is displaced towards the first nucleus; this is also indicated by the proximity of the anion to it.[55]

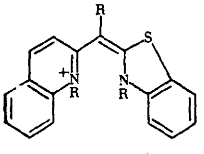


(XIV)

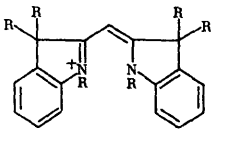


(XV)

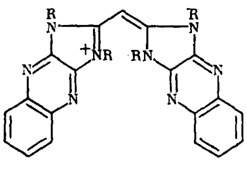
The appearance of a bulky substituent at the *meso*-carbon atom precludes the formation of a planar structure of the cation owing to the strong steric hindrance. Furthermore, the most favourable form in which the cations of the *meso*-methylthiaquinocyanine (XVI) exist in the crystal is the di-cisoid form, in which the angle between the planes of the heterocycles is 60°.[56]



(XVI), $R = CH_3$



(XVII), $R = CH_3$

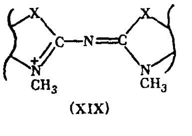


(XVIII), $R = C_2H_5$

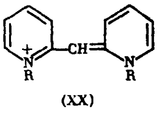
The strong steric interactions of the isopropylidene groups in the hypothetical *trans*-form of monomethine indocyanine are the cause of the non-planar di-*cis*-(*ZZ*)-structure of the cation (XVII). The dihedral angle between the planes of the indolenine rings is 48°.[57]

The monomethine cyanines (XVIII) with terminal 1,1′,3,3′-tetraethylimidazo[4,5-*b*]-quinoxalinium nuclei, which are at an angle of 55°, also belong to non-planar dyes. In view of the high symmetry of the cation, all its conformations are degenerate.[58]

The number of signals of the *N*-alkyl groups can serve as a criterion for the selection of a particular conformation on the basis of ^{1}H NMR spectra. Thus a single signal due to *N*-methyl groups has been detected in the ^{1}H NMR spectra of monomethine quino-, oxa-, and thia-cyanines, which demonstrates, according to the author,[59] the *trans*-(*EE*)-configuration of these compounds. The introduction of a bulky alkyl substituent at the *meso*-carbon atom entails the splitting of this peak, which indicates the mono-*cis*-(*ZE*)-structure of the *meso*-substituted monomethine cyanines in solution. A similar splitting has been observed[59] for the aza-cyanines (XIX) and also for monomethine pyridocyanine (XX, $R = CH_3$). The simple structure of the ^{1}H NMR spectra in the regions corresponding to the resonance of the protons of the ethyl group and also comparison of the observed and calculated "aromatic" components of the spectrum permit the conclusion that compound (XX, $R = C_2H_5$) and its meso-analogue exist exclusively in the *trans*-(*EE*)-form:[60]



(XIX)



(XX)

The influence of the steric structure of substituents on the principal characteristics of the absorption spectra of monomethine cyanines has been observed in a number of studies.[2,61,62] It was found that the sterically unhindered monomethine thiacyanines (XIV, $R^1 = H$, $R^2 = H$ or CH_3; $R^1 = CH_3$, $R^2 = H$) have approximately the same absorption maximum at 425 nm, while the steric interactions in the sterically hindered dyes (XIV, $R^1 = R^2 = CH_3$) lead to an appreciable bathochromic shift of the band. The same pattern has been observed for a series of quinoline dyes. The possibility of the existence of various conformations of the sterically hindered dications has been postulated, but the spectroscopic shifts have been accounted for exclusively by a greater or lesser deviation of the components of the cation from the planar disposition.[2,61]

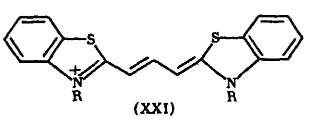
In contrast to this, Scheibe et al.[62] attribute all the spectroscopic changes for a series of monomethine pyrido- and quinocyanines exclusively to transitions to particular conformations. The choice of the geometrical structure of the cations in the above study[62] was based on the oscillator strength. The authors[62] justly assume that, by analogy with streptocyanines, the absorption intensity decreases in the series of structures *trans* > *cis* > di-*cis*. However, they compared dyes which differ both in their electronic structure and in the influence of substituents, on the one hand, and in their tendency towards solvation, on the other. Nor has any account been taken of the fact that the decrease of the absorption intensity can result not only from a *trans*–*cis* transition but also on distortion of the planar structure of the polymethine chain.

The study of the absorption bands of monomethine cyanines has shown that, in assigning the postulated conformers, one should take into account the short-wavelength part of the spectrum, since the presence of the "*cis*-peaks" can serve as proof of the presence of *cis*-forms. However, this procedure requires careful selection of the objects of comparison.[45,63] It has been noted[45,64] that monomethine cyanines do not undergo a photoisomerisation resembling that of streptocyanines or such photoisomerisation takes place with an extremely low quantum yield.

3. The Conformations of Carbocyanines and Their Vinylene Analogues

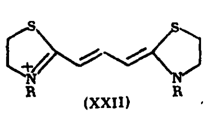
The carbocyanines (XIII, $m = 1$) are pentamethine streptocyanines as regards the length of the polymethine chain and differ from the monomethine cyanines in that the conformational transitions in their cations can take place via both the central and peripheral bonds of the polymethine chain.

X-Ray diffraction analysis of the thiacarbocyanines (XXI) unsubstituted in the polymethine chain has shown that their cations have exclusively the fully *trans*-(*EEEE*)-structure and are almost planar. According to different data, the dihedral angles between the planes of the heterocyclic nuclei and the plane of the remaining atoms of the chromophore range from 3° to 12°.[65–69] These angles depend on the effective bulk of the *N*-alkyl groups. Thus the replacement of an ethyl group by a methyl group leads to an appreciable flattening of the cation.[67–68] The *EEEE*-conformation of the chromophore is also realised in the crystal of thiazolinocarbocyanine (XXII). The polymethine chain and one of the heterocyclic nuclei then have a planar structure, while the second nucleus has the half-chair form.[70]



(XXI)

R = CH$_3$, C$_2$H$_5$

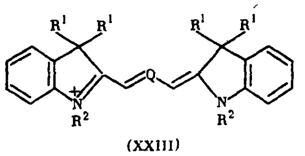


(XXII)

R = C$_2$H$_5$

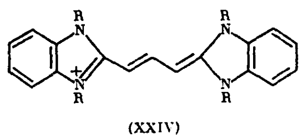
The indocarbocyanine (XXIIIa, Q = CH) also has a transoid structure in the crystal. The dihedral angle between the planes of the indoline nuclei is 13.8°. In the aza-analogue (XXIIIa, Q = N), this angle is 13.3°, while in compound (XXIIIa, Q = P) it amounts to 15.1°. In another crystalline modification, formed by the dyes (XXIIIa, Q = P or As), this angle diminishes to 6.8° and 6.3° respectively.[71]

The deviation of the planes of the heterocyclic nuclei in the crystal of imidocarbocyanine (XXIV) by 8° from one another is caused by the weak steric interaction of the ethyl groups.[72]



(XXIII)

R^1, R^2 = CH$_3$ (a); R^1 = CH$_3$, R^2 = C$_2$H$_5$ (b)



(XXIV)

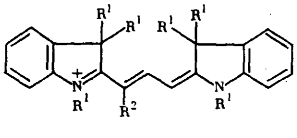
R = C$_2$H$_5$

^{1}H NMR data for unsubstituted carbocyanines rule out the mono-*cis*-conformation with respect to the central bond, because the spin–spin coupling constant for the protons of the polymethine chain is 12–14 Hz and the mono-*cis*-conformation with respect to the peripheral bonds is ruled out owing to the equivalence of the *N*-alkyl groups.[73–75] The study of the indocarbocyanines (XXIIIb, Q = CH, N, or P) with the aid of the nuclear Overhauser effect has made it possible to rule out also the symmetrical di-*cis*-(*EZZE*)-form of these compounds.[76]

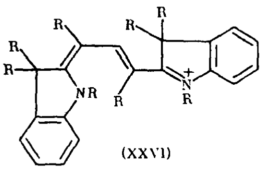
The conformational homogeneity of the unsubstituted thiacarbocyanines has been confirmed also by the fact that their absorption,[77–79] emission, and fluorescence excitation[79] spectra, recorded at room temperature, are virtually identical with the spectra obtained at a low temperature.

The pulsed photoexcitation of the cations of sterically unhindered carbocyanines leads to the appearance of short-lived *cis*-isomers, whose absorption bands have undergone a bathochromic (oxacarbocyanines) or hypsochromic (thiacarbocyanines) shift relative to the parent bands.[4,48,77,80–83] The activation energy for the reverse dark reaction is 50 kJ mol^{-1} for oxacarbocyanine and 63 kJ mol^{-1} for thiacarbocyanine.[64] The introduction of electron-donating substituents in the 6,6′-positions in the benzothiazole rings increases the activation energy, while the introduction of electron-accepting substituents diminishes it. This finding has been explained by the corresponding increase or decrease of the bond orders in the polymethine chain; here it is assumed that the photoisomerisation of carbocyanines unsubstituted in the polymethine chain involves the peripheral 2- and 8-positions.[82] In the photoisomerisation of asymmetric dyes, the activation energy for the *cis* → *trans* relaxation decreases with increase of the difference between the basicities of the terminal heterocycles. Since this is accompanied simultaneously by an enhancement of the alternation of bond orders in the polymethine chain, it is assumed[83] that the dark isomerisation involves a bond with a reduced order, i.e. takes place outside the more basic nucleus.

The introduction of a substituent in the α-position in the polymethine chain of the carbocyanine leads to a steric interaction of the substituent with fragments of the heterocyclic nucleus and the polymethine chain. In the crystals of α-ethylindocarbocyanine (XXV), the energy of such interaction is insufficient for the isomerisation of the cation and the latter therefore exists in a distorted fully *trans*-(*EEEE*)-conformation. The presence of a second substituent in the α′-position precludes the existence of the fully *trans*-form, probably owing to the steric interaction of the substituents, while the crystal of the cation (XXVI) exists in the di-*cis*-(*ZZEE*)-form, the dihedral angle between the planes of the heterocyclic nuclei amounting to 34.7°.[84]

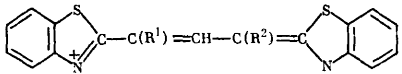


(XXV)
$R^1 = CH_3, R^2 = C_2H_5$



(XXVI)
$R = CH_3$

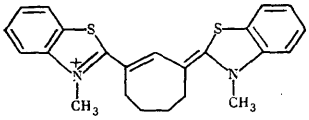
An attempt has been made to separate the steric and electronic effects of the substituents in the α- and αα′-positions in the polymethine chain on the basis of the absorption spectra of the thiacarbocyanines (XXVII).[85-88]



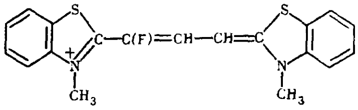
(XXVII)

R^1=H, CH_3, C_2H_5, C_3H_7, iso-C_3H_7, C_6H_5, OCH_3, Cl, $NHCOC_6H_5$, $N(CH_3)C_6H_5$, $COOC_2H_5$ CHO, $C_5H_5\overset{+}{N}$, SC_2H_5, SC_6H_5; R^2=H, CH_3, C_2H_5, C_3H_7, iso-C_3H_7, C_2H_5, OCH_3, SC_6H_5, Cl, $NHCOC_6H_5$, $N(CH_3)C_6H_5$.

The introduction of a substituent of any electronic type as a rule induces a hypsochromic shift of the absorption maximum of the thiacarbocyanine (XXVII). The influence of a similar second substituent in the α′-position is not the same as that of the first and not only quantitatively but also qualitatively. It has been suggested[85,86] that the influence of a single substituent is associated with the breakdown of the electronic symmetry of the chromophore, while the spectroscopic changes in disubstituted dyes are determined by the competition between the electronic nature of the substituents and the steric hindrance to the planar disposition of the cation. Such hindrance commences on monosubstitution and intensifies on disubstitution, which is indicated by the corresponding decrease of the absorption intensity. The *cis*–*trans* isomerisation, which is most likely to involve peripheral bonds of the polymethine chain, probably contributes to the spectroscopic shifts. This is indicated[87] by the almost identical absorption of solutions of αα′-diethylcarbocyanine (XXVII) and the dye (XXVIII) with a seven-membered ring in the chromophore.



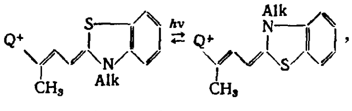
(XXVIII)



(XXIX)

A mixture of the *cis*- and *trans*-isomers of α-fluorothiacarbocyanine (XXIX) was detected from the absorption spectra at a low temperature.[88]

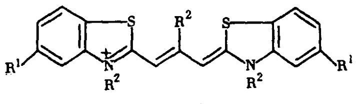
The photoisomerisation of α-substituted carbocyanines proceeds with a high quantum yield, close to that for the unsubstituted compounds. It has been suggested that the photoisomers of the compounds compared have the same nature, i.e. are *EEZ*-isomers and that the isomerisation involves the unsubstituted 2- and 8-positions:[4,89,90]



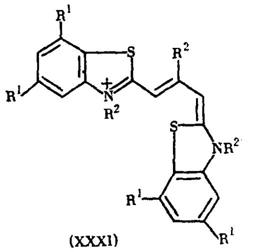
where Q is a heterocyclic nucleus.

The introduction of a bulky substituent in the β-position in the polymethine chain also intensifies the steric interaction of the fragments of the carbocyanine cation. There has been a considerable growth of interest in dyes of this kind, because β-ethylthiacarbocyanine proved to be an effective sensitiser of silver halides.[1-3]

According to X-ray diffraction data, the thiacarbocyanine cation (XXX) has a distorted *EEEE*-structure. Compared with the unsubstituted dye (XXXI), the distance between the sulphur atoms is increased owing to the repulsion of the latter from the ethyl group separating them.[91] In contrast to this, the thiacarbocyanine (XXXI) exists in the solid phase in the non-planar mono-*cis*-(*EEZE*)-form.[3,92]



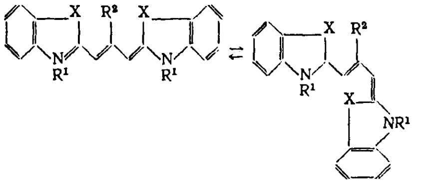
(XXX)
$R^1 = Cl, R^2 = C_2H_5$



(XXXI)
$R^1 = CH_3, R^2 = C_2H_5$

The β-phenylthiacarbocyanine cations exhibit in the crystals the fully *trans*-(*EEEE*) conformation.[93] The phenyl group is then rotated almost at right angles to the long axis of the cation and does not have an appreciable effect on the colour of the dye.[61]

The absorption bands of solutions of β-substituted carbocyanines (XXXII) are split at low temperatures into two bands in close proximity.[78,94-97] The intensity of each band increases on excitation of the neighbouring band by irradiation at the wavelength of its absorption maximum. The cessation of irradiation entails the return of the system to the initial equilibrium state. The experimental data have been interpreted within the framework of the *cis*–*trans* isomerism of the test compound: steric interaction of the β-substituent with the terminal nuclei increases the energy of the ground state of the *EEEE*-form (XXXIIa) and makes it comparable to the energy of the *EEZE*-conformation (XXXIIb):

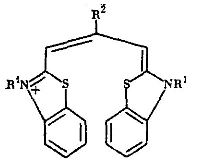


(XXXIIa) (XXXIIb)

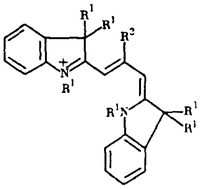
X=O, S, Se; R^1=CH_3, C_2H_5; R^2=CH_3, C_2H_5, C_6H_5, OCH_3, SCH_3

The long- and short-wavelength bands are due to the first and second isomeric forms respectively. The equilibrium position depends greatly on the solvent: the longest *trans*-isomers predominate in weakly polar media, while in strongly polar media they are present only as an admixture to the *cis*-isomer. The luminescence spectra of the carbocyanines (XXXII, R^2 = Alk, OCH_3, or SCH_3) have been investigated over a wide temperature range.[79,95-97] It has been found that the *EEZE*-isomers fluoresce only at a low temperature and that the fluorescence intensity is appreciably lower than for the *EEEE*-isomers.

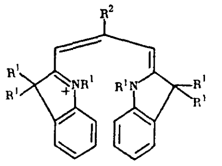
Analysis of the form and number of signals in the ^1H NMR spectra of β-substituted carbocyanines and also the observation in certain cases of the nuclear Overhauser effect make it possible to determine unambiguously the geometrical structure of the conformers and to estimate quantitatively the position of the conformational equilibrium.[75,98] It has been established that an increase of the effective bulk of the substituent in the β-position promotes an increase of the content of the *cis*-isomer. Thus the concentration of the *EEZE*-isomer of the thiacarbocyanine (XXXII) increases in the sequence $H \ll C_6H_5 < CH_3 < C_2H_5$ as R^2 is altered. As a result of the introduction of the t-butyl group, the thiacarbocyanine cation exists both in solution and in the solid phase exclusively in the form of the non-planar di-*cis*-(*EZZE*)-conformer (XXXIII).



(XXXIII)
$R^1 = C_2H_5$, $R^2 = t\text{-}C_4H_9$



(XXXIV)
$R^1 = CH_3$, $R^2 = CH_3, C_2H_5, C_6H_5$



(XXXV)
$R^1 = CH_3$, $R^2 = t\text{-}C_4H_9$

The concentration of the mono-*cis*-(*EEZE*)-isomer increases with increase of the bulk of the heteroatom X in the carbocyanines (XXXII). Finally, only the tri-*cis*-(*ZEZZ*)-form obtains in β-substituted indocarbocyanines (XXXIV), while in solution it exists in a dynamic equilibrium with the identical *ZZEZ*-form. The cation (XXXIV, $R^2 = CH_3$) has the same conformation in the crystal, the angle between the indolenine nuclei reaching 78°. The symmetrical fully *cis*-(*ZZZZ*)-conformation is fixed in the cations of the carbocyanines (XXXV). According to X-ray diffraction data, the system does not have a planar structure: the average torsional angle between the fragments of the polymethine chain is 19° and the angle between the indolenine nuclei is 41°.[98] The activation energy for the isomerisation processes is in the range 35–62 kJ mol^{-1}.[75,98]

The absorption bands of carbocyanines undergo appreciable changes on β-substitution,[2,61,98] but, among the multiplicity of steric and electronic factors, it is difficult to identify the intrinsic contribution of a particular conformation to the absorption.

The photoisomerisation of β-substituted carbocyanines has been investigated fairly widely.[4,64,80,96,99] The rate of this process for the thiacarbocyanine (XXXII, $R^1 = C_2H_5$, $R^2 = CH_3$) at −125 °C depends greatly on the nature of the halide in the solvent and increases in the sequence $C_2H_5Cl < C_2H_5Br$ C_2H_5I. This factor has been attributed[96] to the triplet mechanism of the isomerisation, whose probability increases in parallel with the increase of the spin–orbital coupling constant induced by the presence of neighbouring atoms with a higher atomic number. This factor has also been used[96] to account for the rapid isomerisation of β-methylselenacarbocyanine compared with β-methylthia- and even more so β-methyloxacarbocyanines.

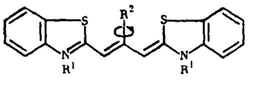
On the other hand, experiments on the triplet–triplet energy transfer have led to the hypothesis[64,99] that a singlet excited state is involved exclusively in the photoisomerisation at room temperature and that its degradation takes place in accordance with the scheme

$$
{}^0S_{trans(cis)} \xrightarrow{h\nu} {}^*S_{trans(cis)} - \left| \begin{array}{l} \rightarrow {}^0S_{trans(cis)} \text{ (fluorescence),} \\ \rightarrow {}^1T_{trans(cis)} \text{ (intersystem crossing),} \\ \rightarrow {}^0S_{trans(cis)} \text{ (internal transition),} \\ \rightarrow {}^0S_{cis(trans)} \text{ (isomerisation);} \end{array} \right.
$$

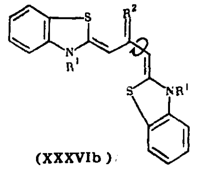
$$
{}^0S_{cis(trans)} \rightarrow {}^0S_{trans(cis)} \text{ (dark reaction).}
$$

According to this scheme, three radiationless processes compete: isomerisation, internal transition, and intersystem crossing. In carbocyanines, with the exception of β-iodothiacarbocyanine, the last process takes place with an extremely low quantum yield. The main factor determining which of the two first processes predominate is steric hindrance to the planar structure of the photoisomer. In contrast to unsubstituted and α-substituted carbocyanines, in the molecules of β-substituted dyes the dominant process leading to the degradation of the excited state is internal transition. The unusually high quantum yield in the photoisomerisation of β-fluorothiacarbocyanine can be explained by the small size of the fluorine atom, which permits isomerisation with respect to the C(2)–C(8) bond.

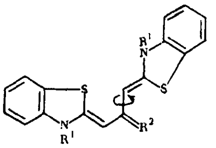
An unusual kind of isomerism, called "allopolar", has been described.[2,100] An obligatory condition for systems having the general formula (XXXVI) and undergoing this type of isomerism is the presence in the polymethine chain of bulky substituents R^2, containing π electrons which can interact under certain conditions with the main π-electron system of the molecule.



(XXXVIa)

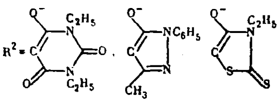


(XXXVIb)



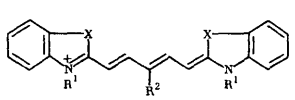
(XXXVIc)

$R^1 = C_2H_5$; $R^2 =$

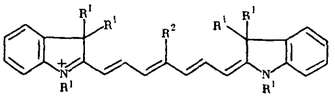


In the betaine (holopolar) form (XXXVIa), the steric interaction between the substituent R^2 and the heterocyclic nuclei makes the plane of the substituent perpendicular to the long axis of the carbocyanine part of the molecule and the influence of the substituent on the electronic absorption spectrum is purely inductive in character. The second isomeric merocyanine form (XXXVIa) is characterised by the fact that the π electrons of the substituent R^2 form a single chromophoric system with one half of the molecule, the second half being perpendicular to the new chromophore. An alternative form is the *trans*-(*EE*)-isomer (XXXVIc). The forms presented above absorb in different parts of the spectrum and this type of isomerism can therefore be observed at room temperature. The ratio of the isomers is sensitive to changes in the dielectric properties of the medium. It has been shown that polar and proton-donating solvents increase the content of the charged form (XXXVIa), while non-polar and aprotic solvents tend to increase the content of the merocyanine forms (XXXVIb, c).

There is little information about the steric structure of the dicarbocyanines (XIII, $m = 2$) and higher vinylene homologues. It is known that the cations of the thiadicarbocyanine (XXXVII, $R^1 = C_2H_5$, $R^2 = H$), indodicarbocyanine (XXXVII, $R^1 = CH_3$, R^2 = cyclopropyl), and indotricarbocyanine [XXXVIII, $R^2 = CH_2CH(OCH_3)_2$] exist in the solid phase in the fully *trans*-conformation and are almost planar.[100–102]



(XXXVII)
X = S, $C(CH_3)_2$; $R^1 = CH_3, C_2H_5$; $R^2 = H, OCH_3, C_3H_5, C_4H_7, C_6H_{11}, CH_3, C_6H_5$, F, Cl, Br, I, $C_6H_5N_2$, CHO, CN, NO_2

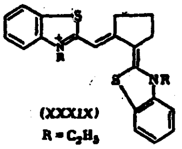


(XXXVIII)
$R^1 = CH_3$; $R^2 = H, CH_2CH(OCH_3)_2$

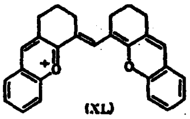
^1H and ^{13}C NMR studies of various γ-substituted dicarbocyanines (XXXVII) and also the indotricarbocyanine (XXXVIII, $R^2 = H$) have shown that these compounds exist in solution exclusively in the fully *trans*-conformation, favouring, other conditions being equal, the maximum overlap of the orbitals and the delocalisation of π electrons.[103-108] These data conflict with the earlier report[109] of the separation of three isomers by chromatographing thiatricarbocyanine on calcium carbonate at room temperature.

Only the photoexcited forms of the stereoisomers of the dicarbocyanines, which as a rule absorb at longer wavelengths than the corresponding forms in the ground state, can be detected.[4,80,110,111] The number of possible steric forms of dicarbocyanines is much greater than for dyes with a shorter polymethine chain. Thus the indodicarbocyanines (XXXVII, R^2 = H or F) give rise to several forms—short-lived (lifetime $\tau = 10^{-6}$ s) and long-lived ($\tau = 10^{-2}$ s).[111] The unstable photoisomers have the sterically highly hindered and therefore non-planar di-*cis*-structure. The angle of rotation of the chromophore fragment is closer to 180° on formation of the long-lived photoisomers but the latter are not fully planar either.

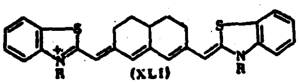
This factor is precisely the reason why the photoisomers fluoresce much less effectively than the corresponding forms in the ground state. This leads to losses in the excitation band owing to the overlap of the fluorescence spectrum of the generating form in the ground state and the absorption spectrum of the photoisomer. Another cause of the impairment of the generating properties of polymethine dyes is the "depletion" of the first excited singlet state owing to losses in the isomerisation proper.[4,5,112,113] These causes may be eliminated by the partial [the cations (XXXIX)–(XLI)] or complete [the cations (XLII) and (XLIII)] fixation of the chromophore in a particular conformation.[114-119]



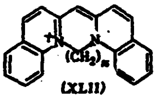
(XXXIX) R = C_2H_5



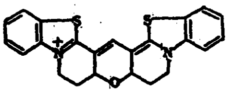
(XL)



(XLI) R = C_2H_5

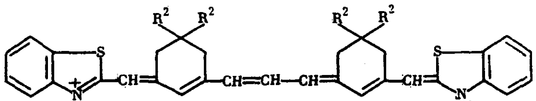


(XLII) n = 1, 2



(XLIII)

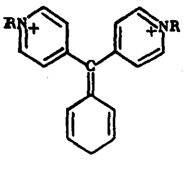
Taking into account the entropy factor, it might have been supposed that an increase in the length of the polymethine chain would reduce the probability of the existence of the di-cations in the fully *trans*-conformation, as happens, for example, in the molecules of saturated linear hydrocarbons.[8] Thus the short-wavelength absorption of the cation (XLIV) has been explained[120] by the existence of the *cis*-isomer. On the other hand, recent studies[121,122] have shown that polycarbocyanines exist in solution in the form of solvates absorbing in different parts of the spectrum.



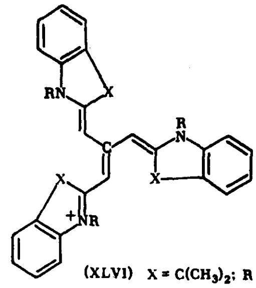
(XLIV)

$R^1 = C_2H_5$; $R^2 = CH_3$

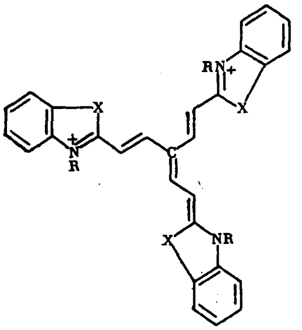
The so-called trinuclear dyes (XLV)–(XLVIII) constitute a special group. They differ by the fact that the *meso*-substituent is yet another heterocyclic nucleus linked directly to the polymethine chain [compound (XLV)] or via the methine [compound (XLVI)], vinylene [compound (XLVII)], or propenylene [compound (XLVIII)] groups. It has been shown from NMR data that the cations or di-cations of these compounds have a propeller-like structure and possess a threefold symmetry axis passing through the central carbon atom.[60,102,103,123] This configuration of the cation (XLVIII) is realised in the crystal.[102]



(XLV) R = CH_3

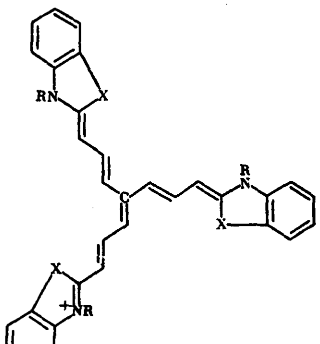


(XLVI) X = $C(CH_3)_2$; R = CH_3, C_2H_5



(XLVII)

X = $C(CH_3)_2$, S, CH=CH; R = CH_3, C_2H_5



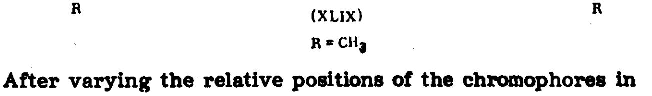
(XLVIII)

X = $C(CH_3)_2$; R = CH_3, C_2H_5

IV. ABSORPTION SPECTROSCOPIC STUDY OF THE CONFORMATIONAL FEATURES OF POLYMETHINE DYES WITH TWO CHROMOPHORES

As mentioned above, electronic spectra proved to be relatively unsuitable for the investigation of the conformations of polymethine dyes owing to the multiplicity of factors masking the contribution of the particular conformation to the absorption. On the other hand, the phenomenon of the interaction of chromophores, discovered by Kiprianov and Mushkalo,[124] showed that the scope of electronic spectroscopy can be greatly increased. A fundamentally new approach to the problem of the study of the conformations of polymethines is based on the characteristic features of the interaction of chromophores bound in a single molecule, in particular on the postulate that the ratio of the intensities of two absorption bands is determined ay the angle between the directions of the chromophores (ADC) in the cation.[15]

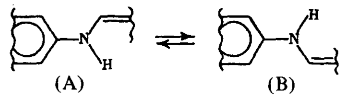
The spectroscopic properties of the readily available hemicyanines (XLIX, n = 0 or 1), which can be regarded as streptocyanines with rigidly fixed terminal arene nuclei, were investigated in the first place:



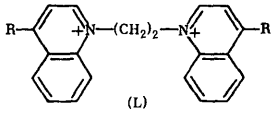
(XLIX)

R = CH_3

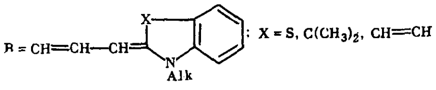
After varying the relative positions of the chromophores in structural isomers by introducing an aryl or heteroaryl connecting nucleus, by introducing various substituents into the latter, and by altering the solvation properties of solvents, the authors[124-132] concluded, from the ratio of the intensity of the two absorption bands, that the conformational equilibrium between the two planar forms (A) and (B) of the hemicyanine fragment is very mobile and depends on all the factors enumerated.



(A) (B)



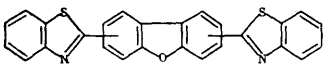
(L)



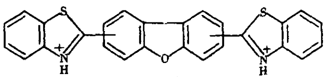
The conformations of the biscarbocyanine (L), in which the heterocyclic nuclei are linked by a polymethine bridge, have been discussed.[132] As in the spectra of bishemicyanines, the ratio of the intensities of the longest-wavelength absorption band in the spectrum of this dye depends on the ADC in each conformer, formed as a result of the hindered rotation about the single bonds in the ethylene connector, and also on the concentration of a particular conformer. It has been shown that an increase of solvent polarity is accompanied by an increase of the intensity of the short- at the expense of the long-wavelength band, i.e. by a shift of the conformational equilibrium towards the formation of skewed (*gauche*) conformers.

The shift towards the formation of the more "compact" conformer (L) takes place also when a high pressure is applied to the solution of the dye.[133]

The absorption spectra of the highly coloured dibenzothiazolyldibenzofurans (LI) and their simple salts (LII) have been examined within the framework of the theory of the interaction of chromophores. The positions and intensities of the bands in the spectra of all the possible planar conformers, formed on rotation of the benzothiazole groups about the bonds with the dibenzofuran nucleus, have been evaluated by quantum-chemical calculation.[134]



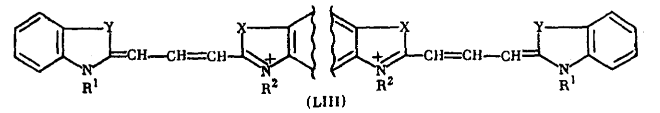
(LI)



(LII)

Unfortunately the broad overlapping absorption bands hinder the interpretation of the spectra of the majority of the compounds mentioned.

The biscarbocyanines (LIII), in which the central nucleus has a rigid structure and which give rise to narrow well resolved absorption bands, proved to be a much more successful model for the study of the characteristic features of the interaction of chromophores:[6,15,135,136]

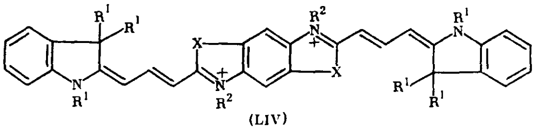


(LIII)

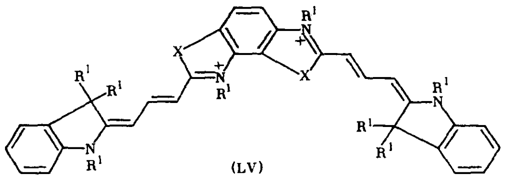
X, Y = O, S, $C(CH_3)_2$; R^1, R^2 = CH_3, C_2H_5

These systems proved to be extremely suitable also for the solution of conformational problems.[137-140]

The fact that the fully *trans*-conformation is the only one for both polymethine chains of the biscyanines (LIII) has been confirmed by the complete similarity of the forms of the absorption curves within each of two families of dyes (LIV) and (LV) in which the ADC should be identical for structural reasons regardless of the bond lengths and valence angles.[137]



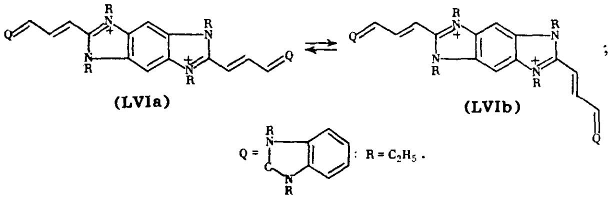
(LIV)



(LV)

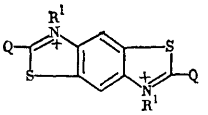
X = O, S, $C(CH_3)_2$; $R^1 = CH_3$; $R^2 = CH_3, C_2H_5$

The identity of the forms of the absorption curves is consistent with the presence of one and only one conformation of the chromophores. The presence in solution of several conformers, each of which has its own ADC, should ultimately affect the ratio of the band intensities. For example, by virtue of its high symmetry, the biscyanine (LVI) can exist in two almost equally probable forms (LVIa) and (LVIb), in one of which the ADC is 180° and in the other 120°. An appreciable short-wavelength band is observed precisely because of the conformational inhomogeneity in the absorption spectrum of the biscyanine (LVI).[137]

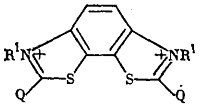


(LVIa) (LVIb)

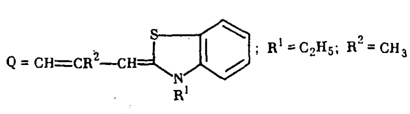
The synthesis and spectroscopic study of the biscarbocyanines (LVII) and (LVIII) with bulky substituents in the β-position in the polymethine chain made it possible to observe the conformational equilibrium between the fully *trans*- and *cis*-forms at room temperature without resorting to special measuring techniques.[137] In the former case the conformational homogeneity is manifested by a distinct short-wavelength band. The presence of this band rules out the possibility that steric hindrance may be eliminated exclusively as a result of the alteration of the valence angles between the atoms of the polymethine chain, since in this case the ADC of 180° would have been retained.



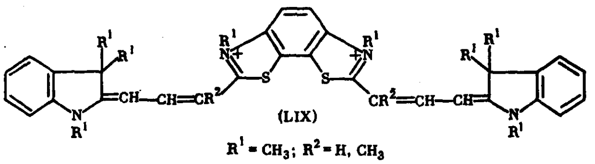
(LVII)



(LVIII)



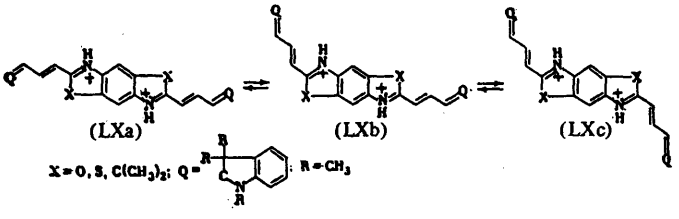
The introduction of a methyl group in the α-position in one and then in the other polymethine chain [in the dyes (LIX)] make it possible to follow the appearance of the corresponding *cis*-isomers from the relative increase of the intensity of the long-wavelength band.[137]



(LIX)

$R^1 = CH_3$; $R^2 = H, CH_3$

The appearance of *cis*-conformations in the two previous cases (α- and β-substitution) is associated with the increase in the steric interaction in the di-cations. The example of NH-biscyanines shows, on the contrary, that conformational inhomogeneity can arise on replacement of the bulky methyl group at the nitrogen atoms of the terminal heterocycles by a hydrogen atom.[138-140] Thus there is no short-wavelength band in the spectrum of *N*-methylated dyes (LIV). This is consistent with the fully *trans*-disposition of both polymethine chains, forming an angle of 180°. However, for the NH-biscyanines (LX) this *trans,trans*-conformer (LXa) is only one of the three possible conformers. Although another conformer (LXc), corresponding to the *cis*-configuration of each polymethine chain, also does not contribute to the short-wavelength absorption, the chromophores of the non-centrosymmetric *cis,trans*-conformer (LXb) form an ADC less than 180°; the short-wavelength band of this particular conformer is in fact partly allowed. If instead of conformational changes the fully *trans*-polymethine chains were fully displaced into the space previously occupied by methyl groups, the ADC would have remained 180° and the prohibition of the short-wavelength band would have remained in force:

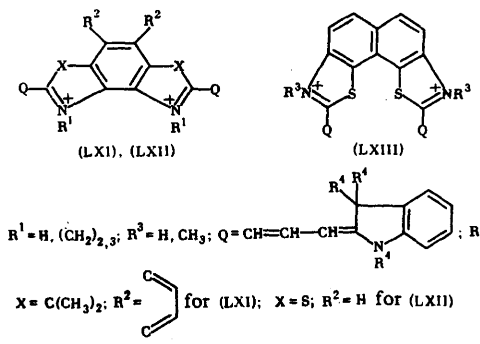


(LXa) (LXb) (LXc)

X = O, S, $C(CH_3)_2$; Q = ; R = CH_3

The conformational changes can be followed most clearly from the absorption spectra of biscyanines with angular central nuclei.

The considerable predominance of the long- over the short-wavelength band in the absorption spectra of the biscyanines [LXI, $R^1 = (CH_2)_{2,3}$] is determined by the obtuse ADC, to which correspond the *trans*-conformations of both polymethine chains. The replacement of the alkylene bridge by hydrogen atoms [in the dye (LXI, R^1 = H)] leads to the inversion of the intensities of the bands with retention of their positions. This is caused by the presence in the equilibrium mixture of the conformer (LXI) whose polymethine chains are in the *cis*-conformations and form an acute angle.



(LXI), (LXII) (LXIII)

$R^1 = H, (CH_2)_{2,3}$; $R^3 = H, CH_3$; Q = CH=CH—CH= ; $R^4 = CH_3$;

X = $C(CH_3)_2$; R^2 = for (LXI); X = S; R^2 = H for (LXII)

The bisthiacyanines (LXII) are structural analogues of the dyes (LXI) but the redistribution of band intensities on passing to NH-biscyanine is not so great. This is associated with the smaller fraction of the *cis,cis*-conformer in the thiazole dye compared with the pyrrolenine dye.[140]

On the other hand, appreciable spectroscopic changes occur after the gradual replacement of the *N*-methyl groups by hydrogen atoms in bisthiacarbocyanines (LXIII). Calculation of the conformational equilibrium[140] has shown that the fraction of the *cis*-conformers of the dyes (LXIII) is greater than for the remaining NH-cyanines derived from benzobisthiazoles. This is caused by the mutual repulsion of chromophores bearing like charges, which is a maximum for conformers with chromophores in structural proximity and a minimum for conformers such as (LXa) and (LXc), i.e. with chromophores remote from one another. In the latter case the conformational equilibrium depends on the steric factor, which is determined by the relative dimensions of the groups NH and X. The Coulombic repulsion of the chromophores is also the cause of the distinct dependence of the conformational equilibrium on the dielectric properties of the medium.[138-140]

---o0o---

Thus it is now possible to identify the main factors on which the steric structures of polymethine dyes depend, including their tendency to exist in the form of different conformers. These are the nature of the terminal heterocyclic nucleus and the substituent at its nitogen atom, the length of the polymethine chain, the effective bulk of the substituent and the site where it is introduced, the properties of the medium, and also the molecular interaction (the possibility of aggregation).

However, despite the evident advances which have been achieved as the spectroscopic technique has been improved and new systems have been synthesised, the identification of conformers remains a fairly complex task to this day. In view of the low activation barrier of the isomerisation process (33–63 kJ mol^{-1}), it is not possible to separate the conformers and to isolate them in a pure state. X-Ray diffraction analysis requires special conditions as regards the preparation of crystalline specimens, which frequently cannot be fulfilled. The geometrical structure of the di-cations in the crystal can differ appreciably from their state in solution. The electronic spectra, which are the most important characteristics of the dyes, are relatively unsuitable in this instance. The amount of information derivable from them increases appreciably in the case of biscyanines, but this involves considerable difficulties in the synthesis of suitable objects. A more effective method for the determination of the steric structures of methine dyes is NMR.

In the future one may probably expect that studies devoted to the conformational analysis of cyanines with non-traditional heterocyclic nuclei and also containing a wider range of substituents will be carried out. The problems postulated will be solved by improving and employing on a wider scale the physicochemical and special synthetic methods.

Hexafluoroisopropylidene-containing Polyheteroarylenes

V.V.Korshak, I.L.Knunyants, A.L.Rusanov, and B.R.Livshits

The methods of synthesis of various condensation monomers containing the hexafluoroisopropylidene groups and the polyheteroarylenes based on them are examined. The influence of the hexafluoroisopropylidene groups incorporated in the main chains of the macromolecules is analysed and it is shown that polyheteroarylenes containing these are characterised by an improved solubility and fire resistance and that the articles based on them have a higher elasticity.
The bibliography includes 88 references.

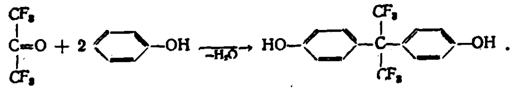
I. INTRODUCTION

Halogen and in particular fluorine-containing condensation polymers have attracted much attention by investigators in the course of the last 25 years. A series of monographs and careful reviews,$^{1-5}$ indicating the enormous variety of the halogen-containing polymers synthesised and their properties, have been devoted to the principal advances in this field. Among the numerous fluorine-containing polymers, aromatic polycondensation systems are of special interest$^{1-3}$ and among them those where the fluorine atoms are located in the side chains and not in the benzene ring.^{3} Typical representatives of such polymers are polycondensates containing hexafluoroisopropylidene groups. A systematic analysis of the advances in this field is not available in the literature. For this reason, the selected subject of this review is an examination of the advances in the synthesis and investigation of condensation monomers and polyheteroarylenes containing hexafluoroisopropylidene groups.

II. CONDENSATION MONOMERS CONTAINING HEXAFLUOROISOPROPYLIDENE GROUPS

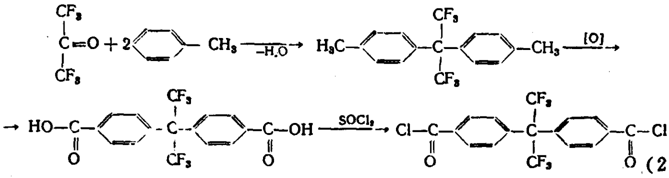
The synthesis of condensation monomers containing hexafluoroisopropylidene groups is based on the reactions of hexafluoroacetone with various aromatic compounds containing mobile hydrogen atoms$^{6-11}$ and the subsequent reaction of the simplest condensation products.$^{7-18}$

Thus Knunyants and co-workers^{16} achieved the condensation of hexafluoroacetone with phenol in the presence of anhydrous HF, which resulted in the formation of 2,2-di(p-hydroxyphenyl)hexafluoropropane produced at the present time in considerable amounts and known under the name "bisphenol AF":^{11}



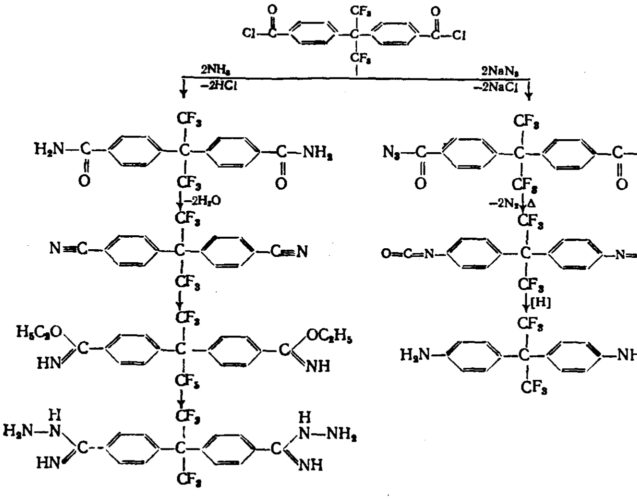
(1)

The development of this approach to the synthesis of bifunctional derivatives of 2,2-diarylhexafluoropropane led to the formation of a whole series of compounds with hexafluoroisopropylidene groups,$^{7-10}$ which are of independent interest as monomers for polycondensation or serving as intermediates in the synthesis of condensation monomers with a complex structure. In particular, a dicarboxylic acid and acid dichloride derived from 2,2-diarylhexafluoropropane have been obtained by condensing hexafluoroacetone with toluene and subsequent reactions of 2,2-di(4-tolyl)hexafluoropropane:$^{7-10}$



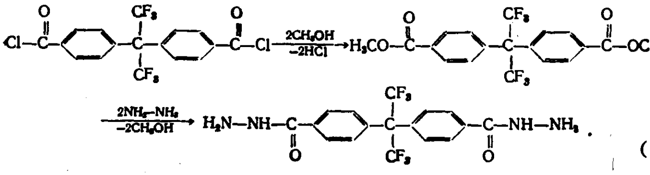
(2)

Subsequent reactions of the dichloride of 2,2-di(p-carboxyphenyl)hexafluoropropane led to the formation of the corresponding diamide, diazide, diisocyanate, and diamine$^{7-9}$ as well as the dinitrile, the diethyl bis(iminoester), and the bisamidrazone of 2,2-di(p-carboxyphenyl)hexafluoropropane:



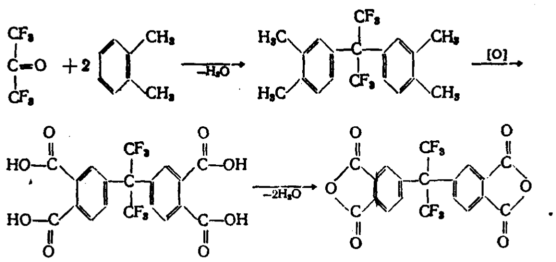
(3)

Subsequently the diphenyl ester, the dimethyl ester, and the dihydrazide of 2,2-di(p-carboxyphenyl)hexafluoropropane were synthesised:^{8}



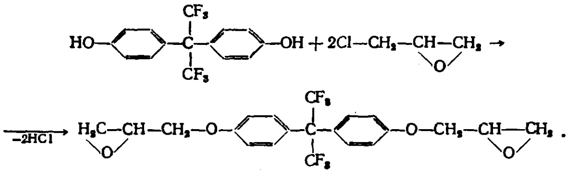
(4)

2,2-Di(3,4-dimethylphenyl)hexafluoropropane, whose oxidation yielded 2,2-di(3,4-dicarboxyphenyl)hexafluoropropane, dehydrated subsequently to the corresponding dianhydride, was obtained by the reaction of hexafluoroacetone with *o*-xylene:[9]



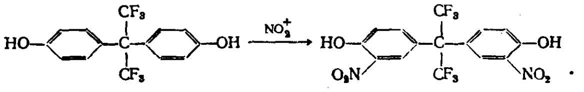
(5)

Evidently the final products and the series of intermediates indicated in Schemes (1)–(5) refer to the majority of the classes of monomers used in polycondensation reactions.[12] On the other hand, many of them have been used in various reactions leading to new monomers. 2,2-Di(4-hydroxyphenyl)hexafluoropropane is used particularly vigorously for this purpose. Thus the di(4-glycidyl) ether of 2,2-di(4-hydrophenyl)hexafluoropropane has been synthesised by its interaction with epichlorohydrin:[13,19]



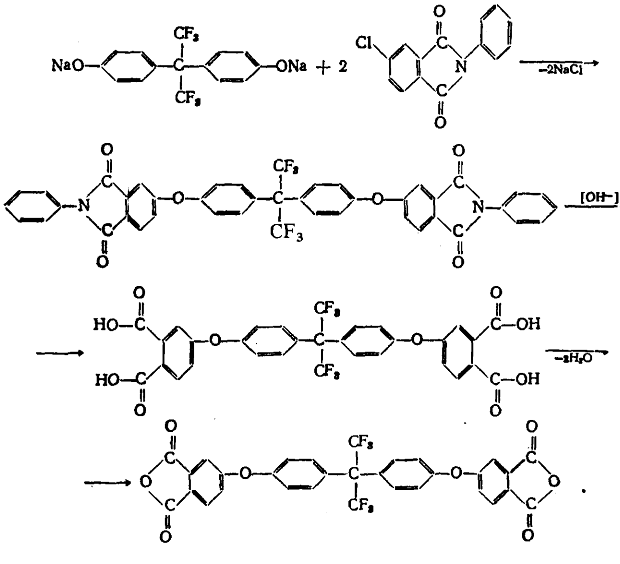
(6)

The nitration of this bisphenol yielded 2,2-di(4-hydroxy-3-nitrophenyl)hexafluoropropane:[14]



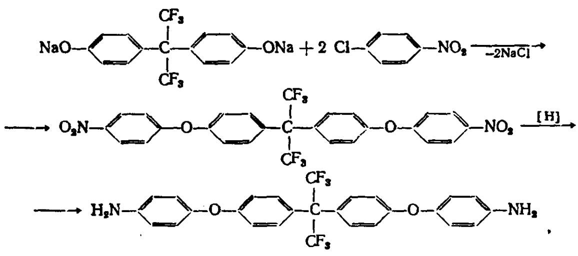
(7)

The reaction of its disodium salt with 4-chloro-*N*-phenylphthalimide and subsequent reactions of the latter afforded the dianhydride of 2,2-di[4-(3,4-dicarboxyphenoxy)phenyl]hexafluoropropane:[15,16]



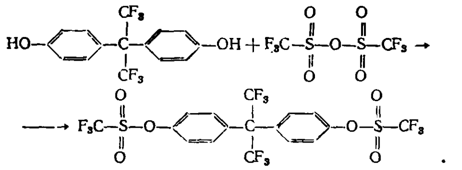
(8)

The interaction of the same diphenoxide with twice the molar amount of *p*-chloronitrobenzene made it possible to obtain 2,2-di[4-(4-nitrophenoxy)phenyl]hexafluoropropane, which was subsequently reduced to 2,2-di[4-(4-aminophenoxy)phenyl]hexafluoropropane:[18]



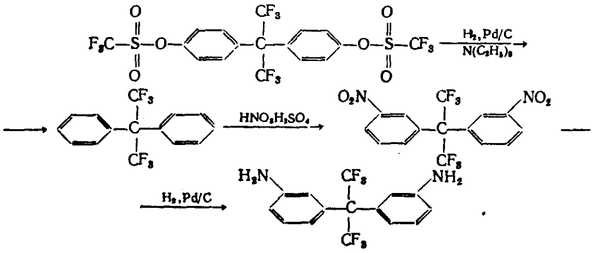
(9)

A considerable amount of hexafluoroisopropylidene-containing monomers have been synthesised[11] from 2,2-di(4-trifluoromethanesulphonyloxyphenyl)hexafluoropropane, obtained by treating bisphenol AF with trifluoromethanesulphonic (triflic) anhydride:[20,21]



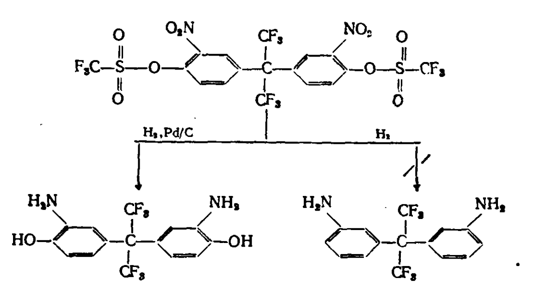
(10)

The ditriflate obtained in this way was reduced catalytically over palladium on charcoal in the presence of triethylamine. This resulted in the formation of 2,2-diphenylhexafluoropropane, whose nitration and subsequent reduction afforded 2,2-di(3-aminophenyl)hexafluoropropane:[11]



(11)

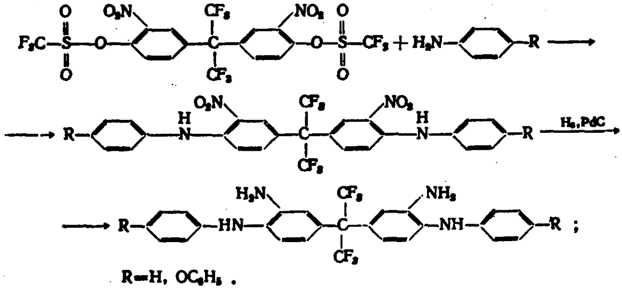
The nitration of the ditriflate gave rise to 2,2-di(3-nitro-4-trifluoromethane-sulphonyloxyphenyl)hexafluoropropane, whose hydration led to the formation of 2,2-di(3-amino-4-hydroxyphenyl)hexafluoropropane instead of the expected 2,2-di(3-aminophenyl)hexafluoropropane:[11]



(12)

We may note that the former product can apparently be obtained also by a simple procedure via the nitration of bisphenol AF[14] and the reduction of the resulting 2,2-di(4-hydroxy-3-nitrophenyl)hexafluoropropane.

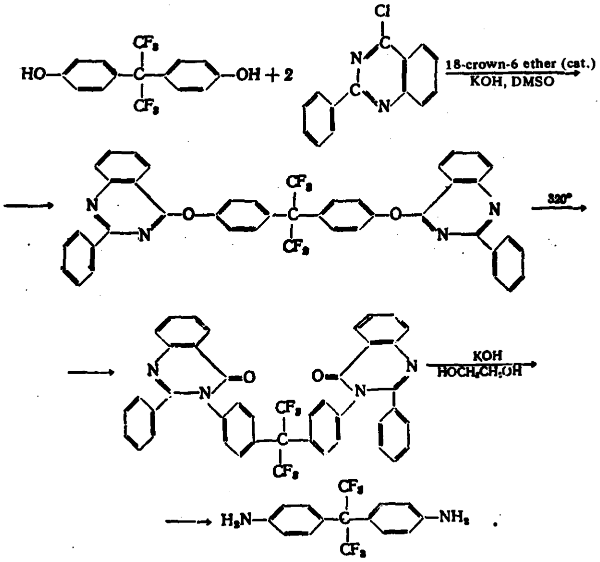
The replacement of the triflate group in 2,2-di(3-nitro-4-trifluoromethane-sulphonyloxyphenyl)hexafluoropropane by aromatic amines with subsequent reduction of the reaction product led to the formation of various 2,2-di(3-amino-4-arylamino)hexafluoropropanes:[11]



R=H, OC_6H_5.

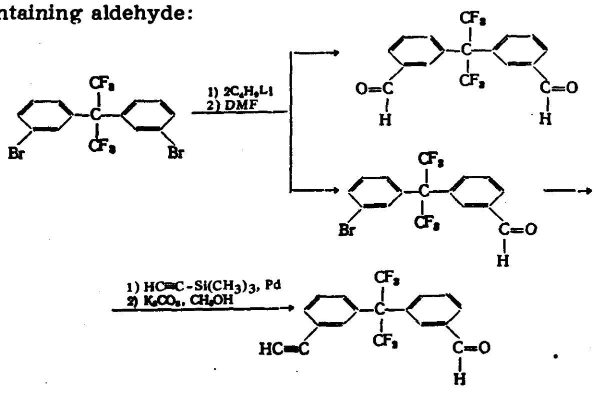
(13)

Finally bisphenol AF has been converted[11] into 2,2-di(4-aminophenyl)hexafluoropropane. A method, which is general for the conversion of phenols and bisphenols into amines and diamines, was used for this purpose:



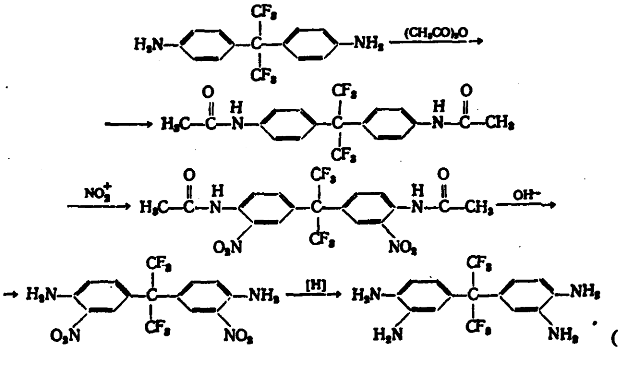
(14)

New monomers have been obtained via a series of reactions also from the isomeric hexafluoroisopropylidene-containing aromatic diamines. Thus 2,2-di(3-aminophenyl)hexafluoropropane was converted via the Sandmeyer reaction into 2,2-di(3-bromophenyl)hexafluoropropane,[11] which was in its turn converted by treatment with organolithium compounds into 2,2-di(3-formylphenyl)- and 2-(3-bromophenyl)2-(3-formylphenyl)hexafluoropropanes and further into an ethynyl-containing aldehyde:



(15)

The corresponding bis(o-phenylenediamine) has been obtained from 2,2-di(4-aminophenyl)hexafluoropropane via stages involving the acetylation of the amino-groups, nitration, the removal of the acyl protecting group, and reduction of the resulting 2,2-di(4-amino-3-nitrophenyl)hexafluoropropane:[9]

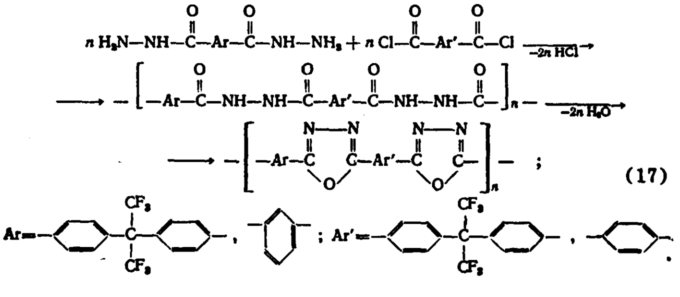


(16)

The simplest monomers containing hexafluoroisopropylidene groups were used successfully at the beginning of the 1960's for the synthesis of heterochain polymers—polyesters,[23] polycarbonates,[23,24] polyarylates,[25] polyamides,[26] polyurethanes,[8] etc. In these and later[27] studies it was already shown that the trifluoromethyl groups as side substituents at the central carbon atom significantly improve the mechanical properties of the polymers and sharply increase their solubility in any solvent, improving thereby their capacity for being worked and converted into articles. Since the capacity for being converted into articles and the deformation-strength characteristics of the latter are in fact the weak features of many polyheteroarylenes,[28] it appeared entirely natural to synthesize polyheteroarylenes containing hexafluoroisopropylidene groups in order to modify the properties of these systems in the required direction.

III. POLYHETEROARYLENES CONTAINING HEXAFLUOROISOPROPYLIDENE GROUPS IN THE MAIN CHAINS OF THE MACROMOLECULES

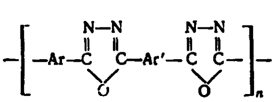
One of the first polyheteroarylenes which have attracted the attention of investigators as regards their modification by hexafluoroisopropylidene groups were poly-1,3,4-oxadiazoles.[27,29] These polymers were synthesised using a traditional approach,[30,31] via the interaction of the dihydrazide and (or) dichloride of 2,2-di(p-carboxyphenyl)hexafluoropropane with monomers of the dihydrazide and acid dichloride series with subsequent thermal cyclisation of the resulting polyhydrazides:[27,29]



Certain characteristics of the poly-1,3,4-oxadiazoles synthesised in this way are presented in Table 1.

Analysis of the data in Table 1 indicates a significant (~50 °C) decrease of the softening temperature of the polyoxadiazoles on passing from the structure lacking hexafluoroisopropylidene groups to one containing the maximum number of the latter. On the other hand, the solubility of poly-1,3,4-oxadiazoles increases with increase of the content of fluorine atoms in the polymer. Polymers based on the dichloride of 2,2-di(p-carboxyphenyl)hexafluoropropane and its dihydrazide are the most soluble.[27] The tendency of the fluorine-containing polymers to dissolve can be accounted for, according to Livshits et al.,[27] both by the affinity of the trifluoromethyl groups for polar solvents and by the nonrigid structure of these polymers as a consequence of the presence in them of bulky groups facilitating the diffusion of the solvent.

Table 1. Certain characteristics of poly-1,3,4-oxadiazoles having the general formula[27,29]



Ar	Ar′	T^{*}_{soft}	Solubility**			
			nitro-benzene	TCE : phenol (3:1)	DMF	DMSO
		370	∓	∓	+	∓
		360	∓	+	+	∓
		330	+	+	+	+
		380	−	−	−	−

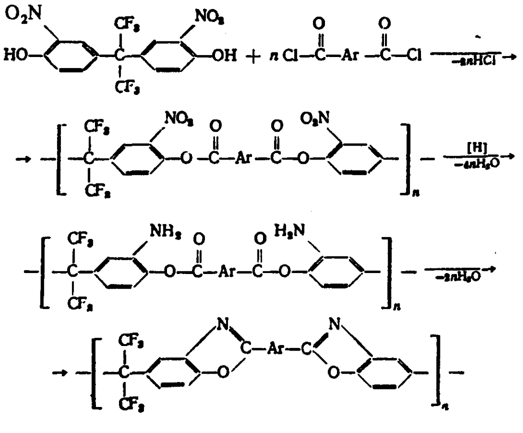
---

*Here and henceforth the softening temperature T_{soft} is assumed to be the value obtained from the thermomechanical curves.

**Here and henceforth the following notation has been adopted in designating solubilities: +—soluble in the cold, ±—soluble on heating, ∓—swells, —insoluble.

It is noteworthy that the data presented in Table 1 refer to polymers obtained by thermal solid-phase polycyclisation (at 275 °C for 20 h). It might have been expected that catalytic cyclisation in solution would lead to the formation of polymers with a still higher solubility. Overall, poly-1,3,4-oxadiazoles containing hexafluoroisopropylidene groups are promising polymers and, provided that the problem of the starting materials can be solved successfully, they may be of significant practical interest.

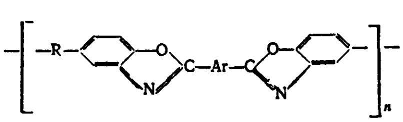
The synthesis of polybenzoxazoles containing hexafluoroisopropylidene groups has also attracted much attention by investigators. These polymers have been obtained by the reductive polyheterocyclisation reaction[14,32] in accordance with the scheme[14,32-34]



(18)

The synthesis in *N*-methyl-2-pyrrolidinone (N-MP) using reduced iron and HCl, which play simultaneously the role of a reductant and the cyclisation catalyst, led to the formation of high-molecular-weight polymers characterised by high degrees of cyclisation. Certain characteristics of the polybenzoxazoles synthesised are presented in Table 2.

Table 2. Certain characteristics of polybenzoxazoles having the general formula[14]



R	Ar	η^{*}_{int}, dl g^{-1}	T^{**}_{soft}, °C	T_{decomp}, °C	Solubility	
					TCE:phenol (3:1)	N-MP
 $-C(CH_3)_2-$		1.20	260—270	400	+	−
 $-C(CH_3)_2-$		1.32	250—260	360	+	+
$-CH_2-$		1.48	280—290	435	+	−
$-CH_2-$		1.37	280—270	410	+	−
 $-C(CF_3)_2-$		0.82	270—280	420	+	+
 $-C(CF_3)_2-$		1.08	240—250	370	+	+

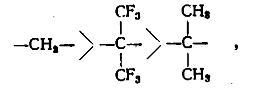
---

*The intrinsic viscosity (η_{int}) was determined in a 3:1 TCE—phenol mixture at 25 °C.

**Here and henceforth the decomposition temperature (T_{decomp}) was assumed to be the temperature at which 10% of the mass was lost under the conditions of dynamic TGA (in air, ΔT = 4.5 K min^{-1}).

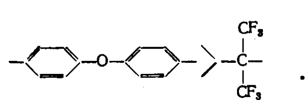
Analysis of the data in Table 2 indicates the relation between the structure and properties of the polymers, which is identical with that found for poly-1,3,4-oxadiazoles (Table 1): the replacement of the traditional aromatic "bridging" groups by hexafluoroisopropylidene fragments leads to the improvement of the solubility of the polymers and at the same time to a decrease of the softening temperatures, the combination of the two factors improving the capacity of polybenzoxazoles for being worked.

Data on the thermal stability of the polyheteroarylenes synthesised have attracted attention. Despite the rather arbitrary nature of the data obtained under the conditions of dynamic thermogravimetric analysis (DTA) thermal stability series are quite clearly manifested: in relation to the "bridging" groups R, series have the following form:



$$-CH_2- > -C(CF_3)_2- > -C(CH_3)_2- \quad (19)$$

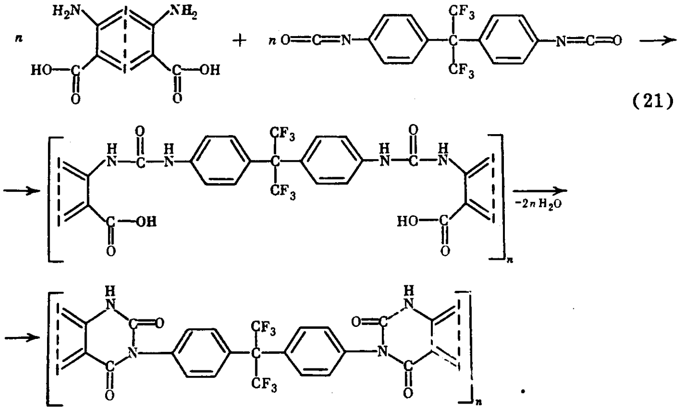
while in relation to dicarboxylic acid residues Ar it is



$$-C_6H_4-O-C_6H_4- > -C(CF_3)_2- \quad . \quad (20)$$

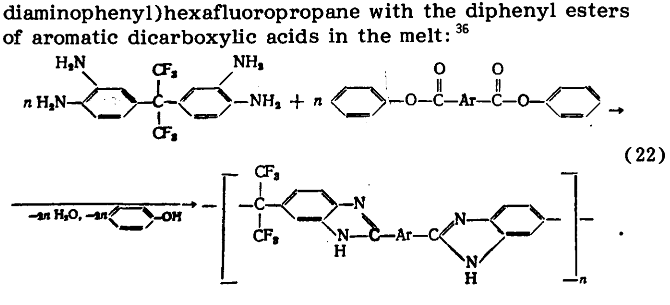
The data obtained agree both with the results of a study[23] where it was claimed that the thermal stability of the polycarbonate based on 2,2-di(4-hydroxyphenyl)hexafluoropropane is greater than that of the polycarbonate based on bisphenol A and with the results of an investigation[27] in which a reduced thermal stability of polyheteroarylenes containing hexafluoroisopropylidene groups was claimed.

The data on the synthesis of polyquinazolinediones[35] and polybenzimidazoles[36] containing hexafluoroisopropylidene groups appear to be somewhat less systematic. Polyquinazolinediones containing hexafluoroisopropylidene groups have been obtained by the reaction of bis(anthranilic acids) with 2,2-di(4-isocyanatophenyl)hexafluoropropane:[35]



(21)

Polybenzimidazoles containing hexafluoroisopropylidene groups have been obtained by the reaction of 2,2-di(3,4-diaminophenyl)hexafluoropropane with the diphenyl esters of aromatic dicarboxylic acids in the melt:[36]



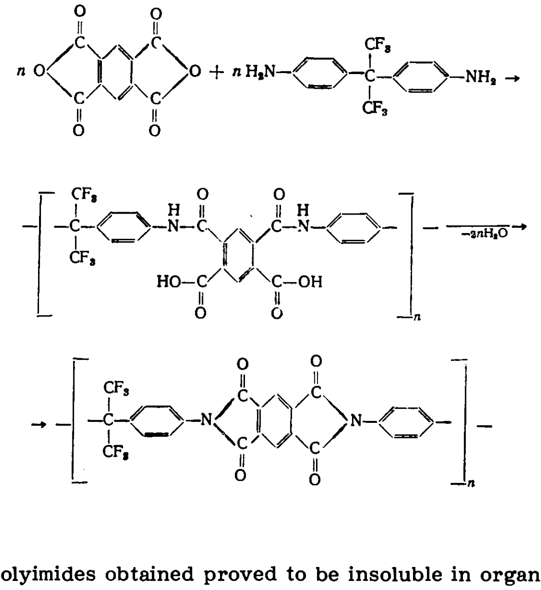
(22)

In all cases the introduction of hexafluoroisopropylidene groups led to the changes in the properties of polymers noted above and in addition to an appreciable increase of their fire resistance. The latter factor is extremely important in view of the considerable interest in fire resistant polymers.[37] Almost all investigators are unanimous in claiming a positive influence of the trifluoromethyl groups on the fire resistance of polymers, but in most cases the results obtained are qualitative rather than quantitative, which naturally hinders the analysis of the dependence of this property of the polymers on the structure.

As can be seen from the foregoing, the modification of the properties of polymers by hexafluoroisopropylidene groups concerned many classes of polyheteroarylenes but polyimides have attracted most attention by investigators.[30,38] This can be explained to a considerable extent by the special place which polyimides occupy among polyheteroarylenes and also by the extensive possibilities for the modification of their structure by hexafluoroisopropylidene groups.

It is noteworthy that analysis of the "structure–properties" and especially "structure–solubility" relations is very difficult precisely for polyimides owing to the differences between the methods of their synthesis (thermal cyclisation of polyamidoacids or catalytic cyclisation of prepolymers in solution), the differences between their viscosity characteristics, etc.

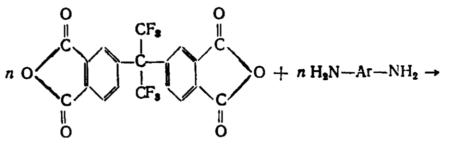
One of the first attempts at the modification of polyimides by hexafluoroisopropylidene groups concerns the synthesis of polypyromellitimide from 2,2-di(4-aminophenyl)hexafluoropropane[27] by a two-stage method:

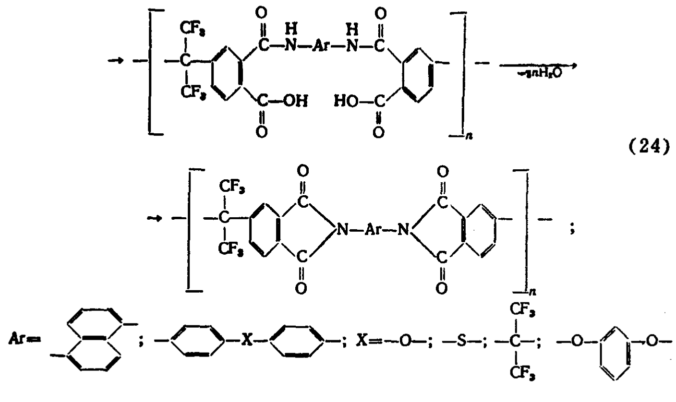


(23)

The polyimides obtained proved to be insoluble in organic solvents.

According to a series of data,[39–43] the polyimides based on the dianhydride of 2,2-di(3,4-dicarboxyphenyl)hexafluoropropane (dianhydride 6F) and various diamines are also soluble only in $SbCl_3$. They were obtained by a two stage method in accordance with the scheme

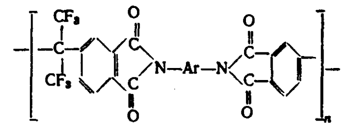




(24)

On the other hand, according to Clair et al.,[17] the polyimides containing hexafluoroisopropylidene groups are characterised in many instances by a satisfactory solubility in dipolar aprotic solvents (Table 3).

Table 3. Certain characteristics of polyimides having the general formula[17]



Ar	η^*_{log}	T_{soft}, °C	Solubility			
			N-MP	DMA	DMF	*m*-cresol
	0.47	260	+	+	+	±
	0.25	288	+	+	+	−
	0.35	311	−	−	−	−
	1.23	248	+	+	+	±
	0.86	272	−	−	−	−
	1.82	290	−	−	−	−
	2.20	307	−	±	+	+
	0.54	303	+	+	+	+
	0.90	339	+	+	+	+

---

*The logarithmic viscosity (η_{log}) was determined in N-MP at 25 °C.

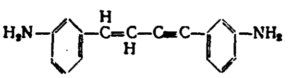
In the search for ways of increasing the solubility of the imides, investigators turned to the use of a diamine and a dianhydride containing in their molecules a combination of one hexafluoroisopropylidene group and two ether linkages, namely 2,2-di[(4-aminophenoxy)phenyl]hexafluoropropane[18] and the dianhydride of 2,2-di[4-(3,4-dicarboxyphenoxy)-phenyl]hexafluoropropane.[15,16,44-46] However, a significant increase of the solubility of the required polyimides could not be achieved by this procedure. Furthermore, an extremely detailed analysis of the relation between the structure of the polyimides based on asymmetric diamines and their solubility[17,47] showed that the polymers based on dianhydride 6F are much more soluble than the polyimides based on the same diamines and the dianhydride of 2,2-di[4-(3,4-dicarboxyphenoxy)phenyl]hexafluoropropane.[17] This at first sight anomalous phenomenon is probably associated with the greater content of hexafluoroisopropylidene units per conventional unit length of the macromolecule in polyimides based on dianhydride 6F. Certain characteristics of the polyimides based on dianhydride 6F and aromatic diamines with symmetrical and asymmetrical structures are listed in Table 3. In the analysis of the data in Table 3, the somewhat unexpected higher solubility of the polyimide based on dianhydride 6F and p-phenylenediamine compared with the polyimides based on dianhydride 6F and diamines such as 4,4'-diaminobenzophenone, di(4-aminophenyl)methane, and di(4-aminophenyl)ether has attracted attention. By analogy with the above, the explanation of the observed phenomenon is probably the greater number of hexafluoroisopropylidene units per conventional unit length of the macromolecule of the polyimide based on *p*-phenylenediamine.

Together with the traditional aromatic amines, systems with a more specific structure have been used in the synthesis of polyimides based on dianhydride 6F. The interaction of dianhydride 6F with diamines containing oligooxymethylene groups, having the general formula

(25)

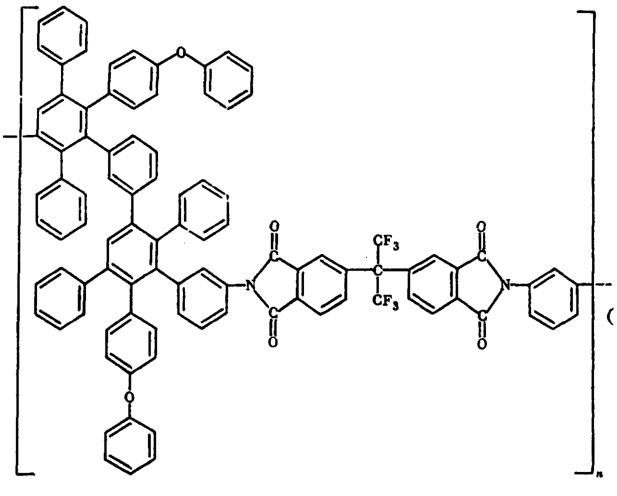
(n = 1,2,3,4), in *m*-cresol at 165–180 °C yielded polyimides which are soluble in chloroform and soften at 135–255 °C, depending on the structure of the diamine.[48,49]

A polyimide soluble in chloroform and dimethylacetamide (DMA) has been obtained under analogous conditions from dianhydride 6F and (*E*)-3,3'-(but-1-en-3-ynylene)dianiline:[44-46]



(26)

A polyimide having the formula



(27)

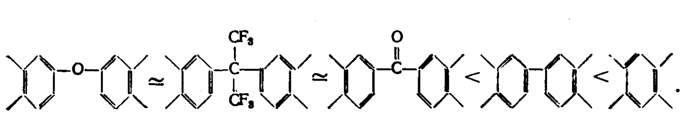
containing, together with hexafluoroisopropylidene groups, also 4-phenoxyphenyl and phenyl side groups which impart an improved solubility to rigid-chain monomers,[51] has been obtained[50] from dianhydride 6F. This polyimide is characterised by a glass point of 240 °C, is soluble in aromatic, chlorinated, and polar aprotic solvents, and retains 80% of its initial mass on thermal ageing at 343 °C for 200 h.[50]

The comparatively low softening temperatures of hexafluoroisopropylidene-containing polyimides make it possible to obtain from the low-molecular-weight polymers of this class articles with effective physicomechanical properties by cast moulding or extrusion.[42,52,53] The most promising polymers of this type—systems based on dianhydride 6F and aromatic diamines—are used by the Dupont Company as a basis for the development of binding or reinforced plastics[54–59] known by the name NR-150. According to Gibbs and Breder,[54] polyimides based on dianhydride 6F and various aromatic diamines are obtained by the chemical cyclisation of poly(*o*-carboxy)amides. The polymers obtained are soluble in pyridine, N-MP, and DMF. The glass points of the polyimides are in the range 229–385 °C, depending on the structure of the diamines. A low content of cavities (~1%) in the final materials is achieved by pressing at temperatures exceeding the glass points of the polyimides. Analogous pressing conditions are a precondition for success in the separation of glass plastics from solutions of poly(*o*-carboxy)amides. In all cases the presence of hexafluoroisopropylidene groups prevents the crystallisation of the polyimides. Glass plastics based on NR-150 have a tensile strength up to 3500 kg cm^{-2}, a modulus of elasticity of 2.24×10^5 kgf cm^{-2}, a static bending strength of 4900 kgf cm^{-2}, and a shear strength of 660 kgf cm^{-2}.[59] The most heat resistant of these systems can be used at 342 °C[54] and they retain 80% of their initial strength characteristics after ageing at 260 °C for 5000 h.[59]

Experiments with various polyimide binders have shown that NR-150 has the highest thermal stability and is most suitable for prolonged use in outer space.[59] Together with their employment as binders, such polyimide systems are of interest as adhesives and coatings.[60]

The positive effect of hexafluoroisopropylidene groups on the solubility of polyimides has been demonstrated also in relation to cardo-copolyimides with various microstructures synthesised using dianhydride 6F[61,62] and 2,2-di(4-aminophenyl)hexafluoropropane among various monomers.[62,63]

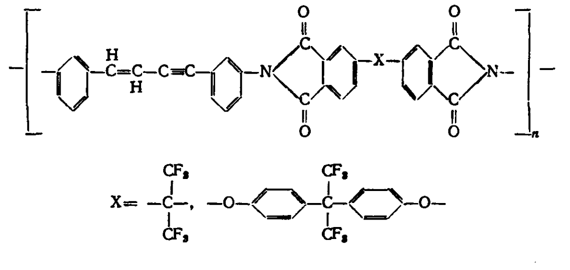
Comprehensive investigation of the properties of the copolyimides synthesised has shown that the introduction of hexafluoroisopropylidene groups tends to increase the solubility of the copolyimides. In terms of their influence on the softening temperatures of the polymers, the dianhydrides of tetracarboxylic acids can be arranged in the following sequence:[62]



(28)

The unique capacity of hexafluoroisopropylidene-containing oligo- and poly-heteroarylenes for being worked made them useful as thermoreactive polymeric systems. In recent years this field, which reduces to the creation of readily worked systems which are hardened after conversion into articles, has become one of the dominant fields in the chemistry of thermostable polymers. In particular, oligomers and polymers with ethynyl groups,[64] capable of cyclotrimerising with formation of trisubstituted phenyl intermolecular units, have attracted much attention. The ethynyl groups can be located in the main chains of the macromolecules, in the side substituents, and in the end groups of the oligo- and polyheteroarylenes. The use of reactive solvents and plasticisers, containing ethynyl groups and capable of participating, on hardening, in the formation of three-dimensional structures, proved to be extremely effective in a number of instances.

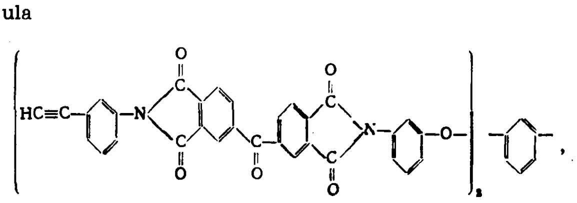
Each of the approaches enumerated above has been applied to some extent to hexafluoroisopropylidene-containing systems. Thus the introduction of ethynyl groups into the main chain of the macromolecule has been achieved in the synthesis of enyne polyimides:[44–46]



(29)

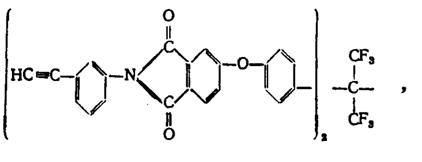
The hardening of these polymers at 265–316 °C led to the formation of "cross-linked" three-dimensional systems.

In order to make it easier to convert into finished articles the imidised oligomer Therimid-600, having the structural formula



(30)

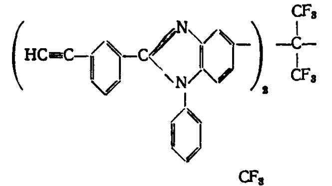
use was made of the reactive plasticiser



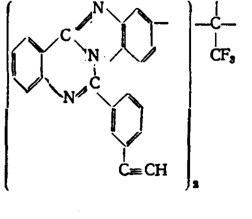
(31)

obtained by the reaction of the dianhydride of 2,2-di[4-(3,4-dicarboxyphenoxy)phenyl]hexafluoropropane [Scheme (8)] with 3-ethynylaniline.[64]

Finally, bis(*N*-phenylbenzimidazole)[65] and bisbenzimidazoquinazoline[66] with ethynyl end groups, i.e.



(32)



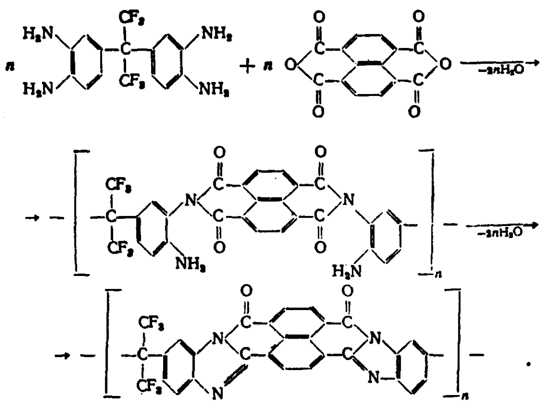
(33)

were converted into thermostable three-dimensional products by thermal polycyclotrimerisation.[64]

The extremely successful use of hexafluoroisopropylidene groups for the improvement of the "workability" of the traditional polyheteroarylenes led Korshak and co-workers to take the next step, namely to attempt the modification of "ladder" polyheteroarylenes by hexafluoroisopropylidene groups. The choice of these systems was dictated by the fact that many ladder systems have high thermal stabilities and heat resistances but are extremely difficult to work with and to convert into articles.[67–71]

The hexafluoroisopropylidene-containing ladder polyheteroarylenes were investigated within the framework of the synthesis of polynaphthoyleneazoles, namely polynaphthoylenebenzimidazoles and polynaphthoylene-*sym*-triazoles, which are the products of the three-stage reactions of bis(naphthalic anhydrides) with tetrafunctional aromatic nucleophiles [bis(*o*-phenylenediamine) and bisamidrazones of dicarboxylic acids][67] and also polybenzimidazoquinazolines and polybenzo(dipyrimidobenzimidazoles), which were obtained in two stages, by the reaction of diamines, containing benzimidazole rings in the *o*-positions relative to the amino-groups, with derivatives of aromatic dicarboxylic acids.[69–71]

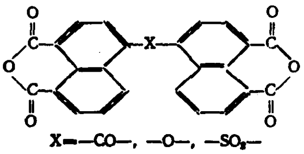
In the course of studies on hexafluoroisopropylidene-containing polynaphthoylenebenzimidazoles, a polymer was developed on the basis of 2,2-di(3,4-diaminophenyl)hexafluoropropane and the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid.[72–75] It was synthesised in accordance with the scheme



(34)

The reaction was carried out in phenolic solvents—*m*-cresol and phenol—using benzoic acid as the catalyst.[76] This made it possible to synthesise the polymer under comparatively mild conditions (at 180 °C). The reaction, occurring under homogeneous conditions, led to the formation of high-molecular-weight polynaphthoylenebenzimidazole with a degree of cyclisation close to 100%.[72–75] The polymer obtained dissolves not only in acid but also in phenolic solvents (*m*-cresol and a mixture of phenol and tetrachloroethane). Films with a tensile strength of 980 kg cm^{-2} at 25 °C and a 60% elongation on rupture, retaining satisfactory deformation-strength characteristics up to 380 °C, have been obtained from such solutions by casting.

In order to increase further the solubility of polynaphthoylenebenzimidazoles, the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid was replaced in reaction (33) by the dianhydrides of carbonyl-, oxy-, and sulphonyl-bis(naphthalic acids):[77–82]



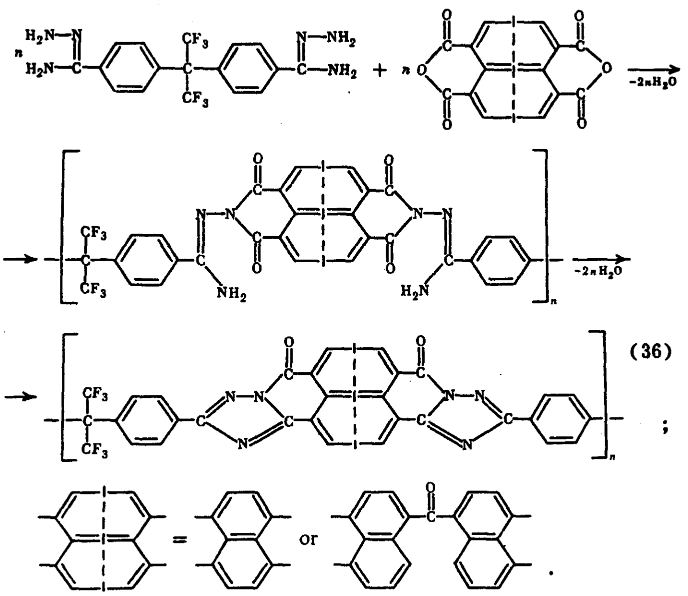
(35)

$X = -CO-,\ -O-,\ -SO_2-$

The resulting polynaphthoylenebenzimidazoles, containing alternating hexafluoroisopropylidene and other "bridging" groups, dissolve not only in phenolic solvents but also in hot N-MP. However, one should note that these polymers had very low viscosities ($\eta_{int} \approx 0.3$ dl g^{-1}), which precludes unambiguous conclusions about the influence of their structure on the solubility.

Overall, polynaphthoylenebenzimidazoles with hexafluoroisopropylidene groups, in the first place the polymer based on 2,2-di(3,4-diaminophenyl)hexafluoropropane and the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid, are of undoubted interest and, provided that the problem of the starting materials can be solved, their use may extend outside the framework of academic research.

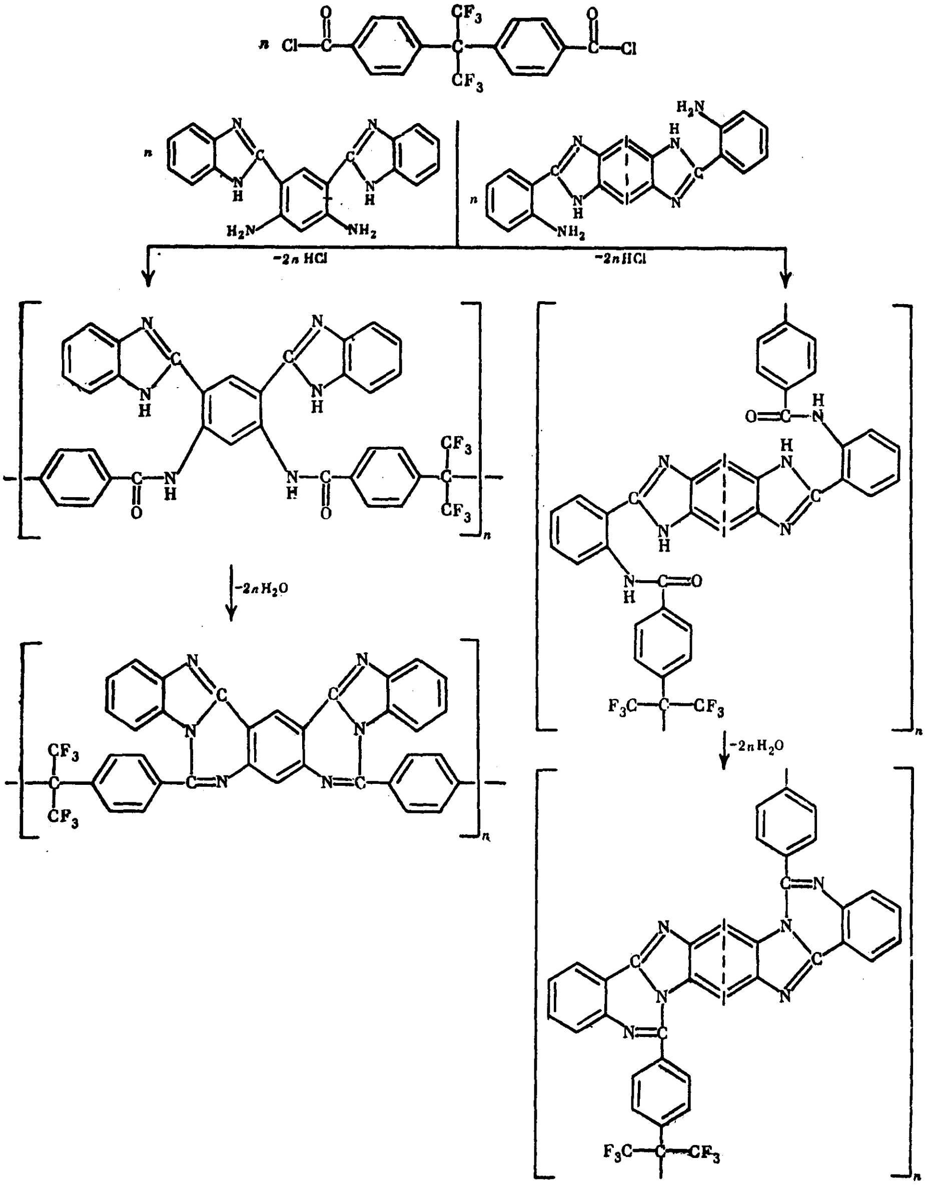
Together with polynaphthoylenebenzimidazoles, polynaphthoylene-*sym*-triazoles, which are the products of the interaction of the bisamidrazone of 2,2-di(*p*-carboxyphenyl)hexafluoropropane with bis(naphthalic anhydrides), attracted the attention of the same group of investigators:[83,84]



(36)

Polynaphthoylene-*sym*-triazoles were synthesised[83,84] under conditions identical to those used to obtain polynaphthoylenebenzimidazoles; high-molecular-weight polymers soluble in phenolic solvents and having softening temperatures in the range 380–420 °C with oxygen indices of 43–46 were obtained.

In order to synthesise polybenzimidazoquinazolines and polybenzo[di(pyrimidobenzimidazoles)] containing hexafluoroisopropylidene groups,[85–89] bis[2(2-aminophenyl)6-benzimidazoles] and 1,3-di(2-benzimidazolyl)-4,6-diaminobenzenes were made to react with the dichloride of 2,2-di(*p*-carboxyphenyl)hexafluoropropane [Scheme (37)].



(37)

The reactions were carried out under the conditions of a two-stage process; the first stage was performed at room temperature in N-MP in hexamethylphosphoramide and the second in the solid phase at 350–380 °C. The resulting polybenzimidazoquinazolines and polybenzo[di(pyrimidobenzimidazoles)] dissolved only in H_2SO_4 and CF_3COOH, but it is not clear whether this is a consequence of the severe conditions in the cyclisation processes or of the chemical structure of the polymers.

---o0o---

Analysis of the data presented in the review shows that the introduction of hexafluoroisopropylidene groups into the main chains of the macromolecules constitutes an effective method of imparting an improved solubility, an improved fire resistance, and also elasticity to rigid-chain polymers. Provided that the starting materials can be obtained, this field may prove to be promising for the preparation of polymers with a valuable set of properties.

Chromatographic Separation of Glucose and Fructose

Yu.E.Kuptsevich, O.G.Larionov, I.D.Stal'naya, L.A.Nakhapetyan, and A.Ya.Pronin

The structures, mutarotation, and the physicochemical properties of glucose and fructose as well as methods for their separation are examined. Their chromatographic separation on cation exchangers in the calcium-form is discussed in detail. A theory of the formation of complexes of carbohydrates with metal cations is described and the mechanism of the separation of glucose and fructose on cation exchangers in the calcium-form is discussed in detail. Factors influencing the chromatographic separation of glucose and fructose on sulphonic acid cation-exchange resins are also considered.
The bibliography includes 138 references.

IV. Physicochemical aspects of the chromatographic separation of glucose and fructose 303

I. INTRODUCTION

The technology used previously (up to the middle 1970's) in the preparation of fructose was based on the application of a scarce and expensive raw material—inulin, which is a fructose polymer. This prevented the wide-scale use of fructose in the food and medical industry. Only in the last decade the application of chromatographic methods permitted the large-scale manufacture of fructose by its isolation from glucose-fructose syrups obtained either as a result of the inversion of sucrose or by converting glucose with the aid of glucose isomerase.

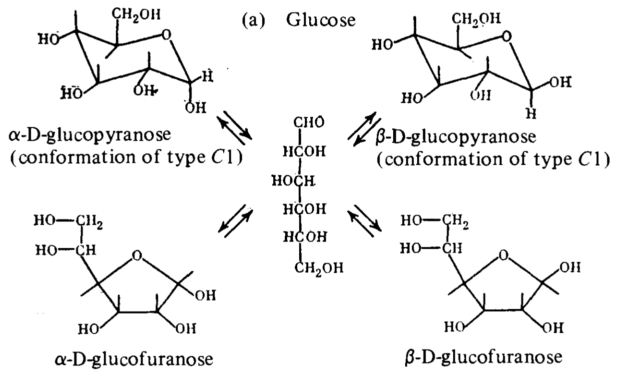
The industrial manufacture of fructose based on the chromatographic separation of glucose-fructose syrups on cation-exchange resins in the calcium-form has already been approved in some countries. The Suomen Sokeri Company [the Finnish Sugar Company] (Finland) is the largest manufacturer of fructose in the world. Its factories in Finland and the USA manufacture about two-thirds of the entire fructose produced throughout the world, i.e. 20000 tonnes annually. France occupies the second place in the manufacture of fructose and is followed by the Federal Republic of Germany and Austria.[1]

In connection with the active development of the technology for the preparation of fructose on the basis of chromatographic methods, it is important to know the properties and characteristics of the behaviour of glucose and fructose under various conditions and also the mechanism of their chromatographic separation.

II. THE STRUCTURES AND PROPERTIES OF GLUCOSE AND FRUCTOSE

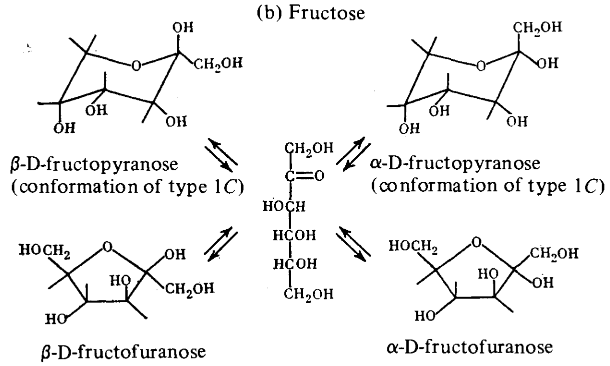
Glucose and fructose mutarotate in solution, which leads to the establishment of equilibrium between five structural forms of each of these compounds, as shown in Scheme 1:

Scheme 1



(a) Glucose

(b) Fructose



The composition of the equilibrium mixture is influenced primarily by the nature of the solvent and temperature. In the case of D-glucose, the equilibrium mixture in aqueous solution at 20 °C consists of 63.8% of β-D-glucopyranose, 36.2% of α-D-glucopyranose, and trace amounts (0.0026%) of the open-chain acyclic structure.[2,3]

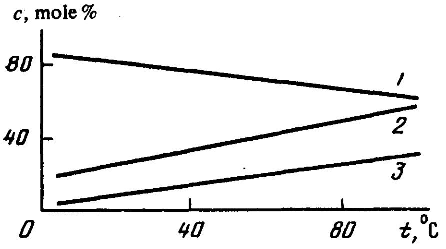
The following equilibrium composition has been established for D-fructose in aqueous solution at 20 °C: 76.4% of β-D-fructopyranose, 19.5% of β-D-fructofuranose, and 4.1% of α-D-fructofuranose.[4]

An increase of temperature leads to a linear increase of the content of fructofuranoses and a corresponding decrease of the content of β-D-fructopyranose.[5] For example, at 0 °C the equilibrium aqueous solution of D-fructose contains 84.8% of β-D-fructopyranose, 11.1% of β-D-fructofuranose, and 4.1% of α-D-fructofuranose, while at 50 °C the corresponding proportions are 55.8, 31.9, and 12.3% respectively.[6]

These data agree with the temperature dependence of the equilibrium composition of a solution of D-fructose in water obtained by Shallenberger[7] (see Figure). Equations permitting the calculation of the content of each form of D-fructose in aqueous solution as a function of temperature t are quoted in the same communication:

$$c_1 = -0.48t + 86.72 \ ,$$
$$c_2 = 0.26t + 14.32 \ ,$$
$$c_3 = 0.23t - 0.55 \ ,$$

where c_1, c_2, and c_3 are the contents of β-D-fructopyranose, β-D-fructofuranose, and α-D-fructofuranose respectively (in mole %).



Temperature dependence of the equilibrium composition of D-fructose in aqueous solution: 1) β-D-fructopyranose; 2) β-D-fructofuranose; 3) α-D-fructofuranose.[7]

The specific rotation of the equilibrium mixture of D-fructose at a temperature t can be calculated from the formula[7]

$$\alpha_D^t = 0.56t - 102.6 \ .$$

The rate of mutarotation is higher the higher the temperature. At 20 °C in aqueous solution the mutarotation process virtually terminates after 20 min.[4]

The temperature dependence of the equilibrium composition of D-glucose has a somewhat different character than for D-fructose. The contents of α-D-glucopyranose and β-D-glucopyranose are respectively 36 and 64% at temperatures ranging from 5° to 30 °C, while at 80 °C the contents are 46 and 54%.[3,8] Unfortunately there are no literature data on the ratios of glucopyranoses in the temperature range 30–80 °C.

The concentration in aqueous solutions of both glucose and fructose has almost no influence on the equilibrium composition; only a weak tendency towards an increase of the content of α-D-glucopyranose with increasing concentration of D-glucose in aqueous solution has been observed, at least in the concentration range from 5 to 65%.[8,9] Similarly, the increase of the concentration of D-fructose from 5 to 80% entails a slight decrease of the fraction of β-D-fructopyranose and the corresponding increase of the content of fructofuranoses.[9,10] The above trends lead to a difference between the equilibrium compositions of D-glucose and D-fructose by only 3–4%.

The fractions of all the forms present in solution depend on their relative free energies. The "chair" form, in which the anomeric OH group is in the axial position, i.e. the 1C conformation, is more stable for D-fructose.[11,12] β-D-Fructopyranose has this conformation also in the crystalline state. In general the furanose form in which the O(2) and O(3) atoms are in the *cis*-positions is more stable for any ketohexose. In this case the interaction between O(3) and the hdyroxymethyl group is weakened. For this reason, the β-D-fructofuranose form of D-fructose, present in aqueous solutions in greater amounts than the α-D-fructofuranose form, is more stable. The stability of furanoses increases in solution in dimethyl sulphoxide (DMSO), while pyranoses are more stable in water.[12]

The composition of the D-fructose equilibrium mixture at 20 °C is presented in the Table as a function of the nature of the solvent. It permits the conclusion that the content of fructopyranoses increases, while that of fructofuranoses diminishes with increasing solvent polarity. This is partly associated with the hydration of the hydroxy-groups, because the large solvated groups are subject to less steric hindrance when the carbohydrate exists in solution in the form of pyranose in the "chair" conformation and not in the form of the furanose ring. In non-aqueous solvents, this effect is less important, because solvation in such solvents cannot be quite so appreciable as in water, the hydroxy-group occupies a smaller volume, and the advantages of the pyranose conformations compared with the furanose conformations diminish.[14]

The influence of the nature of the solvent on the composition of the equilibrium D-fructose mixture at 20 °C.

Solvent	Content, mole %		
	pyranoses	furanoses	refs.
Dimethyl sulphoxide	18.5	81.5	[12]
Ethanol (90%) + water (10%)	43	57	[2]
Ethanol (80%) + water (20%)	49	51	[2]
Pyridine*	53	42	[13]
Water	76	24	[4.12]

*The solution in pyridine contains 5% of the keto-form.

The majority of aldopyranoses, including glucopyranose, exist in aqueous solution in a conformation of type C1, because it is energetically more favourable. For example, the free energy of the C1 conformation of α-D-glucopyranose is 2.4 kcal mol^{-1}, while the energy of the 1C conformation is

6.55 kcal mol^{-1}; in the case of β-D-glucopyranose, the free energies of these conformations are 2.05 and 8.0 kcal mol^{-1} respectively.[15] Thus the type *C*1 conformation predominates for D-glucose (see Scheme 1).

The free energy of α-D-glucopyranose is somewhat higher than that of β-D-glucopyranose owing to the axial disposition of the anomeric OH group. For this reason, a smaller amount of α-D-glucopyranose (36%) is observed in aqueous solution compared with β-D-glucopyranose (64%), in which all the OH groups are equatorial.[2] In aqueous solutions D-fructose exists in a type 1*C* conformation[12] (Scheme 1).

The equilibrium aqueous solution of D-glucose has α_D^{20} = +52.7°, while for the D-fructose solution under the same conditions we have $\alpha_D^{20} = -92.4°$.[16]

D-Glucose and D-fructose are monosaccharides, which readily undergo chemical changes. Under the influence of bases, they undergo isomeric interconversion via the intermediate enol, accompanied by the formation of mannose. Thus a mixture of D-glucose, D-fructose, and D-mannose is obtained from D-glucose in a very dilute solution of alkali.[14] In aqueous alkaline solutions at higher pH (pH ≥ 9), the sugar forms a complex with the alkali, which is followed by alkaline transformation and decomposition.[17] In a study[18] of the kinetics of the decomposition of fructose and glucose in an alkaline medium on heating, it was noted that fructose decomposes appreciably faster than glucose.

In general, fructose is chemically much less stable than glucose. Thus heating of an alkaline solution of D-fructose at pH 8 and 80 °C for 20 min leads to the development of an appreciable yellow colour in solution and, as the pH is raised, the intensity of the colour rises rapidly.[19]

The study of the transformation of sugars in solution in pyridine showed that the double bond can migrate via the enediol mechanism along the entire carbon chain. The same mechanism constituted the basis of a wide variety of reactions of monosaccharides, in particular their cleavage by strong acids and bases.[20] Glucose and fructose, especially glucose, are very resistant to the action of acid. Thus, under mild conditions, the interconversion of the sugars is possible, while under severe conditions dehydration, leading to the formation of furfural and related compounds, takes place.

Heating of D-glucose in dilute sulphuric acid solution at 100 °C leads to the formation of D-fructose, D-arabinose, and small amounts of D-mannose and D-xylose. Under the same conditions, fructose undergoes the aldose–ketose isomerisation.[21]

The products of the conversion of D-glucose by various dilute acids are D-fructose, D-mannose, isomaltose, gentiobiose, etc. The mixture composition depends on the nature of the catalyst employed.[22] Analogous results have been obtained in another study,[23] where, however, it was emphasised that oligomers are formed only in 10% solution of glucose when a 0.01–0.2 *N* solution of hydrochloric acid is used.

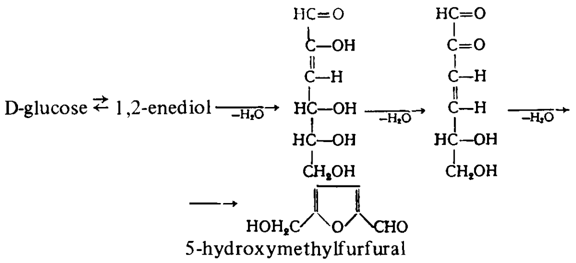
Under more severe conditions, the dehydration becomes the dominant process. The dehydration of hexoses in an acid aqueous medium leads to the formation of not only 5-hydroxymethylfurfural but also of 2-hydroxyacetylfuran.[24] In addition difuryl ether may be formed.[25]

Fructose undergoes condensation in an acid medium mainly at moderate temperatures (~60 °C) and pH 1.3–3.5 with formation of levanbiose, inulobiose, and other products.[26] At pH ≥ 3.9, D-fructose is dehydrated without the formation of 5-hydroxymethylfurfural, while at pH > 4.5 it isomerises to D-glucose.[27]

Thus the conversion of glucose and fructose in alkaline and acid media can result in the formation of a wide variety of products whose composition depends on the pH of the medium, the reaction time, temperature, the nature of the catalyst, and the concentrations of the monosaccharide and catalyst.

The dehydration of D-glucose on heating in aqueous solution can be described by the scheme[28]

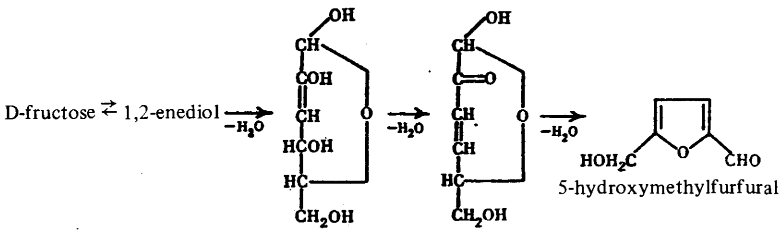
Scheme 2



A 2,3-enediol, which is ultimately converted into 2-hydroxyacetylfuran, can also be formed from D-glucose.

Dehydration of D-fructose on heating in aqueous solution can be described by the scheme[29]

Scheme 3



D-Fructose reacts chemically extremely readily, which has been demonstrated by Shamgar and Leibowitz.[30] After D-fructose has been kept in absolute ethanol at room temperature for some time, methylglyoxal, difructosoanhydrides, diheterolevulosans, β-methyl fructopyranoside, and two glucose derivatives are detected in solution after a time. Thus, under these conditions, D-fructose undergoes anhydridisation, isomerisation, dimerisation, and decomposition into fragments, each containing three carbon atoms. D-Glucose undergoes no changes whatever under the same conditions.[30]

In a cold aqueous solution, fructose is 1.6 times sweeter than sucrose; however, in hot aqueous solution the sweetness of fructose diminishes appreciably. It has been shown[2,4] that the sweetness of fructose depends on the ratio of the tautomeric forms. Fructofuranoses have almost no sweet taste, the carrier of which is in fact β-D-fructopyranose. If the sweetness of sucrose is assumed to be 100%, then that of β-D-fructopyranose is 180–200% and that of fructofuranoses is 0%. The sweet taste of β-D-fructopyranose is determined by the presence of three-component groups incorporating the anomeric hydroxy-group, the oxygen atom in a primary alcoholic group, and the ring methylene carbon atom.[31] Since it has been shown[7] that the amount of β-D-fructopyranose diminishes with increase of temperature and is accompanied by the corresponding increase of the amount of furanoses, the weakening of the sweet taste of fructose in a hot aqueous solution becomes understandable.

III. METHODS OF SEPARATION

There exist many methods for the separation of glucose–fructose mixtures. It is possible to distinguish five main groups of methods.

1. Methods based on dialysis using ion-exchange membranes.[32,33] These methods require the application of very complex equipment and also the expenditure of much electrical energy.[33] For this reason, they are extremely expensive.

2. Methods based on chemical reactions with one of the mixture components (glucose or fructose). Here use is made of the oxidation of glucose to gluconic acid with subsequent precipitation of the latter by calcium salts and its removal from fructose solution,[34,35] the formation of hydrazones from one of the sugars and their subsequent hydrolysis,[36,37] the interaction of the sugars with metal carbonyls and subsequent hydrolysis of one of the resulting products,[38] the formation of chemical compounds of phenol-containing resins with glucose,[39] etc. The fructose obtained by these methods requires careful purification and glucose, which is a valuable sugar, is converted into waste.

3. Methods based on the differential crystallisation of glucose and fructose. Many such methods exist. For example, the following procedures are used: cooling of the invert syrup with subsequent introduction of glucose seed crystals, the crystallisation of glucose, and its separation from the fructose solution;[40] the formation of a complex of glucose and sodium chloride, which crystallises from the solution;[41] preliminary differential crystallisation of glucose and fructose with subsequent separation on a cation exchanger;[42] differential crystallisation in methanol using the difference between the crystallisation temperatures of glucose and fructose.[43,44] However, completely pure glucose and fructose cannot be obtained by these methods.

4. Methods based on the isolation of fructose in the form of complexes with a calcium compound, for example $Ca(OH)_2$ [45–47] or $CaCl_2$.[48–52] These methods are relatively ineffective owing to the low yield of the final product (10–20%).

5. The group of ion-exchange chromatographic methods, which can be in its turn subdivided into three main subgroups:

(a) Chromatographic separation of glucose and fructose on zeolites, including zeolite X, containing K^+ cations and capable of selective adsorption of glucose;[53–56] on a zeolite containing NH_3^+, K^+, Na^+, Ca^{2+}, and Ba^{2+} cations and capable of the selective adsorption of fructose;[57] on zeolites X, Y, or L containing the Li^+, Na^+, K^+, Cs^+, Be^+, Mg^{2+}, Ca^{2+}, Ba^{2+}, etc. cations[58–60] and also on a mineral adsorbent of the "Sorbex" type.[61]

(b) Separation of glucose and fructose on anion-exchange resins. The separation is usually carried out at 40–60 °C on anion-exchange resins, usually of the Dowex I type, in the bisulphite- or sulphite-form, using water as the eluent.[62–72] However, the employment of an anion exchanger in the above forms results in the presence of SO_3H^- and SO_3^{2-} ions in the glucose and fructose obtained, because these are readily eluted by water.[65] In order to avoid the presence of these impurities, it is necessary to employ additional purification columns with the anion exchanger in the OH-form, which entails additional dilution of the sugar solutions. A mixture of an anion exchanger in the bisulphite-form with 5% of a cation exchanger in the sodium- and hydrogen-forms has been used,[77] which made it possible to improve the separation of the glucose–fructose mixture.

(c) The separation of glucose and fructose on cation-exchange resins. Sulphonated polystyrene resins cross-linked by divinylbenzene (DVB) and containing alkali metal or alkaline earth metal cations are usually employed. Other forms are also used. When glucose and fructose were separated on the Dowex 50 × 4 cation-exchange resin in the Ba-form, the glucose and fructose peaks were found to be markedly diffuse, on the Ag-form a weak separation was observed, while on the Sr-form a fairly effective separation was achieved.[78] The use of the sodium-form of the cation exchanger[79] does not allow the separation of the glucose-fructose mixtures, but partial separation of mono-, di-, and tri-saccharides was noted. Comparison of the efficiencies of the various forms of cation-exchangers leads to the conclusions that the Ca^{2+} cation is most suitable for the separation of glucose and fructose. The same conclusion follows from the study of Mountfort.[80]

Cation-exchange resins in the Ca-form with a degree of cross-linking equivalent to 2–8% of DVB are used in most studies.[81–97] The eluent is water, the separation is carried out at 50–70 °C, and the concentration of the syrup introduced amounts to 50% and above in terms of the dry substances. The resin is normally employed in the form of 0.2–0.5 mm beads and an attempt is made to employ as narrow a fraction as possible. An important factor, which influences the efficiency of the chromatographic separation, is the density and uniformity of the packing of the resin bed in the column. A study[98] has been devoted to this question and a method has been proposed whereby a dense packing of the resin in the Ca-form with a bead size of 0.3–0.6 mm can be achieved. It is based on the ability of sulphonated polystyrene resins to swell in a concentrated $CaCl_2$ solution (20%) to a lesser extent than in water. A suspension of the resin in calcium chloride solution is supplied into the column and the resin is then washed with water.

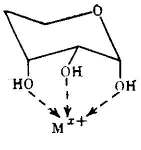
Cation-exchange resins of the Dowex 50 type have been used,[81–98] but other cation exchangers, for example Duolite C 20 × 4,[99] Amberlite IR-120B,[100] Permutit Q,[111] and Duolite C 25[102] have also been employed in the calcium-form under conditions analogous to those indicated above.

Semicontinuous processes have been used in a number of investigations[103–107] for the separation of glucose and fructose: the "modelled moving bed" method[103] on a sulphonic acid cation-exchange resin in the Ca-form; the "fluidised bed" method[104] on a strongly acid cation-exchange resin in the Ca-form; the "cyclic zonal separation" method[105] on an aminoethylcellulose derivative; the "moving inlet" method[106] on a cation-exchange resin in the Ca-form. A procedure has also been developed in which use is made of a column containing alternating reaction and adsorption zones.[107] Glucose then isomerises in the reaction zone to fructose, which is adsorbed in the adsorption zone.

IV. PHYSICOCHEMICAL ASPECTS OF THE CHROMATOGRAPHIC SEPARATION OF GLUCOSE AND FRUCTOSE

Fructose, glucose, sucrose, and other carbohydrates form 1:1 molecular complexes with bases. Reducing sugars, which include glucose and fructose, give rise to more stable complexes than non-reducing sugars, for example, sucrose.[108–110] Metal cations have different complex-forming capacities, which depend on their valence and size. Thus, according to Dangre,[111] univalent metal cations can be arranged in the following sequences in terms of their complex-forming capacities: $Na^+ > K^+ > Li^+$ for glucose and $K^+ > Na^+ > Li^+$ for fructose. The sequences of bivalent cations are as follows: $Sr^{2+} > Mg^{2+} > Ca^{2+} > Ba^{2+}$ for glucose and $Ca^{2+} > Sr^{2+} > Ba^{2+} > Mg^{2+}$ for fructose. However, not all carbohydrates form complexes with cations in aqueous solution and the complexes themselves have different stabilities. It has been possible to demonstrate by NMR and electrophoretic methods that complex formation with metal cations is possible in the presence of three OH groups in favourable steric positions. This situation arises when three neighbouring OH groups are arranged in the sequence axial–equatorial–axial (*a–e–a*).[112–115]

On the basis of NMR and electrophoretic data, Goulding proposed in 1975[116] his theory of the formation of complexes of carbohydrates with metal cations. The most stable complexes are formed in the presence of the *a–e–a* sequence of three neighbouring OH groups in the pyranose ring or the *cis,cis*-sequence of three OH groups in the furanose ring:



a–e–a

The stability constants K_S of such complexes are in the range 1–5 $mole^{-1}$. $K_S = 0.1\ mol^{-1}$ for the *a–e*(*cis*) sequence. The *e–a–e* sequence gives rise to a less stable complex. Finally the *e–e* sequence is even less favourable than the *a–e* sequence and complexes are not formed at all for the *a–a* sequence. Hence follows an important conclusion: the greater the number of favourably oriented pairs of OH groups in the carbohydrate molecule, the more stable the complexes. For example, α-D-glucopyranose and α-D-fructopyranose each have one pair of OH groups in the *a–e* sequence, β-D-fructopyranose has two pairs, while β-D-glucopyranose has no such pairs.

In relation to allose, it has been demonstrated[112] that the complexes of furanoses are always less stable than those of pyranoses.

The optimum radius of the cation for complex formation is ~1.0 Å. The greater the charge of the cation, the easier the formation of the complex: the sizes of Na^+, Ca^{2+}, and La^{3+} are 0.97, 0.99, and 1.02 Å respectively.[112]

It follows from the data of Goulding,[116] who determined the capacity coefficients of sugars (k') on the Aminex A-5 cation-exchange resin with a particle size of 11 ± 2 μm using different cations, that fructose forms fairly stable complexes with K^+, Ag^+, Tl^+, and Ca^{2+} and slightly less stable complexes with Sr^{2+}. On the other hand, on the cation exchanger containing the K^+, Ag^+, and Tl^+ cations, the values of k' for glucose are also fairly high, which means that, when these cations are employed, it is not possible to achieve a satisfactory separation of glucose–fructose mixtures. Since strontium is toxic, one may conclude that the most suitable cation for the selective complex formation with fructose in the presence of glucose is that of calcium.

The mechanism of the separation of glucose and fructose is most probably based on the presence in β-D-fructofuranose of two *cis*-OH groups attached to the five-membered ring.[117] The two pairs of OH groups in the *a–e* sequence in β-D-fructopyranose have hardly any significant influence on the separation, because they can ensure the formation of only very weak complexes with the cation. Glucose, for which only α-D-glucopyranose among all the possible isomers has one pair of OH groups in the *a–e* sequence, forms an even weaker complex. In the course of separation on the column, the sugars mutarotate. The binding of β-D-fructofuranose to calcium shifts the mutarotation equilibrium in the liquid phase. The faster this process, the narrower the peak of the fructose eluted.

An analogous phenomenon takes place also with glucose. Under favourable conditions, where the mutarotation is slow, the glucose and especially fructose peaks can be appreciably diffuse, which can be explained by the fact that β-D-glucopyranose is eluted initially, is followed by α-D-glucopyranose, then β-D-fructopyranose, and finally β-D-fructofuranose. The available data, demonstrating an appreciable narrowing of the carbohydrate peaks with increase of temperature, may serve as confirmation of this finding.[83,84,118] In the case of fructose, an increase of temperature accelerates the mutarotation process itself in the first place and shifts the equilibrium towards furanose in the second place.[7] However, another factor then begins to operate—the stability of the complex of fructose with the cation; an increase of temperature diminishes the stability of the complex. In order to achieve the optimum separation, it is essential to select a temperature at which the optimum combination of the stability of the complex, the rate of mutarotation, and the composition of the initial equilibrium mixture is achieved. Furthermore, there are other factors, which will be described below.

The presence of H^+ and also OH^- ions sharply accelerates the mutarotation and also facilitates the separation of glucose and fructose.[92] It is of interest to note that, when the cation exchanger is converted into the calcium-form by a standard method with a 10% solution of calcium chloride, part of the resin is bound to remain in the H^+-form (3–5%). If the resin is fully converted into the Ca-form (and this is possible at an elevated temperature or when an alkaline solution of calcium chloride is used), then the separation of glucose and fructose is impaired. This demonstrates the possibility of mutarotation processes in chromatographic columns. Apart from the H^+ and OH^- ions, triethyl- and trimethyl-amines cause a sharp acceleration of the mutarotation. The addition of very small amounts of triethylamine to the eluent (water) narrows the fructose and especially glucose peaks.[119] The effect of triethylamine can apparently be explained by the fact that it makes the solution weakly alkaline and this accelerates sharply the mutarotation.

It has also been noted that the stability of the complexes of sugars with metal cations is influenced by the nature of the eluent. The stability constants of the complexes in ethanol are known to be appreciably higher than in water;[120,121] however, owing to the similarity of the partition coefficients of glucose and fructose, it is usually not possible to achieve their satisfactory separation in ethanol.

The employment of anion-exchange resins for the separation of glucose–fructose mixtures leads to undesirable transformations in the individual sugars.[122,123] The decomposition of glucose and fructose with formation of glycolic and citric acids is actually observed on strongly basic anion-exchange resins, for example on Amberlite IRA-400.[124]

The decisive process in chromatography on granular materials, including cation-exchange resins, is diffusion of the sugar within the resin particles,[125] which depends in its turn on the flow rate of the mobile phase, temperature, the resin grain size, the degree of cross-linking of the resin, and the nature of the solvent and the sugar.

An increase of temperature accelerates the diffusion,[126] but, since it entails the narrowing of the peaks of the components separated, it does not always improve the separation of the mixture, since k' diminishes at the same time.[127] On the other hand, at low temperatures sugars are adsorbed more strongly and the resolution can therefore be improved, provided that the influence of the decrease of the rate of mass transfer is small and the influence of mutarotation is suppressed.[119] It has been noted[117,128] that a decrease of temperature improved the separation of glucose and fructose on a cation-exchange resin in the Ca-form.

One of the important factors in the chromatographic separation of sugars is the flow rate of the mobile phase. It is limited by the diffusion of sugars within the resin particles.[129–131] At a high flow rate of the mobile phase, the peaks of the substances being separated become asymmetric, and long "tails" appear, their presence being explained by the fact that a proportion of the sugars continue to diffuse from the resin particles into the mobile phase.

A decrease in the resin particle size increases the rate of mass transfer. For example, the change in the bead size of the Dowex 21(K) resin from 45–75 to 15–40 μm improved the separation of glucose, sucrose, and raffinose by a factor greater than 3, causing a sharp narrowing of the peaks of the test substances.[129] The greater efficiency of the Dowex 50 × 8 cation-exchange resin in Ba-form[132] compared with the Ca-form[133] can be explained by the smaller size of the resin particles employed in the former case (0.038–0.075 mm compared with 0.15–0.30 mm). A relation between the cation exchanger bead size and the yield of pure fructose has been observed:[134] the smaller the bead size, the greater the yield. Furthermore, the employment of narrower resin bead fractions causes an additional improvement in the separation of the test substances, which is apparently largely related to a more uniform packing of the beads in the bed. The use of a resin with a large bead size necessitates the employment of very low flow rates of the mobile phase, owing to the low rate of mass transfer in the large resin beads, and precludes the attainment of a satisfactory separation of the glucose–fructose mixture.[135]

Since sugar molecules have a complex steric configuration and in order to achieve complex formation with the active centre of the cation exchanger they must assume a definite position which ensures the formation of bonds of approximately equal length between the metal and the complex-forming OH groups of the carbohydrate,[114,136] it is clear that the steric structure of the cation-exchange resin must influence the chromatographic separation. The steric structure of the cation exchanger is in its turn determined by the degree of cross-linking. The degree of cross-linking of the cation exchanger must not exceed a definite limit.[79,84,88,90,92,101,137] On the other hand, analysis of the above studies leads to the conclusion that the degree of cross-linking should not be below a definite limit. The most favourable conditions are apparently ensured by a degree of cross-linking by DVB of 4–8%. The use of cation-exchange resins with a lower degree of cross-linking, for example of the KU-2-2(Ca) cation-exchange resin, in which the degree of cross-linking is 2%,[138] has been shown to[137] lower the efficiency of the separation of glucose and fructose. The causes of this are not altogether clear, but the main deficiency of cation-exchange resins with a low degree of cross linking (2% of DVB and below) is their low mechanical strength.

***

Thus, in devising various technologies for the manufacture of fructose, based on chromatographic methods for the separation of glucose–fructose mixtures on cation-exchange resins, account must be taken of several most important factors.

Firstly, glucose and especially fructose are chemically extremely unstable carbohydrates and any operations with these sugars require mild conditions (pH 5–7, temperature ≤60 °C). Secondly, calcium cations are the most suitable for the selective complex formation with fructose in the presence of glucose and the mechanism of their separation on cation-exchange resins in the Ca-form is most likely to be based on the formation of a relatively stable complex of β-D-fructofuranose with calcium. Thirdly, the degree of cross-linking of the cation-exchange resin, equivalent to 4–8% of DVB, apparently ensures the optimum separation of glucose and fructose. Finally, when the cation-exchange resin is treated with a solution of calcium chloride, an attempt to achieve its conversion into the 100% of the Ca-form should not be made; not less than 3–5% of the sulpho-groups of the cation-exchange resin should remain in the H-form.

In optimising the conditions for the chromatographic separation of glucose and fructose, it is essential to take into account the fact that an increase of process temperature lead in this instance not only to the acceleration of the mass exchange of the carbohydrates within the cation exchanger beads but also to a shift of the mutarotation equilibrium of the sugars in the liquid phase and to a decrease of the strength of the complexes of the monosaccharides with calcium. A significant increase of the efficiency of the separation of glucose and fructose can be attained by employing cation exchanger beads with the smallest possible size. The latter makes it possible to improve the resolution of the glucose and fructose peaks, to increase the flow rate of the mobile phase, and to increase the amount of charge applied to the column.

Triplet Exciplexes in the Photochemistry of Quinones

P.P.Levin and V.A.Kuz'min

The results of studies on the kinetics and mechanisms of reactions involving the transfer of an electron and a hydrogen atom to quinone molecules in triplet states are surveyed and the spectroscopic-kinetic characteristics of the triplet exciplexes of quinones and the role of the electron donor-acceptor interactions and hydrogen-bonded complexes in the photochemistry of quinonoid compounds are examined. Attention is concentrated on the experimental investigation of the kinetics and mechanisms of the primary photochemical processes by modern flash photolysis methods.
The bibliography includes 276 references.

INTRODUCTION

Under the influence of light, quinonoid compounds (Q) enter into a wide variety of chemical reactions. In most cases the primary step in the photochemical reactions of quinones is the transfer of an electron and a hydrogen atom to the molecules of quinones in triplet states (^{3}Q), electron donor—acceptor interactions and the formation of a hydrogen bond playing an important role in these processes.

A number of reviews have been devoted to the photochemistry of quinones[1-6] and the photochemical oxidation-reduction reactions of chloroquinones have been examined.[7] This review is devoted to the primary steps in the photochemical reactions of quinones, the transfer of an electron and a hydrogen atom to the molecules of quinones in triplet states, and also the properties of triplet exciplexes.

Important data on the kinetics of the elementary reactions and the mechanism of the transfer of an electron and a hydrogen atom with participation of ^{3}Q have been obtained in recent years, in many respects as a result of the development of methods for the investigation of fast reactions, especially flash photolysis with laser excitation sources in the nanosecond and picosecond ranges; the formation of triplet exciplexes in these chemical processes has been demonstrated.

II. ELECTRON DONOR–ACCEPTOR COMPLEXES OF QUINONES IN THE GROUND AND TRIPLET STATES

1. Electron Donor–Acceptor Complexes of Quinones in the Ground State

Quinonoid compounds are relatively strong electron acceptors and form electron donor–acceptor complexes (EDA complexes) with compounds having electron-donating properties.[8] The energy of the bond between the molecules in the EDA complexes is usually close to that characteristic of the van der Waals interaction and is comparable to or somewhat exceeds kT,[8] the nature of the interaction between the donor and acceptor in the complex being extremely varied.[9]

In the crystalline state and in the absence of a localised interaction, the planes of the rings of the quinone and of the aromatic molecule comprising the EDA complex are parallel and the distance between them is 3.1–3.55 Å.[8] In the presence of a hydrogen bond, the parallel arrangement breaks down; for example, when the donor is phenol, then the angle between the ring planes reaches 10°.[10] The energy of the hydrogen bond in the complex of *p*-benzoquinone (I) with phenol is 5.05 kcal mol^{-1} in the crystalline state, while the entropy is 15 cal mol^{-1} K^{-1}.[11]

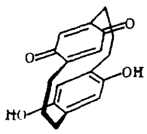
The study of the IR spectra of crystalline complexes of compound (I) with aniline derivatives demonstrated the presence of two non-equivalent carbonyl groups in the molecule of compound (I), which is due to the localised character of the interaction and the appreciable contribution by the ionic component.[2] The formation of complexes between compound (I) and donors having a primary or secondary amino-group is promoted additionally by the presence of a hydrogen bond between the NH and C=O groups to which the ionic component makes an appreciable contribution. The slight non-equivalence of the carbonyl groups in the molecule of compound (I) is also observed in the complex of this compound with *NN*-dimethylaniline and is caused by the localised charge transfer from the unshared pair of the N atom to one of the C=O groups. In the EDA complex of compound (I) with *NNN'N'*-tetramethyl-*p*-phenylenediamine (TMPD) the C=O groups are equivalent in the crystalline state; the complex is ionic with a delocalised interaction.

Quinones do not form EDA complexes with triethylamine and bipyridyl in solutions, apparently as a consequence of the steric hindrance generated by the alkyl substituents in the donor. The formation of EDA complexes with amines of the type of triethylenediamine and quinuclidine in solutions has been noted.[13]

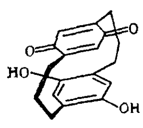
The formation of EDA complexes between quinones and electron donors is accompanied by the appearance in the IR spectrum of a charge-transfer (CT) band.[8] The energy of the CT band is a linear function of the one-electron half-wave potential for the reduction of the quinone in acetonitrile, i.e. $E_{1/2}(Q^-/Q)$, the slope being 0.95 for hexamethylbenzene and 0.8 for other donors.[14] The different slopes of the above relations for hexamethylbenzene compared with other donors may be explained by the steric influence of the methyl groups in the donor, which increases the distance between the donor and the quinone in the EDA complex.[15] The slopes of the analogous relations between the energy of the CT band and the ionisation potential of the aromatic electron donor are close to 0.9.[15,16] A slight deviation from the linear relation between the energy of the CT band and $E_{1/2}(Q^-/Q)$ has been observed for quinones with strong electron-accepting substituents [cyano-derivatives of the quinone (I)].[17]

The occurrence of a localised interaction influences significantly the position of the CT band. This is particularly pronounced for complexes of the quinhydrone type. Thus the formation of a relatively weak hydrogen bond in the EDA complexes of quinones with hydroquinones or *p*-phenylenediamines on passing from a solution to the crystalline state leads to a decrease of the energy of the CT transition by 5000–11000 cm^{-1}.[18–21] This shift is caused precisely by the formation of the hydrogen bond, since the position of the CT band in the spectra of complexes without a hydrogen bond depends only slightly on the state of aggregation.

The pronounced dependence of the interaction in the complexes of the quinhydrone type on the mutual orientation of the quinone and the donor has been demonstrated in a study of the paracyclophane derivatives (A) and (B):[22]



(A)



(B)

The CT band in the spectrum of compound (A) is observed at 462 nm, while the intensity of the absorption of compound (B) in this region is 30 times lower; its CT band has a maximum at 346 nm. The methoxy-derivatives of (A) and (B) behave analogously. Consequently, the hydrogen bonds in these structures do not play any role (the presence of the hydrogen bonds in the crystalline complexes shifts the CT band to the region of 600 nm[19]). The electron donor–acceptor interaction in the given structures is analogous to the interaction in the corresponding π-complexes formed in solution. A CT band has also been observed for multilayer structures analogous to those of compounds (A) and (B) but with an additional benzene ring between the quinone and the hydroquinone; however, the relative orientation of the donor and the acceptor in such structures does not play any role.[23]

The energy of the CT state in the EDA complexes of quinones depends significantly also on the molecular environment. The increase in solvent polarity on passing from cyclohexane to acetonitrile lowers the energy of the CT transition from 1.43 to 1.34 eV for the EDA complex of chloranil (II) with TMPD.[24]

Specific interaction with the medium may exert a strong influence on the formation of quinhydrone complexes in solution. The spectra of the EDA complexes of *ortho*-quinones with the corresponding hydroquinones contain a CT band with the maximum at 440 nm. However, on dissolution of the specimens in alcohols and ethers, the formation of complexes is not observed owing to the presence of hydrogen bonds to solvent molecules.[25]

Quinones are also capable of forming complexes with aromatic amines having an ionic structure.[8,26] The ionic complexes can exist simultaneously with the non-polar EDA complexes and can be detected only in relatively polar solvents or crystals. The dynamics of the system incorporating simultaneously the polar and non-polar EDA complexes has been investigated in detail for complexes of compound (II) with TMPD.[24,27–32] Apart from the absorption characteristic of the non-polar EDA complex, a 3 : 1 mixture of ethyl ether and isopropyl alcohol exhibits bands at 635, 520, and 434 nm due to the absorption by the corresponding radicals and there is an inverse CT band at 1100 nm.[29,30] The formation of radicals in this system has been demonstrated by EPR.[24] The equilibrium

$$Q + D \rightleftarrows Q \ldots D \rightleftarrows Q^- \ldots D^+ \qquad (1)$$

has been postulated.

Ionic complexes arise when the concentration of the non-polar EDA complex exceeds a specific value;[29,30] they are formed on aggregates of non-polar EDA complexes of the cluster type as a result of the increased polarity of the micro-environment in these aggregates, which promotes ionisation. However, the aggregation of neutral EDA complexes has not been observed by Staab and Herz[22] even at temperatures down to 185 K.

In polar solvents neutral EDA complexes of quinones with aromatic amines dissociate into free radical-ions,[8,26,27] whose presence in acetonitrile solutions of compound (II) with TMPD has been detected by EPR.[31] The kinetics of the dissociation reaction have been investigated by flash photolysis in acetonitrile solutions of TMPD and 2.6-diphenyl-1,4-benzoquinone (III);[34] the EDA complexes dissociate with a rate constant of 5.5×10^3 s^{-1} and the enthalpy and entropy of activation are 3.6 kcal mol^{-1} and -29 cal mol^{-1} K^{-1} respectively. The large negative entropy indicates a significant reorganisation of the molecules of the medium on dissociation of the non-polar EDA complex into radical ions. Comparison of the dissociation constants with $E_{1/2}(Q^-/Q)$ for a series of quinones showed that the experimentally observed free energy of electron transfer is below values calculated from the corresponding one-electron potentials.[34]

It is noteworthy that in the quinhydrone complexes thermal electron and hydrogen atom transfer reactions take place.[20,21,25]

Thus the structure of the molecular environment as well as the mutual orientation of the reactants in the complex and the specific features of the interactions between them influence significantly the energy of the state with total charge transfer and hence the kinetics of the reactions involving the charge transfer stage.

2. Triplet Exciplexes of Quinones

The electron affinity of the molecule in an electronically excited state is higher than in the ground state by an amount which is usually set equal to the excitation energy.[35] For this reason, EDA complexes in the triplet state—the triplet exciplexes (TE)—have a structure characterised by a higher contribution of the state with total charge transfer compared with the structure of the corresponding EDA complexes in the ground state. Like the EDA complexes in the ground state, the TE can also be divided on the basis of their structure into polar and non-polar depending on the contribution of the polar state with total CT.

The non-polar triplet states of the EDA complexes of quinones differ significantly in their characteristics from the corresponding ^{3}Q. For example, compound (I) and its derivatives virtually do not phosphoresce in frozen solutions in solvents without electron-donating properties. The introduction of weak electron donors (aromatic hydrocarbons) into these solutions leads to a significant increase of the phosphorescence intensity,[36-38] which is observed on photo-excitation at the wavelength in the region of the CT band. The phosphorescence bands of the EDA complexes of quinones are broadened and displaced to longer wavelengths compared with the phosphorescence spectra of the quinone and to a greater extent the higher the electron-donating capacity of the aromatic hydrocarbon.[38] The phosphorescence spectra of the EDA complexes of compound (I) and its derivatives with aromatic hydrocarbons are similar, as regards the position and form of the bands, to the phosphorescence spectrum of the initial quinone, which shows that the main contribution to the structure of the EDA complexes in the triplet state comes from the structure with excitation localised at the quinone molecule.

The triplet states of the EDA complexes with localised excitation, formed by compound (II) and weak electron donors, have been detected from their absorption by flash[39] and laser[40,41] photolysis methods. The triplet–triplet absorption spectra of solutions of compound (II) in benzene, acetone, and dioxan at room temperature or in a diethyl ether–isopentane–ethyl alcohol (EPA) mixture in the presence of methyl methacrylate at 77 K have weak bands in the range $\lambda > 550$ nm, there is virtually no absorption of compound (II) in the triplet state. The triplet exciplexes formed on quenching of duroquinone (IV) in the triplet state by weak electron donors in non-polar solvents and in acetonitrile have analogous absorption spectra.[42-44]

The photoexcitation of the EDA complexes of quinones in the region of the CT band in systems where the energy of the state with total charge transfer is below that of the triplet state does not lead to the formation of any intermediates.[38,45-48] The main channel leading to the deactivation of the polar electronically excited singlet state of the EDA complex is rapid non-radiative transition to the ground state. The rate of this process is determined by the rate of the vibrational relaxation and the relaxation processes in the molecular environment and amounts to $\geq 10^{11}$ s^{-1}, which is significantly higher than the rate of dissociation into radical-ions and the rate of the singlet–triplet transitions.[49]

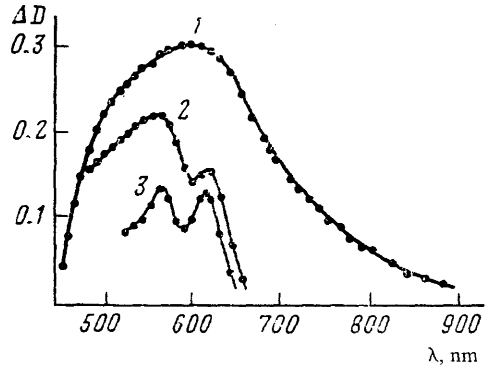


Figure 1. Absorption spectra of solutions of 2,6-diphenyl-1,4-benzoquinone and *NNN'N'*-tetramethyl-1,4-phenylenediamine in dibutyl phthalate (subjected to laser photolysis) obtained at the end of the laser pulse: *1*) ^{3}Q (obtained in the absence of TMPD); *2*) polar TE (obtained at a TMPD concentration of 0.15 M); *3*) absorption spectrum of TMPD radical-cation in acetonitrile.[46]

On quenching ^{3}Q by electron donors in the systems indicated, the formation of polar TE is observed.[43-46] The absorption spectra of the TE contain bands characteristic of the corresponding radical-ions, which is typical for exciplexes with total charge transfer. Absolute agreement between the absorption spectra of the polar TE in inert solvents and the absorption spectra of the corresponding radical-ions is not observed as a consequence of the pronounced overlap of the electron clouds of the radicals in complexes of the "sandwich" type. For example, the absorption spectrum of the polar TE of compound (III) with TMPD contains bands characteristic of the TMPD radical-cation, but the ratio of the intensities of these bands in the spectra of TE and $TMPD^+$ is different (Fig.1). The presence of hydrogen bonds between the radical-ions in the polar TE results in a greater similarity between the absorption spectra of the TE and the radical-ions. For example, the absorption spectrum of the TE of the compound (III)—diphenylamine (DPA) systems shown in Fig.2 is virtually identical with the absorption spectrum of the DPA radical-cation.[45,50] The formation of a hydrogen bond reduces the electron overlap between the radicals as a consequence of the breakdown of the "sandwich" structure. Chemically induced nuclear polarisation (CINP), which arises in the course of photolysis via a triplet mechanism on geminal recombination of the radical-ion pairs, is observed in this system.[50] It has been noted for analogous systems involving compound (II) that the absorption spectrum of the radical-anion components of the hydrogen bonded TE agrees with the absorption spectrum of the radical-anion of compound (II) in alcoholic solutions, where hydrogen bands are formed with solvent molecules.[51,52]

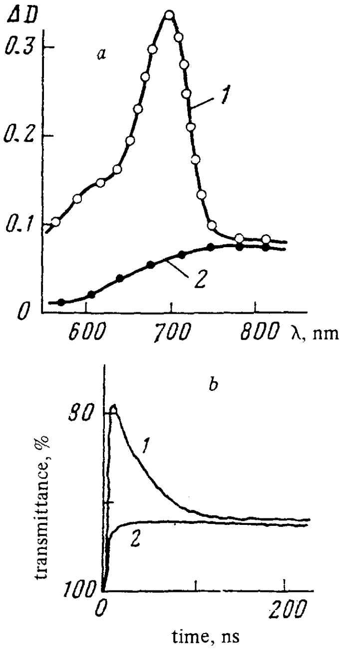

Figure 2. *a*) Absorption spectra of toluene solutions of 2,6-diphenyl-1,4-benzoquinone and Ph_2NH subjected to laser photolysis at −12 °C: *1*) obtained at the end of the laser pulse (superposition of TE and $Ph_2N^\cdot$ spectra); *2*) 150 ns after the laser pulse ($Ph_2N^\cdot$ spectrum); *b*) kinetics of the destruction of TE recorded from the absorption at 690 nm (curve *1*) and of the formation of $Ph_2N^\cdot$ at 830 nm (curve *2*).[50]

The introduction of solvating additives, for example, alcohols, induces a change in the absorption spectra of polar TE. When the methanol content in benzene is 10%, the absorption spectra of the TE virtually correspond to a superposition of the absorption spectra of the corresponding radical-ions.[43,44,53] The alcohol molecules form hydrogen bonds with the quinone radical-anion in the TE.[54] Solvated polar TE have the structure of a solvate-separated ion pair.

In systems characterised by close energies of the state with total CT and a localised excitation, solvation induces the most pronounced changes in the structure of the TE and shifts the equilibrium [a scheme of type (I) with participation of ^3Q] towards the formation of radical-ion pairs in a triplet state.[42–44] For example, the introduction of an insignificant amount of methanol into benzene (the dielectric constant of the solvent hardly changes under these conditions) or an increase of the dielectric constant of the medium to 5 by introducing the corresponding amount of acetonitrile into benzene leads to the formation of radical-ion pairs on photoexcitation of the quinone (IV) in the presence of triphenylamine (TPA) or even at relatively low TPA concentrations, where the formation of a polar TE in this system in benzene is hardly observed.[44] The influence of solvation and of the dielectric constant of the medium is caused by the change in the energy of the state with total CT.

The rate constant for the non-radiative conversion to the ground state (k_{TE}) of polar TE with an energy exceeding 1 eV [for example, the TE of the compound (III)—TPA system] depends only slightly on the polarity and viscosity of the solvent (Table 1). In the case of TE with a low energy, this constant diminishes with increasing polarity of the medium [the TE of the system compound (III)—TMPD (Table 1)]. Solvation by methanol increases or diminishes the k_{TE} of polar TE with high and low energies respectively. The value of k_{TE} increases as the energy of the state with total CT is reduced[43,54] and deviations from this relation are observed only for very low values of the energy indicated.

The kinetics of the non-radiative deactivation of the TE of quinones by transition to the ground state obey the energy gap rule for internal conversion processes, which indicates the important role of the Franck—Condon factor in processes involving the non-radiative deactivation of TE. The same factor is responsible for the increase of k_{TE} on formation of hydrogen bonds with the molecules of the medium or between the radicals in the TE. The constant k_{TE} diminishes slightly when the pressure is raised to 3 kbar.[55]

Triplet exciplexes participate as intermediate species in many photochemical reactions of quinones—photoaddition, photosubstitution, sensitised photoisomerisation, and photodecomposition. Thus p-benzoquinone is photochemically stable in benzene but 4-phenoxyphenol is formed in the presence of difluoroacetic acid.[56] It has been suggested that this reaction includes a stage in which a non-polar TE is formed as a biradical adduct in which acid catalysed proton transfer takes place. The existence of this adduct has been confirmed by the CINP method on photoexcitation of the EDA complex of fluoranil with benzene in the region of the CT band.[57] The TE consisting of a biradical adduct or having a structure with a significant contribution by the state with total charge transfer, also participates in the cycloaddition of olefins to quinones in the triplet state.[58–62] These exciplexes are quenched by O_2, SO_2, and nucleophiles and are protonated in the presence of acids with formation of various products. The simultaneous study by the CINP and picosecond laser photolysis methods of the nature of the intermediates arising in the photolysis of the chloranil—1,1-dimethylindene system in acetonitrile showed that the primary product of the interaction of ^3Q with the olefin is a radical-ion pair.†

It has been suggested that the initial formation of polar TE is a universal process in many photochemical addition reactions involving quinones.[62] The study of the CINP in the photoisomerisation of olefins[63] and various cyclic hydrocarbons,[64-69] in the photodecomposition of thymine dimers,[70] and in the dimerisation of olefins and the dissociation of their cyclic dimers[71] and of the anthracene dimer,[72] all sensitised by quinones, has shown that all these reactions include a step in which radical-ion pairs are formed as a consequence of electron transfer from the reactant to ^3Q. The primary step in the nucleophilic substitution of sulpho-derivatives of 9,10-anthraquinone (V) in the presence of aliphatic amines is electron transfer from the amine to the quinone molecule in the triplet state with subsequent substitution in the radical-ion pair.[73] The photosubstitution of the hydroxy- and amino-derivatives of compound (V) takes place analogously.[74] In the decarboxylation of uric acid sensitised by quinones electron transfer to ^3Q also occurs.[75]

III. ELECTRON TRANSFER TO QUINONE MOLECULES IN TRIPLET STATES

1. Kinetics of the Quenching of Quinone Molecules in Triplet States by Electron Donors

The kinetics and mechanism of the quenching of the triplet states of quinones by electron donors in liquid solutions have been investigated by laser flash photolysis methods. The rate constants for the quenching of the triplet states of compounds (IV),[42,44,76-82] (II),[40,48,51,52,83] and III,[45,46,84] 2-methyl-1,4-naphthoquinone (VI),[85] 2-sulpho-9,10-anthraquinone (VII),[86-88] and anthanthrone (VIII),[89,90] by various electron donors have been obtained (Table 2). The kinetics of the quenching of the triplet state of compound (VIII) by free radicals, which serve as electron donors in this reaction, have also been studied.[91] The rate constants for the quenching of the triplet state of 2,6-disulpho-9,10-anthraquinone (or its solvate) in water by various anions have been estimated as 10^6–10^7 litre mol^{-1} s^{-1}.[92,93] The triplet state of 2-methanesulphonyl-9-10-anthraquinone is quenched by Cl^- in water with a rate constant of ~10^7 litre mol^{-1} s^{-1}.[94]

The quenching of excited states by electron transfer is described by the scheme[95,96]

$$^3\mathrm{Q}+\mathrm{D}\underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}}(^3\mathrm{Q}\cdots\mathrm{D})\underset{k_{32}}{\overset{k_{23}}{\rightleftarrows}}{}^3(\mathrm{Q}^-\cdots\mathrm{D}^+)-\left|\begin{array}{l}\xrightarrow{k_{30}}\mathrm{Q}^-+\mathrm{D}^+,\\ \xrightarrow{k_{31}}\mathrm{Q}+\mathrm{D}.\end{array}\right. \qquad (2)$$

Subject to the condition $k_{31} \ll k_{30}$, which is usually fulfilled in polar solvents, the quenching rate constants k_q can be calculated within the framework of this scheme from the formula

$$k_q=\frac{k_{12}}{1+(1/K_{23}+k_{30}/k_{23})\,k_{21}/k_{30}}. \qquad (3)$$

The rate constants for the elementary steps of reaction (2) are calculated from the formulae

$$k_{23}=k^0\exp(-\Delta G^*_{23}/RT), \qquad (4)$$

$$k_{23}/k_{32}=K_{23}=\exp(-\Delta G_{23}/RT), \qquad (5)$$

where k^0 is the frequency factor and ΔG^*_{23} and ΔG_{23} are the free energy of activation and the standard free energy of electron transfer. It is assumed in the above model[95,96] that $k^0 = k_{30}$ and that k_q in acetonitrile can be calculated from the formula

$$k_q,\ \text{litre mol s}^{-1}=2\cdot 10^{10}\{1+0.25\,[\exp(\Delta G^*_{23}/RT)+\exp(\Delta G_{23}/RT)]\}^{-1}, \qquad (6)$$

ΔG^*_{23} is then related to ΔG_{23} by the equation

$$\Delta G^*_{23}=\frac{1}{2}\Delta G_{23}+\left[\left(\frac{1}{2}\Delta G_{23}\right)^2+(\Delta G_{23}(0))^2\right]^{1/2}, \qquad (7)$$

where $\Delta G_{23}(0)$ is the internal barrier to the electron transfer process, amounting to 2.4 kcal mol^{-1} in acetonitrile. Other relations between ΔG^*_{23} and ΔG_{23} have also been proposed—within the framework of parabolic energy surfaces:[97,98]

$$\Delta G^*_{23}=\Delta G_{23}(0)\,[1+0.25\Delta G_{23}/\Delta G_{23}(0)]^2, \qquad (8)$$

and a formula analogous to the corresponding expression for the energy transfer process:[99]

$$\Delta G^*_{23}=\Delta G_{23}+\Delta G_{23}(0)\ln\{1+\exp[-\Delta G_{23}\ln 2/\Delta G_{23}(0)]\}(\ln 2)^{-1}. \qquad (9)$$

ΔG_{23} can be calculated from the oxidation-reduction potentials and the energy of the triplet state.[95,96,100]

The relations between k_q and ΔG_{23}, calculated by Eqn.(6) using Eqns.(7)–(9), are presented in Fig.3, which also includes experimental data on the quenching of the triplet states of compounds (IV) and (VII) by inorganic ions in water as well as compound (IV) in the triplet state in acetonitrile and benzene by aromatic electron donors (Table 2). The relations corresponding to Eqns.(7) and (9) describe satisfactorily the experimental results in a polar medium. The relation corresponding to Eqn.(8) predicts a decrease of k_q for high negative values of ΔG_{23}, which has not been observed experimentally. The causes of the discrepancy between the theory and experiment (the presence of other reaction channels, the characteristic features of the organisation of the medium around the pair of charged and neutral reactants, and the forms of the energy surface) have been discussed.[101,102]

The satisfactory correlation between k_q and ΔG_{23} is not by itself proof that total charge transfer takes place in the course of the quenching process. Thus, whereas in the quenching of compound (IV) in the triplet state by certain inorganic ions and aromatic donors in hydroxylated solvents yields radical-ions even for low values of k_q,[42,78,80] in acetonitrile radical-ions are formed only for values of k_q close to the diffusional limit.[42] In quenching with low constants k_q, the reaction can be achieved via the formation of a non-polar TE, which dissociates slowly into radical-ions. The protonation of ^{3}Q leads to an increase of the electron-accepting capacity. In the protonation of compound (IV) in the triplet state, k_q for the anions increases and that for the cation diminishes (Table 2).[81]

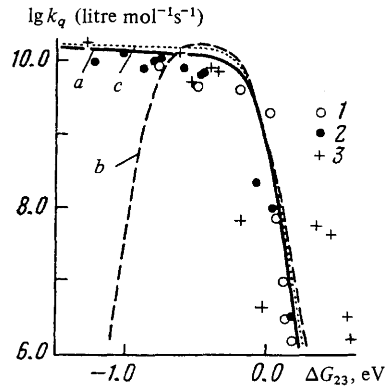

Figure 3. Dependence of lg k_q on ΔG_{23} calculated by Eqn.(6) using Eqns.(7) (*a*), (8) (*b*), and (9) (*c*) and experimental values of k_q obtained in the quenching of quinone molecules in the triplet state by electron donors in different solvents: *1*) water; *2*) acetonitrile; *3*) benzene.

If the intermediate TE is non-polar in both polar and non-polar solvents, then k_q does not change on passing from benzene to acetonitrile (Table 2). Such TE have low dipole moments and their energy depends only slightly on the dielectric constant of the medium ε. The change in the nature of the TE (a transition from non-polar to polar nature) if ε increases entails a sharp break in the relations between k_q and ε, as has been observed in the quenching of certain ^{3}Q by triphenylamine.[44,89] The introduction of solvating additives, which form complexes with TE, is also accompanied by an appreciable increase in k_q (Table 2) as a consequence of the change in the nature and energy of the TE.[42,44,89]

Thus the kinetics and mechanism of the quenching of the triplet states of quinones by electron donors are determined by the properties of the intermediate TE, which are also responsible for the characteristics of the formation reaction of radical-ions in polar media.

2. The Formation of Radical-Ions in Reactions of Quinones in Triplet States

Electron transfer to a quinone molecule in the triplet state in polar media is accompanied by the formation of the quinone radical-anion and the oxidised form of the electron donor, which is frequently the solvent molecule. The radical-ions have been detected by flash and laser photolysis methods in the quenching of the triplet states of compound (IV) by aromatic amines,[34,42,44,54,77–79,82,103,104] aromatic hydrocarbons,[42,78,80] acetone,[78] and inorganic anions;[78,79,81] the triplet state of compound (II) by aromatic amines,[34,48,54,105] heterocyclic compounds,[51,52] aromatic hydrocarbons,[41,42,83,106–108] cyclic hydrocarbons,[64] methyl methacrylate,[40] and certain polar solvents;[39,83,105,108–110] the triplet states of other derivatives of compound (I) by aromatic amines and hydrocarbons;[33,34,45,46,53–55] the triplet state of 1,4-naphthoquinone (IX) by triphenylamine;[54] the triplet state of compound (VI) by pyrimidines,[85] the triplet state of compound (V) and its derivatives by amines[54,111] and inorganic anions;[86,87,92,93,112] the triplet state of compound (VIII) by aromatic amines,[89] and the triplet states of diphenoquinone derivatives by triphenylamine.[54] The formation of radical-ions follows unambiguously from CINP data on the photolysis of compound (II) in polar solvents in the presence of olefins[63,71] and certain cyclic hydrocarbons.[65–69] The formation of radical-ion pairs in the photolysis of t-butyl-substituted derivatives of compound (I) and o-benzoquinone in frozen diethylamine and triethylamine has been observed by EPR,[113,114] but in another study[115] it was concluded that a pair of neutral radicals is formed.

On the basis of chemically induced electron polarisation (CIEP) and CINP data, it has been suggested that the main process in the quenching of ^3Q by aliphatic amines in alcohols is the formation of quinone radical-anions.[116,117] The radical-anion can be formed in the course of secondary proton transfer processes.[118] Thus the formation of quinone radical-anions has been detected by the CIEP method in the photolysis of alcoholic solutions of quinones in the presence of aliphatic amines,[76,119–122] but it has been noted in experimental laser photolysis that the formation reaction of these radicals is slower than the destruction of the initial triplet state.[76] In experiments on picosecond laser photolysis, it was possible to demonstrate unambiguously that the quenching of the triplet state of compound (V) and its chlorinated derivatives by triethylamine in alcohol entails electron transfer.[111] The conclusion, reached on the basis of EPR and CIEP data, that radical-ions are formed in the course of the primary step, in quinone–organometallic donors[118,123–127] and vitamin K_1–vitamin C[128] systems also appears to be fairly unambiguous. In the 9,10-phenanthrenequinone (X)–$Me_3SnSnMe_3$ system, radicals are formed on photoexcitation of the EDA complexes in the region of the CT band.[118] An EPR signal, which was assigned to a radical-ion pair, has been detected in the photolysis of crystalline specimens of 3,6-di-t-butylcatechol with added 3,6-di-t-butyl-1,2-benzoquinone.[129–130]

The formation of radical-ions on interaction of quinones in triplet states with electron donors in polar media usually takes place with yields close to 1.0 in systems where ΔG_{23} is negative and k_q is close to the diffusional limit.[42,78,83] Donors having a radical fragment are an exception, since in this case an ion pair in a doublet spin state is formed. In this state (in contrast to the triplet state) there is no prohibition of the transition to the ground (also doublet) state of the initial reactant.[91] In systems with positive ΔG_{23} and k_q below the diffusional limit, high yields of radicals were observed only in hydroxylated solvents.[42]

Radical-ions are formed in high yields on quenching of ^3Q by electron donors in micellar solutions and microemulsions, where the reactants can be present in both the same and in different phases.[78,79,80,103,104,131] In the latter case electrons are transferred from the surface of the micelle (the site where the donor is located) through the interface to the quinone molecule in the triplet state located within the micelle. This process is very rapid, for example occurring in 40 ns between the molecule of compound (IV) in an anionic micelle and Fe^{2+} [78] and even faster between the same molecule in a cationic micelle and CO_3^{2-},[79] which is due to the operation of a tunnel mechanism. The radicals are not formed in micelles containing Cl^- and Br^- anions owing to the quenching of the triplet state by the latter. This effect is not quite so pronounced in microemulsions, where the molecule in the triplet state is present in the benzene phase and is separated from the ions of the surfactant.[103]

In many cases the quenching of ^3Q by inorganic anions (for example, NO_2^-, CO_3^{2-}, and SO_3^{2-}) is accompanied by the formation of radicals with a high yield.[86,87,92,93,112,132] However, radicals are not formed on interaction with N_3^-, NCS^-, Cl^-, Br^-, and I^-.[81,86,87,92,94] The contribution of quenching due to the heavy atom effect is insignificant, since Cs^+ ions do not quench effectively the triplet state of compound (IV).[81] The dependence of the yield of radicals on the nature of the inorganic anion can be accounted for in terms of the extent of the spin–orbital coupling in the inorganic radical. If the multiplet splitting of the energy levels of the radical, determined by the orbital momentum, exceeds 100 cm^{-1} then the intersystem crossing in the radical pair is accelerated so much that this process becomes the main channel leading to the destruction of the triplet radical pair.[87] The quenching by the NO_2^- anion, which has a triplet state with an energy of 56 kcal mol^{-1}, should be specially mentioned. The quenching by this anion leads to the formation of radicals, i.e. in the presence of two possible reaction channels (energy transfer and electron transfer), both of which are exothermic, the process proceeds via the pathway most favoured by energy factors. It is quite likely that electron transfer is preceded in this instance by energy transfer.

A low quantum yield in the formation of radicals is characteristic also of the quenching by the OH^- anion [in the compound (IV)—OH^- system, the yield of radicals is 10%[77]] as a consequence of the existence of rapid chemical channels leading to the destruction of TE (hydroxylation).[86] Exactly the same adduct formation reaction, competing with dissociation into radical-ions, is responsible for the low efficiency of the formation of radicals on quenching of the triplet state of compound (II) by vinyl monomers.[40]

Low yields of radical-ions have been recorded in the photolysis of quinones in polar solvents without hydroxy-groups [thus the quantum yield is 0.08 in the photolysis of compound (II) in acetonitrile and is smaller by a factor of 3 in propyl cyanide,[40,83] while in the photolysis of compound (IV) in acetone it amounted to 0.08[78]], which is due to the low value of the electron transfer rate constant. The low (0.15) yield of radical-anions in the photolysis of compound (IV) in micellar solutions of sodium lauryl sulphate (the sulphate group is the electron donor) can be explained analogously.[78]

Detailed studies by flash photolysis with measurement of the absorption and electrical conductivity in binary mixtures and viscous alcohols at different pressures have shown that, in the quenching of the triplet states of quinones by aromatic electron donors in media of moderate polarity, radicals are formed as a result of the dissociation of the TE in accordance with the scheme[34,53–55]

$$3Q + D \rightleftarrows TE - \left[\begin{array}{l} \xrightarrow{k_2} Q^- + D^+, \\ \xrightarrow{k_1} Q + D. \end{array}\right. \qquad (10)$$

The rate constant for the dissociation of polar TE into radical-ions (k_2) depends on the viscosity of the medium and can be calculated satisfactorily from the formula for the rate constant for the diffusion-controlled dissociation of ion pairs:

$$k_{dis} = 3e^2D\{\sigma^3\varepsilon kT\,[\exp(e^2/\sigma\varepsilon kT) - 1]\}^{-1}, \qquad (11)$$

where e is the electronic charge, D the mutual diffusion coefficient, and σ the average distance between the ions in the pair.

The values of σ (Table 3), obtained from the dependence of k_{TE} or the yield of radicals on the dielectric constants ε of the binary mixtures (Fig. 4) in most cases significantly exceed the sum of the van der Waals radii of the reactants and also the distance between the unpaired electrons in the analogous radicals pairs in frozen solutions (amounting to 6.0–6.5 Å[38,113]), where the reaction proceeds via EDA or hydrogen-bonded complexes). The presence of a hydrogen bond between the radicals, for example, in the 3-chloro-2,6-diphenyl-1,4-benzoquinone–DPA system, is accompanied by a decrease of σ which is more pronounced the stronger the hydrogen bond. High values of σ reflect the fact that the radicals are formed from solvate-separated radical-ion pairs.

Table 3. The distances (σ/Å) between the radical-ions in triplet exciplexes.*

*The value for the benzene–benzonitrile mixture + 5 vol.% methanol is given in brackets.

In the absence of specific interactions of the radicals with one another or with the molecules of the medium, the values of σ are almost independent of the structure of the quinone and the donor (Table 3), but the introduction of alcohols into the system induces an increase of σ which is greater the stronger the hydrogen bond between the radical-anion of the quinone and the alcohol molecule.

The study of the dynamics of the processes in the radical-ion pair in the picosecond time range in electron transfer from aromatic donors to a molecule of compound (II) in the triplet state in acetonitrile showed that the electron transfer is accompanied by the establishment of equilibrium in the cation–anion–molecular environment system over a period of approximately 0.1–0.5 ns.[106] It has been suggested that this thermodynamic equilibrium is attained due to diffusional processes. In the analysis of the spectral changes in the course of the establishment of equilibrium, it was concluded that the distance over which the electron is transferred is less than the equilibrium distance between the radicals in the pair. Analogous experiments in the compound (V)—triethylamine system in alcohol and acetonitrile also indicate the primary formation of a contact radical-ion pair.[111]# However, studies on the benzophenone–amine system have led the authors[133,134] to the conclusion that the radicals formed after electron transfer come closer together.

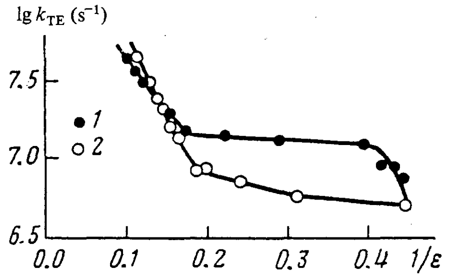

Figure 4. Dependence of lg k_{TE} on 1/ε for the solvent obtained by laser photolysis of solutions of 2,6-diphenyl-1,4-benzoquinone in the presence of triphenylamine in binary benzene–methanol (1) and benzene–benzonitrile (2) mixtures.[53]

IV. HYDROGEN ATOM TRANSFER TO QUINONE MOLECULES IN TRIPLET STATES

The reaction involving the transfer of a hydrogen atom to the molecules of quinones in triplet states can be achieved via three mechanisms. In the two extreme cases their reaction takes place in two stages where an electron is transferred initially followed by a proton [Scheme (12)] or conversely [Scheme (13)]:

$$
\begin{array}{rl}
{}^3Q + RH \rightleftarrows ({}^3Q\cdots RH) \rightleftarrows {}^3(Q^-\cdots RH^+) - & \left[\begin{array}{l}\longrightarrow Q^- + RH^+,\\ \longrightarrow Q + RH,\end{array}\right.\\
\uparrow\downarrow & \\
{}^3(QH^\cdot\cdots R^\cdot) - & \left[\begin{array}{l}\longrightarrow QH^\cdot + R,\\ \longrightarrow Q + RH.\end{array}\right.
\end{array}
\qquad (12)
$$

$$
{}^3Q + RH \rightleftarrows {}^3(Q\cdots RH) \rightleftarrows {}^3(QH^+ \overset{\overset{Q+RH}{\uparrow}}{\cdots} R^-) \rightleftarrows {}^3(QH\cdots R^\cdot) - \left[\begin{array}{l}\longrightarrow QH^\cdot + R^\cdot,\\ \longrightarrow Q + RH.\end{array}\right.
\qquad (13)
$$

In the intermediate case the hydrogen atom is transferred more or less as a single whole:

$$
{}^3Q + RH \rightleftarrows ({}^3Q\cdots RH) \rightleftarrows {}^3(QH^\cdot\cdots R^\cdot) - \left[\begin{array}{l}\longrightarrow QH^\cdot + R^\cdot,\\ \longrightarrow Q + RH.\end{array}\right.
\qquad (14)
$$

Generally speaking the processes enumerated may compete with one another, but the situation where the reaction cannot be assigned to any one of three types is more probable since the intermediate CT stage is described by a superposition of states of different nature and the hydrogen-bonded complex can be characterised by a potential surface with a single minimum for the position of the proton.

#See K.Hamanoue, T.Nakayama, K.Sugiura, H.Teranishi, M.Washio, S.Tagawa, and Y.Tabatu, Chem.Phys.Letters, 1985, 118, 503, and K.Hamanoue, M.Kimoto, Y.Kajiwara, T.Nakayama, and H.Teranishi, J.Photochem., 1985, 31, 143.

The transfer of a hydrogen atom to carbonyl compounds in triplet $n\pi^*$ states has much in common with the analogous process involving alkoxy-radicals and has been considered theoretically as a reaction within the framework of valence bond methods,[135] correlation diagrams,[136] and perturbation theory.[137,138] Furthermore, Formosinho[139,140] carried out calculations for the transfer of a hydrogen atom to carbonyl compounds in triplet states, including quinones, as a tunnel process within the framework of the theory of non-radiative transitions; this approach makes it possible to calculate satisfactorily the rate constants for the transfer of a hydrogen atom in systems with electron donor–acceptor interactions.

1. The Transfer of a Hydrogen Atom in the Interaction of Quinones in Triplet States with Amines

The interaction of quinones in triplet states with secondary and primary aromatic amines in liquid solutions is accompanied by the formation of both radical-ions and neutral radicals as a consequence of electron and hydrogen atom transfer respectively.[34,42,45,50,141] An increase in the temperature of the solution leads to an increased yield of neutral radicals, while the overall yield of radicals does not change. The quenching process takes place with a diffusional rate constant (Table 2); deuteriation of the amino-groups does not cause an appreciable change in the ratio of the yields of radicals of different nature.

Table 4. The equilibrium constant K_H, the enthalpy ΔH_H, and the entropy ΔS_H of the prototropic equilibrium in radical pairs in toluene and acetonitrile.[141]

Quinone	Amine	K_H		ΔH_H, kcal mol^{-1}		ΔS_H, cal mol^{-1} K^{-1}	
		toluene	CH_3CN	toluene	CH_3CN	toluene	CH_3CN
Duroquinone	Diphenylamine	50	2.7	—	5.0	—	19
2,6-Dimethoxy-1,4-benzoquinone	"	34	3.1	8.0	4.8	34	19
2,6-Diphenyl-1,4-benzoquinone	"	25	1.8	9.4	4.5	39	16
3-Chloro-2,6-diphenyl-1,4-benzoquinone	"	8.1	1.0	10.0	4.3	38	15
3,5-Dichloro-2,6-diphenyl-1,4-benzoquinone	"	1.2	0.25	10.4	3.8	36	10
2,5-Dichloro-1,4-benzoquinone	"	0.52	0,17	10.6	3.5	35	9
Chloranil	"	0,04	0.08	11.4	3,3	32	6
3-Chloro-2,6-diphenyl-1,4-benzoquinone	4-t-Butyldiphenylamine	2,8	0.62	9.9	2.7	36	8
"	4,4′-Di-t-butyldiphenylamine	1.4	0.37	10.1	1.6	35	3
"	4,4′-Bis(1,1,3,3-tetramethylbutyl)diphenylamine	1.1	0.28	10.2	1.0	35	1
3,5-Dichloro-2,6-diphenyl-1,4-benzoquinone	4,4′-Di-t-butyldiphenylamine	0.25	0.16	10.8	0.5	34	−2

The above features are characteristic of reactions proceeding via scheme (12). ΔG_{23} is negative and electron transfer is therefore the fastest of the possible reactions. Next, prototropic equilibrium is established in the radical pair and the process also takes place very rapidly in the course of thermodynamic relaxation as a consequence of the presence of a hydrogen bond. Table 4 presents the thermodynamic parameters for the prototropic equilibrium in the radical pairs formed on quenching of the triplet states of quinones by secondary aromatic amines. The reorganisation of the molecules of the medium in the vicinity of the ion pair, which has a significantly higher dipole moment than the pair of neutral radicals, leads to an extremely high ΔS_H. The weakening of the electrostatic field with increase of solvent polarity is accompanied by a decrease of ΔS_H and ΔH_H. The equilibrium shifts towards the ion pair with increase of the acidity of the semiquinone and the basicity of the aminyl radical. A linear relation is observed between the free energy of proton transfer in toluene and acetonitrile, on the one hand, and the free energy of the acid–base equilibrium in water, calculated from the corresponding pK,[141] on the other. U-shaped relations between K_H and ε for the binary toluene–acetonitrile mixture have been obtained, which can be accounted for by the different course of the decrease of ΔS_H and ΔH_H with increase of ε.[141]

The quenching of ^3Q by primary and secondary aromatic amines in the case where ΔG_{23} is positive [for example in systems incorporating compound (IV) or (VIII) and DPA, 4-aminobiphenyl, or 4-bromoaniline] is accompanied by the formation of neutral radicals and takes place with rate constants exceeding significantly the analogous constants obtained for electron donors with the same oxidation potentials but without NH groups in their structure (Table 2).[42,89,90] It has been suggested that the quenching proceeds in accordance with Scheme (14), which includes the formation of a hydrogen-bonded TE ensuring very rapid transfer of a hydrogen atom.[42,89] The question of the degree of charge transfer in the hydrogen-bonded TE remains open; one must take into account the fact that the hydrogen bond reduces significantly the energy of the states with total charge transfer. The quenching rate constants increase with increase of ε of the medium or after the introduction of a solvating additive.[89] In a polar medium or under the conditions of specific solvation, the ΔG_{23} are lower and the reaction therefore proceeds in accordance with Scheme (12).

In certain cases the transfer of a hydrogen atom takes place also on quenching of ^3Q by tertiary aromatic amines, for example, in the compound (IV)—*NN*-diethylaniline system in benzene.[77] The existence of a fairly mobile proton in the amine radical-cation results in the appearance of a channel leading to the destruction of the polar TE—a proton transfer process. Direct observations by picosecond laser photolysis have shown that the proton transfer in the polar TE arising as a result of electron transfer from *N*-methylacridine to a molecule of compound (V) in the triplet state in benzene proceeds over a period of 140 ps.§

The formation of neutral radicals is frequently observed in the interaction of quinones in triplet states with aliphatic amines having a mobile hydrogen atom at the α-carbon atom. On quenching of the triplet state of compound (IV) by triethylamine, neutral radicals are formed in both non-polar and polar solvents.[77] In CINP experiments, it has been shown[117] that the photoinitiated transfer of a hydrogen atom in the compound (I)—triethylamine system in acetonitrile takes place in two stages.[117] This mechanism has been confirmed by direct observations for the systems compound (V)—triethylamine in toluene[111] and benzophenone—triethylamine system in acetonitrile.[142] When electron transfer is thermodynamically unfavourable, an effective transfer of a hydrogen atom as a whole can be achieved provided that the α-CH bond can be arranged parallel to the orbital of the unshared electron pair of the nitrogen atom.[143]

§ See L.E.Manring and K.S.Peters, J.Amer.Chem.Soc., 1985, **107**, 6452.

The photolysis of quinones in the presence of aliphatic and secondary aromatic amines in frozen non-polar solvents is accompanied by the appearance of an EPR signal due to the pairs of neutral radicals formed on phototransfer of a hydrogen atom in the EDA complex.[144–146] The distance between the unpaired electrons in the radical pairs is 5–9 Å.

On the basis of the analysis of the temperature dependence of the yields of radicals of different nature in quinone–amine systems, one may expect that predominantly radical-ion pairs should be formed at low temperatures. However, this is true only in liquid solutions. In frozen solutions the formation of an ion pair may be difficult, since the rotational and translational mobilities of the solvent molecules are restricted, which hinders the reorganisation of the medium necessary for the stabilisation of the ion pair.

2. Interaction of Quinones in Triplet States with Phenols

The photoexcitation of quinonoid compounds in the presence of phenols is accompanied by the formation of semiquinone and phenoxy-radicals both in the liquid state and in a solid matrix. The kinetics and mechanism of the interaction of quinones in triplet states with phenolic compounds as well as the nature of the radicals formed have been investigated by flash photolysis,[41,42,84,89,90,147–165] EPR,[113,114,166] the CIEP method,[116,167–173] and the CINP method.[57,170,172,174–176] The steric structure and dynamics of the radical pairs formed in the photolysis of frozen solutions or crystals of quinones and phenols have been studied by EPR.[113,114,130,177–184]

(a) Kinetics of the reactions of quinones in triplet states with phenols. The quenching of the triplet states of quinones with a fairly high triplet energy by phenolic compounds takes place with high rate constants approaching the diffusional limit (65; see also Table 2).[42,57,84,149,150–152,163,167] As the electron-donating capacity of the phenol decreases, k_q initially falls but subsequently it begins to rise (Fig.5), which indicates a change in the reaction mechanism. The values of k_q diminish following the introduction of t-butyl groups in the *ortho*-position in the phenol owing to the shielding of the reaction centre.[151] Fig.5 shows that the quenching of the triplet state of anthanthrone, which has a low triplet energy, proceeds mainly with lower k_q (see also Table 2).[89,90,151] We may note that, although k_q diminishes as the electron-donating properties of the phenol are weakened, nevertheless the slope of the corresponding relations is significantly smaller than the value expected for electron transfer reactions and the k_q exceed the rate constant for electron transfer in the given systems. The observed set of characteristic features of the influence of the structure of the reactants and of the properties of the medium may be accounted for within the framework of three possible mechanisms [Schemes (12)–(14)].

The reactions between quinones in a high energy triplet state and phenols having fairly strong electron-donating properties (for example, hydroquinones) proceeds in accordance with Scheme (12); the protropic equilibrium in the radical pair is then fully displaced towards the formation of a pair of neutral radicals as a consequence of the extremely high acidity of the phenol radical-cations.

In the case where the free energy of the electron transfer from the phenol to the quinone molecule in the triplet state is large and positive, quenching takes place in accordance with Scheme (14). Hydrogen-bonded TE, in which the transfer of a hydrogen atom takes place, is formed in the first stage of the reaction. Since the triplet state is electrophilic, k_q diminishes as the electron-donating capacity of the phenol is reduced. An increase in the polarity of the medium weakens the hydrogen bond between the reactants in the TE, which is accompanied by a decrease of the rate constant for the transfer of a hydrogen atom.

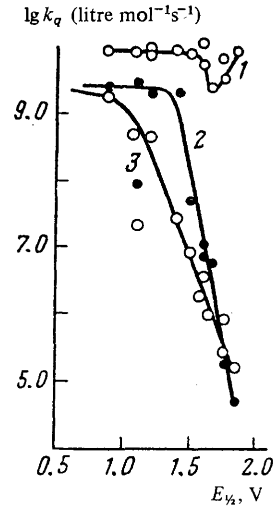

Figure 5. Dependence of lg k_q on the one-electron oxidation potentials $E_{1/2}$ of phenols in the quenching of the triplet states of 2,6-diphenyl-1,4-benzoquinone (energy of the triplet state ~2.3 eV) in benzene (curve *1*) and anthanthrone (energy of the triplet state ~1.6 eV) in benzene (curve *2*) and acetonitrile (curve *3*).[151]

It is noteworthy that the formation of a hydrogen bond in the TE can lead to a significant decrease in the energy of the state with total charge transfer (by approximately 1 eV and even more), which can be explained by the fact that the displacement of a proton from the donor to the acceptor is accompanied by an increase of the electron-donating capacity of the donor and of the electron-accepting capacity of the acceptor. For this reason, in hydrogen-bonded systems, where the free energy of the electron transfer calculated from the oxidation-reduction potentials of the reactants is positive, there is also a possibility of the transfer of a hydrogen atom via Scheme (12). The two-stage transfer of a hydrogen atom in certain analogous systems, where the reaction proceeds with participation of singlet hydrogen-bonded exciplexes, has been demonstrated experimentally as a result of direct observations by the method of picosecond laser photolysis.[185,186]

The quenching of ^{3}Q by phenols with very pronounced acid properties (picric acid, dinitrophenols) is described by Scheme (13). When this mechanism obtains, k_q can increase with increase of the acidity of the phenol and the polarity of the solvent as a consequence of the displacement of the prototropic equilibrium towards the ion pair.

The study of the influence of the viscosity of the medium on the kinetics of the quenching of the triplet state of anthanthrone by phenols made it possible to separate the stages involving the formation of a hydrogen-bonded TE and the transfer of a hydrogen atom in the TE.[90] The constants k_q

for certain phenols are significantly lower than the rate constant for the reaction occurring in each encounter of the reactants in solution, but they depend on the viscosity in the same way as the rate constant for a diffusion-controlled reaction (Fig.6). The rate-limiting stage of the reaction in these systems is the formation of a hydrogen-bonded TE. This process is controlled by the molecular mobility but takes place with a relatively low rate constant, since the formation of a hydrogen bonded complex requires a rigorous relative orientation of the reactants. An increase in the acidity of the phenol diminishes the rate constant for the formation of the intermediate hydrogen-bonded TE,[90] which can be explained by the fact that, in systems where a hydrogen atom is transferred in complexes with a stronger hydrogen bond, the reactants in these complexes are more rigorously oriented relative to one another and such "rigid" orientation hinders the formation of the complex.

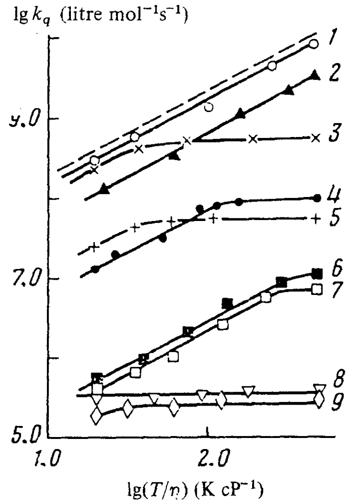

Figure 6. Dependence of lg k_q on lg (T/η) obtained in the quenching of the triplet state of anthanthrone in binary toluene–dinonyl phthalate and toluene–hexadecane mixtures by various compounds: *1*) *NN*-dimethyl-4-methoxyaniline; *2*) 2,4,6-trimethylphenol; *3*) 4-bromoaniline; *4*) 2,6-di-t-butyl-4-methylphenol; *5*) 2,3-dichlorophenol; *6*) 3-nitrophenyl; *7*) 4-nitrophenol; *8*) 4-methoxybiphenyl; *9*) 2,6-dinitrophenol. The dashed line has been calculated from the Debye formula ($8RT/3000\eta$).[90]

The nature of the rate-limiting stage and the mechanism of the quenching of ^{3}Q by phenols determine the observed kinetic isotope effect. The transfer of a hydrogen atom in the TE is characterised by an appreciable kinetic isotope effect, but when the rate-limiting stage of the quenching process involves the formation of an intermediate TE, no isotope effects are observed.[90,151] Low values (close to unity) of the kinetic isotope effect are characteristic also of quenching processes via Scheme (12) and (13), since the rates of these reactions are determined by stages involving charge transfer or the establishment of protropic equilibrium.[89,151]

(b) The formation of radicals in the photolysis of quinones in the presence of phenols. In most systems, the interaction of quinones in triplet states with phenols leads to the formation of semiquinone and phenoxy-radicals in yields close to 100%,[42,89,149,151] but CINP studies on the photolysis of quinones in the presence of phenols indicate an insignificant contribution to the geminal radical pair recombination process,[57,170–172,174–176] which should reduce the yield of radicals. Furthermore, if the process is described by Scheme (12), the decrease in the yield of radicals may be caused by rapid intersystem crossing in the non-equilibrium TE. Thus relatively low yields of radicals in the quenching of the triplet state of chloranil (II) by tetrachlorohydroquinone can be explained in this way.[41,152]

Very low yields of radicals have been observed in the quenching of the triplet state of anthanthrone by picric acid and dinitrophenols in benzene.[151] The reaction in these systems is described by Scheme (13) and the main channel leading to the destruction of the radical pair, formed after proton transfer, is the intersystem transition to the ground state. If the proton transfer reaction in the primary TE competes with the hydrogen atom transfer, then the yield of phenoxy-radicals increases with increase of temperature as a consequence of the shift of the prototropic equilibrium towards the primary TE in which the hydrogen atom is transferred.[151] The existence of the prototropic equilibrium also explains the low yields of radicals (which increase with increase of temperature) in the quenching of polar TE by phenols.[163] The transfer of a hydrogen atom results in the formation of a complex incorporating the phenoxy- and semiquinone radicals and also a molecule of the electron donor (amine). The prototropic equilibrium in this complex is determined by the proton transfer between the amine and the semiquinone.

It has been noted that, in the quenching of ^{3}Q having non-equivalent oxygen atoms, the formation of two types of semiquinone radicals may be expected, their ratio of their yields depending on the reaction mechanism.[151]

Photolysis of frozen solutions of phenols and quinones leads to the formation of radical pairs from phenoxy- and semiquinone radicals.[113,177] The phototransfer of a hydrogen atom takes place in EDA complexes, which are also present in aqueous solutions, this being indicated by the slight scatter of the distance between the unpaired electrons in the radical pair ($\leq$0.1 Å).[177,179] Estimation of the formation constant for these complexes yields 0.2–3 litre mol^{-1} at −90 °C.[181] Analysis of the EPR spectra yielded geometrical parameters characterising the relative disposition of the radicals in the pair—the planes of their rings are parallel and are located at a distance of 1.6 Å.[180] At a low temperature the radical pairs rotate as a whole with characteristic times in the range 0.1–1.0 ms.[182]

Two types of radical pairs with different distances between the unpaired electrons have been detected for o-benzoquinone derivatives, which has been explained by the migration of the proton in the semi-quinone between two non-equivalent oxygen atoms.[177–180,182,184] The formation of two types of radical pairs can also be caused by the existence of EDA complexes of different composition.[183]

Two types of EPR signals of the radical pairs have been recorded in the photolysis of single crystals in polycrystalline specimens of 3,6-di-t-butyl-1,2-benzoquinone and the corresponding catechol.[129,130] One type has been assigned to the radical ion pair and the other to the pair of neutral radicals. These radical pairs are formed and are destroyed independently of one another. Presumably the protropic equilibrium in the crystal is frozen and the hydrogen atom and electron transfer processes therefore proceed in parallel within donor and acceptor pairs, whose structure and molecular environment favour either the transfer of a hydrogen atom or the transfer of an electron. Electron transfer has been postulated in the photoexcitation of the EDA complex of duroquinone and hydroduroquinone in the region of the CT band in alcohol.[187]

3. The Abstraction of a Hydrogen Atom by Molecules of Quinones in The Triplet State from Other Organic Compounds

The transfer of a hydrogen atom to ^{3}Q is a very common reaction and is observed in interactions with hydrocarbons, ketones, ethers, aldehydes, anhydrides, and amides—virtually with participation of all organic compounds.[4–6]

The molecules of quinones in the triplet state can abstract a hydrogen atom even from benzene, although the quantum yield in the formation of radicals is very low.[39,188–191] The rate constant for the quenching of the triplet state of compound (V) by benzene in CCl_4 is 7.2×10^5 litre mol^{-1} s^{-1} and increases to 2.2×10^6 litre mol^{-1} s^{-1} on passing to acetonitrile.[192] The nature of the triplet state is very important in the reaction with benzene; thus the rate constants for the interaction of derivatives of compound (V) having a triplet state of the $n\pi^*$ type with benzene are significantly lower.[192] The transfer of a hydrogen atom from benzene takes place in a non-polar TE (of the type of a biradical adduct[57]) and is a side channel leading to the destruction of this species.

The photochemical reduction of quinones in a mixture with saturated hydrocarbons is relatively ineffective;[78,150,193] nevertheless, it has been possible to detect radicals by EPR[194] and flash photolysis.[39,149,195–198] The quantum yield of the radicals in the photochemical reduction of compound (IV) in cyclohexane is only 0.09[149] and is even lower in hexane.[78,150] In the case of compound (V), which has a triplet state of the $n\pi^*$ type with a higher energy, the quantum yield of the radicals in hexane is 0.11,[196] while $k_q = 8.6 \times 10^5$ litre mol^{-1} s^{-1}.[199]

The reactivity of ^{3}Q in relation to alkylbenzenes, fluorene, and 9,10-dihydroanthracene has been investigated in detail.[200–206] The rate of disappearance of 9,10-phenanthrenequinone (X) increases in the sequence benzene < t-butylbenene < toluene < ethylbenzene < cumene (0.33, 0.42, 1.00, 1.27, and 2.33 respectively).[200] It has been established by the CINP method that the primary step involves the abstraction of a hydrogen atom in α-position in the alkyl substituent with formation of radical pairs, which give rise to adducts on formation of C–C or C–O bonds.[201–206]

Experiments on picosecond laser photolysis demonstrated that a hydrogen atom is transferred from durene to a molecule of chloranil in the triplet state via Scheme (12) in a non-equilibrium polar TE.[48] A small contribution by a slow proton transfer process in the equilibrium TE has also been observed.

In the photolysis of frozen solutions of *p*-benzoquinone and alkylbenzenes on irradiation in the region of the CT band, the formation of radical pairs in the triplet state, incorporating neutral radicals with the distance between the unpaired electrons in the range 5.8–6.1 Å has been noted.[38] The radical pairs are also formed in the compound (I)–α-methylnaphthalene system but not in the system with β-methylnaphthalene, which is due to the different relative positions of the reacting groups (for example, the greater distance of the methyl group from C=O in the EDA complex with β-methylnaphthalene).

It has been shown by flash photolysis that radicals are formed in the photolysis of compound (IV) in chloroform[197] and of compound (II) in 1,2-dichloroethane; the quantum yield is 0.19.[40] It follows from CINP data that the reaction of fluoroanil in the triplet state with chloroform includes a stage in which a radical pair is formed. The latter then recombines to the initial reactants and dissociates into radicals.[57,175,176] A study of the reaction by EPR showed that the effectiveness of the formation of the radicals increases in the presence of traces of acid.[207] Presumably the transfer of a hydrogen atom includes a proton transfer stage.

The formation of semiquinone radicals has been observed in the photolysis of compound (II) in acetonitrile and propionitrile together with charged radicals;[39,40,83,108,110] the yield of radicals in propionitrile is then higher than in acetonitrile.[83] However, it has been concluded that semiquinone radicals are not products of the reaction of compound (II) in the triplet state with solvent molecules but are formed in photochemical side reactions.[108,110]

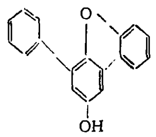
A hydrogen atom is transferred extremely effectively in the reactions of ^{3}Q with olefins. The rate constant for the quenching of the triplet state (X) by 2-methylpropene, *trans*- and *cis*-but-2-enes, 2-methylbut-2-ene, and 2,3-dimethylbut-2-ene in benzene increases from 1.0×10^8 to 1.3×10^9 litre mol^{-1} s^{-1} in this series of compounds.[208] The quantum yield of the reaction then increases from 0.21 to 0.79 and there is a simultaneous increase of the contribution of the R–H addition process, which includes a hydrogen atom transfer stage. A hydrogen atom is transferred in the TE and this process competes with the other TE destruction channel—the formation of cycloaddition products. The formation of various adducts in the TE and in the pair of neutral radicals leads to a low yield of radicals. The quantum yields of semiquinone radicals when the triplet stage of chloranil is quenched by acrylonitrile and methyl methacrylate in 1,2-dichloroethane are 0.2 and 0.08, while radicals were not detected in the quenching by styrene.[40] The quenching rate constants are determined by the ionisation potential of the donor (Table 2).

In the interaction of ^{3}Q with ethers, a hydrogen atom is transferred from the α-position. Radicals have been detected by EPR,[172,190,207,209–216] and flash photolysis.[39,41,215] According to CINP data, the radical pair recombines to adducts.[172,202,203,205,206,217–220] The reactivity of ethers is higher than that of alkylbenzenes. The rates of disappearance of compound (X) in tetrahydrofuran, dioxan, and diethyl ether are 1.78, 2.47, and 3.44 respectively (relative to toluene),[200] which is due to the presence of the oxygen atom with the unshared electron pair participating in the electron donor–acceptor interaction with ^{3}Q in the TE. A hydrogen atom may be transferred on irradiation with light in the region of the CT band in the spectrum of the EDA complex in the triplet state, as has been observed in systems of the type $R{-}X{-}CH_2CO_2H$ (X = O, S, or NH)[221] or in the compound (II)–dioxan system.[41] The yield of radicals in the latter case is 0.13, the rate constant for the formation of radicals from the TE is 3.8×10^4 s^{-1}, and the rate constant for other TE deactivation processes is 2.6×10^5 s^{-1}.

Semiquinone radicals have been recorded by EPR[190,207,209,212,214,222] and by flash photolysis[39,105,110] on photoexcitation of quinones in acetone. The yield of radicals increases in the presence of traces of acids.[207] It has been suggested that semiquinone radicals are formed in a photochemical reaction with participation of the products of a dark reaction between the reactants.[108,110]

The molecules of quinones in triplet states abstract a hydrogen atom from the aldehyde group.[4] The reaction has been investigated by the CINP method and it has been shown that its mechanism is the same as for processes involving the participation of ethers and alkylbenzenes.[206] The reactions involving the abstraction of a hydrogen atom from anhydrides and amides are also known.[4] In the case of amides[4] and phosphates[190,210,212,214] semiquinone radicals have been detected by EPR. Semiquinone radicals are formed on photoexcitation of quinones in microemulsions[104] and in micellar solutions[223–227] as a consequence of the transfer of a hydrogen atom from the surfactant.

There exist numerous photochemical reactions of quinonoid compounds with participation of their substituents. It has been frequently suggested that the primary process is the transfer of a hydrogen atom from the substituent to the carbonyl oxygen atom, but this mechanism is still controversial.[4] A solvent molecule can participate in reactions of this type. For example, the formation of the final product of the photolysis of compound (III), i.e.



can also be accounted for within the framework of the mechanism involving intramolecular transfer of a hydrogen atom, but CINP data showed that the primary step is electron or hydrogen atom transfer from the medium with subsequent abstraction of a hydrogen atom from the substituent in the quinone by a solvent radical.[228,229]

V. PRIMARY PROCESSES IN THE PHOTOCHEMICAL REDUCTION OF QUINONES BY ALCOHOLS

Numerous studies have been devoted to the mechanism of the photochemical reduction of quinones in alcohols; the problem of the nature of the primary step, whether it is electron transfer or the transfer of a hydrogen atom as a whole, has been discussed in many of them.

The photolysis of frozen alcoholic solutions of quinones leads to the formation of semiquinone radicals, detected by UV absorption or by EPR.[38,222,230–235] The study of the nature of the alcohol radicals has shown that alkoxy-radicals are formed initially.[230,232] The primary step is electron transfer with subsequent proton transfer from the hydroxy-group. Hydroxyalkyl radicals are formed in secondary reactions. There exists a second reaction channel—the abstraction of a hydrogen atom from a carbon atom; the contribution of this pathway is 10% in the compound (I)—ethanol system.[222]

The intermediates in the photochemical reduction of quinones in the presence of alcohols in liquid solutions have been investigated by flash photolysis.[39,78,81,93,105,149,150,215,229,236–248] Scheerer and Grätzel[78] concluded that a molecule of compound (IV) in the triplet state abstracts an electron from an alcohol molecule in the 2: 1 water–ethanol mixture. The formation of radical-anions derived from compound (IV) with a quantum yield of 0.2 is observed simultaneously with the destruction of the triplet. The photolysis of compound (II) in ethanol takes place analogously.[7] The interaction of compound (IV) in the triplet state with the solvent in ethanol and isopropyl alcohol leads to the formation of semiquinone radicals with a yield of 0.4.[149,150] Semiquinone radicals are formed in high yields (up to 1.0) in many other systems, but a hydrogen atom can then be transferred via a two-stage mechanism.[229]

Convincing conclusions concerning the mechanisms of the interaction of compound (V) and its halogeno-derivatives with ethanol have been reached in a study[192]¶ of the influence of added acid on the isotope effect in the photochemical reaction. Simultaneous formation of a radical-anion and the semiquinone radical was observed. Deuteriation of the alcohol reduces the yield of the photochemical reduction reaction by a factor of 1.5. The introduction of CF_3COOH does not influence the isotope effects in the case of compound (V) but reduces the isotope effect in reactions involving the halogeno-derivatives, which have a lowest triplet state of the $\pi\pi^*$ type. Thus the molecule of compound (V) in the triplet $n\pi^*$ state abstracts a hydrogen atom from an ethanol molecule, while the halogeno-derivatives of compound (V) in the triplet $\pi\pi^*$ state abstract an electron with subsequent proton transfer. Comparison of the quantum yields in the photochemical reduction in C_2H_5OD and C_2D_5OH showed that the proton is transferred from the α-carbon atom of the alcohol radical-cation.

The rate constant for the quenching of the triplet state of compound (IV) by ethanol and isopropyl alcohol is 3×10^4 litre mol^{-1} s^{-1},[78,249] while that for the quenching by benzyl alcohol is 8×10^5 litre mol^{-1} s^{-1} and increases to 2.7×10^7 litre mol^{-1} s^{-1} on protonation of a molecule of compound (IV) in the triplet state,[81] which suggests electron transfer. A significant increase in the rate constant for the quenching of ^3Q by alcohols has been observed on passing from quinones with lowest triplet states of the $\pi\pi^*$ type [compounds (II), (III), and (IV)] or of the CT type (2-piperidino-9,10-anthraquinone) to quinones with triplet states of the $n\pi^*$ type [compounds (I) and (V)]. In the quenching of compound (V) in the triplet state, the constant k_q ranges from 3×10^6 to 2×10^7 litre mol^{-1} s^{-1},[199,250] while an estimate of k_q for the quenching of compounds (I) in the triplet state by methanol in water yielded a value in excess of 10^8 litre mol^{-1} s^{-1}.[242] This feature indicates a radical mechanism of the reaction, on the basis of which the activity series of alcohols in their photochemical dehydrogenation, which is determined by the mobility of the hydrogen atom in the α-position, has been explained.[251]

The mechanism of the photochemical reduction of quinones by alcohols has been investigated by the CIEP[116,119,167,169,171,173 252–260] and CINP[170,228,229,253,261–264] methods, which in most cases do not yield an unambiguous answer as to the nature of the primary radicals. The conclusion that the primary step is electron transfer was reached in a CINP study in the compound (I)—CCl_3COOH–t-butyl alcohol[263] and compound (III)—n-propyl alcohol[228,229] systems in which CINP arises via a triplet mechanism whose manifestation is possible by virtue of the short electronic relaxation time of the alcohol radical-cation. The study of the latter system simultaneously by the CINP and flash photolysis methods showed that, although the primary step is electron transfer, ultimately neutral radicals emerge from the solvent "cage" owing to the subsequent proton transfer.

The nature of the radicals formed in the photolysis of alcoholic solutions of quinones has been investigated in detail by EPR.[167,189,190,207,210,212,214,215,265–276] Using spin-trapping agents, it has been possible to detect primary (very short-lived) alkoxy-radicals derived from the alcohol.[187,271,272,276] It was concluded that the primary step is in many cases electron transfer. In the case of very distinct triplet states of the $n\pi^*$ type there exists a second reaction pathway—the transfer of a hydrogen via a radical mechanism. The transfer of an electron or a hydrogen atom takes place in a hydrogen-bonded

EDA complex in the triplet state and is induced by the electron donor–acceptor interaction with participation of the unshared electron pair localised on the oxygen atom of the alcohol molecule and the electron located in the *n* orbital of the quinone molecule in the triplet state.

---o0o---

Analysis of the literature data permits the conclusion that the electron transfer processes and the formation of triplet electron donor-acceptor complexes with a particular degree of charge transfer and with a hydrogen bond play an important role in the photochemistry of quinonoid compounds. The kinetics and mechanism of the formation of triplet exciplexes and the processes occurring in them constitute a basis which determines the course of the subsequent chemical reaction. The study of the physicochemical properties of triplet exciplexes constitutes an important field in photochemistry.

Triplet exciplexes are not formed as intermediate species in many photochemical and photobiological systems alone. Modern approaches to the creation of new methods for the recording of information on non-silver materials can also include exciplex systems in which triplet exciplexes play a key role. By virtue of the progress in the field of new methods based on laser techniques, this field is developing rapidly at the present time.

Advances in the Study of Metal Complexes with Tervalent Phosphorus Amides

E.E.Nifant'ev, A.T.Teleshev, and Yu.I.Blokhin

Data on the synthesis, structure, and chemical properties of complexes of non-transition and transition metals with tervalent phosphorus amides are surveyed. An attempt is made to trace the influence of the amide functional group of the ligand on the properties of these compounds. The literature data on the practical use of the metal complexes with formamides are analysed in the review.

The bibliography includes 265 references.

IV. The search for practical applications 336

I. INTRODUCTION

The metal complexes of ligands containing a tervalent phosphorus atom are being vigorously investigated. Studies have been made of their synthesis, structure, physiological activity, chemical properties, and catalytic properties. Analysis of the existing publications has shown that the vast majority of the latter are devoted to complexes with phosphine ligands, namely with triphenylphosphine. Apparently, the availability of triphenylphosphine, the convenience with which it can be employed, as well as Wilkinson's succesful synthesis of effective catalytic systems based on this phosphine, dictated the choice of the ligands. Overall, the tendency to employ a narrow group of well known ligands arose from the passive attitude of organophosphorus chemists to the new field in the boundary region where the interests of coordination chemistry and the chemistry of organophosphorus compounds are interlinked. In recent years the situation changed and complexes with a wide variety of phosphorus ligands—phosphites, phosphonites, phosphinites, phosphorofluoridites, etc.—began to be investigated and fundamentally new results have been obtained. Together with the ligands already enumerated, tervalent phosphorus acid amides (TPAA), which are very interesting from the chemical standpoint, began to be used as ligands. Initially such derivatives were regarded as kinds of "hybrids" of two popular classical ligands—phosphines and amines. Subsequently, novel qualities of formamides, which make the complexes obtained from them very unusual, were discovered.

The field of science devoted to the study of metal complexes of TPAA is at present still in the stage of its establishment. More than 350 articles and patents have been devoted to it. However, it is significant that the existing publications do not as yet constitute a stream of relevant information and chemical ideas. As a rule, they report only new facts which are not compared to any great extent with facts known from related studies and studies on other phosphorus-containing complexes. In view of this, we aimed to prepare the first review in the world literature on metal complexes of TPAA. For this purpose, we have given a systematic account of published data and have analysed (insofar as this is at present possible) the influence of the phosphamide fragment of the ligand on the synthesis, structure, and properties of new coordination systems. It is essential to note the characteristic feature of this review. The relevant problems are considered from the standpoint of organophosphorus chemistry which in our view should have full parity with coordination chemistry in the study of the systems mentioned.

II. SYNTHESIS

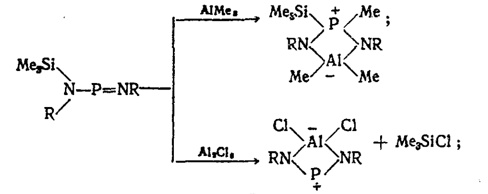
1. Non-transition Metal Complexes

There are only very brief mentions in the literature of the preparation of complexes of TPAA with zinc and cadmium. The complexes $ZnCl_2L_2.2H_2O$ have been obtained from the triethyleneamide of phosphorous acid.[1] The mode of coordination and other structural problems have not been reported. The reactions of the hexamethyltriamide of phosphonous acid (I) and of the tetramethyldiamide of phenylphosphonous acid (II) with CdI_2 have been described;[2] according to the authors, the products $CdI_2.(I)_2$ and $CdI_2.(II)_2$ were obtained. It has been assumed[3] that the coordination of the ligand in the interaction of $Cd(NO_3)_2$ with the di(butylamide) of cyclohexylphosphonous acid is effected via the unshared electron pair of the nitrogen atom. We may note that the structures were not rigorously demonstrated in the above studies.[2,3]

The complexes of bivalent mercury with mono- and bi-dentate ligands have been investigated in greater detail.[2,4-7] It has been established that compounds having the compositions HgX_2L_2 and HgX_2L can then be formed. The coordination of the ligands to the phosphorus atom was elucidated on the basis of ^{31}P NMR data and in addition the *trans*-configuration of the complexes HgX_2L_2 was demonstrated. The formation of the mercury complexes can be accompanied by unusual reactions, for example, the formation of P—P bonds.[2]

Among Group III metals, only aluminium has been studied in reactions with TPAA. Vigorous complex formation by triethylaluminium via phosphorus in interaction with equimolar amounts of amides or imides or phosphinous acid has been demonstrated.[8] In the latter case adducts were obtained in which the two phosphorus atoms are equivalent according to NMR data, indicating the parallel binding of the aluminium atom with two phosphorus atoms. When *HN*-phosphimides are used, the complex formation reaction is supplemented by the metallation of nitrogen. TPAA react also with $AlCl_3$: the formation of monoadducts in this process has been indicated.[9] On dissolution in methylene chloride, the latter can react with formation of phosphorus–phosphorus systems.[10,11] The reaction dynamics has been investigated by ^{31}P NMR. Analogous derivatives can be more simply obtained by the reaction of $AlCl_3$ with phosphoramidochloridites, Salts whose cations have a discoordinate phosphorus atom are then formed initially. Subsequently, they disproportionate or add to the electron-donating TPAA.[9,10,12]

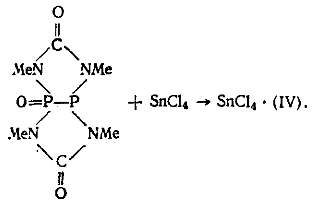
Very interesting results have been obtained[13,14] in the study of *N*-silylated amides of phosphorimidic acids (III):



R=SiMe₃, Bu-t.

The difference between the reactions of the amidoimide (III) with trimethylaluminium and trimethylboron is noteworthy; the latter reaction leads only to a linear system with the boron atom at one of its ends.[14]

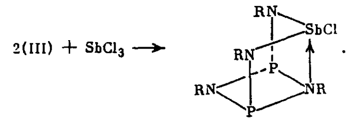
The wide-scale study of the synthesis of phosphorus complexes based on tin halides has been initiated. Compounds having the composition $SnCl_4L_2$ have been obtained from the full amides and amidoesters of phosphorous acids[15,16] and the amides of phosphonous[17,18] acids. The complex $SnCl_4L$ has been synthesised from the complex P–P ligand (IV):[19]



(IV)

The study of the structure of the complexes by ^{31}P NMR, ^{1}H NMR, and infrared spectroscopy led to the conclusion that the ligand is coordinated to the phosphorus atom. It has been shown that the stability of the test substances is determined by the electron-donating capacity of the substituents at the phosphorus atom.[16]

Derivatives of Group V non-transition metals have been little studied in their complex formation reactions with TPAA. It has been reported that $SbCl_5$ chlorinates these compounds, being reduced at the same time to $SbCl_3$. The second stage of the process involves the formation of aminochlorophosphonium hexachloroantimonates.[20] Furthermore, the possibility of the usual complex formation reaction between $SbCl_5$ and the P–P ligand (IV) has been indicated.[19] An unusual reaction involving a stage in which the nitrogen atom of the phosphamide centre is coordinated to SbCl has been described:[21]



The mode of coordination is determined by stereochemical factors, namely by the mutual approach in space of the antimony and nitrogen atoms. The use of $AsCl_3$ does not lead to the closure of the skeletal system.[21]

2. Transition Metal Complexes

The study of transition metal complexes with TPAA was begun comparatively recently, but it is being prosecuted vigorously and is distinguished by highly novel synthetic features. One may say that a much greater number of different types of complexes have been created in this field than in other related fields of coordination chemistry. This situation can apparently be accounted for by the structural variety of the ligands related to TPAA and the wide variety of their chemical properties: the synthesis of complexes of each group will accordingly be considered in a way emphasising the role not only of the metal but also of the corresponding type of phosphamide ligand.

The complexes of metals of the first Groups have been investigated relatively modestly. On the other hand, those of Group VI, VII, and VIII metals have been widely studied and the characteristic features of the individual classes of compounds have been elucidated.

(*a*) *Complexes of metals in the first Groups.* Among the phosphamide complexes of copper, silver, and gold, derivatives of univalent copper have been investigated in greatest detail. The first representatives of compounds of this class have been obtained[22] by the interaction of the salt CuX with the simplest amides of alkylene phosphorous acids. Subsequently the reaction was extended to a wide range of phosphamides,[4,23,24] including cyclic phosphoramidites of carbohydrates.[25,26] The structures of the majority of the complexes obtained have been investigated by NMR and X-ray diffraction, which demonstrated that the ligand is coordinated to the phosphorus atom. In complexes of the phosphorinane type, it was shown that the metal occupies an axial position and that the six-membered ring has the chair conformation.[24]

Certain phosphamide complexes of copper hydride[27] and organocopper compounds[28] have also been studied.

Silver complexes of different composition have been obtained by the reaction of the salts AgX with the phosphamide (I). When X = Cl, CN, or NO_3, the compounds $AgXL_2$ are formed and, in the case where X = BPh_4, systems in which three molecules of the ligand (I) are incorporated in the central nucleus can be isolated. The same picture has been noted in a study with the bicyclic compound $P(NMeCH_2)_3.CMe$ (V) using salts with different anions. The triethyleneamide of phosphorous acid gives rise to the complexes $AgXL_4$ regardless of the type of anion. In all cases the ligand is coordinated to the phosphorus atom, which has been demonstrated by X-ray diffraction.[29] The difference noted in the behaviour of formally similar ligands is apparently associated with the appreciable difference between their geometrical parameters and the wide variety of the electronic effects in the P–N fragment.[30] In confirmation of the latter postulate, we may note that sterically hindered phosphamides are only singly bound to silver salts.[31]

Bidentate ligands have also been investigated in reactions with silver salts.[6,32] The iminodiphosphines (VI) have been studied in special detail:[32]

$$MeN(PPh_2)_2 + AgBr \rightarrow [MeN(PPh_2AgBr)_2]_2 .$$

(VI)

The structure of the adduct whose molecule is based on the $Ag_4Br_2^{2+}$ octahedron has been demonstrated by X-ray diffraction. We may draw attention to the specific influence of the amide unit, manifested in the formation of the octahedral structure. If instead of this unit, two phosphorus atoms are linked by a methylene group, a different polyhedron, namely $Ag_3Br_2^{+}$, is formed.[32]

Complexes of univalent and tervalent gold with TPAA began to be investigated only in very recent years. The amides of phosphinous acids[31] and azaphospholes[33] have been used as monodentate ligands. The problem of the mode of coordination of the ligand still remains controversial in this instance. Iminodiphosphines[34] and the corresponding anions[35] have been used as bidentate ligands.

The study of the complexes of TPAA with Group IV and V metals has been fragmentary. There exists a brief communication about the chelation of the central atom in $TiCl_4$ by 1,3-di-t-butyl-2,4-dichloro-1,3,2,4-diazadiphosphetidine (VII).[36] There has been a very interesting study of the oxidative addition of phosphorous acid triisocyanate to $TiCl_4$ and $ZrCl_4$:[37]

$$MCl_4 + P(N{=}C{=}O)_3 \rightarrow MCl_3P(N{=}C{=}O)_2 + ClN{=}C{=}O\,.$$

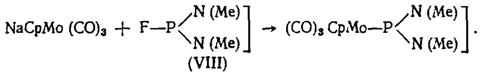
The diethylamides of dimethyl phosphorous and phenylphosphonous acids add to VCl_4; 1 : 1 and 2 : 1 adducts are formed in the former case and only 1 : 1 atoms in the latter.[38] A series of complexes have been synthesised by ligand transfer reactions between $CpV(CO)_3L$ and the full amides of phosphorous,[39,40] and dimethylphosphinous[41] acids:

$$CpV(CO)_4 + L \rightarrow CpV(CO)_3L\,.$$

$CpNb(CO)_4$ reacts in accordance with an analogous scheme but with more extensive substitution.[42]

(*b*) *Complexes of Group VI metals*. Almost all the studies published on this question have been devoted to the derivatives of metals in the lowest oxidation states. A common feature of these investigations is the use of identical or structurally similar initial metal-containing compounds. These are usually hexacarbonyls or mixed carbonyls. The substances mentioned are made to react with TPAA and one mole of carbon monoxide is readily evolved.† When special rules are fulfilled, even more complete substitution of the carbonyl ligand may take place. Acetonitrile, olefins, etc. are displaced from the coordination sphere more readily than carbon monoxide. The principle of ligand displacement constitutes the basis of the most popular direct method of synthesis of the complexes considered. However, this method can be supplemented successfully in many instances by a second, combined procedure. Complexes of the metal with phosphorus acid chlorides or other phosphorus compounds capable of reacting with nucleophiles are obtained in a preliminary step. In the concluding stage the intermediate complexes are made to react with nitrogen-containing bases to form the required products.

Direct synthesis. Chromium and molybdenum complexes may be obtained by electrophilic substitution at the metal atom, i.e. by the reaction of carbonylate anions with aminohalogeno-derivatives of phosphorous acid.[43-45] Substitution takes place readily, since the aminohalogeno-derivatives, especially 2-fluoro-1,3-dimethyl-1,3,2-diazaphospholan (VIII), readily give rise to highly electrophilic phosphamide cations. This results in the formation of phosphometallic systems, for example:



(VIII)

$$NaCpMo(CO)_3 + \left[F{-}P\begin{matrix}N(Me)\\N(Me)\end{matrix}\right] \rightarrow \left[(CO)_3CpMo{-}P\begin{matrix}N(Me)\\N(Me)\end{matrix}\right].$$

The chemical structure of the substances obtained has been demonstrated by X-ray diffraction. The final conclusion about the electronic structure has not yet been reached, although this problem is the subject of a lively discussion.[45,46]

Carbonylate ions have been made to interact with the tetrafluoride of *N*-methyldiphosphorimidic acid (IX):[47]

$$\underset{(IX)}{MeN(PF_2)_2} + NaCpMo(CO)_3 - \begin{cases} \xrightarrow{1:1} F_2PN(Me){-}PF[MoCp(CO)_3]\,; \\ \xrightarrow[1:2]{} F_2PN(Me){-}P[MoCp(CO)_3]_2\,. \end{cases}$$

The reaction proceeds in a more complex manner in another instance:[48]

$$(Me_3Si)_2NPCl_2 + Na_2Cr(CO)_5 \rightarrow Cr(CO)_5[P{-}N(SiMe_3)_2]_2 +$$
$$+ [Cr(CO)_5]_2PN(SiMe_3)_2 + \{Cr(CO)_4[PN(SiMe_3)_2]_2\}[Cr(CO)_5]_2\,.$$

All the substances indicated have been isolated from the reaction mixture by fractional recrystallisation and their structures have been determined by X-ray diffraction. The chemistry of these reactions has not been discussed. Carbonylate anions have been made to react with the aminofluoroderivatives of phosphorous acid in the presence of mercury(II) chloride, which is an oxidant. Derivatives of zero-valent metals are formed in this case:[49]

$$M_2(CO)_{10}^{2-} + F_2PNEt_2 + HgCl_2 \rightarrow M(CO)_5(F_2PNEt_2)\,;$$
$$M{=}Cr,\ Mo,\ W\,.$$

TPAA manifest much more frequently only a ligand transferring activity without the loss of their structural elements, as shown above. We shall consider this possibility in relation to the employment of derivatives of zero-valent metals of different chemical nature—neutral complexes of the type $M(CO)_6$, ionic complexes of the type $[M(CO)_5X]^-$, and other related compounds. These substances effectively undergo ligand transfer reactions with full amides,[1,5,50-55] ester amides,[56] mixed amide–acid halides,[5,57-59] and imino-amides [60,61] of phosphorous acid, the amides of phosphonous and phosphinous acids,[23,41,50,60,62,63] diazaphospholes,[64] and the amides of hypodiphosphorous and other branched P–P acids.[19,65-67] The amides of diphosphonous acids and other bidentate ligands[68-72] as well as cyclic[73,74] and bicyclic[51,56,75] phosphamides play an important role in these reactions.

Monosubstitution of the carbonyl ligand takes place under relatively mild conditions. For this purpose, metal hexacarbonyls or other related substances are heated with an equimolar amount of TPAA in an organic solvent.[41,56,60,76-78] It is useful to carry out the reaction in its photochemical version:[49]

$$M(CO)_6 + THF \xrightarrow{h\nu} M(CO)_5 \cdot THF \xrightarrow{L} M(CO)_5L\,.$$

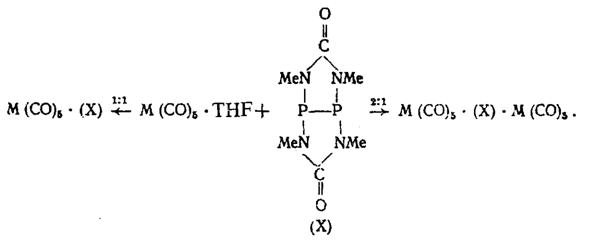
In studies with enantiomeric TPAA and prochiral complexes, diastereoisomers were synthesised[61,62,79] and it proved possible to separate them by the usual methods.

The reactions of ligands with molecules containing two phosphorus atoms, including phosphorus atoms linked directly to one another, have been investigated in various laboratories. If one of these atoms is tervalent and the other pentavalent, the process takes place only once.[19] If both phosphorus atoms are tervalent, as in the ligand (X), then the monosubstitution of the metal can proceed with participation

---

† In the interaction of ionic reagents, carbon monoxide may not be evolved.

of one or both[65,67] phosphorus centres:



(X)

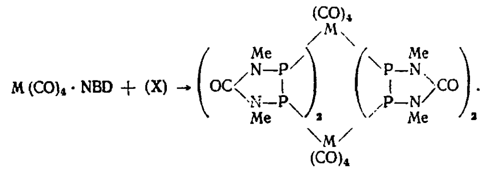
An analogous situation arises in diazadiphosphetidines.[73,77]

In the reactions examined above the difference in the complex formation reactions of chromium, molybdenum, and tungsten carbonyls was hardly manifested. Nevertheless, such a difference can be found by analysing the reactions of these carbonyls with the bidentate phosphimide ligand $(Ph_2P)_2NCH(R)COOMe$ (XI). Tungsten carbonyls react mainly with monosubstitution, while chromium and molybdenum carbonyls react with disubstitution.[80,81]

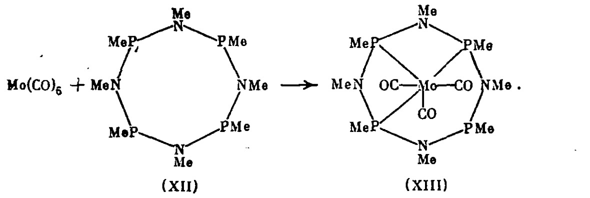
The bis-ligand transfer reaction has also been studied in detail. In order to achieve a satisfactory result, an excess of the ligand is normally employed.[5,52] The synthesis of disubstituted products is of special interest since generally speaking it can lead to geometrically isomeric complexes. It has been noted that the *cis*-forms are formed preferentially in the initial stage and can be converted on heating into the *trans*-forms.[5,57,59] In a number of experiments it proved possible to separate these isomers and to investigate their specific properties.[5,52]

It is essential to consider specially the ligand transfer reactions of phosphamides with other electron-donating centres. The hydrazide of diphenylphosphinous acid reacts with metal hexacarbonyls to form chelates.[82] An analogous result has been achieved with the full amides of αω-alkylenediphosphonous acids. When the distance between the phosphorus atoms in the molecules of the latter reaches a specific value, dinuclear systems are formed.[68,69,72]

Iminodiphosphine ligands of types (VI), (IX), and (XI) have been studied more widely in metallocycle formation.[80–86] Interesting results have also been obtained for the interaction of the norbornadiene (NBD) complexes of chromium and molybdenum carbanions with the P–P ligand (X):[67]



The tris-ligand transfer reaction has been studied relatively little. In relation to metal hexacarbonyls, this reaction yields positive results only when a specific TPAA are used. Such a ligand is the eight-membered phosphazane (XII):[87]

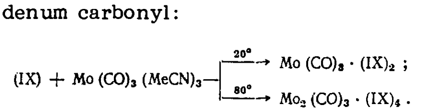


(XII) (XIII)

The fourth phosphorus atom is not coordinated to molybdenum. It is of interest that this phosphorus atom forms the longest bonds with the neighbouring nitrogen atoms (1.742 and 1.728 Å); the lengths of other bonds in the ring are much shorter (1.699 and 1.712 Å). The phosphorus atom not involved in coordination has the smallest endocyclic angle (107.13° against 109.02–110.5°).

On reaction with MeI, the neutral compound $(MeNPMe)_4.Mo(CO)_3$ (XIII) forms the corresponding ionic complex, which can also be prepared by the reaction of the ligand (XII), MeI, and $Mo(CO)_6$.

A study of the tris-ligand transfer reaction of hexacarbonyls with the dimethyl hydrazide of diphenylphosphonous acid has been published.[82] The ligand is bound in this reaction to the metal only via the phosphorus atoms. Nevertheless, in synthesis involving phosphorylated α-aminopyridine, coordination with participation of both the phosphorus atoms and the nitrogen atoms of the pyridine rings has been noted.[89,90] Very interesting results have been obtained[91] in a study of the interaction of the bidentate ligand (IX) with a mixed molybdenum carbonyl:

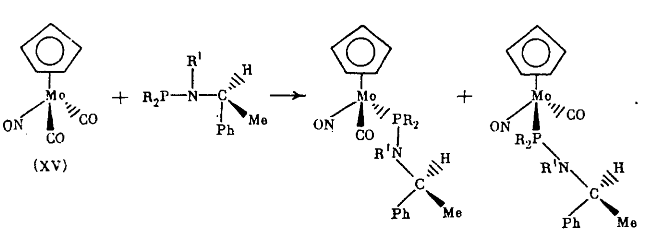


$$(IX) + Mo(CO)_3(MeCN)_3 \begin{cases} \xrightarrow{20^\circ} Mo(CO)_3\cdot(IX)_2\ ; \\ \xrightarrow{80^\circ} Mo_2(CO)_3\cdot(IX)_4\ . \end{cases}$$

The structure of the dinuclear complex was demonstrated by X-ray diffraction. The difference in the ligand environment of the molybdenum atoms and the presence of a direct bond between them are noteworthy. Both these factors are not characteristic of the dinuclear complex obtained from the ligand (X).[66]

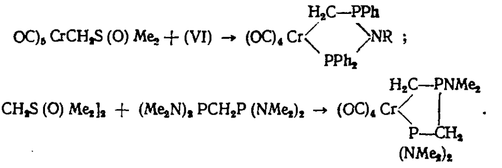
There are isolated mentions in the literature of the possibility of the hexa-ligand transfer reactions of the carbonyls of the metals considered. Thus, when the ligand (IX) is used under the conditions of photochemical stimulation, a spirotricyclic complex is readily formed.[92] Analogous substitution takes place with the tetrafluoride of *N*-phenyldiphosphorimidous acid (XIV).[93] A spirotricyclic complex of chromium has been obtained also on cocondensation of the metal vapour with the ligand (IX), while the monodentate mixed acid amides and fluorides give rise to symmetrical acyclic adducts under conditions of this reaction.[94,95] The cocondensation of chromium vapour with a mixture of ligands gives rise to a set of complexes of different ligand composition, from which the product $[(IX)_2.Cr(F_2PNMe)_2]$ has been isolated in a pure form.[95]

We shall now turn to studies on ligand transfer reactions in which derivatives of Group VI metals in the +1 or +2 oxidation states are used as starting materials. This possibility has been demonstrated in two investigations:[62,96]

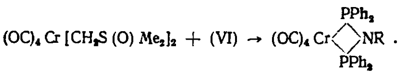


It is significant that the diastereoisomers are formed in unequal amounts; the ratio of the products depends on the type of the groups R and R′. Apparently this result is determined by an associative mechanism; in this case the transition states arising when the ligand attacks via two enantiomeric directions need not necessarily have the same energies.

There are also literature data on the ligand transfer reactions involving bidentate ligands. Thus one carbonyl ligand is displaced from a carbonyl of type (XV) on treatment with the tetrafluoride (IX).[97] It has been established very recently that the complexes of chromium carbonyl with the imides of diphenylphosphinous acid of type (VI) and the octamethyltetramide of methylenediphosphonous acid[98–100] form novel chromium-containing phosphaheterocycles:



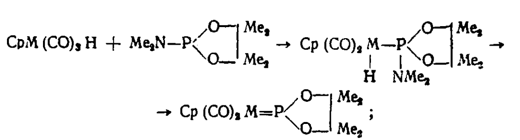
It has been concluded that the chromylide $(CO)_4Cr{=}CH_2$ is probably formed as an intermediate. However, this pathway is not obligatory:[99]



Systems in which the oxidation state of the metal is +2, namely cyclopentadienylmetal tricarbonyl chlorides,[97,101] readily interact with bidentate ligands of types (IX) and (XI) to form chelates. In the complex formation reaction in alcohol, the bidentate ligand (IX) can undergo alcoholysis:[97]

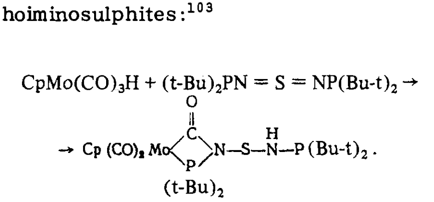
$$CpW(CO)_3Cl + (IX) + ROH \rightarrow CpW(CO)_2[PF(OR)_2]Cl.$$

We may mention specially the non-trivial reactions of hydride complexes. The following reactions have been discussed:[102]



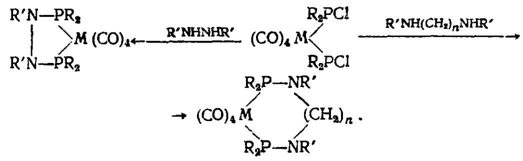
M=Cr, Mo, W.

The structure of compounds with a phosphorus–metal double bond had been demonstrated by X-ray diffraction. The phosphamide (I) enters into similar reactions. The hydrides considered react in an even more complex manner with phosphoiminosulphites:[103]

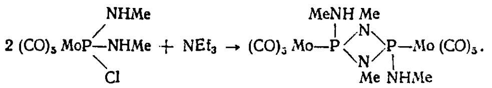


2,8-Dioxa-5-aza-1-phosphabicyclo[3.3.0]octane has been used as a ligand in complex formation reactions of neutral tungstates. It has been suggested that the overlap of the nitrogen and phosphorus orbitals is difficult in this compound for geometrical reasons, so that the phosphorus centre is less electron-donating, as a result of which tungsten is coordinated to the nitrogen atom. If the *P*-borate derivative is used in the complex formation reaction, then a stable *N*-tungsten adduct is formed.[104]

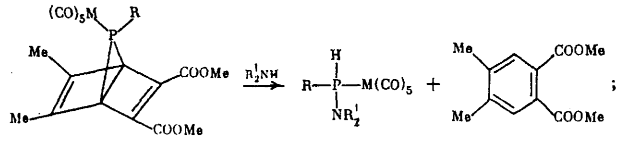
Combined synthesis of phosphamide complexes. Within the framework of this approach, the amido-group is introduced as a result of the substitution of the halogen atoms in halogenophosphine complexes. The simplest version of the synthesis consists in the interaction of monochlorophosphine systems with secondary amines.[105] More complex reactions involving secondary diamines and dialkylhydrazines can also be included here:[106]



The reaction of halogenophosphine complexes with ammonia and primary amines#,[77,107–110] including primary diamines,[106] with other functional groups[108,111] is widely used. We may mention specially the dehydrochlorination of chloramide complexes which can lead to dinuclear complexes inaccessible by other procedures, for example:[107]



The reactions of nitrogen-containing bases with halogenophosphine complexes proceed in an unusual manner in many instances. Thus the coordination compounds of molybdenum with CCl_3PF_2 phosphorylate very readily secondary amines via the P–CCl_3 bonds and not the P–F bonds.[112] The synthesis of hydrogen-containing aminophosphine complexes is chemically even more interesting:[113]



M = Cr, W; R = Ph, Me; R$'$ = H, Et, Ph.

The possible mechanisms of this reaction have been analysed.[113]

In the course of studies designed to demonstrate the structures of the complexes investigated using physicochemical methods, certain interesting rules have been established. Thus it has been shown that the direct coordinate bonds (^{97}Mo–^{31}P [114] and ^{183}W–^{31}P [51]) depend on the electronegativity of the atoms linked to the phosphorus atoms. In the ligand sequence obtained, phosphamides are located between phosphines and phosphites. Qualitatively the same picture can be traced in coordination shifts.[51] It is of interest that each type of complex (phosphine, phosphite, and phosphamide) constitutes a specific family when the direct coordinate bonds (^{183}W–^{31}P) are correlated with the ν(CO) frequencies in the IR spectra.[55]

(*c*) *Complexes of Group VII metals.* The general postulates which we have already mentioned in relation to the synthesis of Group VI metals hold also in relation to the synthesis of complexes of Group VII metals. One can only point to the smaller number of the relevant studies and the fact that they are almost all devoted solely to manganese derivatives. The principal method of synthesis of these compounds is the

---

#The reactions can have specific pathways. In contrast to other primary amines, the interaction of t-$BuNH_2$ with the complex $(CO)_5MoPCl_3$ leads to the formation of a diphosphorus cyclic derivative and not a monophosphorus derivative.[77]

ligand transfer reaction. The dinuclear zero-valent manganese carbonyl complex $Mn_2(CO)_{10}$ has been used in reactions with the phosphamides (I) [115] and (VII).[36] The cyclic iron–arsenic–manganese cluster reacts with the ligand (I) via the dissociation of the manganese–iron bond.[116]

The readily available derivatives of metals in the +1 oxidation state of the type of $CpMn(CO)_3$ [57,117] and $Mn(CO)_5Br$ [41] have been most often used as the initial compounds. One and sometimes also two of their ligands are readily substituted by the simplest TPAA. More complex reactions have also been described, for example:[118]

$$CpMn(CO)_2THF + Ph_2PN{=}CMn(CO)_2Cp \rightarrow Cp(CO)_2Mn{-}PPh_2N{=}CMn(CO)_2Cp.$$

Interesting data have been obtained using tetraphenyldiazaphospholes.[119] The *trans*-isomer ensures the mono-ligand transfer reaction involving $Mn(CO)_5Br$. The *cis*-isomer is capable of double substitution to give *mer*-$Mn(CO)_3L_2Br$. If one begins with the corresponding rhenium derivative, then double substitution takes place with both ligands.

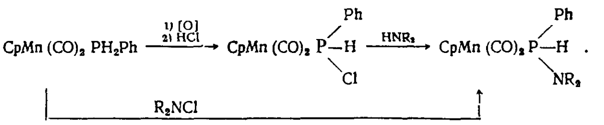
Bidentate ligands have also been used in a series of studies. Thus treatment of $Mn(CO)_5Br$ with the ligand (XI) results in the effective substitution of two carbonyl groups,[80] while in the interaction of $[Re(CO)_3(THF)_2Br]_2$ with 1,3-di-t-butyl-2,4-dimethyl-1,3,2,4-diazadiphosphetidine [120] two THF molecules are substituted. Similar processes also occur in the $CpMn(CO)_3$–ligand (IX) system.[97]§

TPAA with the α-pyridyl residue incorporated in the phosphamide fragment are also capable of single or double insertion in the coordination sphere as a result of the displacement of carbon monoxide.[76]

In the reactions described above coordination involved the phosphorus centre of the ligand. It has been shown[122] that, for the dinuclear complexes of rhenium, there is a possibility of the parallel *PN*-coordination when phosphineiminoamide ligands are used.

Derivatives of manganese in the +2 oxidation state have also been investigated in ligand transfer reactions.[57,123,124] Here we may mention the synthesis of diastereoisomeric components using optically active phosphamides.[123,124]

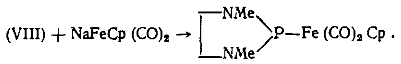
The synthesis of the phosphoramidite complexes of Group VII metals by the combined method has been little studied. Only one communication on this topic has been published:[125]



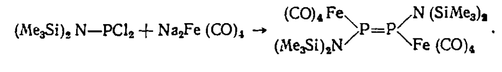
We may mention that the chlorophosphine derivative formed in the first stage is labile and rapidly disproportionates, while the corresponding phosphamide product is stable.

(d) *Complexes of Group VIII metals.* The greatest number of studies have been devoted to the synthesis of the phosphamide complexes of Group VIII metals. Bearing this in mind and also the known specific features of the individual families of elements of this Group, we have divided the entire data into sections in terms of three triads.

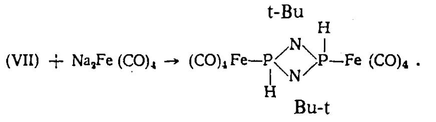
The metals of the first triad (Fe, Ru, Os) exhibit widely the 0, +1, and +2 oxidation states. The coordination systems in which we are interested have been obtained only by direct synthesis. Electrophilic substitution at the metal atom incorporated in the structure of the carbonylate anion has been used within the framework of this method, for example:[43]



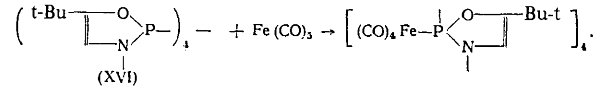
The employment of carbonylates with the more electron-donating iron atom in the interaction with the same acid fluoride (VIII) leads to the formation of a complex of the corresponding amide of hypodiphosphorus acid.[43] An even more complex compound has been obtained in the related reaction based on phosphoramidous chlorides:[48]



The author did not consider the chemistry of this process. An unusual derivative of the diamide of hypophosphorous acid has been obtained by treating the above carbonylate with the ligand (VII).[126] The traces of water present are apparently the source of hydrogen:



The ligand transfer reactions of the simplest complexes of the metals in the triad have been studied in greater detail on treatment with TPAA. In these reactions the TPAA usually do not lose any atoms or groups, as mentioned above. In individual experiments, such loss nevertheless occurs, but the structural element separated from the phosphorus remains part of the composition of the complex. We may mention the principal aspects of the investigations. The phosphamide (I) [127] and monoaminophosphines[41,128] react with $Fe(CO)_5$ to form monosubstitution products. Apart from monodentate ligands, bidentate[129,130] and tetradentate[131] ligands have been used in the reactions with $Fe(CO)_5$. As an illustration, we may quote the reaction



It is significant that the initial tetramer (XVI) behaves differently in the complex formation reactions—in its reaction with boron trifluoride ether, it is converted into the monomeric form and gives rise to a boron complex of a derivative of dicoordinate phosphorus, while in the example quoted only carbon monoxide is displaced from the four $Fe(CO)_5$ molecules. The structure of the iron complex has been demonstrated by X-ray diffraction and a significant difference between the lengths of the P—N bonds has been demonstrated (the distance is 1.737 Å for the bonds involved in both the small and the large rings, while the distance is 1.676 Å for the bonds in the large ring only). This difference is apparently determined by the different interactions of the unshared electron pairs of the nitrogen atoms with the electrons of the two phosphorus–iron coordinate bonds conjugated with them.

Phosphoramidous halides have also been introduced into the ligand transfer reaction.[132–134] If Lewis acids are added to the reaction mixture, then the primary adduct can ionise. In the synthesis of complexes of the type $Fe(CO)_4L$, one may begin with cluster carbonyls whereupon structurally simpler iron carbonyls are usually formed as side products (they sometimes also undergo ligand transfer reactions).[19,53,75,93,]

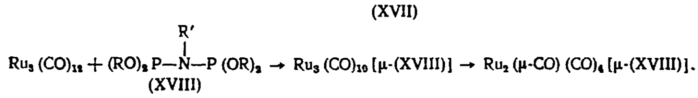
---

§ The carbene complexes of manganese behave analogously.[121]

[132,135–137] It has been suggested that complexes of zero-valent iron with TPAA be synthesised also by the cocondensation of the metal vapour with monodentate[95] and bidentate[95,138] ligands. The iron atoms in these compounds are linked to five phosphorus atoms having identical or different substituents.

The coordination compounds of TPAA with zero-valent ruthenium and osmium have been little studied. The following methods of their synthesis have been described in the literature:[139–141]

$$\mathrm{RuH(O_2CMe)(PPh_3)_3} + \underset{\text{(XVII)}}{\mathrm{F_2PNMe_2}} \rightarrow \mathrm{Ru\cdot(XVII)_5};$$

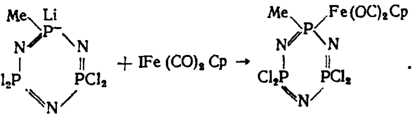


$$\mathrm{Ru_3(CO)_{12}} + \underset{\text{(XVIII)}}{\mathrm{(RO)_2P{-}\overset{\overset{\large R'}{|}}{N}{-}P(OR)_2}} \rightarrow \mathrm{Ru_3(CO)_{10}[\mu\text{-}(XVIII)]} \rightarrow \mathrm{Ru_2(\mu\text{-}CO)(CO)_4[\mu\text{-}(XVIII)]}.$$

The reactions of $Os(CO)_{11}(NCMe)$ and $H_2Os(CO)_{10}$ with the phosphoiminosulphite $(t\text{-}Bu_2PN)_2S$ have been carried out for osmium.[142]

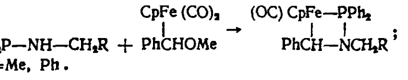
The coordination compounds of iron and the +1 oxidation state having phosphamide ligands have been studied non-systematically. The possibility of the exchange of carbon monoxide for an optically active phosphamide in the prochiral allylnitrosodicarbonyliron complex has been reported.[143] The reaction resulted in the formation of a mixture of two diastereoisomers, which was resolved by the usual procedures.

The synthesis of complexes in the molecules of which the central atom is in the +2 oxidation state has been studied relatively widely. The preparation of coordination compounds by nucleophilic substitution at the metal atom has been described:[144]



The mode of coordination and other related questions have been analysed using X-ray diffraction data. In addition, the usual ligand transfer reactions of carbonylcyclopentadienyliron derivatives, accompanied by the displacement of one or two carbon monoxide molecules on treatment with phosphorous triamide[127] or phosphoramidous fluorides,[57,97] the tetrafluorides of diphosphorimidous acids,[97] and phosphinous acid amides[145–147] have been used in a series of studies. Among the reagents mentioned, optically active substances have been frequently used, which made it possible to obtain systems with a chiral iron atom. The possible epimerisation and migration of the carbonyl in these derivatives has been discussed in a number of studies.[145,147,148]

If the ligand transfer reaction is carried out in its photochemical version, then other profound changes in the system are possible together with the exchange processes, for example:



$$\mathrm{Ph_2P{-}NH{-}CH_2R} + \underset{\mathrm{PhCHOMe}}{\overset{\mathrm{CpFe(CO)_2}}{|}} \rightarrow \underset{\mathrm{PhCH{-}NCH_2R}}{\overset{\mathrm{(OC)CpFe{-}PPh_2}}{|\quad\ \ |}};$$
$$\mathrm{R{=}Me,\ Ph.}$$

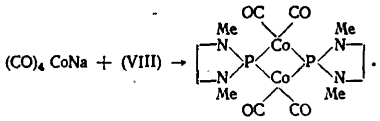
When R = Ph, the iminophosphine complex is obtained.[149]

Ruthenium complexes of the phosphoramidous difluoride (XVII) are readily formed from chlorides stabilised by triphenylphosphine. In the course of the synthesis triphenylphosphine is partly displaced:[150,151]

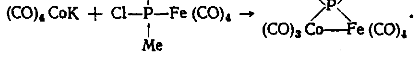
$$\mathrm{RuCl_2(PPh_3)_3} + \mathrm{(XVII)} \rightarrow \mathrm{RuCl_2(PPh_3)_2(XVII)_2}.$$

The adducts with different TPAA based on the chloroarene-ruthenium derivatives[152–154] as well as the corresponding hydrides[155] have been obtained analogously.

The Co, Rh, Ir triad. It has been suggested that electrophilic substitution at the metal atom be used to obtain the cobalt complexes. The carbonylate anions are usually made to react with phosphoramidous halides for this purpose, for example:[156]



Above we considered the analogous reactions of phosphorodiamidous fluoride (VIII) with iron and other transition metal carbonylates and noted that they all lead to mononuclear complexes. It is of interest that the phosphonamidous chloride derivative of iron tetracarbonyl gives rise to a heterometallic complex on interaction with cobalt carbonylate:[137]



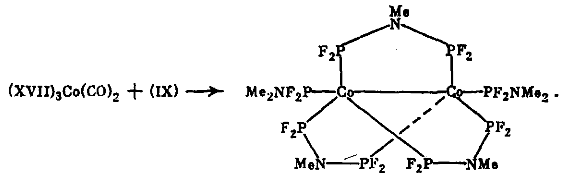
Dinuclear carbonyls, for example $Co_2(CO)_8$ (XIX), can also be involved in the cyclic cluster formation reaction.[157] The cluster obtained proved to be an extremely promising initial compound for the synthesis of other skeletal systems.[158,159]

Together with the electrophilic substitution method, the ligand transfer method has also been used to synthesise cobalt complexes of TPAA, for example:[41,127]

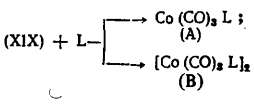
$$\mathrm{CpCo(CO)_2} + \underset{\text{(XX)}}{\mathrm{Me_2PNMe_2}} \rightarrow \mathrm{CpCo(CO)(Me_2PNMe_2)};$$
$$\mathrm{Hg[Co(CO)_4]_2} + \mathrm{(I)} \rightarrow \mathrm{Hg[Co(CO)_3\cdot(I)]_2}.$$

Ligand transfer reactions of this type with structurally similar cobalt complexes $Cp(CO)_2Co(R_F)I$, whose molecules contain the metal atom in the +3 oxidation state, have been achieved using optically active phosphinous amides. Two diastereoisomers are formed in this instance, their ratio being determined by the perfluoroalkyl group R_F.[160]

A relatively complex instance of the ligand transfer reaction makes it possible to obtain a dinuclear complex in a photochemical experiment from a phorphorus-containing mononuclear complex and the ligand (IX):[161]



Cobalt octacarbonyl (XIX) has been studied more widely in the ligand transfer and accompanying reactions. It has been stated that this compound reacts with the ligands (XX) [41] and (I) [127] to give ionic products. The structure of the compounds has not been demonstrated in detail. Subsequently this reaction was investigated in another study[78] where the formation of paramgnetic mononuclear products (A) was established for the full amides of phosphorous acids, while dinuclear diamagnetic substances (B) were found to be produced in the reactions involving the phosphoramidous esters (cyclic and linear):



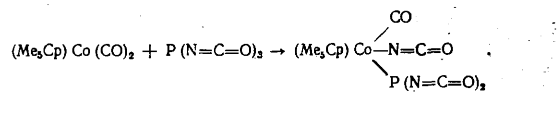
$$\mathrm{(XIX)} + \mathrm{L} \begin{cases} \rightarrow \underset{\text{(A)}}{\mathrm{Co(CO)_3L}}; \\ \rightarrow \underset{\text{(B)}}{\mathrm{[Co(CO)_3L]_2}}. \end{cases}$$

The octacarbonyl (XIX) has been studied in detail in the reaction with the bidentate ligand (IX). The reaction at 20 °C leads to the formation of the dinuclear dicarbonyl $[Co_2(CO)_2(IX)_3]$.¶ On photochemical activation and when an excess of the ligand is used, the product of the full ligand transfer reaction $[Co_2(IX)_5]$ is obtained.[162] There are three chelating ligands in the molecules of each of these complexes, which give rise to five-membered rings with two cobalt atoms. A similar result has been noted also in the reaction of the octacarbonyl (XIX) with the phosphoimine (XIV).[93] Dinuclear systems have also been obtained by the cocondensation of cobalt vapour with the corresponding ligands.[95,161]

The synthesis of cationic cobalt phosphamide complexes by the reaction of cobalt(II) perchlorate with the bidentate ligand $(Ph_2P)_2NPh$ has been reported.[163] Analogous cobalt compounds with α-diphenylphosphamidopyridine have been described.[6] The reactions leading to cobalt–aluminium complexes are chemically more involved:[164]

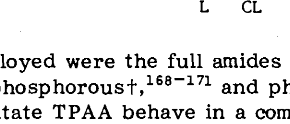
$$CoCl_2[P(NR_2)_3]_2 + AlCl_3 + P(NR_2)_3 \rightarrow CoCl[P(NR_2)_3]_3[AlCl_4].$$

The oxidative addition of the triisocyanate of phosphorous acid to the simplest cobalt complexes merit special attention:[165]



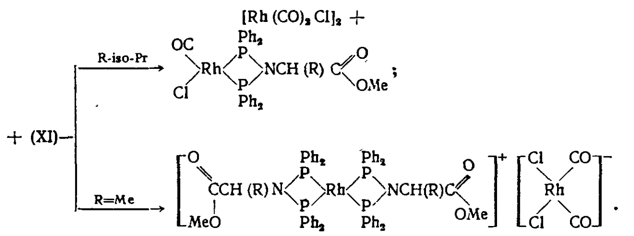
$$(Me_5Cp)Co(CO)_2 + P(N{=}C{=}O)_3 \rightarrow (Me_5Cp)Co(CO)(N{=}C{=}O)(P(N{=}C{=}O)_2).$$

Particularly numerous studies have been devoted to the rhodium complexes of TPAA, which can be accounted for by their catalytic activity. The latter factor affects also the character of the investigations carried out: the published articles frequently describe not individual coordination compounds but compositions comprising them, which are designed for catalysis (such compositions were examined in the Section devoted to catalysis). In contrast to cobalt complexes, the above compounds are more homogeneous in terms of the principal chemical features. As a rule, the central atom of the molecule is in the +1 oxidation state. The methods of synthesis of these systems are also relatively similar. They usually consist in the interaction of carbonyl or olefinic dinuclear complexes with TPAA and the process involves either the substitution of the ligand or the breaking of the $[\mu\text{-}X_2]$ bridges. We shall consider the latter possibility. In many studies the formation of the *trans*-complexes from μ-dichlorotetracarbonyldirhodium has been investigated:



$$[Rh(CO)_2Cl]_2 + 4L \rightarrow Rh(OC)(L)(L)(Cl).$$

The ligands employed were the full amides of phosphorous,[166 167] alkyl phosphorous†,[168–171] and phosphinous[23,172] acids. The bidentate TPAA behave in a complex manner. The cyclodiphosphazan (VII) and the corresponding difluoride give rise to different types of complexes depending on the reactant ratio.[36,173] The ligand (XI) and its analogues ensure the chelation of the metal:[80,81]



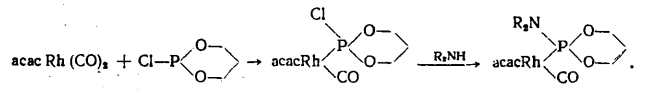
This example demonstrates the detailed influence of structural factors on the course of the complex formation reaction. It has been shown in a number of studies that the interaction of μ-dichlorotetracarbonyldirhodium can lead to not only the mononuclear complexes already examined but also to dinuclear complexes.[166,171,173] According to Nifant'ev et al.[171] such a process involving monodentate phosphamides takes place when the reaction is carried out in the presence of oxygen.

Bidentate ligands make it possible to obtain dinuclear rhodium complexes more frequently than the monodentate ligands. A dinuclear complex with a ruptured chlorine bridge has been obtained from the hard ligand (X),[67] while a complex with the intact bridge has been obtained from the relatively labile imide of diphenylphosphinous acid.[174,175] A result close to the latter case has been obtained in a study with the ethylimides of dimethyl-[176] and diphenyl-phosphorous acids (XVIII),[177] although here too the influence of the ester group on the details of the structure of the dinuclear complexes was manifested.

We shall consider the ligand transfer reactions of olefinic π-complexes of rhodium(I) chloride. These substances can be converted into mono- and di-nuclear coordination systems. Thus, according to the data of Aresta et al.[178], the ethylene π-complex and the phosphamide (I) react at 20 °C to form a product resulting from the rupture of the chlorine bridge. In other studies[179,180] dinuclear complexes were synthesised. Phosphoramidous fluorides of type (XVII) have been introduced into the ligand transfer reaction; the possibility of the complete substitution of the ethylene ligand by phosphamide ligands was demonstrated.[181]

Cyclo-octadiene derivatives of rhodium(I) chloride react with bidentate ligands of type (VII) to form dinuclear complexes in the molecules of which the metal atoms are coordinated to different phosphorus atoms.[82] Extensive, including complete, substitution of primary ligands by the bidentate ligands occurs upon the addition of tetrafluoroborates.[22]

The readily available acetylacetonatodicarbonylrhodium, which readily reacts with a wide variety of 2-amino-1,3,2-dioxaphosphorinanes [183] and 2-amino-1,3,2-oxazaphosphorinanes,[184] can be used for the synthesis of stable mononuclear complexes of univalent rhodium with one phosphamide ligand. The axial orientation of the metal relative to the six-membered ring of the ligand has been established in the complexes obtained. Some of the phosphamide complexes of the type considered have been synthesised in accordance with a two-stage scheme:[183]



On interaction with phosphamide in the presence of perchloric acid, the acetylacetonatorhodium(I) derivative with the cyclo-octadiene ligand exchanges the acetylacetonato-group and not the olefin group.[185]

¶The ligand transfer reaction of cobalt dodecacarbonyl has also been described briefly in the literature.[93]

†The results of the study of Grishina et al.[170] have been partly revised.[171]

In conclusion of the consideration of the synthesis of rhodium coordination compounds, we shall deal with the interconversions of the phosphorus-containing complexes. The partial displacement of PF_3 from the coordination sphere on treatment with the ligand (I) has been reported.[167] The reduction of phosphamide complexes of rhodium(I) is also of great interest.[186,187]

The synthesis of coordination compounds of iridium with TPAA has been little studied.

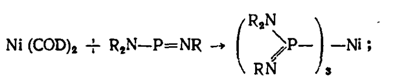
Complexes with the bidentate ligand (VI), obtained from the cyclooctadiene (COD) derivatives of iridium, have been reported:[188]

$$[Ir(COD)Cl]_2 + (VI) \rightarrow [Ir\cdot(VI)_2]Cl\,.$$

The reaction of the complex $[Ir(C_8H_{14})_2Cl]_2$ with an excess of PF_2NMe_2 leads to the formation of the complex $IrCl.\,.(PF_2NMe_2)_3$, in which there are no intermolecular Ir–Ir contacts, in contrast to the PF_3 derivatives.[189]

The Ni, Pd, and Pt triad. The study of the synthesis of complexes of the metals of the last triad with TPAA has its characteristic features. Thus, the relevant derivatives of all the elements of this family have been investigated to approximately the same extent. The second feature is manifested in the relative chemical paucity of the field considered. Thus there are virtually no reactions involving the formation and decomposition of clusters on complex formation, there are almost no unexpected reactions, and the syntheses in the coordination sphere of the metal have been little developed.

We shall consider the formation of phosphamide complexes of zero-valent metals. A series of studies on the ligand transfer reactions of $Ni(CO)_4$ have been published. The process involving the monodentate ligands (I),[2,5,127,190] (V),[75] and (XX),[41] phosphoramidous halides,[2,191] and the complex cyclic phosphamides $P_4(NMe)_6$ [192] and $MeP[N(R)SiMe_2]_2$ [193] is accompanied by the substitution of one or two carbonyl groups. The reaction with the bidentate ligand (IX) can be more far reaching and may even involve complete substitution.[130] The silylated amidoimide complex of zero-valent nickel (XXI) has been synthesised with the aid of the ligand transfer method:[194]



$$Ni(COD)_2 + R_2N{-}P{=}NR \rightarrow \left(\begin{matrix}R_2N\\ \quad\;\rangle P{-}\\ RN\end{matrix}\right)_3{-}Ni\,;$$

$R{=}SiMe_3$.

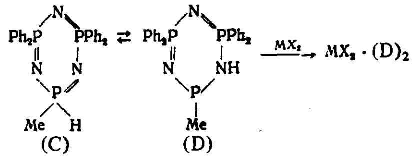
(XXI)

Nickel complexes containing only phosphamide ligands have also been obtained from the metal vapour.[95]

Coordination compounds of platinum have been studied in greatest detail by Scherer, who showed that biscyclooctadieneplatinum reacts with amidoimides of type (III) to form substances having the composition $Pt(III)_3$.[195] The interaction of the ligand (III) with cyclic platinum clusters has also been achieved:[196]

$$Pt_3(\mu\text{-}CNR)_3(CNR)_3 + (III) \rightarrow Pt_3(\mu\text{-}CNR)(CNR)_3\cdot(III)_2\,.$$

The preparation of complexes of bivalent metals has been described fairly extensively. Nickel, palladium, and platinum salts or their benzonitrile and similar derivatives form complexes effectively with various full amides[1,5,75,78,197,198] and amidoesters[104,199–202] of tervalent phosphorus acids and the amidoimides (III).[202] The reaction of acetonitrile solutions of palladium and platinum halides with an unusual cyclotriphosphazene is of special interest:[203]



According to ^{31}P NMR data, the initial phosphazene exists almost fully in the form (C), which, however, being a prototropic system can be converted into the form (D) to form a complex.

The study of the interaction of triethylphosphine derivatives of platinum and palladium dichlorides with di- and triazaphospholes established that the primary adducts can have different compositions. It has been suggested that the ligand is coordinated with both phosphorus and nitrogen atoms.[204]

Bivalent metal salts have been made to react with bidentate ligands (VII),[205] (XI),[80,81] (VI),[85] and (XVIII) [71] and mononuclear, including chelate, and dinuclear complexes were obtained. Nickelocene, π-allylpalladium chloride, Zeise's salt, and other similar organometallic compounds have been widely investigated in reactions with TPAA. The full amides[206,207] and amidoesters[202,208,209] of phosphorus acid, including those containing carbohydrate residues in their molecules,[168,210] as well as the bidentate ligands (VII) [211] and (VI) [212] have been resorted to as the latter.

In conclusion we shall deal with the intracoordination synthesis of phosphamide complexes. Phosphatrihalogeno-,[197,213–215] phosphamidohalogeno-,[216] and phosphinohalogeno-derivatives[80,214,217] of metals react satisfactorily with amines, being converted into the required complexes. Unfortunately the reaction is not of general importance.[213,214] Metal amides are phosphorylated more effectively than amines.[214,215]

III. CHEMICAL PROPERTIES

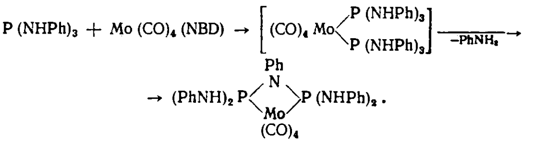
The publications on this question are divided into three groups. The first, main group includes studies on reactions involving the phosphamide (phosphimide) fragment of the ligand without affecting the coordination sphere. The data obtained are important for the synthesis of new types of phosphorus-containing complexes. At the same time they are of fundamental significance in a general chemical sense, because they demonstrate the influence of the metal on the reactivity of coordinated organophosphorus systems. The second group includes studies devoted to the preparation of complex organic compounds, the phosphorus-containing and metallic components of the complexes fulfilling only auxiliary functions. Studies on the last group are concentrated on the inorganic aspect of the chemistry of complexes—oxidation-reduction processes, additional complex formation via the functional groups in the side chains, and ligand transfer reactions.

1. The Reactions of the Coordinated Ligand Via the Phosphamide (Phosphimide) Bond

In the first place we shall consider the reactions of complexes involving a single P–N bond. TPAA are known to be labile and to undergo readily reactions via the phosphamide functional group on treatment with reagents whose molecules contain a mobile hydrogen atom or a polar double bond.[218] The possibility of involving also metallic complexes of TPAA in similar reactions has been discussed in a series of studies in recent years. It has been established that their P–N bond is cleaved by hydrogen chloride with formation of phosphochloro-[41,59,62,113,117,135,136,219,220] or amidophosphochloro-complexes.[107,137]# In many cases hydrochlorination is accompanied by profound skeletal rearrangements.[91] Overall, the hydrochlorination of the complexes proceeds readily, although it requires more severe conditions than the corresponding reactions of the free ligands.[136] The complexes synthesised, which are as a rule difficult to obtain by other methods, are widely used for the preparation of a wide variety of types of phosphorus-containing coordination systems (see, for example, Refs.113, 137).

The phosphamide complexes also react with hydrogen bromide,[69,72,107,113,117,136,219] hydrogen iodide,[107,113,117,219] and hydrogen fluoride.[117,146] Instead of the last compound, it is sometimes convenient to use benzoyl fluoride.[117] The deamination reaction considered makes it possible to solve simply certain coordination-chemical problems; for example, it permits the synthesis of enantiomeric complexes with a chiral metal atom.[146]

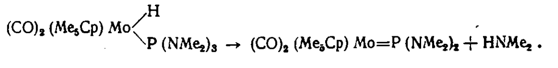
The hydrolysis[59,162] and alcoholysis[24,59,77,199] of the phosphamide complexes have been reported. The influence of the nature of the metal on the ease of the process has been established in relation to these reactions. Thus it has been shown that the copper complexes react more readily than the platinum complexes. In the latter case a positive effect is achieved only when acid catalysts are employed.[199] A characteristic reaction of the complexes, which has not been very widely investigated, is transamidation.[107] It leads to the disproportionation of the ligands:[221]



Thus the metal is a factor promoting the conversion of the trianilide of phosphorous acid into bis(phosphorodianilidato)-phenylamine and aniline. We may point out another possibility of inner-sphere phosphorylation:[222]

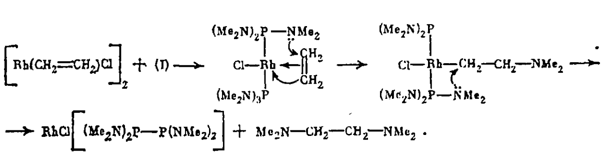
$$cis\text{-}\{(CO)_4Cr[(Ph_2P)_2NH]\} \xrightarrow[\text{2) } Ph_2PCl]{\text{1) BuLi}} cis\text{-}\{(CO)_4Cr[(Ph_2P)_3N]\}.$$

It is significant that this process is more effective than the analogous reaction without the participation of the metal. Phosphorylation accompanied by the formation of the P=M double bond is of great interest:

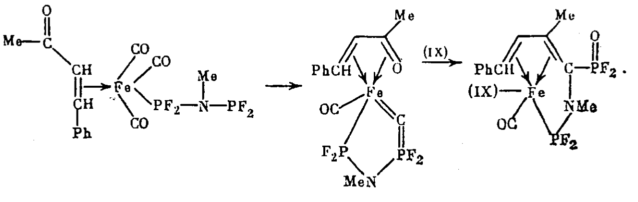


In the compounds obtained, sulphur, diazomethane, carbon disulphide, and iron carbonyls are inserted in this bond with formation of novel three- and four-membered cyclic derivatives.[102] The interaction of the phosphamide complexes with carbon dioxide, accompanied by the insertion of the reactant in the P–N bond, is no less important.[178]

The reaction of the phosphamide complexes with ethylene which has no analogy in the series of phosphamides, merits special attention:[178]

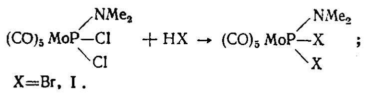


The reactions of benzylideneacetone, carbon monoxide, and the ligand (IX) coordinated jointly to the iron atom are formally similar to the above reaction:[129]



Individual motifs of this scheme can also be found in the paper of Newton and King.[223] On the basis of the data analysed, one may conclude that the possibilities of metal complex synthesis have begun to extend also to the synthesis of organic compounds which are difficult to obtain, including compounds which are extremely complex. Further development of this field of study is already urgently required. Success can be ensured only by a close cooperation between organophosphorus chemists and specialists in metal complex reactions.

The reactions of the coordinated phosphamide are not manifested solely by the degradation of the P–N bond. It is extremely significant that this structural unit can facilitate the substitution of other groups linked to the phosphorus atom. Thus the molybdenum complex with PCl_3 does not exchange chlorine atoms on treatment with hydrogen bromide and iodide. However, this reaction does occur with the corresponding phosphoramidous chloride complex:[107]

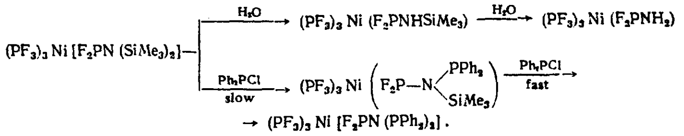


The amido-group probably exhibits a mesomeric electron-donating capacity in relation to the phosphorus atom, which promotes the heterolysis of the P–Cl bond.§ Nevertheless the unshared electron pair of the amido-group can ensure the formation of borate complexes[77] and protonation products. A stable ammonium compound has been detected only in a study involving a complex in which effective d_π, p_π-conjugation in the phosphamide fragment was not ensured for geometrical reasons.[220]

#For the description of the anomalous course of this reaction, see Müller and Vahrenkamp.[137]

§In relation to the hydrogen atom in the amidophosphohydride complexes, the amido-group exhibits electron-accepting properties. These complexes are readily deprotonated with formation of phosphorus-centred anions, which readily enter into reactions with electrophiles, forming various substances, including those which are virtually unobtainable in other ways.[224]

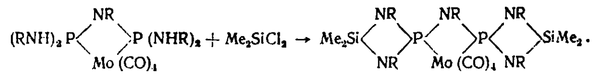
Among other reactions involving nitrogen, we may mention the desilylation of coordinated *N*-silylphosphamides:[214]



$$(PF_3)_3Ni[F_2PN(SiMe_3)_2] \xrightarrow{H_2O} (PF_3)_3Ni(F_2PNHSiMe_3) \xrightarrow{H_2O} (PF_3)_3Ni(F_2PNH_2)$$

$$(PF_3)_3Ni[F_2PN(SiMe_3)_2] \xrightarrow[slow]{Ph_2PCl} (PF_3)_3Ni\left(F_2P{-}N\begin{matrix}PPh_2\\SiMe_3\end{matrix}\right) \xrightarrow[fast]{Ph_2PCl} (PF_3)_3Ni[F_2PN(PPh_2)_2].$$

Heterocyclic condensations are of interest,[106,110,222] for example:



The reactions of phosphimide complexes, i.e. systems with a P=N double bond, should be considered separately. These compounds are readily hydrated[202,225] and combine with alcohol,[202] forming the usual phosphamide coordination compounds. Certain complexes of Group VI metals with cyclic phosphimides readily undergo cyclo-oligomerisation.[74]

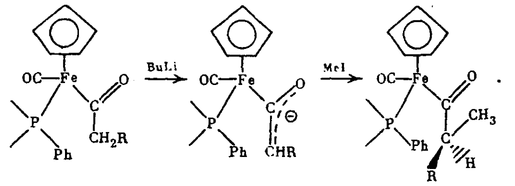
The deimidation of chromium complexes of the amidoimides of phosphorous acid is a reaction without analogy in the chemistry of classical organophosphorus compounds:[60]

$$\underset{\displaystyle Cr(CO)_5}{R_2N{-}\overset{}{P}{=}N{-}R'} + SO_2 \rightarrow \underset{\displaystyle Cr(CO)_5}{R_2N{-}P{=}O} + R'N{=}S{=}O.$$

2. The Use of the Phosphamide Complexes in Fine Organic Synthesis

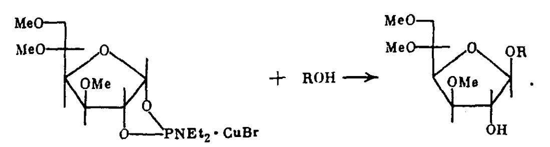
It has been shown[28] that the copper-lithium complexes stabilised by the hexaethyltriamide of phosphorous acid yield very satisfactory results in the specific α-alkylation of αβ-unsaturated ketones. The hydrolysis of the reaction mixture entails in this instance the complete decomposition of the complex and the decomposition of the ligand to water-soluble substances, which ensures the preparative employment of this important reaction.

The alkylation of Fe-acyl derivatives stabilised by phosphorus-containing ligands is of interest:[226]



It has been shown that the interaction of the O-anionic end of the ambident component of the side group with the benzene ring results in a definite diastereoselectivity. The most marked manifestation of this effect has been noted when phenylphosphamide ligands were employed.

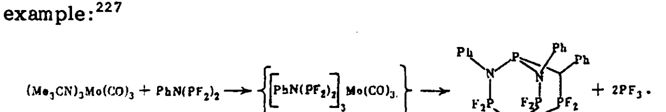
It has been suggested that the copper complexes of cyclic phosphoramidites (derivatives of carbohydrates) be used in glycosylation,[26] for example:



The cyclic phosphoramidites themselves behave in this reaction as phosphorylating agents. Thus complex formation involving the phosphorus atom alters significantly the nature of these derivatives.

3. Other Reactions

We shall consider the reactions involving the metal atom in the phosphamide complexes. The disproportionation of asymmetric ligands is sometimes observed. The disproportionation yields especially satisfactory results and the formation of highly symmetrical skeletal systems is possible, for example:[227]

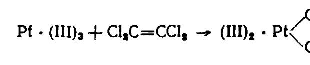


Another type of disproportionation has been described. It reduces to the redistribution of the ligands between individual molecules of the complex without altering their structure. As an illustration, we may mention the equilibrium established over a year at 20 °C:[191]

$$2Ni(CO)_2L_2 \rightleftarrows Ni(CO)_3L + Ni(CO)L_3\,;$$
$$L{=}Me_2NPF_2,\ EtNPF_2\,.$$

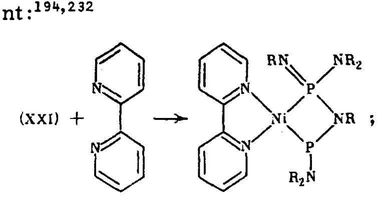
The displacement of one phosphamide ligand by another[228] or by P-ligands of a different chemical type[145,195] from the complexes has also been reported. Ligand transfer may be accompanied by profound changes in the structure of the coordination compound, for example, by the migration of the organophosphorus ligand from the metal to the π-bound benzene ring.[154]

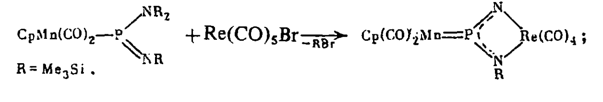
We shall now turn to reactions accompanied by a change in the oxidation state of the metal. The complexes may be reduced by chemical and electrochemical methods[15,115,229,230] and can be oxidised. The latter is especially interesting, because it can lead to structurally unusual results, for example:[225]



$$Pt\cdot(III)_3 + Cl_2C{=}CCl_2 \rightarrow (III)_2\cdot Pt\begin{matrix}CCl_2\\ | \\ CCl_2\end{matrix}.$$

In conclusion of this Section, we may point to the reactions of complexes having ligands with C–N groups in the side chains. These compounds can react with the simplest derivatives of metals, forming complex dinuclear systems.[231] The reactions of complexes whose ligands have P–N groups are even more interesting. In this case complex formation is accompanied by a far-reaching intracoordination rearrangement:[194,232]





IV. THE SEARCH FOR PRACTICAL APPLICATIONS

1. Catalysis

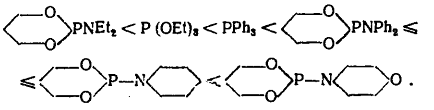
Functioning as ligands in metal complex catalysts, TPAA are in principle analogous to phosphines. Nevertheless, they are characterised by a wide variety of electronic and steric parameters to a greater extent in phosphines and other derivatives of tervalent phosphorus, which leads to very realistic prospects for the regulation of the activity and selectivity of catalytic systems. An important factor is also the availability of many TPAA.

Hydrogenation processes in the presence of complexes with phosphamide ligands have been studied in greatest detail. The first communications[233,234] on this question were devoted to the hydrogenation of styrene in the presence of the $[RhCl.(C_2H_4)_2]_2 + nL$ system. It has been established that the activity of the catalysts increases significantly on passing to phenylphosphamides whose molecules contain piperidine, pyrrolidine, or morpholine residues. The use of derivatives of less basic amines or amines with branched groups weakens sharply the catalytic properties. The general activity series summarised by James[235] are as follows:

$$PPhA_2,\ PPh_2A > PPh_3 > PA_3 \gg PAlk_3;$$
$$PPh_3 > PPh_2Alk \approx PAlk_2A > PPhAlk_2 > PAlk_3.$$

where A is the residue of the main and sterically unhindered secondary amine.

The influence of the nature of the ligands on the rate of hydrogenation has been observed in greater detail in a study[183] devoted to the acetylacetonate derivatives acacRh.(CO)L. The activity of the catalysts increases in the sequence



In many cases interesting results were obtained also with complexes having bidentate phosphamide ligands, for example, the ligand (XI).[80]

The substrate and the solvent[234,236] and also admixtures of oxygen play an important role in hydrogenation in the presence of various phosphamide complexes of rhodium. Oxygen oxidises the phosphamide ligands in mononuclear *trans*-complexes, which leads to the appearance of dinuclear complexes having a comparatively high catalytic activity.[171]

The use of optically active phosphamides to synthesise enantio-selective rhodium catalysts proved to be extremely fruitful. A wide variety of monodentate[237,238] and bidentate[239–248] ligands¶ were used for this purpose, the latter exhibiting the best activity overall. Optically active phosphoramidite complexes immobilised on mineral carriers have also been investigated, but their application does not yield appreciable advantages.[253]

The enantioselectivity of the phosphamide complexes and the configuration of the products of asymmetric hydrogenation probably depend on the nature of the amido-groups at the phosphorus atom.[240,245,254] Thus when the compounds $[Rh(CO)L]ClO_4$ are used in the hydrogenation of *N*-acylaminocinnamic acid, the transition from (1*R*, 2*R*)-bis(diphenylphosphinoamino)cyclohexane to (1*R*, 2*R*)-bis(diphenylphosphino-*N*-methylamino)cyclohexane leads to the inversion of the stereochemical result of the reaction.[254]

The use of palladium complexes with TPAA in hydrogenation is less well known. The full amides of phosphorous acid exhibited a high activity in the $C_3H_5PdLCl–NaBH_4–O_2$ system in the reduction of nitrobenzene, alkenes, and alkynes.[206,255] Systems obtained from phosphoramidites (derivatives of carbohydrates)[168,210,256] and cyclophosphorylated ephedrine[208,209] showed some catalytic activity. The possibility of using ruthenium complexes with the ligand (VII) in the hydrogenation of oct-1-ene has been indicated in the literature.[257]

The rhodium(I) complexes of TPAA yielded satisfactory results in the catalysis of hydroformylation.[172,258,259] The influence of the ligand on the direction of the process has been traced in relation to the hydroformylation of hex-1-ene. It has been shown that the increase of the π-acceptor capacity of the phosphoramidite, observed when aryl residues are introduced at the nitrogen atom, leads to an increase of the yield of the aldehyde having the normal structure. A decrease of π-acceptor capacity entails the formation of large amounts of the isomeric aldehyde. The use of polymeric complexes of the type $P–OC_6H_4NMePPh_2.RhCl(CO)$ has been reported.[172] It has been indicated that there is a possibility of the enantioselective hydroformylation of prochiral alkenes and of the hydrosilylation of ketones using rhodium complexes with optically active ligands.[249] The carboxylations of propene in the presence of a palladium catalyst, promoted by the full alkylamides of phosphorous acid, has also been described. The process selectivity reaches 79.5% with respect to isobutyric acid, which exceeds the selectivity of the catalytic system using PPh_3.[260]

We shall now turn to the catalysis of oligomerisation and polymerisation. A number of nickel and cobalt complexes containing the hexaalkyltriamides of phosphorous acid[164,261,262] and phosphamide bidentate ligands[163] are of technical interest for the polymerisation and oligomerisation of α-olefins and dienes. It is significant that nickel catalysts of this type can be used in an aqueous medium.[263] The oligomerisation of acetylenes in the presence of the $Pd(acac)_2.AlEt_3.L$ system has been investigated.[264] When $L = Ph_2PNMe_2$, the amount of dimer formed is smaller by a factor of two and the amount of higher oligomers is twice as great as in the case where $L = PPh_3$.

Among other possibilities of catalysis using the above complexes, we may point to the conversion of methanol into ethanol[89] and to the acceleration of diffusional photographic processes in sensitive layers of polymers.[265]

2. The Synthesis of Medicinal Drugs

Data on the synthesis of platinum complexes and positive results of their tests in the treatment of oncological affectations have been published.[1,200] Studies initiated at the present time are being extended to the field of complex biogenic systems.[199] It has been suggested that gold complexes based on azaphospholes be used in chrysotherapy.[33,204]

---oOo---

Thus metal complexes of TPAA constitute a large class of coordination compounds which are constantly attracting increasing attention. An important feature of these systems is that their ligands are chemically varied. They are frequently extremely labile or do not exist at all as individual substances but are entirely stable in the coordinated state. Consequently the only source of any information about these phosphorous compounds is the study of their metal derivatives.

Complexes with TPAA enter into a wide variety of reactions in the coordination sphere of the metal. An important role is due in this instance to the phosphamide component of the molecule which either changes as a result of the dissociation of the P–N bond, or activates a neighbouring group, or

---

¶ **Recently, particular attention has been devoted to ligands obtained by phosphorylating optically active aminoalcohols.**[249–252] influences the properties of the metal. In other words, the behaviour of the complex is not determined simply by the central ligand atom but also by the functional group based on it.

Organotellurium Compounds in Organic Synthesis

I.D.Sadekov, B.B.Rivkin, and V.I.Minkin

The review gives a systematic account of the survey of data on the application of organic compounds of tellurium in the synthesis of hydrocarbons, halogeno-derivatives, and carbonyl compounds.
The bibliography includes 94 references.

IV. Synthesis of carbonyl compounds 350
V. Conclusion 353

I. INTRODUCTION

The chemistry of organotellurium compounds has developed extremely vigorously during the last 10–15 years. It is sufficient to point out that the number of studies published during these years exceeded the number of publications during the entire preceding 130 years of the development of organotellurium chemistry. The synthesis of organotellurium compounds, their reactivity, and their structures in the crystalline state and in solution have been considered in a number of monographs[1,2] and reviews.[3–11] As the chemistry of organic compounds of tellurium has developed, their applications in preparative organic chemistry for the synthesis of various classes of organic compounds have expanded vigorously, although in this respect tellurium compounds are so far inferior to organoselenium compounds.[12–14]

The wide variety of applications of tellurium compounds in organic synthesis is based on a number of their specific features, among which the following may be included: (1) the ease of converting tellurium(II) derivatives into tellurium(IV) derivatives and vice versa; (2) the high nucleophilicity of the RTe^- and Te^{2-} anions; (3) the much higher stability of derivatives of tetracoordinate tellurium (σ-telluranes) of the type $RTeX_3$, R_2TeX_2, and Ar_4Te compared with the analogous sulphur and selenium compounds; (4) the relative ease of eliminating the tellurium atom from tellurium(II) derivatives.

A series of new data on the application of organic derivatives of tellurium in the synthesis of a wide variety of organic compounds are described systematically and surveyed in the present review.

II. SYNTHESIS OF HYDROCARBONS

One of the most thoroughly investigated applications of organotellurium compounds in preparative organic chemistry involves their use for the preparation of hydrocarbons. This applies in the first place to unsaturated compounds and biaryls. The only reaction described hitherto in which organotellurium reactants have been used to synthesise benzene derivatives is based on the oxidation of arylhydrazines by di(p-methoxyphenyl)tellurium oxide,[15,16] leads to arenes in comparatively low yields, and can hardly be regarded as of preparative importance.

1. Saturatated Hydrocarbons

Saturated hydrocarbons are readily formed in 70–90% yields on reduction of organyltellurides (I) with triphenyltin tetrahydroborate in benzene at 20–80 °C [17] (judging from the analogous reaction with selenides,[17] $R^2TeSnPh_3$ is probably a side product):

$$\underset{(\mathrm{I})}{R^1TeR^2} \xrightarrow{Ph_3SnH} R^1H;$$

$$R^2{=}Me,\ R^1{=}C_{12}H_{25};\ R^2{=}Ph,\ R^1{=}C_{12}H_{25},\ C_8H_{19}CH_2CH(Me),$$
$$C_8H_{17}CH(OH)CH_2,\ C_8H_{17}CH(OCOMe)CH_2,\ Me(CH_2)_2CH(OH)\underset{|}{C}H(CH_2)_2Me.$$

The reduction does not involve functional groups such as OH, OCOR, and C=O, which makes it possible to obtain also the corresponding substituted derivatives in high yields.[17]

It is noteworthy that diorganyltellurium dichlorides are reduced more readily than tellurides, but the reason for this is not clear since tellurium dichlorides are reduced via the formation of tellurides:[17]

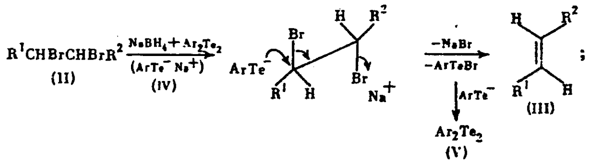
$$RTeCl_2Ph \xrightarrow{Ph_3SnH} RH;$$
$$R{=}C_{12}H_{25},\ C_8H_{19}CH_2CH(Me).$$

2. Olefins and Acetylenes

Various types of organotellurium compounds are used to obtain unsaturated compounds—olefins and acetylenes: derivatives of monocoordinate tellurium—tellurolate[18] and phosphorotellurolate anions;[19,20] derivatives of dicoordinate tellurium—diaryltellurides,[21,22] phenoxatellurin,[23,24] and diaryl ditellurides;[25] derivatives of tricoordinate tellurium—telluroxides,[12,26–29] and tellurium imides;[30,31] derivatives of tetracoordinate tellurium (σ-telluranes)—diaryltellurium dihalides[32] and organyltellurium trihalides.[32,33]

(a) *Catalytic Reactions with Particiation of Derivatives of Monocoordinate Tellurium*

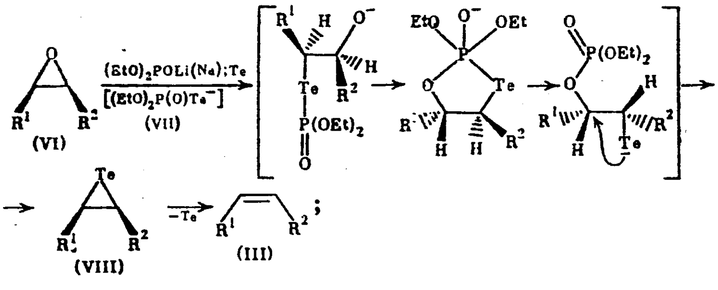
One of the most important and promising applications of organotellurium reagents in organic synthesis involves the possibility of using them under catalytic conditions. The application of diaryl ditellurides (V) [for di(2-thienyl) ditelluride as an example] as catalysts of the debromination of vicinal dibromides (II) in the presence of $NaBH_4$, which leads to the unsaturated compound (III) in high yields, may serve as a typical illustration:[18]



Ar = 2-thienyl; R^2 = Ph, Me, CO_2Et: R^1 = H, R^2 = C_8H_{17}; R^1 = Ph, R^2 = COOH; R^1 = R^2 = COOH; —$(CH_2)_6$—; (II) = 5α, 6β-dibromocholestan-3β-ol.

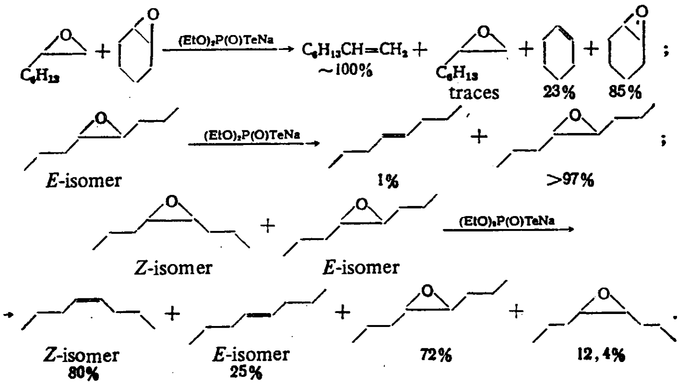
It has been suggested[18] that the main active species in this catalytic cycle is the tellurophenoxide anion (IV), formed on reduction of a diaryl ditelluride, whose halogenophilic attack on the bromine atom is accompanied by the anti-elimination of a second halogen atom with formation of the olefin (III). The course of this reaction (carried out in an atmosphere of nitrogen) is readily followed from the change in the colour of the solution from dark red (ditelluride) to colourless (tellurophenoxide anion).

Alkali metal *OO*-diethyl phosphorotellurolates (VII), among which the lithium derivative is the most active, are extremely effective reagents, which make it possible to convert the epoxides (VI) into olefins in high yields.[19,20] The deoxygenation of the epoxides as well as the dehalogenation of dibromides described above are carried out catalytically by adding tellurium (0.1–0.25 mmol) to a solution of diethyl phosphite (1–2 mmol) and epoxide (1 mmol).[19] The probable reaction mechanism includes the formation of unstable epitellurides (VIII):[20]



R^1 = C_6H_{13}, R^2 = H; R^1 = C_8H_{17}, R^2 = H; R^1 = $C_{18}H_{37}$, R^2 = H.

Compared with their selenium analogues, compounds (VII) are much more reactive and participate in catalytic deoxygenation reactions much more actively. Among epoxides, the terminal derivatives react most readily and among these the most reactive are the *Z*-isomers, which has been confirmed by the competing reactions shown below, with participation of the corresponding 1 : 1 mixtures of the epoxides. The deoxygenation with the aid of *OO*-diethyl phosphorotellurolates is stereospecific and *Z*- (or *E*-)epoxides always yield the *Z*- (or correspondingly *E*-)olefins:[20]



(b) Derivatives of Dicoordinate Tellurium

When a series of different diaryl tellurides (I, $R^1 = R^2 = Ar$) react with vicinal dibromides (II), the olefins (III) and diaryltellurium dihalides (IX) are obtained in high yields:[21]

$$\underset{(II)}{R^1CHXCHXR^2} + \underset{(I)}{Ar_2Te} \rightarrow R^1CH{=}CHR^2 + \underset{(IX)}{Ar_2TeX_2};$$

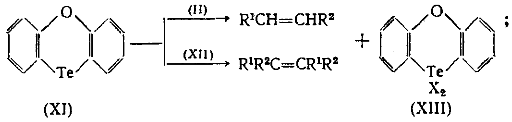
X=Br, Cl.

The reaction of diphenyl telluride (I, $R^1 = R^2 = Ph$) with 1,2-dibromoethane (II, $R^1 = R^2 = H$, X = Br) under mild conditions (refluxing for 30 min) affords a 74% yield of 1,2-bis(diphenyltelluronia)ethane dibromide (X), whose recrystallisation from glacial acetic acid produces diphenyltellurium dibromide (IX) and ethylene. The possibility of the intermediate formation of telluronium derivatives of type (IX) in reactions with participation of the substituted dibromides (II), arising in this connection, has not so far been investigated:

$$2Ph_2Te + CH_2BrCH_2Br \rightarrow \underset{(X)}{Ph_2\overset{+}{Te}CH_2CH_2\overset{+}{Te}Ph_2\ 2Br^-} \xrightarrow{AcOH,\Delta} \underset{(IX)}{Ph_2TeBr_2} + CH_2{=}CH_2.$$

Another dehalogenating agent in the series of derivatives of dicoordinate tellurium is phenoxatellurin (XI).[23,24] Its interaction with vicinal [compound (II)] and geminal [compounds (XII)] organic dichlorides and dibromides results in the formation of the corresponding olefins and 10,10-dihalogenophenoxatellurins (XIII) in high yields.

Presumably in the series of vicinal dibromides the reactions proceed via the intermediate formation of telluronium salts of type (X) and in the case of the geminal dibromides via carbenes:



(XI)
X=Cl, Br.

(XIII)

The reactions with participation of diaryl tellurides and phenoxatellurin are not, however, general, because the number of vicinal and geminal dihalides, such as 1,2-dichlorocyclohexane[23] and benzylidene chloride and bromide,[24] are not dehalogenated under the conditions indicated.

Phenoxatellurin is a more active dehalogenating agent than phenothiatellurin, which is in its turn superior to phenoxaselenin.[24] Phenoxatellurin is used also for the dehalogenation of unsaturated vicinal di-iodides, which makes it possible to obtain the corresponding acetylenes in high yields:[23]

$$PhCX{=}CXR + (XI) \rightarrow PhC{\equiv}CR + (XIII);$$

X=I, R=H (80%), COOH (87%).

Together with diaryl tellurides and phenoxatellurin, diaryl ditellurides (V) are also used as dehalogenating agents.[25] The interaction of these compounds with the dibromide (II) is accompanied by the elimination of elemental tellurium with formation of the olefins (III) and the symmetrical diaryl tellurium dibromides (IX).

The possible ways of obtaining unsaturated compounds via the dehalogenation of vicinal and geminal dihalides by various organic derivatives of tellurium (II) are presented in the Table.

(c) Derivatives of Tricoordinate Tellurium

Telluroxides. Like selenoxides[12–14] telluroxides are now beginning to be used in the synthesis of olefins having different structures.[12,26–29] The possibility of employing telluroxides for the preparation of olefins was first investigated by Sharpless et al.[12] When alkyl phenyl tellurides were oxidised by t-butyl hydroperoxide in benzene, a mixture of olefins, probably formed via the *syn*-elimination of the intermediate telluroxides, was obtained in a low yield.[12]

The synthesis of olefins from diorganyl dihalides and organic derivatives of tellurium(II).

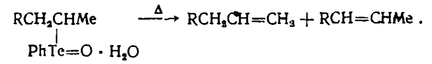
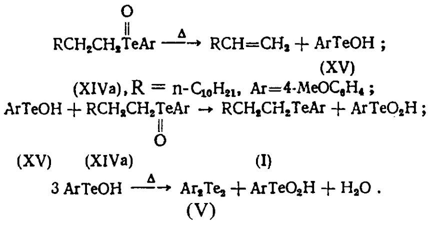
Subsequent studies[26–29] showed that the thermal decomposition of telluroxides can be used for the synthesis of olefins of different structures and compositions. The conditions in the thermolysis of telluroxides are determined by the structure of the alkyl group. Alkyl phenyl telluroxides (XIV), containing secondary alkyl groups, rapidly decompose at room temperature with formation of a mixtures of olefins in high yields.[29] Thus s-octyl phenyl telluroxides (XIV, $R = C_5H_{11}$) gives rise on decomposition to a mixture of oct-1-ene and *cis*- and *trans*-oct-2-enes in 80% yield together with a small amount of 2-octanol and 2-octanone. Telluroxides containing s-alkyl groups, such as 2-dodecyl, 2-tetradecyl, cycloheptyl, cyclo-octyl, and cyclododecyl, combined with other alkyl groups behave analogously.[29] On the other hand, cyclohexyl phenyl telluroxide (XVI) is extremely stable and decomposes only at 200–290 °C with formation of cyclohexane in a yield exceeding 70%;[29] however the causes of the increased resistance of this telluroxide to heating are not clear.



(XIV)

$$\underset{\underset{PhTe=O\cdot H_2O}{|}}{RCH_2CHMe} \xrightarrow{\Delta} RCH_2CH{=}CH_2 + RCH{=}CHMe\,.$$

In contrast to telluroxides with s-alkyl groups, those containing primary alkyl groups [compound (XIVa)] decompose under more severe conditions.[26,29] Thus n-dodecyl phenyl telluroxide (XIVa, $R = C_{10}H_{21}$, Ar = Ph) is cleaved with formation of dodec-1-ene (50%) at 1-dodecanol (11%)[29] at 200–240 °C, while n-dodecyl 4-methoxyphenyl telluroxide (XIVa, $R = n\text{-}C_{10}H_{21}$, $Ar = 4\text{-}MeOC_6H_4$) affords a mixture of dodec-1-ene and the telluride (I) in proporations of 1 : 1 and 1.4 : 1 after refluxing for 24 h in CCl_4 or 12 h in toluene respectively.[26] The authors[26,29] believe that the primary intermediate in the decomposition reaction of telluroxide is tellurinic acid (XV), which reduces half of the telluroxide (XIV) to the telluride (I) in the next stage of the process. At the same time there is also a possibility of the disproportionation of this acid at a high temperature leading to the diaryl ditelluride (V):[26]



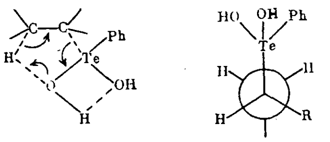
$$RCH_2CH_2\overset{\overset{O}{\|}}{Te}Ar \xrightarrow{\Delta} RCH{=}CH_2 + \underset{(XV)}{ArTeOH}\,;$$

$$(XIVa), R = n\text{-}C_{10}H_{21},\ Ar{=}4\text{-}MeOC_6H_4\,;$$

$$\underset{(XV)}{ArTeOH} + \underset{(XIVa)}{RCH_2CH_2\underset{\underset{O}{\|}}{Te}Ar} \rightarrow \underset{(I)}{RCH_2CH_2TeAr} + ArTeO_2H\,;$$

$$3\,ArTeOH \xrightarrow{\Delta} \underset{(V)}{Ar_2Te_2} + ArTeO_2H + H_2O\,.$$

It is believed[29] that the causes of the difference between the reactivities of telluroxides with primary [compounds (XIVa)] and secondary [compounds (XIV)] alkyl groups, which exist in the form of dihydroxytelluranes, are determined by the difference between the stabilities of the carbonium ions formed on cleavage of the C–Te bond (A) and also be the difference between the steric environments of these two types of telluroxides (B):

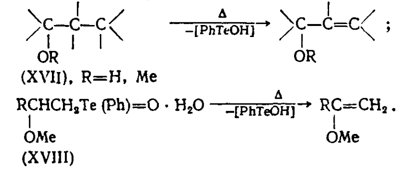


(A) (B)

(XIV), R = Alk: (XIVa), R = H.

In the case of telluroxides elimination takes place in such a way that terminal olefins are formed preferentially.[29] Thus the ratio of the mono- and di-substituted olefins [formed on decomposition of the telluroxides (XIV, $R = n\text{-}C_5H_{11}$ or $n\text{-}C_7H_{15}$], amounting to (2.48–2.50) : 1, is much higher than in the elimination reactions of the analogous selenoxides (1.56 : 1)[34] and sulphoxides (1.5 : 1).[35]

Like alkyl phenyl and cycloalkyl phenyl telluroxides, their analogues containing hydroxy- and methoxy-groups [compounds (XVII) and (XVIII)] are also capable of undergoing thermal decomposition; their decomposition leads to allyl alcohols and allyl and vinyl ethers in high yields:[27–29]



$$\overset{PhTe=O\cdot H_2O}{\overset{|}{\underset{\underset{OR}{|}}{>C}{-}C{-}C<}} \xrightarrow[-[PhTeOH]]{\Delta} \overset{|}{\underset{\underset{OR}{|}}{>C}{-}C{=}C<}\,;$$

(XVII), R=H, Me

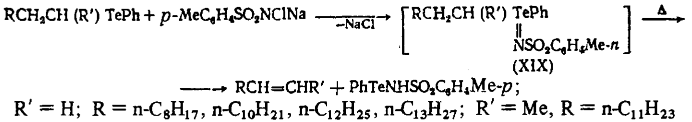
$$\underset{\underset{OMe}{|}}{RCHCH_2Te(Ph){=}O\cdot H_2O} \xrightarrow[-[PhTeOH]]{\Delta} \underset{\underset{OMe}{|}}{RC{=}CH_2}\,.$$

(XVIII)

Bearing in mind the relative ease of synthesis of alkyl phenyl telluroxides of the type of compounds (XIV) and (XVII)–(XVIII), there are good prospects that the reactions examined in this Section will be applied in organic synthesis.

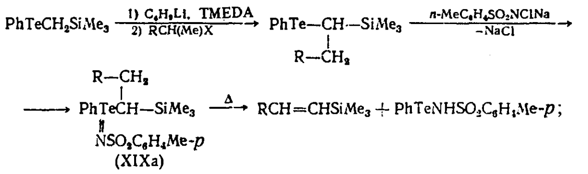
Tellurimides. It has been shown recently that olefins may be formed also on decomposition of tellurimides (XIX), which are believed tentatively to arise *in situ* on interaction of alkyl phenyl tellurides with an excess of chloramine T

(*N*-chloro-4-methyl-*N*-sodiobenzenesulphonamide) in boiling tetrahydrofuran (THF):[30]



$R' = H$; $R = n\text{-}C_8H_{17}$, $n\text{-}C_{10}H_{21}$, $n\text{-}C_{12}H_{25}$, $n\text{-}C_{13}H_{27}$; $R' = Me$, $R = n\text{-}C_{11}H_{23}$ (molar ratio $n\text{-}C_{12}H_{25}CH = CH_2/trans\text{-}n\text{-}C_{11}H_{23}CH = CHMe = 2.5 : 1.0$).

The tellurimides (XIXa), a scheme for the synthesis of which is presented below, afford fairly satisfactory yields of alkylvinylsilanes in the form of a 1 : 1 mixture of the *Z*- and *E*-isomers on pyrolysis *in situ* in boiling THF:[31]



$R = n\text{-}C_9H_{19}, n\text{-}C_{11}H_{23}, n\text{-}C_{13}H_{27}, n\text{-}C_{15}H_{31}$.

(*d*) *Arylation of Olefins*

Like arylmercury chlorides[36,37] and arylthallium(III) derivatives[38] as well as the phenyl derivatives of magnesium (ArMgX),[39] Group IV elements (Ph_4Sn,[36] Ph_4Pb [36]), and Group V element (Ar_3P,[40] Ph_3As,[41,42] Ph_3Sb,[41,42] and Ph_3Bi [41,42]), the σ-telluranes Ar_2TeX_2 and $ArTeX_3$ [32] can be used to arylate olefins by carrying out the reaction in the presence of stoichiometric amounts of $PdCl_2$/MeCOONa. Mainly products with the *trans*-configuration (XX) together with small amounts of the biaryls (XXI) (1—6%) are then formed:[32]

(XX) (XXI)

Ar=Ph, R=Ph, COOMe, CN, CHO, COMe, CH_2OCOMe; R=Ph, Ar=4-MeC_6H_4, 4-BrC_6H_4, 4-$MeOC_6H_4$.

The most varied olefins enter into the reaction: styrene, acrylic acid esters, acrylonitrile, methacrylonitrile, acroleine, methyl vinyl ketone, allyl alcohols, and allyl halides. In the reaction involving acrylonitrile, a 1 : 3 mixture of the *cis*- and *trans*-isomers was obtained while that of methacrylonitrile gave rise to a mixture of compounds (XX)—(XXIV) in proportions of 1 : 1 : 1.5:[32]

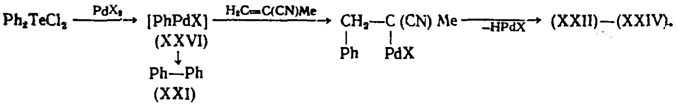
(XXII) (XXIII) (XXIV)

In the reactions of allyl alcohol and allyl bromide, the main products formed are β-phenylpropionaldehyde and allylbenzene respectively, as in the interaction of these compounds with phenylmercury derivatives.[37] The use of *p*-substituted diaryltellurium dihalides in this reaction leads (in the reaction involving styrene) to lower yields of *trans*-stilbenes than in the reaction with diphenyltellurium dichloride. The replacement of a chlorine atom by the acetoxy-group at the tellurium atom does not influence appreciably the yields of the arylated olefins. The reaction proceeds analogously also when rhenium(III) and rhodium(III) chlorides are used, but the yields of the olefins (XX) are then somewhat lower. Like diaryltellurium dihalides, aryltellurium trichlorides (XXV) give rise to *trans*-stilbenes on interaction with styrene:[32]

(XXV) (XX) (XXI)

Ar=Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$.

The olefin arylation reactions can be carried out also in catalytic amounts of $PdCl_2$, provided that a suitable oxidant is added to the reaction mixture: t-butyl hydroperoxide or copper(II) chloride (which is especially effective in solution in acetic acid). As in the case of mercury derivatives,[36,37] the arylation of olefins by organotellurium compounds proceeds via reactive arylpalladium intermediates (XXVI), which can either add to the double bond with subsequent β-elimination of HPdX (or BrPdX in the case of allyl bromides) or undergo reactive dimerisation with formation of biaryls (XXI). Both these reactions pathways can be illustrated in relation to the arylation of methacrylonitrile by diphenyltellurium dichloride in the presence of palladium(II) salts:[32]



Analogously to σ-telluranes, the interaction of diphenyl telluride with ethyl acrylate in the presence of $Pd(OCOCH_3)_2$ leads to ethyl cinnamate together with a certain amount of biphenyl.[22]

(*e*) *Geometrical Isomerisation of Olefins*

An interesting application of organyltellurium trichlorides is their use for the geometrical isomerisation (inversion) of olefins by coupling *cis*-tellurotrichlorination and *trans*-dechlorotelluration processes.[33] When olefins interact with one equivalent of $TeCl_4$ in acetonitrile or chloroform,[33,43–45] 2-chloroalkyltellurium trichlorides (XXVII) are formed in high yields. The reduction of these compounds with an aqueous solution of Na_2S leads to the liberation of elemental tellurium and the reformation of the initial olefin, but this time in the form of a mixture of *E*- and *Z*-isomers with the inverted form predominating. Thus the reaction involving *E*-but-2-ene yielded but-2-ene with the isomer ratio *Z* : *E* = 97 : 3.[33] The ratio of the isomers formed depends on the nature of the olefin and the solvent employed.

(III) (XXVII a-c) (III)

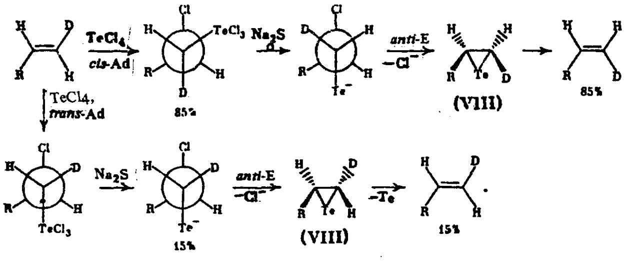
a) $R = n\text{-}C_8H_{17}$, $R' = H$; b) $R = n\text{-}C_8H_{17}$, $R' = D$; c) $R = R' = Me$.

The preferential *cis*-addition to the olefin has been demonstrated by studying the ^1H NMR spectra of the products of the addition of the $TeCl_4$ to *E*-[1-D]dec-1-ene.[33]† When this mixture is reduced with an aqueous solution of Na_2S, a mixture of the *Z*- and *E*-[1-D]dec-1-enes (85 : 15) is formed in

---

† The formation of 15% of the *trans*-adduct can be explained according to the authors[33] by the contribution of the electrophilic addition of $TeCl_4$, having the structure $TeCl_3^+Cl^-$ according to Krebs et al.[47]

conformity with stereospecific anti-elimination, which probably proceeds via the epitelluride (VIII):



(f) Synthesis of 1,5-Dienes

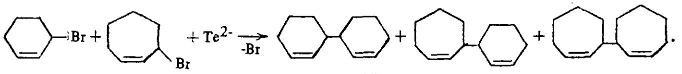
When diphenyl telluride is heated with allyl bromide at 180 °C in a sealed tube, diphenyltellurium bromide and diallyl are formed:[21]

$$Ph_2Te + H_2C{=}CHCH_2Br \rightarrow Ph_2TeBr_2 + H_2C{=}CHCH_2CH_2CH{=}CH_2 .$$

However, a more promising method of synthesis of 1,5-dienes of type (XXVIII) involves the interaction of alkyl halides of the allyl type with lithium telluride in boiling THF or a dioxant–THF mixture.[48] According to the data of Clive et al.,[48] the reaction proceeds via the initial formation of dialkenyl tellurides of type (XXIX) with their subsequent decomposition into radicals of the allyl type, which then dimerise:

(XXIX) (XXVIII)

This mechanism has been confirmed by the finding that the interaction of a mixture of 3-bromocyclohexene and 3-bromocycloheptene with the Te^{2-} anion yields an almost statistical mixture of 2,2'-bicyclohexenyl (XXVIII), 3-(2'-cyclohexenyl)-cycloheptene (XXX), and 2,2'-bicycloheptenyl (XXXI) in proportions of 1 : 1.2 : 1:[33]



(XXVIII) (XXX) (XXXI)

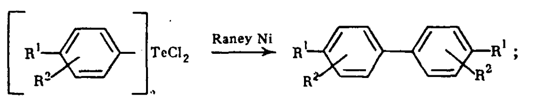
In contrast to dicycloalkenyl tellurides (XXIX), their selenium analogues are extremely stable. Thus the interaction of 3-bromocyclohexene with the Se^{2-} anion under conditions analogous to those examined above leads mainly to the selenium analogue of compound (XXIX); in addition, a small amount of 2,2'-bicyclohexenyl (2%) is formed.[33]

3. Biaryls

One of the first examples of the application of organotellurium compounds in organic synthesis is in the synthesis of biaryls by the reductive cleavage of derivatives of tetracoordinate[32,49,50] and dicoordinate tellurium.[22,49–51] Although biaryls are formed (together with diaryl tellurides) also on thermal decomposition of tetra–aryltellurium derivatives Ar_4Te (Ar = Ph,[52,53] C_6F_5,[54] or 4-MeC_6H_4 [53]), the latter reaction cannot be regarded as of preparative significance because the starting compounds for the synthesis of the tetra-aryltellurium derivatives are diaryltellurium dichlorides, from which biaryls can be obtained directly (see below).

(a) Reactions of Derivatives of Tetracoordinate Tellurium with Raney Nickel

When diaryltellurium dichlorides (IX, X = Cl) are treated with degassed Raney nickel in methylcellosolve, the biaryls (XXI) are obtained in good yields (58–91%).[49] The use instead of degassed Raney nickel of a catalyst obtained by boiling commercial nickel in 2-methoxyethyl ether or ethylene glycol gives rise to lower and less reproducible yields of biaryls:[49]



(IX) (XXI)

R^2 = H, R^1 = OMe, OEt, H, Me, Br, 4-Me_2N; R^1 = OMe,
R^2 = 3-Me, 3-OMe, 2-OMe; R^1, R^2 = 3,4-C_4H_4 .

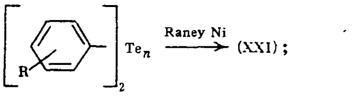
Aryltellurium trichlorides (XXV) are less suitable for the synthesis of biaryls,[49] although in the case of 2-naphthyltellurium trichloride, the yield of 2,2'-binaphthyl is 98%.[50]

(b) Reactions of Derivatives of Tetracoordinate Tellurium with Palladium(II) Salts

It was already mentioned above that, when olefins are arylated by diphenyl telluride[22] and σ-telluranes[32] in the presence of palladium(II) salts, the biaryls (XXI) are formed as side products together with arylated olefins. If the reactions of σ-telluranes (1 mol) with palladium(II) salts (2 mols) are carried out in the absence of olefins, then the arylpalladium intermediates (XXVI) undergo reductive dimerisation and the biaryls (XXI) are formed as sole products in moderate yields.[32]

(c) Reactions of Derivatives of Dicoordinate Tellurium with Raney Nickel

Like σ-telluranes,[49,50] the diaryl tellurides (I, $R^1 = R^2 =$ Ar) and diaryl ditellurides (V) are converted into the biaryls (XXI) in high yields (60–90%) on treatment with degassed Raney nickel:



(I), n = 1; (V), n = 2
R = 4-OMe, H, 4-Me, 4-OEt, 4-Br.

(d) Reactions of Diaryl Tellurides with Organomagnesium Compounds

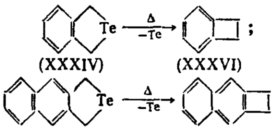
Another way of using diaryltellurides (I) in the synthesis of the biaryls (XXI) involves their treatment of Grignard reagents in ether or THF in the presence of phosphine complexes of nickel and cobalt [$NiCl_2(PPh_3)_2$, $NiCl_2(Ph_2PCH_2CH_2.$ $.PPh_2)$, and $CoCl_2(PPh_3)_2$], which leads to the cross-coupling products (XXXII) and the homo-coupling products (XXXIII) together with the biaryls:[51]

$$\underset{(I)}{Ar_2Te} + RMgBr \xrightarrow{Ni(II)\ or\ Co(II)} \underset{(XXXII)}{Ar{-}R} + \underset{(XXI)}{Ar{-}Ar} + \underset{(XXXIII)}{R{-}R} .$$

The reaction mechanism proposed by Uemura and Fukuzawa[51] includes the formation of diorganylnickel (or diorganylcobalt) complexes, their subsequent conversion, on treatment with diaryl tellurides, into aryltelluronickel (or the corresponding cobalt) complexes, and the decomposition of the latter with the elimination of tellurium and the formation of the final products.

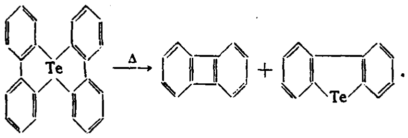
4. Cyclic Hydrocarbons

The synthesis of cyclic hydrocarbons of various types with the aid of organotellurium compounds is based on the ease of elimination of elemental tellurium from the corresponding tellurium-containing heterocycles.[55,56] For example, the thermal decomposition of compounds (XXXIV) and (XXXV) leads to benzo[*b*]cyclobutene (XXVI) and naphtho[*b*] cyclobutene in high yields:[55]



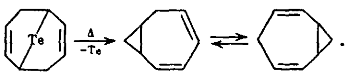
(XXXIV) (XXXVI)
(XXXV) (XXXVII)

Like cyclic tetra-aryltellurium derivatives,[52–54] bis(diphenylene)tellurium(XXXVIII) gives rise on thermolysis to a heterocyclic diaryl telluride—dibenzotellurophen (yield 96%) and biphenylene (XXXIX) (yield 52%).[57,58] Together with the latter compound, also traces of polyphenylenes were detected in this reaction:



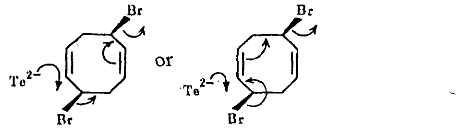
(XXXVIII) (XXXIX)

In certain cases processes of the type considered are accompanied by rearrangements. Thus, when 9-tellurabicyclo[3.3.1]nona-2,6-diene (XL) is heated in deuteriotoluene (in a sealed tube) at 175 °C, bicyclo[5.1.0]octa-2,5-diene (XLI) is formed in a quantitative yield[56] and is in equilibrium with its isomeric diene (XLIa):



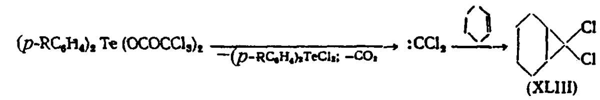
(XL) (XLI) (XLIa)

It is noteworthy that compound (XLI) is capable of being formed (in 20% yield) [together with compound (XL) in 18% yield] also under conditions ruling out the possibility of the thermal decomposition of compound (XL), on interaction of the dibromide (XLII) with Na_2Te in dimethylformamide (DMF), which the authors[56] explain by the following scheme



(XLII) (XLII)

Diaryltellurium bis(trichloroacetate) (IX, X = $OCOCCl_3$) decomposes on heating with formation of diaryltellurium dichlorides (IX, X = Cl), carbon dioxide, and dichlorocarbene,[59] which makes it possible to employ them for the synthesis of dichlorocyclopropanes. When compound (IX) is refluxed in the presence of cyclohexene in *p*-xylene (or diglyme, 2,2-dichlorobicyclo[4.1.0]heptane (XLIII) is formed in low yields (20–30% together with diaryltellurium dichlorides (60–70%):[59]



(XLIII)

R=H, Me, OMe, Me_2N.

III. SYNTHESIS OF HALOGENO-DERIVATIVES

The formation of mono- and di-halogeno derivatives of various types is frequently observed in reactions involving σ-telluranes.[43,44,60–65] However, these processes are by no means equivalent as regards preparative importance and some of them, for example, the formation of alkyl halides on thermal decomposition of alkylphenyltellurium dihalides[60] and di(chloroalkyl)- and di(chlorocycloalkyl)-tellurium dichlorides,[43,44,61] are relatively unpromising. Indeed alkyl phenyl tellurides, which are the starting materials in the synthesis of alkylphenyltellurium dihalides, are obtained by the reaction of tellurophenoxide anions with alkyl halides, while the pyrolysis of di(chloroalkyl)- and di(chlorocycloalkyl)-tellurium dichlorides results in the formation of a series of side products together with halogeno-derivatives of different structure.

1. Aromatic Halogeno-derivatives

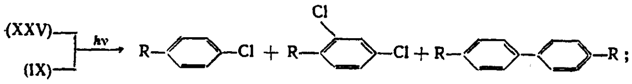
Aromatic halogeno-derivatives are formed on photolytic[62] or hydroperoxide-induced α-elimination[63] and also on elimination of tellurium halides (by treatment with bromine or iodine) from σ-telluranes of the type Ar_2TeX_2 and $ArTeX_3$.[64]

(a) *Photolytic α-Elimination from σ-Telluranes*

Reactions involving photolytic α-elimination of organyl halides from σ-telluranes are fairly general and lead to the formation of aromatic monohalogeno-derivatives and also dihalogeno-derivatives of cyclic and ethylenic hydrocarbons[62] (see below).

p-Chloroanisole (XLIV, R = OMe, X = Cl) is formed in a high yield (70%) together with small amounts of 2,4-dichloroanisole (XLV, R = OMe, X = Cl) and 4-methoxybiphenyl (XXI) (1%) on photolysis of *p*-anisyltellurium trichloride (XXV, R = OMe, X = Cl) in benzene. Metallic tellurium is liberated during the reaction probably as a consequence of the disproportionation of the $TeCl_2$ formed initially.[62] Other aryltellurium dichlorides behave analogously. In the reactions of diaryltellurium dichlorides, the yield of aryl halides is reduced; instead of elemental tellurium, a mixture of inoganic and organic tellurium compounds of unknown structure is produced and the amount of asymmetric biaryls increases.

p-Anisyltellurium tribromide, di(*p*-anisyl)tellurium diacetate, and *p*-anisyltellurium triacetate [obtained *in situ* from di(*p*-anisyl) ditelluride and lead tetra-acetate] enter into analogous reactions, which lead to *p*-anisyl bromide and p-anisyl acetate in yields of 30% and 6 and 15% respectively:[62]



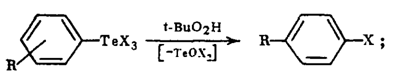
(XLIV) (XLV) (XXI)

X=Cl, R=OMe, Me.

The selective formation of the C–X bond (X = Hal) in the *unco*-positions [2- and 4-positions (Ed.of Translation)] in the molecule and the limited involvement of the solvent (benzene) in the formation of products (low yield of biaryls) suggest that the photolysis of σ-telluranes considered here does not entail the formation of free radicals. This is also indicated by the finding that the ratio of the reaction products does not change significantly in the photolysis of *p*-anisyltellurium trichloride or di(*p*-anisyl)tellurium dichloride in the presence of t-butyl peroxide.[62]

(b) α-Elimination Induced by Hydroperoxides

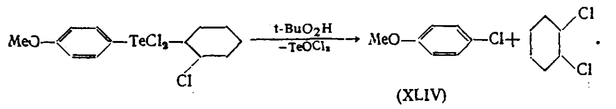
After the acetic acid solution of *p*-anisyltellurium trichloride (XXV, R = *p*-Ome, X = Cl) (1 mol) and t-butyl hydroperoxide (2 mols) has been refluxed for a short time, *p*-chloroanisole (XLIV) is obtained in 53% yield.[63] Tellurium is then converted into tellurium oxide chlorides, although the structure of the inorganic products has not been accurately established:[63]



(XXV) (XLIV)

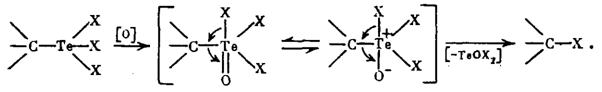
X = Cl, R = OMe, 4-Me, 2.3-C_4H_4; X = Br, R = 4-OMe .

When 2-chlorocyclohexyl-*p*-methoxyphenyltellurium dichloride is treated with t-butyl hydroperoxide in acetic acid, a mixture of *p*-chloroanisole (22%) and 1,2-dichlorocyclohexane (55%) (configuration not indicated) is formed, which indicates a greater liability of the C_{Alk}–Te bonds in the α-elimination reactions compared with C_{Ar}–Te:



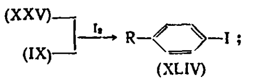
(XLIV)

The authors[63] suggest that organyl halides are formed via a mechanism involving the 1,2-tellurium halide shift in an instable hexacoordinate tellurium derivative formed on oxidation of σ-telluranes:



(c) Reactions Involving the Halogen-induced Elimination of Tellurium from σ-Telluranes

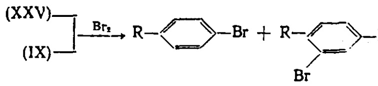
When *p*-anisyltellurium trichloride (XXV) reacts with iodine in boiling acetonitrile, *p*-iodoanisole (XLIV, X = I) is formed in 13% yield;[64] the presence of the *o*- and *m*-isomers was not detected under these conditions. The introduction of potassium, caesium, or ammonium fluorides into the reaction mixture increases the yield of *p*-iodoanisole to 85%. Treatment of diaryl tellurium dichlorides (IX, X = Cl) under analogous conditions also leads to aryl iodide, but in lower yields. On passing from *p*-anisyl- to phenyl- and *p*-bromphenyl-tellurium trichlorides, the yields of aryl iodides fall sharply, which indicates the electrophilic character of the process. The nature of the electronegative substituents at the tellurium atom (Cl, OCOMe, and $OCOCF_3$) does not have a significant influence on the yields of aryl iodides:[64]



(XLIV)

X=Cl, R=OMe, Me, H; X=OAc, R=OMc, H; X=$OCOCF_3$, R=H.

Somewhat different results have been obtained in the study of the elimination of tellurium bromide from σ-telluranes.[64] In the reaction of *p*-anisyl-tellurium trichloride with bromine in different solvents (actonitrile, dioxan, acetic acid), mainly 2,4-dibromoanisole (XLV, R = OMe, X = Br) and a small amount of *p*-bromoanisole (XLIV, R = Ome, X = Br) are formed. The preferential formation of the dibromo-derivatives (XLV) from *p*-anisyltellurium trichloride is the result of the ready bromination of the monoaryl bromides (XLIV) formed initially in the presence of tellurium(IV) derivatives playing the role of catalysts of electrophilic substitution in the aromatic ring. As in the elimination of tellurium iodide, the weakening of the electron-donating properties of the substituent in the arene rings (phenyl- and *p*-bromophenyl-tellurium trichlorides) leads to a sharp decrease of the yield of aryl bromide even in the presence of caesium and ammonium fluorides:[64]



(XLIV) (XLV)

R=OMe, Me, H .

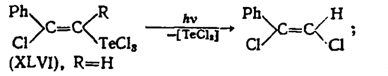
The chlorine-induced elimination of tellurium from aryltellurium trichlorides by reaction with chlorine, $SbCl_5$, and t-butyl hypochlorite affors very low yields of aryl chloride even in the case of *p*-anisyltellurium trichloride (not more than 5%). The cyanide-induced elimination of tellurium from aryltellurium trichlorides by reaction with copper(I) cyanide in DMF proceeds in approximately the same manner (yield 8%).[63]

2. Dihalogeno-derivatives of Olefinic and Cyclic Hydrocarbons

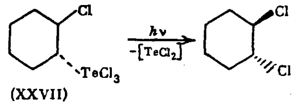
The formation of derivatives of organic compounds of these classes has been observed in the same reactions as the formation of aryl halides: photolytic[62] and hydroperoxide-induced α-elimination from σ-telluranes[63] and also halogen-induced elimination of tellurium from 2-chlorovinyltellurium trichlorides.[65]

(a) Photolytic α-Elimination

Irradiation of a benzene solution of *Z*-2-chlorovinyl-2-phenyltellurium trichloride (XLVI, R = H) with UV light leads to *Z*-1,2-dichloroethylene (yield 39%); the composition and structure of other reaction products were not established; this may indicate that the α-elimination proceeds in this case with retention of configuration.[62] The photolysis of *trans*-2-chlorocyclohexyltellurium trichloride (XXVII) results in the formation of *trans*-1,2-dichlorocyclohexane in 28% yield[62] (the formation of the *cis*-isomer was not observed):



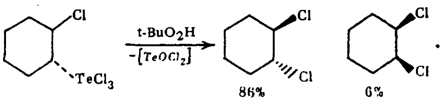
(XLVI), R=H



(XXVII)

(b) α-Elimination Induced by Hydroperoxides

Dihalogeno-derivatives of the types considered can be formed also by the hydroperoxide-induced α-elimination of organic halides from organyltellurium trihalides.[63] Thus, when *trans*-2-chlorocyclohexyltellurium trichloride is briefly refluxed with two equivalents of t-butyl hydroperoxide, a mixture of *trans*- and *cis*-1,2-dichlorohexanes is formed in yields of 86% and 6% respectively:

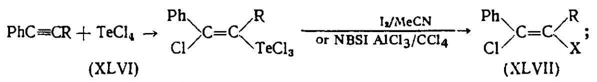


The analogous reaction with *trans*-2-chlorocyclohexyltellurium triiodide, which leads to only *trans*-1,2-chlorodiiodocyclohexane (64%), takes place also when t-butyl hydroperoxide is replaced by hydrogen peroxide, cumenyl hydroperoxide, and *m*-chloroperbenzoic acid, but the yields are then appreciably lower.[63]

Z-1,2-dichloroethylenes are formed together with small amounts of the *E*-isomers (ratio approximately 9 : 1) in the reaction involving *Z*-2-chlorovinyltellurium trichlorides (XLVI, R = H or Ph).[63]

(c) Halogen-induced Elimination of Tellurium from 2-Chlorovinyltellurium Trichlorides

The halogen-induced elimination of tellurium from 2-chlorovinyltellurium trichlorides (XLVI), whose *Z*-isomers are readily obtained (in 80–90% yield) by the addition of $TeCl_4$ to substituted acetylenes, has been used to synthesise 1,2-dihalogenoethylenes. Thus the iodine-induced elimination of tellurium from compounds (XLVI) by treatment with iodine (in acetonitrile or methanol) and the bromine-induced elimination of tellurium by treatment with *N*-bromosuccinimide (NBSI) ($NBSI/AlCl_3$ in CCl_4 or $NBSI/CuBr_2$ in acetonitrile) proceeds with retention of configuration, as for many β-substituted vinyl organometallic compounds investigated previously, and leads to *Z*-1,2-chloroiodo(or bromo)ethylenes (XLVII) in high yields:[65]



$$PhC{\equiv}CR + TeCl_4 \rightarrow \underset{\text{(XLVI)}}{\overset{Ph}{\underset{Cl}{}}\!\!>C{=}C<\!\!\overset{R}{\underset{TeCl_3}{}}} \xrightarrow[\text{or NBSI AlCl}_3/\text{CCl}_4]{I_2/MeCN} \underset{\text{(XLVII)}}{\overset{Ph}{\underset{Cl}{}}\!\!>C{=}C<\!\!\overset{R}{\underset{X}{}}};$$

X=I, R=H, Me, Et, Ph; X=Br, R=H, Ph.

Bearing in mind that, in contrast to other reagents (for example $HgCl_2$ [66]), which give rise to *E*-isomers as a result of *trans*-attack, the addition of $TeCl_4$ to substituted acetylenes always leads to *Z*-isomers (XLVI) and that the elimination of tellurium from the latter proceeds with retention of configuration, the above reaction sequence can be regarded as a convenient method of synthesis of *Z*-chloro(or bromo)-alkanes from alkynes.

(d) Dihalogeno-derivatives of Saturated Hydrocarbons

A single example of the synthesis of dihalogeno-derivatives of this type in reactions of organotellurium compounds has been described, namely the formation of 1,1-dibromoalkanes in high yield or thermal decomposition of 1,1-bis(phenyldibromotelluro)alkanes in the presence of sodium bromide in DMF.[63] The initial compounds are obtained in 80–85% yield by the reaction of alkyl halides with bis(phenyltelluro)methyllithium[67] and subsequent bromination of the intermediate bistellurides:

$$RX \xrightarrow[2)\ Br_2]{1)\ LiCH(TePh)_2} RCH\,(TeBr_2Ph)_2 \xrightarrow{NaBr} RCHBr_2\,;$$
$$R{=}C_{11}H_{23},\ C_{12}H_{25},\ C_{14}H_{29},\ C_{16}H_{33},\ Ph\,(CH_2)_3\,.$$

IV. SYNTHESIS OF CARBONYL COMPOUNDS

Carbonyl compounds of different classes, namely aldehydes,[60,68,69] ketones,[15,16,70–72] and carboxylic acids[72,73] and their derivatives (esters[15,16,70,74–76] and anhydrides[59,77,78]) can be formed in reactions of monocoordinate,[71,72] dicoordinate,[69] tricoordinate,[15,16,70,76,78] and tetracoordinate[59,68,73–75,77] derivatives of tellurium.

1. Aldehydes
