
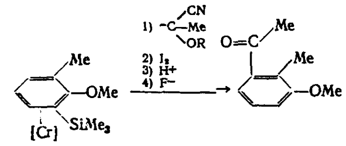
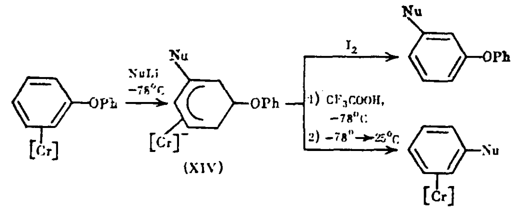
R=CH_2CN, CMe_2CN

DMF = dimethylformamide.

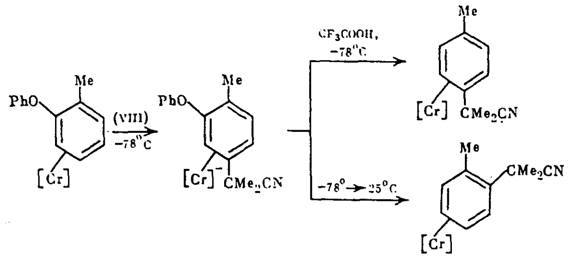


It has been shown[71] that (diphenylether)ChTC reacts with stabilised carbanions to form *m*-substituted diphenyl ethers after oxidation. If the anionic complex (XIV) is treated with CF_3COOH at −78 °C or is heated to room temperature, then the product of the substitution of the PhO group by the nucleophile is formed:

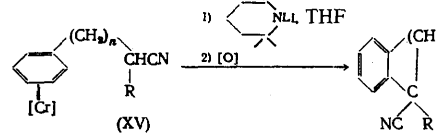


Nu = CH_2CN, CHMeCN, CMe_2CN, $CHMeCO_2Bu$-t, C(Ph)—S—$(CH_2)_3$—S

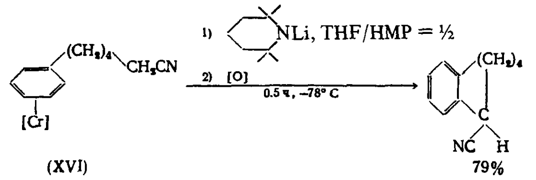
The high regioselectivity of the substitution of the phenoxy-group has been established for the reaction of (*o*-phenoxytoluene)ChTC with compound (VIII): treatment with CF_3COOH leads to a p-disubstituted complex, while heating to room temperature affords the *o*-disubstituted complex:



The nature of the product formed has been investigated as a function of the number of methylene units separating the aromatic ligand and the CN group for systems capable of intramolecular addition.[72] 1-Cyanotetralin is formed from the complex (XV, *n* = 3);

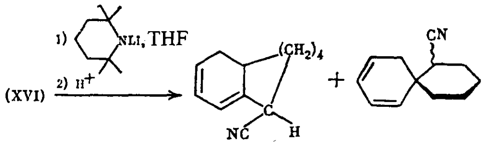


When *n* = 4, the position where the nucleophile adds depends on the reaction time and temperature:

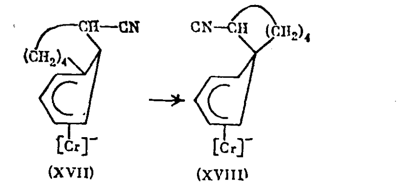


With increase of temperature and of the reaction time, the fraction of high-molecular-weight products also increases.

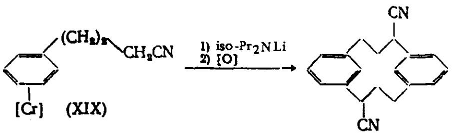
High yields of monomeric products are retained under protonation conditions, but their ratio also depends on the reaction time and temperature. For example, the amounts of condensed and spiro-products at 0 °C are 25 and 75% after 4 h and 3 and 97% respectively after 24 h:



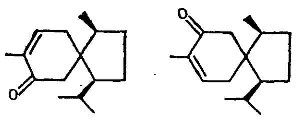
The most rational explanation involves the initial formation of compound (XVII) as the kinetically controlling product; a 1,2-carbon shift converts this adduct into the thermodynamically more favourable complex (XVIII):



For low homologues (XIX, *n* = 2), the formation of both spirocyclic and condensed products is favourable, so that dimeric compounds are formed:

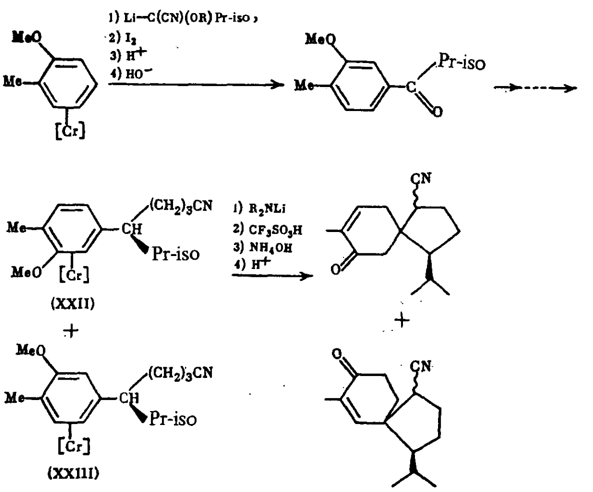


The characteristic features of the addition of nucleophiles have been used in the synthesis of spiro[4.5]decane system—acorenone (XX) and acorenone B (XXI):[14]



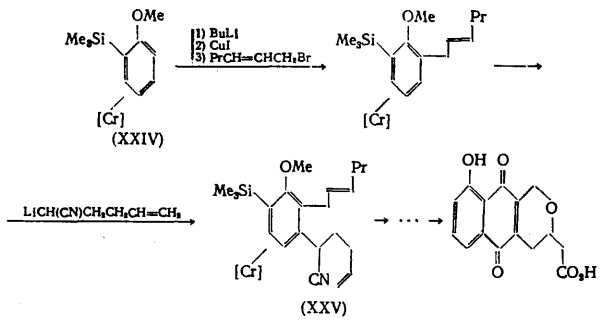
(XX) (XXI)

The strategy used in the synthesis is based on the *m*-directing effect of the methoxy-group in the nucleophilic addition to the anisole complex; *exo*-attack is then controlled by the configuration of the spiro-carbon:



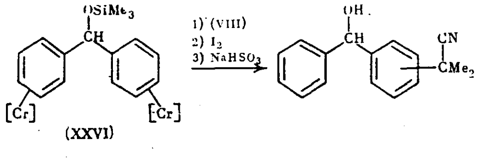
The diastereoisomeric mixture of the complexes (XXII) and (XXIII) was separated by preparative liquid chromatography; the low efficiency of the spirocyclisation complexes vitiates the prepartive importance of this synthesis.

Complex formation with ChTC has been a convenient method of preparation of synthons on the way from frenolicin to deoxyfrenolicin—antibiotics based on the isochromanquinone skeleton.[74] The fundamental factor is the use in the initial stages of the *p*-directing effect of the Me_3Si group and the *m*-directing effect of the MeO group in the nucleophilic addition of the complex (XXIV); this results in the selective formation of compound (XXV), from which the Me_3Si group can be readily removed. It is noteworthy that the lithio-derivative of the complex (XXIV) does not react directly with 2-hexenyl bromide and was therefore converted into an organocopper derivative:

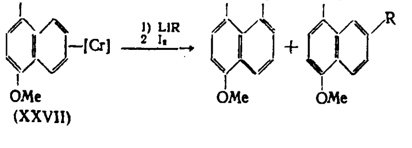


The overall yield of deoxyfrenolicin is 4% after a 15-stage synthesis.

The decisive role of the conformation of ChTC in the mode of nucleophilic attack on the BCT has been confirmed.[75] The reaction of 2-lithio-2-methylpropionitrile with the complex (XXVI), for which the *syn*-eclipsed conformation is characteristic, and subsequent oxidation yielded a mixture of monosubstituted diphenylmethanols with the ratio $m/p = 9/1$:

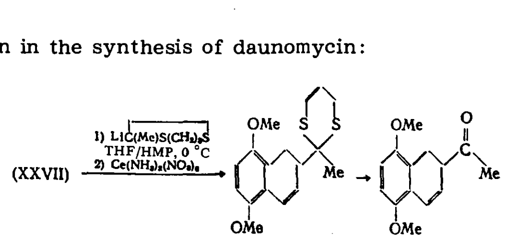


The addition of nucleophiles to polycyclic aromatic complexes is of considerable interest. In this case the steric requirements of the arene substituent and the nucleophile have a marked influence on the regioselectivity of the nucleophilic attack together with the conformational effect and the nature of the substituent in the nucleus.[76] The reaction of the small $LiCH_2CN$ molecule with the complex (XXVII) affords mainly the α-substitution product, while the more bulky compound (VIII) gives rise to the β-substitution product:

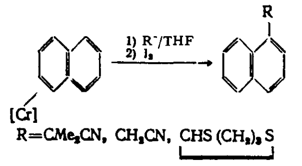


Depending on the reaction time and temperature, different ratios of the α- and β-products are observed and the β-addition product rearranges via dissociation with elimination of a carbanion to the thermodynamically favourable α-addition product.

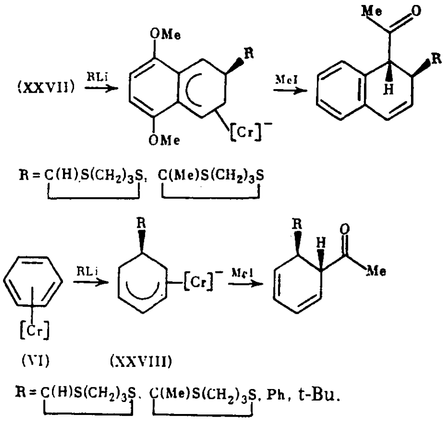
In the case of 2-lithio-2-methyl-1,3-dithiane, the β-addition is irreversible and this reaction has been used to synthesise 6-acetyl-1,4-dimethoxy-5,6-dihydronaphthalene—the synthon in the synthesis of daunomycin:



However, carbanions add to (naphthalene)ChTC in the α-position:

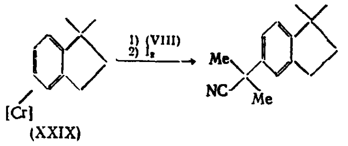


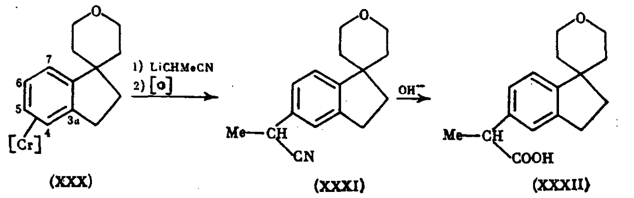
The ability of *S*-stabilised carbanions to add irreversibly to BCT with formation of anionic complexes, which react with electrophiles (MeI), is the basis of a general method of synthesis of disubstituted dihydronaphthalenes and cyclohexadienes:[78]



The insertion of CO has been observed when the reaction was carried out both in an atmosphere of carbon monoxide and in its absence. Other electrophiles also proved to be effective in the synthesis of 5,6-disubstituted cyclohexa-1,3-dienes.[9]

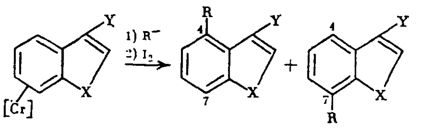
The ability of nucleophiles to add preferentially to the eclipsed carbon atoms of the arene liquid is manifested strikingly in the reactions of 1,1-disubstituted indan complexes.[66,80] The reactions of cyano-stabilised carbanions with the complexes (XXIX) and (XXX) and subsequent oxidation lead to 5-substituted indans:



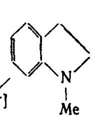


Hydrolysis of compound (XXXI) affords the pharmacologically valuable 5-substituted acid (XXXII). According to the results of X-ray diffraction analysis of the complex (XXX),[80] the CO groups are in the eclipsed conformation relative to the 3a, 5-, and 7-positions in the arene ligand.

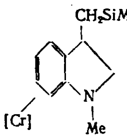
The method involving the addition/oxidation of reactive *C*-nucleophiles to BCT has been extended to complexes of *N*-substituted indoles, *N*-methylindoline, and benzofuran.[81,82] The attack by the nucleophiles is then directed to C(4) and C(7) and the product ratio is regulated by electronic and steric factors determined by the size of the substituents at the nitrogen atom and C(3) and also by the nature of the nucleophile:



Compound (VIII) adds to the C(4) atom in the complexes with Y = H and X = NMe (XXXIII), NCH_2Ph (XXXIV), $NSiPh_2Bu$-t (XXXV), and NCO_2Bu-t (XXXVI) with a selectivity in excess of 90%. In the reaction of the complex (XXXIII), the less bulky anion $LiCH_2CN$ exhibits a lower selectivity [C(4)/C(7) = 75/25]. On the other hand, 2-lithio-1,3-dithiane and 1-lithio-3-dimethylsilylprop-2-ene reacts with the complex (XXXIII) preferentially at the C(7) atom, forming a mixture of substitution products [C(7)/C(4) = 6/1]. In contrast to the *N*-methylindole complex (XXXIII), the dithiane anion acts only on the C(4) atom in the *N*-methylindoline complex (XXXVII), which, bearing in mind the ease with which the indoline system can be converted into the indole system,



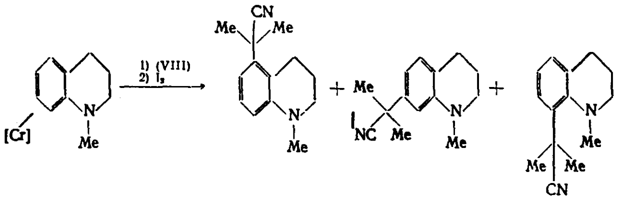
(XXXVII)



(XXXVIII)

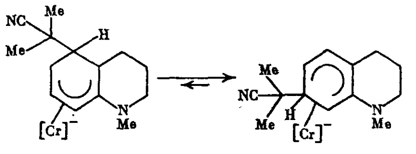
leads to the possibility of the selective synthesis of 4- and 7-substituted indoles. The addition of nucleophiles to the benzofuran complex is directed mainly to the C(4) position [C(4)/C(7) is 73/27 for R = CMe_2CN, 63/37 for R = CH_2CN, and 86/14 for R = ]. The introduction of substituents at the C(3) atom in the indole system reduces the yield of the 4-substituted product and, in the case of the complex (XXXVIII), for example, C(4)/C(7) = 17/83 for R = CMe_2CN. The opposite effect is produced by bulky substituents at the nitrogen atom [the complexes (XXXV) and (XXXVI)].

An elegant study of the reaction of (η^6-methyl-1,2,3,4-tetrahydroquinoline)ChTC with compound (VIII) revealed the influence of kinetic and thermodynamic control on the ratio of the regioisomers:[83]



(XXXIX) (XL) (XLI)

The isomer (XLI) is formed in small amounts (1–2%) and the ratio of the isomers (XXXIX) and (XL) depends on the reaction time and temperature and also on the nature of the solvent, the increase of the relative content of the isomer (XL) when the reaction is carried out in THF indicating the thermodynamic control of the reaction, while the more highly substituted anion (XLII) is converted into the sterically more favourable anion (XLIII):



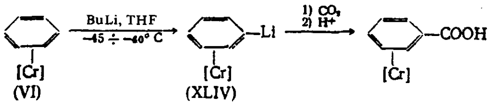
(XLII) (XLIII)

In the presence of added hexamethylphosphoramide (HMP), which strongly solvates the lithium cation, a constant ratio of the regioisomers, reflecting the kinetic control of the nucleophilic addition, is retained and in this instance there is no isomerisation. The combination of these results constitutes convincing evidence for the reversibility of the addition of nucleophiles to BCT.

IV. REACTIONS OF LITHIO-DERIVATIVES

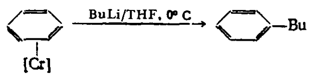
One of the most important properties of BCT is the increased acidity of the ring hydrogen atoms, which is the reason for their ability to be substituted by a metal on treatment with metallating agents. The nature of the metallating agent has a decisive influence on the direction of the process—soft nucleophiles add to the complex, while hard nucleophiles substitute a hydrogen atom.

The metallation of BCT was first achieved, by Nesmeyanov and co-workers, on treatment with BuLi; the yield of the acid after carboxylation was 19%:[84]



(VI) (XLIV)

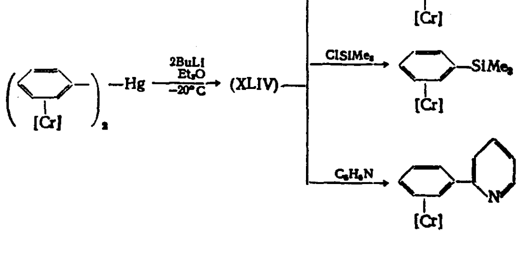
It has been shown[19,85–87] that BCT reacts with BuLi to form the complex (XLIV) almost quantitatively at −20 °C in THF but heating of the solution to 0 °C or the addition of BuLi to the BCT solution at 0 °C leads to butylbenzene in a yield greater than 80%:



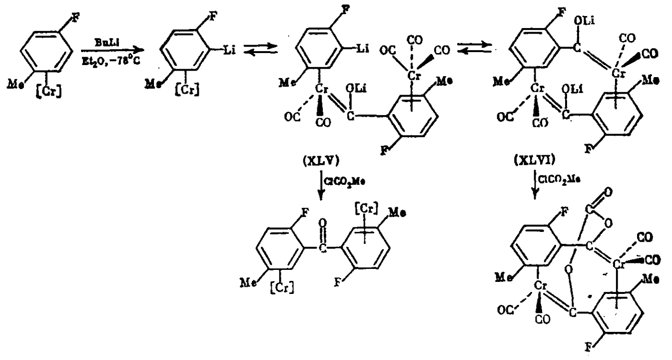
(VI)

The oxidation stage is not then required. The mechanism of the formation of butylbenzene is obscure but it is undoubtedly different from the mechanism of the coupling of soft nucleophiles to BCT.

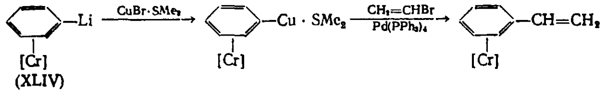
The lithio-BCT (XLIV) is readily obtained by the transmetallation reaction between dibenchrotrenylmercury and butyl-lithium and readily reacts with chlorophosphines, chlorosilanes, and pyridine:[88]



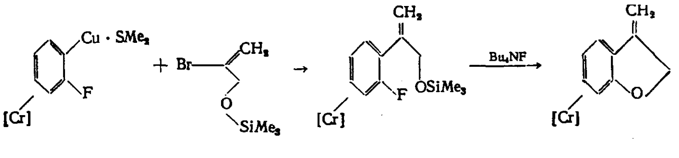
In relation to the metallation of (*p*-fluorotoluene)ChTC, it has been shown that the monomeric compounds of type (XLIV) formed at a low temperature are in equilibrium with the dimeric complexes (XLV) and (XLVI). This is manifested in reactions with electrophiles having more than one potential leaving group, for example, methyl chlorocarbonate, whereupon derivatives of benzophenone and carbonate are formed:[89]



A characteristic property of lithio-BCT is their anomalously low nucleophilicity compared with their basicity and the set of electrophiles which react with them is therefore limited.[87,90] Lithio-BCT do not react with propyl iodide and alkanesulphonates, giving rise to low yields of products even in reactions with active electrophiles such as MeCOCl and CH_2CHCH_2Br. It has been found[90] that the addition of the complex CuBr.SMe_2 to compound (XLIV) leads to copper-BCT, which react successfully with a large set of electrophiles, affording substitution products. The application of palladium catalysis made it possible to extend the scope of the reaction to include the products of cross-coupling with vinyl bromide and iodobenzene:

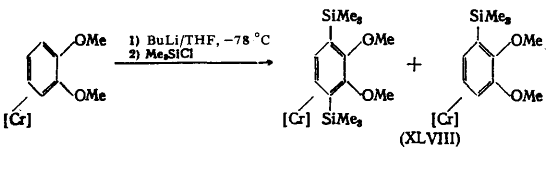


The reaction of (*o*-fluorophenyl-lithio)ChTC with the complex CuBr.SMe_2 and the subsequent coupling of the Cu-derivative with 2-bromoallyltrimethylsilyl ether give rise to the complex (XLVII), which undergoes intramolecular cyclisation, after desilylation, to the 3-methylene-2,3-dihydrobenzofuran complex:[91]



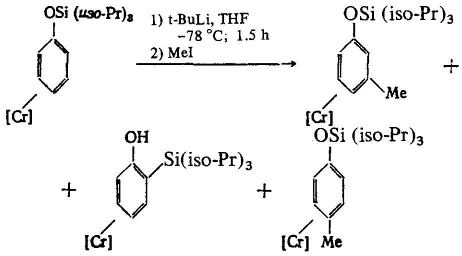
A characteristic feature of the latter is the lack of a tendency towards isomerisation to the 3-methylbenzofuran isomer, which is the product of the aromatisation of 3-methylene-2,3-dihydrobenzofuran not bound in a complex.

Metallation of (veratrole)ChTC by BuLi with subsequent silylation leads to a mixture of the mono- and di-silylated complexes in approximately equal amounts:[92]

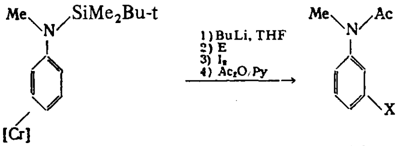


According to ^1H NMR and X-ray diffraction data, the complex (XLVIII) in solution and in the solid state has the conformation in which the bulky Me_3Si group is eclipsed by the CO group.[93]

Protection of the hydroxy-group in (phenol)ChTC leads to marked shielding of the *o*-positions and the metallation takes place in the *m*-position to the extent of 90%.[94] The yield of the *o*-substituted product does not exceed 3%:

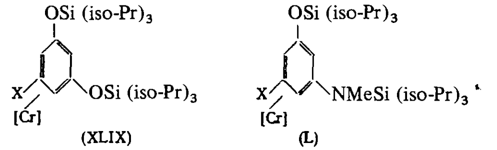


The methylation of (*N*-butyldimethylsilyl-*N*-methylaniline)-ChTC proceeds with a high regioselectivity in the *m*-position; *m*-substituted aniline can be obtained by subsequent reactions of the electrophile and the removal of ChTC.[95] The complete absence of *o*-substitution is noteworthy:



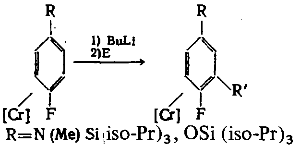
E^+=PhCHO, MeCHO, $HCONMe_2$, MeI, MeSSMe, PhCN;
X=CH (OR) Ph, CH (OH) Me, CHO, Me, SMe, COPh

The substitution of resorcinol and *m*-aminophenol by lithium takes place exclusively in the 5-position, so that the 1,3,5-trisubstituted complexes (XLIX) and (L) are formed after reactions with electrophiles:



X=Me, $SiMe_3$, CO_2Me

The metallation of tri-isopropylsilyl derivatives of *p*-fluorophenol and *p*-fluoroaniline, where the hydrogen atoms in the *o*-position relative to the fluorine atom are substituted, is especially noteworthy:

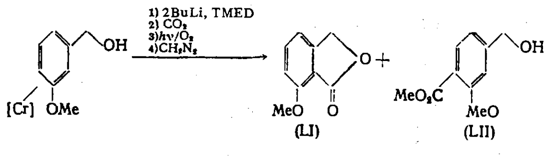


R=N (Me) Si (iso-Pr)$_3$, OSi (iso-Pr)$_3$;
R'=Me, $SiMe_3$, CO_2Me

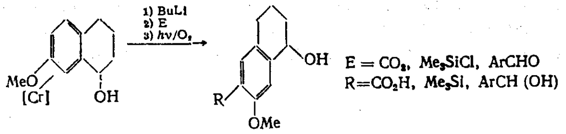
These results are the opposite to those of the metallation of sterically unhindered arenes and arenes not bound in a complex, for example, *p*-fluoroanisole and *p*-fluorodimethylaniline, where the metal always enters the *o*-position relative to the heteroatom.

The change in the regioselectivity of the metallation of the benzene ring after coordination to ChTC can be traced distinctly in relation to benzyl alcohols.[96,97] (3-Hydroxymethyl-1-methoxybenzene)ChTC reacts with two equivalents of BuLi to form the benzofuranone (LI) and the benzoic acid ester

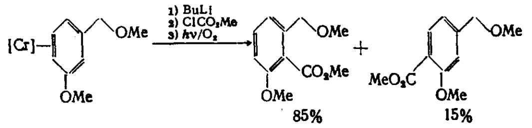
(LII) in proportions of 23 : 77 after carboxylation and methylation, while the analogous sequence of reactions with the arene not bound in a complex yields the ratio 9 : 1. With increase of the bulk of the metallating agent, the content of the 5-methylated product (LII) increases (85% for s-BuLi and 95% for t-BuLi):



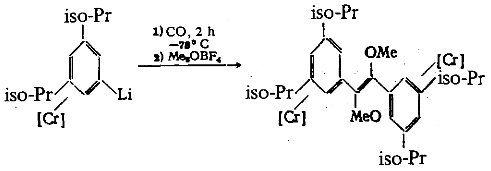
The coordination of a hard system, such as, for example, 7-methoxy-1-tetralinol, to ChTC leads to metallation exclusively in the 6-position, while the substitution of free tetralinol by lithium yields the 8-substituted product:



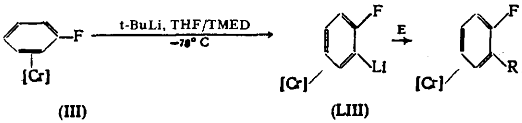
Alkyl benzyl ethers and the acetals of benzaldehydes are not *o*-metallated owing to the tendency towards deprotonation in the benzyl position with subsequent Wittig rearrangement or cleavage of the acetal linkage. The formation of a complex with TC makes it possible to metallate successfully the aromatic ring containing the above substituents with the predominant formation of 1,2,3-trisubstituted-products:



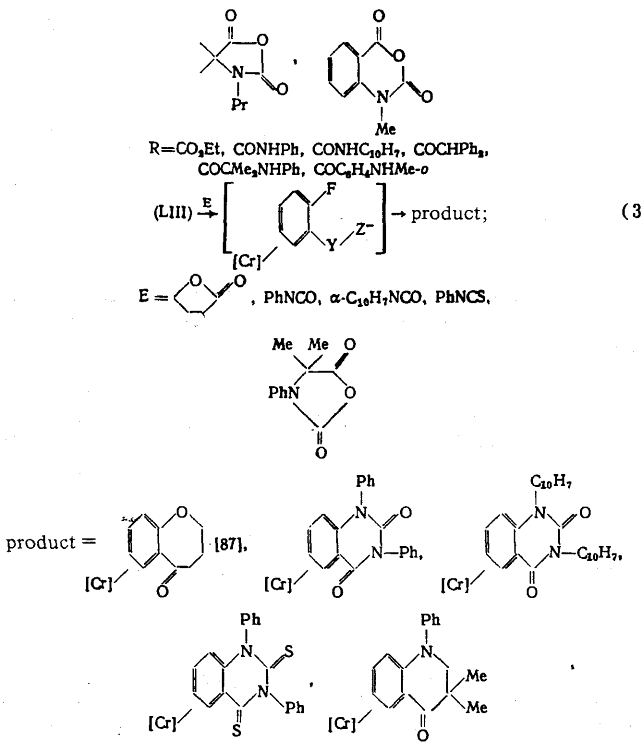
The reaction of *m*-di-isopropylbenchrotrenyl-lithium with CO and subsequent methylation with trimethyloxonium tetrafluoroborate lead to a dinuclear complex in 15% yield:[98]



A novel application of the characteristic features of benchrotrenyl systems in synthesis has been achieved by Chavshow and Widdowson,[99] who showed that the metallation of the complex (III) results in the formation of (*o*-fluorolithiobenzene)ChTC (LIII), which react smoothly with various electrophiles; depending on the ratio of the substrate and the reactant, substitution products [Eqn.(2)] or cyclisation products [resulting from the simultaneous nucleophilic substitution of the fluorine atom—Eqn.(3)] are obtained:



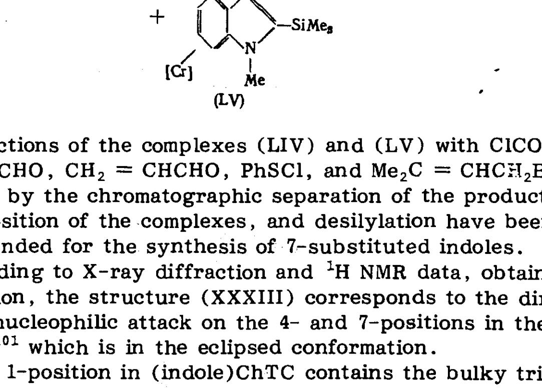
(2)



(3)

The method proposed for the synthesis of benzo-condensed systems may find an application in the chemistry of heterocyclic compounds.

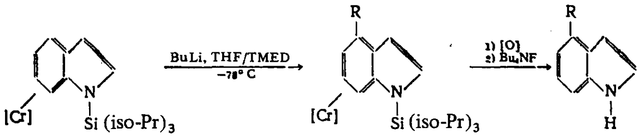
The metallation of (1-methylindole)ChTC (XXXIII) occurs in the first place in the 2-position. If this position is occupied, then attack is directed to the aromatic ring in the 7- and 4-positions in the proportions ≥4 : 1:[100]



The reactions of the complexes (LIV) and (LV) with ClCO$_2$Et, MeI, PhCHO, CH$_2$ = CHCHO, PhSCl, and Me$_2$C = CHCH$_2$Br followed by the chromatographic separation of the products, decomposition of the complexes, and desilylation have been recommended for the synthesis of 7-substituted indoles.

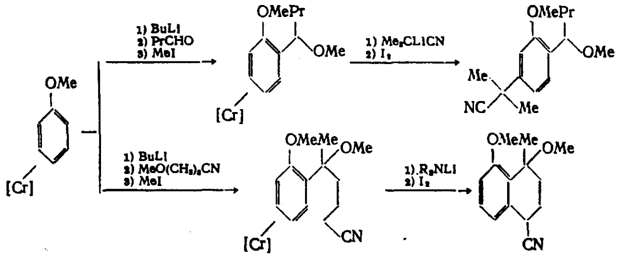
According to X-ray diffraction and ^{1}H NMR data, obtained in solution, the structure (XXXIII) corresponds to the direction of nucleophilic attack on the 4- and 7-positions in the ligand,[101] which is in the eclipsed conformation.

If the 1-position in (indole)ChTC contains the bulky triisopropyl group, then the metallation of the complex is directed mainly to the 4-position together with formation of a certain amount of 5- and 6-isomers.[102] Decomposition of the complexes and desilylation lead to 4-substituted indoles in 70% yield:



R = Me_3Si, EtO_2C, MeO_2C, PhS, $Me_2C{=}CHCH_2$

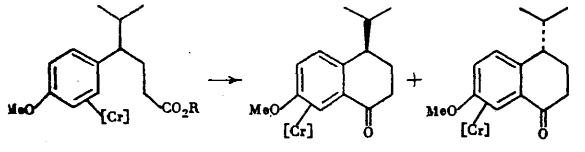
The metallation of BCT combined with nucleophilic addition or substitution has been used to synthesise trisubstituted benzenes:[87]



Favourable prospects for the employment of (lithioarene)-ChTC in synthesis, especially for the preparation of natural products, have become apparent. The synthesis of natural anthraquinones, namely 3-deoxyrabelomycin (LVI) and aclavinone (LVII),[103] is illustrated in Eqns.(4) and (5):[103]

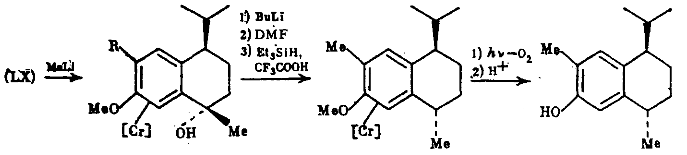
The metallation of the (tetralinol)ChTC complexes proceeds regioselectively, yielding the 6-lithio-derivatives (LVIII) and (LIX).

Temporary coordination to ChTC has been used in the synthesis of *cis*- and *trans*-7-hydroxycalamenenes.[104] The complex of 4-(*p*-methoxyphenyl)-5-methylhexanoate and $Cr(CO)_6$ was hydrolysed to the acid and the *exo*-isopropyltetralinone complex (LX) together with a small amount of the *endo*-isomer (LXI) were obtained by cyclising the acid chloride with $AlCl_3$:

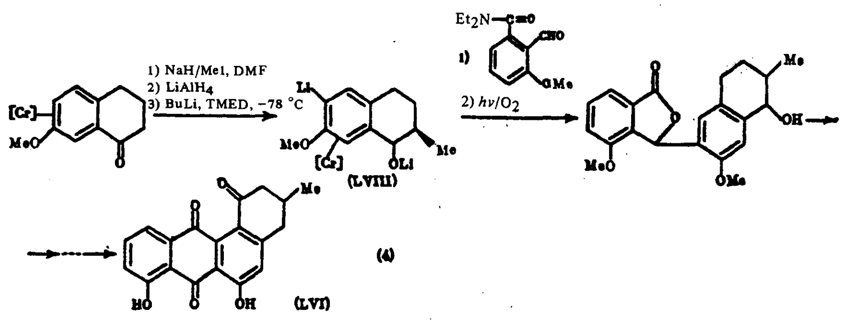


(LX) (LXI)

The reaction of the complex (LX) with MeLi leads to the *exo*-methylated product, which was metallated with BuLi in DMF and a benzaldehyde derivative was obtained. In the course of ionic hydrogenation, the reduction of the aldehyde functional group to the methyl group and hydride substitution in the benzyl position were observed simultaneously:

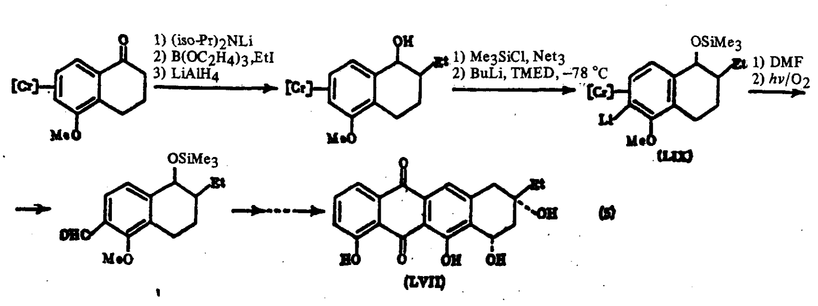


(LXII)



(LVIII)

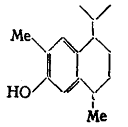
(LVI) (4)



(LIX)

(LVII) (5)

Decomposition of the complex and *O*-demethylation lead to *trans*-7-hydroxycalamenene (LXII) in a satisfactory yield. *cis*-7-Hydroxycalamenene (LXIII) was obtained from the *endo*-complex (LXI) in accordance with an analogous scheme:

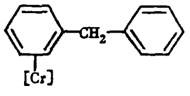


(LXIII)

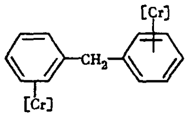
V. BENZYL ACTIVATION OF ALKYL-SUBSTITUTED DERIVATIVES

The reduced electron density on the arene ligand in BCT is responsible for the considerable increase of the acidity of the benzyl hydrogen atoms. According to an approximate estimate, their acidity in BCT derivatives is greater by two orders of magnitude than the acidity of the corresponding hydrogen atoms in the substrate not bound in the complex.[105,106]

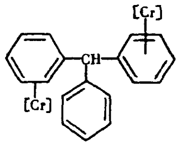
The acidifying effect of ChTC was estimated by measuring the rate of abstraction of a proton by the methoxide ion from the complexes (LXIV)–(LXVI) in the $MeOH–Me_2SO$ system:



(LXIV)



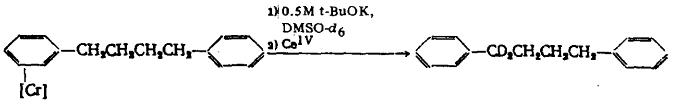
(LXV)



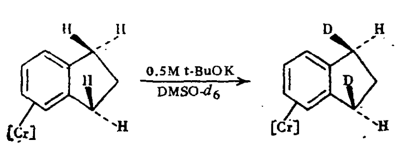
(LXVI)

Actually their kinetic acidities are similar, which has been explained by the unfavourable steric influence of the second ChTC group in diphenylmethane on the rate of ionisation of the exocyclic CH bond. However, their thermodynamic acidities increase in proportions of 1 : 2.6 : 7.4, which reflects the greater stability of the carbanion formed following the introduction of electron-accepting groups.[107]

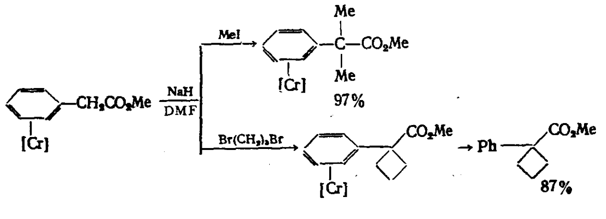
The α-hydrogen atoms of alkyl-BCT are involved in fairly rapid protophilic deuterium exchange; for example, (η^6-1,4-diphenylbutane)ChTC can be involved in the exchange with 0.5 M t-BuOK in DMSO-d_6 and after the decomposition of the complex affords 1,1-dideuterio-1,4-diphenylbutane:[108]



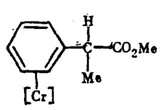
It is striking that (indan)ChTC exchanges only two of the benzyl protons, which constitutes convincing proof of the *exo*-attack by the base on the complex:



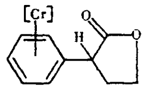
The effect of the formation of a complex with ChTC is strikingly manifested in the alkylation of phenylacetic acid esters and acetophenones.[20,109] Whereas methyl phenylacetate is not alkylated by MeI/NaH in DMF, its ChTC complex forms the dialkylated derivative almost quantitatively under these conditions and the reaction with 1,3-dibromopropene affords cyclobutane:



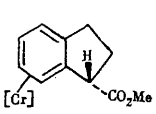
The complexes of the esters (LXVII)–(LXIX) are alkylated smoothly by the active alkyl halides RX (MeI, $PhCH_2Br$, $CH_2=CHCH_2Br$, and $HC\equiv CCH_2Br$) not only in the NaH/DMF system but also under the conditions of phase-transfer catalysis using cetyltrimethylammonium iodide:[110–112]



(LXVII)



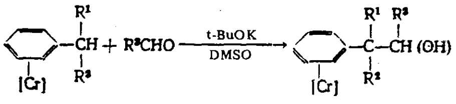
(LXVIII)



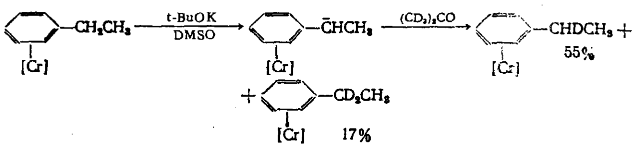
(LXIX)

The stereochemistry of the reactions is virtually the same, the electrophile attacking from the side opposite to that of ChTC.

The reaction of alkyl-BCT with formaldehyde and benzaldehyde in the presence of t-BuOK in DMSO has been used to obtain β-hydroxy-compounds, but in many instances the preparative value of the method is low owing to the low yield of products:[113,114]

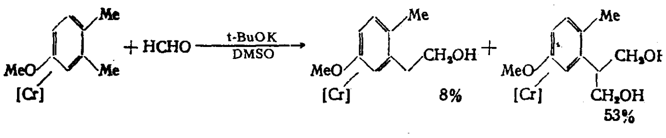


If the carbonyl compound is capable of giving rise to the enolic form, the arene complex enters only into the proton exchange reaction with formation of the corresponding alcohol:



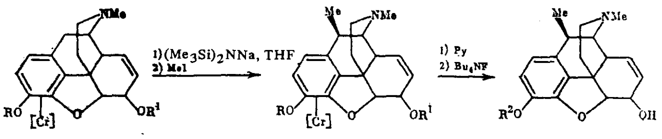
The attack by the acyclic carbanion is stereospecific and gives rise to the *exo*-product only.

It has been shown[115] that, in the presence of an alkoxy-group in the benzene ring, there is a possibility of the selective formation of α-carbanions in the *m*-position, while *p*-alkyl groups are inert:



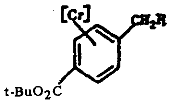
These features are responsible for the successful regio- ar stereo-specific addition of formaldehyde and alkyl halides to alicyclic compounds, especially oestrogens.[115,116]

The interaction of [6-O-t-butyl(dimethyl)silylcodeine]ChT and {3,6-bis[t-butyl(dimethyl)silyl]morphine}ChTC with $(Me_3Si)_2NNa$ and MeI leads to 10(*S*)-methyl derivatives. On subsequent decomposition of the complex with pyridine and desilylation, 10(*S*)-methylcodeine and 10(*S*)-methylmorphine are formed smoothly respectively:[117]

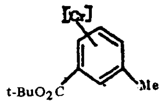


$R = R^2 = \mathrm{Me}$, $R^1 = \mathrm{t\text{-}BuMe_2Si}$; $R = R^1 = \mathrm{t\text{-}BuMe_2Si}$, $R^2 = \mathrm{H}$.

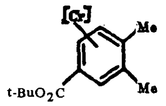
The presence of a strong electron-accepting group in the aromatic rings of the complexes alters the regioselectivity of the attack by the aldehyde in the presence of t-BuOK and activates the alkyl groups. For example, the diol, triol, and alkenol complexes (LXXIII)–(LXXVI) are formed from the complexes (LXX)–(LXXII) on reaction with formaldehyde:[118]



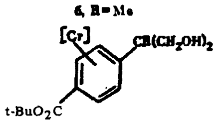
(LXX)
a, R = H
б, R = Me



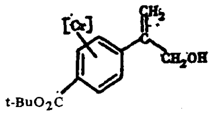
(LXXI)



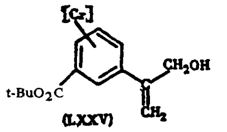
(LXXII)



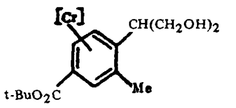
(LXXIII)
a) R = CH2OH
b) R = Me



(LXXIV)

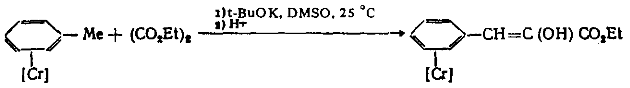


(LXXV)

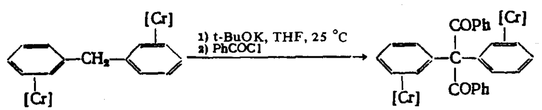


(LXXVI)

The reaction of (toluene)ChTC with t-BuOK in the presence of diethyl oxalate leads to a stable enol, derived from phenylpyruvic acid, whose structure has been demonstrated by X-ray diffraction:[119,120]



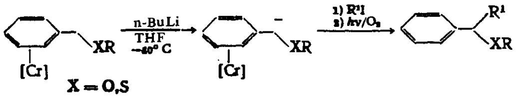
The α-protons in alkyl-BCT are readily abstracted in the reaction with t-BuOK in THF and the carbanions formed react with MeI,[121,122] diethyl oxalate and benzaldehyde,[123] and PhCOCl,[121] for example:



(LXV) 56%

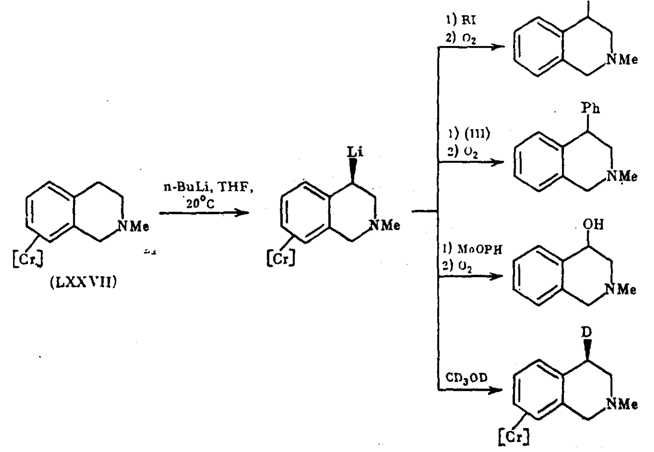
The α-metallation of alkyl-BCT by the KH/18-crown-6 ether system has been described.[124]

The α-metallation of certain BCT derivatives is achieved effectively with the aid of butyl-lithium and in this respect the ChTC derivatives of alkyl benzyl ethers and alkyl benzyl sulphides exhibit interesting features.[125] The α-carbanions derived from alkyl benzyl ethers and sulphides readily undergo the Wittig rearrangement, while coordination with ChTC leads to the possibility of achieving smoothly alkylation by various agents with formation, after the decomposition of the complex, of α-substituted benzyl ethers:



X = O,S

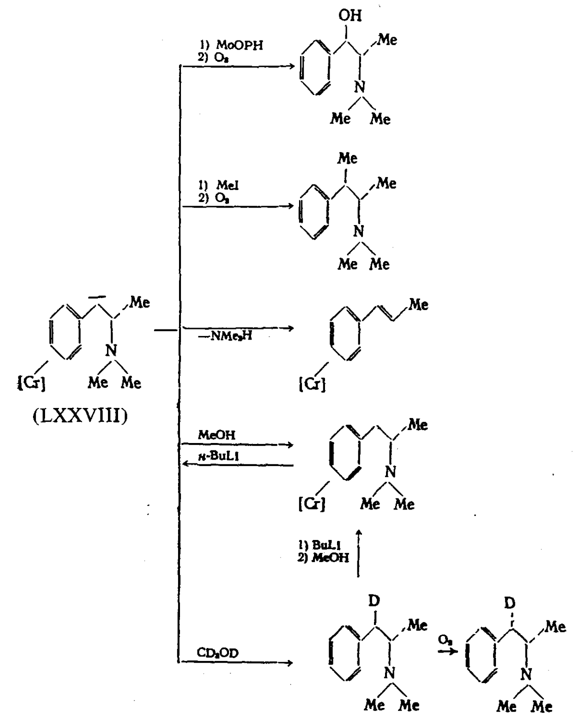
The formation of the transient complex between the aromatic ring and ChTC proved to be useful in the selective synthesis of 4-substituted 1,2,3,4-tetrahydroisoquinolines, which exhibit a selective pharmacological activity.[126] Metallation of the complex (LXXVII) leads to the substitution of the *exo*-hydrogen in the 4-position and the formation of a lithio-derivative, which is alkylated smoothly by alkyl halides, is phenylated by (fluorobenzene)ChTC, and reacts with oxodiperoxomolybdenumhexamethylphosphoramide (MoOPH) to form a 4-*exo*-hydroxylated product:



(LXXVII)

The coordination of *NN*-dimethylamphetamine to ChTC stabilises the corresponding benzyl carbanion in relation to the elimination of the amino-group and makes it possible to carry out smoothly stereospecific benzyl substitution.[127]

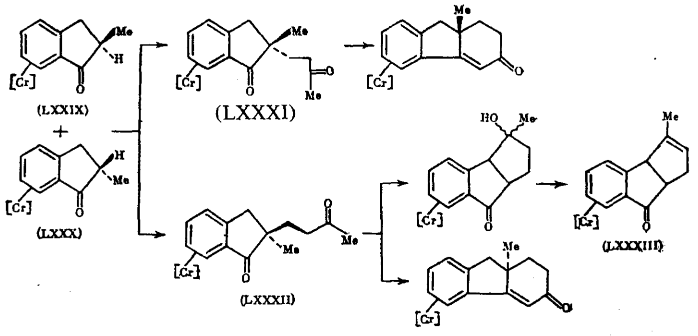
Metallation of the complex (LXXVIII) by n-BuLi at −40 °C and above leads to the elimination of Me_2NH and the formation of (*E*-β-methylstyrene)ChTC. However, at −78 °C the anion formed initially is stable and readily reacts with electrophiles (MeI, MoOPH, CD_3OD) to form derivatives of the complex (LXXVIII), from which free radicals are readily produced:



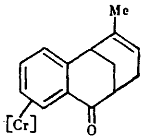
(LXXVIII)

A notable feature of the above substitution reactions is their high stereospecificity.

The increased acidity of the α-hydrogen atoms in BCT constitutes the basis of the synthesis of certain condensed systems, modelling natural products, from indanone and tetralinone complexes.[128,129] Thus the diastereoisomers (LXXIX) and (LXXX), which exist in equilibrium in acid and basic media, readily undergo the Michael reaction with methyl vinyl ketone in the presence of 1,5-diazabicyclo[4.3.0]non-5-ene to form two adducts—the *exo*-adduct (LXXXI) and the *endo*-adduct (LXXXII) in proportions of 13 : 87. The complexes are able to undergo a base-catalysed cyclisation and compound (LXXXII) affords mainly (>90%) the products of cyclisation at the benzyl position, the unsaturated tricyclic system (LXXXIII) being obtained after dehydration:



The system (LXXXIV) has been obtained analogously from tetralinone complexes:



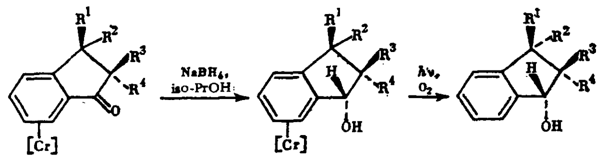
(LXXXIV)

The, at first sight, anomalous *exo*-attack by the ketone on the benzyl position becomes readily explicable from the standpoint of the activating effect of ChTC on the hydrogen atom in the α-position. In view of the regioselective activation of the benzyl CH bond, the stereochemical control of the annelation reaction, and the ease of the regeneration of the arene ligand from its TC complex, the method is exceptionally useful for the synthesis of various optically active compounds.

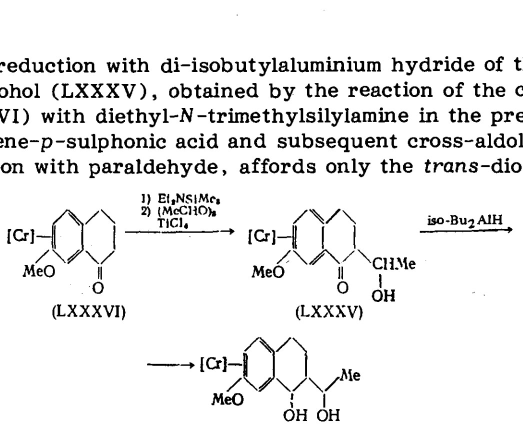
VI. STEREOCHEMICAL FEATURES OF ARENECHROMIUM TRICARBONYLS

The coordination of an arene to ChTC leads to the steric shielding of one of the sides of the aromatic ligand, which is the reason for the *exo*-attack by various agents on this ligand and for the direct binding of the functional groups with it.

The hydride reduction of (indanone)ChTC, (tetralinone)ChTC,[130] and various (alkylindanone)ChTC (*exo* and *endo*-, α- and β-) [131–134] proceeds stereoselectively and leads to the formation of *endo*-alcohols. The amount of *exo*-alcohols did not exceed 10% in any one instance, amounting to 3% as a rule. Together with the quantitative decomposition of the complexes, this property provides an effective pathway to *cis*- and *trans*-indanols, for example:

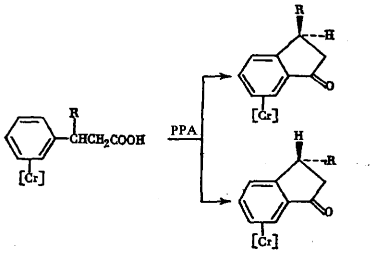


The reduction with di-isobutylaluminium hydride of the ketoalcohol (LXXXV), obtained by the reaction of the complex (LXXXVI) with diethyl-*N*-trimethylsilylamine in the presence of toluene-*p*-sulphonic acid and subsequent cross-aldol condensation with paraldehyde, affords only the *trans*-diol:[135]

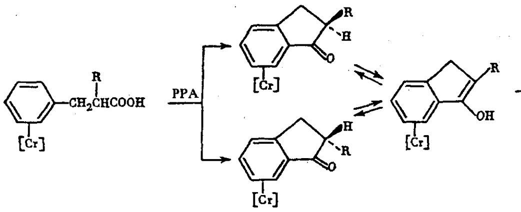


In the absence of the ChTC group, a mixture of the *trans*- and *cis*-diols is formed in proportions of 12 : 88.

When the α- and β-alkyl-substituted benchrotrenylpropionic acids are cyclised, a definite regular behaviour is observed—the amount of *exo*-isomer increases with increase of the bulk of the substituent. The 2-indanone complexes formed can undergo the *exo* ⇌ *endo* transitions via the intermediate enolic form:[131,132]



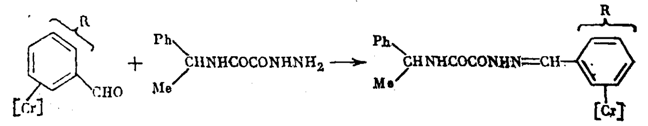
R	*exo/endo*
Me	65/35
Et	80/20
iso-Pr	95/5



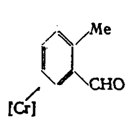
R	*exo/endo*
Me	48/52
Et	60/40
iso-Pr	75/25
t-Bu	95/5

PPA = polyphosphoric acid.

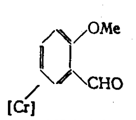
Chiral BCT with functional-group substituents, characterised by both planar and central chirality, are of special interest for asymmetric synthesis. BCT with two different substituents in the *o*- or *m*-positions are chiral and can be resolved into optical isomers.[136–143] For example, the resolution of the racemates of aldehydes has been achieved with a high yield via their reaction with (*S*)-(−)-5-(α-phenylethyl)-semioxamazide with subsequent chromatography. Acid hydrolysis results in the quantitative regeneration of the optically pure aldehydes:[144]



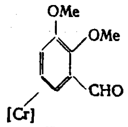
The aldehydes (LXXXVI)–(XC) have been resolved into the optically pure isomers by this method:



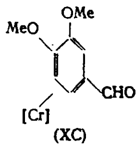
(LXXXVII)



(LXXXVIII)

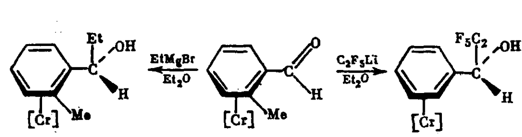


[LXXXIX]



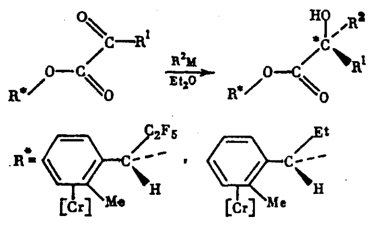
(XC)

The reaction of the optically active aldehyde (LXXXVII) with ethylmagnesium bromide or perfluoroethyl-lithium gives rise to alcohols with an enantiomeric excess of 100 and 88% respectively:[145]



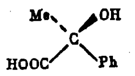
E.E. 100% (+)15-(LXXXVII) E.E. 88%

The chiral alcohols obtained were used in the Prelog type synthesis:

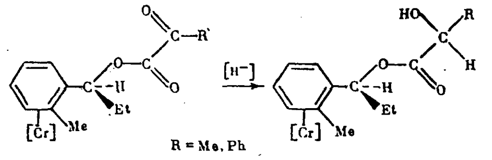


R^1 = Me, Ph; R^2 = C_2F_5, Me, PrC≡C, Ph

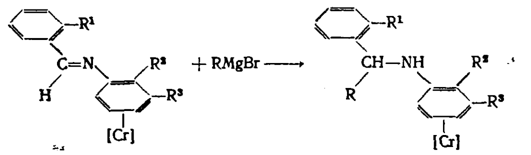
The asymmetric synthesis proceeds with a high enantiomeric excess (between 85 and 100%); for example, (+)-*S*-atrolactonic acid has been obtained by the addition of MeMgI to the optically pure ketoester and subsequent hydrolysis:



The reduction of a chiral α-ketoester by various reductants to α-hydroxyesters has been investigated:[146]



A high percentage of asymmetric induction is observed when "L-selectide" LiBH(Bu-s)$_3$ is used as the reductant (E.E. = 84–90%). Just as high a degree of asymmetric induction has been obtained in reactions of Grignard reagents with complexes of aromatic Schiff bases (XCI):[147]

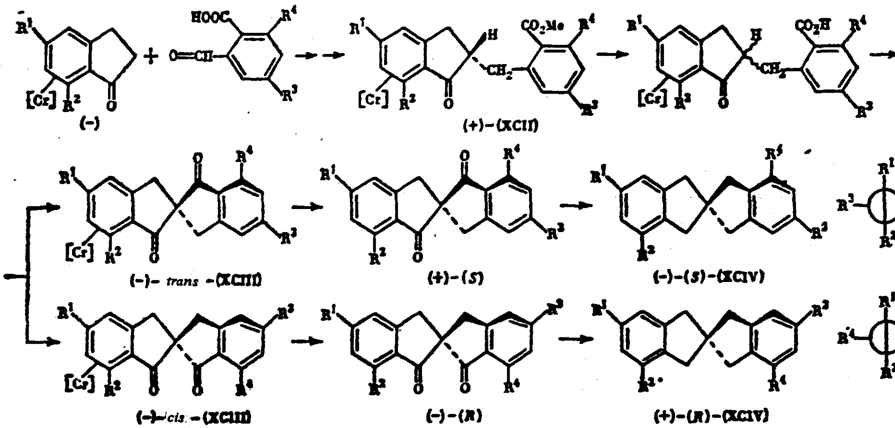


R = Me, PhCH$_2$;
R^1 = H, Me, OMe, Cl;
R^2 = H, Me, Et, Ph;
R^3 = H, Me

When an asymmetric Grignard reagent was allowed to react with (benzophenone)ChTC and (fluorenone)ChTC, partly resolved tertiary alcohols were obtained.[148]

The formation of complexes with ChTC had led to a simple and universal method of the synthesis of optically active benzospirans with a specific chirality from optically active (1-indanone)ChTC.[149,150]

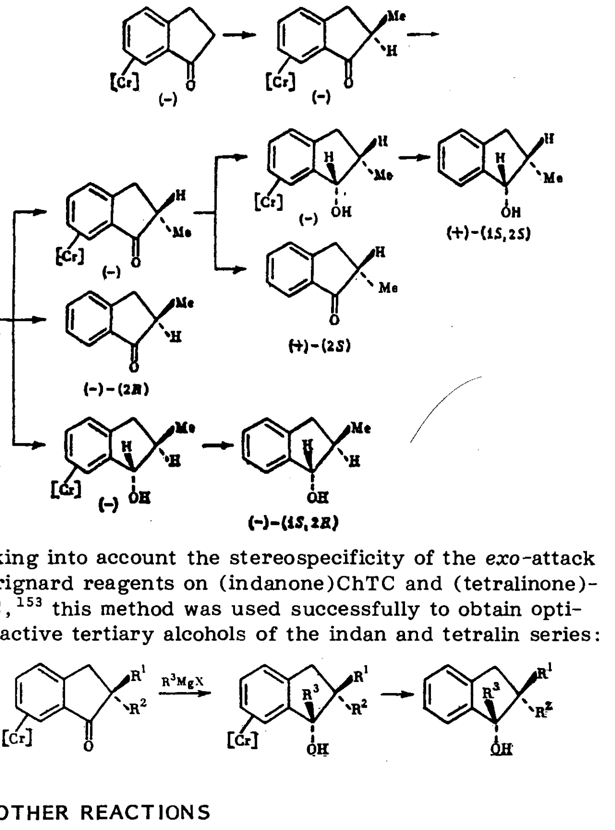
The condensation of the complex with phthalic monoaldehyde [*o*-formylbenzoic acid?] produced a benzylidene complex from which the *endo*-benzyl derivative (XCII) was obtained after esterification and hydrogenation. On alkaline hydrolysis of the latter, epimerisation at the C(2) atom of the indanone was observed. Cyclisation of the complexes with polyphosphoric acid leads to a readily resolvable mixture of diastereoisomeric spiroindanone complexes—the *cis*- and *trans*-isomers of compound (XCIII). Optically active 2,2′-spirobi-indans (XCIV) were obtained by the decomposition of the complexes to 2,2′-spirobi-indan-1,1′-diones and subsequent catalytic hydrogenation:



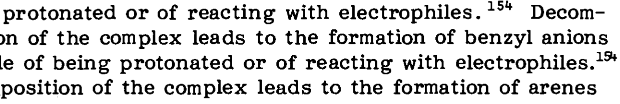
R^1, R^2, R^3, R^4 = H, Me, OMe

A cycle of reactions with the optically active complexes (I) and (II) has been carried out by Jaouen and Meyer.[151,152] The racemic compounds (I) and (II) were resolved into their enantiomers by the fractional crystallisation of the cinchonidinium salts of their acid succinates. Optically active indanone and tetralinone complexes are obtained by oxidising the corresponding alcohols with MnO_2 and the decomposition of the complexes of the enantiomers leads to optically active alcohols.

The *exo*-alkylation of the complexes in the 2-position leads to the formation of a new asymmetric centre in the system and creates a convenient preparative method of synthesis of optically active 2-methylindanones, 2-methyltetralinones, and the *trans*-alcohols. The possibility of obtaining the *cis*-alcohols from 2-methyl-*endo*-ketone complexes has been demonstrated in principle, although the separation of the *exo*- and *endo*-isomers requires a special technique. The reactions involved (indanone)ChTC, but all the characteristics are valid also for (tetralinone)ChTC:[151,152]

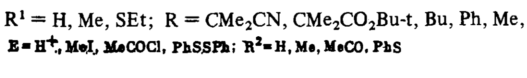


Taking into account the stereospecificity of the *exo*-attack by Grignard reagents on (indanone)ChTC and (tetralinone)-ChTC,[153] this method was used successfully to obtain optically active tertiary alcohols of the indan and tetralin series:

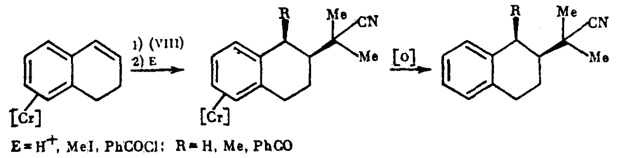


VII. OTHER REACTIONS

The reaction of vinyl-BCT with carbanions opens up wide prospects for organic synthesis.[154] It has been shown that a fairly large set of nucleophiles add to the β-position of the η^6-styrene ligand with formation of benzyl anions capable of being protonated or of reacting with electrophiles.[154] Decomposition of the complex leads to the formation of benzyl anions capable of being protonated or of reacting with electrophiles.[154] Decomposition of the complex leads to the formation of arenes with functional-group substituents:

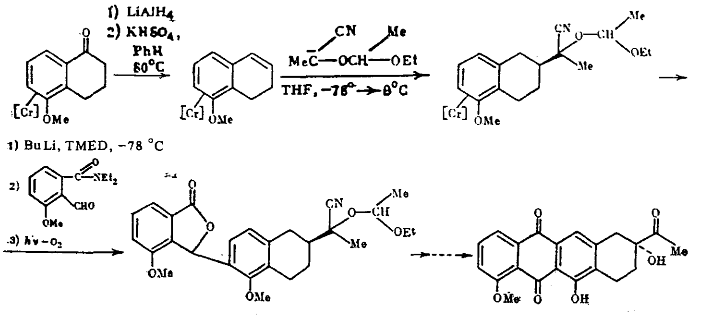


R^1 = H, Me, SEt; R = CMe_2CN, CMe_2CO_2Bu-t, Bu, Ph, Me, etc;
E = H^+, MeI, MeCOCl, PhSSPh; R^2 = H, Me, MeCO, PhS



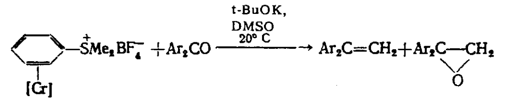
E = H^+, MeI, PhCOCl; R = H, Me, PhCO

The application of BCT to the synthesis of 11-deoxyanthracyclinones, exhibiting an anti-cancer activity, has been described.[155] The method is based on the characteristic features of the addition of the carbanion to alkenyl-BCT and on the regioselectivity of the metallation of the coordinated methoxyarene:



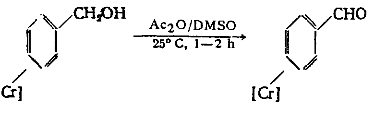
Among the practical aspects of the application of the BCT, mention should be made of their use as catalysts of the hydrogenation of dienes and polyenes[156,157] and as a label in molecular biology.[158–160]

On reaction with aldehydes and ketones, benchrotrenylsulphonium ylides form mixtures of an oxiran and an olefin, while purely organic sulphonium ylides produce only oxirans in this reaction:[161]

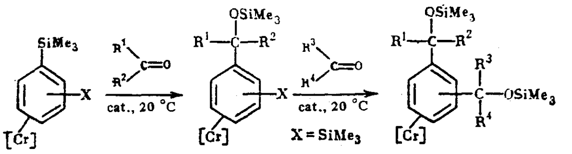


Preliminary results on the activating effect of the formation of complexes with ChTC on the oxidation of diphenylmethane to benzophenone have been published.[162] Whereas diphenylmethane is not oxidised by KO_2 in dimethyl sulphoxide, the complexes $(Ph_2CH_2)Cr(CO)_3$ and $(Ph_2CH_2)[Cr(CO)_3]_2$ are converted into benzophenone in 59 and 63% yields respectively.

A general method has been proposed for the oxidation of benchrotrenylcarbinols to aldehydes without the removal of ChTC, in 55–75% yield:[163]

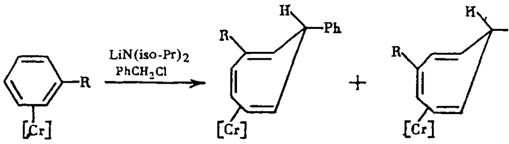


Mono- and bis-(trimethylsilyl)-BCT readily enter into reactions with aldehydes and ketones catalysed by t-BuOK or CsF, forming products of addition to the C=O groups:[164]



The electrochemical reduction of (benzophenone)ChTC, $(benzophenone)(ChTC)_2$, and (fluorenone)ChTC in the presence of 1,3-dibromopropane[165] and acetic or benzoic anhydride[166] has been recommended for the synthesis of diphenylmethyl derivatives.

The reaction involving ring expansion in the aromatic ligand in alkylbenchrotrenes on treatment with $PhCH_2Cl$ and lithium di-isopropylamide is of interest:[167]



According to X-ray diffraction data, the phenyl group has the *endo*-orientation. The reaction has been extended to Ph_2CHCl and $CH_2{=}CHCH_2Cl$.

Physicochemical Properties of Layered Compounds of Graphite

G.S.Petrov, A.S.Skoropanov, and A.A.Vecher

The results of studies carried out in recent years on certain physicochemical properties (heat capacities, enthalpies of formation, compressibilities, thermal expansions, and thermal stabilities) of layered compounds of graphite are surveyed. The bibliography includes 126 references.

I. INTRODUCTION

Many compounds with anisotropic layered structures (typical representatives of which are graphite and transition metal dichalcogenides), in which the bonding forces between the species within the layer are much stronger than between the layers, are able to form compounds of a new type as a result of the insertion of various substances in the interlayer space. Among compounds of this kind, those of graphite occupy the principal place, which is in many respects due to the possibility of their extensive application in various fields.

Many substances (metals, alloys, metal halides, oxides, acids, etc.) capable of being inserted in the graphite lattice with formation of new compounds are now known. However, despite the fact that the synthesis of such compounds was described as early as the first half of the past century, their systematic investigation began only about 40 years ago and such research has developed on a wide scale only in the last 25 years.

We may note that hitherto there has been no single terminology in the naming of compounds of this kind. Thus in the Soviet literature they are usually referred to as layered compounds of graphite, graphite interstitial compounds, graphite occlusion compounds, graphite clathrate compounds, graphite intercalation compounds, intercalated graphites, or simply graphitides. In foreign literature they are called "graphite intercalation compounds", "graphite lamellar compounds", intercalated graphites", and "graphitides", although according to the recommendations of the latest International Conference on these compounds[1] it is recommended that the term "graphite intercalation compounds" (abbreviated to GICs) be used.

We shall henceforth employ mainly the term "graphite layered compounds" (GLC), because in our view it emphasises the layered character of the structure of these compounds. The term "graphite interstitial compound" (GISC) appears to be less apt, since the term "interstitial phases" is usually employed, for example in the metallurgical literature, for the designation of completely different substances. The term "graphitides" can be applied only to compounds of graphite with metals or alloys, because it emphasises the difference between compounds of this class and the carbides and acetylides of the corresponding metals.

As mentioned above, the growing interest in GLC is in many respects due to the constantly expanding fields of their practical application. Thus GLC catalyse various processes (for example, the synthesis of ammonia, artificial diamonds, etc.[2,3]); they are good conductors of electricity and can be used as cathodic materials in chemical current generators.[4] The use of GLC in systems designed for the storage of "thermal" energy,[5] as additives for the improvement of the physicomechanical properties of certain types of abrasive materials and powdered alloyed steels, and also as the raw material for the preparation of a new variety of carbon materials with regulated physicochemical properties, the so-called thermally cleaved graphite,[6] is promising. The increasing interest in GLC is indicated by the establishment in the USA of the Intercal Company specialising in the practical application of these compounds.

In order to be able to predict the behaviour of GLC under operating conditions and for the optimisation of their preparation processes, it is essential to have information about their physicochemical properties. Such information also makes it possible to understand the nature and characteristic features of the interspecies interaction in GLC, which is of considerable practical interest. However, hitherto there have been comparatively few data in the literature on the thermodynamic properties, compressibilities, thermal expansion, and thermal stability of GLC;[7-27] some of the individual properties of the GLC listed above have been subjected to a critical examination in early review publications.[28-35]

In recent years there has been a sharp growth of studies of the properties of GLC (see, for example, Refs.36–42). Regular international conferences on GLC are being held and the international scientific journal "Synthetic Metals", specialising to a large extent in the publication of data on GLC, has been organised. Numerous papers presenting the results of studies on certain physicochemical properties of GLC have been published.

The aim of the present review is to give a systematic critical account and a survey of the literature data of recent years obtained in studies of the heat capacities enthalpies of formation, the influence of high pressure on the properties, thermal expansion, and thermal stabilities of GLC.

II. THERMODYNAMIC PROPERTIES

Hitherto there have been few systematic studies designed to determine experimentally the thermodynamic properties of GLC† (see, for example, Refs.7–13), although in recent years several attempts have been made to carry out such investigations by a calorimetric method.

The heat capacity *Cp* of the lithium graphitide C_6Li has been investigated[43] in the range 4–300 K and a small anomaly was observed in the heat capacity at ~200 K which, according to the authors,[43] can be related to a structural phase transformation of the compound. The heat capacities of GLC with bromine, containing 0.5, 2.2, and 9.6 at.% of bromine, have been measured in the temperature range 1.5–6 K and the electronic component of the heat capacity as well as the Debye temperatures were calculated.[44] It was shown that the bromine atoms are insignificantly ionised (~1%) in all the GLC.

With the aid of differential scanning calorimetry (DSC), Wu and Vogel[45] investigated stage 1 GLC with antimony pentafluoride in the range 4.2–300 K; a phase transformation of the "order–disorder" type was observed near 185 K. Unfortunately the above authors[45] do not quote either the composition of the GLC investigated or any numerical values of its thermodynamic functions. The heat capacities *Cp* and magnetic susceptibilities of the GLC $C_{6.2}FeCl_3$, $C_{17}FeCl_3$, and $C_{11.3}NiCl_2$ have been measured.[46] An anomalous behaviour of the heat capacities of the compounds was observed in the vicinity of 4, 1.7, and 20 K respectively and the authors[46] attributed them to the occurrence in the compounds investigated of transitions to states of the "spin glass" type. In the study of stage 2 GLC with $NiCl_2$, Suzuki et al.[47] observed two regions of anomalous behaviour of the magnetic susceptibility at 18.0 and 21.3 K. However, heat capacity measurements revealed an anomaly only in the vicinity of the second temperature but no appreciable changes in heat capacity were observed at the first temperature. Murakami et al.[51] investigated stage 2 GLC with $CoCl_2$ and observed two magnetic transitions at 8.0 and 9.1 K. The temperature variation of the heat capacity of this compound revealed an anomaly only at the second temperature.

A low-temperature DSC study of GLC with titanium(IV)[48] and tin(IV)[49] chlorides showed that the decomposition of the compound with $TiCl_4$ is observed at 247 ± 1 K (the melting point of $TiCl_4$ is $T_m = 249$ K[48]) and that of the compound with $SnCl_4$ occurs at 237 ± 1 K ($T_m = 240$ K for $SnCl_4$ [49]) regardless of the stage of the compound, i.e. the GLC decompose at temperatures close to the melting points of the intercalants. A DSC study of the products of the reduction of GLC with $SnCl_4$ by potassium showed[50] that the enthalpy of decomposition of the compounds (with fusion of the intercalated tin) is close to the enthalpy of fusion of pure tin, which indicates a weak interaction of the latter with the graphite lattice. Unfortunately none of the past studies[48-50] quote numerical values of *Cp* for the GLC.

A DSC investigation of the *Cp* of the unsaturated stage 1 GLC $C_{32}SbCl_{4.7}$ [52] revealed a phase transition to the vitreous state at 210 K; on the other hand, the transition did not occur for the saturated stage 1 compound. In a DSC study of the stage 1 GLC C_8Cs, Ubbelohde and Drummond[53] observed a phase transformation at ~250 K whose form depended to a large extent on the type of graphite used for the synthesis. They also estimated the enthalpy and entropy of the observed phase transformation, amounting to ~111.7 J g-atom^{-1} and 0.4 J g-atom^{-1} K^{-1} respectively.

Suematsu et al.[54] investigated the heat capacity of the graphitide $C_{24}Rb$ below room temperature and observed four anomalies in the heat capacity at 48, 103, 162, and 210–220 K, which are associated with phase (including structural) transformations. However, no numerical values of the corresponding thermodynamic functions are quoted in the above study.[54] The heat capacity of the stage 1 compound $C_{10}Al.Cl_{3.3}$ has been investigated by DSC in the range 120–300 K[55] and an anomaly has been found in *Cp* near 226 K, associated with a transformation of the "order–disorder" type, whose enthalpy was 900 ± 50 J mol^{-1}, which is within the same limits as for other GLC; the entropy of this transformation has been estimated as 4.0 ± 0.5 J mol^{-1} K^{-1} (Fig.1). However,

---

†Depending on how many carbon layers separate two nearest layers of the intercalant, GLC are subdivided into compounds with stage 1, stage 2, etc. intercalation.[1] Depending on the degree of filling of the intercalant, GLC are subdivided into saturated (with the limiting content of the adduct) and unsaturated (for which the content of the adduct is less than the limiting value).

no anomalies have been observed in the experimental temperature range for stage 4 GLC with $AlCl_3$ of the type $C_{50}Al.$ $.Cl_{3.3}$.[55]

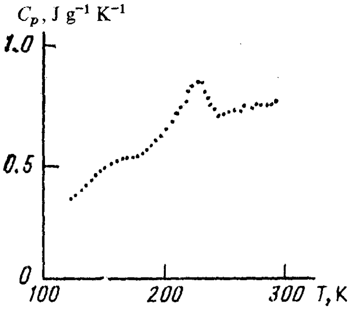

Figure 1. Temperature variation of the heat capacity of the compound $C_{10}AlCl_{3.3}$.[55]

The heat capacities of the compound C_6FeCl_3 (stage 1) and $C_{12}FeCl_3$ (stage 2) have been measured[56] by the DSC method in the range 298–570 K with an error of ±2.8%; the temperature dependence of the heat capacity (J mol^{-1} K^{-1}) of the compounds investigated is described by the equations

$$C_p(C_6FeCl_3) = 141.7 + 0.037T$$
$$C_p(C_{12}FeCl_3) = 176.0 + 0.277T.$$

We may note that, according to a number of data,[27,57–61] the decomposition of the GLC with $FeCl_3$ begins at ~573 K to which should correspond an anomalous change in Cp near 573 K. However, the authors[56] observed no anomalies in the $Cp(T)$ relation. Such discrepancy between the data of different investigations can be explained, in particular, by the different methods of synthesis of the compounds and the different composition and type of graphite used in the synthesis.

The heat capacities of GLC with certain 3*d* metal chlorides, namely $C_{4.68}CuCl_2$ (stage 1), $C_{6.35}CuCl_2$ (stage 1), $C_{7.73}CuCl_2$ (stage 1 with an admixture of stage 2),[62,63] $C_{6.97}CoCl_2$ (stage 1), $C_{16.8}CoCl_2$ (stage 2),[63] $C_{7.7}FeCl_3$ (stage 1),[58,59] $C_{11.83}FeCl_3$ (stage 2),[58] $C_{16.2}NiCl_2$ (stage 2), and $C_{5.5-6.5}\cdot$ $.MnCl_2$ (stage 1),[64] have been investigated[58,59,62–64] by the triple thermal bridge method (with an error ≤ 3%). The experimental results are presented in Figs.2 and 3. Least squares treatment of the results yielded the coefficients *a*, *b*, and *c* in the equations relating the heat capacities of the GLC investigated to temperature (Table 1). For the compounds $C_{7.7}FeCl_3$, $C_{11.83}FeCl_3$, and $C_{5.5-6.5}$-$MnCl_2$, the authors[58,59,64] observed anomalies in the heat capacity with maxima at 455 ± 5, 445 ± 5, and 450 ± 2 K respectively, associated with reversible solid-phase transformations of the GLC. The enthalpies of the above transformations were found to be 0.13 ± 0.03 kJ mol^{-1}, 2.78 ± 0.41 kJ mol^{-1}, and 1.33 J g^{-1}.

We may note that no anomalies in the heat capacities of the saturated GLC with $FeCl_3$, having the compositions C_6FeCl_3 and $C_{12}FeCl_3$, have been observed.[56] One of the causes of the discrepancy between the result of the studies of Skoropanov and co-workers[58,59] and Solozhenko et al.[56] for the GLC $C_{7.7}FeCl_3$ and C_6FeCl_3 may be the fact that, as in the case of the GLC with $SbCl_5$,[52] in the unsaturated compound, in contrast to saturated compounds, the transition within the layer involving a change in the structure of the intercalated component are sterically unhindered. Account should also be taken of the different methods of synthesis of the compounds by Skoropanov and co-workers[58,59] and Solozhenko et al.[56] and also of the differences in the type of graphite matrix.

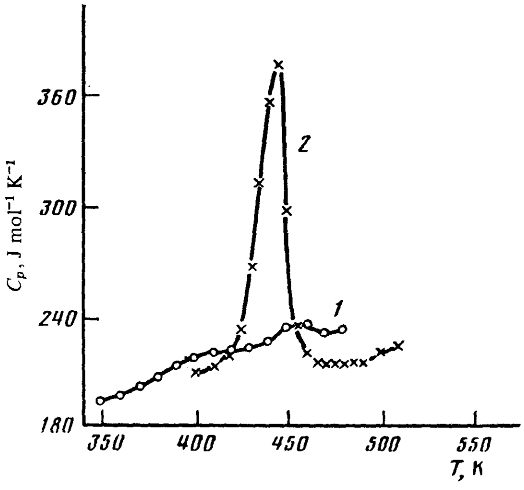

Figure 2. Temperature variation of the heat capacity of the GLC with $FeCl_3$:[58,59,62–64] 1) stage 1; 2) stage 2.

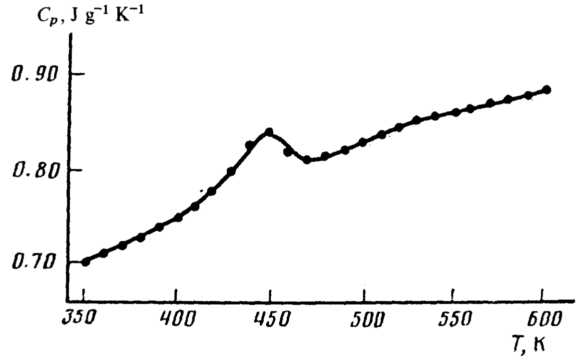

Figure 3. Temperature variation of the heat capacity of the compound $C_{5.5-6.5}MnCl_2$.[64]

The enthalpy of the reaction

$$16C_{graphite}(cryst.) + Br_2(liq) \rightleftarrows C_{16\pm0.3}Br_2(cryst.)$$

has been determined at 308.0 ± 0.5 K[65] and the enthalpy of formation of the compound $C_{16\pm0.3}Br_2$ has been calculated as −16.43 ± 0.76 kJ mol^{-1}.

On the basis of isobaric-thermoanalytical studies, Solozhenko et al.[56] calculated the standard enthalpies of formation of stage 1 and stage 2 GLC with $FeCl_3$:

$$\Delta H^0_{f,298}(C_6FeCl_3) = -(491 \pm 13)\ \text{kJ mol}^{-1};$$
$$\Delta H^0_{f,298}(C_{12}FeCl_3) = -(456 \pm 10)\ \text{kJ mol}^{-1}.$$

III. THE INFLUENCE OF HIGH PRESSURES

The study of GLC at high pressures is of considerable theoretical and practical interest, especially in connection with the possibility of employing GLC in the synthesis of artifician diamonds.[3] However, the majority of studies have been devoted to the investigation of the influence of pressure on the electronic or electrical properties of GLC and also on their structure. At the same time data on the compressibilities and phase transformations of GLC under the influence of high pressures are of significant interest.

Table 1. The coefficients *a*, *b*, and *c* in the equation for the temperature variation of the heat capacity: C_p (kJ mol^{-1} K^{-1}) = $a + 10^{-3}bT + 10^6cT^{-2}$.[58,59,62–64]

Compound	*a*	*b*	*c*	*T*, K **
$C_{4,68}CuCl_2$	104.729	95.1342	−2.01471	350—550
$C_{6,35}CuCl_2$	72.9829	121.622	1.00163	370—520
$C_{7,73}CuCl_2$	190.694	−37.0157	−5.68839	370—500
$C_{6,97}CoCl_2$	130.236	97.2574	−2.23586	350—600
$C_{16,8}CoCl_2$	244.854	209.482	−8.54369	350—600
$C_{7,7}$ FeCl$_3$	−157.539	815.818	7.94588	350—410
$C_{16,2}NiCl_2$*	0.721254	0.561208	−0.0226657	350—600
$C_{5,5+6,5}MnCl_2$*	−0.323501	2.18667	0.0315135	350—400
	0.969003	0.0680034	−0.0426992	480—600

*For $C_{16.2}NiCl_2$ and $C_{5.5-6.5}MnCl_2$, C_p was expressed in J g^{-1} K^{-1}; for $C_{5.5-6.5}MnCl_2$, the coefficients *a*, *b*, and *c* were calculated by ourselves from the data of Petrov et al.[64]
**Temperature range.

Table 2. The compressibilities of the GLC with HNO_3 and $SbCl_5$.[66,67]

Compound	Stage	$10^{-3}K_c$, kbar^{-1}	$10^{-3}K_a$, kbar^{-1}
Graphite	—	2.9±0.3	0.1±0.3
GLC with HNO_3	3	5.0±0.7	0.0±0.3
GLC with $SbCl_5$	2	2.0±0.5	0.0±0.5

Notation: $K_c = (d/d)/c$ and $K_a = (da/dp)a$, where *a* and *c* are the unit cell parameters and *p* is the pressure.

Thus the influence of hydrostatic pressure up to 0.8 GPa on the properties of GLC with HNO_3 (stage 3) and $SbCl_5$ (stage 2) has been investigated.[66,67] Table 2 presents the compressibilities along the *c* and *a* axes for the test compounds as well as the graphite from which the GLC have been synthesised. It is seen from the Table that the compressibility along the *c* axis for the GLC with HNO_3 is greater by a factor of ~1.7 than for the initial graphite, while the compressibility along the *a* axis is much smaller in both cases than along the *c* axis. At the same time, the pressure dependence of the electrical resistance of the GLC with HNO_3 shows an anomaly at 0.5 GPa, which can be related, according to the authors,[66,67] to a structural transition of the compound (however, the nature of this transition is not explained[66,67]). Unfortunately the exact compositions of the compounds investigated are not given in the two studies.[66,67]

The compounds C_8Cs and $C_{36}Cs$ have been investigated by X-ray diffraction at a high hydrostatic pressure (up to 1.2 GPa) and room temperature.[68] The compressibility of C_8Cs along the *c* axis was determined as $K_c = (dc/dp)_{p=0}/c = (1.57 \pm 0.05) \times 10^{-12}$ cm^2 dyn^{-1}, which is much less than the corresponding values for the compounds C_8K (2.1×10^{-12} cm^2 dyn^{-1}) and C_8Rb (2.25×10^{-12} cm^2 dyn^{-1}). The greater "rigidity" of the caesium compound compared with the analogous potassium and rubidium compounds implies, according to the authors,[68] that in this GLC there is marked overlapping of the wavefunctions of the 6s electrons of caesium and the π electrons of graphite along the *c* axis. No pressure-initiated structural transformation was observed for the compound C_8Cs. A reversible phase transformation (with formation of a stage 4 GLC), i.e. a transformation with a change in the stage index of the GLC, was observed[68] in the compound $C_{36}C_S$.

The potassium graphitide C_8K (stage 3) has been studied by neutron diffraction[69] at hydrostatic pressures up to 2 GPa. A reversible phase transition was observed in the pressure range 1.5–1.9 GPa, which leads to the formation of GLC with a non-integral stage index (3/2).

The behaviour of the graphitides C_8M and $C_{12n}M$ (M = Rb or Cs; *n* = 2, 3, 4) has been investigated with the aid of X-ray diffraction and changes in Raman spectra at hydrostatic pressures up to 1 GPa.[70] Pressure-initiated phase transformations with a change in stage index, characterised by reversibility, hysteresis, and a dependence on the nature of the specimen, were observed for all the GLC with $n \geq 2$. The following transitions were noted: GLC (stage 2) → GLC (stage 3); GLC (stage 3) → GLC (stage 4) +GLC (stage 5); GLC (stage 4) → GLC (stage 4) + GLC (stage 5) → GLC (stage 6). It was also observed that the pressure of the transition involving a change in stage index is higher for $C_{24}Cs$ than for $C_{24}K$ and $C_{24}Rb$, which implies, according to the authors,[70] that the repulsive intralamellar interactions are more intense for caesium than for potassium and rubidium (possibly as a consequence of the greater size of the caesium ions). In addition, the compressibilities $K_d = (\partial d/\partial p)_{p=0}/d_0$ where *d* is the packing thickness at a pressure *p* and d_0 the packing thickness at *p* = 0) of the compounds C_8Cs and C_8Rb were measured as $(1.56 \pm 0.05) \times 10^{-12}$ and $(2.42 \pm 0.12) \times 10^{-12}$ cm^2 dyn^{-1} respectively [$K_d = (2.73 \pm 0.09) \times 10^{-12}$ cm^2 dyn^{-1} for the initial graphite and $K_d = (2.13 \pm 0.09) \times 10^{-12}$ cm^2 dyn^{-1} for the analogous potassium compound C_8K].

The compressibility of the stage 1 graphitide C_4KHg has been measured along the *c* axis[71] and has been found to be $(4.4 \pm 0.1) \times 10^{-12}$ cm^{2}dyn^{-1}, which is approximately twice as large as for the analogous stage 1 GLC C_8K, i.e. the compound C_4KHg is much "softer" in the direction of the *c* axis than C_8K. According to Kim et al.,[71] the ternary compound can therefore allow a significant decrease of volume without the formation of ultradense islands of the intercalant and also "corridors", which is the driving force of the pressure-initiated transformations with change of stage index in the compound C_8K.

The stage 1 GLC C_6Li has been investigated by NMR at 232 and 293 K and external pressures $p \leq 0.5$ GPa.[72] It was shown that the quadrupole interaction constant for the graphitide is independent of temperature, but increases linearly (at a rate of 1.5 kHz bar^{-1}) with increase of pressure. The degree of charge transfer to each carbon atom estimated by the authors[72] was −e/12, which agrees with the results of band calculations. The compressibility of the compound C_6Li along the *c* axis, estimated in the above study,[72] was $K_c = 1.7 \times 10^{-12}$ cm^{2}dyn^{-1}, which agrees with the analogous values for the graphitides C_8M (M = K, Rb, or Cs).

A thermodynamic model permitting a satisfactory explanation of, in particular, transitions involving a change in stage index under the influence of high pressure by the formation of GLC with a non-integral stage index at high pressures, and also certain other experimental effects in alkali metal graphitides has been proposed.[73]

A phase transition with a change (non-multiple) in the stage index from two to three has been observed by studying the Shubnikov–de Haas effect for the stage 2 GLC $C_{16}ICl$ at room temperature and a hydrostatic pressure of ~1.2 GPa.[74] A characteristic feature of this transition was a monotonic (in all probability non-threshold as regards pressure) increase of the content of stage 3 regions (having the composition $C_{24}ICl$) and a decrease of the content of the stage 2 regions (having the composition $C_{16}ICl$) with retention of the single crystal nature of the corresponding regions. This transition was explained[74] on the basis of the domain model of the GLC.

The influence of high hydrostatic pressures (up to 2.2 GPa) on the electrical properties of the graphitides C_4KHg (stage 1) and also C_8KHg and C_8RbHg (stage 2) has been investigated.[75–77] Transitions to the superconducting state were observed at atmospheric pressure and temperatures of 1.88 and 1.41 K for the stage 2 GLC C_8KHg and C_8RbHg respectively. The application of hydrostatic pressure lowers the temperature of the transition to the superconducting state at rates of -6.3×10^{-5} and -5.3×10^{-5} K bar^{-1} for the potassium and rubidium compounds respectively.[77]

Results of measurements of the pressure dependence of the temperatures of the transition to the superconducting state for the graphitides C_4MHg and C_8MHg (M = K or Rb) as well as the compounds $C_4KCl_{1.5}$, C_8K, and $C_{24}K$ have been surveyed and discussed.[78–80] It was shown that the electrons in the intercalant zone and not those in the graphite zone play the main role in the superconductivity of materials of the given class and that the two-dimensional anisotropy of the properties of the GLC investigated is important under these conditions.

The influence (at room temperature) of solid-phase pressures (up to 8.5 GPa) on a series of GLC with *d* elements and their chlorides has been investigated[81] and it has been shown that the structures of the compounds investigated do not undergo appreciable changes after their treatment at a pressure up to 8.5 GPa.

We may note that in all the studies discussed above, the influence of high pressures on the properties of various GLC was investigated at room temperature or below room temperature, while the behaviour of the GLC at high pressures and temperatures was not considered, although such data are extremely important and necessary, in particular, in considering the possibilities of the synthesis of artificial diamonds from GLC. The behaviour of a stage 1 GLC with $FeCl_3$ has been investigated under the conditions of quasi-hydrostatic pressures (2–8 GPa) and high temperatures (up to 2000 K) in only one study.[82] It was shown that at $T <$ 700 K the test compound undergoes no changes over the entire experimental pressure range, but it does decompose as the temperature rises with formation of a mixture of higher stage GLC and iron(II) and iron(III) chlorides. On the other hand, the formation of diamonds from the GLC investigated was not observed under the experimental conditions.[82]

IV. THERMAL EXPANSION

The coefficients of thermal expansion (CTE), whose knowledge is especially necessary when the possibility of obtaining artificial diamonds from the corresponding GLC is considered, have been determined in recent years for certain GLC.

The CTE have been measured along the *a* and *c* axes in certain alkali metal graphitides by X-ray diffraction in the temperature range 10–300 K.[83,84] It was shown that the thermal expansion along the *c* axis depends greatly on the density of the arrangement of alkali metal atoms in the interplanar spaces within the GLC and also on the stage index of the compound, being greatest for the potassium graphitide C_8K. It has also been observed that the thermal expansion along the *a* axis of the potassium compounds C_8K and $C_{24}K$ and also of the highly oriented pyrolytic graphite is negative in the experimental temperature range. The results obtained[83,84] are listed in Table 3.

Table 3. The coefficients of thermal expansion along the *a* ($\alpha_\parallel$) and *c* ($\alpha_\perp$) axes of graphite and the GLC with alkali metals.[83,84]

Graphite	19.14	25.6

*Only the stage indices of the compounds are indicated in the original communication, but their chemical compositions are not given.

The temperature variation of the repeat period of the GLC with sulphuric acid having four stage indices (from 1 to 4) has been measured by X-ray diffraction in the temperature range 83–303 K.[85] For all the compounds, an anomalous thermal expansion was observed at temperatures from 173 to 213 K, its value gradually diminishing (from 0.097 Å for the stage 1 compound to 0.040 Å for the stage 4 compound). The coefficients of linear thermal expansion α for all the GLC investigated, which proved to be 1.5–3 times greater than the corresponding values for the initial graphite, have been published[85] for two temperature ranges (83–173 and 223 to 303 K). Some of the data obtained[85] are compiled in Table 4 (we may note that, unfortunately, the above communication[85] contains no information about the chemical composition of the test compounds, which to some extent hinders the interpretation of the results).

Vangelisti et al.[86] determined by X-ray diffraction the value of $\alpha_\perp$ for the stage 1 GLC with $AlCl_3$ and $GaCl_3$ and highly oriented pyrolytic graphite and obtained $\alpha_\perp$ $(K^{-1}) = 38.0 \times 10^{-6}$

(in the range ~0–300 K), 29.4 × 10^{-6} in the range ~0–100 K), and 26.5 × 10^{-6} (in the range ~100–300 K).

The structure of the stage 2 GLC $C_{11.3}NiCl_{2.13}$ has been investigated by neutron diffraction and it was found that, when the temperature is raised from 5 to 300 K, the repeat period along the *c* axis increases by 0.078 Å compared with the analogous value (0.071 Å) for the stage 1 GLC with $FeCl_3$. The authors[87] found that at room temperature the CTE of the compound $C_{11.3}NiCl_{2.13}$ is ~4 × 10^{-5} K^{-1}.

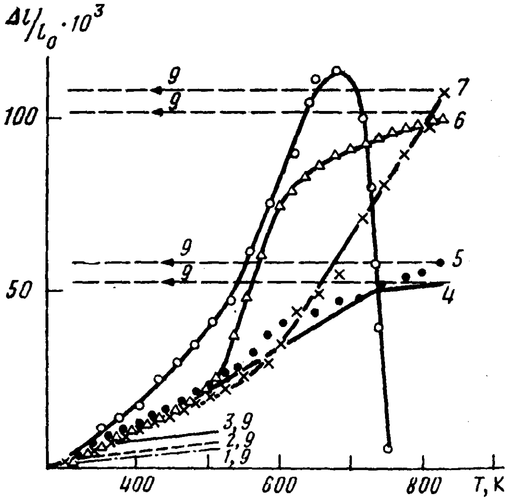

Figure 4. Temperature variation of the relative elongation in the axial direction ($\Delta l/l_0$) of pressed cylindrical specimens of the graphite from the Zaval'evsk deposit (curve *1*), cobalt (curve *2*) and (curve *3*) dichlorides, and the compounds $C_{9.5}CuCl$ (curve *4*), $C_{6.97}CoCl_2$ (curve *5*), $C_{6.35}CuCl_2$ (curve *6*), $C_{16.8}CoCl_2$ (curve *7*), and $C_{7.7}FeCl_3$ (curve *8*) on heating (curves *1–8*) and cooling (curve *9*).[58,59,63,88,89]

Table 5. The coefficients of thermal expansion (α) of certain GLC with metal chlorids.[58,59,63,88,89]

Compound	Stage	$\alpha\cdot10^6$, K^{-1}	*T*, K
$C_{6.35}CuCl_2$	1	9.9	290–440
ditto	1	13.5	450–520
»	1	70.0	530–590
»	1	19.7	600–820
$C_{6.97}CoCl_2$	1	11.7	290–540
ditto	1	26.5	550–590
»	1	8.0	600–800
$C_{16.8}CoCl_2$	2	10.2	300–580
ditto	2	31.1	590–820
$C_{9.5}CuCl$	1	7.2	300–370
ditto	1	14.0	380–715
»	1	1.5	725–820
$C_{7.7}FeCl_3$	1	20.7	310–540
ditto	1	66.7	560–640

We may note that the above studies[83–87] were performed below room temperature and that CTE data in the range above room temperature appeared for the GLC only recently. The results of studies of the characteristic features of the thermal expansion at temperatures up to 820 K for pressed cylindrical specimens of certain GLC (obtained using graphite from the Zaval'evsk deposit) with cobalt(II), copper(II), copper(I), and iron(III) chlorides have been published[58,59,63,88,89] and are summariesed in Fig.4 and Table 5. It is shown that the CTE of the GLC are significantly greater than for the corresponding graphite–salt mixtures, depend on the type of intercalated salt and the stage index of the GLC and are characterised by anisotropy and the possibility of hysteresis. It has been shown[63] that the application of cyclic cold pressing (up to 0.2 GPa) in the formation of cylindrical specimens of the GLC with $Co(Cu)Cl_2$ leads to an increase of the linear CTE and that the influence of such pressing on the stage 1 and 2 GLC is tentative (Fig.5). With increase of the number of the "heating to 523 K–cooling to 300 K–pressing of the specimen until attainment of the initial dimensions" cycle, the linear CTE of the stage 1 GLC diminishes and that of the stage 2 compound increases.

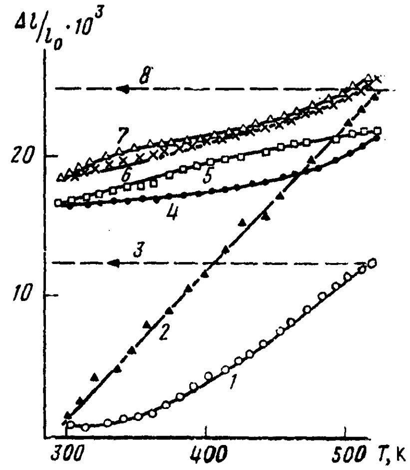

Figure 5. The influence of the previous thermal and baric history on the thermal expansion of the GLC with $CoCl_2$:[63] 1), 2), 4), and 6) heating; 3), 5), 7), and 8) cooling; 1), 3), 6), and 7) $C_{6.97}CoCl_2$; 2), 4), 5), and 8) $C_{16.8}CoCl_2$; "heating–cooling": 6) and 7), 4) and 6) the second and subsequent cycles; "heating–cooling–pressing": 1) and 3), 2) and 8) the fourth cycle.

It has also been established that the process involving the removal from the test compounds of the intercalated components is superimposed on their thermal expansion proper, which in the case of the stage 1 GLC with $FeCl_3$ at a temperature in excess of 660 K leads to the complete breakdown of the initial form of the test specimen.[58,59] It has been suggested that the marked increase in the size of the specimen on heating to 820 K for the stage 2 GLC with $CoCl_2$ compared with the stage 1 compound is probably caused by the preferential alteration of the distances between the carbon networks of the graphite skeleton (in the regions where there is no intercalated component) in the stage 2 GLC as a consequence of the decrease of the electron density caused by the donor–acceptor interaction between the carbon layers and the cobalt chloride (the carbon layers function as electron donors), while the distance between the carbon layers and the salt in the GLC with $CoCl_2$ corresponding to both stage indices increases to a lesser extent.

V. THERMAL STABILITY

Despite the great practical value of data on the thermal stability of GLC, for the majority of them (even for the compounds with $FeCl_3$ which have been most thoroughly characterised from this standpoint[20–27]), the question of their behaviour on heating has not been finally solved.

The behaviour of GLC with homogeneous (1) and mixed (1 + 2) stage indices having the composition graphite + $FeCl_{3-y}$ (where $0 \leq y \leq 1$) on heating has been investigated by Raman spectroscopy[90] and it was found that after the compounds had been kept at 648 K, a fraction of the stage 3 compound appeared. The increase of y (i.e. of the fraction of intercalated $FeCl_2$) after heating was also confirmed by measuring the Mössbauer effects.

An isobaric thermoanalytical investigation of the decomposition processes in nitrogen, helium, and argon atmospheres of GLC with $FeCl_3$ corresponding to stage 1 (C_6FeCl_3) and 2 ($C_{12}FeCl_3$) has been carried out in the temperature range 298–750 K and in the pressure range 10–700 mmHg.[56] It was shown that the thermal decomposition of these compounds takes place in steps. Thus at a low pressure the stage 1 compound decomposed in two steps:

$$\text{GLC (stage 1)} \rightarrow \text{GLC (stage 2)};$$

$$\text{GLC (stage 2)} \rightarrow \text{graphite} + FeCl_3.$$

At higher pressures the thermograms showed a single peak which the authors assigned[56] to the process

$$\text{GLC (stage 1)} \rightarrow \text{graphite} + FeCl_3.$$

We may note that the formation of GLC with $FeCl_2$ or $FeCl_2$ was not observed[56] in the decomposition of the compounds investigated, which conflicts with the results of other studies.[22,24,57–60,90]

In a DSC study of GLC with titanium(IV) and tin(IV) chlorides corresponding to different stage indices showed that, regardless of composition, these compounds decompose below room temperature—near the melting point of the corresponding pure intercalated component (249 K for $TiCl_4$ and 240 K for $SnCl_4$).[48,49]

The behaviour of the stage 2 GLC with aluminium bromide, having the composition $C_{20.8}AlBr_{3.5}$, has been investigated by differential thermogravimetric analysis (heating to 1173 K at a rate of 10 K min^{-1} in an atmosphere of dry nitrogen and a pressure of 10^5 Pa) (Fig.6).[91] The specimen lost mass in three stages: 1) initially (at 343–473 K) the excess bromine was probably lost (weight loss 7%); 2) next there was a stepwise transition from the stage 2 compound to one corresponding in terms of its composition to stage 6 (at 693 K the weight loss was 38.5% and the rate of decomposition slowed down sharply); 3) on further heating to 1173 K, the weight loss reached 43–47% (on the other hand in the case of the complete decomposition of the substance, the weight loss of the specimen should be 55%). The authors explained this[91] by the low rate of desorption of the GLC decomposition products, the relatively short decomposition time, and also the formation of a residual graphite compound.

The thermal behaviour of the graphitides C_4KHg and $C_4KTl_{1.5}$ has been studied[92] and proved to be significantly different for the two compounds. Thus the melting points of the pure alloys and the alloys intercalated in graphite and having the same composition were found to be 449 for KHg, ~673 K for KHg in C_4KHg, ~593 K for $KTl_{1.5}$, and ~603 K for $KTl_{1.5}$ in $C_4KTl_{1.5}$. This enabled the authors[92] to assume, in conformity with crystallographic data, that the interaction between the layers of the intercalated "alloy" and the neighbouring layers of the graphite is much weaker for thallium compounds than for mercury compounds.

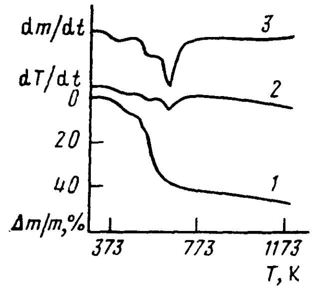

Figure 6. Thermal analysis curves for the compound $C_{20.8}$.$AlBr_{3.5}$: 1) weight loss by the specimens; 2) DTA; 3) DTA.[91]

The results of an investigation of GLC with metal fluorides having the compositions $C_9F(MgF_2)_{0.08}$, $C_{11}F(MgF_2)_{0.14}$, and $C_{11}F(AlF_3)_{0.09}$ and also of the graphite fluoride $(C_2F)_n$ by differential thermal analysis in air have been published.[93] Starting from 463 K, a broad exothermic peak was observed for the compounds $C_x(MgF_2)_y$ (the decrease of the weight of the specimen began at the same temperatures). For the compound $C_{11}F(AlF_3)_{0.09}$, the broad exothermic peak began at 503 K. The authors did not elucidate the nature of these peaks.[93] The peaks near 1103 K, which were observed for all three compounds, were assigned to the oxidation reaction of the graphite residue. For the graphite fluoride, two exothermic peaks were noted at 846 and 970 K, the first corresponding to the decomposition of the compound and the second to the oxidation of the residual carbon.

The decomposition in air of mixed GLC with uranium hexafluoride and Freon 113, having the composition $C_n[UF_6$.(Freon 113)], has been investigated by thermogravimetric analysis.[94] It was found that the ternary compound decomposed in four stages: (1) at 313–473 K; (2) at 448–523 K; (3) at 473–723 K; (4) at 703–988 K. The graphite fluorination products with intercalated UF_6 molecules are obtained in the first three decomposition stages (analogous products are formed on thermal decomposition of the GLC with UF_6) and uranium is not removed from the compound. During the fourth (exothermic) stage, the residual Freon is evolved with simultaneous loss of carbon, which is proportional to the uranium content. The amount of Freon in the initial GLC and the intermediate products of their decomposition is not correlated with the uranium content but is proportional to the amount of graphite. In the most stable intermediates, formed after the third decomposition stage, there are approximately 12 carbon atoms per Freon 113 molecule.

The removal of ammonia from the ternary GLC $C_{12}M(NH_3)_2$ (where M = lithium, sodium, potassium, rubidium, caesium, calcium, strontium or barium) has been investigated by chemical analysis and X-ray diffraction.[95] In terms of their behaviour as regards the elimination of ammonia, the GLC were classified[95] in three groups: (1) GLC with caesium and rubidium, from which the entire ammonia is removed; (2) GLC with sodium and potassium, which also evolve most of the ammonia and are themselves converted into new GLC; (3) GLC with lithium and alkaline earth metals, which give rise to amides on decomposition and the decomposition process itself is extremely complex.

It has been shown[96] that the graphite compounds $C_2F.yEFn.zR$ of a new type, which have the cage structure (the molecules of the fluoride in them are, as it were, located in cages formed by the carbon layers and fluorine atoms), exhibit a fairly high (in our view) thermal stability (up to 573–673 K). It has been established by differential thermal analysis (DTA) that the compound $C_2F.0.35BrF_3.0.17SnF_4$ decomposes at 553–623 K in several stages (although the stages themselves have not been described). It has been shown[98] that the GLC $C_{10.3}MoF_6$ is stable up to 523 K and the compound $C_{53.7}.WF_6$ is stable up to 503 K, both GLC decomposing on heating to 823 K with formation of pure graphite.

Studies on the graphite compounds $(CF_{0.97}.0.05HSO_3F)_n$ and $(CF_{1.23-1.25})_m$ showed[99] that their thermal stability depends both on the type of the initial graphite and on the conditions under which the compounds are obtained, varying in the range from 533 to 733 K. It has been shown with the aid of DTA[100] that, on heating to 373 K, hydrogen fluoride is evolved endothermically from the compound $C_xF.yNO_3.zHF$, while in the temperature range 623–673 K the complete exothermic decomposition of the compound takes place. The thermal stability of the compounds $[C_xF_y(NH_2)_z]_n$ and $C_xF_x.Cl_y.zN_2O_4$ has been investigated[101] and it has been shown that the graphite aminofluorides are thermally stable up to 373 K, and that their decomposition involves the formation of carbon, nitrogen, and hydrogen fluoride. When the compound $C_xF_yCl_y.zN_2O_4$ is heated to temperatures in the region of ~473 K, NO_2 is evolved into the gas phase (but the composition of the solid residue was not indicated). A definite correlation has been observed[102] between the thermal stability of graphite fluorides (according to DTA data) and the interplanar spacing in these compounds: the temperatures of the onset of decomposition are higher for compounds with a smaller interplanar spacing.

In a study of the thermal stability of the graphite oxide fluoride $C_8O_{0.8}F_{3.6}$,[103] two exothermic effects were observed on the derivatogram: at 453 K (this peak is characteristic of oxygen-containing graphite compounds) and at 673 K (graphite fluorides normally decompose in this temperature range). The mass spectrum of the gaseous decomposition products of the compound revealed the presence of the ion CF^+, CF_2^+, CF_3^+, COF_2^+, CO^+, and CO_2^+. The thermal stability of GLC with metal fluorides having the composition C_8MoF_5, $C_{22.9}.NbF_5$, and $C_{13.6}TaF_5$ has been investigated[104] and it has been shown that the compound C_8MoF_5 decomposes in the temperature range 443–608 K. The decomposition is accompanied by a large number of superimposed exothermic and endothermic effects, which can be explained, according to the authors,[104] by the disproportionation of the intercalated MoF_5. In the decomposition of other GLC, a smooth weight loss was observed in the temperature ranges 673–763 K (for $C_{22.9}.NbF_5$) and 563–683 K (for $C_{13.6}TaF_5$); in this case there was apparently no disproportionation of NbF_5 and TaF_5.

Lisitsa et al.[105] investigated the amino-derivatives of graphite $C_3O(NH_2)_{1.3}$ and $C_3(NH)_{1.3}$ and found that the former compound is almost fully converted into volatile products in the region of 673 K in an inert atmosphere. According to mass-spectrometric data, the compound $C_3(NH)_{1.3}$ is stable up to 573 K, decomposing in the region of 773 K with evolution of gaseous hydrogen cyanide, ammonia, and hydrogen. It has been demonstrated by ^{19}F NMR[106] that reversible disproportionation of ClF_3 with formation of ClF and ClF_5 takes place within the crystal structure of the compound $C_{3.65}.F_{2.17}Cl_{0.42}$. With the aid of derivatographic studies of the carbon fluorides $(CF_x)_n$, it has been shown[107] that, depending on the fluorine content and the conditions in the preliminary treatment of the specimens, the temperature of the onset of their decomposition is in the range 543–653 K and the maximum rate of decomposition is attained at temperatures in the range 753–833 K. A relation between the structure of the initial carbon material and the thermal stability of fluorocarbon materials has also been noted in another investigation;[108] fluorination of materials with a more ideal structure yielded specimens with a lower thermal stability.

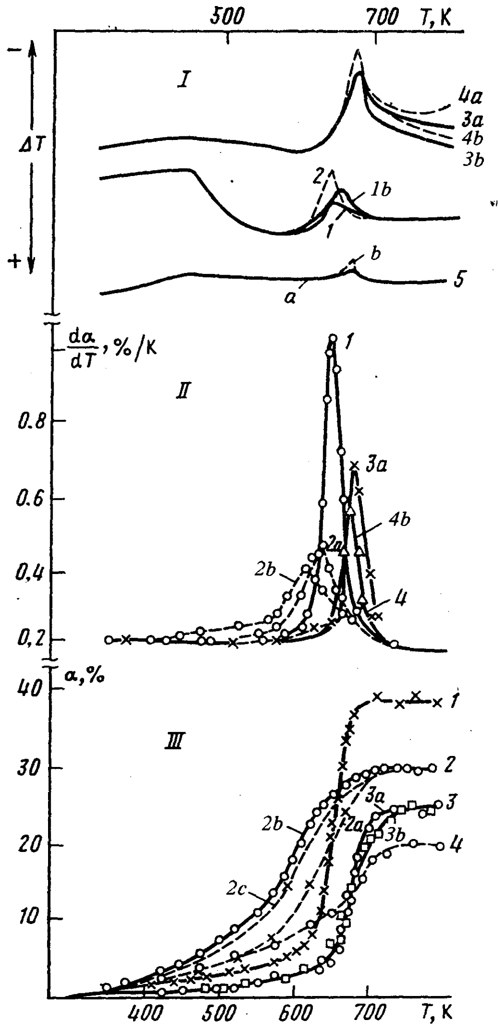

Figure 7. DTA (I), DTG (II), and TG (III) curves for $C_{7.7}FeCl_3$ (curves *1*, *3*, and *5a*) and $C_{11.83}FeCl_3$ (curves *2*, *4*, and *5b*) *in vacuo* (curves *1* and *2*), in air (curves *3a* and *4a*), in argon (curves *3b* and *4b*), and in a sealed tube (curve *5*), the specimens (30 mg) having particle sizes ≤0.25 mm curves *1*, *2a*, and *2b*) and 0.25–0.5 mm (curves *1b* and *2b*), at heating rates of 1 K min^{-1} (curves *2b* and *2c*) and 5 K min^{-1} (curves *1*, *2a*, and *3–5*) α is the degree of conversion of the specimen).[58,59]

The thermal decomposition of the compound $C_{16.1}BrF_{9.3}$ has been studied[109] with heating at a rate of 10 K min^{-1} in argon and with the specimen kept for 1 h in nitrogen at 513, 573, and 713 K. It was shown that the decomposition takes place stepwise. Processes involving the oxidative fluorination of the graphite skeleton and leading to the expansion of the lattice in the direction of the c axis take place in the first stage. The new phase is formed in the second stage (at 713 K and above) and decomposes destructively at 833–863 K and above with formation of gaseous fluoro-derivatives of carbon having unsaturated and saturated compositions[110] and also an amorphous carbon residue.

Table 6. The energy characteristics (the apparent activation energies E_a, the enthalpies ΔH, and the entropies ΔS) of the solid-phase transformations and the enthalpies of thermal decomposition along the section E–F (ΔH^*) in the thermostimulated processes in GLC.[57–60,111–114]

Note. The sections are indicated in Fig.8 and have been assigned to definite thermoinitiated processes.

A number of studies[57–60,111–114] have been devoted to the investigation of the kinetics, thermodynamics, and mechanism of the pyrolysis of GLC and layered compounds of carbon fibres (LCCF) with iron(III), copper(II), and other metal chlorides by dynamic thermogravimetric measurements (TG), quantitative DTA combined with X-ray diffraction and chemical analysis, time of flight mass spectrometry, and Mössbauer spectroscopy. It was shown that the GLC with $CuCl_2$ ($FeCl_3$) begin to undergo thermal decomposition at relatively low temperatures (460–500 and 320–350 K respectively) and that the physicochemical parameters of the linear pyrolysis depend on a number of experimental factors: the degree of dispersion of the GLC particles, the mass of the sample, the rate of heating of the specimens, the gaseous environment (vacuum, inert gas, air), the external pressure, and the nature of the carbon matrix [Zaval'evsk graphite, carbon fibres based on cellulose hydrate, polyacrylonitrile (PAN), etc.] (Figs.7–11 and Table 6). When the GLC are heated, hydrogen chloride and water, present in the materials (at the defects in the graphite skeleton and at the edge molecules of the intercalated chlorides) by virtue of the methodological features of the synthesis,[115] are removed initially (section A–B in Fig.8 corresponds to this process for the GLC with $FeCl_3$). It was found that the stage 2 GLC have a somewhat higher thermal stability than the stage 1 compounds, but that their main thermal degradation occurs approximately within the same temperature limits as for the pure salts, which indicates a low strength of the bond between the layers of the graphite matrix and the intercalated component. On passing from GLC to LCCF, the thermal stability of the compounds falls somewhat, being lower for the LCCF based on a cellulose hydrate than for the LCCF based on PAN (cf.Figs.9 and 11). It was established that, when the GLC with $FeCl_3$ is heated to 800 K, $FeCl_3$ ... # from them at $T > 370$ K (section C–D in Fig.8), while at higher temperatures $FeCl_3$ dissociates in the interplanar space within the graphite skeleton into $FeCl_2$ and in Cl_2 with formation of a GLC with $FeCl_2$ and the removal of Cl_2 (section E–F in Fig.8). This conclusion agrees with other data[22,24,90,116,117] but conflicts with the results of Solozhenko et al.[56] The possible causes of the discrepancies between the two sets of data in Refs.57–60 and 56 may be, in particular, different experimental conditions, different type and degree of dispersion of the initial graphite, etc.

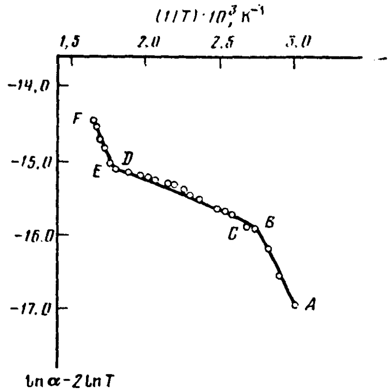

Figure 8. A typical form of the dependence of $\ln\alpha - 2\ln T$ on $1/T$ for the linear pyrolysis *in vacuo* of the GLC with $FeCl_3$ used[58,59] to estimate the apparent activation energies.

Several studies of the properties of LCCF have been published in recent years. Oshima et al.[118] obtained LCCF with $CuCl_2$, consisting of a mixture of stage 1 and 2 compounds, and demonstrated by electrical resistivity measurements that the LCCF with $CuCl_2$ are stable in air up to 450 K.

The compounds formed on interaction of gaseous fluorine and lithium fluoride with graphite materials of different nature (natural and pyrolytic graphite as well as carbon fibres) and having the composition $C_xF(LiF)_y$ (where x and y are 9–13 and 0.1–0.002 respectively for graphite) have been investigated by X-ray diffraction, ^{19}F NMR, thermogravimetric analysis (TGA), and conductimetric measurements.[119] The thermal stability in air was a maximum for the compounds obtained from carbon fibres: the LCCF decomposed at 680 K (a decrease in mass and an endothermic reaction were recorded at this temperature), while the compounds based on natural graphite decomposed at 537 K. We may note that, after

---

#Misprint in Russian text (Translator).

prolonged exposure to air at room temperature, the specimens obtained from carbon fibres underwent reversible changes (manifested, in particular, by a decrease of their resistivity).

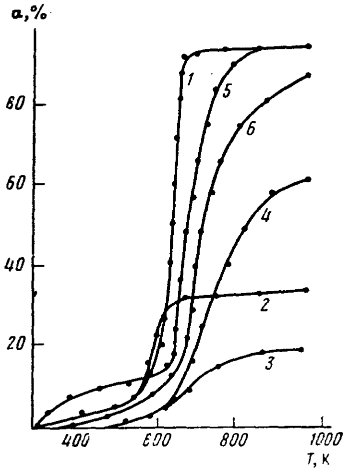

Figure 9. TGE curves for $CuCl_2$ (curve *1*) and LCCF with $CuCl_2$ based on viscose (curves *2* and *5*) and PAN (curves *3–6*) and the compound $C_{6.35}CuCl_2$ (curve *4*) *in vacuo* (curves *1–4*) and in air (curves *5* and *6*); α is the degree of decomposition of the test specimen; heating rate 5 K min^{-2}.[112]

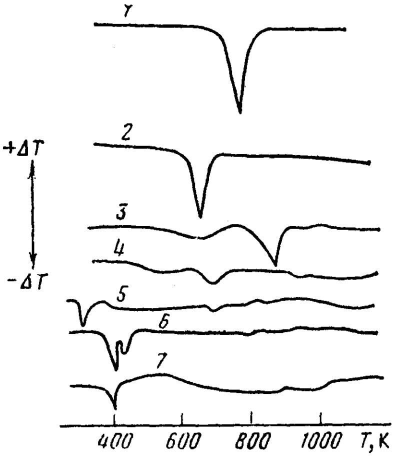

Figure 10. DTA curve for $CuCl_2$ (curves *1* and *2*), the compound $C_{6.35}CuCl_2$ (curves *3* and *4*), and the LCCF with $CuCl_2$ [based on viscose (curves *5* and *7*) and PAN (curve *6*)] *in vacuo* (curves *2*, *4*, and *5*), in argon (curves *1*, *3*, and *6*), and in air (curve *7*); heating rate 5 K min^{-1}.[112]

By measuring the temperature variation of the resistivity of LCCF with $FeCl_3$ and $CuCl_2$ ($4 < T < 600$ K), Endo et al.[120] showed that the desorption of the intercalated component from the compound is not observed up to ~513 K (for $CuCl_2$) and 613 K (for $FeCl_3$). It was also found that both LCCF are stable in air. A LCCF with potassium has been synthesised[121] and its electrical properties have been investigated. The authors[121] established the formation of compounds with different stage indices in the case of the LCCF and also found that the LCCF with potassium undergo the same phase transformations as the layered compouds of potassium with synthetic graphite, although the transition temperature and the rate of transformation can differ for different materials.

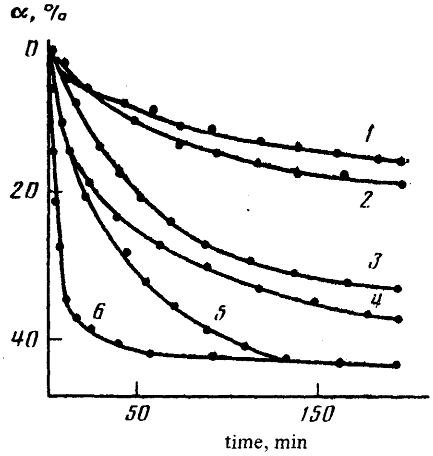

Figure 11. Dependence of the degree of decomposition (α, %) of specimens of the LCCF with $CuCl_2$ based on viscose (curves *1*, *2*, *5*, and *6*) and the compound $C_{6.35}CuCl_2$ (curves *3* and *4*) on the duration of their heat treament *in vacuo* at different temperature (K): 1) 523; 2) 548; 3) and 5) 573; 4) and 6) 623.[112]

The intercalation of certain strong acceptors (AsF_5, SbF_5, SO_3, and HSO_3F) and their mixtures in carbon fibres and the electrical properties of the resulting LCCF have been studied.[122] It was shown that the LCCF with AsF_5, enclosed in a Teflon envelope, retained their thermal stability up to 373 K. Natarajan et al.[123] investigated the electrical properties of LCCF with ICl, Br_2, and $CuCl_2$ and showed that the LCCF with $CuCl_2$, which are stable in air, retain their themal stability up to 373 K. Dziemianowicz and Forman[124] investigated the properties of LCCF with certain acceptors (nitric acid, $AlCl_3$, and $FeCl_3$). It was noted that both chlorides form LCCF with different stage indices. In contrast to the data of Endo et al.,[120] Dziemianowicz and Forman[124] noted that the LCCF with $AlCl_3$ and $FeCl_3$ are extremely unstable in air (they are rapidly and irreversibly hydrated and drying of the hydrated product does not lead to the reformation of the initial LCCF).

In the above studies the compounds were investigated under the usual pressure. Solozhenko and Kalashnikov[82] investigated the behaviour of GLC with $FeCl_3$ at high pressures (2 to 8 GPa) and temperatures (300–2000 K) showed that the observed decomposition reactions of the stage 1 compound can be described by means of the scheme

$$\begin{tikzcd}
\text{GLC with } FeCl_3 \text{ (stage 1)} \arrow[r] & \text{GLC with } FeCl_3 \text{ (higher stages)} \arrow[d] & + FeCl_3 \arrow[d, shift left] \\
 & FeCl_3 + \text{C(graphite)} & FeCl_2 + 0.5Cl_2 \arrow[u, shift left]
\end{tikzcd}$$

As was in fact suggested by the authors,[82] the decomposition of the GLC with $FeCl_3$ at high static pressures and temperatures then proceeds via a qualitatively different mechanism than in the case of high dynamic pressures.

We may note that, according to a number of data,[61,125,126] the removal of the intercalated components of the GLC does not necessarily require heating and has been observed for a number of compounds even at room temperature. Thus Hwang et al.[125] investigated the behaviour of the stage 1 compound C_8Cs, whilst it was maintained *in vacuo* (10^{-9} mmHg, room temperature) for a week. It was shown that caesium is removed from the GLC, which leads to the appearance of a multiphase structure in which the size of the domains is ~1 μm. By measuring the Mössbauer effect, it was demonstrated[126] that, after prolonged (up to 1 year) exposure to air of the specimens of the GLC with $FeCl_3$ corresponding to stage indices, the following phenomena were observed: an appreciable decrease of the iron content [and hence of iron(III) chloride] in the specimens; in the case of the specimens containing a certain number of vacancies, $FeCl_3$ was converted into the $FeCl_4^-$ ions; after the formation of the $FeCl_4^-$ ions, the GLC specimens with individual stage indices were converted into disordered substances.

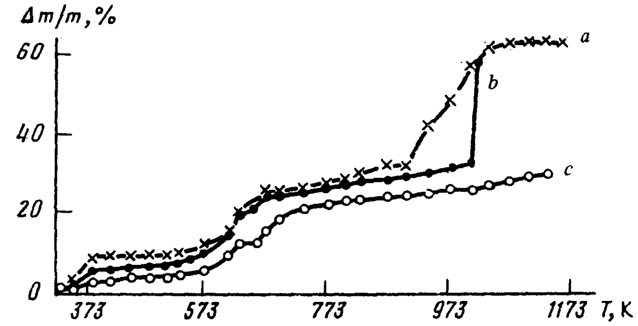

Figure 12. TGA curves for the GLC with $FeCl_3$: *a*) freshly prepared; *b*) after storage in air; *c*) after storage (the maximum weight loss for the stage 1 GLC is 65%).[61]

An extensive study of the behaviour of the GLC with $FeCl_2$ and $FeCl_3$ under different conditions (in particular, during storage, heating, and treatment with water and various solvents) has been carried out[61] by the gravimetric, X-ray diffraction, electron microscope, and Mössbauer spectroscopic methods[61] (Fig.12). Two main types of processes were observed: a gradual conversion of the initial compound into GLC with higher stage indices or direct removal of the component intercalated in the graphite skeleton. A mechanism of the possible reactions occurring when the GLC are kept in air for a long time (up to 40 days) was put forward[61] and it was shown that the products of the decomposition of the compound are iron(II) and iron(III) chloride hydrates and oxide hydrates, disordered graphite, etc.

---o0o---

It is seen from the results presented above that, despite the apparently large number of data on the physicochemical properties of GLC which have been published in recent years, there are no systematic data of this kind for the majority of the compounds.

A future systematic study of the physicochemical properties of GLC over a wide range of temperatures and pressures will be necessary and it will be desirable to carry out a simultaneous combined study of various properties on identical specimens, since it has been demonstrated that many properties of GLC depend on the previous history of the specimens (in particular, on the duration and conditions of their storage). The latter factor makes it necessary to approach the comparison of data obtained by different investigators with much caution and makes it essential to take into account the form of the graphite matrix in the compound.

Unfortunately, there are very few data on the thermophysical and thermodynamic properties of GLC, the need for which (especially for accurate data) is great. It is desirable that the relevant communications should present the results of the chemical analysis of the compounds (and should not simply indicate the stage index of the GLC, as is being done at the present time in many investigations), because certain properties of GLC depend on whether the given compound is saturated or unsaturated. The lack of information about the formula composition of the test substances frequently makes it difficult to both interpret the data obtained and to compare the results of different investigations with one another. The accumulation of reliable data on the physicochemical properties of GLC will permit further progress in the elucidation of the relation between their structure and properties.

Nitroxy-radicals in the Liquid-phase Oxidation Reactions of Organic Compounds

S.A.Maslov and G.E.Zaikov

The review is devoted to the mechanism of the action of stable nitroxy-radicals in liquid-phase oxidation reactions of organic compounds. The chemical reactions which take place with participation of nitroxy-radicals are examined and their kinetic parameters are presented. The causes of the high inhibition coefficients and the possible ways of regenerating the nitroxy-radicals from their reaction products are discussed. The phenomenon of the selective inhibition of polymerisation processes accompanying oxidation is described and the conditions necessary for selective inhibition and the possibility of using nitroxy-radicals for this purpose are discussed.
The bibliography includes 97 references.

I. INTRODUCTION

Stable nitroxy-groups are nowadays finding increasing application in various branches of scientific research and in industrial practice. In particular, they are used as stabilisers in the storage of organic substances, as spin labels and paramagnetic probes in molecular biophysics, and as acceptors and counters of free radicals in the study of the mechanisms of chemical reactions. Numerous data concerning the ways of preparation, properties, and applications of nitroxy-radicals have been published.[1–7] The principal characteristic of nitroxy-radicals, which distinguishes them from other stable organic radicals, is the absence of delocalisation of the unpaired electron.[1,8]

One of the causes of the great interest shown in nitroxy-radicals is that they are effective stabilisers of the oxidative degradation and photodegradation of polymers, in the first place polyolefins.[9–20] The characteristic features of the action of nitroxy-radicals as UV-stabilisers of polymeric materials have been examined in detail,[11,14] but much less attention has been devoted to problems of their antioxidant stabilisation. It is known that many processes occurring in polymers can be successfully investigated using simpler reactions with participation of low-molecular-weight substances, for example, monomers, as models. The study of the mechanism of the action of nitroxy-radicals in the oxidation of monomers is of interest also from this point of view. The criteria of the applicability of such monomeric models to the solution of problems in the field of the degradation and stabilisation of polymers have been formulated.[9,21–23]

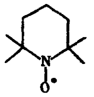
This review is devoted to the action of nitroxy-radicals in the liquid-phase oxidation reactions of monomeric organic compounds which make it possible to obtain many important products of organic synthesis. Fairly numerous interesting results exist in this field but hitherto they have not been surveyed or described systematically. The review deals with the principal experimental data obtained in the study of the reactions of nitroxy-radicals in chain oxidation processes during the last 20–25 years, i.e. virtually since the inception of this field of research. This led to a number of generalisations and certain mathematical relations describing the action of nitroxy-radicals in oxidation systems are given.

II. CHEMICAL REACTIONS WITH PARTICIPATION OF NITROXY-RADICALS IN OXIDATION REACTIONS OF ORGANIC COMPOUNDS

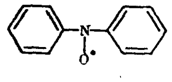
Stable nitroxy-radicals are able to inhibit radical chain processes. The inhibiting effect of nitroxy-radicals is due to the fact that they are able to enter into reactions, involving the saturation of the valence, with other species having an unpaired electron, in particular with free organic radicals propagating the oxidation chain.

For an oxidative chain reaction, it is possible to determine even from concentration relations which of the radicals, the alkyl radical $R^{\cdot}$ or the peroxy-radical $RO_2^{\cdot}$, participates in chain termination (i.e. in recombination by adding to the nitroxy-radical). If the chain of oxidation depends on the partial pressure of O_2 in the system, this means that the radicals $R^{\cdot}$ are responsible for the chain termination. When the rate of reaction is independent of the oxygen content, the $RO_2^{\cdot}$ radicals are responsible for chain termination. Another way of determining the nature of the termination consists in the identification of the termination product by chemical and spectroscopic methods.

It has been established unambiguously that heterocyclic and aliphatic† nitroxy-radicals, in particular radicals of the piperidine series having the general formula (I), react solely with the alkyl radicals $R^{\cdot}$ and do not interact with the peroxy-radicals $RO_2^{\cdot}$.



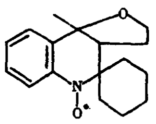
(I)
2,2,6,6-Tetramethylpiperidin-1-yloxy-radical



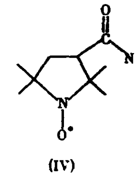
(II)
Diphenylnitroxy-radical

---

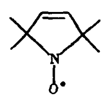
† All these non-aromatic radicals will henceforth be referred to for brevity simply as heterocyclic radicals.



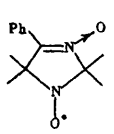
(III)
4-Methyl-2-spirocyclohexyl-3,4,2′,3′-tetrahydrofurano-1,2,3,4-tetrahydroquinolin-1-xyloxy-radical



(IV)
3-Carbamoyl-2,2,5,5-tetramethylpyrrolidin-1-yloxy-radical



(V)
2,2,5,5-Tetramethylpyrrolin-1-yloxy-radical



(VI)
2,2,5,5-Tetramethyl-4-phenyl-3-oxoimidazolin-1-yloxy-radical

This was demonstrated in the oxidation of ethylbenzene,[24,25] polyethylene and polypropylene,[26] and cumene and cyclohexyl methyl ether,[27] in the radiolysis of organic compounds,[28,29] and in the decomposition of azoisobutyrodinitrile.[30] It has been established that, in the radiolysis of water,[31] the nitroxy-radicals (VI) of the imidazoline series react with H atoms and with a hydrated electron but do not react with the $HO_2^{\cdot}$ radical. Fig.1 illustrates the reactivity of heterocyclic nitroxy-radicals. It is seen that, in an atmosphere of oxygen, where the $RO_2^{\cdot}$ radicals propagate the oxidation chain, the nitroxy-radical (I) is not consumed in the oxidation of ethylbenzene. The stationary concentration of the $RO_2^{\cdot}$ radicals, characterised by the chemiluminescence intensity (I/I_0), then also remains unchanged.

In the oxidation of many compounds, especially aromatic hydrocarbons, the stationary concentration of peroxy-radicals is much higher than the concentration of the alkyl radicals $R^{\cdot}$, as a result of which the heterocyclic nitroxy-radicals cannot be effective inhibitors of such reactions. On the other hand, in the oxidation of olefins characterised by relatively high concentrations of the radical $R^{\cdot}$, the inhibition of the reaction by heterocyclic nitroxy-radicals has been observed. As an illustration, Fig.2 presents the kinetic curves for the liquid-phase oxidation of hex-1-ene inhibited by a nitroxy-radical of type (I).[32] An analogous picture has been observed in the oxidation of β-carotene (a polyene).[33]

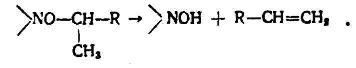
The interaction of heterocyclic nitroxy-radicals with alkyl radicals results in the formation of the corresponding hydroxylamine ethers:[29,34–36]

$$>NO^{\cdot} + R^{\cdot} \xrightarrow{k_a} >NOR\ .$$

The disproportionation reaction is also possible:

$$>NO^{\cdot} + R^{\cdot} \xrightarrow{k_b} >NOH + \text{olefin}.$$

According to Berger et al.,[30] the ratio $k_b/k_a = 0.21$ for the nitroxy-radical (I) and the radicals $(C_6H_5)_2\dot{C}(CH_3)$ and does not change over the range 60–80 °C. In the presence of hydrogen atoms in the α-position, a decomposition reaction can occur,[37,38] for example:



$$>NO{-}\underset{\large CH_3}{CH}{-}R \rightarrow >NOH + R{-}CH{=}CH_2\ .$$

In an acid aqueous medium, hydroxylamine ethers are capable of being deprotonated and of dissociating:[29]

$$>NOR + H^+ \rightarrow -\overset{+}{N}HOR\ ;$$

$$-\overset{+}{N}HOR \rightleftarrows >\bar{N}OR + H^+_{aq}\ .$$

The pK_a for the equilibrium depends on the nature of the radical R and the nitroxy-radical.

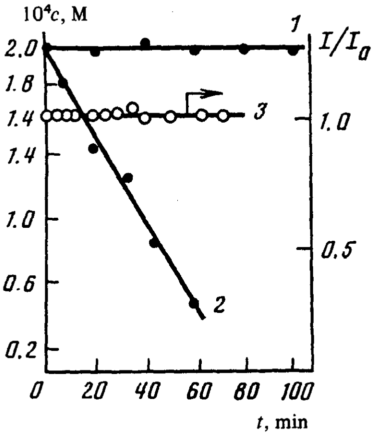


Figure 1. The time (t) variation of the concentration of type (I) nitroxy-radicals (c) in ethylbenzene at 60 °C with the solution bubbled with air (line *1*) and helium (line *2*) and variation of the relative intensity of chemiluminescence (line *3*) under the same conditions for the solution bubbled with air.[25]

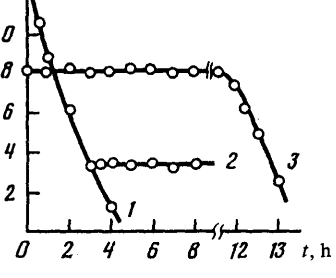

Figure 2. Kinetic curves for the consumption of hex-1-ene during its oxidation with air in acetone (145 °C, 50 atm):[32] 1) without inhibitor; 2) in the presence of 3×10^{-3} M 4-hydroxy derivative of the radical (I); 3) in the presence of 5.2×10^{-4} M 4-hydroxy derivative of the radical (I).

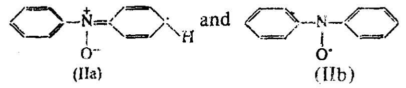
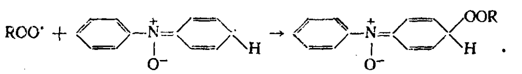
Aromatic nitroxy-radicals, for example, the radicals (II) of the diphenylamine series, can react not only with the radicals $R^{\cdot}$ but also with $RO_2^{\cdot}$. Nitroxy-radicals of type (II) can exist in two forms:[39,40]

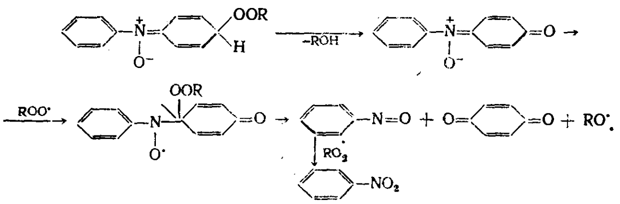


(IIa) (IIb)

The radicals $RO_2^\cdot$ are destroyed with participation of the mesomeric form (IIa), which can be represented as follows:[24,39]



This reaction is accompanied by the irreversible consumption of the nitroxy-radical via the mechanism:



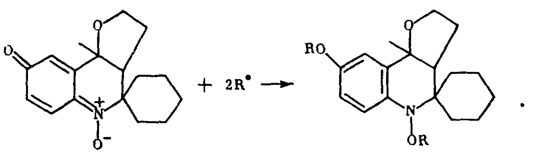
(1)

It has been suggested[41] that the nitroxy-radical (II) interacts with the $RO_2^\cdot$ radical as follows:

$$>NO^\cdot + C_nH_{2n+1}O_2^\cdot \xrightarrow{k_b} >NOH + O_2 + C_nH_{2n}\,. \qquad (2)$$

When cumene is heated in the absence of oxygen but in the presence of an initiator, namely azobisisobutyrodinitrile (AIBN), the aromatic nitroxy-radical (II) reacts with the radicals $R^\cdot$, forming a hydroxylamine ether, as in the reaction involving heterocyclic nitroxy-radicals.

According to Lobanova and co-workers,[42,43] the spiran nitroxy-radical (III) also interacts not only with alkyl but also with peroxy-radicals. The quinone-nitrone formed in the latter case does not react further with $RO_2^\cdot$, but functions as an acceptor of alkyl radicals:



The nitroxy-radical (III) is capable of reacting also with alkoxy-radicals $RO^\cdot$, but the product formed has not been identified. On the other hand, it does not react with phenoxy-radicals.

The reactions of nitroxy-radicals with other free radicals, formed in the oxidation of alcohols and amines, are distinguished by certain characteristic features. Both "alkyl" and peroxy-radicals derived from alcohols and amines can be destroyed by any nitroxy-radicals[44,45] and the reaction product is not an ether but the corresponding hydroxylamine itself:

$$>NO^\cdot + HO{-}\dot{C}< \;\rightarrow\; >NOH + O{=}C<\,. \qquad (3)$$

While the alcohol is converted into a carbonyl compound, the amine is converted into a Schiff base:

$$>NO^\cdot + H_2N{-}\dot{C}< \;\rightarrow\; >NOH + {-}N{=}C<\,. \qquad (4)$$

Reactions of types (3) and (4) have been observed in an inert atmosphere for different heterocyclic nitroxy-radicals and the nitroxy-radical (II). The interaction of heterocyclic nitroxy-radicals with the peroxy-radicals formed in the oxidation of secondary and tertiary aliphatic amines has been described.[45,46] The peroxy-radicals are destroyed via the reaction:

$$-NH{-}\overset{|}{\underset{|}{C}}OO^\cdot + >NO^\cdot \rightarrow >NOH + {-}N{=}C< + O_2\,. \qquad (5)$$

The inhibition of the oxidation reactions can be achieved not only by the addition of complete nitroxy-radicals but also as a result of the introduction into the oxidation system of primary and secondary amines, which are capable of being converted into nitroxy-radicals under these conditions.[47-49] Thus in the presence of diphenylamine the following reactions take place:

$$(C_6H_5)_2NH + RO_2^\cdot \xrightarrow{k_c} (C_6H_5)_2N^\cdot + ROOH\,; \qquad (6)$$

$$(C_6H_5)_2N^\cdot + RO_2^\cdot \xrightarrow{k_d} (C_6H_5)_2NO^\cdot + RO^\cdot\,. \qquad (7)$$

Nitroxy-radicals are usually not formed in the oxidation of tertiary amines.[47] The oxidation reactions of tertiary amines derived from indoline are an exception.[50]

In the oxidation of cumene, $k_d = 6 \times 10^3$ litre mol^{-1} s^{-1} at 57 °C [41] and $k_c = 4 \times 10^4$ litre mol^{-1} s^{-1} at 65 °C.[30] At the same temperature, $k_d > k_c$ according to Berger et al.[30] According to the data of Howard and Wiles,[51] the abstraction of a hydrogen atom from secondary aliphatic amines is much slower than the abstraction from aromatic amines.

Nitroxy-biradicals exhibit fundamentally the same inhibiting properties as the monoradicals. According to Brownlie and Ingold[52] and Ruban et al.,[53] the inhibition reaction is preceded by the decomposition of the biradical into the two corresponding monoradicals. The question of the reactivity of the nitroxy-biradicals and nitroxy-polyradicals has been discussed in detail.[2] Nitroxy-radicals can be introduced into the reaction also in an immobilised form. Thus polystyrene containing t-butylnitroxy-groups (one $>NO^\cdot$ group per 250 to 300 monomer units) is an effective inhibitor of radical reactions.[54]

Taking into account the ability of nitroxy-radicals to interact with alkyl radicals, it is to be expected that they inhibit not only oxidation reactions but also other radical processes. Indeed they behave as inhibitors of polymerisation, especially of chloroprene, acrylates and methacrylates, vinyl monomers, styrene, etc.[1,54,55]

III. KINETIC CHARACTERISTICS OF NITROXY-RADICALS AS ANTIOXIDANTS

In order to be able to discuss the kinetic parameters characterising the inhibiting capacity of nitroxy-radicals, we shall make use of the general mechanism of the oxidation processes accompanied by polymerisation in the presence of nitroxy-radicals. This scheme is based on the available published experimental data:

Scheme 1

$$RH \xrightarrow{O_2} R^\cdot\,, \qquad (0)$$

$$R^\cdot + O_2 \xrightarrow{k_1} RO_2^\cdot\,, \qquad (1)$$

$$RO_2^\cdot + RH \xrightarrow{k_2} ROOH + R^\cdot\,, \qquad (2)$$

$$ROOH \xrightarrow{k_3} RO^\cdot,\ OH,\ RO_2^\cdot\,, \qquad (3)$$

$$R^\cdot + R^\cdot \xrightarrow{k_4} \text{molecular products}\,, \qquad (4)$$

$$R^\cdot + RO_2^\cdot \xrightarrow{k_5} \text{molecular products}, \qquad (5)$$

$$RO_2^\cdot + RO_2^\cdot \xrightarrow{k_6} \text{molecular products}, \qquad (6)$$

$$R^\cdot + >NO^\cdot \xrightarrow{k_7} >NOR\,, \qquad (7)$$

$$RO_2^\cdot + >NOR \xrightarrow{k_8} ROOR + >NO^\cdot, \qquad (8)$$

$$RO_2^\cdot + >NOR \xrightarrow{k_9} \text{molecular products}, \qquad (9)$$

$$RO_2^\cdot + >NO^\cdot \xrightarrow{k_{10}} [RO_2^\cdot \cdots >NO] \text{ or } >NOH + >C{=}C< + O_2\,, \qquad (10)$$

$$>NO^\cdot + RH \xrightarrow{k_{11}} >NOH + R^\cdot\,. \qquad (11)$$

When the compound being oxidised contains C=C double bonds or when an unsaturated compound M is added to a saturated substance undergoing oxidation, the mechanism must be supplemented by the following reactions:

$$\rangle NO^{\cdot} + M^{\cdot} \xrightarrow{k_{12}} \text{molecular products,} \tag{12}$$

$$\rangle NO^{\cdot} + M \xrightarrow{k_{13}} M^{\cdot}, \tag{13}$$

$$M^{\cdot} + O_2 \xrightarrow{k_{14}} MO_2^{\cdot}, \tag{14}$$

$$MO_2^{\cdot} + M \xrightarrow{k_{15}} M^{\cdot}, \tag{15}$$

$$MO_2^{\cdot} + MO_2^{\cdot} \xrightarrow{k_{16}} \text{molecular products.} \tag{16}$$

Here R$^{\cdot}$ is an alkyl radical, $\rangle NO^{\cdot}$ the nitroxy-radical, and M the olefin molecule.

Apart from the usual reactions characteristic of the non-inhibited chain oxidation process,[56] the scheme includes stages involving the destruction of free radicals by the nitroxy-radical [reactions (7), (9), (10), and (12)] and the regeneration of the nitroxy-radicals from their reaction products [reaction (8)]. Reactions (11) and (13) refer to the initiation of free radical chains by the nitroxy-radicals as a result of their addition to the double bond or the abstraction of a hydrogen atom from the molecule of the organic substrate. All these reactions will be discussed in greater detail below.

The efficiency of nitroxy-radicals as oxidation inhibitors can be characterised very approximately by measuring the induction period. Naturally, when different nitroxy-radicals are compared, the determination must be carried out with identical amounts of the inhibitor and under the same experimental conditions. In particular, by measuring the induction periods, it has been established that nitroxy-radicals derived from quinoline and carboline are less effective inhibitors of the oxidation of polypropylene and of the oxidative degradation of polyformaldehyde than the nitroxy-radicals of type (I).[57] The antioxidant efficiencies of 15 nitroxy-radicals having different structures have been characterised[55] from the induction periods in the oxidation of polypropylene. It is of interest that the induction period in the oxidation of polypropylene[55,58] continues even after the apparent consumption of the nitroxy-radicals , i.e. after the disappearance of the corresponding EPR signal. One can therefore assume that in certain systems the nitroxy-radical behaves as an inhibitor even at very low stationary concentrations in the system—below the sensitivity limit of the EPR method.

The inhibiting capacity of nitroxy-radicals is characterised much more accurately by the rate constants for the elementary stages of the inhibition process. When alkyl radicals are destroyed by a nitroxy-radical, the rate constant k_7 or the ratio k_1/k_7 is usually determined.[25,27,51] The rate constants k_{10} for type (II) nitroxy-radicals have been measured in the oxidation of ethylbenzene and styrene. The study of the inhibited oxidation of alcohols and amines yielded the combinations of rate constants $k_{10}/k_6^{1/2}$ for nitroxy-radicals of different structure. The rate constant k_{10} refers in this instance to a disproportionation reaction of type (5) and not to the recombination of radicals.

A novel method of characterising nitroxy-radicals as inhibitors has been proposed.[59] In contrast to the traditional approach requiring the comparison of the rates of chain propagation [reaction (1)] and chain termination by the nitroxy-radical [reaction (7)] in Scheme 1, here the rates of chain termination were compared in the presence and absence of the nitroxy-radical. An expression was then obtained for the minimum concentration of the nitroxy-radical necessary for the inhibition of the oxidation of the organic compound RH:

$$[\rangle NO^{\cdot}]_{\min} > \frac{k_1 \sqrt{W_0 k_6}\,[O_2]}{k_2 k_7\,[RH]}, \tag{8}$$

where W_0 is the rate of chain initiation in reaction (0) in Scheme 1.

Eqn.(8), which relates the minimum concentration of nitroxy-radicals necessary for the complete arrest of the reaction to the principal kinetic parameters of the system, can be used to determine the constant k_7 by measuring $[{>}\mathrm{NO}^{\cdot}]_{\mathrm{min}}$.

The available literature data for the kinetic parameters of the interaction of nitroxy-radicals with free radicals are presented in Table 1.

When nitroxy-radicals are used as inhibitors, one must bear in mind that they can participate in free radical formation reactions. Nitroxy-radicals are hardly involved in chain branching via interaction with the hydroperoxide formed in the oxidation process, which has been demonstrated, for example, in the study of the decomposition of propene hydroperoxide.[24] However, in the presence of certain catalysts, nitroxy-radicals can accelerate the decomposition of hydroperoxides. Thus the promoting effect of the nitroxy-radical (I) in the decomposition of tetralinyl and cyclohexyl hydroperoxides in the presence of copper-containing catalysts has been established.[60,61] The effect of nitroxy-radicals can be attributed to the formation of a complex with the catalyst. In particular, it is known that they are capable of forming complexes with univalent and bivalent copper.[62] An interesting observation has been made in the study of the kinetics of the decomposition of peroxide initiators—benzoyl peroxide[63] and dicyclohexyl peroxydicarbonate[64]—in the presence of nitroxy-radicals. It was established that, in the absence of catalysts, nitroxy-radicals are able to accelerate the decomposition of peroxide compounds, provided that the concentration of the nitroxy-radical in the system is comparable to that of the peroxide.

On the other hand, nitroxy-radicals can generate free radicals by abstracting a hydrogen atom from the molecule of the organic compound [reaction (11)] or by adding to the double bond [reaction (13) in Scheme 1]. The importance of the latter reaction also lies in the fact that nitroxy-radicals have found a practical application as inhibitors of the polymerisation of unsaturated compounds. Reaction (11) has been investigated in ethylbenzene,[65] toluene,[66] phenylhydrazones,[67] di-t-butylphenol,[68] hydrazobenzene,[69] and mercaptans.[70] Reaction (13) has been investigated only for styrene and heterocyclic nitroxy-radicals.[71-73] In the case of α-methylstyrene, where the reaction involved the participation of monoradicals, addition to the double bond was not observed even at 180 °C. However, under the same conditions, the nitroxy-biradical adds readily to α-methylstyrene. This difference between reactivities can be accounted for by the greater probability for the biradical of the adiabatic reaction pathway characterised by a low activation energy.[2] The rate constants for reactions (11) and (13) are presented in Table 2.

Taking into account the possibility of the initiation by free radicals via reaction (13) in Scheme 1, we shall estimate the optimum amounts of the nitroxy-radical necessary for the inhibition of the oxidation of hydrocarbons via Scheme (1) presented above. If the compound oxidised RH has no double bond, it is assumed that an unsaturated compound, which is a source of additional initiation, constitutes a second component of the oxidation system. An increase in the induction period with increased concentration of the nitroxy-radical has been observed experimentally, but at sufficiently high concentrations it ceases to change. This can be explained by the fact that the rate of initiation by the nitroxy-radical

Table 2. The rate constants for the reactions of nitroxy-radicals leading to the formation of free radicals.

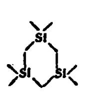
*The biradical $ROOC(CH_2)_4COOR$, where R is the radical residue from the nitroxy-radical (I).

**The activation energies are almost identical for all the nitroxy-radicals.

***At a pressure of 2000 atm.

****The silane is



becomes higher than the rate of thermal initiation. The induction period is given by

$$\tau=\frac{p}{k_2}\cdot\frac{k_7\left[>\mathrm{NO}^{\cdot}\right]}{W_0+k_{13}\left[>\mathrm{NO}^{\cdot}\right][\mathrm{M}]}\ ,$$

where p is the fraction of the substrate which has reacted at the instant when the induction period ends. At the nitroxy-radical concentration corresponding to the start of the region of constant τ, we have

$$k_{13}\left[>\mathrm{NO}^{\cdot}\right][\mathrm{M}]\gg W_0\ ;$$

whence

$$\tau=\frac{pk_7}{k_2k_{13}[\mathrm{M}]}\ . \qquad (9)$$

The rate of the oxidation process is then given by

$$W=k_2k_{13}[\mathrm{RH}][\mathrm{M}]/k_7$$

Eqn.(9) describes the region where the induction period is independent of the concentration of the nitroxy-radical. The optimum concentration of the nitroxy-radical, corresponding to the region of the independence of the induction period, is

$$\left[>\mathrm{NO}^{\cdot}\right]_{\mathrm{opt}}=W_0/k_{13}[\mathrm{M}]\ .$$

An increase in the concentration of the nitroxy-radical above $[>\mathrm{NO}^{\cdot}]_{\mathrm{opt}}$ is undesirable, since it does not lead to a further increase of the induction period. Calculation of the quantity $[>\mathrm{NO}^{\cdot}]_{\mathrm{opt}}$ may be of practical value when nitroxy-radicals are used for the antioxidant stabilisation of materials containing double bonds. The parameter characterising the inhibiting efficiency of nitroxy-radicals under the conditions of significant additional initiation can be deduced from Eqn.(9):

$$K=k_7/k_2k_{13}$$

IV. THE INHIBITION COEFFICIENT AND REGENERATION OF NITROXY-RADICALS

One of the most important characteristics of the inhibitors of radical processes, including nitroxy-radicals, is the stoichiometric inhibition coefficient f. The integral definition, according to which f is equal to the number of free radicals destroyed by one inhibitor molecule, is widely used in the chemical literature:

$$f\cdot[\mathrm{InH}]_0=W_0\tau\ ,$$

where $[\mathrm{InH}]_0$ is the initial inhibitor concentration. A method of determining f in the case of weak inhibitors which do not give rise to a distinct induction period has been described.[39]

However, in the integral definition no account is taken of the fact that f depends on the ratio of the rates of the individual elementary stages of the inhibition process. The role of this ratio is evident from the following simple example. In a system containing the free radicals $\mathrm{R}^{\cdot}$ to which the inhibitor InH has been introduced, two radical destruction reactions can take place:

$$\mathrm{R}^{\cdot}+\mathrm{InH}\rightarrow\mathrm{RH}+\mathrm{In}^{\cdot}\ , \qquad (10)$$

$$\mathrm{R}^{\cdot}+\mathrm{In}^{\cdot}\rightarrow\mathrm{RIn}\ . \qquad (11)$$

Even in this case the quantity f depends on the ratio of the rates of reactions (10) and (11). If the rate of reaction (11) greatly exceeds that of reaction (10), then $f = 2$. In the opposite case $f = 1$ and for comparable rates of the two reactions we have $1 < f < 2$.

A differential, i.e. "rate" treatment of the quantities f for the reactions involving inhibition by nitroxy-radicals has been described.[59] In this case the expression for f represents the ratio of the sum of the rates of the elementary stages in which the chain propagating free radicals are destroyed to the sum of the rates of the elementary stages in which the inhibitor is consumed. According to Scheme 1,

$$f=\frac{1+\beta\left[>\mathrm{NOR}\right]/\left[>\mathrm{NO}^{\cdot}\right]}{1-\{k_8/(k_8+k_9)\}\cdot\beta\cdot\left[>\mathrm{NOR}\right]/\left[>\mathrm{NO}^{\cdot}\right]}\ , \qquad (12)$$

where

$$\beta=\frac{(k_8+k_9)[\mathrm{RO}_2^{\cdot}]}{k_7[\mathrm{R}^{\cdot}]}=\frac{(k_8+k_9)k_1[\mathrm{O}_2]}{k_2k_7[\mathrm{RH}]}\ .$$

The rate of change of the concentration of $>\mathrm{NOR}$—the product of the reaction of the initial nitroxy-radical—in the course of the oxidation process is described by the expression

$$\mathrm{d}\left[>\mathrm{NOR}\right]/\mathrm{d}t=k_7[\mathrm{R}^{\cdot}]\left[>\mathrm{NO}^{\cdot}\right]-(k_8+k_9)[\mathrm{RO}_2^{\cdot}]\left[>\mathrm{NOR}\right]\ .$$

The rearrangement of this equation and integration using the approximation $[\mathrm{RO}_2^{\cdot}] = [\overline{\mathrm{RO}_2^{\cdot}}]$, i.e. for the average concentration of the radicals $\mathrm{RO}_2^{\cdot}$ in the course of the entire process, lead to the expression

$$\frac{\left[>\mathrm{NOR}\right]}{\left[>\mathrm{NO}^{\cdot}\right]}=\frac{1}{\beta}(1-\mathrm{e}^{-2t/t_c})\ . \qquad (13)$$

The time during which the rates of formation and consumption of the product $>\mathrm{NOR}$ become equal is

$$t_c=2/(k_8+k_9)[\overline{\mathrm{RO}_2^{\cdot}}]=2(\beta W_0)^{-1}\left[>\overline{\mathrm{NO}^{\cdot}}\right]\ .$$

Comparison of Eqns.(13) and (12) shows that, when $t = t_c$, the ratio $[>\mathrm{NOR}]/[>\mathrm{NO}^{\cdot}]$ is close to $1/\beta$. During the reaction, the quantity f changes from 1 at the beginning of the oxidation to $2[1 + (k_8/k_9)]$. Estimation of the parameters β and t_c using the known rate constant k_7, k_{14},[48] k_8,[24,32] and k_{15}[74] leads to $\beta = 10^{-3}$–10^{-2} and $t_c = 10^4$–10^5 s. For short reaction times (up to 3–4 h), the condition $t = t_c$ is not attained and f continuously increases during the reaction without reaching, however, its maximum value.

According to Vardanyan et al.,[75] the inhibition coefficient in oxidation inhibited by amines is defined by the equation

$$f=2(k_8+k_9)/k_9\ . \qquad (14)$$

This expression is a special case of Eqn.(12) and is valid for systems where $k_8 \gg k_7$, i.e. the time required for the attainment of a stationary concentration of the inhibitor reaction product is much shorter than the duration of the oxidation reaction. In studies of the oxidation of polypropylene,[26,76] it has been stated that f increases with increase of oxygen concentration in the system. Indeed an increase in the O_2 concentration increases the efficiency of the inhibition by the nitroxy-radical as a result of the decrease of t_c. On the other hand, the maximum value of f, defined by Eqn.(14), is independent of the oxygen concentration.

The high absolute values of f under conditions where nitroxy-radicals are used in oxidation processes are caused by the inhibitor regeneration reaction [reaction (8) in Scheme (1)] and the increase of f during the process is associated with the increase of its rate as the primary product of the interaction of the nitroxy-radical with the alkyl radical $\mathrm{R}^{\cdot}$ accumulates. The increase of f naturally leads to a decrease of the apparent rate of consumption of the nitroxy-radical during the oxidation process. The inhibition coefficients in different systems are listed in Table 3.

Table 3. The inhibition coefficients (f) of nitroxy-radicals.

In particular, it follows from Table 3, that in the oxidation of higher paraffins, f = 15–35 for aromatic nitroxy-radicals, 225 for the aliphatic t-butylnitroxy-radical, and 500–600 for heterocyclic nitroxy-radicals. The observed difference between the values of f is apparently associated with the fact that aromatic nitroxy-radicals readily enter into side reactions, which lead to their irreversible consumption [reaction (1)].

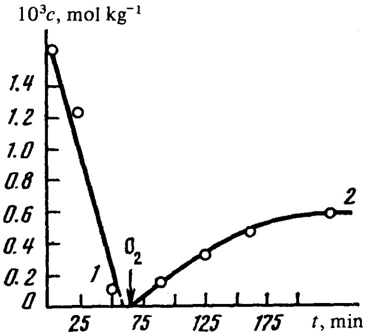

Figure 3. Kinetic curves for the consumption of the 4-hydroxy-derivatives of the nitroxy-radical (I) in an atmosphere of argon (curve *1*) and for the accumulation of the nitroxy-radical after the admission of oxygen (curve *2*) in isotactic polypropylene at 114 °C.[27]

The idea that the regeneration reaction (8) is in fact responsible for the high values of f is nowadays generally accepted. The occurrence of this reaction is convincingly indicated by the available experimental data. In an inert atmosphere, nitroxy-radicals interact with organic free radicals generated in the system, which results in the complete consumption of the nitroxy-radicals. When oxygen is passed subsequently through the reaction mixture, nitroxy-radicals reappear and their concentration increases to a stationary value (Fig.3). In particular, such regeneration has been observed in the interaction of nitroxy-radicals and nitroxy-biradicals with the products of the radiation-chemical reactions of n-octane[35] and the photochemical reactions of rubber[79] and also in the decomposition of the initiator AIBN in polypropylene,[76] aliphatic alcohols, and amines.[45]

A detailed study has been made of the kinetics of certain reactions which can, in principle, lead to the generation of nitroxy-radicals.[27] Apart from the primary reaction (8) in Scheme 1 already mentioned, the following reactions were also investigated:

$$\rangle NOR \xrightarrow{k_e} R^{\cdot} + \rangle NO^{\cdot}, \qquad (15)$$

$$\rangle NOR + O_2 \xrightarrow{k_f} \rangle NO^{\cdot} + \text{products}. \qquad (16)$$

The rate constants for different regeneration reactions are listed in Table 4. The data presented confirm the conclusion that reaction (8) is the main process responsible for the regeneration of nitroxy-radicals from their reaction products.

*Obtained by extrapolation.

**$RO_2^{\cdot} = n\text{-}C_8H_{17}OO^{\cdot}$.

***$RO_2^{\cdot} = (CH_3)_2CNOO$.

****$RO_2^{\cdot} = (CH_3)_2CHC_6H_4\text{-}p\text{-}C(CH_3)_2\text{-}OO^{\cdot}$.

The regeneration of nitroxy-radicals can apparently proceed not only with participation of the peroxy-radicals $RO_2^{\cdot}$ but also in the interaction with the oxy-radicals $RO^{\cdot}$. However in real oxidation systems the $RO_2^{\cdot}$ concentration usually exceeds by two orders of magnitude the $RO^{\cdot}$ concentration, as a result of which the main regenerating agent is in fact the peroxy-radical. In the styrene–acetaldehyde binary system, the type (I) nitroxy-radical is consumed at the same rate as in the oxidation of styrene alone,[59] which shows that the regeneration is effected by the peroxy-radicals derived from styrene, whose concentration is much higher than the concentration of acetyl peroxy-radicals. According to Vardanyan and Denisov,[77] the radicals $HO_2^{\cdot}$ are also capable of regenerating nitroxy-radicals.

It has been suggested[48] that the regeneration is caused by the hydroperoxide:

$$\mathrm{ROOH} + {>}\mathrm{NOH} \rightarrow \mathrm{RO}^{\bullet} + {>}\mathrm{NO}^{\bullet} + \mathrm{H_2O}\ .$$

However, the available experimental data do not allow one to rule out the possibility that the nitroxy-radical is regenerated by the free radicals which can be formed from the hydroperoxide. The regeneration of nitroxy-radicals in an inert atmosphere under the influence of polymers subjected to prior oxidation has been investigated.[26] The oxidised polymer contains hydroperoxy-groups, which the authors[26] believe decompose with formation of the radicals $\mathrm{RO}^{\bullet}$ responsible for the regeneration of the nitroxy-radical.

The peroxy-radicals $\mathrm{RO}_2^{\bullet}$ are capable of regenerating the nitroxy-radical not only from the ethers but also from the hydroxylamine itself:[80]

$${>}\mathrm{NOH} + \mathrm{RO}_2^{\bullet} \rightarrow {>}\mathrm{NO}^{\bullet} + \mathrm{ROOH}\ .$$

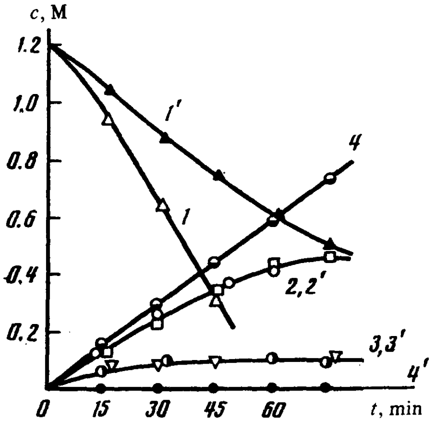

Figure 4. Kinetic curves for the consumption of styrene (curve *1*) and the accumulation of benzaldehyde (curve *2*), styrene oxide (curve *3*), and a polymeric product (curve *4*) in the coupled oxidation of styrene and acetaldehyde by air in benzene (70 °C, 50 atm); the primed numbers designate the corresponding curves in the presence of 2.2×10^{-3} M 4-hydroxy-derivative of the nitroxy-radical (I).[59]

The formation of hydroxylamines and the above regeneration mechanism have been observed mainly for chain termination resulting from the interaction with nitroxy-radicals having labile hydrogen atoms (for example, in the oxidation of alcohols or amines). In this cast too, the regeneration by the radicals $\mathrm{RO}_2^{\bullet}$ takes place at a higher rate than in the interaction with O_2 or with the hydroperoxide. It is noteworthy that the rate of regeneration of the nitroxy-radical from hydroxylamines is higher than from their ethers. The regeneration of nitroxy-radicals from hydroxylamine ethers as a result of the abstraction of a hydrogen atom in the β-position is also possible:

$$\mathrm{R^1CH_2CH_2ON}{<} + \mathrm{RO}_2^{\bullet} \rightarrow {>}\mathrm{NO}^{\bullet} + \mathrm{R^1CH{=}CH_2} + \mathrm{ROOH}\ .$$

The regeneration phenomenon must also be taken into account in those cases where the nitroxy-radicals are used to determine the rate of chain initiation W_0. In order to obtain the true values of W_0, it is essential to have accurate information about the inhibition coefficient in each specific case. On the other hand, the measurement of the rate of consumption of nitroxy-radicals in an inert atmosphere constitutes an extremely convenient method for the study of the kinetics of the decomposition of radical process initiators,[41,44,76] in particular the study of solvent cage effects in the decomposition process.[81] Nitroxy-radicals can be used as radical counters, for example in radiolytic processes[82] and in the determination of sulphur-containing radicals.[83]

In a study[84] of the oxidation of β-carotene (a polyunsaturated hydrocarbon) in the presence of the nitroxy-radical (III), it was shown that the observed high inhibition coefficients are related to an unusual type of regeneration—a relay process. In this instance, the regeneration effect is due to the "relay" radical reaction of the nitroxy-radical and its reaction products, which interact alternately with peroxy- and alkyl radicals derived from the substrate. An essential condition for such relay chain termination by the nitroxy-radical is a definite ratio of the concentrations of the alkyl and peroxy-radicals in the system:

$$10^{-3} - 10^{-2} \leqslant [\mathrm{R}^{\bullet}]/[\mathrm{RO}_2^{\bullet}] \leqslant 10^{-1}\ .$$

However, one should note that the nitroxy-radicals cannot evidently be regenerated in all cases from the reaction products. This is indicated by the finding that $f = 1$ is observed also for nitroxy-radicals in a number of instances, for example, in the oxidation of cumene.[41]

V. CHEMICAL REGULATION OF OXIDATION PROCESSES WITH THE AID OF NITROXY-RADICALS

In our investigations under the supervision of Emanuel' and with participation of Blyumberg and Tavadyan, it was established that nitroxy-radicals can be used to regulate the composition of the products in the oxidation of organic compounds. This possibility is associated with the phenomenon of the selective inhibition of many-centre chain processes, first described by Maslov and co-workers.[85,86] When the nitroxy-radical (I) was introduced into the coupled oxidation reaction of acetaldehyde and styrene[85] or of acetaldehyde and allyl chloride,[86] an appreciable increase in selectivity of the formation of monomeric oxygen-containing products was observed. In the absence of the nitroxy-radical, most of the initial unsaturated compound was converted into a polymeric product. Thus, in the case of styrene, an increase of selectivity with respect to monomeric products from 50 to 95 mole % and in the case of allyl chloride from 35 to 70 mole % was achieved.

The acetaldehyde—styrene binary oxidation system was selected for the detailed investigation of the mechanism of the selective inhibition by nitroxy-radicals. The conditions for selective inhibition, which will be briefly discussed below, were selected in relation to this system.[59] The kinetic curves for the coupled oxidation of styrene and acetaldehyde are illustrated in Fig.4. Examination of the experimental data permits the conclusion that in the system investigated there are two reaction chain carriers—the acetylperoxy-radicals $\mathrm{RCOOO}^{\bullet}$ and the polyperoxy-radicals $\mathrm{MO}_2^{\bullet}$ (M = styrene molecules), which propagate two independent process pathways—monomeric and polymeric respectively. This claim is supported in particular by the absence of dependence of the rate of accumulation of the monomeric products on the presence of nitroxy-radicals in the system. The existence of a definite nitroxy-radical concentration at which the radicals do not inhibit the oxidation of the aldehyde but fully inhibit the formation of polymeric products, indicates the independence of the concentration of the radicals RCOOO$^{\cdot}$ or the concentration of the radicals $MO_2^{\cdot}$, i.e. a negligibly low rate of the radical "exchange" reaction

$$MO_2^{\cdot} + RCHO \xrightarrow{O_2} RCOOO^{\cdot} + MOOH \ .$$

In this case the addition of the radicals RCOOO$^{\cdot}$ to the double bond of the monomer is in essence a reaction involving the destruction of the chain in the monomeric reaction pathway:

$$RCOOO^{\cdot} + M \xrightarrow{k_g} M^{\cdot} \qquad (17)$$

Taking into account the simultaneous occurrence in the system of two independent processes, one may conclude that, as a result of reaction (12) (see Scheme 1), the nitroxy-radical reduces the concentration of the radicals $MO_2^{\cdot}$ without affecting the stationary concentration of RCOOO$^{\cdot}$. The appreciable change in the ratio of the concentrations of the radicals propagating different process pathways in favour of RCOOO$^{\cdot}$ leads to the observed increase of the selectivity of the reaction with respect to monomeric products.

The presence of the induction period caused by the introduction of the nitroxy-radical indicates the fulfillment of the condition $W_7 \gg W_{17}$: on the other hand, at the end of the induction period $W_{17} > W_7$. The rate of reaction (12) should then exceed the rate of reaction (16) (in Scheme 1), which is a condition for the inhibition of the polymeric process pathway, i.e.

$$k_7[\mathrm{RCO}^{\cdot}]\left[\rangle \mathrm{NO}^{\cdot}\right] < k_g\,[\mathrm{RCOOO}^{\cdot}]\,[M]\ ,$$

$$k_{12}\,[\mathrm{M}^{\cdot}]\left[\rangle \mathrm{NO}^{\cdot}\right] > k_{16}\,[\mathrm{MO}_2^{\cdot}]^2 \quad .$$

Bearing in mind that, during the occurrence of the chain propagation reactions

$$\mathrm{RCOOO}^{\cdot} + \mathrm{M} \xrightarrow{k_h} \mathrm{H_2C}\overset{\mathrm{O}}{\overline{\quad}}\mathrm{CH{-}C_6H_5} + \mathrm{RCOO}^{\cdot}\ , \qquad (18)$$

$$\mathrm{RCOOO}^{\cdot} + \mathrm{M} \xrightarrow{k_i} \mathrm{C_6H_5CHO} + \mathrm{RCOO}^{\cdot} + \mathrm{HCHO}\ , \qquad (19)$$

we have

$$\frac{[\mathrm{RCOOO}^{\cdot}]}{[\mathrm{RCO}^{\cdot}]} = \frac{k_1\,[\mathrm{O_2}]}{(k_h + k_i)[\mathrm{M}]};\ \frac{[\mathrm{MO}_2^{\cdot}]}{[\mathrm{M}^{\cdot}]} = \frac{k_{14}\,[\mathrm{O_2}]}{k_{15}\,[\mathrm{M}]}\ ,$$

$$k_g\,[\mathrm{RCOOO}^{\cdot}]\,[\mathrm{M}] = k_{12}\,[\mathrm{M}^{\cdot}]\left[\rangle \mathrm{NO}^{\cdot}\right] = W_0\ ,$$

the following equation is obtained:

$$\frac{k_1 k_g[\mathrm{O_2}]}{k_7(k_h + k_i)} > \left[\rangle \mathrm{NO}^{\cdot}\right] > \frac{k_{14}\,(W_0 k_{16})^{1/2}\,[\mathrm{O_2}]}{k_{12}k_{15}\,[\mathrm{M}]}\ . \qquad (20)$$

Condition (20) defines the limits of the nitroxy-radical concentration range in which selective inhibition of polymerisation processes, accompanying the oxidation in the acetaldehyde–styrene system, should be observed. The boundary condition for other systems can be derived analogously.

The phenomenon of selective inhibition can be observed in the oxidation of not only binary systems but also of individual compounds having several functional groups with different reactivities, for example, unsaturated aldehydes. This has been used, in particular, in the development of an effective method for the preparation of methacrylic acid[87] by the liquid-phase catalytic oxidation of methacrolein in the presence of the nitroxy-radicals (I) or their 4-hydroxy-derivatives. It is distinguished by simplicity and economy compared with the industrial method of synthesis of methacrolein from acetone via the cyanohydrin. Fig.5 illustrates kinetic curves for the liquid-phase oxidation of methacrolein to methacrylic acid. The use of nitroxy-radicals makes it possible to increase the selectivity in the formation of methacrylic acid to 75–80 mole %. Acetic acid, which also has many applications, is mainly formed as a side product.[97]

In conclusion we shall formulate the necessary and sufficient conditions for selective inhibition:

(1) the existence in the system of two types of free radicals each of which is responsible for the formation of a specific product or group of products; (2) the independence of the concentration of radicals of one type from that of the radicals of the other type; (3) the presence in the system of a definite amount of inhibitor satisfying condition (20); (4) the maintenance of the required inhibitor concentration for a period sufficiently long to ensure the occurrence of a chemical reaction; when nitroxy-radicals are used, this condition is usually fulfilled by means of effective regeneration.

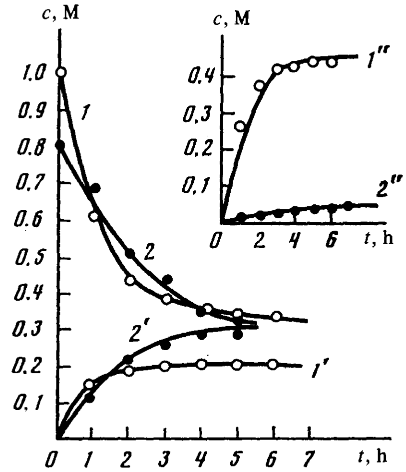

Figure 5. Kinetic curves for the consumption of methacrolein (curves *1* and *2*) and the accumulation of methacrylic acid (curves *1'* and *2'*) and the sums of the side products (curves *1''* and *2''*) in the liquid-phase oxidation of methacrolein by air in benzene (70 °C, 25 atm, 2.5 g litre^{-1} of the TiB_2 catalyst: 1) without inhibitor; 2) in the presence of 1.2×10^{-5} M 4-hydroxy-derivative of the nitroxy-radical (I).[97]

The possibilities in the application of nitroxy-radicals in chemistry are not limited to those already known, the most important of which at the present time are the photostabilisation and inhibition of the oxidative degradation of polymers, the stabilisation of monomers, and also the detection and determination of the active chemical species. Under conditions where the petrochemical raw material resources are diminishing, the ability of nitroxy-radicals to increase the selectivity of the oxidative conversion of hydrocarbons into the required products is very important from both theoretical and practical points of view. The possibility of increasing the efficiency of such processes is associated with the search for new, more effective and at the same time cheap nitroxy-radicals and also with the development of economical methods of synthesis of nitroxy-radicals which are likely to satisfy the future requirements of the chemical industry.

Compounds of the Halogen Cations

B.D.Stepin

The conditions for the synthesis, the thermodynamics of the formation and decomposition, the structure, and the nature of the chemical bond in the halogen cations are examined. The electronic, vibrational, nuclear quadrupole resonance, and nuclear magnetic resonance spectra are analysed and questions concerning the practical application of the halogen cations as some of the most powerful oxidants, are discussed.
The bibliography includes 216 references.

I. INTRODUCTION

The compounds of halogen cations are complexes with a singly charged cation $[Hal(Hal'_nHal''_m)]^+$, where Hal is the complex forming halogen (Cl, Br, I, or At) in the +3, +5, or +7 oxidation states, while Hal' and Hal" are halogen ligands (ranging from F to At). The ligands can also be numerous interhalogen compounds and apparently pseudohalogens. Fluorine is the commonest ligand.

The term "halogen cations" was introduced by Arotsky and Symons[1] and has come to be widely used.[2-5] The first review of the chemistry of the halogen cations was published in 1962[1] and was followed by others.[4,6-9] During the period since the publication of the last review, the number of studies on the chemistry of the halogen cations has doubled and it became necessary to give a systematic account of the accumulated data and to describe more fully the studies by Soviet workers.

There is now no doubt that the complex forming agent in the cation $[Hal(Hal'_nHal''_m)]^+$ is always the most electropositive of the halogens. With increase of its electropositivity and also with increase of the strength of the Lewis acids from which the anions have been derived ($BF_3 < PF_5 < PtF_5 < SbF_5 < AsF_5$). the stability of the halogen cation compounds increases. The compounds of halogen cations are mainly ionic species with a certain amount of covalent character in the chemical bonds, which is manifested by the formation of halide bridge bonds between the cation and the anion. Extremely electrophilic cations, namely $[I_3]^+$, $[ICl_2]^+$, $[IF_6]^+$, $[ClF_2]^+$, etc., can exist only in media with very weak basic properties (superacids, SO_2, SbF_5, IF_5, etc). With weakly basic anions, such as $[SbF_6]^-$, $[AlCl_4]^-$, $[SbCl_6]^-$, etc., cations of this kind form crystalline phases.

The synthesis of the halogen cation compounds is based on the interaction of interhalogen compounds, halogens, or their mixtures with strong Lewis acids (acceptors of halogen atoms), for example in accordance with the mechanism

$$BrF_3+AsF_5=[BrF_2][AsF_6] \ .$$

On the other hand, if a strong Lewis base (a halogen atom donor) is introduced into the reaction instead of the Lewis acid, then representatives of another group of complexes, namely compounds of halogenate anions,[10-12] are formed from the solution, for example:

$$BrF_3+CsF=Cs[BrF_4] \ .$$

For this reason in solutions of interhalogen compounds, compounds of halogen cations and the halogenate anions interact as Lewis acids and bases:[6,13,14]

$$[BrF_2][AuF_4]+Ag[BrF_4]=Ag[AuF_4]+2BrF_3 \ .$$

The chemistry of the halogen cation compounds is so far in the initial stage of its development. In this review, which is the first in the Soviet literature, an attempt is made to identify the most promising research trends and to describe the principal properties and reactions of the halogen cation compounds and the methods of their synthesis.

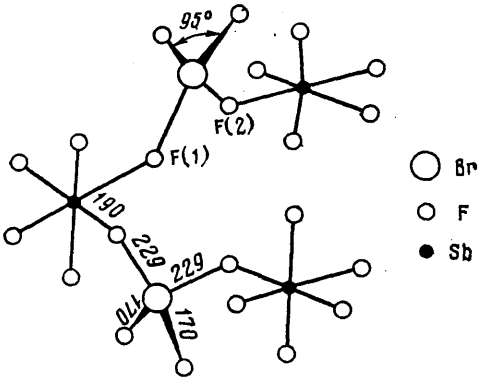

Figure 1. Schematic illustration of the structure of $[BrF_2]$. $.[SbF_6]$ [17,18] (the interatomic distances are indicated in pm).

II. THE STRUCTURE AND NATURE OF THE CHEMICAL BOND

All the triatomic halogen cations, namely $[I(I)_2]^+$, $[BrF_2]^+$, $[ClF_2]^+$, and similar species, have a bent structure (Fig.1), in which the angle between the bonds is 91–103° (C_{2v} symmetry).[15-21] We may note that the triatomic halogenate anions, i.e. $[I_3]^-$, $[BrF_2]^-$, $[ICl_2]^-$, etc, are linear and symmetrical.[10] With increase of the electronegativity of the central atom, its effective positive charge diminishes $\{\delta = 1.48$ for $[BrF_2]^+$ and 0.98 for $[ClF_2]^+\}$ and at the same time the effective charge of the ligands changes (from $\delta = -0.24$ to $\delta = 0.01$ for the same cations).[16,22-27] The effective charges on the central atom and the ligands in the cation $[Cl(ClF)]^+$ are respectively 0.324 and 0.338.[23-29] The values of δ quoted in the literature differ and depend on the methods of calculation. In particular, δ for Hal = I in the $[I_3]^+$ cation varies over the range 0.55–0.79.[15,30,31]

As in the triatomic halogenate anions, in the triatomic halogen cations only the *p* orbitals of the central atom and the ligands participate in the formation of the bond.[32] The population of the *d* orbitals in the $[I_3]^+$ and $[I_3]^-$ ions is insignificant and their involvement in bond formation is not obligatory. When an electron pair is removed from the $[I_3]^-$ anion with formation of the $[I_3]^+$ cation, the valence state of the central atom remains unchanged and only the degree of its oxidation increases.[32] An increase in the overall *f*-electron density on the complex-forming agent (iodine) compared with the free I^- ion has been noted but the complex-forming agent–ligand interatomic distance in the $[I_3]^+$ ion is the same as in gaseous iodine.

Under certain conditions, iodine atoms can produce the diamagnetic cation $[I_4]^{2+}$, which has no complex-forming agent[34-36] and the chain cations $[I_{15}]^{3+}$ (Fig.2). The latter cation consists of three $[I_5]^+$ ions linked to one another with the central atoms E(1), I(1), and E(2). The bond lengths in the ligands and in the gaseous iodine molecule are comparable, the smallest distance between the iodine atoms in neighbouring chains being 390.6 pm.[37] According to Chung and Cady,[38] the existence of the cation $[I_7]^+$ is doubtful.

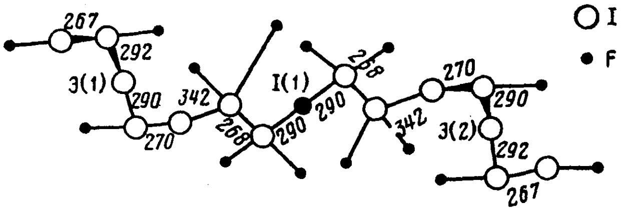

Figure 2. The configuration of the ion $[I_{15}]^{3+}$ [37] (the interatomic distances are given in pm): E(1), E(2), and I(1) are central atoms.

The angular structure of the cations $[ClF_2]^+$ and $[BrF_2]^+$ (Fig.1) corresponds best to the model comprising localised *p* orbitals with two covalent p_σ bonds.[16,22-26,39] The ligands of the cations together with the *cis*-bridging halogen atoms of the anion [F(1) and F(2), see Fig.1] form a deformed square. The sterically active unshared electron pairs of the complex-forming agent are in the *trans*-positions above and below the plane of the square (Fig.3*b*) and the cations are therefore classified as pseudohexacoordinated.[15,20,26,27] If the cation is regarded as a planar square, then the chemical bonds can be represented by two mutually perpendicular asymmetric four-electron semi-ionic p_σ bonds formed by the np_x and np_y orbitals of the central atom. The involvement of the *nd* orbitals is in this case insignificant and they are regarded[23,40] merely as having polarisation functions. For example, the population of the 3*d* orbital of the chlorine atom in the cation $[ClF_2]^+$ is only 0.05e.[40]

Fig.3 presents models of the valence bonds in the triatomic cations. When E = Cl or Br and X = Y = F, the interatomic X–X, Y–Y, and X–Y distances are 340, 230–250, and 270–280 pm respectively.[16] The E–X bond length increases, for the same complex-forming agent, on passing from X = Cl to X = I.[17,41] The E–Y bond order is 0.42–0.47.[42] The bond length ratio (E–X)/(E–Y) in the cations considered is 1.04–1.05 and diminishes with increase of the E–Y bond strength on passing from E = Cl to E = I.[8]

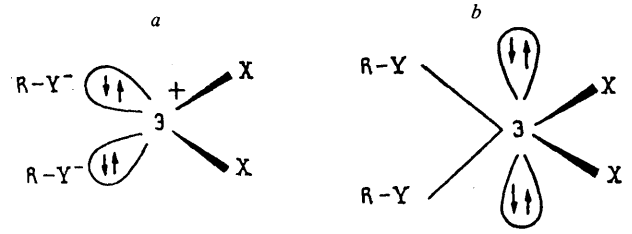

Figure 3. The planar ionic (*a*) and bridged (*b*) structures of the halogen cation compounds with an angular cation;[15,26] E = complex forming agent, X = ligands, and Y = bridging ligands of the anions.

With decrease of the bond angle in the cation, the degree of covalence of the bond between the complex-forming agent and the bridging ligand increases.[26] If the bridging ligands of the anions form strong bonds with the complex-forming agent in the cation, then all the electron pairs occupy octahedral sites with the angle between the bonds approximately 90°.[39,43] It is believed[27] that the strength of the covalent bond between the cation $[BrF_2]^+$ (Fig.1) and the anions increases from $[SbF_6]^-$ to $[GeF_6]^- \cong [Sb_2F_{11}]^-$.[23-25,27] Owing to the strong solvation of $[BrF_2]^+$ in liquid BrF_3, the Br–F bond length increases, which induces a shift of the ν_1 band in the Raman spectrum from 705–707 cm^{-1} to 625 cm^{-1}.[44] In the crystals of $[ICl_2][SbCl_6]$, the iodine atoms of the two ligands of the cation and the two bridging ligands are disposed virtually in the same plane, as in the structure of the anion $[ICl_4]^-$.[19,30,45]

The interhalogen compounds $[I(ICl)_2]^+$ (Fig.4)[46-48] and $[I(IBr)]^+$[48] can also serve as ligands in the cations. In the coordinated ICl and IBr molecules the bonds are shorter than in the single molecules. The anion $[SbCl_6]^-$ converts the cation $[I(ICl)]^+$ into a symmetrical ion, while the anion $[AlCl_4]^-$ converts it into an asymmetric ion.[48] The anion $[AlCl_4]^-$ alters also the interatomic distances in the ICl ligand: I(2)–Cl(1) ≠ I(3)–Cl(2). Nevertheless the cation remains planar (Fig.4).

The attempts[49,50] to represent the cation $[Cl(ClF)]^+$ as having a symmetrical structure in which the central atom is fluorine failed. Analysis of the vibrational spectra and quantum-mechanical calculations showed that this cation is asymmetric.[8,22]

Among the penta-atomic cations $[(Hal(Hal')_4]^+$, only compounds of the type $[HalF_4]^+$ (Hal = Cl, Br, or I) are so far known. They have a trigonal-bipyramidal structure (C_{2v} symmetry) with the unshared electron pair in the equatorial plane.[51-53] This structure has been confirmed by X-ray diffraction and NMR. Quantum-mechanical calculations lead to the C_{2v} symmetry only when the *d* orbital of the central atom is used.[54,55] The hepta-atomic cations $[Hal(Hal')_6]^+$ are also known only with fluoride ligands. The octahedral structure of the cations $[ClF_6]^+$, $[BrF_6]^+$, and $[IF_6]^+$ has been explained either by the sp^3d^2 hybridisation of the atomic orbitals of the central atom or by the involvement of all of its three delocalised pairs of *p* electrons in the formation of three polar three-centre four-electron σ-bonds of the *p*–*p* type.[56,57] The high symmetry of the environment of the complex-forming agent has been confirmed by the analysis of ^{129}I Mössbauer,[58,59] NMR,[60,61] and vibrational spectra.[62]

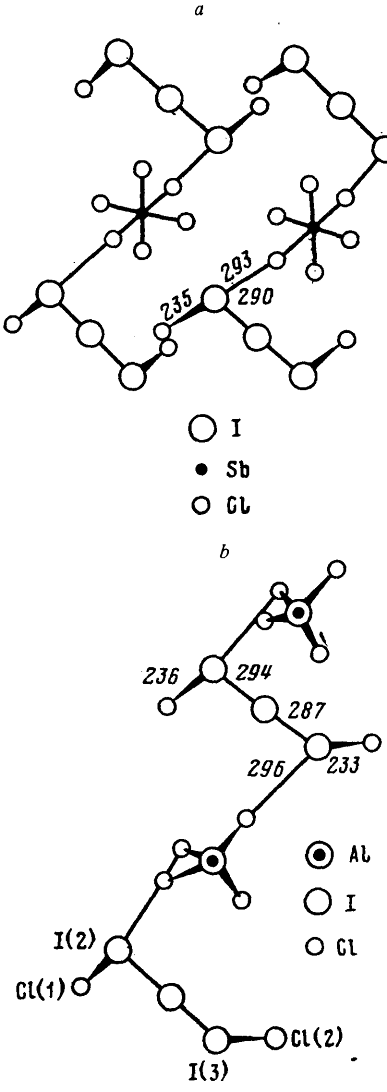

Figure 4. Fragments of the structures of $[I(ICl)_2][SbCl_6]$ (*a*) and $[I(ICl)_2][AlCl_4]$ (*b*)[48] (the interatomic distances are given in pm).

The effective charges on Cl(VII) and Br(VII) in the cations $[ClF_6]^+$ and $[BrF_6]^+$ are respectively +2.998 and +2.859, while those on the ligands are −0.332 and −0.310.[23–25] Most of the halogen cations investigated form crystals belonging to the triclinic and monoclinic systems (Table 1). Almost all the anions, except $[AlCl_4]^-$ and $[BF_4]^-$, have a somewhat distorted octahedral symmetry, ranging from O_h to D_{4h}, owing to the presence of bridging ligands.[17] The octahedral structure of the cations and anions increases the symmetry of the crystal lattice of the halogen cations to the symmetry corresponding to the cubic system (space group P_a3). In particular, $[IF_6][AuF_6]$, $[IF_6][SbF_6]$, $[IF_6][AsF_6]$, $[BrF_6]\cdot[AsF_6]$, and $[ClF_6][PtF_6]$ crystallise in the cubic system with the parameter *a* equal to respectively (pm) 957.3,[8,65] 606.9,[8,66] 949.3,[56,65] 939.4,[8,67] and 939.[68] Only the crystal lattice of $[IF_6][RuF_6]$ has different parameters (space group $P2_1/n$; $a = 981$, $b = 761$, and $c = 580$ pm; $\beta = 107.8°$).[65]

*Abbreviations for crystal systems: Tr = triclinic, M = monoclinic, Or = orthorhombic, and T = tetragonal.

It is noteworthy that the cation $[BrF_2]^+$ forms with many singly charged anions crystals having almost identical crystal lattices (Table 1). The crystal lattices of $[I(IBr_2)][SbCl_6]$ and $[I(BrCl)][SbCl_6]$ are also very similar despite the different nature of the ligands in the cations. The replacement of the ligands in the anions for the same cation alters sharply the crystal system—cf $[ICl_2][SbCl_6]$ and $[ICl_2][SbF_6]$ in Table 1.

The crystal lattices of the halogen cation compounds consist of infinite chains of cations and anions linked by halide bridges. The compounds are therefore regarded as partly covalent *cis*-bridged polymers.[42] The most important optical constants of the crystals of the halogen cation compounds are still to be determined, but one can already say that the vast majority of the crystals must be optically anisotropic and biaxial.

III. THE ELECTRONIC, VIBRATIONAL, NQR, and NMR SPECTRA

The electronic spectra (Table 2) are mainly used for the identification of the cations from the values of ε, the wavelengths of the absorption band maxima, and the shape of the latter. The bathochromic and hypsochromic effects and the presence of isosbestic points, which might yield information about the number of different cations in solution, have not been investigated. It follows from Table 2 that, for a number of halogen cation compounds, the absorption band in the range 435–470 nm apparently corresponds to the $\Pi^0 \rightarrow \Pi^*$ transitions which should have a low value of ε ($\lg \varepsilon < 3.30$).

*There is a low-slope shoulder on the absorption curve.

The electronic spectra of solutions of certain halogen cation compounds have been little investigated. The cation $[I_5]^+$ in solution in HSO_3F is characterised by absorption bands at 240, 270, 345, and 450 nm, while in solution in 96% H_2SO_4 it is characterised by bands at 330 and 450 nm.[8] Absorption bands at 270 nm ($\lg \varepsilon = 3.0$), 340 nm ($\lg \varepsilon = 2.5$), and 488 nm ($\lg \varepsilon = 1.9$) correspond to the cation $[I(BrCl)]^+$ in solution in 96% H_2SO_4.[77,78] The reddish-brown colour of the solution and the appearance of absorption bands at 305 and 470 nm are characteristic of the cation $[I_3]^+$. The absorption band at 440 nm (solution in SO_2 [46]) corresponds to the cation $[I(ICl)_2]^+$, while the bands at 248–252 and 305 nm (solution in SbF_5) correspond to the cations $[BrCl_2]^+$ and $[Br(BrCl)]^+$.[72]

The main information about the vibrational spectra of polycrystalline halogen cation compounds are presented in Tables 3–5. They have been fairly completely analysed by Shamir.[8] It is noteworthy that the assignment of many bands is still obscure. According to Gillespie and Morton[4] and Surles and Quarterman,[88] the band at 384–387 cm^{-1} in the Raman spectrum of the cation $[ClF_2]^+$ corresponds to ν_2 vibrations, while according to Christe and co-workers[39,89] the band at 544 cm^{-1} corresponds to these vibrations. The same discrepancy has been observed also in the assignment of the 537 cm^{-1} band in the IR spectrum of the same cation. The identification of the bands in the vibrational spectra of the cations $[IBr_2]^+$ and $[ICl_2]^+$ is also uncertain.

The angular structure of the triatomic cations has been confirmed not only by the activity of the three normal vibrations ($2A_1 + B_1$) in the IR and Raman spectra but also by the similarity of the ν_1 and ν_3 frequencies. Furthermore, the virtual identity (to within ±10 cm^{-1}) of the vibration frequencies of the halogen cation compounds dissolved in HF and of the crystals of their compounds indicates the presence in the liquid and solid phases of the same discrete ions $[Hal(Hal')_2]^+$.

The frequencies of all nine species of the normal vibrations of the cations $[Hal(Hal')_4]^+$ ($4A_1 + A_2 + 2B_1 + 2B_2$) have been found in the Raman and IR spectra (Table 4). The most intense band in the range 720–820 cm^{-1} corresponds to the symmetrical (ν_1) and antisymmetric (ν_8) equatorial vibrations of the Hal–Hal' bond. The frequencies of the antisymmetric (ν_6, B_1) axial vibrations are apparently identical with the frequencies of the type ν_1 vibrations.

Table 5 shows that $\nu_1 < \nu_2$ for the cations $[BrF_6]^+$ and $[IF_6]^+$, in contrast to $[ClF_6]^+$. This has also been confirmed by quantum-mechanical calculations.[104] In the octahedral ions with heavy complex-forming agents, the fully symmetrical vibration leads to the appearance of polarised lines in

R = Raman spectrum (Editor of Translation).

the Raman spectrum (ν_1), while lower symmetry vibrations give rise to depolarised scattered radiation (ν_2) and causes the reversal of the frequencies ν_1 and ν_2.[104]

The vibrational spectrum of the cation $[ClF_6]^+$ resembles the spectrum of the isoelectronic SF_6 molecule and the isotopic splitting ($^{35}Cl-^{37}Cl$) of the ν_3 band (890 cm^{-1}), amounting to 13 cm^{-1}, agrees well with the calculated value (12.5 cm^{-1}) for the octahedral structure.[99] In the Raman spectrum of the cation $[ClF_6]^+$, the weak band at 706 cm^{-1}, identified[62] as the $2\nu_6(A_{1g} + E_g + F_{1g} + F_{2g})$ band, is involved in Fermi resonance with the $\nu_1(A_{1g})$ band at 688 cm^{-1} (Table 5).

For the series of cations $[ClF_6]^+$, $[BrF_6]^+$, and $[IF_6]^+$, the stretching force constants f_r are respectively 4.98, 4.90, and 5.42 mdyn A^{-1}.[67] These values are highest for the Cl–F, Br–F, and I–F bonds owing to the high oxidation states of the complex-forming agent.

Extensive investigations of the NQR spectra of the ligand and central atom nuclei established the non-equivalence of the halogen atoms in the cations and the presence of bridge bonds between the cation and anion.[8,105] In particular, analysis of the ^{127}I NQR spectrum of the compound $[I_3][AlCl_4]$ confirmed that one of the iodine atoms in the cation is the complex-forming agent,[30,31] and the cation $[I_3]^+$ should therefore be described by the formula $[I(I)_2]^+$. Furthermore, the dimorphism of $[I_3][AlCl_4]$ has been observed. The frequency 400 ± 5 MHz in the ^{127}I NQR spectrum characterises the complex forming agent in the cation $[I_5]^+ = [I(I_2)_2]^+$.[30]

The frequency of the ^{35}Cl signal in the NQR spectra (at −195 °C) of the halogen cations $[ClF_2]^+$ and $[ClF_4]^+$ is determined, according to the authors,[106,107] by the electron-accepting capacity of the anion. The signal is more intense, the higher the electron-accepting capacity of the anions, which can be arranged in the following sequence in terms of the increase of this capacity: $[TaF_6]^- < [NbF_6]^- < [SbF_6]^- < [AsF_6]^- < [Sb_2F_{11}]^-$. The asymmetry parameter η of the electric field gradient of the complex forming atoms of the cations $[ClF_4]^+$ and $[IF_4]^+$ is 48–50%.[108] After the appearance in the halogen cations of the *cis*-configuration of the Cl–F and I–F bridge bonds with the two SbF_6 octahedra of the $[Sb_2F_{11}]^-$ anions, the values of η and the quadrupole interaction constants diminish somewhat.[108]

Many halogen cation compounds have been investigated by NMR. Two equally intense signals (δ = −256 and −274 p.p.m.), measured relative to $CFCl_3$ at a temperature below −60 °C, in the ^{19}F NMR spectrum of the cation $[ClF_4]^+$ indicate the non-equivalence of the positions of the two fluorine atoms.[53,109,110] which corresponds to a trigonal-bipyramidal structure of the cation and the presence of bridging F atoms. Analysis of the ^{35}Cl and ^{127}I NMR spectra of the cation $[I(ICl)]^+$ established[30,31] that one of the iodine atoms is the complex-forming agent, while the other is the ligand. The angular structure of the cations $[ClF_2]^+$ and $[BrF_2]^+$ [109–112] and the octahedral structure of the cations $[ClF_6]^+$ and $[BrF_6]^+$ [61,99,109,113] have been confirmed.

The ^{129}I Mössbauer spectrum of the cation $[IF_6]^+$ consists of a single signal with the isomeric shift δ = −4.68 mm s^{-1}, which is characteristic of highly symmetrical cations.[8,59]

IV. THERMODYNAMICS OF FORMATION AND DECOMPOSITION

The appearance in solution of the cations $[Hal(Hal')_n]^+$ is not associated with the usual complex-forming reactions and the problem of consecutive equilibria. However, such cations are complex species and enter the ligand substitution, addition, and redistribution reactions characteristic of complex compounds. For example, the following reactions take place in solution in HSO_3F:[77,78]

$$[IBr_2]^+ + Cl_2 \rightleftarrows [ICl_2]^+ + Br_2;\ [IBr_2]^+ + [ICl_2]^+ \rightleftarrows 2[I(BrCl)]^+;$$
$$[I(I)_2]^+ + [ICl_2]^+ \rightleftarrows 2[I(ICl)]^+;\ I(SO_3F) + IBr \rightleftarrows [I(IBr)](SO_3F).$$

When the anion is replaced, some of these reactions become impossible under previous conditions. In particular, the reaction

$$I(SO_3CF_3)+Hal_2 \rightleftharpoons [I(Hal)_2](SO_3CF_3)$$

takes place only with participation of $Hal_2 = Br_2$; this is due to the low solubility of $I(SO_3CF_3)$ and its polymeric structure.[77,78]

In the reactions presented above, the more electropositive ligand is always substituted by a more electronegative one and the less electropositive complex-forming agent is replaced by a more electropositive one. Reactions are known[114] in which two ligands are substituted at once:

$$[Cl(ClF)][AsF_6]+Cl_2 \rightleftharpoons [Cl(Cl)_2][AsF_6]+ClF\ ;$$
$$[Cl(ClF)][AsF_6]+SOF_2 \rightleftharpoons [Cl(SOF_2)][AsF_6]+ClF\ .$$

The latter reaction occurs even at −130 °C with 85% yield. The substitution of two ligands is apparently preceded by an elimination reaction with formation of two radical species, $Cl^{\bullet}$ and $F^{\bullet}$, which then combine to form the molecule ClF.

The substitution reactions make it possible to establish the following stability series of the cations:[115,116]

$$[IF_2]^+>[BrF_2]^+>[ClF_2]^+;\ [ICl_2]^+>[BrCl_2]^+>[Cl(Cl)_2]^+.$$

The mechanism of the formation of halogen cation compounds has not been ultimately elucidated. It has been suggested that[6,8,9,117] interhalogen compounds or halogens initially dissociate:

$$2BrF_3 \rightleftharpoons [BrF_2]^+ + [BrF_4]^-;\ 3IBr \rightleftharpoons [I(IBr)]^+ + [IBr_2]^-;$$
$$4ICl \rightleftharpoons [I(ICl)_2]^+ + [ICl_2]^-;\ 3I_2 \rightleftharpoons [I_3]^+ + [I_3]^- \text{ etc.,}$$

According to the data of Surles and Hyman,[93,118] on dissociation of BrF_3 (at 30 °C), the concentration of the ions formed is 0.9 ± 0.1 M. The equilibrium constant for the reaction

$$BrF_3+ClF_3 \rightleftharpoons [ClF_2]^+ + [BrF_4]^-$$

at 25 °C and for a BrF_3 mole fraction of 0.22–0.85 is 1×10^{-4}.[116,119] The introduction of electrophiles and nucleophiles (AsF_5, $SbCl_5$, $AlCl_3$, etc.) shifts the equilibrium towards the formation of halogen cation compounds:

$$[BrF_4]^- + SbF_5 \rightleftharpoons BrF_3 + [SbF_6]^-;\ [ICl_2]^- + AlCl_3 \rightleftharpoons ICl + [AlCl_4]^- \text{ etc.,}$$

In the intermediate stages of the formation of the cations, there is a possibility of the appearance of radical-anions. For example, it has been assumed[120] that the abstraction of electrons from Cl_2 can induce the formation of the planar radical cation $Cl_4^{\dot{+}}$ from $Cl_2^{\dot{+}}$ and Cl_2 (weak $\pi-\pi^*$ interaction).

In our view, another mechanism for the formation of halogen cation compounds is also possible:

$$BrF_3+SbF_5 \rightleftharpoons BrF_3\cdot SbF_5 \rightleftharpoons [BrF_2][SbF_6]\ .$$

According to this scheme, an adduct without a rigid nuclear configuration is formed initially and then bridge bonds arise between BrF_3 and SbF_5 as a result of the migration of the nuclei and the redistribution of electron density by virtue of the low activation energy. After this, the fluoride ion is transferred.

The calorimetric method has not so far come to be widely used in the study of the formation reactions of halogen cation compounds. Systematic investigations in this field are only just beginning. In particular, the enthalpies of solution (at 25 °C) of SbF_5, SnF_4, and TaF_5 in BrF_3, which represent the overall energies of the dissolution process and the chemical reaction, are respectively −92.3 ± 0.3, −58.8 ± 0.7, and −45.2 ± 0.8 kJ per mole of the dissolved fluoride.[119] On the other hand, the enthalpies of formation ($-\Delta H^0_{298}$) of $[BrF_2][SbF_6]$, $[BrF_2]_2[SnF_6]$, and $[BrF_2][TaF_6]$ are respectively 1773, 1505, and 2251 kJ mol^{-1}. The last quantity includes ΔH^0_{298} for the formation of BrF_3 and TaF_5. On the other hand, the enthalpies of solution of the same halogen cation compounds in BrF_3 at 25 °C are respectively −4.94, −2.00, and −1.40 kJ mol^{-1}.[119] For the reaction

$$K[BrF_4]+[BrF_2][SbF_6]=K[SbF_6]+2BrF_3\ ,$$

in BrF_3, $\Delta H^0_{298} = -19.1 \pm 1.0$ kJ mol^{-1}. With increase of the degree of solvolysis of the interacting substances, this quantity diminishes and amounts to −15.3 ± 0.8 kJ mol^{-1} for the same reaction involving $[BrF_2][TaF_6]$.[119]

The thermal stabilities of the halogen cation compounds are different. Whereas the compounds containing the cation $[Cl_3]^+$ decompose fully at 25 °C, $[Br_3][AsF_6]$ dissociates only above 70 °C with evolution of Br_2, while in an atmosphere of nitrogen it sublimes without decomposition at 30–50 °C.[71] The halogen cation compounds $[I_3][AlCl_4]$ and $[I_3](SO_3F)$ melt congruently at 45° ± 1 °C[30,31] and at 92–101 °C[38,74] respectively.

Table 6 presents certain thermodynamic characteristics of the thermal decomposition reactions.

$$[Hal(Hal')_n][MHal'_m] \rightleftharpoons Hal(Hal')_{n+1}+MHal'_{m-1}\ .$$

The enthalpies of the thermal dissociation reactions ΔH^0_g, listed in Table 6, were found from the slopes of the $\lg p = f(1/T)$ curves subject to the condition that the enthalpies of sublimation of the test substances are zero.

Table 6. Certain thermodynamic characteristics of the thermal dissociation of halogen cation compounds.

Substance	$\lg p$ (mmHg)	T, K	ΔH^0_g, kJ mol^{-1}	$-\Delta H^0_{298}$, kJ mol^{-1}	Refs.
$[ClF_2][BF_4]$	$\frac{-2576+16}{T}+(12.00\pm0.06)$	243–293	98.7	1394.5	[14, 89, 121]
$[ClF_2][PF_6]$	$-1798/T+10.53$	—	68.6	1827.1	[8, 14, 89]
$[Cl(ClF)][AsF_6]$	$-2391.6/T+11.71$	209–255	137.2	1487	[50]
$[BrF_2][SbF_6]$	$-3030/T+7.66$	498–623	116.3	1773*	[12, 119, 122]
$[ClF_4][AsF_6]$	$-2763.6/T+12.2$	242–283	105.6	1576.5	[123]
$[IF_6][AsF_6]$	$-4800/T+16.42$	—	183.7	2251	[56]

Notation: p is the thermal dissociation pressure and ΔH^0_g the enthalpy of thermal dissociation.

*Found from calorimetric measurements.[119]

The complex $[ClF_2][BF_4]$ dissociates fully into ClF_3 and BF_3 in the gas phase at temperatures above 30 °C, while $[Cl(ClF)][BF_4]$ decomposes already at temperatures above −112 °C and in the liquid state this substance is unknown.[50] The products of the thermal decomposition of the complex $[Cl(ClF)][AsF_6]$ are gaseous ClF and AsF_5. $\Delta G^0_T = 9.0$ kJ mol^{-1} and $\Delta S^0_T = 491.2$ J mol^{-1} K^{-1} for this reaction.[50] The enthalpy of the thermal dissociation of $[BrF_2][SbF_6]$ in the range 130–350 °C, calculated from vapour pressure data, is 116.3 kJ mol^{-1}, while the calorimetric value is 186 kJ mol^{-1}.[119] The thermal dissociation pressure of $[BrF_2][BF_4]$ at −31 °C is 4 mmHg, while at 23 °C the halogen cation compound decomposes fully.[124]

The stability of the complexes with the cation $[IF_2^+]$ increases in the series of anions $[BF_4]^- < [AsF_6]^- < [SbF_6]^-$. Whereas the compound $[IF_2][BF_4]$ is stable only in solution of acetonitrile, the compound $[IF_2][SbF_6]$ withstands heating to 45 °C.[125,126] $\Delta G^0_T = 2.9$ kJ mol^{-1} and $\Delta S^0_T = 344.3$ J mol^{-1} K^{-1} have been found[123] for the reaction

$$[ClF_4][AsF_6](\text{cryst.}) = ClF_5(\text{gas}) + AsF_5(\text{gas})$$

The products of the dissociation of $[ClF_4][PtF_6]$ above 25 °C (the vapour pressure at 23 °C is 2 mmHg) are ClF_5, PtF_4, and PtF_6.[91]

The thermal decomposition of substances containing the cation $[ClF_6]^+$ is accompanied by the evolution of fluorine.[62,100] The complex $[ClF_6][PtF_6]$ dissociates above 140–180 °C,[68] while $[IF_6][AsF_6]$ sublimes at 120–140 °C with decomposition into IF_7 and AsF_5 ($\Delta G_T^0 = 32.6$ kJ mol^{-1} and $\Delta S_T^0 = 506.3$ J mol^{-1} K^{-1}).[56,127]

Among the known compounds of the hexafluoride (VII), the complex $[IF_6][BF_4]$ is the least stable, the vapour pressure amounting to 10 mmHg at −60 °C.[127]

V. SYNTHESIS OF HALOGEN CATION COMPOUNDS

The methods of synthesis of halogen cation compounds are based mainly on reactions between interhalogen compounds and halogens and the halides of Group IIIA–VA elements in their highest oxidation states. The halogen cation compounds obtained by one or other preparative method but having the same compositions can exhibit appreciably different melting points[8] and other physical characteristics, which is due to the presence of admixtures of the initial reactants and side products of the reaction. The degree of contamination is reduced only after carrying out the synthesis within the limits of the region of crystallisation of the target products, determined from the phase diagrams of the corresponding systems.

The cation $[Cl(Cl)_2]^+$. The appearance of a phase containing $[Cl_3]^+$ has been observed in the systems Cl_2–ClF–AsF_5 (SbF_5, $SbCl_5$, HF) at −76 °C and below,[4,7,28,70] in the system $[Cl(ClF)][AsF_6]$–Cl_2 at −78 °C,[28] and in the system Cl_2–$SbCl_3$ at −51 °C.[128] The formation of the cation $[Cl_3]^+$ has not been observed in the systems HSO_3F–SO_3–Cl_2–$SbCl_5$ (25 °C, 3 atm)[85] and ClF–Cl_2–BF_3 (at temperatures from 130° to 25 °C).[4,7]

The cation $[Br(Br)_2]^+$. When BrF_5 and Br_2 are condensed in a quartz reactor containing a 30% excess of $AsF_5(SbF_5)$ at −196 °C, brown crystals are formed[71] via the reaction

$$7Br_2+BrF_5+5AsF_5=5[Br_3][AsF_6]\ .$$

The reaction,[71,129]

$$2O_2[AsF_6]+3Br_2=2[Br_3][AsF_6]+2O_2\ .$$

leads to the same result. In order to avoid the formation of the cation $[Br_2]^+$, the molar ratio Br_2/BrF_5 in the first reaction should not exceed 4.5.[72]

The appearance of the cation $[Br_3]^+$, noticed in a number of investigations[4,7,29,70,130,131] in the systems Br_2–$S_2O_6F_2$ (SbF_5, HSO_3F, SO_3) is caused by reactions of the type

$$3Br_2+S_2O_6F_2\rightleftharpoons2[Br_3]^++2SO_3F^-\ .$$

The cations $[I(I)_2]^+$ *and* $[I(I_2)_2]^+$. The formation of new phases with the cations $[I_3]^+$, $[I_5]^+$, and $[I_7]^+$ has been postulated in the systems I_2–$S_2O_6F_2$ [38] and I_2–ICl–$AlCl_3$.[30,31] These phases could not be isolated from the melt. Spectroscopic analysis (^{19}F NMR, IR) of the liquid phases failed to confirm the formation of the cations $[I_3]^+$ and $[I_7]^+$ in the first system. The results of cryoscopic measurements for the same system are contradictory and do not lead to unambiguous conclusions.[38,75,132]

The black-brown powder of $[I_3](SO_3F)$ was obtained[74] only after prolonged treatment of an excess of I_2 with pure $S_2O_6F_2$ at 20 °C with subsequent heating of the mixture to 85 °C and cooling to −180 °C. The possibility of the synthesis of the complex has been pointed out in several investigations.[4,36,133] At a low temperature the interaction of I_2 and $S_2O_6F_2$ leads to formation of the diamagnetic cation $[I_4]^{2+}$ together with $[I_3]^+$,[4,35,36,134] while according to a number of other data[7,29,75] the cation $[I_5]^+$ is also formed.

The compounds $[I_3][AsF_6]$,[15,135] $[I_5][SbF_6]$,[37] and $[I_7]\cdot[SO_3F]$[38] have been obtained in a crystalline state by purely preparative methods. The composition of the last phase requires confirmation.

The results of the study of the systems I_2–HIO_3 (KI, ICI, I_2O_5)–H_2SO_4($HSClO_3$, $K_2S_2O_8$) by conductimetric titration methods, the reddish-brown colour of the solutions, and the electronic spectra indicate the formation of the cation $[I_3]^+$.[1,73,76,133,136] It has been suggested that the cation $[I_3]^+$ should also be formed in the systems I_2–$H_2S_2O_7$,[137] I_2–HSO_3F,[138] I_2–SO_2–SbF_5,[70] ICl–H_2SO_4, I_2–HCl–BCl_3–$K_2S_2O_8$, I_2–CF_3COOH–BF_3–$K_2S_2O_8$, and ICl–BF_3–CF_3COOH.[136] The cation $[I_5]^+$ has been detected in the systems I_2–HIO_3–H_2SO_4 with a molar ratio $I_2/HIO_3 > 7$,[73,133] and also in the systems I_2–H_2SO_4–SO_3 [139] and I_2–SbF_5–AsF_3.[37,140]

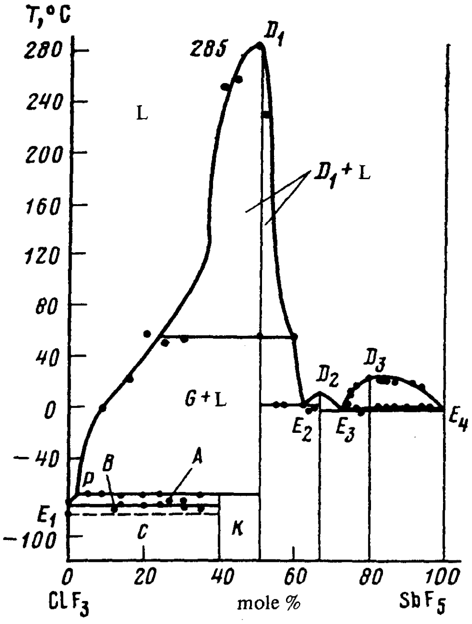

Figure 5. Phase diagram for the system ClF_3–SbF_5:[141] D_1 = α-$[ClF_2][SbF_6]$; D_2 = $ClF_3.2SbF_5$; D_3 = $ClF_3.4SbF_5$; G = β-$[ClF_2][SbF_6]$; P = $3ClF_3.2SbF_5$; A = $3ClF_3.2SbF_5$ + L; B = $3ClF_3.2SbF_5$ + α-ClF_3; C = $3ClF_3.2SbF_5$ + β-ClF_3; L = liquid phase; K = $3ClF_3.2SbF_5$ + β-$[ClF_2][SbF_6]$.

The cation $(ClF_2)^+$. A thorough study[141] of the system ClF_3–SbF_5 (Fig.5) showed that the interaction of its components can result in the formation of not only $[ClF_2][SbF_6]$ and $[ClF_2][Sb_2F_{11}]$ but also of two new phases: $3ClF_3.2SbF_5$ (P) and $ClF_3.4SbF_5$ (D_3). The coordinates of the eutectic points are E_1 = 98 mol% ClF_3, m.p. −72 °C; E_2 = 37.95 mol%, 2 °C; E_3 = 27.50 mol%, 0 °C; E_4 = 1.2 mol%, +7 °C. The compound $[ClF_2][SbF_6]$ is dimorphic with a phase transition temperature of 55 °C. The congruent melting points of the phases D_2 and D_3 are respectively 11° and 25 °C.

Compounds with the cation $[ClF_2]^+$ are synthesised either by condensing ClF_3 on AsF_5 {SbF_5, BF_3, PtF_6, $O_2[PtF_6]$} at −196 °C with subsequent removal of the excess ClF_3 in a stream of nitrogen or by the direct reaction of ClF_3 with AsF_3 (SbF_3, BF_3), which proceeds vigorously even at −70 °C. The excess ClF_3 can convert the chlorides or fluorides of the elements in the lowest oxidation state initially into Lewis acids and then into compounds with the cation $[ClF_2]^+$.[127,142] The compounds $[ClF_2][SbF_6]$,[16] $[ClF_2][AsF_6]$,[26,89,127,143] $[ClF_2][BF_6]$,[12,14,89,121] and $[ClF_2][PtF_6]$ [90,144–146] were obtained in this way in the crystalline state. The individuality of some of these compounds is open to doubt, in particular the melting point data[127,142] for $[ClF_2][SbF_6]$ (75–78 °C) differ by 207–210 °C from those in another study[141] (Fig.5).

The synthesis of $[ClF_2][IrF_6]$ and $[ClF_2][PF_6]$ has been reported.[12,26] The system ClF_6–HF is of the eutectic type (44% ClF_3, m.p. −110.7 °C),[9,12,88,147] although the cations $[ClF_2]^+$ have also been detected in solution.[88,148] The components of the ClF_3–UF_6 system do not interact either.[9,149]

The cation [Cl(ClF)]⁺. Using the synthetic methods described above, the compound $[Cl(ClF)][AsF_6]$, which is stable below −70 °C, was obtained.[50] In solution in the HF–SbF_5 mixture, the cation decomposes even at −76 °C.[4,28]

The cation [BrF₂]⁺. The formation of not only $[BrF_2]$.$[SbF_6]$ (m.p. 129 °C) but also of a series of other new phases, namely $BrF_3.3SbF_5$ (m.p. 33.5 °C), $3BrF_3.2SbF_5$, and $3BrF_3.SbF_5$ has been established in the system BrF_3–SbF_5 (Fig.6). The incongruent melting points of the last two phases are respectively 30.8° and −16.3 °C.[150]

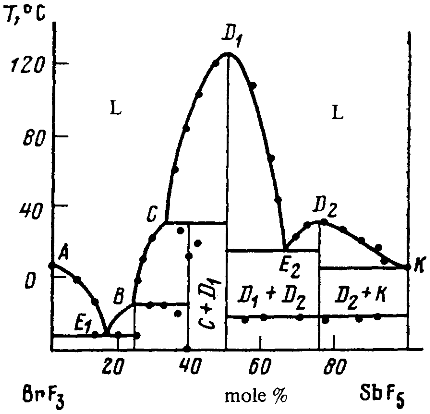

Figure 6. Phase diagram for the system BrF_3–SbF_5;[150] $D_1 = [BrF_2][SbF_6]$; $D_2 = BrF_3.3SbF_5$; $A = BrF_3$; $B = 3BrF_3.SbF_5$; $C = 3BrF_3.2SbF_5$; $K = SbF_5$. Coordinates of the eutectic points: E_1 = 83.0 mole % BrF_3, m.p. 33.1 °C; E_2 = 33.5 mole % BrF_3, m.p. 15 °C.

The formation of the compound $[BrF_2]_2[SnF_6]$, melting incongruently at 93° ± 1 °C, has been observed[151] in the system BrF_3–SnF_4, which has been only partly investigated owing to the high viscosity of the melt. The formation of two incongruently melting phases has been established in the BrF_3–PtF_4 system:[152] $[BrF_2]_2[PtF_6]$ and $7BrF_3.PtF_4$.

A whole series of compounds with the $[BrF_2]^+$ cations have been obtained, incorporating the following anions apart from those indicated above: $[AsF_6]^-$,[92] $[BF_4]^-$,[63,124,153] $[NbF_6]^-$, $[TaF_6]^-$, $[BiF_6]$,[17,154,155] $[GeF_6]^{2-}$,[27,63,92] $[PdF_4]^-$, $[RuF_6]^-$, $[AuF_4]^-$, and $[RhF_6]^-$.[154,156–159] The data concerning the synthesis[153] of $[BrF_2][BF_4]$, allegedly stable at room temperature, were not confirmed.[124] The interaction of BrF_3 and BF_3 affords the compounds $[BrF_2][BF_4]$ (stable below −80 °C) and $[BrF_2][B_2F_7]$ (stable below −120 °C).[63,124] The separation of these compounds without the preliminary study of the system BrF_3–BF_3 is very difficult.

The above halogen cation compounds are synthesised by the methods involving the direct interaction of the fluorides, chlorides, and oxides of the elements with an excess of BrF_3. The residual BrF_3 is then removed *in vacuo*.[92,160–162] The reaction with the oxides proceeds vigorously and is accompanied by the evolution of O_2, Br_2 being introduced into the reactor to slow it down.

The method involving the direct interaction of BrF_3 with powdered metals at temperatures ranging from 190 °C and above has also been recommended.[155,156,158,159,161,163] For platinum metals, a mixture of BrF_5 and Br_2 is used instead of BrF_3.[164] The reactions of BrF_3 with SO_3, $Br(SO_3F)_3$, and $F(SO_3F)$, and of BrF_5 with SO_3 result in the formation of the same compound $[BrF_2](SO_3F)$.[111,165]

The cations [BrCl₂]⁺ and [Br(BrCl)]⁺. They exist only in liquid phases of the systems Cl_2–$Br(SO_3F)$–SbF_5 and Cl–$Br_2(Sb_3F_{16})$.[72]

The cation [IF₂]⁺. It is formed in the systems IF_3–BF_3–CH_3CN (at −45 °C) and $I(SO_3F)$–SO_3F_2.[12,74] The interaction of IF_3 with $AsF_5(SbF_5)$, cooled to −78 °C, results in the formation in the solid state of $[IF_2][AsF_6]$ (decomposes at −22 °C) and $[IF_2][SbF_6]$, which can withstand heating to 45 °C.[125,126]

The cation [ICl₂]⁺. It forms red and orange-red crystals with the anion SO_3F^- when $I(SO_3F)$ is acted upon by liquid chlorine (at −70 °C) with subsequent increase of temperature to 20 °C [74,77,82] or when a suspension of I_2Cl_6 in CCl_4 (below −10 °C) is mixed with a limited amount of SO_3.[166,167] The compounds of dichloroiodine (III) have been obtained with the following anions: $[SbF_6]^-$—by adding I_2Cl_6 to a solution of SbF_5 in SO_2ClF with subsequent removal of the excess SO_2ClF by slow distillation;[42] $[Sb_2F_{11}]^-$—by the reaction of I_2Cl_6 with SbF_5;[78] $[SbCl_6]^-$—by the reaction of I_2Cl_6 with an excess of $SbCl_5$ at 100 °C [19,81,83,168] or on mixing I_2, $SbCl_5$, and an excess of liquid chlorine (at −196 °C) with subsequent raising of the temperature to −80 °C;[80,84,169] $[AlCl_4]^-$—by heating equimolar amounts of I_2Cl_6 and $AlCl_3$ in CCl_4 or $CHCl_3$ [19,81,168,169] and also by the reaction of I_2Cl_6 with $AlCl_3$ in a sealed tube at 100 °C.[83]

The cation [I(ICl)]⁺. It follows from the phase diagram for the system ICl–$AlCl_3$ [30,170] that the reaction of ICl with $AlCl_3$ leads to the formation of the compound $2ICl.AlCl_3$ = $[I(ICl)][AlCl_4]$, melting incongruently at 53 °C, in which the ligands are the I^- and Cl^- ions. Signs of the appearance of an analogous compound have been observed[171,172] also in the system ICl–$AlCl_3$–$C_6H_5NO_2$. According to Pohl and Saak,[48] only the compound $[I(ICl)_2][AlCl_4]$ is formed in the reaction of ICl with $AlCl_3$. The reaction

$$I_2 + 2SbCl_5 \rightleftharpoons [I(ICl)][SbCl_6] + SbCl_3 .$$

is apparently possible in the system I_2–$SbCl_5$.[140,173–176] The dark-brown crystals of $[I(ICl)][SbCl_6]$ have been obtained by the interaction of ICl and $SbCl_5$ and of I_2, $SbCl_5$, and

Cl_2 (at −196 °C).[47,70,80,84] It has been suggested[8,80] that the last reaction is followed by the side process

$$I_2+Cl_2 \rightleftharpoons 2ICl$$

which initiates the reaction

$$ICl+Cl_2+SbCl_5=[ICl_2][SbCl_6] \ .$$

It is believed[8] that the nI_2 + ICl + $SbCl_5$ interaction (n = 1–3) always entails the formation of the cation $[I(ICl)]^+$ in the first stage regardless of the ratio of the initial components, pressure, and temperature.

The formation of two compounds, namely $[I(ICl)][SbCl_6]$ and $[I(ICl)_2][SbCl_6]$, melting congruently at almost the same temperature (62.5 °C), has been established in the system $ICl–SbCl_5$.[177] Whereas the compound $[I(ICl)]$.$[GaCl_4]$, melting incongruently at 28.5 °C, is formed in the system ICl–GaGl,[173] the only product in the system ICl–$SbCl_3$ is the adduct $SbCl_3$.5ICl [178] (ICl.$SbCl_3$ is formed according to other data[173,179]). No interaction has been observed between ICl and $AsCl_3$.[180] Similarly only the adduct ICl.$TaCl_5$, melting incongruently at approximately 102 °C, is formed in the system ICl–$TaCl_5$, while the system ICl–$NbCl_5$ is of the purely eutectic type.[181]

The reactions of $I(SO_3F)$ and ICl (at 50 °C) and of $[I_3]$.(SO_3F) and $[ICl_2](SO_2F)$ in a stream of dry nitrogen[77,78] lead to the formation of $[I(ICl)](SO_3F)$.

The cation $[I(ICl)_2]^+$. The mechanism of reactions in which the ICl molecules become the ligands while iodine acquires the +1 oxidation state has not been ultimately elucidated. Thus the reaction of ICl with $SbCl_5$ or $AlCl_3$ entails the formation, together with the cation $[I(ICl)]^+$, also of the cation $[I(ICl)_2]^+$.[48,174,182,183] According to other data,[46,47] the compound $[I(ICl)_2][SbCl_6]$ can also cyrstallise from a solution of I_2Cl_6 and $SbCl_3$ in SO_2.

The cation $[IBr_2]^+$. Compounds with this cation cannot be obtained by the direct interaction of Lewis acids (SbF_5, AsF_5, $AlCl_4$, etc.) with IBr_3 or I_2Br_6, since the latter have not so far been obtained. For this reason, $[IBr_2][Sb_2F_{11}]$ is synthesised in the following manner. A solution of SbF_5 in SO_2 is mixed initially with IBr until the appearance of a precipitate of SbF_5, which is filtered off and SO_2 is removed; the final product is extracted from the paste-like residue with SO_2ClF.[41] The same compound can be obtained in the exchange reaction of $[IBr_2](SO_3F)$ with a large excess of SbF_5 on heating to 70 °C.[78] Compounds with the anions SO_3F^- and $SO_3CF_3^-$ are formed on heating to 50 °C a mixture of $I(SO_3F)$ or $I(SO_3CF_3)$ with Br_2.[77,78,82]

The cation $[IBr_2]^+$ has been detected in the system $I_2–Br_2–HIO_3–H_2SO_4$ at 25 °C with the molar ratio I_2/HIO_3 = 2.0.

The formation of the cations $[IBr_2]^+$ has not been established in the systems IBr–$AlBr_3$,[184] IBr–$GaBr_3$,[173] IBr–$SbBr_3$,[178] and IBr–$AlBr_3(SbBr_3)$–$C_6H_5NO_2$.[182,185] The adduct IBr.$AlBr_3$ was isolated in the first system.

The cations $[I(IBr)]^+$ and $[I(IBr)_2]^+$. When $I(SO_3F)$ and IBr interact (at 50–75 °C), the compound $[I(IBr)](SO_3F)$, melting incongruently at 70 °C, crystallises,[77] while the almost black crystals of $[I(IBr)_2][SbCl_6]$ can be obtained by the reaction of ICl, IBr, and $SbCl_5$.[48] Both cations apparently exist in the same systems and their crystallisation regions are determined by the ratio of the components, as in the systems of the cations $[I(ICl)]^+$ and $[I(ICl)_2]^+$.

The cation $[I(BrCl)]^+$. It enters into the composition of two compounds: $[I(BrCl)][SbCl_6]$ and $[I(BrCl)](SO_3F)$. The first was obtained[41,80] by the interaction of IBr, Cl_2, and $SbCl_5$ in SO_2 (at −78 °C) and the second by mixing equimolar amounts of $[IBr_2](SO_3F)$ and $[ICl_2](SO_3F)$ at 95 °C.[78] It is believed[33,41] that this entails the formation of a disordered mixture of the cations $[IBr_2]^+$, $[ICl_2]^+$, and $[I(BrCl)]^+$ which are in equilibrium

$$2[I(BrCl)]^+ \rightleftharpoons [IBr_2]^+ + [ICl_2]^+.$$

The cation $[ClF_4]^+$. The study of the system ClF_5–SbF_5 (Fig.7) led to the observation[186] of three new congruently melting phases containing the cation $[ClF_4]^+$: $[ClF_4]$.$[SbF_6]$ (m.p. 120 °C), $[ClF_4][Sb_2F_{11}]$ (m.p. 64 °C), and $[ClF_4][Sb_4F_{11}]$ (m.p. 62 °C), the last two compounds having very small crystallisation regions. The first compound has two polymorphic modifications (α and β) with a phase transition temperature of approximately 40 °C. The melting point data,[52,123] for the compound $[ClF_4][SbF_6]$, obtained by preparative synthesis, disagree with the more accurate data.[186] It has been established that HF cannot be used as the solvent for the synthesis of this compound.[186] The system ClF_5–HF is distinguished by the complete absence of the miscibility of the components in both liquid and solid states.[187]

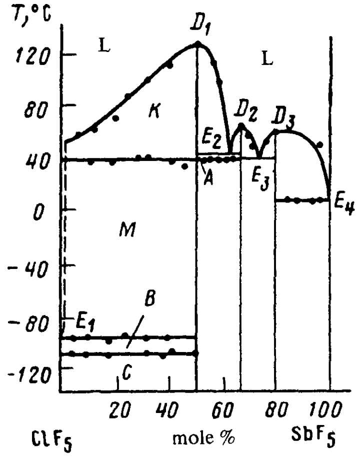

Figure 7. Phase diagram for the system ClF_5–SbF_5:[186] D_1 = $[ClF_4][SbF_6]$; D_2 = $[ClF_4][Sb_2F_{11}]$; D_3 = $[ClF_4]$.$[Sb_4F_{21}]$; A = α-$[ClF_4][SbF_6]$ + $[ClF_4][Sb_2F_{11}]$; B = β-$[ClF_4][SbF_6]$ + α-ClF_5; C = β-$[ClF_4][SbF_6]$ + β-ClF_5; K = α-$[ClF_4][SbF_6]$ + L; M = β-$[ClF_4][SbF_6]$ + L.

The synthesis of $[ClF_4][AsF_6]$ and $[ClF_4][PtF_6]$ is based on the repeated heating and cooling of a mixture of ClF_5 and $AsF_5(PtF_6)$ in the temperature range between −196° and +20 °C.[91,123] The system ClF_5–BF_3 is characterised by the absence of miscibility of the components in both liquid and solid states over the entire concentration range.[188]

The cation $[BrF_4]^+$. In contrast to the previous system, the interaction of BrF_5 and SbF_5 leads to the formation of five new phases (Fig.8), among which only one, $[BrF_4]$.$[Sb_2F_{11}]$, melts congruently (at 81 °C).[189] The low melting point (60–61 °C) observed for this phase elsewhere[113,190] is caused by the presence of impurities.

A general method of synthesis of compounds of halogen cations, incorporating the ion $[BrF_4]^+$, involves the condensation of BrF_5 at −196 °C in a reactor containing the fluorides or oxides of the elements in the highest oxidation states with subsequent alternate heating and cooling of the reactor. In the last stage of the synthesis, the excess BrF_5 is removed *in vacuo*. The cation halogen compound of tetrafluorobromine (III) with the anions $[Sb_2F_{11}]^-$,[53,61,97] $[AsF_6]^-$,[53] $[SnF_6]^{2-}$,[9,192] and $[RuF_6]^-$ [12] (all in the crystalline state) and also with the anions SO_3F^- [190] and $[PtF_6]^-$ [90,91] (in the form of viscous liquids which do not crystallise at low temperatures) were obtained in this way.

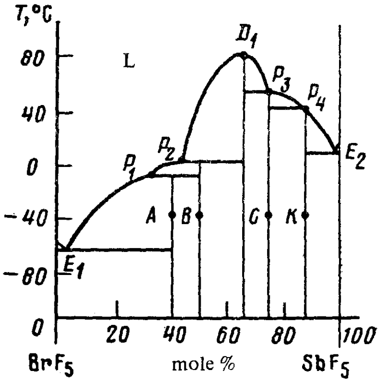

Figure 8. Phase diagram for the system BrF_5–SbF_5:[189] D_1 = dystectic composition $[BrF_4][Sb_2F_{11}]$ (m.p. 81 °C); m.p. of peritectic phases (°C): $P_1 = -8$; $P_2 = 0$; $P_3 = +50$; $P_4 = +40$; E_1, E_2 = eutectic points; $A = 3BrF_5.2SbF_5$; $B = BrF_5.SbF_5$; $C = BrF_5.3SbF_5$; $K = BrF_5.7SbF_5$.

The formation of the cation $[BrF_4]^+$ has not been established in the systems BrF_5–BF_3(NbF_5, BiF_5),[8,97,188] BrF_5–PF_5(TiF_4),[113] BrF_5–UF_6,[9,149] and BrF_5–HF.[9,12,22,88]

The cation $[IF_4]^+$. When IF_5 and SbF_5 interact, three new phases appear (Fig.9):[192] the congruently melting $[IF_4].[SbF_6]$, the incongruently melting $[IF_4][Sb_2F_{11}]$, and the $IF_5.6SbF_5$ phase whose nature has not been elucidated.

The method of synthesis of the majority of the cation halogen compounds with the cation $[IF_4]^+$ is analogous to that used for $[BrF_4]^+$. The compound $[IF_4][CrF_4.Sb_2F_{11}]$ has been synthesised[98] by the reaction in liquid IF_5 at 60 °C (yield 100%):

$$3IF_5+2O_2[CrF_4\cdot Sb_2F_{11}]=[IF_4][CrF_4\cdot Sb_2F_{11}]+2O_2+IF_7\ .$$

The compound decomposes at 153 °C. Compounds with the anions $[SbF_6]^-$,[53,64,108,115,192,193] $[Sb_2F_{11}]^-$,[51] $[PtF_6]^-$,[144,145] and $[CrF_4.Sb_2F_{11}]^-$ [8,98] have been obtained in the crystalline state. The compound $[IF_4](SO_3F)$ is formed in the liquid.[193]

The system IF_5–HF is the eutectic type,[194] the cations $[IF_4]^+$ being detected only in the liquid phase.[9,194]

The cation $[ClF_6]^+$. The synthesis of the cation halogen compounds with the cation $[ClF_6]^+$ proved to be possible only[62] when a powerful oxidant, such as KrF_2, is used under the conditions of cyclic heating from −196° to +20 °C and cooling:

$$ClF_5+KrF_2+AsF_5=[ClF_6][AsF_6]+Kr\ .$$

The excess ClF_5 used as a solvent increases the yield of the complex, which crystallises without an admixture of the cations $[ClF_4]^+$. The compound $[ClF_6][SbF_6]$ was obtained analogously. The synthesis of $[ClF_6][BF_4]$ is possible only via the exchange reaction of $[ClF_6][AsF_6]$ and $Cs[BF_4]$ in HF on raising the temperature from −196° to +25 °C and subsequent cooling of the mixture to −78 °C.[100] The $Cs[AsF_6]$ residue is separated and $[ClF_6][BF_4]$ is crystallised from the filtrate in 55% yield. The synthesis of $[ClF_6][AuF_6]$ is believed to be possible.[195] According to a series of data,[68,86,99]

$$2ClF_5+2PtF_6=[ClF_6][PtF_6]+[ClF_4][PtF_6]$$
$$6ClO_2F+6PtF_6=[ClF_6][PtF_6]+5(ClO_2)[PtF_6]+O_2$$

take place when mixtures of the reactants are heated slowly from −196° to +25 °C with simultaneous UV irradiation (water–Pyrex filter) for several days. The reaction products could not be fully separated.

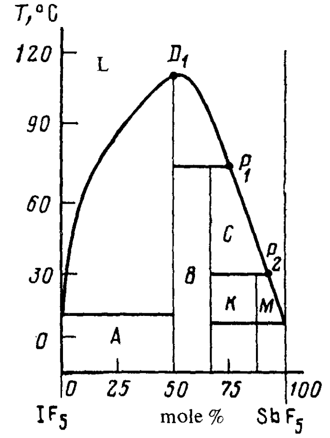

Figure 9. Phase diagram for the system IF_5–SbF_5:[192] D_1 = dystectic composition $[IF_4][SbF_6]$ (m.p. 111 °C); P_1 and P_2 = the peritectic phases $[IF_4][Sb_2F_{11}]$ (m.p. 72 °C) and $IF_5.6SbF_5$ (m.p. 27 °C) respectively; $A = IF_5 + [IF_4].[SbF_6]$; B = mixture of the solid phases D_1 and P_1; $C = [IF_4][Sb_2F_{11}] + L$; $M = IF_5.6SbF_5 + L$; K = mixture of the solid phases P_1 and P_2.

The interaction of the components in the systems ClF_5–F_2–SbF_5(AsF_5) and ClF_5–F_2–BF_3 was not observed at pressures in the range 30–40 atm and temperatures in the range 100–225 °C.[86] Instead of the oxidation of ClF_5 to ClF_7, the former decomposes to ClF_3 and Cl_2 with formation of compounds having the cation $[ClF_2]^+$.

The cation $[BrF_6]^+$. The attempts to synthesise compounds with the above cation by mixing BrF_5, F_2, and AsF_5(SbF_5) were unsuccessful despite the use of increased pressures (125–200 atm) and temperatures (200–250 °C) and varying the molar ratios of the components. Only when a new powerful oxidant KrF_2 was employed, was it possible[60,61,67] to synthesise $[BrF_6][AsF_6]$ and a mixture of $[BrF_6][Sb_2F_{11}]$ with $[BrF_4][Sb_2F_{11}]$. The latter compound is removed from the mixture *in vacuo* at 50 °C. However, after this operation, the composition of the residual cation halogen compounds becomes indefinite:[67] $[BrF_6][SbF_6].xSbF_5$ ($x < 1$). The reaction involving KrF_2 proceeds in BrF_5 at −196 °C. The excess BrF_5 and KrF_2 are removed by evacuation. The yield of the halogen cation compounds with the ion $[BrF_6]^+$ does not exceed 20%. The reasons for the formation of $[BrF_6][Sb_2F_{11}]$ instead of $[BrF_6][SbF_6]$ remain obscure.

The cation $[IF_6]^+$. Cation halogen compounds containing the anions $[AsF_6]^-$,[6,9,12,56,127,196–198] $[SbF_6]^-$,[66] $[Sb_3F_{16}]^-$,[12,127,197,198] $[BF_4]^-$,[6,127] $[BF(TeOF_5)_3]^-$,[199] and $[AuF_6]^-$ [65] have been obtained with this cation.

A general method of synthesis of the compounds is joint condensation in a single reactor at −196 °C of the initial reactants with subsequent increase of temperature to 0 °C; the remaining reactants are removed by evacuation.[56,59,127,200,201] If one of the reactants $[IF_7)$ boils before the other (SbF_5) becomes liquid, then the reaction is carried out by passing gaseous IF_7 through a melt of SbF_5 at 20 °C.[127] The structure of $[IF_6][Sb_3F_{16}]$ has not been ultimately elucidated.

A reaction which takes place even at 20 °C but leads to the formation of a mixture of two solid phases has been proposed for the synthesis of the compound with the anion $[AuF_6]^-$:[65]

$$3IF_5+4O_2[AuF_6]=3[IF_6][AuF_6]+4O_2+AuF_3 \ .$$

VI. APPLICATIONS

The cation halogen compounds have a multiplicity of novel physical and chemical properties which lead to a wide variety of possibilities in their practical use. In the first place, being strong oxidants, they have been recommended as components of rocket fuels and in the technology of the processing of nuclear materials.[9]

The compounds $[Cl(ClF)][AsF_6]$, $[ClF_4][SbF_6]$, and $[BrF_2][SbF_6]$ proved to be excellent fluorinating agents at comparatively low temperatures in closed reactors and at low pressures developed in the process;[122,141,150,162] $[BrF_6].[AsF_6]$ is more effective than F_2 under the usual conditions, oxidising, for example Xe and O_2:

$$[BrF_6][AsF_6]+Xe=(XeF)\ [AsF_6]+BrF_5 \ ,$$

$$[BrF_6][AsF_6]+O_2=O_2[AsF_6]+BrF_5+0.5F_2 \ .$$

The effectiveness of the halogen cation compounds in organic synthesis has been mentioned frequently.[202,203] In particular, it is technologically convenient to synthesise fluorinated aromatic derivatives of iodine(VII) with the aid of $[IF_4][SbF_6]$.[203] The authors believe[203] that the halogen cation compounds lead to new possibilities for the synthesis of compounds containing Ar–Hal (Hal = I, Br, or Cl). The halogen cation compounds $[Cl(ClF)][AsF_6]$, $[ClF_2][AsF_6]$, $[ClF_4][SbF_6]$, and similar compounds can be used as solid sources of chlorine fluorides and devices for their storage. When necessary, these fluorides can be regenerated in a pure form.[141]

The most promising application of the halogen cation compounds is the synthesis of new substances by mixing solutions containing the corresponding halogen cation compound (Lewis acid) and the halogenate anion (Lewis base). The solvent in this instance is the interhalogen compound whose autoionisation leads to the formation of the cation and anion of the reactant. An example is provided by the reaction

$$[BrF_2][PF_6]+Ag[BrF_4]=Ag[PF_6]+2BrF_3 \ .$$

Numerous complexes, whose synthesis had been regarded as impossible previously, have been obtained by this method.[12,113,115,155,156,160,162,163] The reversibility of some of the reactions and the solvolysis of the product are complications in **synthesis** of this kind.

The exchange reactions involving the complex cations may be used for synthesis:[12,204]

$$[BrF_2][AuF_4]+SeF_4=(SeF_3)[AuF_4]+BrF_3 \ .$$

These reactions can be employed also for the purification of chemical fluorides.[205]

The determination of chemically combined oxygen in minerals, raw materials (ores), and metal oxides and phosphates is a difficult analytical problem whose solution has become possible after the appearance of the halogen cation compounds. In particular, when thermostable oxides (ThO_2, Al_2O_3, ZrO_2, etc.) and phosphates are heated with $[BrF_2][SbF_6]$ to temperatures above 330 °C, oxygen is evolved quantitatively.[12,122] The same reagent has been proposed[206] for the direct quantitative determination of chemically combined oxygen in alcohols and aliphatic and aromatic acids.

The reaction

$$Rn+[IF_6][SbF_6]=(RnF)[SbF_6]+IF_5$$

has been recommended[66,207] for the separation of a mixture of Rn, Xe, and Kr, for the determination of Rn in air, and for the removal of the radioactive radon impurity in air. The use of halogen cation compounds makes it possible to eliminate radon and other carcinogenic substances (^{218}Po, ^{214}Po, ^{214}Pb, and ^{214}Bi) almost completely from air in uranium mines.[207] The xenon evolved on dissolution of spent radioactive fuel may be utilised by means of reactions involving the formation of the adducts $2IF_5.XeF_2$ [208,209] and $IF_5.XeF_4$.[210,211]

VII. CONCLUSIONS

It follows from the data presented above that, in the direct synthesis of halogen cation compounds with halide ligands, halogens and diatomic interhalogen compounds should be used only together with powerful oxidants. Otherwise molecular ligands appear in the inner sphere with the complex-forming agent in the +1 oxidation state, for example, $[I(I_2)_2]^+$ and $[I(ICl)_2]^+$.[212–214] The halogen cation compounds with the cations $[ICl_4]^+$ and $[IBr_4]^+$ have not so far been obtained owing to the extreme instability of ICl_5 and IBr_5.[215]

The halogen cation compounds examined in this review are not distinguished by a wide variety of anions. The anions are mainly $[AsF_6]^-$, $[SbF_6]^-$, $[SbCl_6]^-$, $[BF_4]^-$, $[AlCl_4]^-$, and a few others. The properties of powerful halide ion acceptors can also be manifested by the fluorides and chlorides of elements capable of being converted into acido-complexes.

The dependence of the stability of the halogen cation compounds on the nature of the anions has not so far been accounted for. For example, BF_3 exhibits an appreciable accepting capacity in relation to fluoride ions, but it does not interact with either ClF_5 or with BrF_5 to form the cations $[ClF_4]^+$ and $[BrF_4]^+$.[188] The most stable halogen cation compounds contain almost always the anion $[AsF_6]^-$. The appearance in the anion of bromide or iodide ligands, which are readily oxidised, precludes the synthesis of the halogen cation compounds. Such ligands destabilise the cations, reconverting them into halogens or interhalogen compounds.

The more exothermic the formation reactions of anions of the type,

$$SbF_5+F^-\rightleftharpoons[SbF_6]^-,$$

the more stable should apparently be the resulting halogen cation compounds. Thus their stabilisation is also promoted by the electrolytic dissociation of interhalogen compounds[213] and by the ready solubility of the latter in Lewis acids functioning as halide ion acceptors. It has been established that the energy of abstraction of fluoride ions from halogen fluorides diminishes from ClF_5 to IF_5. The stability of the halogen cations associated with the same anion increases in the same direction:

$$[ClF_4]^+ < [BrF_4]^+ < [IF_4]^+.$$

The interaction of halogen fluorides and Lewis acids in the liquid phase is as a rule rapid and proceeds with a high yield.

Little is known about the mechanism of the formation reactions of the halogen cation compounds. The conditions governing the equilibria in solutions between the ions $[I_2]^+$ and $[I_3]^+$ and between $[I_3]^+$ and $[I_4]^{2+}$ or the causes preventing the appearance of the cations $[I_5]^+$ in the system I_2–$S_2O_6F_2$ or the cation $[I_3]^+$ in the system I_2–$AlCl_3$–NaCl [214] and favouring their formation in the system I_2–ICl–$AlCl_3$ have not been elucidated. The possibility of reactions of the type

$$3ICl \rightleftharpoons [I(ICl)]^+ + [ICl_2]^- \text{ or } 3ClF \rightleftharpoons [Cl(ClF)]^+ + [ClF_2]^-$$

is open to doubt. The dismutation

$$3ClF \rightleftharpoons ClF_3 + Cl_2 \text{ or } 3ICl \rightleftharpoons ICl_3 + I_2$$

followed by other reactions is more likely. It may be that in this process one of the stages involves an elimination reaction with formation of radicals. The appearance of the latter, for example $Cl_3^{\cdot}$, $ClF_2^{\cdot}$, [212] or $Cl_4^{\overset{+}{\cdot}}$, [120] has been frequently mentioned.

A fundamentally new method of synthesis of halogen cation compounds is that involving the explosive interaction between two different halides of the same metal. Single crystals of $[ClF_6][CuF_4]$, for example, have been obtained by this method from a mixture of CuF_2 and $CuCl_2$. [216]

In conclusion, it should be noted that the study of the chemistry of the halogen cation compounds is only just beginning and much still remains to be done before it occupies its due place in modern inorganic chemistry.

Reactions of Unsaturated Systems with Hexavalent Chromium

Sh.O.Badanyan, T.T.Minasyan, and S.K.Vardapetyan

The literature data on the interaction of unsaturated compounds with hexavalent chromium reagents are surveyed. Attention is concentrated on reactions with coordination complexes of hexavalent chromium and also methods suitable for the chemospecific, regiospecific, and stereospecific oxidative generation of functional groups in highly unsaturated systems. The advances in the application of chromium(VI) in the synthesis of natural structures are described.

The bibliography includes 389 references.

II. Reactions of unsaturated alcohols 740
III. Reactions of carbon-carbon multiple bonds 743
IV. Allylic oxidation 748

I. INTRODUCTION

The oxo-derivatives of manganese, chromium, ruthenium, and osmium have been applied to an increasing extent in recent times for the generation of functional groups in organic molecules. Among the selectively acting oxo-derivatives of variable-valence metals, chromium compounds play the most important role, because the oxidative reactions based on them can be readily carried out and the reagents themselves are readily available and cheap. The oxidation of carbon–carbon multiple bonds by chromium(VI)–containing reagents leads to the formation of epoxides, glycols, aldehydes, ketones, and carboxylic acids.[1-9] Furthermore, if we add to this that coordination complexes of chromium can be used successfully for the conversion of hydroxy into the carbonyl groups in unsaturated systems, the prospects for their application in the chemistry of unsaturated compounds become evident.[10-19] For these purposes, one uses chromic acid (in water or in acetic or sulphuric acids), the dichromate ion (in water or in acetic acid), chromyl acetate (in acetic anhydride or in its mixture with acetic acid), t-butyl chromate, chromyl nitrate, coordination complexes of chromium dioxide, and chromyl chloride (in inert solvents).

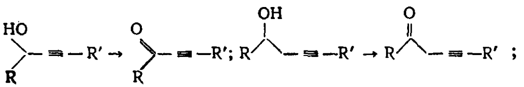
The literature data on the application of chromium compounds as oxidising agents for organic substrates available in foreign literature have been partly considered and surveyed.[20-27] Despite the enormous importance of the above reagents, there have been no Soviet reviews, which led us to compile and arrange systematically the data on the interaction of hexavalent chromium compounds with unsaturated compounds. The reactions of chromium derivatives with unsaturated systems can be arbitrarily divided into the following groups: (1) oxidation of hydroxy-groups and other functional groups; (2) oxidation of multiple bonds; (3) allylic oxidation.

II. REACTIONS OF UNSATURATED ALCOHOLS

The search for readily available and selectively active reagents for the oxidation of alcohols to carbonyl compounds has been for a long time the object of numerous investigations. An enormous number of reagents containing chromium(VI) were tested but the majority of them did not exhibit an adequate activity and selectivity and as a result proved to be unsuitable for use in modern organic synthesis.[28] However, the series of reagents considered in this review had been used successfully in reactions with unsaturated alcohols.

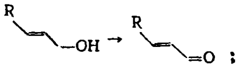
1. Oxidation by Chromic Acid, the Dichromate Ion, and t-Butyl Chromate

Chromic acid (H_2CrO_4) was first used as an oxidant in the conversion of derivatives of cyclopentenol into cyclopentenones and it was recommended that the reaction be carried out in acetic acid (Fieser's reagent) or in sulphuric acid.[29,30] A major advance in the oxidation of the hydroxy-group to the carbonyl group in unsaturated alcohols and in particular in acetylenic systems by chromium trioxide in sulphuric acid has been the successful employment of acetone as the solvent (Jones' reagent), which ensured high yields of carbonyl compounds:[31-38]



R = alkyl, aryl; R' = H, alkyl.

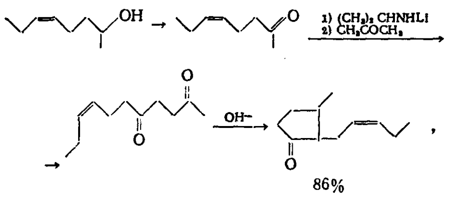
It has been reported that various primary allyl alcohols give rise to aldehydes in moderate yields on oxidation by the chromate ion in sulphuric acid:[39-43]



R = alkyl, alkenyl.

According to the results of a number of investigators,[30,31,44-48] when concentrated sulphuric acid is used, reactions with unsaturated primary alcohols do not stop at the aldehyde formation stage but continue until the formation of the corresponding acid. This fact has been used in the synthesis of the pheromone of the black carpet beetle—megatomoic acid.[47]

Other literature data exists concerning the oxidation of unsaturated alcohols to aldehydes with the aid of the Jones reagent.[49-51] Among them the use of chromic acid in the synthesis of *cis*-jasmone, in accordance with the scheme[52]



is of great interest.

The synthesis of a series of α-acetylenic carbonyl compounds is also of interest.[53–60]

The above methods have been used successfully in the conversion of polycyclic unsaturated carbinols into ketones.[61–64]

The dichromate ion $[Cr_2O_7]^{2-}$ in acetic or sulphuric acid has been used to oxidise various allyl alcohols.[65] The above reagent has been used successfully also to convert cholesterol into cholestanone[66] and also for the oxidation of propargyl alcohols.[67]

t-Butyl chromate ($t\text{-}Bu_2CrO_4$) has been used on a comparatively wide scale for the oxidation of the hydroxy-group in unsaturated systems, which demonstrates its advantage over other reagents. Studies in this field have been examined and surveyed by Matsuura and Suga.[68] Chromium trioxide in t-butyl alcohol was first used as the reagent for the oxidation of hydroxy-groups in unsaturated alcohols in the conversion of geraniol into geranial in 85% yield:[69]

Subsequently this reagent was applied successfully for the conversion of various allyl alcohols into unsaturated carbonyl compounds[70–72] and also for the oxidation of octa-3,5-diene-2,7-diol into the corresponding diketone.[73]

In the 1970's oxidising agents based on chromium trioxide began to be used in the presence of carriers. When chromium trioxide is added to a solution of an alcohol in a 1:3 mixture of diethyl ether with dichloromethane in the presence of celite, carbonyl compounds are formed.[74] There are data concerning the oxidation of unsaturated alcohols by chromic acid deposited on a polymeric carrier[75] and adsorbed on silica gel,[76] by the graphite chelate of chromium trioxide,[77] by chromium trioxide in hexamethylphosphoramide[78–80] deposited on wood charcoal[81] or on a polymer,[82] and by the dichromate of polyvinylpyridine.[83]

The mechanism of the oxidation of alcohols on polymers of saturated compounds has been the subject of investigations by many workers. It follows from these studies that the rate of oxidation depends on the concentration of the acid ester of chromic acid;[84–97] this dependence and the isotope effect[98] show that the slow stage involves the rupture of a C—H bond at the carbon atom linked to the hydroxy-group. The fact that the reaction is faster in deuterium oxide than in water is no less important.[99] These data agree with the hypotheses of both one- and two-electron transfer in the rate-limiting stage. According to Watanabe and Westheimer,[100] these two alternatives can be distinguished by employing the unusual ability of manganese(II) ions to induce the reaction. Thus, in the oxidation of isopropyl alcohol in the presence of a large excess of manganese(II) ions, half a mole of manganese dioxide is formed for each mole of acetone in accordance with the equations

$$(CH_3)_2CHOH + Cr^{VI} \rightarrow (CH_3)_2C{=}O + Cr^{IV} \;;$$
$$2Cr^{IV} + Mn^{II} \rightarrow MnO_2 + 2Cr^{III} \;.$$

In the absence of the alcohol, the reaction between hexavalent chromium and bivalent manganese does not take place. In the presence of a large excess of the alcohol, manganese(II) ions decrease the rate of oxidation by a factor of two:

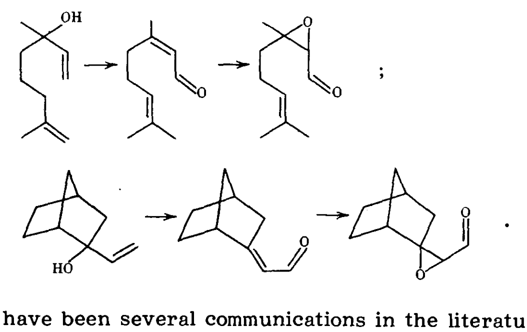
$$(CH_3)_2CHOH + Cr^{VI} \rightarrow (CH_3)_2C{=}O + Cr^{IV} \;;$$
$$Cr^{VI} + Cr^{VI} \rightarrow 2Cr^{V} \;;$$
$$2[Cr^{V} + (CH_3)_2CHOH \rightarrow (CH_3)_2C{=}O + Cr^{III}] \;.$$

It is seen from the equations presented that the oxidation is only one-third induced by hexavalent chromium and is two-thirds induced by quinquevalent chromium. The above examples of the induced oxidation demonstrate that chromium(IV) and chromium(V) complexes are formed as intermediates in the oxidation by chromium(VI). We may note that the latter are in fact effective oxidants which convert unsaturated alcohols into the corresponding carbonyl compounds.[101] In the rate-limiting stage, the intermediate chromic acid esters of primary and secondary alcohols are decomposed.[102,103] It has been suggested that the reaction proceeds via the formation of acid chromates,[104,105] which agrees best not only with the observed kinetics and the isotope effect but also with the presence of acid esters in the reaction medium.[106] Some workers assume that the reaction proceeds via the direct elimination of the hydride ion,[87,107,108] while others claim that chromic acid esters are formed initially.[103,109] However, despite the numerous data available,[82–86,105,110–123] it is difficult to make a final choice between the proposed mechanisms. Furthermore, since the rate of oxidation is independent of the oxidant concentration and corresponds to the rate of the acid-catalysed dehydration of alcohols to alkenes, some investigators have concluded that the initial stage involves the formation of an alkene, which is then oxidised by chromic acid.[124–126]

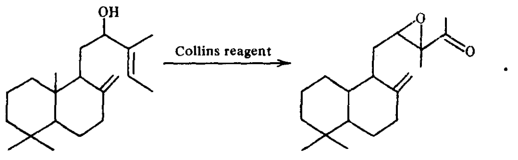
2. Oxidation by Coordination Complexes of Chromium Trioxide

First Sarett and co-workers[127] and then Collins et al.[128] demonstrated that the complex of chromium trioxide with pyridine[129] can be used successfully for the oxidation of alcohols to carbonyl compounds. Subsequently pyridine chromate (PC) ($C_5H_5.CrO_3$), the reagent of Sarett and Collins, was used to oxidise allyl and benzyl alcohols[130–131] — geraniol, nerol, citronellol, and cinnamyl alcohol[131] and bicyclic and tricyclic unsaturated carbinols,[132,133] including cholesterol[134] and cholesteryl acetate,[135] also in the synthesis of prostaglandins.[136]

The oxidation of tertiary and secondary allyl alcohols by the Collins reagent involves an oxidative rearrangement with formation of αβ-unsaturated aldehydes.[16] Under the reaction conditions, the latter are mainly converted into epoxy-derivatives:



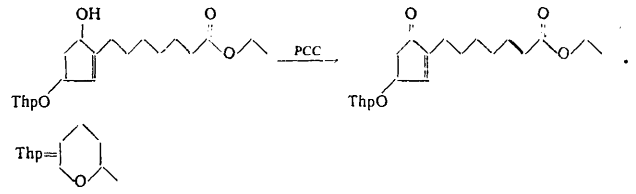
There have been several communications in the literature about the formation of epoxy-derivatives as a result of oxidation by other chromium reagents,[137–146] but none has been synthetically useful. In this sense the example presented below is valuable in biogenetic syntheses:[16]



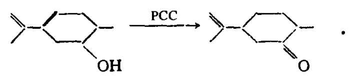
However, following the publication of the interesting report by Corey and Suggs,[10] who proposed pyridinium chlorochromate (PCC) $\{C_5H_5\overset{+}{N}H[CrO_3Cl]^-\}$ as a safe and readily available reagent, PC began to be used to a lesser extent.

In contrast to the Sarett and Collins oxidant, the Corey complex is non-hygroscopic, is safe, and there is no need to employ it in a fivefold and sixfold excess.[10,147] Hitherto, the Corey reagent has been used in somewhat modified forms; it is employed in a buffer mixture,[10] and in the forms where it is deposited on celite,[148] alumina,[149] poly(vinyl alcohol),[150] and molecular sieves.[151]

The Corey reagent is an effective oxidant for the conversion of many allyl[10,149,150] and homoallyl[151,152] alcohols into the corresponding carbonyl compound. With its aid, citronellal can be obtained in satisfactory yields from citronellol.[10,149] The reaction of a hydroxyacid ester presented below is of interest:[153]

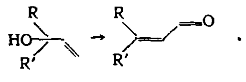


Isopulegone can be obtained in a quantitative yield in accordance with the following scheme:[149]



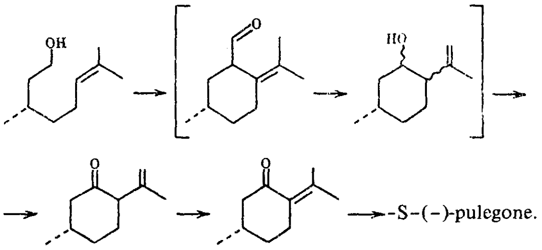
When alkenyl alcohols with a specific configuration of the double bond are oxidised, *cis–trans* isomerisation is observed.[10] In steroids containing several hydroxy-groups, including some of the allyl type, it is possible to oxidise the required hydroxy-group by varying the conditions.[154–157]

On interaction with PCC, tertiary and certain secondary allyl alcohols undergo an oxidative rearrangement, forming exclusively an unsaturated aldehyde and ketones in almost quantitative yields:[15,16,158]



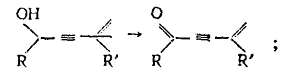
Such oxidation with a rearrangement is caused, according to the authors, by the weakly acid character of PCC, under the influence of which tertiary alcohols rearrange to primary alcohols and the oxidation of the latter leads to unsaturated aldehydes.[16,158]

Another promising synthetic application of the Corey reagent is in the oxidative cyclisation of unsaturated alcohols. Thus (–)-citronellol can be readily converted into (–)-pulegol by treatment with PCC:[13]



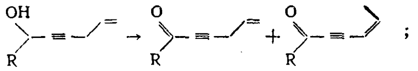
The acid properties of PCC, which induces the annelation of a number of other linear and cyclic unsaturated alcohols or aldehydes to form cyclohexanone derivatives, also promote this course of the reaction.[14] The above reaction is suitable for the asymmetric synthesis of prostaglandins.[159,160]

Pyridine chlorochromate has been used successfully also for the oxidation of certain propargyl alcohols;[10,161,162] it is exceptionally suitable for the synthesis of vinylacetylenic aldehydes and ketones:[163–165]



R = H, alkyl, aryl; R′ = H, CH₃.

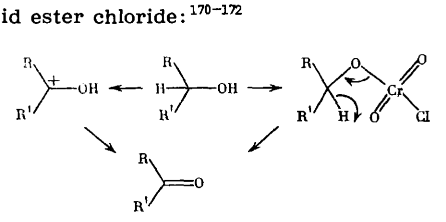
It is noteworthy that reactions of primary and secondary allylacetylenic carbinols with PCC are accompanied by a prototropic rearrangement with formation of mixtures of allyl- and propenyl-propargyl aldehydes and ketones:[166]



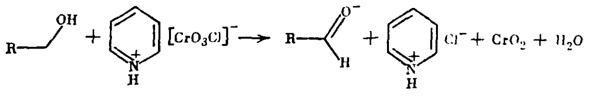
R = H, alkyl.

This reagent has also been used successfully for the oxidation of propenyl-acetylenic[166] and vinylallenic alcohols,[166] for the synthesis of *cis*-tagetone[167] and ocimenone,[168] and for reactions in the series of gibberellins.[51] The oxidation of unsaturated alcohols to butanolide derivatives is also of interest.[169]

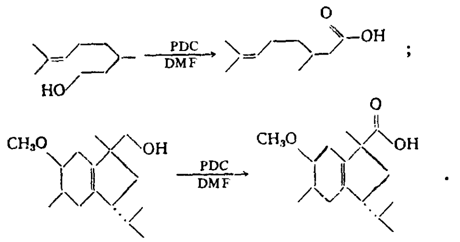
The mechanism of the oxidation of alcohols by pyridinium chlorochromate has been investigated by a number of workers.[170–177] Two main pathways whereby alcohols are converted into carbonyl compounds have been suggested: via the intermediate formation of the carbonium ion or via a chromic acid ester chloride:[170–172]



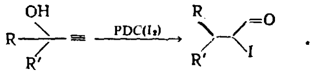
The authors believe that in both cases three electrons are transferred and that the oxidation state of chromium changes from +6 to +3 during the reaction. However, it has been noted that[177] two electrons are transferred in the above reaction in accordance with the mechanism



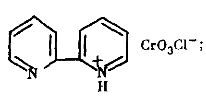
Pyridinium dichromate (PDC) $(C_5H_5\overset{+}{N}H)_2Cr_2O_7^{2-}$ in dimethylformamide (DMF) was suggested in 1979 as the oxidant for the selective conversion of the hydroxy-group into the carbonyl group.[12] The reagent oxidises rapidly 2-cyclohexanol, cinnamyl alcohol, and geraniol to 2-cyclohexenone, cinnamaldehyde, and geranial respectively in quantitative yields. In many instances the formation of the corresponding acids from the alcohols has been observed, for example:



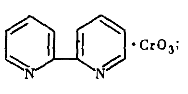
PDC in methylene chloride proved to be an even milder oxidant.[12] Regardless of the nature of the substrate, the reaction proceeds in this instance only as far as the formation of aldehydes. For example, citronellol gives rise to citronellal in 92% yield. It has also been noted that allyl alcohols are oxidised faster than their saturated analogues (2-cyclohexenol 10 times faster than cyclohexanol). Pyridinium dichromate in methylene chloride has been used to synthesise a series of αβ-unsaturated carbonyl compounds containing both double and triple bonds. Here it is noteworthy that the oxidation of geraniol to geranial involves partial inversion (9%). This *E*/*Z* isomerisation takes place before oxidation to geranial in the stage involving the formation of the intermediate chromate ester as a consequence of a reversible allyl rearrangement. PDC has been used successfully in the syntheses of pheromones.[178,179] In the presence of iodine in methylene chloride, this reagent converts smoothly tertiary acetylenic carbinols into αβ-unsaturated α-iodoaldehydes:[180]



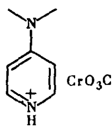
2,2′-Bipyridyl chlorochromate (BPCC) and the corresponding chromate (BPC)[181–183] as well as 4-(dimethylamino)pyridinium chlorochromate (DMAPCC),[184,185] have been proposed as oxidants for the oxidation of the hydroxy-group to the carbonyl group:



BPCC

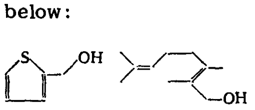


BPC

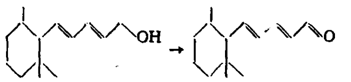


DMAPCC

2,2′-Bipyridyl chlorochromate containing an internal buffer (the 2,2′-bipyridyl system) has been recommended for the oxidation of alcohols containing acid-sensitive groups, of the type presented below:



As regards BPC, one should note, on the one hand, certain difficulties in its use, which are also characteristic of the Collins reagent (increase of the reaction time and the necessity to use an appreciable excess of the reagent and, on the other hand, the special selectivity in the oxidation of allyl and benzyl alcohols). The authors note that DMAPCC combines the selectivity of BPC and the advantages of BPCC. DMAPCC has been used successfully for the selective oxidation of polyols.[184] This reagent converts geraniol into geranial in a quantitative yield. The oxidation of the exceptionally sensitive vitamin A synthone into the corresponding aldehyde also proceeds smoothly:[184]



However, when DMAPCC is used in certain cases, the complete inversion of the configuration of the initial *Z*-alcohols is observed together with oxidation, and *E*-aldehydes are obtained.[184] Despite its limited applicability compared with its chlorine analogue, pyridinium fluorochromate has a less pronounced acidity and is an effective agent for the oxidation of a number of polycyclic organic substrates.[186–188]

Ammonium dichromate $(NH_4)_2Cr_2O_7$, which has been used to convert primary allyl alcohols, including geraniol and nerol, into aldehydes, manifested oxidising properties.[131] Among nitrogen complexes of chromium trioxide, mention should also be made of naphthyridinium chlorochromate $(C_8H_6\overset{+}{N}_2H.CrO_3Cl^-)$,[189] pyrazinium chlorochromate $(C_4H_4.\overset{+}{N}_2H.CrO_3Cl^-)$,[189] tetrabutylammonium chlorochromate $(Bu_4\overset{+}{N}.CrO_3Cl^-)$,[190] dimethylpyrazole chromate $(C_5H_8N_2.CrO_3)$,[16,191,192] tetrabutylammonium dichromate $(Bu_4\overset{+}{N}_2Cr_2.O_7^{2-})$,[193] the pyridine complex of oxodiperoxochromium $(C_5H_5N.CrO_5)$,[194] and the dipyridine complex of chromium trioxide $(2C_5H_5N.CrO_3)$ in acetic acid.[195] Poly(4-vinylpyridinium dichromate) (PVPDC) $P-C{=}CHCH{=}NH(Cr_2.O_7)_{0.5}CH{=}CH_2$—the polymeric analogue of pyridinium chlorochromate—has been proposed recently.[196] It has been noted that the main advantage of the polymeric reagent is the ease of the purification of the final product, because both the initial polymer, used in excess to complete the reaction, and the reaction product are insoluble in the reaction medium and can be removed by simple filtration.

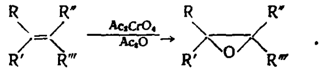
III. REACTIONS OF CARBON–CARBON MULTIPLE BONDS

There are literature data on the oxidation of double bonds both with decomposition of the unsaturated systems and without change in the carbon chain. The latter are of great interest and will be the subject of further discussion.

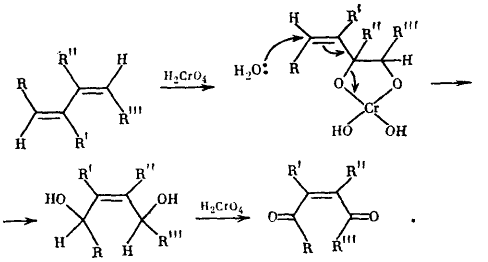
1. Oxidation by Chromic Acid, Chromyl Acetate, and Chromyl Nitrate

The oxidation of tetraphenylethylene by chromium trioxide (CrO_3) in acetic acid leads to an epoxide.[9,197,198] Alkenes of various types have been introduced into the reaction but mainly allylic oxidation was observed under these conditions.[199–213] The reactions of alkenes in aqueous acid media usually lead to products of the rearrangement of the epoxides formed initially.[2,5,6,214–218] Furthermore, on treatment with acid, camphene oxide affords camphenaldehyde, while the reaction of camphene with chromic acid leads to camphor and not to camphenic acid.[7] Assuming that the acid-catalysed rearrangement of camphene hydrate to isoborneol is faster than the oxidation of camphene, the authors conclude that camphor is obtained by the oxidation of isoborneol. In contrast to this, the reaction of 1,1-diarylethylenes with chromic acid affords only the cleavage product but not the epoxides, which were shown to be unreactive under the conditions used.[219,220] It has therefore been suggested that epoxides cannot be intermediates in the oxidation of the multiple bonds by chromic acid. It is also of interest that the very electrophilic addition of chromic acid is disproved by the fact that the carbonium ion formed in this process should have given rise to a large amount of a rearranged product.[221,222]

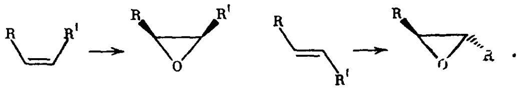
The reactions of alkenes with chromyl acetate (Ac_2CrO_4) proceed more successfully. They have been studied in detail in a number of investigations.[1,3,4,192,219,220] Here the main products of the interaction are epoxides, whose yield is higher the greater the degree of substitution at the double bond:



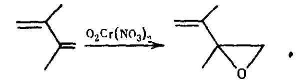
It is noteworthy that both the products of the rearrangement of the postulated epoxides[3,4,6,223–225] and acetates[226] and pinacol carbonates[8] are then isolated. Conjugated dienes also react successfully with chromic acid, which leads to the formation of enediones:[206–208,227]



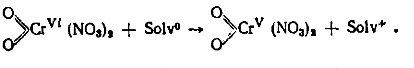
Chromyl nitrate $O_2Cr(NO_3)_2$ has been proposed recently as a reagent for the epoxidation of olefins.[228] It has been shown that different alkenes react stereospecifically at −78 °C in aprotic media (pyridine, DMF, or methylene chloride) with chromyl nitrate to form epoxides:



A high degree of retention of configuration has also been observed in the oxidation of olefins by chromyl acetate.[229,230] The products of the oxidation in acetone were ketals.[228] 2,3-Dimethylbutadiene enters smoothly into this reaction:



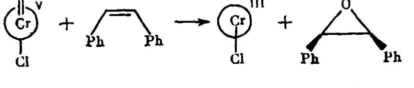
The authors believe that oxochromium(V), formed from chromium(VI) as a result of the preliminary one-electron oxidation of the solvent (Solv), is the active species in epoxidation by chromyl nitrate:[228]



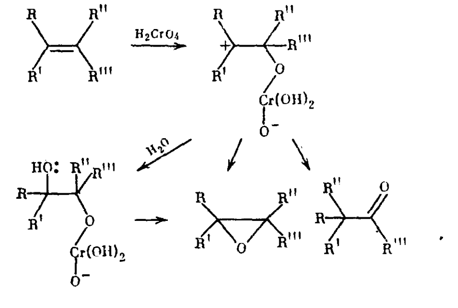
$$O_2Cr^{VI}(NO_3)_2 + Solv^0 \rightarrow O_2Cr^{V}(NO_3)_2 + Solv^+ .$$

The reaction then proceeds in accordance with the equation

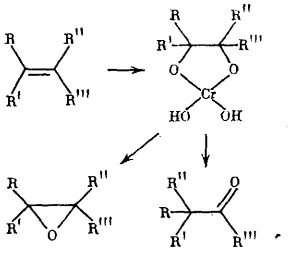
The active involvement of the intermediate chromium(V) has been confirmed by comparison with the ability of "macrocyclic oxochromium(V)" to convert alkenes effectively with a high degree of stereospecificity:[231]



The corresponding intermediates have been detected by EPR.[229] Despite the inadequacy of data concerning the role of chromium(IV) and chromium(V), the influence of substituents and stoichiometry, etc., it is believed that electrophilic attack on the double bond takes place:[219,220,232,233]



Cycloaddition, by analogy with oxidation by permanganate, is not ruled out either:[221,222]



The non-stereospecific epoxidation of tetraarylethylenes by chromyl acetate indicates indirectly that the reaction proceeds via a carbonium ion, in contrast to the oxidation of alkenes by permanganate,[234–236] where process stereospecificity is observed. The hypothesis of the intermediate formation of carbonium ions in the oxidation of alkenes by chromium trioxide in acetic anhydride to oxirans has been developed in other investigations.[219,220,237,238] These conditions ensure satisfactory yields of oxirans, while in the presence of hydrogen in the allyl position, the competing allylic oxidation is observed.[239]

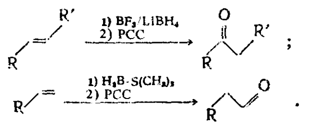
Kinetic data have shown that the rate of oxidation by chromic acid increases with increase of the degree of branching of the olefin chain. It has been established that the rate depends on the number of alkyl substituents to a greater extent than on the configuration of the olefin.[240] The acceleration of the reaction by the substituent at the double bond has also been noted in the oxidation of chalcones (phenyl styryl ketones); it was shown that electron-donating groups in the *para*-position in the benzene ring increase the rate, while electron-accepting groups diminish it.[241] In terms of their influence on the activity, the groups can be arranged in a sequence indicating the electrophilic character of the process:

$$4\text{-}OCH_3 > 3\text{-}OCH_3 > 2\text{-}OCH_3 > 4\text{-}Cl > 3\text{-}Cl > H > 3\text{-}NO_2 > 4\text{-}NO_2 .$$

The reaction is thought to proceed via a three-membered cyclic activated complex.[241,242] Analogous complexes have been postulated in the oxidation of alkenes by chromyl chloride.[243,244]

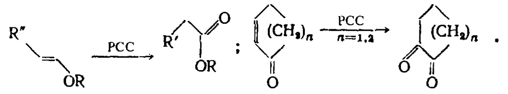
2. Oxidation by Coordination Complexes of Chromium Trioxide

The oxidation of multiple bonds by chromium trioxide complexes proceeds via the preliminary conversion of alkenes into organoelemental derivatives.[245–247] A promising variant involves their interaction with hydroborating agents and subsequent oxidation with PCC:[248,249]

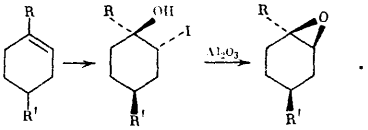


Numerous alkenes, including some with functional-group substituents, have been converted into aldehydes and ketones by this method.[250–252] A series of unsaturated carbonyl compounds have been synthesised in an analogous way via the dissociation of the C–Sn bond in organotin compounds by the pyridine complex of chromium trioxide.[253]

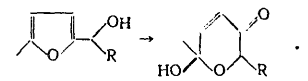
As already mentioned, direct oxidation of multiple bonds by pyridinium chlorochromate is difficult and, furthermore, its inertness with respect to double[10] and triple[10,254] bonds has been reported. Nevertheless, it has been established that vinyl ethers interact smoothly with PCC:[255]



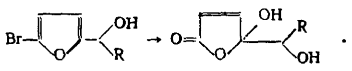
In the presence of iodine, trisubstituted olefins are converted by PDC regiospecifically and stereospecifically into iodohydrins and epoxides.[256] Certain natural polyenes, subjected to an analogous treatment, have been converted selectively into iodohydrins and then into epoxides:[256]



Substituted furans are also fairly sensitive to PCC:[257–261]

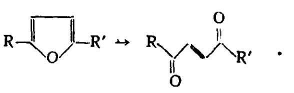


In the case of bromofurylcarbinol, ring expansion is not observed and the reaction leads to the formation of γ-hydroxybutenolides:[262–268]



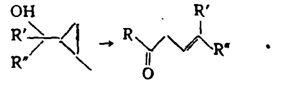
Under analogous conditions, nitrofurylcarbinol is converted into a ketone:[269]

Among these reactions, the oxidative opening of the rings of arylfurans to form linear diketones is no less important:[270]



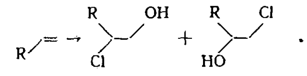
It is believed that the mechanism of the oxidation of furans by PCC includes the initial electrophilic 1,4-addition with subsequent ring opening.[270,272,273]

Ring opening has been observed also in the conversion of cyclopropylcarbinols into unsaturated ketones:[271]

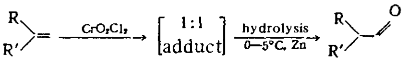


3. Oxidation by Chromyl Chloride

The oxidation of alkenes by chromyl chloride was already known at the beginning of the century.[274–281] However, the products thus obtained were first identified only in 1950.[282] It was found that the oxidation entails the preferential formation of chlorohydrins with a primary-hydroxy-group:[282,283]

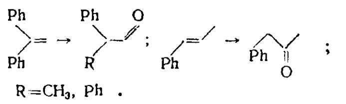


When cycyoalkenes are used in this reaction, mixtures of *cis*- and *trans*-chlorohydrins are formed. It is remarkable that the *trans*- and *cis*-isomers predominate respectively for cyclohexene and cyclopentene.[283] The formation of carbonyl compounds has also been noted under these conditions.[282,283] Other workers obtained mainly aldehydes from disubstituted terminal olefins;[279] the reaction involving phenylmethylethylene produces benzyl methyl ketone.[284] However, a more detailed study of the reaction[279, 282,283,285] showed that the reductive hydrolytic stage is mainly responsible for the reaction pathway and the yields of products. When zinc dust was used as the reductant instead of sulphur dioxide,[286] it was possible to obtain carbonyl compounds in high yields:[285]



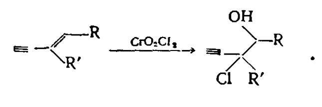
This reaction is of practical interest and has been used in the synthesis of chrysomelidial and gastrolactone.[287]

Among substituted olefins used in the reaction with chromyl chloride, styrenes are of great interest. A particular reason for this is that the familiar Etard reaction (oxidation of arylalkanes) proceeds according to many investigators via the intermediate formation of arylalkenes.[283, 286, 288–290] The interaction of chromyl chloride with *trans*-1-phenylpropene yielded at least seven compounds, including 1-phenyl-2-propanol.[288] However, other workers isolated only 1-phenyl-2-propanol.[284,291] Satisfactory results have been achieved in the oxidation of both 1,1- and 1,2-disubstituted styrenes (1-methyl-1-phenylethylene, 1,2-diphenylethylene, *trans*-1-phenyl-1-propene) by chromyl chloride at a low temperature where the reductive hydrolysis of the intermediate was carried out with the aid of zinc dust:[291]



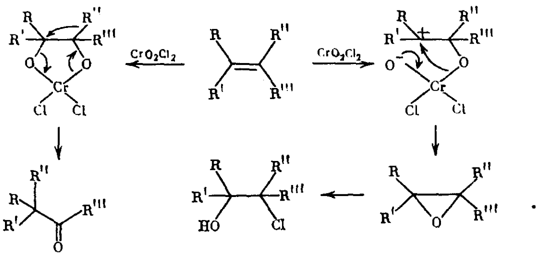
The oxidation of alkenes,[282,285,292] cycloalkenes,[284,293] and styrenes[291,293] by chromyl chloride has been the subject of controversy. It has been reported that treatment with an excess of chromyl chloride results in the formation of chlorohydrins in low yields,[282,292] while the reaction involving the use of equimolar ratios of the reactants produces carbonyl compounds.[243,285]

It has been established quite recently that various enynes interact selectively with chromyl chloride via the double bond with formation of alkyne chlorohydrins:[294]



A whole series of different enyne ethers, esters, and ketones have been introduced into this reaction.[294]

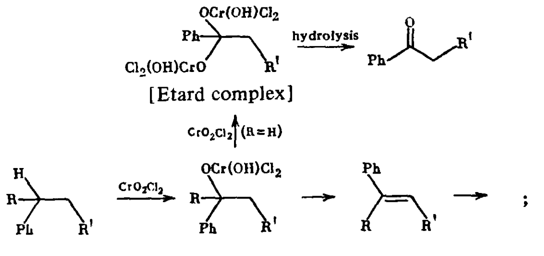
The interaction of chromyl chloride with multiple bonds is usually represented as proceeding via cyclic intermediates[282,283,291,295,296] in accordance with the scheme[243,285]

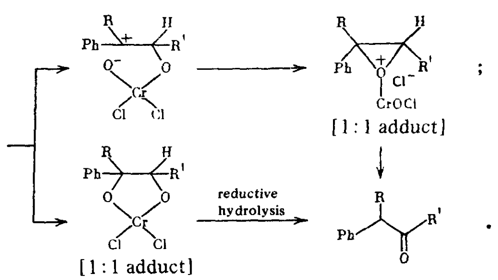


However, this hypothesis required confirmation with the aid of kinetic studies. Freeman and Yamachika[297] attempted to investigate the kinetics of the oxidation of cyclopentene, cyclohexene, and norbornene by chromyl chloride.[297]

The influence of ring size on the nature of the activated complex and on the rate of epoxidation,[298] oxidation with chromic acid,[240] and the addition of dibromocarbene and phenyl and picryl azides[299–301] had been investigated earlier. For example, in 1,3-dipolar cycloaddition reactions (via a five-membered cyclic activated complex), norbornene reacts 10^3—10^4 times faster than cyclohexene,[297] while the difference between the rates of epoxidation, addition of dibromocarbene to cyclopentene and cyclohexene or their epoxidation (which proceed via a three-membered ring) is very small.[299–301] Measurements of the rate constants for the oxidation of the above compounds by chromyl chloride and of the thermodynamic parameters under the conditions of a large excess of the cycloalkene and their comparison led the authors to the conclusion that the activated complexes in the case of cyclopentene and cyclohexene may be three- and five-membered cyclic compounds,[297] while in the case of norbornene only a five-membered transition state is produced. The same workers believe that, in the interaction of norbornene with chromyl chloride, an intermediate should be formed with a structure such that it can be converted into a *cis*-glycol or an epoxide rearrangement product.[242] However, it was soon established that, in the oxidation of norbornene and many of its substituted analogues at −80 °C, 74% of the isolated products are due to the initial formation of an *exo-cis*-chlorohydrin[302] and only 5% correspond to those predicted by Freeman. In contrast to the reaction of chromyl chloride with alkenes,[283] a mixture of *cis*- and *trans*-isomers is not formed in this instance—the interaction is stereospecific in the *exo*-position.[302]

In the early communications on the oxidation of styrene and its derivatives with chromyl chloride,[283,285,291,297,303,307] kinetic data were not quoted. However, styrenes[283] and cycloalkenes[296] were postulated as intermediates in the oxidation of cycloalkanes and arylalkanes respectively,[291,303,308] so that the overall process mechanism was represented as follows:



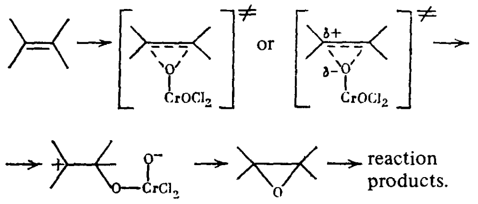


Subsequently, in the study of the kinetics of the reaction of chromyl chloride with styrenes, it was concluded[244] that it is of first order (first order with respect to each reactant) and that there is a correlation between the σ^+ constants of the substituents and the rate constants. These data as well as the thermodynamic parameters of the reaction agree with the mechanism involving electrophilic attack by chromyl chloride on the multiple bond with formation of resonance-stabilised partially bridged five-membered or three-membered activated complexes. From the value $\rho^+ = 1.99$, it was assumed in other investigations[309–312] that these complexes are hardly likely to be products of *cis*-addition, although this type of mechanism with an unbalanced charge in the transition state in cycloaddition has in fact been postulated.[313,314] However, since values of ρ^+ ranging from −3 to −5 were noted in reactions with a high degree of carbonium ion character of the transition state, the relatively low value $\rho^+ = -1.99$ conflicts with the idea that there is a full positive charge on the benzyl carbon.[244] Spectrophotometric data for the interaction of alkenes with chromyl chloride agree best with the idea that a three-membered cyclic intermediate complex is formed in the rate-determining stage.[243,291] The data obtained in the oxidation of bicyclic systems suggested that here too three-membered cyclic transition states are produced.[291] Next, the study of the kinetics of the addition of chromyl chloride to substituted styrenes showed that the rate of reaction increases after the introduction of electron-donating substituents. α-Methylstyrene is more reactive than *cis*-β-methylstyrene. The latter is oxidised at a lower rate than *trans*-β-methylstyrene, while *cis*-stilbene reacts twice as fast as *trans*-stilbene and 1,1-diphenylethylene is almost twice as reactive as α-methylstyrene and is superior to styrene by a factor of 13.[242] However, the question of the relative reactivities of the *cis*- and *trans*-isomers is not always susceptible to interpretations; for example, the higher reactivity of *cis*-stilbene compared with *trans*-stilbene has been observed in bromination reactions[315–317] and in oxidation with peracetic acid.[318,319] In contrast to this, *trans*-stilbene reacts faster than the *cis*-isomer in oxidation with chromic acid[240] and in *cis*-1,3-dipolar cycloaddition.[320] It is also essential to emphasise that neither *cis*- nor *trans*-stilbene afforded the expected carbonyl product on oxidation with chromyl chloride under the experimental conditions employed[285,291,321,322] and that they were successfully oxidised by chromyl chloride to carbonyl compounds only by varying the conditions.[323]

In the study of the kinetics of the oxidation of a number of alkenes, the first order of the reaction with respect to each reactant was observed.[243] The reaction is little influenced by steric factors and is characterised by low enthalpies of activation ($\Delta H^{\neq} = 5.4-7.2$ kcal mol^{-1}) and high negative entropies of activation ($\Delta S^{\neq} = -27.4 - -40.7$). Excellent correlations have been obtained between the rate constants and Taft σ^+ constants as well as a good correlation based on the Hammett equation.[243] Comparison of the relative reactivities in the oxidation with chromyl chloride and in other electrophilic reactions of alkenes (the addition of bromine and chlorine, oxidation with chromic acid, and epoxidation) suggested that the rate limiting stage involves a partially positively charged three-membered activated complex like the activated complex in the epoxidation of alkenes by peracids[324] or in the oxidation of alkenes with chromic acid.[240] From these data, the authors rule out the concerted *cis*-1,3-dipolar addition of chromyl chloride to the multiple bond in the rate determining stage, since this does not agree with kinetic data obtained for ring- or chain-substituted styrenes.[244,282] On this basis,[243] using the principle of the relative reactivities in solvolytic reactions,[325] oxidation with chromic acid,[239] epoxidation,[298,324] chlorination,[326] bromination,[327] and the addition of carbenes,[290,328] Freeman et al.[243] elucidated the nature of the activated complex in the oxidation of alkenes with chromyl chloride. The relative reactivities of alkenes in relation to chromyl chloride were obtained:[243]

pent-1-ene	1.22	2,3,3-trimethylbut-1-ene	**10.5**
hex-1-ene	1.00	2,4,4-trimethylpent-1-ene	**23.6**
oct-1-ene	0.77	*cis*-pent-2-ene	**14.8**
dec-1-ene	0.88	*trans*-pent-2-ene	**15.1**
2-methylpent-1-ene	8.00	2-methylbut-2-ene	**202.0**
3,3-dimethylbut-1-ene	5.36	2,3-dimethylbut-2-ene	**3910**
4,4-dimethyl-2-neopentylpent-1-ene	7.54	2,4,4-trimethylpent-2-ene	**1380**
cyclopentene	4.9	norbornene	**312**
cyclohexene	1.0	styrene	**366**

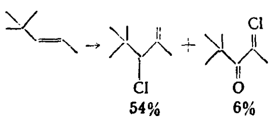
It is noteworthy that the mechanism of the oxidation of single and multiple carbon—carbon bonds with chromyl chloride still remains controversial.[292,293,304,305,329–335] Nevertheless, for the intermediate complex the rate of formation of which determines the rate of the entire reaction, a three-membered structure was adopted in the case of alkenes[282,293,296,297,329] and three- and five-membered asymmetric structures in the case of styrenes.[242,244,335] In an attempt to elucidate further the nature of the oxidation of cycloalkenes by chromyl chloride,[335] the kinetic data and thermodynamic parameters obtained were compared with data for the rearrangement of the epoxides;[218,219,242,334,336,337] the authors concluded that the process proceeds via the formation of epoxides, but the possibility of the intermediate formation of a carbonium ion was not ruled out:



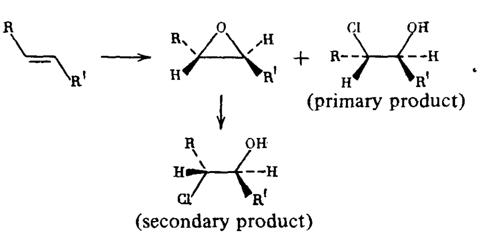
In their view, the fact that the rate of oxidation increases with increase of the number of methyl groups at the double bond agrees with the hypothesis. The involvement of a positively charged asymmetric three-membered activated complex in the rate limiting stage is indicated also by the fact that almost identical mixtures of final products are obtained from the following pairs of compounds in their reactions with chromyl chloride: 1-methylcyclopentene and methylenecyclopentane, 1-methylcyclohexene and methylene cyclohexane, and 1-methylenecycloheptene and methylenecycloheptane.[335]

The mechanism of the oxidation of multiple bonds has been formulated in a different way by Sharpless et al.,[230] who believe that reactions involving oxidation by metal oxo-compounds in general and by chromyl chloride in particular, begin with attack by the organic reductant on the metallic centre.[293] They believe that the mechanism proposed in a number of studies,[242,243,282,283,291,292,335,338,339] involving the formation of a three-membered intermediate, obtained by the electrophilic interaction of $[CrO_2Cl]^+$ with the olefin, followed by the attack on the latter from the rear by a chloride ion, is based on data showing that cyclohexene gives rise to *trans*-chlorohydrin, while the terminal olefins are products of the addition of the elements of the addend contrary to the Markovnikov rule. However, the authors note that this picture disagrees with the result of a study[283] where both *cis*- and *trans*-chlorohydrins were obtained from cyclohexene and cyclopentene. It was therefore necessary to assume that the reaction proceeds via a carbonium ion intermediate and that the latter is responsible for the formation of the *cis*- and *trans*-products.

It has been shown that the oxidation of *E*-t-butylmethylethylene with chromyl chloride in acetone results in the formation of mainly a ketone and the product of the Wagner—Meerwein rearrangement:[340]

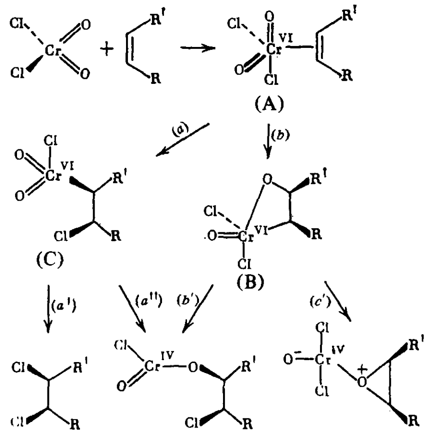


The authors believe that this result conflicts with the possibility of the existence of the intermediate structures presented above. On the other hand, it is known that the oxidation of olefins with chromyl chloride leads mainly to complex mixtures of compounds.[282,283,339] However, it has been reported recently[341,342] that epoxides are formed at a low temperature, although it has in fact been stated[302] that *exo*-*cis*-chlorohydrin is the main product in the reaction of chromyl chloride with norbornene. Sharpless et al. established unexpectedly that *cis*-addition is a common feature of the reactions of chromyl chloride with olefins.[230] On comparing the results of the oxidation of different alkenes with chromyl chloride at low temperatures and of the addition of the elements of HOCl to the same olefin, the authors concluded that the epoxides and chlorohydrin are the results of *cis*-addition and are the primary oxidation products, while the isomeric chlorohydrin (the product of *trans*-addition) is a secondary product obtained as a consequence of the opening of the epoxide ring:



It has been found that, analogously to other chromium reagents,[343] chromyl chloride is stereospecific and that epoxides with the geometry of the initial olefin are formed when it is used.

It has been shown[230] that the oxidation yields also a certain amount of dichloro-derivatives, which are likewise formed as a result of *cis*-addition. In their view, this can be in no way accounted for by the mechanisms proposed previously. On the basis of these data and also the fact that carbonyl compounds (aldehydes and ketones) give rise to nucleophilic reactions involving exclusively the carbon of the carbonyl group despite being less polarised than metal oxides, the authors assume that the oxidation of alkenes with chromyl chloride proceeds via the formation of organometallic intermediates:[230]



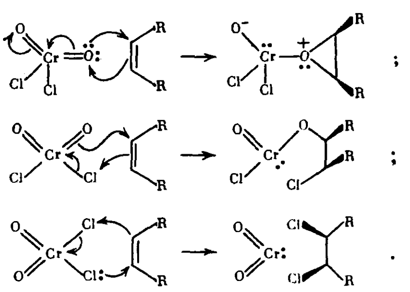
It has been suggested that the complex (A) is formed initially from the olefin and chromyl chloride. In the case of ligands more basic than olefins, stable type (A) complexes are known (chromium trioxide–bipyridyl, osmium tetroxide–pyridine). In a transition metal complex of type (A), the displacement of the coordinated olefin with formation of a metal-ligand either π- or σ-bond is a likely process. For this reason, the authors proposed two reaction pathways, (*a*) and (*b*), for chromyl chloride, which lead to organometallic intermediate complexes of chromium(VI). Via pathway (*a*), the olefin is inserted in the chromium–carbon bond (*cis*-chlorometallation), forming the alkylchromium intermediate complex (C), which is converted into the dichloride, pathway (*a*′), involves reductive elimination or [conversion?]† into the chromium derivative of chlorohydrin, and pathway (*a*″) involves migration of the alkyl group from chromium to oxygen. Both these processes take place with retention of the configuration of the carbon centre and result in *cis*-addition. Reductive elimination with formation of a chlorine–carbon bond (pathway *a*′) is well known in organic chemistry and takes place with retention of the configuration at the carbon atom.[344–346] The migration of 1,2-shift via pathway (*b*′) can take place, by analogy with the Stevens rearrangement, only with retention of the configuration at the carbon atom.[347] The earlier hypothesis of high-valence organometallic compounds such as the compounds (A), (B), and (C) would seem to be unrealistic. However, the literature, starting from as early as 1970's has been saturated by examples of organometallic derivatives of vanadium,[348,349] tantalum,[350] chromium,[351,352] tungsten,[353] and rhenium.[354,355] A tungsten complex (CH_3WO_2Cl), whose structure is very similar to that of organometallic type (C) intermediates, has been isolated and characterised.[353]

The mechanism presented actually involves [2 + 2] addition. The competing pathways (*a*) and (*b*) are especially sensitive to the nature of the medium, as expected. When the reaction is carried out in acetone or in the presence of a nucleophile (the chloride ion), the yield of chlorides increases.[341,356] Next it was established that, in oxidation with chromyl chloride in the presence of lithium bromide, only bromohydrins and bromoketones are obtained, because the bromide ion is more nucleophilic than the chloride ion:

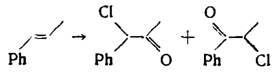
$$CrO_2Cl_2 \xrightarrow{2Br^-} CrO_2Br_2 + 2Cl^- \ .$$

The *cis*-addition of chromyl bromide leads to the final product.[230]

Sharpless and co-workers also did not rule out a mechanism involving direct attack on the heteroatom in accordance with the following schemes:



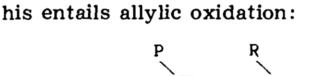
They had already established that different internal olefins can be converted into α-chlorohydrins by oxidation with chromyl chloride in acetone.[340] *cis*-Olefins react more slowly and with lower yields;[357] when the reaction mixture is treated with zinc dust, ketones are isolated.[340] In certain cases, for example with *E*-methylphenylethylene, a mixture of isomeric chloroketones in proportions of 3 : 1 is produced:



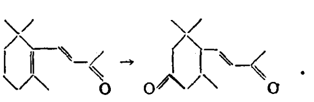
Thus new aspects of the oxidation of alkenes with chromyl chloride (via the initial formation of a high valence complex of the transition metal with a chromium–carbon σ-bond) have been examined and it has been shown that the primary oxidation products are epoxides and chlorohydrins.

IV. ALLYLIC OXIDATION

Treibs and Schmidt[358] showed for the first time that chromium trioxide in acetic anhydride is able to oxidise cyclohexene, α-pinene, tetralin, and other unsaturated compounds with formation of unsaturated ketones. It was later established[359] that this entails allylic oxidation:

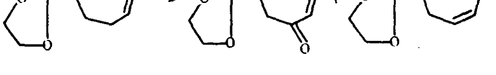


It was subsequently demonstrated that a more convenient reagent for allylic oxidation is di(t-butyl) chromate:[77]



Cholesteryl acetate also gives rise to quantitative yields of the ketone;[77] the reaction was carried out in a non-polar solvent with added acetic anhydride. The latter reagent has been used successfully for the oxidation of various terpenoids in the allyl position.[360–373] Cyclohexadiene and cyclopropene also react with hexavalent chromium at the allyl carbon–hydrogen bond.[374]

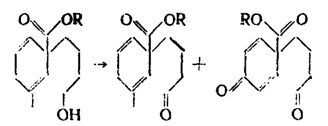
The reaction of dienes with PCC is of interest:[375]



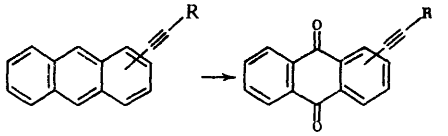
---

† Word(s) missing in Russian text. (Editor of Translation).

The 1,4-diene ester shown below is oxidised analogously in the allyl position:[376]

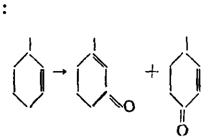


The oxidation of polynuclear aromatic hydrocarbons to quinones by chromium trioxide in acetic acid merits attention.[377] Alkylethynyl-substituted aromatic hydrocarbons are converted into quinones under similar conditions:[378]

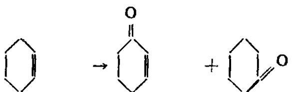


It is noteworthy that, in contrast to the manganese compounds which react rapidly with alkenes and alkynes[379,380] to form 1,2-diols and 1,2-diketones, chromium compounds (chromyl acetate,[358] chromic acid,[359] t-butyl chromate,[69] and the pyridine complex of chromium trioxide[381]), which are readily available and cheap oxidants,[382–385] interact slowly to form α-oxidation products.

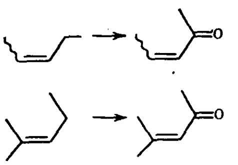
When substituted cyclohexenes and steroids interact with the dipyridine complex of chromium trioxide in methylene chloride, the allyllic methylene groups are oxidised slowly.[381] If there is more than one methylene group in the conformationally flexible molecule, then enones are obtained as a result of attack directed to a series of possible positions, while in a conformationally rigid system a rigorous selectivity of the oxidation reaction is observed; attack at the methine position (wherever this is possible) leads to the formation of the isomeric enone:



An analogous picture has been observed also in a sterically shielded methylene system, for example:[381]



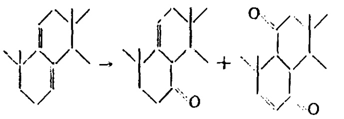
These reactions are characteristic also of substituted cyclopentenones.[386] The hexavalent chromium ion has been used also for the allylic oxidation of acyclic alkenes:[205]



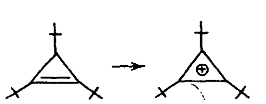
The allylic oxidation of alkynes has been demonstrated in two investigations.[254,387] Various internal alkynes react with chromium(VI) compounds to form α-diketones and allylic oxidation products, high yields of the latter being attained in the presence of the bipyridyl complex of chromium trioxide.[387]

When α-steryl acetate is made to react with chromic acid in acetic acid, allylic oxidation takes place together with epoxidation.[200] α-Cholestenyl acetate,[388] α-spinosterol,[202,203] and other polycyclic alkenes[204,205] react analogously.

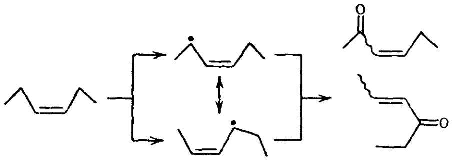
The reaction of steroid dienes, where allylic oxidation takes place with formation of diketones, is of special interest.[206–209]



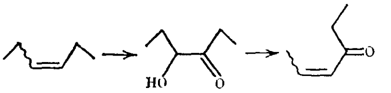
On the other hand, it has been estaalished that in the oxidation of a multiple bond in steroids the formation of ketols is also observed.[210–212] Cyclohexadiene reacts at room temperature with chromium trioxide in acetic acid with formation of benzene.[365] Under analogous conditions, tri(t-butyl)cyclopropene affords the tri(t-butyl)cyclopropenylium cation:[389]



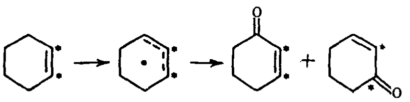
It has been suggested that allylic oxidation does not involve the initial attack on the multiple bond and proceeds either via the allyl radical or via a carbonium ion, which may lead to the isomerisation of the double bond, as is in fact observed in reality:[199]



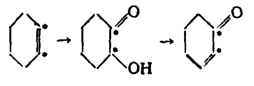
The initial oxidation of the multiple bond via epoxides to the corresponding hydroxyketones, which subsequently afford αβ-unsaturated ketones after eliminating water, has been suggested as an alternative:[210]



Since isomeric products are formed on oxidation, it has been postulated that the process proceeds via the first of the mechanisms postulated. Indeed, it has been established by the tracer atom method (at the multiple bonds) that both the methylene and methylidyne groups are oxidised in the reaction of cyclohexene with chromic acid:[199]



If the reaction proceeded via a hydroxyketone, then only one isomer would have been formed:



It is believed that an intermediate in which chromium is in the +4 oxidation state is obtained in allylic oxidation.[337,364]

---o0o---

The data presented in this review demonstrate the extensive synthetic possibilities of the application of hexavalent chromium compounds as reagents in the chemistry of unsaturated compounds. Many oxidants, which are quite usual in organic chemistry, are unsuitable for alkenes, alkynes, alkadienes, enynes, etc. with functional groups as substituents. As regards chromium reagents, the most promising proved to be the coordination complexes of hexavalent chromium, in particular, the pyridine complexes. Pyridinium chlorochromate, which is irreplaceable in the generation of functional groups in highly unsaturated carbinols and polyols, is comparatively universal. However, one should note the impossibility of using it in the synthesis of compounds which are exceptionally sensitive to increased acidity and which can readily undergo prototropic transformations. The growing interest in chromium(VI) coordination complexes has led to the discovery of reagents with a less pronounced acidity: pyridinium dichromate, 2,2′-bipyridyl chlorochromate, and 4-(dimethylamino)pyridinium chlorochromate, as well as reagents on carriers and polymeric supports. For example, the possibility of the selective oxidation of diene carbinols by 4-dimethylaminopyridinium chlorochromate has been demonstrated. Chromyl nitrate proved to be irreplaceable in the stereospecific epoxidation of dienes. An interesting approach to the formation of acetylenic epoxides involving the chemoselective oxidation of enynes by chromyl chloride has been discovered.

The main bulk of studies on the oxidation of unsaturated systems having functional groups as substituents by chromium reagents are not only of theoretical but also of practical importance and can find further applications in the construction of natural structures and in the synthesis of hormones, pheromones, prostaglandins, and their synthones. In the future, the studies in this field will in all probability be directed to finding new oxidising systems, which will permit smooth regiospecific, chemospecific, and stereospecific syntheses.

The Interaction of Carbenes and Nitrenes with Azo-compounds

A.A.Suvorov and M.A.Kuznetsov

A critical analysis of the literature on the interaction of carbenes and nitrenes with azo-compounds is presented, attention being concentrated on the reactions of aminonitrenes.
The bibliography includes 83 references.

CONTENTS

I. Introduction 756
II. The addition of carbenes to azo-compounds 756
III. The addition of nitrenes to azo-compounds 758

I. INTRODUCTION

The study of the reactions of unstable intermediate species is one of the most fruitful "growth points" in modern organic chemistry. Its branches, such as the chemistry of carbonium ions, carbanions, and free radicals, have already become classical but at the same time it continues to develop vigorously. During the last decades, very much attention has been devoted to the study of the reactions of carbenes, nitrenes, and their analogues—neutral intermediates incorporating an atom with an incomplete six-electron (sextet) electron shell. Owing to the exceptional wide variety of reactions of such compounds, which has stimulated both applied, synthetic development and numerous studies by theoreticians (see, for example, the corresponding chapters in the annual reviews "Organic Reaction Mechanisms" or "Annual Reports on the Progress in Chemistry").

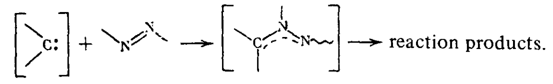
The most important trend in this field concerns the study of the interaction of carbenes and nitrenes with unsaturated groups. Their addition to the C=C, C≡C, and C=X (X is a heteroatom) bonds constitutes an effective general method of synthesis of three-membered rings, strained polycyclic systems, and a very great variety of products of further reactions. This is why thousands of papers and tens of reviews and monographs have been devoted to the above branch of chemistry of carbenes and their analogues and their number continues to grow.

Azo-compounds have been one of the few exceptions in this field and the interaction of carbenes and nitrenes with compounds containing the N=N group has not been investigated systematically until recently. However, since the beginning of the 1970s, a whole series of studies have been carried out in which it has been demonstrated that the usually fairly inert azo-group reacts smoothly with these sextet species to form new classes of unusual polynitrogen compounds. So far, fairly extensive data have accumulated in this field requiring a survey, which has been the reason why this review, in which we have tried to cover the literature until the beginning of 1985, has been written.

II. THE ADDITION OF CARBENES TO AZO-COMPOUNDS

In contrast to the majority of other reactions, the reaction with azo-compounds has been investigated in less detail for carbenes than for nitrenes. Furthermore, it has been found that certain reactions, assigned to this type, in reality proceed without the participation of carbenes. Thus investigation of the kinetics of the reactions of diazo-compounds with a series of azo-compounds, in the first place with azodicarbonyl compounds, showed that the initial diazo-compound itself usually reacts with the azo-group and that only then is the nitrogen molecule split off[1] (among the later studies in this field see, for example, Korobitsyna and co-workers[2,3] and the literature quoted therein).

Nevertheless, it has been suggested that in many instances it is precisely carbenes that react with azo-compounds. This entails the formation, as a rule, of the corresponding 1:1 adducts to which the structure of diaziridines or the isomeric 1,3-dipolar compounds—azomethineimines (I)—was attributed in early studies. Later it was demonstrated that in reality the reaction products have a different structure and can be usually formally regarded as a result of the 1,4-addition of the carbene to the N=N−C=X fragment (X = O, N, or C) of the initial conjugated azo-compound. However, although the azomethineimines (I) are not in fact the final products in any of the reactions of carbenes with azo-compounds known at the present time, their involvement as intermediates has been suggested:



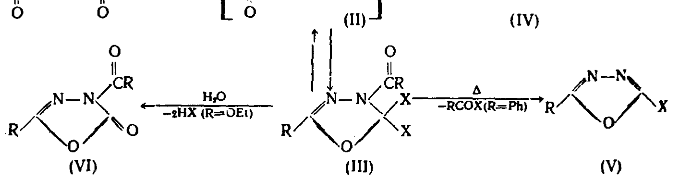
(I)

The reactions of carbenes with azo-compounds can be divided into several types: interaction of dihalogeneocarbenes with azo-compounds; the addition of methylene and its aromatic derivatives to 2,2'-azopyridine and its analogues; the addition of alkylidenecarbenes to aromatic azo-compounds and the reaction of alkoxyalkylcarbenes with oxadiazolines.

1. The Reactions of Dihalogenocarbenes with Azo-Compounds

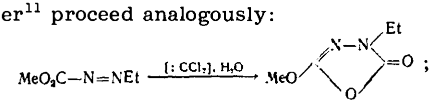
In reactions with various azo-compounds dihalogeneocarbenes were usually generated by the thermal decomposition of trihalogenomethylphenylmercury[4-8] or sodium trichloroacetate.[4,5,9] The addition of dihalogeneocarbenes to azodicarbonyl compounds has been studied in greatest detail:

$$\mathrm{PhHgCX_2Br} \xrightarrow[-\mathrm{PhHgBr}]{20\,^\circ\mathrm{C\ or\ }\Delta} [:\mathrm{CX_2}] \xleftarrow[-\mathrm{NaX},\,-\mathrm{CO_2}]{\Delta} \mathrm{CX_3CO_2Na}\ ;$$
$$\mathrm{X_2{=}Cl_2,\ ClBr,\ Br_2}$$



At room temperature, the products in this instance are oxadiazolines (III), which are apparently formed as a result of the cyclisation of the intermediate azomethineimines (II).[4-8] If the reaction is carried out with heating, then, depending on the nature of the substituent, the oxadiazolines (III) are either rearranged to the hydrazones (IV), probably again via the azomethineimines (II),[4,5] or they split off the RCOX molecule with formation of the oxadiazoles (V);[6,7] in the presence of water, the main reaction products are the oxadiazolinones (VI).[9]

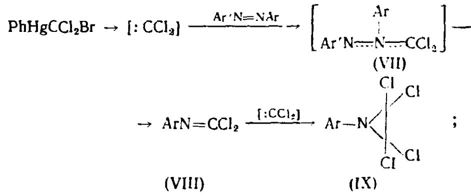
The addition of dichlorocarbene to methyl ethylazocarboxylate (in the presence of water)[9] and to bis(trimethylsilyl)diimide[10] and also the addition of dicyanocarbene, generated by the decomposition of dicyanodiazomethane, to azodicarboxylic ester[11] proceed analogously:



$$\mathrm{Me_3SiN{=}NSiM_3 \xrightarrow{[:\,CCl_2]} (Me_3Si)_2N{-}N{=}CCl_2}\ ;$$

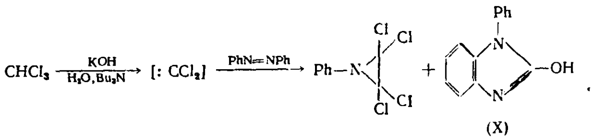
$$\mathrm{EtO_2CN{=}NCO_2Et \xrightarrow{[:\,C(CN)_2]} (EtO_2C)_2N{-}N{=}C(CN)_2}\ .$$

Dichlorocarbene reacts significantly differently with azoarenes. In this case, the phosgeneimines (VIII) and the products of the further addition of the carbene (IX) are formed in this reaction:[4,8]



Ar = Ph, *p*-Tol, *p*-ClC$_6$H$_4$.

When dichlorocarbene was generated by the phase transfer method, the formation of phosgeneimine in the reaction with azobenzene was not noted, but 2-hydroxy-1-phenylbenzimidazole (I) was islated as an additional product:[12]

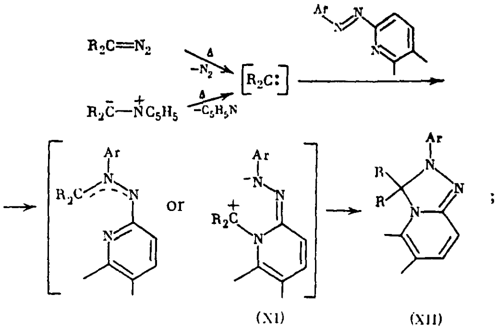


It has been suggested that the azomethineimines (VII) [8] (or the isomeric diaziridines[8,12]) are formed initially in this instance and then lose an arylnitrene[8] or rearrange to benzimidazole derivatives (cf. the Section below). The mechanism of the elimination of the arylnitrene was not discussed.[8] It may be that the intermediate azomethineimines (VII) react with a second molecule of dichlorocarbene to form two phosgeneimine molecules.

The same products are obtained also in the reaction of dichlorocarbene with azoxyarenes, probably as a result of the intermediate formation of azo-compounds.[8,12]

2. The Addition of Methylene and Arylcarbenes to 2,2′-Azopyridine and Its Analogues

The reactions of methylene and its aryl-substituted derivatives with 2,2′-azopyridine, 2-phenylazopyridine, and 2,2′-azoquinoline involve the formation, like the reactions of dihalogeneocarbenes with azodicarbonyl compounds, of (formally) the products of the 1,4-addition of the carbene to the N=C—N=N fragment, namely the triazolopyridines (XII).[13,14] The carbenes were generated by the thermolysis of the corresponding diazo-compounds or pyridinium ylides:

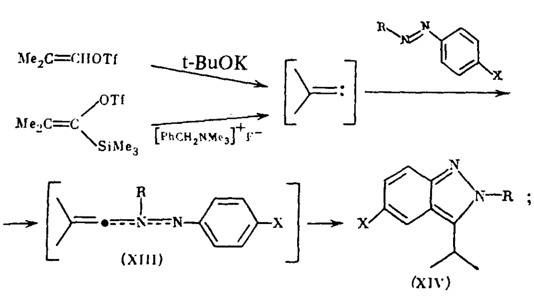


R = H, Ph: R$_2$C = PhCH, 9-fluorenylidene;
Ar = Ph, 2-pyridyl, 2-quinolinyl.

The authors of the first studies of this reaction[15,16] assumed that carbenes are not formed in the course of the reaction. However, it was shown later[13] that the interaction of diazo-compounds with 2,2′-azopyridine and its analogues proceeds only under these conditions when the diazo-compounds are unstable and decompose with formation of carbenes. The rate of reaction then varies with temperature, like the rate of decomposition of the initial diazo-compound in the absence of substrates, which indicates the carbene mechanism of this reaction.[13] However, it is noteworthy that, apart from the azo-group, the molecules of 2,2′-azopyridine and its analogues contain yet another potential reaction centre—the nitrogen atom of the pyridine ring and it is not known whether the initial attack is in fact directed to the azo-group or whether an alternative mechanism with formation of the intermediates (XI) operates.[13]

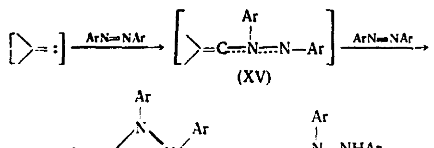
3. The Addition of Alkylidenecarbenes to Azoarenes

The reaction of 2-propylidenecarbene with a number of azoarenes and t-butylazobenzene results in the formation of, formally, the products of the 1,4-addition of the carbene to the N=N—C=C system, probably via the intermediate azomethineimines (XIII):[17-20]



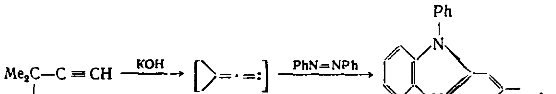
OTf = OSO$_2$CF$_3$; R = T-Bu, *n* = YC$_6$H$_4$; X, Y = H, Me, OMe, F, Cl .

The reactions with asymmetric substrates yield comparable amounts of both possible isomeric benzopyrazoles (XIV).[18,19] In the reactions with azoarenes containing strong electron-accepting substituents, the 2 : 1 adducts (XVI) or (XVII), regarded as the results of the 1,3-dipolar addition of the intermediate azomethineimines (XV) to the initial azo-compound, were isolated in low yields:[19,20]



Ar=4-$CF_3C_6H_4$, 3,5-$(CF_3)_2C_6H_3$.

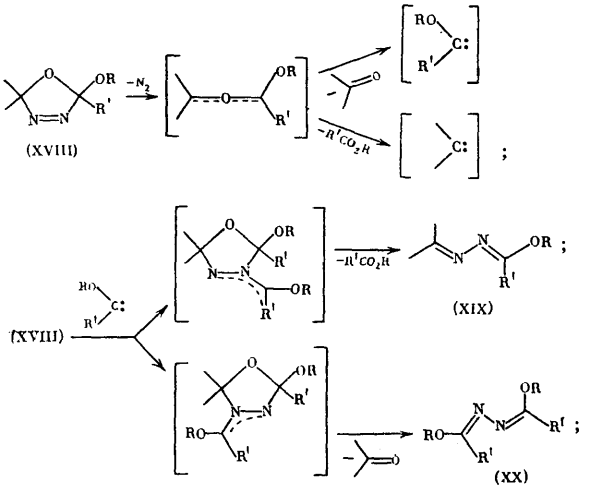
The initial adducts of dimethylvinylidenecarbene with azobenzene rearrange with dissociation of the nitrogen–nitrogen bond:[21]



The reaction of fluorenylidenecarbene with azobenzene leads to the formation of a small amount of a 1 : 1 adduct, whose structure has not, however, been established.[22]

4. The Reaction of Alkoxycarbenes with 1,3,4-Oxadiazol-3-ines

The thermal decomposition of a series of 2-alkoxy-1,3,4-oxadiazol-3-ines (XVIII) results in the formation of dialkyl- and alkylalkoxy-carbenes, which react with the initial compounds:[23]



R = Me, Et, CH_2CF_3, CH_2CCl_3; R' = Me, Et, iso-Pr; RR' = $(CH_2)_3$.

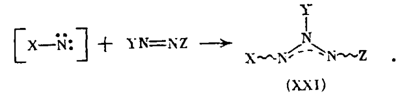
The main reaction pathway involves the intermediate formation of alkoxycarbenes and the subsequent addition to the nitrogen atom in the 3-position in the oxadiazoline ring, which ultimately leads to the asymmetric azines (XIX).[23] However, the reaction mixtures usually contain also the azine (XX) and dimethylketazine, which the authors[23] regard as a result of the participation in the reaction of not only the alkoxycarbene but also of dimethylcarbene.

III. THE ADDITION OF NITRENES TO AZO-COMPOUNDS

A fairly large range of examples of the interaction of nitrenes with azo-compounds has now been investigated. It has been found that the addition takes place only in those cases where the substituents in the nitrene and in the azo-compound differ greatly in their electronic nature. On the other hand reactions with participation of many nitrenes such as aryl-, perfluoroalkyl-, amino-, and imido-nitrenes as well as others frequently result in the formation of their formal dimers—azo-compounds[24]—in high yields, but there have been no communications about the products of further addition of nitrenes to these compounds. This indicates most probably the inertness or low reactivity of nitrenes in relation to azo-compounds having the same substituents (although one cannot rule out also the possibility that nitrenes do nevertheless add in this instance by the resulting adducts are unstable and decompose with formation of the initial azo-compound).

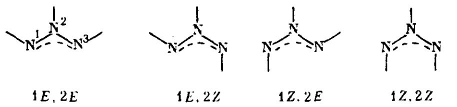
In our view, this type of dependence of the reactivity of nitrenes in relation to azo-compounds on the electronic nature of the substituents justifies the assumption that, when the nitrene molecule contains electron-donating substituents and the azo-compound molecule contains electron-accepting substituents (as in the reactions of dialkylamino- and diarylamino-nitrenes with azodicarboxylic acid derivatives), the addition of the nitrene to the azo-group is nucleophilic, while in the opposite case (the addition of phthalimidonitrene and alkoxycarbonylnitrenes to azoalkanes and azoarenes) this interaction is electrophilic.

In contrast to the addition of carbenes, where the formation of azomethineimines as intermediates is usually postulated, almost all the known reactions of nitrenes with azo-compounds lead to stable 1,3-dipolar compounds—the azimines (XXI):



(XXI)

E,*Z*-isomerism is possible in relation to both partially double nitrogen–nitrogen bonds and the azimines containing different substituents at the terminal nitrogen atoms can exist in principle in the form of four stereoisomers:

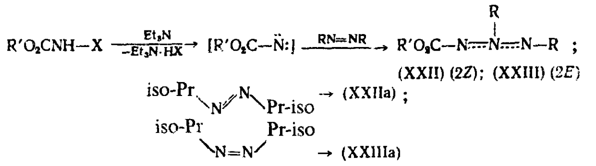


A non-empirical calculation of the relative stabilities of the isomers of the simplest azimine N_3H_3 [25] showed that the *Z*,*Z*-isomer is the most stable, that the energy of the *E*,*Z*-configuration is slightly higher, and that the *E*,*E*-structure is energetically extremely unfavourable. Taking into account steric factors, one may expect that the *E*,*Z*- and *Z*,*E*-isomers will be the most stable for the substituted azimines and that in all the known acyclic azimines the two nitrogen–nitrogen bonds do indeed have the opposite configurations.

1. The Addition of *C*-Nitrenes to the Azo-Group

As mentioned above, arylnitrenes and a series of other *C*-nitrenes apparently do not react with azo-compounds containing the same substituents as those in the nitrene molecule. In particular, the reaction of azocycarbonylnitrene with diethyl azodicarboxylate could not be achieved.[26,27]

On the other hand, alkoxycarbonylnitrenes add to nitrogen-containing compounds without electron-accepting substituents—azoalkanes and azoarenes—with formation of the esters of the corresponding azimine-1-carboxylic acids (XXII) or (XXIII):[28,29]



(XXII) (2*Z*); (XXIII) (2*E*)

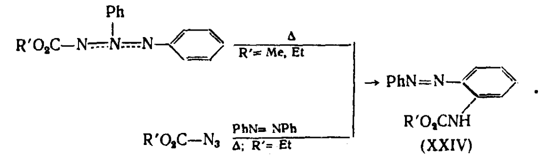
(XXIIa); (XXIIIa)

$X = OSO_2C_6H_4NO_2$-*p*; R′ = Me, Et; R = iso-Pr (a), Ph (b), *p*-Tol (c); R_2 = 1,3-cyclopentylene (d).

The alkoxycarbonylnitrenes were generated under mild conditions by the α-elimination of *p*-nitrobenzenesulphonic acid from the corresponding sulphonyloxycarbamates in the presnece of an equimolar amount or an excess of the azo-compound.

The reaction with *E*- and *Z*-2,2′-azopropanes proceed with retention of the configuration of the azo-group and lead respectively to 2*Z*- and 2*E*-azimines (XXIIa) and (XXIIIa).[28,29] On the other hand, the same product, whose geometry has not been established, is formed from the isomeric *E*- and *Z*-azoarenes.[29]

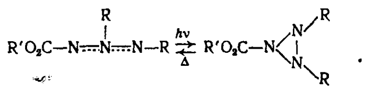
The adducts of alkoxycarbonylnitrenes with azobenzene rearrange on heating with migration of the alkoxycarbonylimino-group to the *ortho*-position in the benzene ring and the formation of the products (XXIV).[29] The same substances are formed on thermolysis of ethoxycarbonyl azide in the presence of azobenzene:[30,31]



(XXIV)

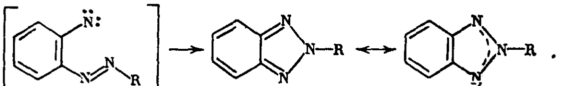
Probably ethoxycarbonylnitrene adds in this instance to azobenzene with subsequent thermal rearrangement of the adduct (XXIIb) or (XXIIIb).[30,31]

It is of interest to note that derivatives of a three-membered ring with three nitrogen atoms, namely triaziridines (XXV), were obtained for the first time by the cyclisation of the azimines (XXIIa) and (XXIIId).[28,32] These compounds are comparatively unstable and gradually recyclise to the initial azimines even at room temperature:[28,32]



(XXIIa), (XXIIIg)

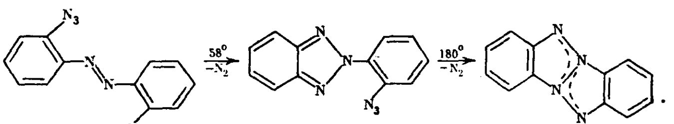
In contrast to carbonylnitrenes, alkyl- and aryl-nitrenes have been much more rarely introduced into intermolecular reactions[24] and there are no examples in the literature of their interaction with azo-compounds. However, a series of reactions which can be formally treated as intermolecular addition of arylnitrenes to the azo-group, usually located in the *ortho*-position, have already been known for more than 100 years:



(XXVI)

The oxidation of *o*-aminoazo-compounds by various oxidants,[33-39] the reduction of *o*-nitroazo-compounds,[40-44] and the thermolysis and photolysis of the corresponding azides[31,34,45-50] belong to these reactions. Their products are 2*H*-benzotriazoles (XXVI), related to azimines, or the initial heterocyclic compounds containing the azimine chain in their structure.

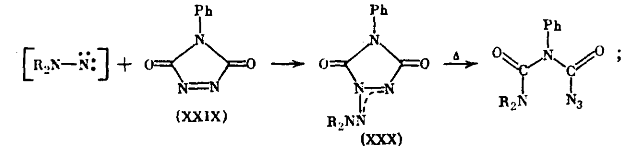
However, in the majority of cases the reactions enumerated above apparently proceed via intermediate species other than nitrenes[38] and also as concerted processes.[45] The involvement of nitrenes is assumed in this instance by analogy with other reactions,[41-43] is regarded as one of the possible variants, and as a rule has not been reliably demonstrated (cf. for example, Butler[38] and Dyall,[39] Spagnolo et al.,[47] Spagnolo et al.,[48] etc.); at the same time even formally very similar compounds can have different mechanisms. As an illustration, one may quote a series of syntheses of tetraazapentalene systems of type (XXVIII),[51-55] where it has been demonstrated, in relation to the thermolysis of *oo*′-diazidoazobenzene (XXVII), that the elimination of the first nitrogen molecule is a concerted process and that the nitrene mechanism is possible only for the second stage (but has not been demonstrated):



(XXVII) (XXVIII)

2. The Interaction of Dialkylamino- and Diarylamino-nitrenes with Derivatives of Azodicarboxylic Acid

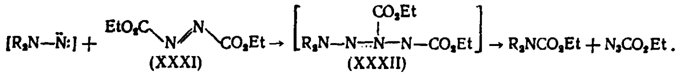
The first communication about the reaction of aminonitrenes and nitrenes in general with nitrogen-containing compounds was published in 1970.[56] In this and in a series of later studies it was shown that dialkylamino- and diarylaminonitrenes add to 4-phenyl-1,2,4-triazoline-3,5-dione (XXIX), a cyclic derivative of azodicarboxylic acid, with formation of the stable adducts (XXX),[56,57] the azimine structure of which has been confirmed by ^{1}H NMR, IR, and UV spectra, as well as mass spectra and, in the case of the adduct of diphenylaminonitrene (XXXa), also by X-ray diffraction.[58] On heating, the aminoazimines (XXX) rearrange with the opening of the five-membered ring:[56,59]



(XXIX) (XXX)

R = Ph (a), CH_2Ph (b), Me (c), Et (d); R_2N– = MePhN– (e), $(CH_2)_5N$–(f).

The reaction of the same aminonitrenes with diethyl azodicarboxylate (XXXI) leads in each instance to a mixture of the corresponding urethane with ethoxycarbonyl azide, but the full analogy of this set of substances with the products of the thermolysis of the azimines (XXX) makes it possible to postulate also the intermediate formation of the aminoazimines (XXXII):[56,60,61]



(XXXI) (XXXII)

The high thermal stability of the cyclic aminoazimines (XXX) has been explained by the fact that the migration of the carbonyl group to the amino-nitrogen atom is hindered in this instance by steric factors.[60]

The aminonitrenes were generated in these reactions by oxidising the corresponding 1,1-disubstituted hydrazines using azodicarbonyl compounds as oxidants;[56,60,61] in addition, dibenzylaminonitrene was obtained by decomposing dibenzylamino-*N*-azide:[57]

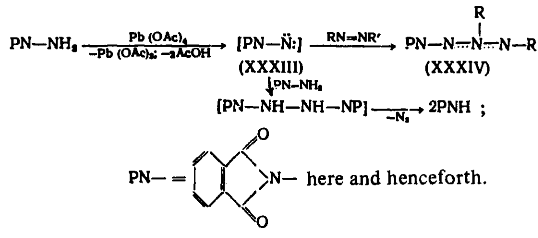
$$R_2N{-}NH_2 \xrightarrow[-XNHNHX]{XN{=}NX} [R_2N{-}\ddot{N}{:}] \xleftarrow[R=CH_2Ph]{-N_2} R_2N{-}N_3 \, .$$

The involvement of aminonitrenes in the reaction is indicated by the following data. Firstly, the same aminoazimine (XXXb) is formed from both 1,1-dibenzylhydrazine and from dibenzylaminoazide in the reaction with triazolinedione (XXIX) and in the latter case the rate of decomposition of the azide (the rate of evolution of nitrogen) is independent of the presence of the azo-compound (XXIX) in the mixture.[56] Secondly, in the reaction of 1,1-disubstituted hydrazines with azodicarboxylic ester (XXXI) the formation of a small amount of tetrazenes—typical products of the interaction of aminonitrenes with the initial hydrazines—was observed and the yield of the tetrazenes increased greatly (sometimes by a factor of hundreds) when the azo-compound was added to hydrazine instead of *vice versa*.[56,60,61]

3. The Interaction of Phthalimidonitrene with Azo-Compounds

Among all the sextet species, phthalimidonitrene (XXXIII) has been studied in greatest detail in its reaction with azo-compounds. Its addition to the azo-group was first reported in 1971 [62] and since then many studies have been devoted to this reaction and its products.[62–81]

In all cases, phthalimidonitrene (XXXIII) was generated by oxidising *N*-aminophthalimide with lead tetraacetate in the presence of an equimolar amount of an azo-compound:

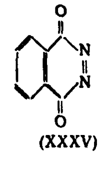


$$PN{-}NH_2 \xrightarrow[-Pb(OAc)_2;\,-2AcOH]{Pb(OAc)_4} \underset{(XXXIII)}{[PN{-}\ddot{N}{:}]} \xrightarrow{RN=NR'} \underset{(XXXIV)}{PN{-}N{=}\overset{R}{\overset{|}{N}}{=}N{-}R'} \, ;$$

$$\downarrow^{PN-NH_2}$$

$$[PN{-}NH{-}NH{-}NP] \xrightarrow[-N_2]{} 2PNH \, ;$$

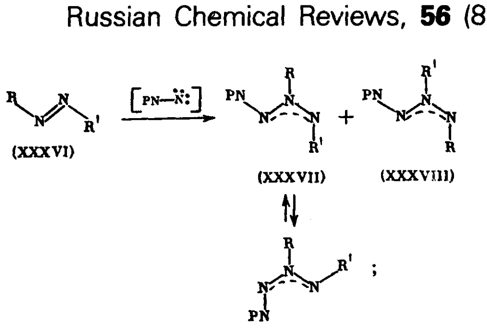
Phthalimidonitrene (XXXIII) adds readily and with high yields (up to 95%) to substrates containing hydrocarbon substituents at the azo-group with formation of 2,3-disubstituted 1-phthalimidoazimines (XXXIV), but it does not react with the azodicarbonyl compounds (XXXI) and (XXXV).[30,31]



(XXXV)

Phthalamide, formed apparently as a result of the interaction of the nitrene (XXXIII) with the initial *N*-aminophthalimide, is usually a side product of the reaction.[82] The structure of the reaction products has been established by spectroscopic methods (^{1}H and ^{13}C NMR, UV, etc.) and also by X-ray diffraction for 1*E*, 2*Z*- and 1*Z*, 2*E*-2,3-dimethyl-1-phthalimidoazimines (XXXVIIa) and (XXXIXa).[64,65]

The addition of phthalimidonitrene (XXXIII) to *E*-azoalkanes (XXXVI) proceeds stereospecifically with retention of the configuration of the azo-group and fully stereoselectively,[67,68] leading to 1*E*, 2*Z*-2,3-dialkyl-1-phthalimidoazimines (XXXVIIa) and (XXVIIIa):[62,63,66–68]



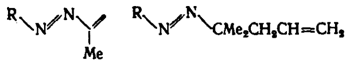
(XXXVI) (XXXVII) (XXXVIII)

(XXXIX)

R = R' = Me (a), Et (b), iso-Pr (c), CHMePh (d);
R = Me, R' = Et (e), iso-Pr (f), t-Bu (g), CH$_2$CH$_2$CH = CH$_2$ (h);
R' = iso-Pr, R = Et (i), CH$_2$CH$_2$CH = CH$_2$ (j), CHMeCH$_2$CH = CH$_2$ (k).

The asymmetric *E*-azoalkanes (XXXVI, e–g and I) give rise to mixtures of the regioisomeric 2,3-dialkyl-1-phthalimidoazimines (XXXVII) and (XXXVIII) with predominance of the isomer (XXXVII) containing a smaller substituent at the central nitrogen atom of the azimine system.[67,68] The regioselectivity of the reaction increases on passing from *E*-methylazoethane (XXXVIe) to the more asymmetric substrates (XXXVI, f and g).[67,68]

The reaction of phthalimidonitrene with γδ-unsaturated analogues of *E*-azoalkanes (XXXVI, h, j, and k) proceeds fully analogously.[69] The addition of the nitrene to the azo-group only is then observed; the products of addition to the C=C bond were not detected.[69] However, αβ-unsaturated azo-compounds—*E*-2-alkylazopropenes (XL)—proved to be extremely inert in relation to phthalimidonitrene.[69] The reasons for this are obscure.



(XL) (XLI)
R = Me, iso-Pr.

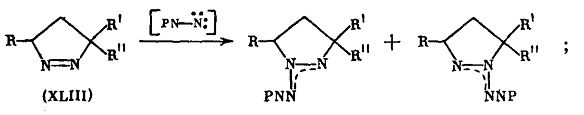
When a tertiary substituent is introduced at the azo-group, the reactivity of *E*-azoalkanes diminishes sharply.[67–69] The addition of phthalimidonitrene to *E*-2-methyl-2-methylazopropane (XXXVIg) can be achieved only by employing a special method whereupon the side reaction involving the formation of phthalimide is suppressed [even in this case most of the azo-compound (XXXVIg) is preserved in the course of the reaction[67,68]] and the reaction with unsaturated tertiary azo-compounds (XLI) could not be carried out at all.[69] The main product of the addition of phthalimidonitrene to *E*-2-methyl-2-methylazopropane (XXXVIg) is 1*E*, 2*Z*-3-t-butyl-2-methyl-1-phthalimidoazimine (XXXVIIg), but the reaction is overall more complex than that with the sterically unhindered *E*-azoalkanes (XXXVI, a–f and i) and small amounts of unstable products, whose structure has not been established, are formed.[67,68]

The reaction of phthalimidonitrene with *Z*-2,2'-azopropane (XLII) affords a high yield of 1*Z*, 2*E*-2,3-diisopropyl-1-phthalimidoazimine (XXXIXc), which, however, is configurationally extremely unstable and is readily converted into the 1*E*, 2*Z*-isomer (XXXVIIc):[66]

$$\text{iso-Pr}{-}N{=}N{-}\text{Pr-iso} \xrightarrow{[PN-\ddot{N}:]} (XXXIXc) \rightarrow (XXXVIIc).$$

(XLII)

The addition of phthalimidonitrene to cyclic analogues of azoalkanes with a fixed *Z*-configuration of the azo-group, namely 1-pyrazolines (XLIII, a–d)[67,69,70] and 2,3-diazabicyclo]2.2.1]hept-2-ene (XLIIIe),[66] leads to the corresponding 2,3-trimethylene-1-phthalimidoazimines (XLIV) and (XLV). The reaction with asymmetric 1-pyrazolines (XLIII, b–d) leads to the formation of two regioisomeric adducts (XLIV) and (XLV), in each case with the sterically less hindered isomer (XLIV) predominating,[67,69,70] i.e. the influence of the bulk of the substituents on the mode of reaction is in this case qualitatively the same as in the series of acyclic *E*-azo-compounds. At the same time, the yields of the adducts with the cyclic azo-compounds (XLIII) are higher than for the adducts with the *E*-azoalkanes (XXXVI);[66,67,70] even for the adducts with 1-pyrazolines (XLIII, c and d), formally containing a tertiary substituent at the azo-group, the reaction proceeds without complications and leads to both regioisomeric adducts (XLIV, c and d) and (XLV, c and d).[67,70] This can apparently be accounted for by the greater steric accessibility of the azo-group when it has the *Z*-configuration



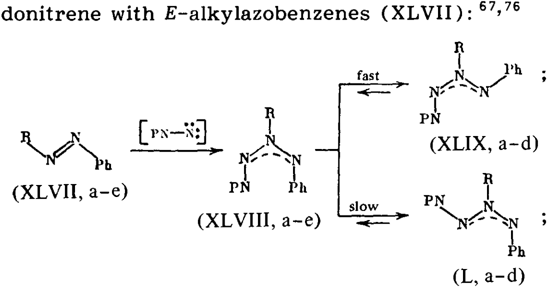
R = R′ = H, R″ = H (a), Me (b); R′ = R″ = Me, R = H (c), Me (d); RR′ = 1,3-cyclopentylene, R″ = H (e).

On the other hand, 3*H*-diazirines (XLVI), both mono- and di-substituted, proved be be almost inert in relation to phthalimidonitrene,[67,69] which is evidently associated with the relatively deep position of the highest occupied molecular orbital in these compounds:[83]

R = H, R′ = t-Bu, Ph; R = Me, R′ = Et; RR′ = $(CH_2)_5$

(XLVI)

The reaction of phthalimidonitrene with the markedly asymmetric *E*-alkylazobenzenes (XLVII)[67,71–76] takes place stereospecifically with retention of the configuration of the azo-group and usually fully regioselectively and stereoselectivity with formation of 1*Z*, 2*Z*-2-alkyl-3-phenyl-1-phthalimidoazimines (XLVIII).[67,74,76] With the exception of the t-butyl derivative (XLVIIIe), the latter are unstable at temperatures above approximately 0 °C and rapidly equilibrate in solution with 1*Z*, 2*E*-azimines (XLIX) and much more slowly with the 1*E*, 2*Z*-isomers (L). The principal components of the equilibrium mixtures of stereoisomers are 1*Z*, 2*E*-azimines (XLIX).[67,75,76] Their rapid formation from the intermediate 1*Z*, 2*Z*-isomers (XLVIII) leads to the apparent inversion of the configuration of the azo-group in the reaction of phthalimidonitrene with *E*-alkylazobenzenes (XLVII):[67,76]

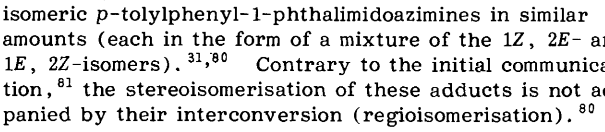


R = Me (a), Et (b), Pr (c), iso-Pr (d), t-Bu (e).

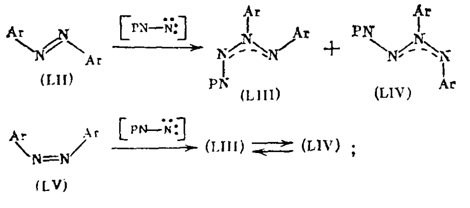
With increase of the bulk of the alkyl substituent, the relative stability of the 1*Z*, 2*Z*-isomers (XLVIII) and hence their equilibrium content increase sharply.[67,75] As a result, 1*Z*, 2*Z*-2-t-butyl-3-phenyl-1-phthalimidoazimine (XLVIIIe) is configurationally completely stable and is the first example of a stable acyclic 1*Z*, 2*Z*-azimine.[67,74,75]

The kinetically controlled formation of 1*Z*, 2*Z*-azimines (XLVIII) in the reaction of phthalimidonitrene with *E*-alkylazobenzenes (XLVII) can probably be accounted for by secondary orbital interactions stabilising the *cis*-disposition of the phthalimide group of the nitrene and of the phenyl substituent of the azo-compound in the transition state.[67,76] One cannot rule out that the same interactions determine also the regioselectivity of the reaction.

The possible breakdown of regioselectivity in the addition process has been noted only for *E*-isopropylazobenzene (XLVIId). In this case, the regioisomeric 1*E*, 2*Z*-3-isopropyl-2-phenyl-1-phthalimidoazimine (LI) (25% of the overall amount of adducts) is apparently formed together with the adducts (XLVIIId), (XLIXd), and (Ld):[67,75]



The reaction of phthalimidonitrene with *E*-azoarenes (LII) yielded mixtures of 1*Z*, 2*E*- and 1*E*, 2*Z*-2,3-diaryl-1-phthalimidoazimines (LIII) and (LIV),[31,62,63,77–81] between which equilibrium is gradually established at room temperature. Here the main reaction products are 1*Z*, 2*E*-azimines (LIII) and their content in the mixtures of isomers isolated exceeds somewhat the equilibrium value:[63,80]



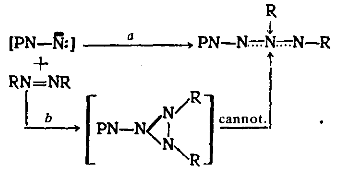
Ar = Ph (a), *p*-Tol (b).

The mechanism of the addition has not been investigated in detail, but, by analogy with *E*-alkylazobenzenes (XLVII), presumably the preferential inversion of the configuration of the azo-group can be explained in this case too by the rapid stereoisomerisation of the intermediate 1*Z*, 2*Z*-2,3-diaryl-1-phthalimidoazimines.[67,76]

The addition of phthalimidonitrene to *Z*-azoarenes (LV) leads to 1*Z*, 2*E*-2,3-diaryl-1-phthalimidoazimines (LIII) with a small admixture of the 1*E*, 2*Z*-isomers (LIV)[62,63,77–80] probably owing to the partial stereoisomerisation of the primary products (LIII). As for other types of azo-compounds, the yields of 1-phthalimidoazimines in the reaction with *Z*-azoarenes are much higher than in the reaction with the *E*-isomers.[62,63,77–80]

The reactions of phthalimidonitrene with both *E*- and *Z*-4-phenylazotoluenes result in the formation of both regioisomeric *p*-tolylphenyl-1-phthalimidoazimines in similar amounts (each in the form of a mixture of the 1*Z*, 2*E*- and 1*E*, 2*Z*-isomers).[31,80] Contrary to the initial communication,[81] the stereoisomerisation of these adducts is not accompanied by their interconversion (regioisomerisation).[80]

The most probable mechanism of the addition of phthalimidonitrene to azo-compounds, which can explain almost all the features of this reaction, involves electrophilic attack on the sextet nitrogen atom via the highest non-bonding orbital of the azo-group, in actual fact via the unshared electron pair of one of the nitrogen atoms. In this single-stage process, the azimine π-electron system is formed together with the N–N σ-bond; according to experimental data, the reaction should proceed with retention of configuration (pathway *a*):



The alternative two-stage mechanism with the intermediate formation of triaziridine (pathway *b*) is significantly less realistic.[67,68,76]

Within the framework of the single-stage mechanism, it is possible to explain satisfactorily the influence of electronic and steric factors on the course of the reaction of phthalimidonitrene with azo-compounds.[67,68,76] Furthermore, we we are justified to expect that the principal features of the reactant—substrate interaction will be retained also for the electrophilic addition of other sextet species via the azo-group, i.e. that this mechanism will prove valid for a wide range of related objects.

The Molecular-crystal Structure of Cellulose

O.K.Nugmanov, A.I.Pertsin, L.V.Zabelin, and G.N.Marchenko

The structural models of the principal polymorphic varieties of cellulose proposed by different workers during the last two decades are analysed, the results obtained by the main structural methods are considered, and the reliability of a particular structural model is estimated. The ambiguity of the solution of the structural problems for cellulose in the cases of the existing diffraction data, even when stereochemical and packing limitations are invoked, is demonstrated. The results of semiempirical energy calculations for the stable structure of cellulose are discussed.
The bibliography includes 106 references.

I. INTRODUCTION

The processes occurring in the industrial processing of cellulose are as a rule heterogeneous and take place under diffusional conditions, which determines the dependence of the degree and kinetics of the reactions occurring on the structure of the solid polymer phase.

Several hierarchical levels of structural organisation can be differentiated in cellulose. These are the supermolecular structure with a characteristic distance ranging from several tens of angstroms and above and two lowest levels—crystalline and molecular, with characteristic distance of one angstrom. The higher structural levels are readily susceptible to study by electron and optical microscopic methods and low angle X-ray diffraction and have been fairly fully investigated.[1–8] The study of the molecular-crystal structure of cellulose constitutes the main problem.

Cellulose was one of the first polymers subjected to structural analysis. However, despite the large number of crystallographic studies of cellulose, the detailed structure of the crystalline region still remains the subject of extensive controversy.[9–11] This applies to all the known polymorphic varieties of cellulose, including the most thoroughly investigated varieties—cellulose I (CI, native) and cellulose II (CII, regenerated and mercerised). A large number of structural models, which conflict as regards fundamental characteristics such as the symmetry of the crystal lattice, the relative orientation of the chains, and the system of hydrogen bonds let alone even finer structural details, have been proposed.

The present review analyses the literature data on the molecular and crystal structures of CI and CII, the principal results of the structural investigations are considered, and the reliability of the existing concepts and structural models is estimated.

II. GENERAL INFORMATION ABOUT THE STRUCTURE OF CELLULOSE

Cellulose (C) consists of poly-(1 → 4)-β-D-glucopyranose, $(C_6H_{10}O_5)_n(C_6H_{12}O_6)_2$, where n (the degree of polymerisation) varies in the range 800–8000 depending on the nature of the specimen.[9–13] The structural formula of cellulose is presented in Fig.1, which also indicates the numbering of the atoms adopted in the stereochemistry of sugars and carbohydrates.[14–21]

1. The Symmetry and Parameters of the Unit Cell

The principal source of information about the molecular-crystal structure of cellulose is X-ray diffraction of highly oriented fibres. Typical X-ray diffraction patterns of cellulose contain darkened regions distributed continuously along layer lines which are caused by the one-dimensional diffraction and characterise the degree of ordering of the centres of gravity of the scattering molecules. The discrete spots of different intensity are due to three-dimensional diffraction. The number of independent spots of this type does not usually exceed 30–40.

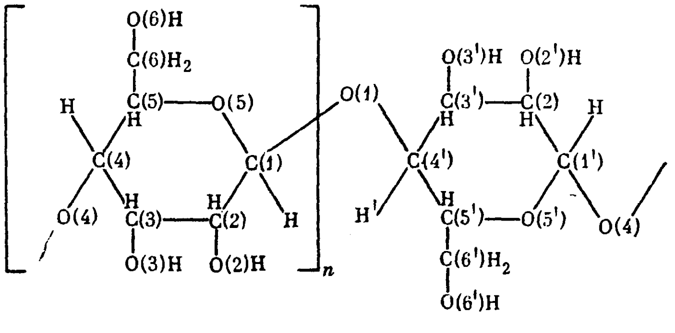

Figure 1. The structural formula of cellulose.

The paucity of the diffraction pattern is to some extent characteristic of the X-ray diffraction of polymers,[22–24] but, compared with the majority of synthetic polymers, the X-ray diffraction patterns of cellulose exhibit a steeper decrease of intensity with increase of the Bragg angle, which additionally limits the region of the possible reflections.[25] Such decrease of intensity can be caused either by the intense thermal movement of the structural elements of cellulose or by statistical disorder.

The only symmetry element of the crystal structure of cellulose is a twofold screw axis parallel to the axis of the fibre (space group $P2_1$).[25] The presence of this axis is indicated by the systematic extinction of the $00l$ reflection $l = 2n + 1$ on the X-ray diffraction patterns of cellulose.

Among the observed reflections, the strongest are the $hk0$ reflections, the most intense being those for which $h + k = 2n$ (i.e. 200, 110, etc.). This shows that the centres of the scattering molecules are separated by a distance $R(x, y, z)$ with $x = a/2$ and $y = b/2$. Consequently, two chains pass through the unit cell of cellulose, one of which is the "angular" chain with the coordinates $(0, 0, z)$, and the other is the "central" chain with the coordinates $(1/2, 1/2, z)$. Two versions of the arrangement of chains are then possible. In the first the chains occupy common positions and are linked by a screw axis in the $(1/4, 1/4, z)$ position. In this case the symmetrically independent unit of the crystal and the repeat unit of the polymer chain consists of a cellobiose fragment, the chains have the same direction (are parallel), and are displaced relative to one another by half the translation along the c axis. In the second version, the chain structures are located on the 2_1 screw axes, are crystallographically non-equivalent, and can be both parallel and anti-parallel. The symmetrically independent unit of the crystal consists of a pair of glucose residues (one in each chain); the repeat unit is also a glucose residue.

The choice between the above two versions of the structure is made on the basis of the intensity of the meridional 002 and 004 reflections. In the first version of the packing, the centres of the glucose units are displaced by $c/2$ along the z axis. For this version, the 002 reflection should be more intense than the 004 reflection, which conflicts with experiment. In the second version of the structure, the displacement of the glucose rings of the neighbouring chains is arbitrary and there are no limitations as regards the ratio of the intensities of the 002 and 004 reflections.

Thus the unit cell of cellulose, constructed on the basis of X-ray diffraction data, has the space group $P2_1$ (monoclinic system) and contains two crystallographically non-equivalent chains intersecting the ab plane at the origin of coordinates and at the centre. The symmetrically independent unit of each cell is the glucopyranose residue. In order to account for the observed intensity ratio of the even meridional reflections, it is usually assumed that the central chain in the two-chain unit cell is displaced by approximately $c/4$ relative to the angular chain.

The repeat period along the axis of the cellulose fibre, calculated from the distance between the meridional reflections on the X-ray diffraction pattern, is approximately 10.3 Å. The remaining unit cell parameters are found by indexing the diffraction patterns. Wellard[26,27] first drew attention to the fact that, even within the framework of a single polymorphic modification of cellulose, the unit cell parameters are within a fairly wide range. For example, the parameter a in CI varies within the limits 8.17–8.35 Å, the parameter b within the limits 7.78–7.90 Å, and the monoclinic angle γ in the range 96.0–96.5°. In CII the ranges of variation of the parameters are even greater: 7.83–8.14 Å for a, 8.99–9.38 Å for b, and 116.6–118° for γ. It is believed[3] that celluloses of different origin do indeed have different unit cells. The unit cell parameters depend on the content of impurities, the defectiveness of the crystallites, the heterounit nature of the polymer chain, and other factors, which can be determined to a large extent by the methods used to isolate and purify cellulose.

The model of the cellulose unit cell described above has been frequently criticised. Thus a number of workers[28–30] observed weak odd meridional $00l$ reflections, which cast doubt on the presence of the 2_1 axis in the structure. Special studies have shown, however, that these reflections are very weak and may be accounted for by the overlapping of neighbouring reflections.[31,32]

Norman[32] and Kitaigorodskii[34] drew attention to the fact that the appearance of odd meridional reflections may be a consequence of one-dimensional diffraction. However, one-dimensional diffraction calculations for the third layer line yielded an appreciably smaller intensity (by approximately 30%) than its observed value. According to Kitaigorodskii and Tsvankin,[33,34] cellulose nevertheless possesses a screw axis symmetry and the differences between the calculated and observed intensities can be associated with structural defects.

A simple model of the defects in the crystal structure of cellulose has been examined by Stipanovic and Sarko,[35] who suggested, as regards the calculation of the theoretical intensities, that the hydroxymethyl groups of the neighbouring residues in the chain are in different positions linked to one another by 120° rotation. However, the theoretical intensities of the 001 and 003 reflections, calculated for the given disordered model, proved to be much higher than the observed values, which permitted the conclusion that, even if orientational disorder of this kind is present in the cellulose structure, it involves only very few chains, for example, the chains located on the surfaces of crystallites.

Apart from diffraction data, NMR and IR spectroscopic data have been invoked for the discussion of the model of the cellulose unit cell described at the beginning of this Section. Thus the splitting of the signals due to the C(1) and C(4) atoms has been observed in the high resolution NMR spectrum of solid cellulose.[36,37] These two well resolved doublets indicated the presence in cellulose of symmetrically different pairs of C(1) and C(4) atoms and were interpreted as proof of the absence of the 2_1 screw axis from cellulose. An analogous situation obtained also in the study of the IR spectra,[38] where the bands with parallel dichroism at 3448 and 3488 cm^{-1} were attributed to two non-equivalent O(3)H...O(5′) hydrogen bonds alternating along the axis of the cellulose macromolecule.

The use of the above experimental facts as proof that the cellulose chain is not a helix with 2_1 symmetry constitutes in our view a misunderstanding. As noted above, the cellulose unit cell, constructed using the X-ray diffraction data, includes two crystallographically non-equivalent chains. In these chains the C(1) and C(4) atoms can have different local environments just as the O(3)H...O(5′) hydrogen bonds can have different structures. These differences are fully capable of giving rise to the difference in the NMR and IR spectra, so that their interpretation does not in any way make it necessary to "deprive" the cellulose chain of 2_1 symmetry.

In discussing the two-chain model of the cellulose unit cell with $P2_1$ symmetry, it is necessary to mention separately the structural studies of certain specific varieties of natural cellulose. Thus the X-ray diffraction patterns of seaweed[28,39] (*Valonia ventricosa*, *Chaetomorpha*) were found to contain three weak reflections (d = 8.61 and 4.42 Å along the first layer line and d = 3.29 Å along the third), which are absent from the X-ray diffraction patterns of cotton, ramie, flax, and wood cellulose. These reflections cannot be indexed on the basis of a two-chain unit cell model and require the doubling of the parameters a and b, which formally leads to models with eight crystallographically non-equivalent chains per unit cell. It may be that such non-equivalence of the chains in the increased cell reduces to a simple shift of the neighbouring chains relative to one another by $c/4$ along the axis of the fibre.[40,41]

Yet another feature of the cellulose from seaweed was observed in an electron diffraction study of specimens with biaxial surface orientation.[29,30] It was found that the intensities of certain *hkl* and $\bar{h}\bar{k}l$ reflections do not coincide, which requires the reduction of this symmetry to triclinic.

Despite the fact that the electron diffraction data[29,30] are not entirely convincing (owing to the strong dependence of the intensity of the reflections on the orientation of the reflecting planes), it should probably be recognised that cellulose from seaweed can indeed have an "individual" unit cell.

2. Conformation of the Monomer Unit

Whereas the symmetry and size of the cellulose unit cell have been determined by direct experimental studies, unfortunately only indirect data are available as regards the conformation of the monomer unit of cellulose. These are in the first place X-ray diffraction data for crystals of low-molecular-weight sugars and carbohydrates and also the results of theoretical conformational analysis.

It has been established experimentally and theoretically[18–21,42–47] that β-D-glucose, which is the elementary unit of the cellulose helix, has the "chair" form and is in the C1 conformation in terms of Reeves' nomenclature.[48–50] Three independent X-ray diffraction studies of β-cellobiose[51–53] showed that the conformation of its monomer units corresponds to the C1 form. Arnott and Scott[54] analysed the X-ray diffraction studies of the single crystals of low-molecular-weight sugars and carbohydrates. Statistical analysis of 27 model compounds, whose monomer unit is a pyranose ring (among these, 17 compounds contained a glucopyranose ring), showed that they all have the C1 conformation. The standard deviations of the geometrical parameters of the ring from the corresponding average values are extremely insignificant, which indicates a high conformational rigidity of the pyranose rings.

Conformational analysis of D-aldopyranoses, carried out by Rao and co-workers[55,56] and then in other investigations,[18,45–47] showed that, whatever the spatial disposition of the side groups, the C1 form is preferable on energy grounds and the ring geometry depends only slightly on the perturbing influence of the side groups. The valence angles at the carbon atoms remain close to the tetrahedral value and the angle at the oxygen ring atom is 112–114°. We may note that the ring conformation remains unaltered even in the presence of bulky substituents such as the nitrate groups.[57]

3. The Conformation of the Cellulose Helix

Bearing in mind the high conformational rigidity of the glucopyranose ring and also the constancy of the valence bonds and angles in the side groups, one may assume that the model of the cellulose chain which permits the variation of only the orientations of the side groups and of the parameters of the junction of the monomer units is fully acceptable. The valence angle β of the glucosidic oxygen atom (Fig.2) and also the torsional angles ϕ and ψ for the rotation of the monomer units about the C(1)–O(1) and O(4)–C(4′) bonds are usually employed to describe the geometry of the junction of the monomer units. The angles ϕ and ψ are determined by the sets of four atoms H(1)–C(1)–O(1)–C(4′) and C(1)–O(4)–C(4′)–H(4′) respectively.

The angles β, ϕ, and ψ are extremely convenient for the description of the geometry of the junction, since they make it possible to use standard computer programs for conformational analysis in order to generate the fragments of the cellulose macromolecule. At the same time, the parameters ϕ, ψ, and β suffer from a significant disadvantage, namely the cellulose chain does not meet the symmetry requirements for their arbitrary values. In other words, in generating the model of the cellulose chain with the aid of the above parameters, one cannot make use of the experimental fact that the cellulose chain is a helix with 2_1 symmetry.

Yet another experimental result, which cannot be used to describe the junction of the monomer units in terms of the angles ϕ, ψ, and β is the fact that the repeat period of the cellulose chain is approximately 10.3 Å and remains the same in all the polymorphic modifications of cellulose.[7–11]

It is easy to show that, for the specified conformation of the monomer unit and symmetry of the helix (2_1), only two parameters are needed to describe the conformation of the main chains. It has been suggested that the angle δ, determining the rotation of the monomer unit about the virtual O(4)...O(4′) bond, and the angle ε, determining the slope of this virtual bond relative to the axis of the helix (Fig.2), be used as such parameters.[58,59] The idea of switching to parameters describing the junction of not real but virtual bonds was developed in the so called variable virtual bond method.[60,61] The independent conformational parameters of the main chain are the angle δ and the half-period $c/2$ (or h), while the conformational parameters of the junction (ϕ, ψ, and β) are dependent variables. This algorithm is applicable to molecules with any structure of the main chain provided that its symmetry is known.

Passing now to the determination of the parameters specifying the orientation of the side groups in the cellulose chain, we may note immediately that in the vast majority of structural

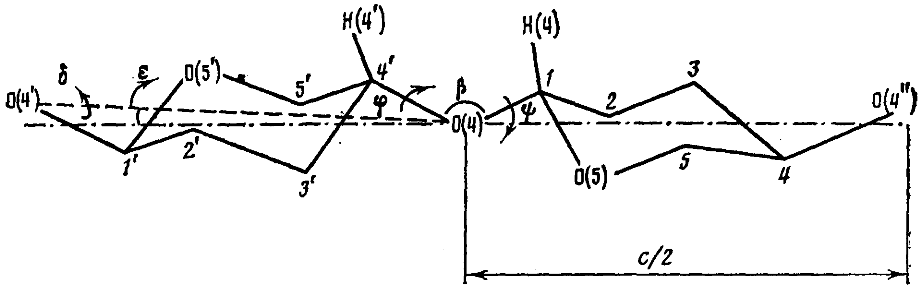

Figure 2. The structural parameters used to describe the conformation of the main chain of the macromolecule.

studies on cellulose hydrogen atoms are disregarded.[28,35,62-64] In this case it is sufficient to introduce only one angle, describing the rotation of the hydroxymethyl group about the C(5)–C(6) bond. The following designations have been adopted for the description of the position of the hydroxymethyl group:[65]

(a) *gt*—*gauche*-position of the C(6)–O(6) bond relative to the C(5)–O(5) bond and *trans*-position relative to the C(4)–C(5) bond;

(b) *tg*–*trans*-position of the C(6)–O(6) bond relative to the C(5)–O(5) bond and *gauche*-position relative to the C(4)–C(5) bond;

(c) *gg*—*gauche*-position relative to both bonds.

A number of investigators believe[36] that the *gt*-orientation of the CH_2OH group is most probable for cellulose chains, because this conformation is typical of crystalline monosaccharides[46,47,66] and certain oligosaccharides.[51-53,67,68] However, experimental data for cellotetraose[69,70] agree best with the hypothesis of the *tg*-conformation of the hydroxymethyl group.

In the entire set of parameters describing the conformation of the cellulose chain, the angle β at the glucosidic oxygen atom has been most reliably determined. According to the statistics of Arnott and Scott,[54] β varies in the range 115.7 to 117.6° in model compounds whose monomer unit is the glucopyranose ring. This range can be adopted as the most probable range of variation of the angle β.

In the early structural models of cellulose, proposed by Meyer and co-workers,[71,72] the angle β was assumed to be 109° and the torsional angles ϕ and ψ were assumed to be zero. (The conformation of the chain with $\phi=\psi=0°$ is usually referred to as the "straight" conformation, in which the plane of the glucosidic bonds is perpendicular to the plane of the glucopyranose ring). The hydroxymethyl group is close to the *tg*-position. For this set of parameters, there are no intermolecular hydrogen bonds in the system. The straight conformation can hardly be regarded as acceptable owing to the presence of certain short non-valence contacts between successive units [in particular the distance between the H(1) and H(4) atoms is 1.7 Å].

The so called "bent" conformation of Hermans et al.[73] is more realistic. This conformation can be obtained from the straight conformation by the rotation of the monomer units about the C(1)–O(1) and O(4)–C(4) bonds by angles of approximately 25°. In the bent conformation there are no shortened non-valence contacts and the distance between the O(3) and C(5′) atoms in successive units is close to 2.7 Å, which indicates the possibility of the formation of the O(3)H...O(5′) intramolecular hydrogen bond. We may note that in crystalline cellobiose[51-53] the relative positions of the glucopyranose rings correspond precisely to the "bent" conformation with its characteristic O(3)H...O(5′) hydrogen bond.

In the structural studies mentioned above,[58,59] the optimum conformation of the β-D-(1 → 4)-linked residues is also close to the bent conformation. It has been shown that reasonable values of δ (which do not lead to short non-valence contacts on either side of the oxygen bridge) are in a narrow range, where there is a possibility of the formation of the O(3)...O(5′) hydrogen bond.

Conformational analysis of the β-D-glucose residues linked in different ways to give a dimeric fragment (linkages of the 1 → 2, 1 → 3, and 1 → 4 types) has been carried out[56] within the framework of the semiempirical model of molecular mechanics.[21] The potential energy of the system, including the energy of the non-valence interactions and the energy of the hydrogen bonds, was calculated as a function of two angles, ϕ and ψ, for the fixed angle $\beta = 117.5°$. The calculations showed that the global minimum of the potential energy of the (1 → 4)-linked dimer is close to the conformation corresponding to the 2_1 symmetry. Furthermore, it has been established that only 4% of the space of the changing variables does not lead to short covalent contacts between the atoms in successive units. This agreed qualitatively with the results of the calculations by Jones[58] and confirmed the view of Rees and co-workers[74,75] that cellulose chains are highly rigid.

In the analogous conformation calculations by Sarko and Muggli,[28] the potential energy of the system was recorded as the sum of the squares of the deviations of the geometrical parameters of the structure from standard values. Analysis of the ϕ–ψ map showed that the conformation of the chain with the *tg*- and *gt*-orientations of the O(6) atom, corresponding to the 2_1 conformation and a repeat unit of 10.3 Å, is close to the potential energy minimum. In the case of the *tg*-orientation, there is a possibility of the formation of the O(2)H...O(6′) bond on the other side of the oxygen bridge in addition to the O(3)H...O(5′) hydrogen bond.

Panov et al.[76] included the energies of the non-valence and electrostatic interactions, the torsional potentials, and the energy of the hydrogen bonds in the conformational energy of the dimeric cellulose chain fragment. The angle β was assumed to be 116.0°. The conformation with the *tg*-orientation of the hydroxymethyl group and the parameters ϕ and ψ corresponding to the 2_1 symmetry proved to be most preferred as regards energy. Two hydrogen bonds, O(3)H...O(5′) and O(2)H...O(5′), were present in the system and according to the authors only these bonds can be formed simultaneously. The conformations with hydrogen bonds of the type O(6)H...O(2′) and O(6)...O(1′) are less favourable as regards energy.

A more detailed analysis of the conformational possibilities in the cellulose macromolecule has been carried out recently.[61] The method of the variable virtual bond is used in constructing the main chain, since the search for the optimum chain conformation was restricted *a priori* by the subset of conformations satisfying the helical 2_1 symmetry. The conformational energy included the energy of the atom–atom non-valence interactions, the torsional contributions, the deformation energy of the angle β, and the potentials of the hydrogen bonds. In order to discover the regions of the permissible conformations of the main chain, a preliminary calculation was carried out in which the pitch of the helix was assumed to be constant and the angle δ was varied from −180° to 180°. It is seen from Fig.3 that two comparatively narrow regions correspond to reasonable values of the angle β ($114 \leq \beta \leq 118°$): $44° \leq \delta \leq 58°$ and $-70° \leq \delta \leq -56°$. The same Figure presents the dependence of the O(2)...C(6′) distance on the angle δ. Evidently the range $-70° \leq \delta \leq -56°$ can be eliminated from consideration with full justification owing to the presence of unduly short O(2)...C(6′) contacts. Subsequent calculations by Pertsin et al.[61] consisted in minimising the conformational energy in the space of six changing variables. The variables included four tortional angles $\tau_i (i = 1, \ldots, 4)$, confirming the orientation of the side groups, the angle δ, and the pitch of the helix *h*. The calculations revealed the six stable conformations of the isolated cellulose helix. These conformers are designated in Figs.4–6 by *A*1, *A*2, *B*1, *B*2, *C*1, and *C*2. Their conformational energies were −4.8, 3.1, 0.3, −0.5, −0.1, and 2.6 kcal mol^{-1} respectively.

Evidently all the stable conformers of the isolated helix are characterised by the presence of the O(3)H...O(5′) bond. As mentioned above, the presence of bonds of this kind has been confirmed by numerous experimental findings. In the conformer *A*1, which is most preferred as regards energy, there is also the O(4)...O(6)H...O(2′) hydrogen bond, which includes one donor and two acceptor oxygen atoms. The possibility of the formation of such bonds has been recently demonstrated by a non-empirical quantum-chemical calculation[77,78] and by a neutron diffraction study of carbohydrate crystals.[79,80] (Bonds of this type will henceforth be referred to as a biacceptor in contrast to the bidonor bonds of the type OH...O...HO).

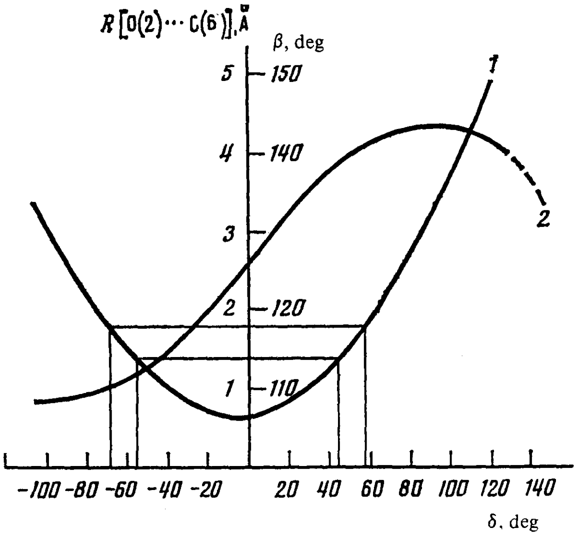

Figure 3. The permissible ranges of variation of the angles δ:[61] 1) dependence of β on δ; 2) dependence of the interatomic O(2)...C(6') distance on δ.

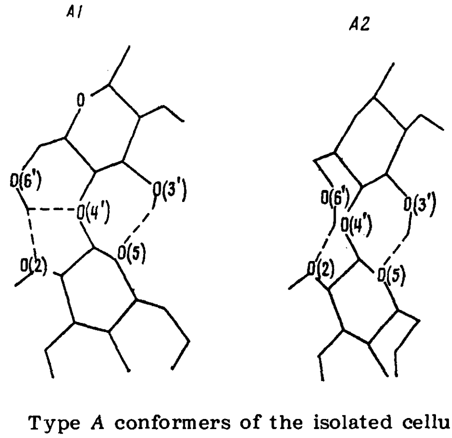

Figure 4. Type *A* conformers of the isolated cellulose helix. (Here and henceforth the hydrogen bonds are shown by dashed lines; for clarity, the ring hydrogen atoms are not shown).[61]

The hydroxymethyl group of the conformer *A*1 is close to the *tg*-position ($\tau_1 = 60°$). The rotation of this group by approximately 83° brings the hydroxymethyl group closer to the *gg*-position ($\tau_1 = -60°$) and affords the new stable conformer *A*2 (Fig.4). The bond O(6)H...O(4) is then broken and only the usual O(6)H...O(2') hydrogen bond remains. The O(6)...O(2') hydrogen bond can be formed also via the proton at the O(2) atom, which becomes the donor, and the O(6) atom—the proton acceptor. The situation described is characteristic of conformers of type *B* (Fig.5), which constitutes their principal difference from type *A* conformers. As for type *A* conformers, there is a possibility of two different positions of the hydroxymethyl group leading to the formation of the O(2)H...O(6') bond. In the conformer *B*1, the orientation of the O(6) atom is close to the *tg*-position, while in the conformer *B*2 it is close to the *gg*-position.

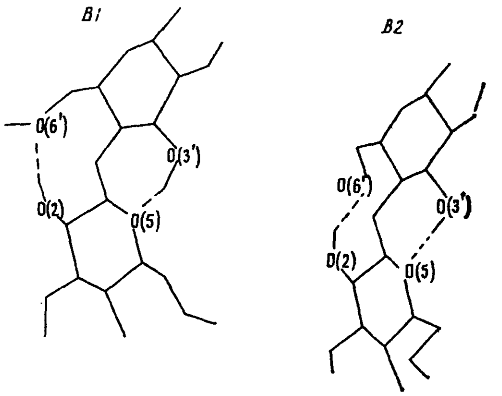

Figure 5. Type *B* conformers of the isolated cellulose helix.

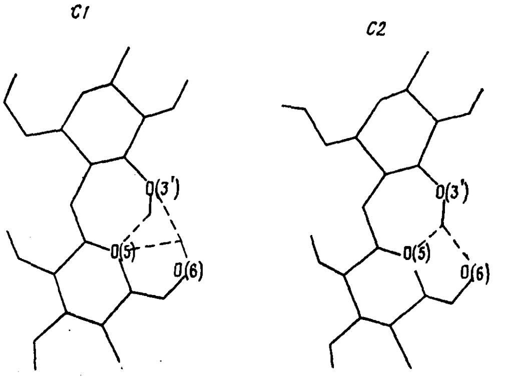

Figure 6. Type *C* conformers of the isolated cellulose helix.

It is seen from Fig.6 that there are also two stable *C*1 and *C*2 conformers whose hydroxymethyl groups are close to the *gt*-position ($\gamma_1 = 180°$). The biacceptor O(3')...O(6)H...O(5') bond and the bidonor O(6)H...O(5)...HO(3') bond are present in the conformer *C*1. In the conformer *C*2, whose energy is smaller than that of the conformer *C*1 by approximately 2.7 kcal mol^{-1}, only the biacceptor bond of the type O(5')...O(3)H...O(6') is present.

All six stable conformers of the isolated cellulose helix have an equilibrium period close to the observed repeat period (approximately 10.3 Å). The equilibrium values of the angle β are also close to those in carbohydrates and polysaccharides (115.7–117.6°). Furthermore in all the conformers there are vacant sites for the formation of intermolecular hydrogen bonds. For this reason, each of the conformers found can in principle exist in the crystal.

The results of the conformational analysis reveal extremely extensive conformational possibilities in the cellulose macromolecule, indicating thereby the impossibility of an unambiguous prediction of its crystal structure from the consideration of an isolated chain. Evidently the packing of the macromolecules in the crystal and, in particular, the formation of intermolecular hydrogen bonds can affect significantly the relative stabilities of particular conformers.

III. STRUCTURAL MODELS OF THE MAIN POLYMORPHIC VARIETIES OF CELLULOSE

In describing the crystal structure of cellulose, the following packing parameters are usually employed: two angles of rotation of the chains about their bonds, the shift of the chains relative to one another, and two parameters specifying the direction of the chains. Here and henceforth we shall adhere to the following notation: the angles of rotation ϕ^k of the angular ($k = 1$) and central ($k = 2$) chains, the shift S of the O(4) atom of the central chain relative to the O(4) atom of the angular chain along the c axis (in fractions of the period c), and the directional parameter $p^k = \pm 1$ ($p^k = \pm 1$ if $z_{O(5)} \gtrless z_{C(5)}$ for the kth chain).

1. Cellulose I

As already mentioned, natural celluloses of different origin, for example, from cotton, flax, hemp, ramie, wood, etc., belong to this polymorphic modification.

The first X-ray diffraction studies on flax and hemp celluloses were carried out ten years before it was established that cellulose is a glucose polymer. At the end of the 1920's and 1930's, the familiar structural studies by Meyer and Mark,[71] Meyer and Misch,[72] Pierce,[83,84] etc. were published. These have played a decisive role in the development of ideas about the structure of crystalline regions of cellulose. Among the early structural investigations, we may also include the studies by Frey-Wyssling,[85] Marrinan and Maan,[86,87] Liang and Marchessault,[88,89] etc. carried out during the period between the 1940's and 1960's.

At the present time most of the early studies are of purely historical interest, because the structural models proposed in them conflict with later experimental data.

Thus it was assumed in Pierce's model[83,84] that the glucopyranose ring is in a planar conformation, which conflicts with experimental data considered in Section II. In Frey-Wyssling's model,[85] there is a free hydroxyl at C(2), which conflicts with IR spectroscopic data,[9,15,45,90] according to which all the hydroxy-groups of cellulose are involved in hydrogen bonds. Many early structural models, in particular the well known model of Meyer and Misch,[72] to not agree with data for the IR dichroism of the stretching vibrations of the OH groups. According to these data, in the region of such stretching vibrations[9,15,90] there are five bands, of which two exhibit perpendicular dichroism while the remaining exhibit parallel dichroism. This shows that there should be at least two OH groups in solid cellulose with preferential perpendicular orientation relative to the axis of the fibre and at least three OH groups with preferred parallel orientation. In Meyer and Misch's model mentioned above,[72] there are only intermolecular hydrogen bonds with preferential perpendicular orientation, i.e. the existence of three bands with parallel dichroism could not be accounted for in terms of this model.

Of the structural models belonging to the end of the 1960's, mention should be made of those of Maan and Marrinan[86] and Liang and Marchessault.[88] Maan and Marrinan's models were based mainly on the IR dichroism data mentioned above. X-Ray diffraction data were scarcely taken into account in these models (with the exception of the unit cell parameters). In the analysis of the structure of cellulose, Liang and Marchessault[88,89] combined spectroscopic data with the intensities of well resolved reflections. All the models proposed by the authors agreed satisfactorily only with the IR dichroism of the OH groups but conflicted with X-ray diffraction data.[58,59]

The first serious attempt to reconcile the stereochemical, IR spectroscopic, and X-ray diffraction data was undertaken by Jones.[58,59] Seven alternative CI models, differing in the relative polarities of the chains, the rotation of the monomer unit about the virtual O(4)...O(4′) bond, and the orientation of the hydroxymethyl group and the chains in the unit cell were considered. All the models considered satisfied the stereochemical criteria and agreed with IR spectroscopic data. The best agreement could be observed in X-ray reflection intensities (among the models examined) obtained for the antiparallel model, whose parameters are close to those of the modern structural models of CI.

The Jones model includes two intramolecular bonds, O(3)...O(5′) and O(2)...O(6′) [The orientation of the O(6) atom is close to *tg*] and the intermolecular O(6)...O(3″) bond located in the (200) plane. The chains are uncoiled around their axes in such a way that the planes of the glucopyranose rings are arranged almost parallel to the *ac* plane, forming a layered structure. The O(6)...O(3″) bond forms translationally identical chains, i.e. is located within the layer. The main difference between the Jones model described and the earlier structural models is the absence of interlamellar hydrogen bonds (between the angular and central chains).

As regards the structural model proposed by Jones for CI,[58] mention should be made that it has not been optimised in the sense that it does not correspond to the optimum of any specific criterion in the space of the changing variables. In essence, the Jones model is only the best among the seven discrete models examined by the author.

The search for the structural models of cellulose was first reduced to the optimisation problem in a study by Gardner and Blackwell.[91] The crystallographic divergence factor (R factor) was adopted as the target optimisation function:

$$R = \sum_{m=1}^{M} \Delta F_m / \sum_{m=1}^{M} |F_{m(\mathrm{obs})}| \qquad (1)$$

where $\Delta F_m = |F_{m(\mathrm{obs})} - F_{m(\mathrm{calc.})}|$ and the F_m are structural amplitudes. The summation in Eqn.(1) is carried out with respect to M observed reflections. The calculated structural amplitudes were obtained from the formula

$$F_{m\,(\mathrm{calc})} = K \left\{ \sum_{hkl} [F^{hkl}_{m\,(\mathrm{calc})} \exp(-B_T d_m^2/4)]^2 \right\}^{1/2} \qquad (2)$$

where K is the scaling factor, B_T the average isotropic temperature factor, and d_m the interplanar distance in the inverse lattice. The summation in Eqn.(2) is carried out with respect to all the hkl planes contributing to the mth reflection.

By comparing alternative models, Gardner and Blackwell[91] also calculated weighted R factors:

$$R' = \sum_{m=1}^{M} w_m^{1/2} \Delta F_m / \sum_{m=1}^{M} w_m^{1/2} |F_{m\,(\mathrm{obs})}| \qquad (3)$$

$$R'' = \left\{ \sum_{m=1}^{M} w_m \Delta F_m^2 / \sum_{m=1}^{M} w_m F^2_{m\,(\mathrm{obs})} \right\}^{1/2} \qquad (4)$$

where w_m are the weighting factors:

$$\Delta F_m^2 = |F_{m\,(\mathrm{obs})}^2 - F_{m\,(\mathrm{calc})}^2|.$$

In contrast to Eqn.(2), the summation in Eqns.(3) and (4) is carried out not only with respect to the observed reflections but also with respect to the postulated refelctions. The postulated reflections are included in the calculation of the R factor in order to avoid the appearance of intense theoretical reflections for planes which are not observed experimentally. The experimental set of values of $|F_m(\mathrm{obs})|$ was obtained on fibres from *Vallonia ventricosa.* The meridional $00l$ reflections were not included in the calculation of the R factor because of certain difficulties associated with the measurement of their intensities and the introduction of the Lorentz and polarisation corrections.

In the search for the most preferred structure of CI, the following initial trial models were employed;[91]

(1) P_1—parallel chains ($p^1 = p^2 = 1$), $S = {}^1/_4$;
(2) P_2—parallel chains ($p^1 = p^2 = -1$), $S = {}^1/_4$;
(3) a_1—antiparallel chains ($p^1 = 1$, $p^2 = -1$), $S = -{}^1/_4$;
(4) a_2—antiparallel chains, $S = {}^1/_4$.

In constructing the cellulose helix, the bond lengths and valence angles were set equal to their standard values.[54] The conformation of the main chain was assumed beforehand to be that corresponding to the helical symmetry 2_1 and the repeat period 10.38 Å and was not varied in the course of the calculations. The parameters of the junction of the monomer units were assumed to be equal to the values for which the O(3)...O(5′) hydrogen bond may be formed between the O(3) and O(5′) atoms ($\phi = 23°$, $\psi = -27.7°$, $\beta = 144.8°$).[56]

The optimum model was sought in the space of six changing variables.[91] These included the angle τ_1, describing the rotation of the hydroxymethyl groups (in both chains simultaneously), the three packing parameters ϕ^1, ϕ^2, and S, and also the parameters B_T and K which occur in the formulae for the calculation of the structural amplitudes [Eqns.(2)].

The model obtained from the P_1 approximation ($R = 0.254$, $R' = 0.233$, $R'' = 0.215$, and $B_T = 2.5$ Å^2) was found to be best. The shift in the optimised P_1 model was $S = 0.266$. In these models the intermolecular O(6)...O(3″) hydrogen bond is located in the (020) plane. In addition to the O(3)...O(5′) intramolecular bond, whose presence is predetermined by the initial chain conformation, the O(2)H...O(6′) bonds arises on the other side of the oxygen bridge. This bond is formed when the O(6) atom is located in a position differing from *tg* by 20°. The values of τ_1 corresponding exactly to *tg*, *gt*, and *gg* are found to be stereochemically unsuitable in the crystal and give rise to high values of the R'' factor (0.24, 0.29, and 0.35 respectively).[91]

The assumption by Gardner and Blackwell of the absolute rigidity of the main chain of the macromolecule can apparently be regarded as the main disadvantage of their treatment,[91] because the monomer units of cellulose exhibit a definite freedom of rotation about the virtual bonds. The neglect of this rotation can significantly impair the "packing possibilities" of the cellulose chains. In particular, the packing of rigid chains can lead to shortened contacts, which might have been avoided by means of small changes in the conformation of the main chain.

Among the disadvantages of the treatment of Gardner and Blackwell,[91] one should include also the fact that, in selecting the initial approximations, the authors, considered only two discrete values of the parameter $S(\pm{}^1/_4)$, leaving uninvestigated most of the range of variation of this parameter. Here it is appropriate to mention that the values $S = \pm{}^1/_4$ arise from the intensity of the 002 and 004 reflections only if we assume that the scattering centres of the cellulose chain are concentrated at the centres of the glucopyranose rings. The above approximation is fairly rough and, as will be shown below, the observed intensity ratios of the four meridional reflections can be obtained for values of S extremely remote from $\pm{}^1/_4$.

A more complex method for the refinement and selection of the optimum cellulose model was adopted by Sarko and co-workers.[28,93] The optimum model was determined by minimising a target function Φ of the following type:

$$\Phi = 100fR'' + (1-f)Y \tag{5}$$

where $f = 0.8$ is the weighting factor and Y is the sum of the standard deviation functions taking into account the deviation of the geometrical parameters of the model from their standard values.[93] In the calculation of the R'' factor, the authors used in Eqn.(5) the X-ray diffraction data obtained using ramie fibres.

In order to test the hypothesis that the 2_1 axis is present in the crystal structure of cellulose, the authors[28,93] eliminated the limitations associated with the $P2_1$ symmetry and varied all the geometrical parameters of the model with the exception of their bond lengths (23 parameters in all). Apart from the geometrical parameters, the average temperature multiplier was also varied, being assumed to be anisotropic in the given instance and having three dependent components.

Two structural models were found to be most suitable as regards the value of Φ. These are a model with parallel packing of the chains ($R'' = 0.193$) and the antiparallel model ($R'' = 0.246$). In both cases the deviations from the symmetry of the 2_1 screw axis were found to be insignificant and did not exceed 1–2° for the valence and torsional angles in the ring and in the junction of the monomer units. In order to discover the best models, the authors resorted to Hamilton's statistical tests.[92] If a one-dimensional hypothesis is assumed (i.e. that either the parallel or the antiparallel model is possible), then the differences in the R' factor for the fifty observed reflections supporting the parallel model are found to be significant at a level of significance of 99.5%.

In terms of its structural parameters and especially the system of hydrogen bonds, the model proposed by Sarko and co-workers[93] proved to be close to the P_1 model of Gardner and Blackwell.[91] In assessing the method used by Sarko and co-workers[28,35,60,62,93] for the elucidation of the cellulose structure, it is necessary to note the following points. Firstly, the inclusion in the optimisation of "rigid" variables such as the valence angles and bond lengths has little justification.[35,62] The variation of these variables usually sharply impairs the convergence of the optimisation process, so that the target function becomes sensitive mainly to the "rigid" variables. The search for the optimum values of the "sensitive" parameters (torsional angles, the rotations of the chains, etc.) becomes greatly hindered owing to the oscillations in the "rigid" variables about their equilibrium values.

Yet another disadvantage of the method of Sarko and co-workers[93] is the absence, in an explicit form, of terms describing hydrogen bonds in the target function (5). For this reason, the endeavour by the system to achieve the maximum saturation by hydrogen bonds is not reflected in the optimisation of the target function.

Finally, it is essential to note also the serious error which Woodcock and Sarko[93] made in applying Hamilton's tests to the comparison of the best parallel (P) and antiparallel (a) models. As already stated, in determining the significance of the differences in the R'' factors between the a and P models, the authors assumed a one-dimensional hypothesis. This would evidently be correct if the a and P models differed only by the relative chain polarities. In reality the a and P models differ also by all the remaining parameters, whose number (23) actually determines the dimensions of the hypothesis. If the dimensions of the hypothesis are assumed to be 23, then the a and P models are found to be statistically indistinguishable whatever the level of significance.

The insolubility of the problem of the relative chain polarities in CI was yet again demonstrated in French's study.[94] This was the best founded and interesting crystallographic investigation of CI based on thoroughly analysed and corrected experimental data (obtained from ramie cellulose) and a well balanced computational model.

As regards the experimental part of the study, the author was able to determine for the first time the intensities of the meridional 002 and 004 reflections, which proved to be extremely significant in finding the orientation of the hydroxymethyl group. From the standpoint of the selection of the changing variables, French's computational model occupies an intermediate position between the model of Gardner and Blackwell and the model of Sarko and co-workers. On the one hand, French's model is free from the defects of Gardner and Blackwell's model, since it assumes the deformation of the main macromolecular chain (as a result of the rotation of the monomer units about the virtual bond). On the other hand, in contrast to the model of Sarko and co-workers, in French's model there are no "rigid" parameters, since all the bond lengths and valence angles are assumed to be constant in the course of the solution of the structural problems (with the exception of the valence angle at the glucosidic oxygen atom).

Altogether French's computational model included nine changing variables, among which were the angles τ_1^k, ϕ^k, and δ^k as well as the parameters p^k and S described previously. Initially French[94] assumed different values of τ_1^k and δ^k in the angular and central chains and also in two successive monomer residues, but this proved to be superfluous; neither the abandonment of the 2_1 symmetry nor the introduction of conformational differences between the angular and central chains entailed an appreciable improvement of the R'' factor.

The antiparallel model ($R'' = 0.158$), designated by the author[94] as the a_1 model, proved to be most suitable as regards the R'' factor. In this model, the macromolecules are linked into layers by intermolecular O(6)...O(3″) hydrogen bonds. Apart from the O(3)...O(5′) intramolecular bond, when the position of the O(6) atom is close to *tg*, there is a possibility of the formation of two hydrogen bonds of the type O(2)...O(6′) and O(6)...O(4). The existence of the latter bond is extremely doubtful according to French,[94] since it differs markedly from the linear bond and in addition the bridging O(4) oxygen atom is a weak proton acceptor.

The best "parallel" models found by French (the P_1 and P_2 models) differed very insignificantly from the a_1 model as regards the value of the R'' factor ($R''_{P_1} = 0.185$ and $R''_{P_2} = 0.175$). This made it impossible for the author[94] to reach the unambiguous conclusion that the packing of the chains in CI is antiparallel. Application of Hamilton's test[92] shows that the hypothesis of the parallel disposition of the chains in CI can be rejected only for an extremely low level of significance (95.0%).

The difficulties arising in the interpretation of the diffraction data for cellulose made it necessary to resort to non-crystallographic criteria, in particular to the energy criterion. Thus Nugmanov and co-workers[95,96] sought the structure of CI by optimising a target function of the type

$$\Phi = U + \omega R'' \qquad (6)$$

where U is the potential energy of the system and ω the weighting factor chosen to ensure that the maximum statistically insignificant changes in U and R'' make identical contributions to Φ ($\omega = 15$ kcal mol^{-1}). The potential U was calculated by the method of atom–atom potentials;[20,96,97,98] it included both intramolecular and intermolecular components. The optimum structure was sought in the space of 16 variable parameters: τ_i^k, δ^k, ϕ^k, S, p^k, and B_T.

A considerable number of local minima in the target function were discovered in the course of the calculations.[95] The characteristics of the deepest of these are presented in Table 1. The fact that the values of the R'' factor for the best structural model lie within the comparatively narrow range 0.24–0.16 is striking when Table 1 is analysed. Application of Hamilton's statistical test[92] shows that, for the usual 99% level of significance, the vast majority of the models considered (with the exception of the a_3 and a_4 models) are statistically equivalent. This illustrates clearly yet again the ambiguity of the solution of the structural problem for CI on the basis of the available diffraction data even when stereochemical packing limitations are introduced.

Table 1. Certain characteristics of the most probably structural models of CI.[95,96]

Model*	R''	U, kcal mol^{-1}	Φ, kcal mol^{-1}	Model*	R''	U, kcal mol^{-1}	Φ, kcal mol^{-1}
$\bar{P}_1$	0.165	−19.9	−17.4	a_1	0.213	19.7	−16.5
$\bar{P}_2$	0.187	−19.7	−16.9	a_2	0.155	−18.6	−16.1
$\bar{P}_3$	0.182	−17.9	−15.2	a_3	0.240	−19.7	−16.0
P_1	0.167	−17.5	−14.6	a_4	0.240	−19.7	−16.0

*The parallel models, designated by P_i and $\bar{P}_i$, correspond to the "average" polarity $p = (p^1 + p^2)/2 = \pm 1$, while the antiparallel a_i models correspond to the polarity $p = 0$.

It is significant that, in the course of the search for a global minimum in the target function Φ,[95] many structural models proposed previously for CI were discovered. Thus the models designated in Table 1 by P_1 and a_3 respectively are analogues of the Gardner–Blackwell–Sarko[64,93] and French[94] models just considered above. Here the analogy is manifested both by the similarity of the geometrical parameters of the models and by the complete identity of the hydrogen bond systems. Evidently the P_1 and a_2 models are not best as regards either the energetic standpoint or as regards the value of the R'' factor.

The global minimum in the target function was found within the framework of a parallel arrangement of the chains whose direction was opposite to that in the P_1 model (the $\bar{P}_1$ minimum in Table 1). The best "antiparallel" model a_1 was found to have similar energy to the $\bar{P}_1$ model and was statistically equivalent to the latter as regards the R'' factor. Projections of the P_1 and a_1 models onto the a^*c plane are illustrated in Figs. 7 and 8.

Despite the differences between the directions and polarities of the chains in the P_1, $\bar{P}_1$, and a_1 models, the chain conformations and the hydrogen bond systems are virtually similar in all three models. In each of the symmetrically independent layers, the chains are in a conformation close to *B*1 with the system of intramolecular hydrogen bonds O(3)H...O(5′) and O(2)H...O(6′) characteristic of *B*1. The macromolecules within the layer are linked via the intermolecular O(6)H...O(3″) hydrogen bonds, while the interlamellar hydrogen bonds are absent from the system.

An interesting feature of the $\bar{P}_1$ model is its ability to be converted into the next model ($\bar{P}_2$) as a result of the jump of the proton at the O(6) atom in the central chain, while the positions of all the remaining atoms remain virtually unchanged. The $\bar{P}_1 \rightarrow \bar{P}_2$ transition is accompanied by the rupture of the O(6)H...O(3″) intermolecular bond and the formation of the O(4″)...O(6)H...O(5″) interlamellar biacceptor bond. The similarity of the $\bar{P}_1$ and $\bar{P}_2$ models as regards structure and energy and also the small barrier to the transition make it possible to regard these two models as a single structural model with a labile system of hydrogen bonds.

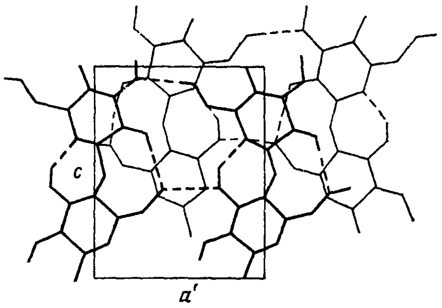

Figure 7. The $\bar{P}_1$ structural model corresponding to the global minimum in the target function Φ [Eqn.(7)] within the framework of the parallel version of the packing of the chains.[95,96]

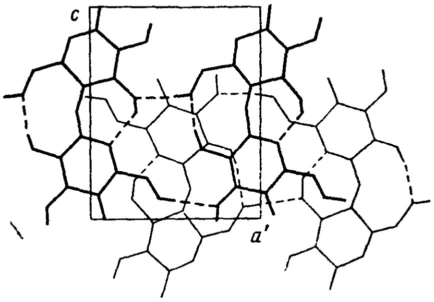

Figure 8. The a_1 structural model for CI corresponding to the global minimum in the target function Φ [Eqn.(7)] within the framework of the antiparallel version of the packing of the chains.[95,96]

A small energy barrier (<1 kcal mol^{-1}) is observed also for the $a_1 \rightarrow a_3$ and $a_1 \rightarrow a_4$ transitions. However, in these cases the probability of the transition is very insignificant owing to the large differences in the relative shift of the layers (~0.7 Å) between the models indicated. Clearly, such a shift requires the concerted collective displacement of the atoms within the limits of the target layer, which is an extremely improbable event. (Formally this implies that the pre-exponential factor in the expressions for the probabilities of the $a_1 \rightarrow a_4$ transitions is very small).

2. Cellulose II

The CII structural modification is formed when cellulose is regenerated from its derivatives or on reprecipitation from solutions [regenerated cellulose (RC)] and also when cellulose preparations are treated with concentrated solutions of alkali metal hydroxides [mercerised cellulose (MC)].[9-11] The regenerated and mercerised celluloses are characterised by virtually identical X-ray diffraction patterns and IR spectra and on this basis they are regarded as a single polymorphic modification.

Whereas well-resolved X-ray diffraction patterns typical of CII can be obtained on mercerising cotton, ramie, and wood cellulose, the attempts to obtain CII by mercerising the *Valonia ventricosa* fibres were not successful.[28,89,94] This confirms yet again the above hypothesis that cellulose from seaweed apparently possesses an individual crystal structure different from that of ramie, cotton, and wood cellulose.

It is important to note that the polymorphic transition from CI to CII is monotropic. The claim that CII is the more stable polymorphic modification of cellulose is based on precisely this experimental fact.

Analysis of the equatorial reflections in the X-ray diffraction patterns of CII shows that the CII unit cell is analogous to that in CI. One macromolecule intersects the *ab* face at the beginning of the crystallographic coordinate system, while the other makes an intersection of the centre of the face. It follows from the analysis of the intensities of the (110) and (020) reflections that the average plane of the glucopyranose rings in CII should be rotated by a somewhat greater angle relative to the *ac* plane than in CI.

The polymorphic transition from CI to CII is accompanied by significant changes in the IR spectra. Thus, whereas three bands with parallel dichroism (at 3275, 3350, and 3375 cm^{-1}) and two bands with perpendicular dichroism (at 3305 and 3405 cm^{-1}) are observed in the CI spectrum in the region corresponding to the vibrations of the OH groups, in the CII spectrum two bands with parallel dichroism (at 3407 and 3488 cm^{-1}) and three bands with perpendicular dichroism (at 3175, 3305, and 3350 cm^{-1}) are observed.[9,90] The above differences (both in the stretching vibration frequency of the OH groups and in the dichroism) indicate a significant rearrangement of the hydrogen bond system on passing from CI to CII. X-Ray diffraction patterns of CII were first obtained and indexed by Andress[99] within the framework of a monoclinic unit cell for the $P2_1$ space group. The unit cell parameters were a = 8.14 Å, b = 9.19 Å, c = 10.3 Å (fibre axis), and γ = 118°. Thus CII has lattice periods similar to those in CI but a significantly different monoclinic angle γ.

Crystallographic studies on CII were carried out simultaneously with such studies on CI using the same method and frequently the same workers were involved.[72,84,87,89,100,101] This obviates the need for .... structural CII models with parallel and antiparallel .... the CII models proper.†

As for CI, it is best to begin a detailed examination of structural models with the model put forward by Jones,[58,59] who examined structural CII models with parallel and antiparallel packing of the chains. A satisfactory agreement with IR spectroscopic and X-ray diffraction data was achieved for the model with the opposite direction of the chains and the shift S = 0.29. The positions of the O(6) atom in the angular and central chains were close to the *tg*-conformation

---

†Parts of the Russian text appear to be missing (Translator).

and *gt*-conformation respectively. The angular chain was stabilised by the two intramolecular hydrogen bonds O(3)H...O(5′) and O(2)...O(6′) and the single central bond O(3)H...O(5′). The intermolecular bonds were in the (110) plane. These are two symmetrically non-equivalent hydrogen bonds of the O(6)...O(3″) type and the O(2)...O(2″) bond.

In the analysis of the structure of CII, Kolpak and Blackwell[63,102] used the approach proposed by Gardner and Blackwell[64] for the elucidation of the structure of CI. The same four trial models P_1, P_2, a_1, and a_2 were used as the initial approximation as in the analysis of the packing of CI. Both regenerated and mercerised celluloses were examined.

The optimised a_2 model, which is also free from short contacts, was found to be most suitable as regards the R'' factor. Application of Hamilton's test showed that, in terms of the R'' factor, the models obtained from a_1, P_1, and P_2 can be rejected for a level of significance higher than 99%. Comparison of the a_2 models optimised with respect to X-ray diffraction data for RC on the one hand, and MC, on the other showed that they are fairly similar but not identical. The main difference is in the value of the parameter S, which is 0.216 for RC and 0.227 for MC. Significant differences are observed also in the optimised values of the average isotropic temperature factor B_T, which are 20 Å^2 for RC and 32 Å^2 for MC.

The system of hydrogen bonds in the a_2 model resembles the system of such bonds in the Jones model.[59] The O(6)...O(3″) bond is located in the plane of the central chains, while the O(6)...O(2″) bond is in the plane of the angular chains. The O(2)...O(2″) bond is located in the (110) plane. According to the authors,[63,102] the presence of the last bond is in fact the main and fundamental difference between the structures of CI and CII and is the main cause of the increased stability of the CII polymorphic modification.

The structure of CII was also examined by Stipanovic and Sarko.[35] The optimum structural model of CII was selected from the condition for the minimum in the target function (5) with all the geometrical variables, including the bond lengths and the valence and torsional angles, varied. The average isotropic temperature multiplier was likewise varied. The model with the antiparallel disposition of the chains, which is close in terms of its parameters to the structural models of RC and MC proposed by Kolpak and co-workers,[63,102] was found to be most suitable. However, according to the author's calculations,[35] apart from the O(2)...O(2″) bond in the (110) plane there is also a possibility of the formation of the interlamellar O(6)...O(3″) bond.

A structural model of CII with a parallel arrangement of the chains has been proposed recently.[103] The unit cell in this model is made up of the diagonals of the Wellard cell and includes one symmetrically independent chain. This study[103] was based on the existing definite similarities between the X-ray diffraction patterns and IR spectra of CII and cellotetraose, whose unit cell contains one crystallographically non-equivalent molecule.[104] However, the above model[103] had an inadmissibly high value of the R factor ($R = 0.50$) and in addition conflicted with data for the IR dichroism of the stretching vibrations of the OH groups. This attempt demonstrates perhaps the error of the "mechanical" transfer of data obtained solely on the basis of a single model compound (cellotetraose) to the structure of a complex polymer such as cellulose.

The energy criteria have been resorted to in order to determine the structure of CII.[98,105,106] The optimum structural model was sought in a manner fully analogous to the method described above in the discussion of the studies by Nugmanov and co-workers.[61,95,96] The characteristics of the most probable structural models of CII are presented in Table 2. The following factors are striking in the analysis of Table 2. Firstly, it is evident that in the case of CI the available diffraction data are too few for an unambiguous solution of the structural problem (for a 99% level of significance, all the models presented are statistically equivalent). Secondly, comparison of the data in Tables 1 and 2 shows that the optimum models of CII are more favourable on energy grounds than the optimum models of CI by approximately 1–2 kcal mol^{-1}, which agrees with the view that CII is a more stable polymorphic modification of cellulose. Finally, it is seen from Table 2 that, among the models most suitable as regards energy, there are no models with a parallel arrangement of the chains. The difference of approximately 2 kcal mol^{-1} obtained between the best parallel model (P_1) and the best antiparallel models is sufficiently convincing to reject the hypothesis of a parallel arrangement of the chains in CII.[103] Among the antiparallel models in Table 2, mention should be made of the a_6 model, which is in essence a structural analogue of the familiar model of Stipanovic and Sarko[35] and also of Kolpak and co-workers.[63,102] Evidently the a_6 model is appreciably inferior to the best antiparallel models as regards energy and the value of the target function.

Table 2. Certain characteristics of the most probable structural models of CII.[98,105,106]

Model*	R''	U, kcal mol^{-1}	Φ, cal mol^{-1}	Model*	R''	U, kcal mol^{-1}	Φ, cal mol^{-1}
a_1	0.179	—21.4	—18.7	a_5	0.186	—20.4	—17.6
a_2	0.178	—21.2	—18.5	a_6	0.124	—19.4	—17.5
a_3	0.183	—21.2	—18.5	P_1	0.167	—19.4	—16.9
a_4	0.164	—20.1	—17.6	P_1	0.164	—17.5	—15.1

*The same notation is used as in Table 1.

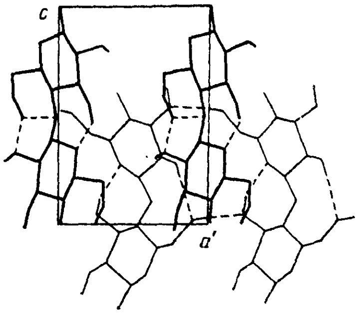

Figure 9. The optimum structural model a_1 for CII.[98,105,106]

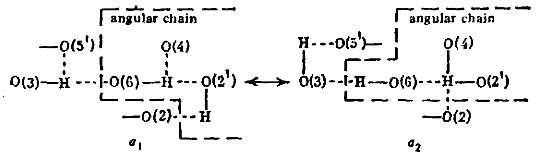
The a_1 model, whose projection on to the $a'c$ plane is illustrated in Fig.9, is best in terms of the value of the target function. Evidently the a_1 model represents alternating layers parallel to the ac plane. The (020) layer in the a_1 model is constructed analogously to the layers in the structural a_1 and P_1 models for CI described above in the discussion of the studies of Nugmanov and co-workers.[95,96] In the (020) layer there are the intramolecular hydrogen bonds O(3)...O(5′) and O(2)H...O(6′) and the intermolecular bond

O(6)H...O(3″). The conformation of the macromolecules in the (010) layer of angular chains is close to the *A*1 conformation with its typical O(4)...O(6)H...O(2) biacceptor bond. There are no intermolecular hydrogen bonds in the (010) plane. The neighbouring layers in the a_1 model are linked by intermolecular bonds: the strong O(2)H...O(2″) bond and the weak O(3)H...O(6″) bond. The proton at O(3) is then found to be involved in the O(5′)...O(3)H...O(6″) biacceptor bond.

The a_2 structural model can be obtained from a_1 by changing the orientation of the O(6)H and O(2)H hydroxyls of the angular chain and the a_3 model can be obtained by altering the orientation of the O(6)H hydroxyl in the central chain. The rearrangement of the hydrogen bond system in the transition from the a_1 model to the a_2 model is illustrated schematically below (for clarity, only the hydroxyls involved in the rearrangement are shown); the OH groups of the angular chain are differentiated by a dashed line):



The hydrogen bond system remains uninvolved in the $a_1 \rightarrow a_3$ transition and only the position of the proton at the O(6) atom changes relative to the line connecting the donor and acceptor oxygen atoms.

It is seen from Table 2 that the a_1, a_2, and a_3 structures have similar energies and in addition the barriers to the transitions between them are low (0.9 and 0.2 kcal mol^{-1} for the $a_1 \rightarrow a_2$ and $a_1 \rightarrow a_3$ transitions respectively). As for the $\overline{P}_1$ and $\overline{P}_2$ models of CI, this factor suggests that all three structures can exist simultaneously in CII and can be interconverted as a result of the thermal migration of protons.

IV. CONCLUSION

Analysis of the data presented shows that the problem of the determination of the molecular-crystal structure of cellulose is still far from its final solution. In fact only the data for the symmetry and size of the unit cell as well as the conformation of the glucopyranose residue in the main macromolecular chain can now be regarded as fully non-controversial information about the structure of cellulose. The data enumerated do not, however, allow the complete reproduction of the architecture of the crystal owing to the extensive conformational possibilities associated with the side groups and the wide variety of different versions of the disposition of the cellulose chains in the crystal arising from this. The available diffraction data are too limited to make an unambiguous choice between several alternative versions of the structure.

The semiempirical energy calculations, which apparently possess a greater "resolving capacity" than crystallographic criteria such as the *R* factor and the principle of close packing, can apparently help significantly in solving the structural problem. However, even in this case calculation yields several possible versions of the structure which have extremely similar energies.

In our view, a more well defined situation obtains for the stable CII polymorphic modification of cellulose where the most suitable model is separated from the remaining possible versions of the structure by an "energy gap" of approximately 1 kcal mol^{-1}. Bearing in mind that the error in the calculation of the lattice energy by the method of atom–atom potentials is usually systematic and is to a large extent compensated when different versions of packing of the same molecules are compared, one may expect that the ~1 kcal mol^{-1} energy difference is entirely significant. An interesting feature of the most probable model of CII is the lability of its hydrogen bond system, i.e. the capacity for ready rearrangements as a result of the thermal movement of individual protons.

In the case of CI the best models are distributed more or less uniformly with respect to energy and the best parallel and the best antiparallel models ($\overline{P}_1$ and a_1 in Table 1) are almost equivalent as regards energy and are statistically indistinguishable with respect to the R'' factor. An important argument in support of the antiparallel version of the structure is the finding that the fibres swell only slightly on mercerisation leading to the transition of CI into CII. An appreciable structural rearrangement (in particular in the change of the arrangement of the chains) cannot then occur, which entails a different similarity of the structures of CI and CII. Comparison of the a_1 models for CI and CII does indeed reveal a similarity of significant parameters such as the orientation of the hydroxymethyl groups and the relative shift of the chains.

The Synthesis and Polymerisation of Macromonomers

K.S.Kazanskii, P.Kubisa, and S.Penczek

Problems concerning the synthesis and reactions of macromolecular monomers (macromonomers)-polymeric molecules containing at least one polymerisable, usually unsaturated, end group or a fragment capable of polycondensation reactions—are considered. They are usually obtained by a radical or ionic polymerisation method in which the use of special chain initiating or terminating agents as well as intense chain transfer ensures the introduction of the reactive group. Studies on the polymerisation and copolymerisation of macromonomers are surveyed and the characteristic features of these processes, determined by the low concentration of the reacting group and the presence of a polymeric substituent, are analysed. The applications of macromonomers in polymer engineering, mainly in the synthesis of cone, star, graft, and other hybrid polymers, are examined.

The bibliography includes 119 references.

I. INTRODUCTION

Reactive oligomers constitute a large family of polymers having at least one functional end group capable of further reactions. Macromolecular monomers or macromonomers (MM) are reactive monofunctional oligomers capable of participating in chain propagation reactions via these groups. The term macromonomer (or even more briefly "macromer") was introduced by Milkovich[1] as the trade name for a group of polystyrene oligomers with a wide variety of polymerisable end groups. According to a later definition,[2] macromers are short-chain polymers coupled quantitatively at one of the ends of the chain to polymerisable unsaturated groups. The unsaturation is naturally not the only possible source of the polymerisability of MM, since the end group can be cyclic or of another type, although the number of examples of such groups is small. These groups can be introduced into the MM molecule in the stage involving the initiation or limitation of the growth of the chain (chain transfer and termination) and also as a result of the conversion of one set of end groups into another.

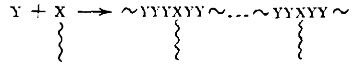
In reality MM were known long before the time when this term appeared. Thus siloxane MM with styrene groups (polysiloxanestyrene MM) were synthesised as early as 1962 and were used to obtain polystyrene with grafted polysiloxane side chains.[3] All these features resemble the history of "living" polymers, which existed long before they came to be referred to by this term, but the introduction of the latter was extremely useful for the purposes of classification and the elucidation of preparative possibilities.

Thus a MM can be represented schematically as a polymer chain having one end group X capable of entering into chain propagation reactions:

$$\sim\!\sim\!\sim X$$

although in a number of studies bifunctional and even polyfunctional oligomers of different type have also been classified as MM, which is incorrect.

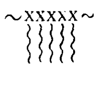
When preparative aspects associated with MM are considered, then MM are usually regarded as intermediates in the synthesis of graft copolymers with a vigorously defined structure, in particular as regards the length of the grafted chains:



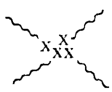
$$Y + \underset{\wr}{X} \longrightarrow \sim YYY\underset{\wr}{X}YY\sim \ldots \sim YY\underset{\wr}{X}YY\sim \qquad (1)$$

where Y is a low-molecule-weight comonomer.

The homopolymerisation of the MM itself affords a regular comb polymer (I), while in the case of very low degrees of polymerisation the same reaction leads actually to a star polymer (II):



(I)



(II)

Together with other familiar methods of preparative polymer chemistry, the procedures based on MM give rise to the prospect of obtaining polymeric products of the types indicated, whose nature is extremely varied. The possibility of combining in a single macromolecule units of the kind that cannot be joined together by direct or successive copolymerisation and other similar methods is of special interest. Thus macromonomers give rise to the possibility of overcoming the inability of certain monomers to polymerise via a single mechanism.

MM are identified by the usual methods, characterising mainly the molecular weight ($\overline{M}_n$) and the average functionality ($\bar{f}_n$) with respect to the groups X:

$$\bar{f}_n = \frac{\overline{M}_n N_x}{g},$$

where g is the mass of the sample analysed and N_x the number of functional groups found in the specimen. It is noteworthy that, in contrast to the telechelic polymers used in the synthesis of polymer networks, in the case of MM there is no need to attain a high functionality, although naturally in most synthetic studies the authors endeavoured to obtain compounds with a functionality close to unity. The deficiency of polyfunctional reactive oligomers as regards functionality usually has serious consequences when they are employed in the synthesis of polymeric materials.[4]

II. METHODS OF SYNTHESIS OF MACROMONOMERS

Polymerisable groups can be introduced into the macromolecule in virtually any stage of its formation process. In polymerisation such groups can be a direct result of a specific mechanism of chain initiation, destruction, or transfer and also of the introduction into the reactive mixture of special substances (chain initiating, terminating, or transferring agents). Finally, groups capable of subsequent polymerisation can be formed during the reaction of some other end groups which were present in the initial oligomers and in this case polycondensation oligomers can also be employed for the synthesis of MM.

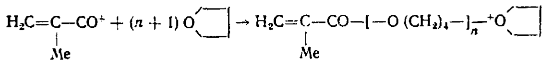
1. Polymerisation Methods

(a) Initiation

Initiation with subsequent "living" polymerisation is one of the most direct methods of synthesis of MM. It is necessary that the initiation under the influence of the initiator introduced should be the only reaction leading to the appearance of growing polymer chains and that side processes, including the polymerisation of the end group formed, should not occur. We shall consider certain examples of such syntheses.

Cationic polymerisation. Only a few monomers polymerise via the "living" mechanism under the conditions of cationic initiation. Some of them are used to synthesise MM.

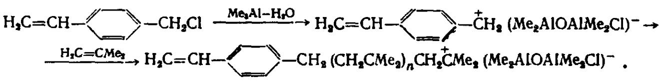
The polymerisation of tetrahydrofuran under the influence of the unsaturated acylium salt (III), i.e.



(III)

leads to a polymer the first of the end groups of which is the methacrylate group, while the second is available for the generation of any kind of functional group.[5] This method is suitable for the "living" cationic polymerisation of various monomers, because the oxocarbenium ions (III) can initiate the polymerisation of heterocycles such as acetals, sulphides, and amines.

A study,[6] whose authors were the first to synthesise polyisobutylene MM using as the initiator the p-vinylbenzyl chloride—Me_3Al—water system under conditions ruling out chain transfer, may serve as an example of the employment of the cationic polymerisation of vinyl monomers:



The number of styryl groups per chain in the MM synthesised was close to 1.0 according to UV spectrophotometric data (255 nm, $\varepsilon = 1.68 \times 10^4$ litre mol^{-1} cm^{-1}), but the authors[6] noted some decrease of functionality with respect to these groups when the synthesis was carried out at low monomer concentrations or with high degrees of conversion. In a modified method,[7] the initiator employed was therefore p-(β-bromoethyl)cumenyl chloride, which, after its incorporation in the chain, was converted into the styryl group by treatment with potassium t-butoxide.

Certain characteristics of the MM based on isobutylene obtained by these procedures are presented in Table 1, which also includes information about isobutylene MM synthesised by other methods.

The polymerisation of vinyl ethers on treatment with the $HI-I_2$ system takes place without chain termination and transfer and leads to monodisperse polymers. This fact was used to synthesise MM from ethyl vinyl ether:[11]

$$H_2C{=}\underset{Me}{C}{-}COO(CH_2)_2OCH{=}CH_2 + nEtOCH{=}CH_2 \xrightarrow{HI-I_2} H_2C{=}\underset{Me}{C}{-}COO(CH_2)_2O\underset{Me}{CH}(CH_2\underset{Et}{CH})_nOMe\ .$$

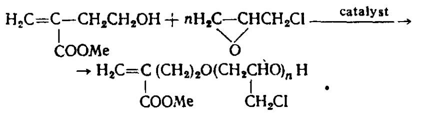
*Methods for the introduction of end groups: A–initiation; B–reactions via end groups; C–method employing a combined agent–initiator and chain transfer agent ("inifer"[9]).

**A bifunctional derivative.

The polymerisation was carried out at −40 °C in toluene; chain termination was achieved by introducing methanol. The degree of polymerisation was varied by varying the ratio of the monomer and the initiator in the range 5–100. A study of the MM obtained by gel-permeation chromatographic (GPC) and NMR methods confirmed the proposed structure.

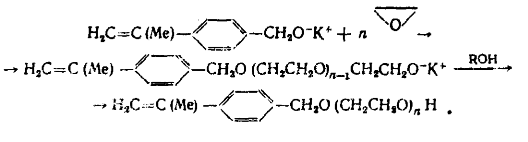
Recently, in the development of methods for the preparation of oligomers having a specified structure on cationic initiation, much hope was associated with the so called "activated monomer" mechanism, which makes it possible to avoid many typical complications, in particular macrocyclisation. This procedure, in which a proton-containing initiator "specifies" the polymer end group, has been used recently to obtain MM based on epichlorohydrin:[12]



It is entirely possible that this approach is fairly universal.

Anionic polymerisation. The range of monomers polymerising via the "living" mechanism under the conditions of anionic initiation is much wider than in the cationic processes. Anionic polymerisation reactions of styrene and its derivatives, dienes (buta-1,3-diene, isoprene), 2- and 4-vinylpyridines, methacrylates (under conditions ruling out chain transfer), certain cyclic ethers (usually epoxyethane), three- and four-membered cyclic sulphides, lactones, cyclosiloxanes,[†] and other less readily available groups of monomers can be used virtually without limitations for the synthesis of MM by the direct initiation procedure. The formation of living polymers is not the only precondition for the successful synthesis of MM: it is necessary that the initiation mechanism should ensure the incorporation of the future polymerisable group in the polymer chain.

For example, alkoxides derived from p-isopropenylbenzyl alcohol have been used to synthesise polyoxyethylene MM:[13]



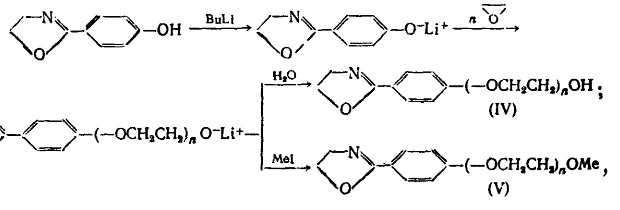
(2)

The MM, formed in 75–85% yield, had molecular weights in the range 2000–4500. They were characterised by different methods; it has been shown that the calculated and observed characteristics agree satisfactorily. The molecular weights of two specimens based on the data of Masson et al.[13] are presented below:

From the ratio of the monomer and initiator concentrations	2000	4500
From the titration of unsaturated groups	1850	5200
From ^{1}H NMR data—the ratio of the signals of the protons in the aromatic end groups and oxyethylene units	1700	4700
From the UV spectrum (250 nm, ϵ = 12 700 litre mol^{-1} cm^{-1})	2000	4200
From light scattering data	2100	4500

The results of the study of Masson et al[13] show that the process does indeed proceed via mechanism (2), but a high functionality is hardly guaranteed in this instance, because any proton-containing admixture participates in this process as a coinitiator (see, for example, Sepulchre et al.[14]), generating chains without specified functional groups.

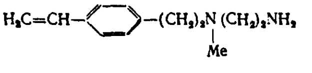
Polyoxyethylene MM with 2-oxazoline end groups, suitable for subsequent cationic polymerisation, were synthesised in an analogous way.[15] When the reactions are carried out in accordance with the scheme



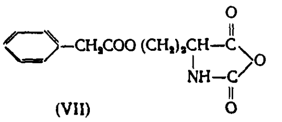
the MM (IV) and (V) are obtained, their degrees of polymerisation amounting to ~20 and 40 respectively according to gas-phase osometric data; a chain length of ~20 can also be obtained from the ratio of the peak areas of the methylene and aromatic protons in the NMR spectrum of compound (IV); compounds (IV) and (V) homopolymerise and copolymerise on treatment with BF_3 etherate.

Here mention should also be made of the synthesis of reactive oligomers of epoxyethane and propene on treatment with alkoxides derived from allyl alcohol,[16] but in this case there is even less guarantee of the formation of MM homogeneous as regards functionality since intense chain transfer to the monomer is characteristic of the polymerisation of epoxypropane.

It is known that the polymerisation of the *N*-carboxyanhydrides of α-aminoacids on treatment with primary amines proceeds in many instances with quantitative initiation via addition to the monomer. This has been used[17] for the synthesis of polyaminoacid MM, which are of great interest from the standpoint of their subsequent use for the preparation of biomedical materials. Amino-derivatives of styrene, for example compound (VI), were used as the initiators, while the monomer was the *N*-carboxyanhydride of γ-benzyl-L-glutamic acid (VII):

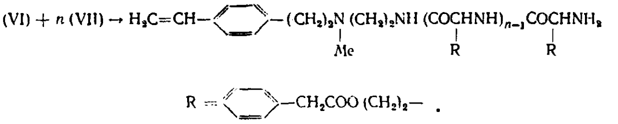


(VI)



(VII)

The polymerisation reaction via mechanism (3) leads to MM with a styrene end group:



(3)

Salts of various weak acids, which are effective only in the presence of activators such as crown ethers, are known to be suitable for the initiation of the polymerisation of β-propiolactone. The use for this purpose of the potassium methacrylate–dibenzo-18-crown-6 ether made it possible to obtain the corresponding MM:[18]

$$\underset{\text{Me}}{\underset{|}{H_2C{=}C}}{-}COO\,(CH_2CH_2COO)_n\,R\ ;$$

R = H, CH_2Ph .

with a molecular weight of 1000–15 000 and with a quantitative functionality. An analogous approach is applicable also to epoxyethane.

b) Reactions Involving the Deactivation or Destruction of Active Centres

Cationic polymerisation. "Living" cationic polymerisation mechanisms, which constitute an essential condition for the quantitative introduction of the required end groups at the deactivation stage, has been established most reliably for heterocycles. It has been correctly stated recently,[19] in the analysis of the problem of the introduction of functional end groups under the conditions of cationic polymerisation with ring opening, that the main obstacle in this instance is chain transfer to the polymer, which should be eliminated or negligible. Macrocyclisation gives rise to analogous difficulties.

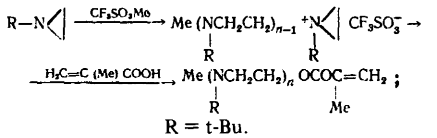
There are virtually no complications in the preparation of MM from tetrahydrofuran, cyclic sulphides, or aziridines if the process is carried out up to low degrees of conversion. At later stages of the process, chain transfer to the polymer complicates the synthesis of MM in these and similar systems and the problem is not limited to macrocyclisation, the broadening of the molecular weight distribution (MWD), and the impossibility of achieving total conversion. An even more serious obstacle is the disproportionation of living polymers, in which they are partly converted into a mixture of inactive and bifunctional growing macromolecules:

$$AAA^* + AAA^* \rightarrow AA + {}^*AAAA^*$$

which completely rules out the possibility of obtaining MM homogeneous as regards functionality during their subsequent deactivation.

[†] Macrocyclisation at high degrees of conversion is characteristic of the last two groups of monomers.

The use of sterically hindered monomers partly or fully suppresses the undesirable chain transfer to the polymer; one of the examples of this is provided by the successful synthesis of methacrylate MM from *N*-t-butylaziridine:[20]

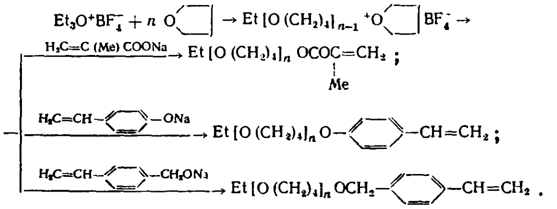


R = t-Bu.

Gas-phase osmometric and ^{1}H NMR data confirm the structure of the MM obtained, whose finite functionality was not determined in the above study.

Many different MM have been obtained from tetrahydrofuran, which is perhaps the most typical monomer polymerising via the cationic "living" mechanism.

MM have been synthesised[21-23] from tetrahydrofuran with methacrylate and styrene end groups via mechanism (4), the polymerisation being interrupted by introducing the appropriate reagents at a low degree of conversion:



(4)

Table 2. Characteristics of MM based on polytetrahydrofuran obtained by cationic polymerisation methods.

*Methods for the introduction of end groups: A—deactivation; B—initiation; C—the method of "inifers" (see the footnote to Table 1).

**Bifunctional derivative (R—H or Me).

Other functional groups have been introduced into polymers via procedures similar to scheme (4). Certain characteristics of MM based on tetrahydrofuran, obtained by the deactivation of living polymers and also by other ionic polymerisation methods, are listed in Table 2. Evidently in most cases, where the reaction is continued only up to a low degree of conversion, the target functionality is nearly obtained. There is no doubt that a wider assortment of polymerisable end groups is also possible.

Anionic polymerisation. The synthesis of MM by the method involving the directed deactivation of living anionic polymers was achieved for the first time in relation to polystyrene.[1,26,27] A multiplicity of different functional groups, capable of polymerisation via a multiple bond or with ring opening and also of polycondensation or polyaddition, were introduced.

The deactivation of macroanions leads to much more extensive possibilities than in the case of the analogous cations, because, as already mentioned, a much greater number of monomers polymerise in this instance with formation of living polymers. The realisation of these possibilities is illustrated in Table 3, where the majority of the MM obtained by this procedure at the present time are listed. The method for the introduction of functional groups in the synthesis of all the MM investigated is in principle the same and consists in the reaction of the nucleophilic living macroanion (usually in the state of an ion pair) with an electrophilic deactivator.#

Table 3. Characteristics of MM obtained by the deactivation of "living" anionic polymers.

*MM based on polystyrene with the groups $\sim CH{=}CH_2$, $\sim C(Me){=}CH_2$, $\sim OCH{=}CH_2$, , , $\sim OCOC(Me){=}CH_2$, $\sim OCOCH{=}CH{-}COOH$, $\sim CH_2COOCH{=}CH_2$, and $\sim CH(OH){=}CH_2OH$ have been obtained,[1,26,27] but have not been characterised quantitatively.

**Polymer of 8-oxa-6-azabicyclo[3.2.1]octan-7-one.

The probability of side reactions, i.e. the non-selectivity of the reaction involving the introduction of the functional group, increases with increasing reactivity of the anion. Its conversion into a less active form yields in many instances positive results, of the kind achieved, for example, by the preliminary conversion of the polyvinylpyridine carbanion into an oxa-anion by reaction with epoxyethane.[32]

#The polymerisation of a bicyclic oxalactam, which proceeds via the activated monomer mechanism, is an exception;[31] in this instance the anion of the deactivator attacks the growing end of the chain.

Radical polymerisation. One of the possible mechanisms of chain termination in radical polymerisation is disproportionation of the macroradicals in accordance with the scheme

$$2\sim CH_2\dot{C}HX \rightarrow \sim CH{=}CHX + \sim CH_2CH_2X \ .$$

This reaction leads to a polymeric product, half of the macromolecules of which contain an unsaturated end group. This termination mechanism predominates in the polymerisation of methyl acrylate, methyl methacrylate, and other monomers.[34] We may note that, owing to the higher activation energy than in the recombination reaction, the contribution of the disproportionation to the destruction of macroradicals increases with increasing temperature. However, the tendency towards the formation of symmetrically substituted double bonds does not give rise to prospects for the use of such MM owing to their low reactivity.

(c) Chain Transfer

The synthetic applications of the chain transfer reaction as a method for the introduction of functional groups require that it should proceed effectively, predominating among other reactions limiting the length of the polymer chain. It is desirable that the chain transfer agent should not influence the polymerisation kinetics, i.e. that the new species arising in the chain transfer step should initiate the next chain. In essence, this is merely the definition of true chain transfer. Chain transfer systems and agents acting according to this principle have long been known, especially in radical polymerisation.

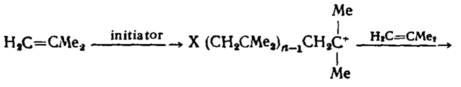
There are several radical and ionic polymerisation processes in which MM are formed via a mechanism natural for these processes, i.e. without the introduction of any special chain transfer agents. The most obvious variant of this method of synthesis of MM is polymerisation with intense chain transfer to the monomer. Generally speaking, two cases are possible, for example, for vinyl monomers:

$$\sim CH_2\dot{C}HX + H_2C{=}CHX - \begin{cases} \xrightarrow{a} \sim CH_2CH_2X + H_2C{=}\dot{C}X \ ; \\ \xrightarrow{b} \sim CH{=}CHX + Me\dot{C}HX \ . \end{cases} \qquad (5)$$

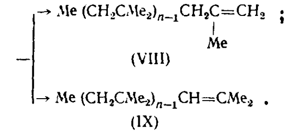
If there are no other initiation and termination processes in the given system, the double bond is fixed in the initial (pathway *a*) or terminal (pathway *b*) fragment of the chain. Chain transfer of type (5) in processes of different chemical nature proceeds with transfer of a hydrogen atom, proton, hydride ion or, more rarely, a larger species.

Cationic polymerisation. Two types of chain transfer reactions lead to MM in cationic polymerisation—chain transfer to the monomer and elimination of a proton from the active fragment of the growing macromolecule.

Chain transfer to the monomer is characteristic of the cationic polymerisation of certain unsaturated compounds. It has long been known, for example, that the cationic polymerisation of isobutene results in the formation of a macromolecule containing unsaturated groups at the end of the chain.[35,36] A more detailed analysis demonstrated that the number of such groups in the polymer is equal to the total number of macromolecules to within 5% (in the range of molecular weights 700–2000),[37] i.e. intense chain transfer takes place via the mechanism:



$$H_2C{=}CMe_2 \xrightarrow{\text{initiator}} X\,(CH_2CMe_2)_{n-1}CH_2\overset{\overset{\displaystyle Me}{|}}{\underset{\underset{\displaystyle Me}{|}}{C^+}} \xrightarrow{H_2C=CMe_2} \qquad (6)$$



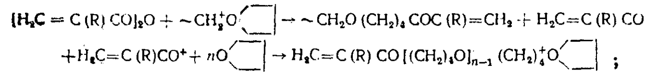
$$- \begin{cases} \rightarrow Me\,(CH_2CMe_2)_{n-1}CH_2\underset{\underset{\displaystyle Me}{|}}{C}{=}CH_2 \ ; \\ \qquad (VIII) \\ \rightarrow Me\,(CH_2CMe_2)_{n-1}CH{=}CMe_2 \ . \\ \qquad (IX) \end{cases}$$

NMR data have shown[37] that, together with groups (VIII) and (IX), other isomeric structures are formed in the MM via a reaction involving mechanism (6) but the entire wide variety of the different kinds of terminal unsaturation reduces exclusively to groups of type (VIII) when di-t-butylpyridine is used in the reaction as a cationic trapping agent.[38]

The cationic polymerisation of styrene[39] and α-methylstyrene[40] also leads to polymers with unsaturated end groups. They are formed in high yields in the polymerisation of styrene by CF_3SO_3H in non-polar media.[41] It has been established[42] that the yield of double bonds in acenaphthylene polymers formed via the cationic mechanism is quantitative.[42]

Reactions involving chain transfer to the monomer with formation of polymers having unsaturated end groups proceeds also in the polymerisation of certain heterocycles—ε-caprolactone,[43] oxepan,[44] and 2,2-dimethyloxetan.[45]

Transfer to the chain transfer agent, specially introduced into the system, has been used to obtain bifunctional MM. It has long been established[46] that acid anhydrides, for example, acetic anhydride, act as effective chain transfer agents in the polymerisation of tetrahydrofuran, which makes it possible to regulate the chain length and the composition of the end groups. This same procedure has been used recently to obtain bifunctional acrylate and methacrylate MM:[25,47]



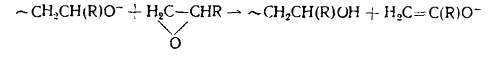
(7)

R = H, Me .

There is a purely formal analogy between reaction (7) and polymerisation under the influence of "inifers"—substances which act simultaneously as initiators and chain transfer agents and introduced into polymer practice by Kennedy.[48] In the studies already quoted[8–10] this method has been used to synthesise various polyisobutylene MM (see Table 1).

The use of effective proton trapping agents—the so called "proton sponges", especially di-t-butylpyridine which gives rise to effective proton transport—is also promising in this instance.

Anionic polymerisation. The best known instance of the direct formation of MM in ionic polymerisation is provided by processes involving substituted oxirans.[49] The increased acidity of the hydrogen atoms in the molecules of these monomers, on the one hand, and the presence of the highly nucleophilic alkoxide anions, on the other, increase sharply the rate of the processes involving chain transfer to the monomer:



(8)

whose contribution is extremely significant for the anionic polymerisation of the majority of substituted epoxides. We may recall that their oligomerisation processes are usually employed to generate hydroxylated telechelate polymers for the synthesis of polyurethanes and in this sense reaction (8) prevents the attainment of the required functionality.

These reactions have been studied in greatest detail in relation to epoxypropane, where two variants of terminal double bonds are possible:

$$H_2C{=}CH{-}CH_2O{\sim}\ \text{(X)} \qquad Me{-}CH{=}CH{-}O{\sim}\ \text{(XI)} \ .$$

Under the polymerisation conditions, the allyl groups (X) isomerise to the *cis*-propenyl groups (XI).[50] The maximum number of unsaturated groups does not, however, exceed 50–55% and their content depends on the temperature of the synthesis, the radius of the alkali metal counter-ion, which has been omitted in scheme (8), and also on the concentration of alcohol in the polymerisation system.[51,52] Reactions (8) have been observed also in the polymerisation of substituted glycidyl ethers: up to 87% of unsaturated macromolecules are formed in the polymerisation of, for example, *o*-chlorophenyl glycidyl ether and up to 79% in copolymerisation with epoxypropane.[52]

Since the introduction of polyether fragments into the macromolecules is of practical interest, the set of problems associated with chain transfer as a method of synthesis of MM requires a more serious analysis.

Chain transfer to the monomer is characteristic under certain conditions of the polymerisation of ethylene under the influence of Ziegler type catalysts,[53,54] which creates the possibility of the controlled conversion of ethylene into C_6–C_{20} α-olefins, which can then be used as MM. Mainly vinyl end groups are then formed and these then partially isomerise to internal double bonds. The fractions of vinyl groups β in ethylene oligomers are listed below:[54]

n	6	8	10	12	14	16	18
β, mole %	90.4	88.4	86.4	85.5	84.8	84.1	82.5

Variation of the monomer pressure, of the nature of the solvent, and other conditions makes it possible to increase the functionality with respect to these groups almost to 100%. The possibility of the quantitative epoxidation of α-olefins obtained by this method is of great interest,[55] because the subsequent copolymerisation of such MM opens a way to polyethers with hydrocarbon side chains.

Radical polymerisation. The formation of reactive oligomers (introduction of functional groups) with the aid of the chain transfer reaction has been the object of many investigations. The successful insertion of reactive groups into macromolecules via a chain transfer agent specially introduced into the system depends on the reactivity of the monomer (M) and the corresponding macroradical and also on the reactivity of the chain transfer agent (SH) in chain transfer and reinitiation processes:

$$SM_nM^{\cdot} + SH \rightarrow SM_{n+1}H + S^{\cdot};\quad S^{\cdot} \xrightarrow{M} SM^{\cdot} \xrightarrow{nM} SM_nM^{\cdot} \ . \qquad (9)$$

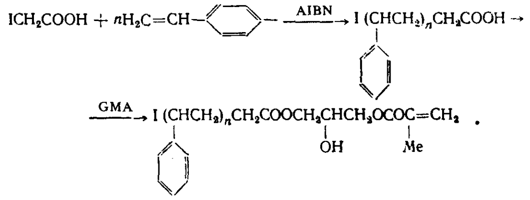
Thus the effectiveness of the reinitiation is low for inactive monomers, which give rise instead to reactive macroradicals, which are more reactive than the radical S in Scheme (9).

One of the most thoroughly investigated transfer processes having a practical application is the telomerisation of ethylene by CCl_4:[56]

$$CCl_4 + nH_2C{=}CH_2 \xrightarrow{R} CCl_3(C_2H_4)_nCl \ \text{(XII)} \ .$$

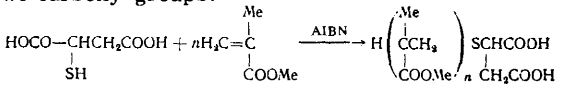
A wide variety of reactions of the telomer (XII) are possible and it can be regarded as the intermediate in the synthesis of MM. There are examples of the use of the telomerisation of various monomers for the direct synthesis of MM.[57–62]

The radical polymerisation of styrene and methyl methacrylate in the presence of iodoacetic or thioglycolic acids leads to a monocarboxylate polymer, into which functional groups have been introduced.[57,58] For example, styrene has been telomerised by treatment with azobisisobutyronitrile (AIBN) with subsequent introduction of functional groups by means of glycidyl methacrylate (GMA) in accordance with the scheme:



The reaction leads to the corresponding MM (with molecular weights of 4300–7700) in yields up to 90%.[58]

The use of thiomalic acid as the telogen makes it possible to introduce into the macromolecule a telechelic fragment with two carboxy-groups:[59]



$$HOCO{-}\underset{SH}{CH}CH_2COOH + nH_2C{=}\overset{Me}{\underset{COOMe}{C}} \xrightarrow{AIBN} H\left(\overset{Me}{\underset{COOMe}{C}}CH_2\right)_n\underset{CH_2COOH}{SCHCOOH} \ .$$

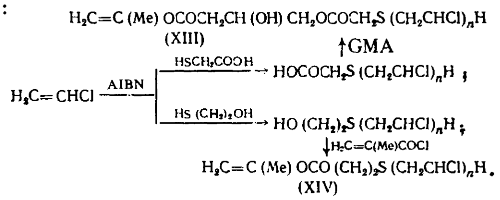
The authors[59] emphasise that this is the first synthesis of MM for subsequent polycondensation with diols, diamines, etc.

MM containing the diol group at one end of the poly(methyl methacrylate) chain have been obtained analogously using thioglycerol:[60]

$$H(CCH_2)_nS\underset{CH_2OH}{CH}CH_2OH \ ,$$

These MM can also be used in polycondensation or polyaddition reactions, for example, for the synthesis of modified polyurethanes.[60]

Radical telomerisation with subsequent introduction of unsaturated groups has been used recently to synthesise vinyl chloride and vinylidene chloride MM.[61,62] In the case of vinyl chloride, two different telogens were used and correspondingly two agents for the introduction of functional groups:



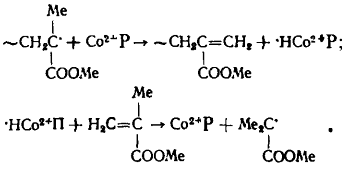
$$H_2C{=}CHCl \xrightarrow{AIBN}\ \xrightarrow{HSCH_2COOH} HOCOCH_2S(CH_2CHCl)_nH \xrightarrow{GMA} H_2C{=}C(Me)OCOCH_2CH(OH)CH_2OCOCH_2S(CH_2CHCl)_nH \ \text{(XIII)} \ ;$$

$$H_2C{=}CHCl \xrightarrow{AIBN}\ \xrightarrow{HS(CH_2)_2OH} HO(CH_2)_2S(CH_2CHCl)_nH \xrightarrow{H_2C=C(Me)COCl} H_2C{=}C(Me)OCO(CH_2)_2S(CH_2CHCl)_nH \ \text{(XIV)} \ .$$

The products (XIII) and (XIV) have been comprehensively characterised—they have molecular weights in the range 1000–2400 and copolymerise with standard monomers.

We shall now return to chain transfer to the monomer. By itself, this reaction is unable to ensure the required functionality under the usual conditions. In fact, for example, in the usual polymerisation of methyl methacrylate (in bulk at initial concentration 1 M, 50 °C, and rates of initiation in the range 10^{-8}–10^{-6} mol litre^{-1} s^{-1}), f_n with respect to unsaturated end groups does not exceed 0.3–0.4, which can be shown by estimates based on kinetic parameters.[34]

A sharp acceleration of chain transfer by catalysts has been observed and studied in detail recently.[63] It has been shown, for example, that in the presence of cobalt complexes of porphyrin $Co^{2+}P$, a hydrogen atom is transferred with a high efficiency from the radical to the monomer in the polymerisation of methyl methacrylate:



$${\sim}CH_2\overset{Me}{\underset{COOMe}{C^{\cdot}}} + Co^{2+}P \rightarrow {\sim}CH_2\underset{COOMe}{C}{=}CH_2 + {\cdot}HCo^{2+}P;$$

$${\cdot}HCo^{2+}\Pi + H_2C{=}\overset{Me}{\underset{COOMe}{C}} \rightarrow Co^{2+}P + Me_2\underset{COOMe}{C^{\cdot}} \ .$$

There are a number of pieces of evidence (obtained by NMR, electrochemical, etc. methods) for this mechanism, which results in the formation of a substituted methyl methacrylate group in each macromolecule.

(d) Other Polymerisation Methods

The polymerisation of acrylamide is initiated by lithium alkyls via a mechanism involving the abstraction of a proton with retention of the vinyl group:[64]

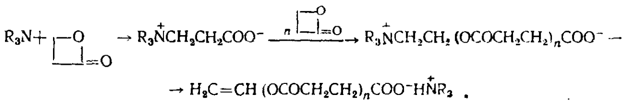
$$H_2C{=}CHCONH_2 + RLi \rightarrow RH + \underset{(XV)}{H_2C{=}CHCONH^-Li^+}\ .$$

The latter is then introduced into the chain of the poly-β-alanine (nylon-3) formed:

$$(XV) + nH_2C{=}CHCONH_2 \rightarrow H_2C{=}CHCONH\,(CH_2CH_2CONH)_n^-Li^+\ .$$

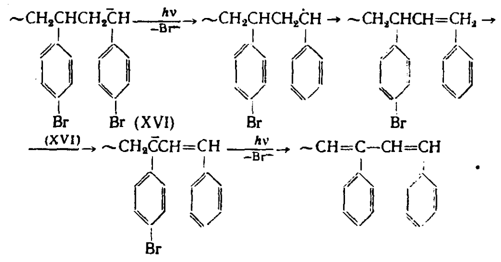
The highest functionality ($\bar{f}_n$ = 0.95–1.10) with respect to these groups has been shown to be attained[64] on initiation with t-butyl-lithium. The MM formed polymerises under the influence of radical and ionic initiators.[65]

The polymerisation of *N*-carboxyanhydrides on treatment with amines, which proceeds with retention of the initial group of the initiator at the end of the macromolecule, was examined previously. In the case of a number of monomers (for example, β-propiolactone, epoxyethane, etc.) and tertiary amines, the polymerisation is complicated by the instability of the primary zwitter-ionic active centres:



This instability leads to the appearance of unsaturated end groups in the macromolecules, which is analogous to the method of synthesis of olefins via the Hofmann rearrangement. In the polymers of β-propiolactone,[66] epoxethane,[67] and glycidyl phenyl ether,[68] there is a double bond in each macromolecule. It is essential to note that only the acrylate end groups of poly-β-propiolactone formed via this mechanism are of real interest from the standpoint of the possibility of the subsequent employment of MM.

A novel method for the generation of double bonds has been devised in a study of the photochemical decomposition of living poly-*p*-bromostyrene:[69]



(10)

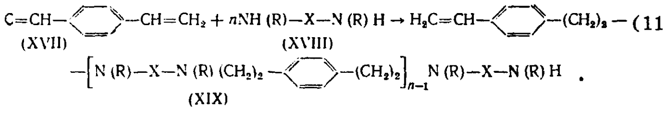
Under certain conditions, the reaction leads to the formation of polymers with 1,3-diphenylbuta-1,3-diene end groups in quantitative yield and it has been shown that the MM formed (molecular weight 50 000) are readily converted into high-molecular-weight comb polymers with anionic initiators. The photochemical reaction (10) can also proceed further, leading ultimately to polyphenylacetylene.

The relatively easy rupture of the poly(methyl methacrylate) chain on mechanical treatment has also been used to synthesise products resembling MM.[70] Ultrasonic treatment in benzene in the presence of *p*-divinylbenzene and subsequent deactivation of the system with methanol result in the formation of MM with molecular weights in the range 130 000–230 000 and functionalities of 2.2–12.0. They possess a broad molecular weight distribution and are highly inhomogeneous as regards functionality. Copolymers with styrene and methyl methacrylate have been obtained from them.[70]

2. Polyaddition and Polycondensation

There is a very limited number of examples of the application of the polyaddition and polycondensation reactions for the synthesis of MM. The point is that in the majority of processes of this type, the lengthening of the polymer chain is achieved by employing bifunctional monomers and the nature of the end groups is determined by statistical factors and the reactant ratio. The excess of one of the reactants or the use of a monofunctional terminating agent makes it possible to guarantee with a high degree of accuracy the nature of only the two end groups. These methods are hardly used in the synthesis of monofunctional MM.

An apt example, which indicates the new possibilities which have appeared in this field, is provided by the catalytic polyaddition with participation of secondary diamines and divinylbenzene:[71,72]



(11)

The first stage in scheme (11) is rapid and quantitative. The residual vinyl group is then highly passivated, as a result of which it is possible to achieve the preliminary synthesis of the stoichiometric adduct (XX) and its subsequent poly-addition:

(12)

Analysis of the resulting polyamine MM by gas–liquid chromatography and ^{13}C NMR[71] indicates molecular weights in the range 1800–6600, which corresponds to degrees of conversion of 0.84–0.93 in reaction (11).

Reactions of types (11) and (12) can be used also for the introduction of various groups, for example, crown ethers, into the macromolecule, which has been used successfully in one investigation.[73]

Polycondensation has not so far provided examples of the synthesis of MM.

3. The Reactions of the Functional Groups of Macromolecules

It is possible to obtain MM by the quantitative replacement of any end group by one capable of polymerisation. Such a reaction requires the activation of the group to be substituted by the use of a reactive agent for the introduction of functional groups, so that the method involving the deactivation of living polymers is in this sense more natural. On the other hand, in the methods based on the modification of the end groups, it is possible to use a much greater range of reactions. The main requirement which they must meet is complete conversion.

Historically, the first example of the synthesis of MM refers to precisely this field. In 1962 Greber and Reese[3] achieved the reaction

and obtained polydimethylsiloxane MM in ~50% yield, which were then copolymerised with styrene.

Subsequently a number of communications concerning the introduction of a wide variety of polymerised fragments by the reaction of end groups with the corresponding agents for the introduction of functional groups were published. One of the convenient methods for the introduction of such functional groups is the use of poly(ethylene glycols) (PEG) and its monofunctional analogues, whose hydroxy-groups are readily activated. In particular, the synthesis of oligoacrylate esters, widely used for the synthesis of three-dimensional polymers, is based on these reactions.[74]

There is no doubt that the attempt to obtain monofunctional MM by the same methods as a result of the selection of the corresponding stoichiometry should lead to a mixture of products. This remark applies fully, for example, to a study[75] where a number of glycols were esterified via the scheme

$$H(OC_2H_4)_nOH + HOCOCH{=}CH_2 \xrightarrow{H^+} H(OC_2H_4)_nOCOCH{=}CH_2\ ,$$

but the monofunctionality of the final product was not reliably established.

The only real possibility of the synthesis of MM involves therefore the use of the initial monofunctional polymers and the factors which determine the choice of method for the direct introduction of functional groups in the polymerisation stage of the replacement of groups in the finished polymer is the stability of the polymer chain as regards the action of the corresponding reagents and the attainment of the required functionality.

We shall consider several of the latest examples of the synthesis of MM using these reactions. Mono- and divinylethers of PEG have been synthesised with high degrees of conversion:[76,77]

$$H(OC_2H_4)_nOH + HC{\equiv}CH \xrightarrow[180°]{Na} \begin{cases} H(OC_2H_4)_nOCH{=}CH_2\ , \\ H_2C{=}CH(OC_2H_4)_nOCH{=}CH_2\ . \end{cases} \qquad (13)$$

These are of interest from the standpoint of the subsequent synthesis of macromolecules with crown ether rings in the chain. Reaction (13) is accompanied by the degradation of the main chain, as shown by the results of the chromatographic analysis, presented below, of a mixture of bifunctional oligomers with different chain lengths *n* according to the data of Mathias et al.:[77]

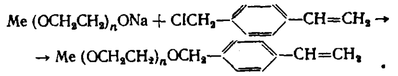
Initial PEG	Products			
	$n=2$	$n=3$	$n=4$	$n=5$
$n=3$	43%	57%	—	—
$n=4$	23%	33%	44%	—
$n=5$	—	27%	64%	8%

In this connection an assortment of milder conditions is necessary, in particular, the use of phase transfer catalysts.[76] The same approach can be applied to monofunctional polymers.

Monofunctional allyl[78] and acrylate[79] derivatives of oligoethers, i.e.

$$Ar(OCH_2CH_2)_nONa + HOCOCH{=}CH_3 \rightarrow Ar(OCH_2CH_2)_nOCOCH{=}CH_2\ , \qquad (14)$$
$$Ar = C_9H_{15}C_6H_4,\ Ph$$

as well as their styrene derivatives,[79] i.e.

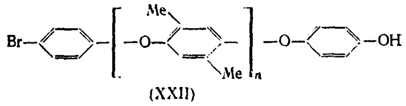


have been obtained by analogous methods, i.e. by the activation of hydroxy-groups with alkali metals.

Detailed analysis of the acrylate MM formed by capillary gas chromatographic and high performance liquid chromatography yields the distribution of the MM with respect to chain lengths but at the same time an appreciable amount of the initial school is detected, which shows that reaction (14) does not go to completion.

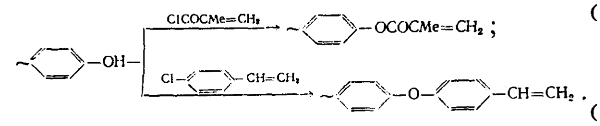
Fundamentally new types of MM have been obtained recently by the introduction of functional groups into polyethersulphone (XXI) and poly(2,6-dimethyl-1,4-phenylene oxide) (XXII):[80]

(XXI)



(XXII)

The method of synthesis of the polymers ensured in both cases the presence of one phenolic end group, which was then converted into methacrylate or styrene groups in accordance with the schemes:



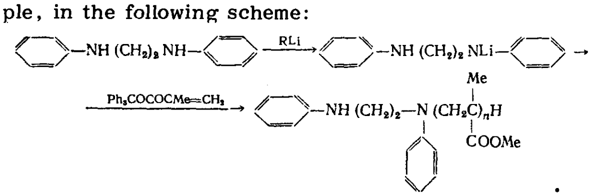
(15)

(16)

Reaction (15) was carried out in the presence of 4-*NN'*-dimethylaminopyridine and triethylamine and reaction (16) was carried out under phase transfer conditions.

The initial polymers (XXI) and (XXII) as well as the MM based on them have been investigated in detail by IR spectroscopy and ^1H and ^{13}C NMR. The equality of the signal intensities of the halogenophenyl and phenolic groups or the unsaturated groups demonstrates the presence of the planned MM structure. The complete absence of absorption due to the OH groups in the terminal phenolic fragments in the IR spectra demonstrates additionally that the introduction of functional groups is complete.[80]

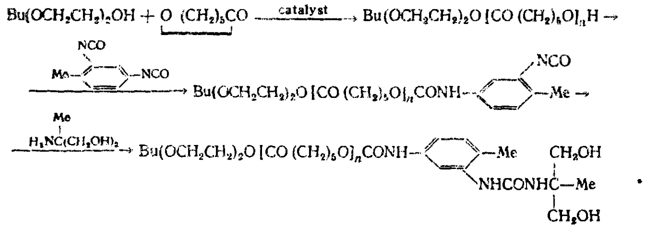
One may quote the example of the synthesis of poly(methyl methacrylate) optically active MM[81] as an example of the wide variety of the possibilities and prospects for the synthesis of MM. Such MM are of undoubted interest as the starting materials for the creation of chiral sorbents and chromatographic phases. The polymerisation of racemic triphenylmethyl methacrylate on treatment with lithium initiators in the presence of chiral diamines leads to polymers having high optical activities with different signs—$[\alpha]_D$ ranges from −354° to +194°. The end groups of the polymers are determined by the initial lithium amide initiator, for example, in the following scheme:



(XXIII), $n = 45$

The subsequent reaction of compound (XXIII) via the N–H bond with methacryloyl chloride leads to a MM whose acrylamide end groups have been clearly identified by IR spectroscopy. These MM copolymerise with methyl methacrylate via a radical mechanism.

In a number of instances the specific synthesis of MM presupposes special regulation of the nature of the end group already in the stage involving the formation of the polymer in order to be able to replace it subsequently. One of the illustrations of this approach may be provided by the synthesis of the MM from ε-caprolactone:[82]



The MM obtained can enter into polyaddition reactions via the two hydroxy-groups in the terminal fragment. They are used to synthesise modified polyurethanes.

Having completed the consideration of the problems of the synthesis of MM, we may note that in recent years a set of methods have been devised for the introduction of polymerisable groups (mainly styrene and acrylate groups) into macromolecules of different types both directly in the stage of their synthesis and via secondary reactions. The methods involving the deactivation of living polymers lead to MM with the highest functionalities. In those cases where this procedure is impossible, good results can be achieved with the aid of reactions via the end groups but here too the feasibility of the quantitative introduction of the corresponding group (or groups) must be inherent in the precursor polymer.

III. POLYMERISATION OF MACROMONOMERS

It has been assumed *a priori* that the capacity of MM for polymerisation and copolymerisation with other monomers must be complicated by a number of factors. The impossibility of achieving high MM concentrations in the reaction medium as a result of their high molecular weight should be regarded as the first although the most trivial of these. The low MM concentrations can in the first place give rise to thermodynamic prohibitions of polymerisation, particularly in those cases where the polymeric substituent is attached directly to the double bond, which as a rule decreases sharply the heat of polymerisation. Under homopolymerisation conditions, this factor should reduce the rates and average degrees of polymerisation of MM and the MM copolymerisation processes always proceed for this reason under conditions where there is an excess of the "small" comonomer. The second factor is diffusion-dependent limitations, which in the given instance extend also to chain propagation via the reaction between the macromolecules.

The polymeric substituent can naturally exert a strong steric and polar influence on the reactivity of the double bond. In this sense the MM with styrene and acrylate groups are most preferred especially if the polymer chain is on the periphery, i.e. in the benzene ring or in the ester fragment respectively.

Finally, one must reckon with the possible instability of the polymer chains of the MM in relation to the active centres propagating the polymerisation. For example, polyoxyethylene is known to exhibit a tendency to be cleaved by radical, cationic, and even anionic agents. The polymer chains of MM based on lactones and siloxanes, in which chain dissociation and macrocyclisation reactions take place readily, cannot be regarded as fully stable in relation to ionic initiators. Because of these causes, the tendency to introduce into the MM groups capable of polymerisation via a radical mechanism predominates.

Purely polymeric effects, such as, for example, the matrix influence of the MM chain on the growth of new macromolecules (the orientation of the monomers and their polymerisation in the bound state, the formation of stereocomplexes, and other matrix growth mechanisms) as well as the thermodynamic incompatibility of the initial and final chains, which may be manifested both by the segregation into separate phases and by purely kinetic effects, are also possible.

All these complications occur to some extent in processes involving MM. For example, the MM formed via the chain transfer mechanism in the radical polymerisation of methyl methacrylate[63] does not copolymerise directly with the initial monomer apparently owing to steric hindrance and thermodynamic prohibition. The characteristic features of the kinetics of the polymerisation of poly(tetrahydrofuran-styrene) MM and the low chain lengths of the polymers obtained can be accounted for by the low concentration of the MM.[83] The copolymerisation of acrylic acid with polyoxyethylene-methacrylate proceeds in a significantly different manner in the pH ranges corresponding to the comonomers bound in a complex or in a free state.[84]

The kinetics and thermodynamics of the homopolymerisation of MM have, however, been so far investigated to an extremely insignificant extent, which precludes a more detailed analysis of the above features of these processes. Much more attention has been devoted to the copolymerisation of MM, because it is the main pathway to polymers of practical interest.

1. Copolymerisation With Participation of Macromonomers

Copolymerisation is the main procedure in the synthesis of polymers based on MM. Radical initiation is regarded as the most preferred in view of its universality. The usual equation for the composition of the copolymer of a "small" monomer (M_1) with a macromonomer (M_2) has to be modified because of the low concentration of the MM:[85]

$$\frac{d[M_1]}{d[M_2]}=\frac{[M_1]}{[M_2]}\cdot\frac{r_1[M_1]+[M_2]}{[M_1]+r_2[M_2]}\simeq r_1\frac{[M_1]}{[M_2]}\ ,$$

which corresponds to the case of the so called "ideal" copolymerisation ($r_1r_2 = 1$) and leads to a simple kinetic equation:

$$r_1=\ln(1-\alpha_1)/\ln(1-\alpha_2)\,, \tag{17}$$

where α_1 and α_2 are the degrees of conversion of the monomers M_1 and M_2 respectively. This evidently simplifies the determination of the reactivity of the monomer M_1, but hinders and frequently altogether precludes the determination of the reactivity of the MM. The copolymerisation of MM has beeen analysed by gas–liquid chromatography.[86]

It is also easy to show that only single MM units should be incorporated in the chain during copolymerisation. Indeed, the probability of the formation of the diad M_2M_2 and hence its fraction in the comonomer

$$f_{M_2M_2}=r_2\frac{[M_2]}{[M_1]}\left(1+r_2\frac{[M_2]}{[M_1]}\right)^{-2}\simeq r_2\frac{[M_2]}{[M_1]}$$

are very small and the following probabilities can be obtained for the average block lengths:

$$\bar{p}_1=1+r_1\frac{[M_1]}{[M_2]}\gg 1\ ;$$
$$\bar{p}_2=1+r_2\frac{[M_2]}{[M_1]}\simeq 1\ .$$

In other words, the copolymerisation considered is as a rule close to statistical copolymerisation and the variation of the constants r_1 and r_2 rarely alters this situation, because the aim of the tactics employed is usually to make sure that the polymerisable groups of the MM have structures identical to that of the "small" comonomer.

Table 4 presents the copolymerisation constants for systems with participation of MM. In the main, they refer to the "small" comonomer and in this case we obtain information about the reactivity of the MM, because

$$1/r_1 = k_{12}/k_{11} \qquad (18)$$

is the ratio of the rate constants for the addition of the MM and the "small" comonomer to the radical of the latter. The quantities r_2 are of great interest from the standpoint of the analysis of the complications caused by the macromolecular nature of the MM, but they are known only in rare cases.

Table 4. The reactivities of monomers in radical copolymerisation processes with participation of MM.

MM (M_2) *	Comonomer (M_1)	r_2**	r_1**	Refs.
Poly(ethylene oxide)-styrene	Styrene	1.04 (1.00)	1.18 (1.00)	[87]

"	Methyl methacrylate	—	0.60 (0.52)	[92]

---

*The first part of the name of the MM refers to the chain structure and the second to that of the end group.

**The values for low-molecular-weight models are given in brackets.

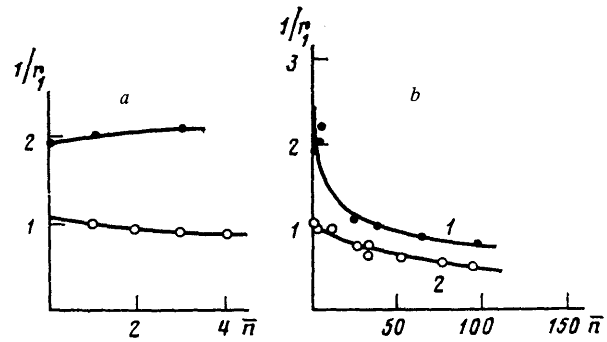
***When the MM chain length is varied.

****When the solvent is varied.

The data in Table 4 demonstrate in the first place the absence of any appreciable polymeric effects in copolymerisation, because in most cases the constants r_1 are close to those characteristic of the same pairs of low-molecular-weight monomers (indicated in brackets in Table 4) and the same applies to the few values of r_2 in Table 4. Systems where microphase separation occurs in consequence of the incompatability of the MM macromolecules and the polymer obtained are an exception. This applies to a considerable extent to, for example, copolymerisation of the polyisobutylene-styrene MM with styrene and methyl methacrylate.[90] A particularly marked effect is exerted by the increase of the molecular weight of the MM (from 4200 to 48 000), which leads to an increase of r_1 from 1.2 to 6.6 in the copolymerisation with styrene; in the latter case the reaction mixture is appreciably opalescent. Similar phenomena have been observed also in other systems.[27, 88]

The incompatibility of the polymers may play an even greater role in emulsion copolymerisation, because in this case there is a possibility of the formation of several phases and the rate of diffusion of the MM may prove to be the decisive factor. In particular, it has been shown that the emulsion copolymerisation of styrene with the polyisobutylene-styrene MM takes place with formation of the graft copolymer only in monomer drops, while the usual variant leads to polystyrene and the MM which failed to react.[93]

In the absence of explicit phase separation, the antagonism between the macromolecules of the growing polymer (consisting mainly of M_1) and the MM may be manifested by certain kinetic effects. Ito et al.,[88] who investigated in detail the dependence of the reactivity of poly(ethylene oxide) MM on the chain length (see Figure) tend towards this view. It can be seen from Fig.*a* that, in the region of short chains, there is virtually no dependence of n_1 on chain length, which indicates an insignificant inductive and steric influence of the substituent on the reactivity of the polymerisable group in the MM. In the region of great chain lengths (up to 10^2) (Fig.*b*), a monotonic decrease of $1/r_1$ is observed, which most probably indicates the corresponding decrease of the reactivity of the MM in relation to the growing macromolecule, i.e. a decrease of k_{12} in Eqn.(18). These changes are attributed to the kinetic effect of the excluded volume in intermacromolecular reactions. However, quantitative agreement with the theory of this effect has not been obtained and the idea of macromolecular antagonism has been formulated.[88]



The reactivities of poly(ethylene oxide) MM of different lengths ($\bar{n}$) in the radical copolymerisation with styrene (M_1);[88] MM with methacrylate (curves *1*) and *p*-vinylbenzyl (curves *2*) end groups.

It is essential to note that, overall, the approach to the study of the problem of the reactivity of the end groups in polymers via the investigation of the copolymerisation of MM is perhaps more correct than analysis of the processes involving the conversion of telechelate polymers into network polymers.[4] The theory of copolymerisation has been developed in detail, which makes the first approach even more justified.

On passing to the ionic copolymerisation of MM, which has not so far been touched upon, solvation interactions, matrix effects, etc. should be manifested to a considerable extent.

IV. APPLICATIONS OF MACROMONOMERS IN POLYMER ENGINEERING

The synthesis of graft copolymers clearly predominates in the preparative applications of MM. Strictly speaking, this field as a whole arose owing to the need to combine in a single macromolecular system at least two different frequently opposite properties, which cannot always be achieved by methods involving the successive copolymerisation of different monomers and block or graft copolymerisation. In graft polymers, there is a possibility of significantly different ratios of the main and grafted chains. The relatively greater freedom of the latter compared with the corresponding fragments in block copolymers leads in many instances to more favourable conditions for microphase separation, which results in qualitatively new mechanical properties of the material.

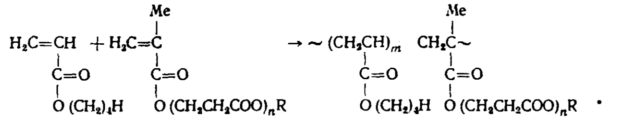
Virtually all the MM whose synthesis and polymerisation were examined in previous sections have been used to obtain graft copolymers with different "small" comonomers. The homopolymerisation of MM, leading to strictly regular comb polymers, has attracted significantly smaller and purely theoretical interest, although it is evident that in this sense the MM method is promising for the formation of liquid crystal materials.

We shall now consider the principal trends in the synthesis of graft copolymers based on MM.

It is known that the introduction of a rubber-like phase into plastics (polystyrene, materials based on epoxy-resins) increase their impact strength. A fundamentally new procedure has been proposed by Kennedy and Lo,[93] who achieved an increase by a factor of 2.5 of the impact strength of polystyrene by introducing into the latter, in the formation stage, approximately 10% of grafted polyisobutylene fragments, using the appropriate MM. The microphase separation and the enhancement effect were observed only for MM with relatively high molecular weights ($\bar{M}_n = 5 \times 10^4$). According to the authors,[93] an advantage of this method over the traditional introduction of rubbers (usually polybutadiene) is the high stability of the properties of the material as a function of time, including its stability in relation to the action of natural factors, for example, UV irradiation. The results of this study can hardly be regarded as final and it leads to new prospects for the solution of problems of this kind.

Another physicomechanical modification procedure, which is the direct opposite as regards the results achieved, involves the introduction of crystallisable fragments into elastomers. Microphase separation leads in this case to the formation of thermally reversible cross-links and to materials of the type of thermoelastoplastics. Polymeric fragments based on lactones, which are highly crystalline and give rise to a high rate of formation of the given phase, are of great interest in this connection. Their use in block copolymers is known.[94,95]

The graft copolymers of poly-β-propiolactone with butyl acrylate were first synthesised recently[18] via MM using the scheme



$$H_2C{=}CH(C{=}O)O(CH_2)_4H + H_2C{=}C(Me)(C{=}O)O(CH_2CH_2COO)_nR \rightarrow \sim(CH_2CH(C{=}O)O(CH_2)_4H)_m\,CH_2C(Me)(C{=}O)O(CH_2CH_2COO)_nR\sim \; .$$

They do indeed have the properties of unfilled acrylate rubbers. The copolymers obtained by treatment with AIBN have molecular weights in the range 30 000–60 000 and contain 46–80 wt.% of the ester fragments of poly-β-propiolactone, which corresponds on average to 1.7–3.5 grafted chains per macromolecule. In terms of their mechanical properties—strength and elongation on rupture (12 MPa and 380% respectively)—these materials approach filled rubbers based on butyl acrylate (12 MPa and 250% respectively). The properties of thermoelastoplastics based on the above MM are fully restored after the "fusion–crystallisation" cycle and have attracted evident interest.

A number of examples of the directed modification of traditional polymeric materials by means of the macromonomer techniques have been described in a recent communication by Milkovich,[1,27] who is undoubtedly a pioneer in this field. He employed polystyrene MM with methacrylate groups having molecular weights ranging from 11 000 to 16 000. The copolymers of such MM with ethyl and butyl acrylates, obtained in solution or in suspension, exhibit markedly the properties of reinforced rubbers with microphase separation, in which the rigid polystyrene domains simulate a solid filler. The majority of the copolymers are thermoplastic and their mechanical properties improve significantly when subjected to shearing influences, for example, extrusion, apparently as a result of the creation of a more homogeneous physical network. The principal mechanical characteristics of a series of ternary MM copolymers (molecular weight 16 × 10^3) with a 1 : 1 mixture of ethyl and butyl acrylates according to Milkovich's data[1] are given below:

MM content, wt.%	25	30	40	45	50
Yield point, MPa	—	1.9	8.3	12.4	18.0
Tensile strength, MPa	9.0	11.7	15.2	17.2	20.7
Limiting elongation, %	730	550	400	350	240

With increase of the content of MM, the copolymers undergo a change in a set of properties, being converted from thermoplastic elastomers capable of effective recovery of properties (20–30% MM) to flexible thermoplastic materials with high yield points and tensile strengths (35–45%) and finally to thermoplastic materials capable of being moulded and having a high tensile strength (45–55%).

The introduction of polystyrene MM into polyacrylonitrile (10 and 50 wt.% of the MM) makes it possible to improve significantly the conditions for the formation of films by casting methods at 150 °C. Positive effects following the introduction of MM have been observed also in the properties of poly(vinyl chloride).[27]

Other types of studies involving graft copolymers are associated with imparting various specific properties to materials. Many heterochain polymers are known to exhibit a high solvating power in relation to cations[96,97] and they are therefore used widely, together with crown ethers, as sorbents, solubilising additives, phase transfer catalysts, etc. Polyoxyethylene is perhaps of greatest interest and there have been a number of studies designed to produce the appropriate materials on the basis of its MM.[98,99]

Cross-linked polymeric sorbents based on network styrene—divinylbenzene copolymers, containing free suspended polyoxyethylene chains, have been obtained using MM.[98] It is possible to overcome in this way the low mechanical stability of the cross-linked polyoxyethylene, which precludes its direct employment as a chromatographic sorbent. The solvating power of network graft copolymers, containing different amounts of MM, have been studied in relation to the Williamson reaction

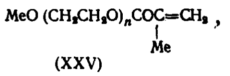
(XXIV)

R = n-Bu, C_7H_{15} . (19)

This reaction is extremely sensitive to the solvation of the cation and the ion pair (XXIV) and this is why it has become the traditional kinetic test for the solvating power of the medium.[96,100,101]

The pattern in the activation of reaction (19) by a cross-linked polymeric catalyst and also by analogous graft copolymers proved to be extremely complex. In the case of networks, the activation effect depends on the content of the MM, the degree of cross-linking, the porosity, and also the degree of swelling of the polymer and its thermodynamic compatibility with the medium and the alkyl bromide. In particular, the maximum in the dependence of the rate of reaction on the content of the MM in the network, which occurs at 5 mole %, has been attributed[98] to the character of the distribution of the reactants in the network polymer–liquid phase system. Overall, this interesting study[98] merely leads to a new approach to the synthesis of phase transfer catalysts based on polyoxyethylene, without solving the many other problems in this field.

The ability of systems of this kind to immobilise the corresponding reagents has been demonstrated in relation to gels obtained from MM of type (XXV) and methyl methacrylate with addition of 3–5% of cross-linking agents:[99]



$MeO(CH_2CH_2O)_nCOC(Me){=}CH_2$,

(XXV)
$n = 4-7$.

In the swollen state, such gels are optically transparent, which permits a spectrophotometric study of the degree of binding by the latter of alkali metal picrates as a convenient model (see, for example, Arkhipovich et al.[102]), and also of the state of the latter in a polymeric solvating medium. Experiments have shown that the equilibria

$$\text{gel} + \text{PiNa} \overset{K_1}{\rightleftarrows} \text{Gel.PiNa},$$

$$\text{gel.PiNa} + \text{glyme} \overset{K_2}{\rightleftarrows} \text{gel} + \text{glyme.PiNa}$$

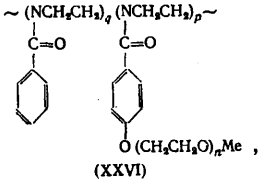
in dioxan and chloroform are strongly displaced towards sodium picrate (PiNa) immobilised in the network. The constants K_1 and K_2 proved to be ~300 litre mol^{-1} and 0.1–0.4 for networks based on MM of type (XXV) and glymes of similar length; the constants change somewhat as the chain length is altered.

These data indicate the higher solvating power of glymes in the polymer than in solution, although this is hardly likely to be achieved owing to cooperative effects, because glymes with this chain length are themselves fairly effective solvating agents.[103,104]

Spectroscopic studies[99] of the state of picrates in gel films have also confirmed the high level of solvation, because the spectra obtained correspond to solvate-separated ion pairs; the wavelengths of the absorption maxima are 368, 374, 377, and 378 nm for Li^+, Na^+, K^+ and Cl^+ respectively after the removal of the solvent. It has been suggested that the gels obtained and other analogous gels are promising for the study of the reactions of the reagents with the state solvated by macromolecules.

One of the important applications involves the creation of effective surfactants using MM. Comb polymers with a hydrophilic base and hydrophobic grafted chains (and conversely) have been used fruitfully for a long time for the steric (antropic) stabilisation of various dispersions, emulsifications, etc. (see, for example, Barrett[105]), but the approach using MM greatly simplifies the formation of such substances and extends the range of the possible structural variants. Polymers of this type are also of interest for the modification of the surfaces of polymeric materials and the solution of the problem of their compatibility. There have been several studies illustrating these possibilities.[92,106–109]

Using polyoxyethylene MM of types (IV) and (V), Kobayashi et al.[106] synthesised graft copolymers with the structure (XXVI):



(XXVI)
$n = 19-43$.

Owing to the presence of hydrophilic (polyoxyethylene) and hydrophobic (polyphenyloxazoline) fragments, these copolymers exhibit a high surface activity at the air–water interface. The surface tensions (γ, dn cm^{-1}) of water and 1% solutions at 28.5 °C are given below:

Water	71.4
MM	56.9
MM homopolymer ($p = 3$)	54.8
The copolymer (XXVI) ($p/q = 1:8.5$)	28.8

It has been suggested that these non-ionogenic surface-active graft copolymers would prove to be effective stabilisers of dispersions and also antistatic agents when they are introduced into plastics, like the analogous block copolymers.[107]

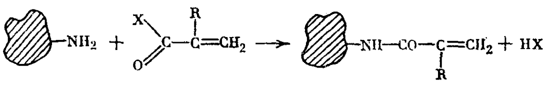
Extremely interesting and very promising surface effects have been observed after the introduction into polystyrene or poly(methyl methacrylate) films of small amounts of the corresponding graft copolymers containing hydrophilic polyamide[108] or, conversely, hydrophobic polydimethylsiloxane fragments.[92,109] Measurement of the wetting angles in water for polystyrene films obtained by casting onto glass plates has shown, for example, that the polyamide (see the footnote to Table 3) blocks are concentrated on the surface adjoining glass even when their content in the film is ~0.2%. This has been confirmed also by IR total internal reflection Fourier spectroscopic data. The surface of the film turned towards air does not differ in any way from that of the usual polystyrene.

The opposite picture has been observed for the system comprising poly(methyl methacrylate) and the graft copolymer of methyl methacrylate with polydimethylsiloxane-methacrylate.[110] In this case the siloxane blocks are concentrated on the "air" surface of the film, rendering it markedly hydrophobic; cos θ, where θ is the wetting angle, changes from 0.5 to −0.2 when not more than 0.5 wt.% of the siloxane component is introduced. The other surface of the film is also somewhat enriched in the graft copolymer and its distribution with respect to the thickness of the film follows clearly from IR reflectance spectroscopy. This effect, caused by the macroscopic separation of the copolymer in the bulk phase, is extremely stable and is almost fully retained after prolonged washing of the surface with n-hexane—an effective solvent for polydimethylsiloxane. In the case of similar modification of surfaces by static or block siloxane copolymers and also siloxane homopolymers, such washing eliminates the hydrophobic effect almost completely.

Presumably the application of biphilic graft copolymers constitutes a promising means of influencing the compatibility of polymers in composites, the character and stability of the microphase separation, and the modification of polymer films and fibres.

The biphilic property is one of the main qualities of graft copolymers widely used in the synthesis of biomedical materials. By virtue of MM, a series of new approaches have been discovered in this field also.

Plate and co-workers[111–113] have been consistently developing the immobilisation of biologically active compounds (BAC)—proteins, enzymes, etc.—on macromolecules or in cross-linked hydrophilic gels via intermediate "macromonomers". The principle of the method consists in the synthesis of MM by the acylation of BAC, i.e.



(BAC) (XXVII)

and the subsequent copolymerisation of the resulting acrylamide MM with an appropriate comonomer in the absence or presence of a cross-linking agent. It is possible to graft compound (XXVII) to various materials, for example, under the influence of γ-radiation. The functionality of the MM (XXVII) naturally depends on the number of the initial amino-groups in the BAC and on the degree of their substitution, which has been considered in detail in novel studies by this group of workers (see the review of Plate et al.[112]).

An important condition for the attainment of the final aim is the retention by the BAC of its activity at all the stages of the immobilisation process. It has been shown in relation to human serum albumin[113] and a number of other proteins that the BAC retain their secondary structure and that their binding centres are unaffected on modification.

The approach considered made it possible to create new effective sorbents for biospecific chromatography and materials with improved haemocompatibility, which is adequate even for making artificial veins. An important consequence of these studies is also clear-cut correlations between the haemocompatibility of the polymer and the effectiveness of its action on the clotting system of blood.

Another application concerned with the creation of biomedical materials, employing purely synthetic MM, has also been developing effectively.[17,73,114-116] The introduction of polyaminoacid, polyamine, polyamide, and also polysaccharide fragments, exhibiting "biological" affinity, into the usual polymers, most often polystyrene, which plays the role of an inert hydrophobic carrier, makes it possible to obtain two-phase materials which constitute the base for the creation of biosorbents, specific membranes, and anticlotting coatings.

The problem of the separation of *B*- and *T*-lymphocites, which is one of the key problems in modern chemical immunology, has attracted much interest recently.[117] The materials created on the basis of MM exhibit a high selectivity in such separation and are being studied vigorously. The selectivity coefficients A_B/A_T of the adsorption of the corresponding cells on polystyrene and graft copolymers with polyaminoacids [see Scheme (3)] and polyamine fragments (XIX), based on the results of several studies,[114-116] are presented below:

Polystyrene (PS)	—	1.18
PS with grafted polyaminoacid	(26%)	1.54
Ditto	(50%)	2.15
PS with grafted polyamine	(9%)	4.47
Ditto	(15%)	2.89
"	(25%)	2.45
"	(50%)	3.16

The mass content of the graft copolymers is indicated in brackets. Their selectivity is frequently antagonistic to the overall absorption of lymphocites on columns of this type.[115] However, the latest estimates have shown that the population of *T*-lymphocites can be obtained in yields up to 50% and with a purity of approximately 95% (for example, by employing the copolymer of polystyrene with a 9% content of polyamine). For this purpose, the columns are additionally modified by proteins, for example, albumin[115] or additives regulating the hydrophilic properties of the material.

Overall, the biomedical applications of MM have been developing most vigorously in recent times.

---o0o---

Thus a new field, which has significantly enriched synthetic polymer chemistry, has arisen among reactive oligomers and has been developing vigorously. The use of MM containing one polymerisable end group, frequently an unsaturated group, made it possible to obtain a number of fundamentally new comb and graft polymers. Methods for the introduction of functional groups—initiation and deactivation in ionic polymerisation and radical telomerisation—have been developed in detail. The first reviews of studies in this new field have already appeared.[118,119] Presumably this field and also the synthesis of block copolymers, developing in parallel, will serve as sources of new polymeric materials for various purposes.

Some Problems of the Development of the Physicochemical Principles of Modern Extraction Technology

V.S.Shmidt (deceased)

The latest advances in the quantitative prediction of the influence of the composition of the aqueous and organic phases, the nature of the functional groups of the extractants and the substituents attached to these groups, and the nature of the diluent on the position of extraction equilibria in the extraction of various metals are examined. The influence of these factors on the selectivity in the separation of different elements as well as elements with similar properties and on the possibility of the far reaching removal of impurities comprising weakly extractable elements from the element to be extracted is analysed and their influence on the properties of extraction systems, as determined by the interfacial tension, is estimated. It is shown that the corresponding quantitative prediction can be made with adequate accuracy for a wide range of systems on the basis of equations derived from linear free energy relations and the tabulated parameters ID, ID*, ΔG^*_{hydr}, etc., obtained by statistical treatment of the available extensive sets of extraction data, as well as the parameters σ^*, σ_φ, E^*_S, H, etc. known in physical organic chemistry. The ways of applying the methods for the prediction of extraction equilibria in combination with mathematical modelling to the optimisation of the structure and regimes of technological extraction schemes are considered. The bibliography includes 182 references.

CONTENTS

I. Introduction 792
II. Prediction and optimisation of the properties of extraction systems 792
III. Optimisation of the structure of extraction schemes 803

I. INTRODUCTION

During the latest decades, extraction has come to be used in industry as the basis for the technological schemes whereby rare and radioactive elements as well as certain non-ferrous metals can be obtained and separated. With an appropriate choice of components of the organic phase (extractants and diluents) and aqueous phase (acids and salts), this procedure permits the selective extraction of the required individual elements from complex mixtures.

The aim of scientific research in the field of extraction technology is the selection of optimum conditions ensuring the most complete extraction and separation of the elements as far as possible with the smallest consumption of the reagents and using the simplest possible and most compact equipment. An important question in this connection is the creation of waste free or low waste technological schemes which require the use of extractants, diluents, and water soluble reagents whose application would not entail the contamination of the environment. In many instances ultrahigh purification of a valuable element by a factor greater than 10^6-10^8 in a small number of operations is needed.

A clear example of the exceptionally effective application of liquid extraction is its use for the extraction and separation of uranium, plutonium, and neptunium in the regeneration of spent fuel from atomic power stations whereby these valuable elements are separated from several tens of radioactive elements treated as impurities (fission products) in a relatively small number of operations and for a very small consumption of reagents. Liquid extraction is also used to extract many valuable elements from ores and other natural mixtures with a complex composition.

The extraction schemes for the processing of atomic power station fuel developed in the USSR, presented at a series of International Conferences,[1-4] are greatly superior to those described in the world literature in terms of all the parameters, for example, the purification coefficients for valuable components in a single cycle (by a factor up to 10^6). The parameters attained are to a large extent the result of the high level of development of the physicochemical principles of extraction technology. Soviet investigators have made a major contribution in ensuring a high level of research in this field.

Among the large number of problems in extraction chemistry which are of interest for the development of extraction technology, the present review deals, first, with the principles for the selection of the optimum qualitative and quantitative composition of the phases in extraction systems, and, second, with the principle for the selection of the optimum structure of the flows of aqueous and organic phases in technological schemes based on extraction.

One of the most important conditions governing such choice involves the estimation and comparison of numerous possible variants. This requires the development of ideas and models which would make it possible to predict without experiments, or after carrying out a minimal number of experiments, various properties of extraction systems of interest for technology. This is particularly important for systems incorporating radioactive elements, since experiments involving such elements are laborious. This is probably why the main advances in the field considered were made as a result of many years' work by radiochemists, although the results obtained may find and are finding extensive applications in the extraction technology of the processing of non-radioactive materials as well.

II. PREDICTION AND OPTIMISATION OF THE PROPERTIES OF EXTRACTION SYSTEMS

For the prediction of the partition coefficients of the elements D, one must bear in mind that the extraction of inorganic compounds is usually determined by the consecutive or simultaneous occurrence of two processes: (a) the reaction involving the formation of a hydrophobic compound (solvate, hydratosolvate, chelate, or salt) as a result of the interaction of the inorganic ion or compound extracted from the aqueous phase with the extractant molecules;

(b) the partition of the hydrophobic compound between the phases without the formation of new compounds and for this reason referred to as "physical partition".

We shall consider both these processes in succession.

The Formation of a Hydrophobic Compound

When the solvate of a metal salt (MA_n) or acid (H_nA) is formed as a result of solvation by the nucleophilic extractant† (S), the process can be represented schematically by equations of the following type respectively:

$$M^{n+} + nA^- + m\bar{S} \overset{K}{\rightleftarrows} \overline{MA_nS_m} \;, \tag{1}$$

$$nH^+ + A^{n-} + m\bar{S} \overset{K}{\rightleftarrows} \overline{(H_nA)S_m} \;, \tag{2}$$

where the bar denotes the compound present in the organic phase.

When a chelate of the salt of the metal extracted with a hydrophobic acid HX is formed, a cation exchange reaction described by equations of the type

$$M^{n+} + n\overline{HX} \overset{K}{\rightleftarrows} \overline{MX_n} + nH^+;\; M^{n+} + n\overline{M'X} \overset{K}{\rightleftarrows} \overline{MX_n} + nM'^+. \tag{3}$$

takes place. When the system contains a nucleophilic extractant, reaction (3) may be supplemented by the formation of a chelatosolvate in accordance with the equation

$$M^{n+} + n\overline{HX} + m\bar{S} \overset{K}{\rightleftarrows} \overline{MX_nS_m} + nH^+. \tag{4}$$

When a salt incorporating the element extracted in the form of a simple or complex anion Y^{n-} is formed, the extraction reaction is described by the equation

$$n\overline{RA} + Y^{n-} \overset{K}{\rightleftarrows} \overline{R_nY} + nA^-. \tag{5}$$

Eqns.(1)–(5) describe the fundamental basis of the main types of extraction reactions involving solvate, cation exchange, chelatosolvate, and anion exchange mechanisms. In reality, there is a possibility of more complex varieties of these processes, associated, for example, with the existence of extractants or compounds extracted in the form of associated species[6] or even micelles.[7] There is also a possibility of the hydration of the extractant or compounds extracted and of incomplete displacement by the extractant molecules of the water hydrating the compound extracted. For example, if the nucleophilicity of the extractant used in extraction in accordance with Eqns.(1) and (2) is insufficient for the displacement of water from the inner coordination sphere of the metal cation M^{n+} or the proton H^+, then extraction via a mechanism referred to as the hydrate-solvate mechanism[8] and described by equations of the type

$$[M(H_2O)_p]^{n+} + nA^- + m\bar{S} \overset{K}{\rightleftarrows} \overline{[M(H_2O)_xA_yS_z]\,A_{n-y}S_{m-z}} + (p-x)H_2O, \tag{6}$$

$$n[H(H_2O)_p]^+ + A^{n-} + m\bar{S} \overset{K}{\rightleftarrows} \overline{[H(H_2O)_x]_nAS_m} + n(p-x)H_2O. \tag{7}$$

takes place.

The incomplete displacement of water or the association of the molecules of the compound involved can also complicate reactions of types (3) and (5). However, regardless of the specific composition of the hydrophobic compound extracted, its formation via the corresponding chemical reaction, which obeys the Law of Mass Action, is essential for extraction to take place.

Partition between Phases of the Hydrophobic Compounds Formed

This process does not involve the additional formation of new compounds. For example, the partition between the phases of the solvate formed via a type (1) reaction may be described by the equation

$$MA_nS_m \overset{P_0}{\rightleftarrows} \overline{MA_nS_m} \;. \tag{8}$$

If the compound present in the aqueous phase is itself hydrophobic (without the additional incorporation in it of extractant molecules), then the extraction reduces to one process of type (8), frequently referred to as "physical" partition. The quantitative description of the equilibria (1)–(7) and (8) requires the determination of the constants K and P_0 referred to as the extraction constant and the partition constant respectively.

The Relative Contributions of the Influence of the Chemical Reaction and of the "Physical" Partition on the Extraction Equilibrium

Under conditions where the hydrophobic compound formed via reactions of type (1)–(7) passes almost completely to the organic phase, the partition coefficient D_0 may be calculated[9–13] with the aid of equations derived from the Law of Mass Action using the extraction constant K. For example, equations of the following type can be used for reactions of type (1):

$$D_0 = K[A^-]^n[S]^m \frac{(\gamma^{\pm}_{MA_n})^{n+1}(\gamma_S)^m}{\gamma_{MA_nS_m}} = K\Pi \;, \tag{9}$$

where γ are the activity coefficients of the corresponding compound and Π is the product of all the terms of Eqn.(9) which follow K.

Eqn.(9) is the limiting case of a more general equation (10), which takes into account both complex formation and partition. In the general case, where the solvate extracted is not very hydrophobic and remains partly in the aqueous phase, the measured partition coefficient D is smaller than the "ideal" coefficient D_0 calculated from Eqn.(9), and it has been shown[14] that it is related to D_0 in the following manner:

$$\frac{1}{D} = \frac{1}{D_0} + \frac{1}{P_0} = \frac{1}{K\Pi} + \frac{1}{P_0} \;. \tag{10}$$

It is readily seen that, when the solvate is very hydrophobic, i.e. when $P_0 \to \infty$, the term $1/P_0 \to 0$ and D therefore tends to $D_0 = K\Pi$ for finite values of K and D_0. This makes it possible to restrict the calculations to Eqn.(9) for the partition in such systems. Equations of type (9) are used to calculate the partition coefficients in the majority of systems of practical importance. Highly hydrophobic extractants are usually chosen for such systems (in order to eliminate losses due to their solubility in water and to reduce to a minimum the contamination of aqueous streams by the extractant), which form moderately stable complexes via reaction (1) (to facilitate both the extraction and the subsequent re-extraction).

The wide scale and successful application of Eqn.(9) sometimes has led investigators to lose sight of its special character and to use it for less hydrophobic systems, obtaining thereby results which were not fully adequate. At the same time, in the general case where stable complexes are formed via reaction (1) (i.e. K is very high), even the use of highly hydrophobic extractants may result in a value of K so high that $1/D_0$ is comparable to $1/P_0$. Account must then evidently be taken of the contributions of both terms of the right-hand side of Eqn.(10) to the real partition coefficient D. The influence of physical partition on the extraction equilibrium must be taken into account also in extraction via reactions of types (2)–(8).

---

†Trialkyl phosphates, phosphine oxides, sulphoxides, carboxylic acid amides, the salts of amines and quaternary ammonium bases, and other hydrophobic compounds incorporating functional atoms having electron-donating properties and hence capable of forming coordinate bonds with electrophilic metal cations or hydrogen bonds with proton donating molecules may be classified as nucleophilic extractants.[5]

Thus in the general case the prediction of the extraction capacity reduces to the prediction not only of the constants# K but also of P_0, to which attention has been drawn.[14,15]

The Principal Approaches to the Prediction of the Quantities K and P_0

In the first stage of the selection of the optimum extraction system, one is usually guided by the familiar criteria governing the capacity of the cations, anions, and molecules of extractants for the formation of compounds via reactions (1)–(8) (in order to estimate K) and by the general ideas concerning the enhancement of hydrophobic properties with increase of the bulk of the organic part of the extractant molecule (in order to estimate P_0). However, at the stage involving more accurate optimisation, and particularly when mathematical models are used, not only qualitative but also quantitative prediction of the influence of various factors on K and P_0 is frequently necessary. In both instances the approach based on the use of the principal linear free energy relations, which has been developed in the USSR for extraction during the last two decades,[12,14,16–29] is more convenient for technological predictions. This approach is widely used in physical organic chemistry.[30–32] In the field of extraction, priority§ as regards the employment of this approach belongs to Soviet investigators. The principle of the linear free energy relations involves the employment of empirical parameters which reflect quantitatively the overall influence of various factors of the extraction equilibrium.

It is essential to note that other approaches to the description of the influence of the nature and concentration of the components of extraction systems on the extraction equilibrium are also possible and have been widely investigated. However, one can apply to the majority of the approaches discovered the apt definition put forward by Belousov and Popov,[34] formulated in the words "formally rigorous" approaches. The rigour of these approaches consists in the fact that, in the derivation of formulae relating K to the composition and nature of the components of the phases, the influence of a large number of different details of the extraction mechanism is taken into account, for example, all the complex formation equilibria (with allowance for the stability constants and activity coefficients of all the complexes formed in the aqueous and organic phases), the hydration and association equilibria of the extractant molecules[8,20,35–39] or the molecules extracted by them,[13,40,41] etc. On the other hand, the formality of the treatment consists in the fact that the "rigorous" expressions obtained, taking into account particular details of the interactions in the system investigated, usually include at the same time a series of new relations, whose form cannot so far be predicted theoretically and ultimately requires an empirical determination. For example, when account is taken of hydration, an empirical determination of the dependence of the activity of water in the aqueous phase on the concentrations of various components dissolved in it is required;[8,10,35] when complex formation is taken into account, one has to determine the activity coefficients of all the ions present in the aqueous phase[40] and of the molecules of the extractant and the compound extracted in the organic phase[41] as well as the stability constants of all the complexes formed in the system and their activity coefficients.

Without wishing to diminish in any way the cognitive importance of the "formally rigorous" approaches for a meaningful description and investigation of the extraction mechanism, one should note that, when they are applied to the practical prediction of extraction equilibria in the development of technological processes, it is usually necessary to carry out a larger volume of empirical investigations than is necessary when equations based on the principle of linear free energy relations are employed. Furthermore, the amount of experimental work essential in the "formally rigorous" approach is frequently so large that it is much simpler to measure experimentally the partition coefficients instead of predicting them theoretically. As a result of this, methods employing the dependence of the partition coefficients on various factors (to which equations have sometimes been fitted and which frequently do not take into account the details of the process mechanisms[42–44]) and simple formulae based on the principle of linear free energy relations, which achieve a combined allowance for the interaction of a large number of various details of the mechanism influencing the extraction equilibrium, are used for the prediction of technological parameters in most cases and not the "formally rigorous" approaches. The "formally rigorous" approaches to the description of extraction equilibria will probably assume ever increasing importance in the future as the theory of solutions develops and the contribution of relations predicted on fully theoretical grounds increases.

All the modern approaches to the quantitative description of extraction equilibria have been described in a monograph.[8] In the present review, devoted to the methods for the optimisation of technological extraction processes most widely used in practice, attention has been mostly concentrated on equations based on the principle of linear free energy relations. The application of these equations makes it possible to made predictions most simply and apparently with least expenditure of labour, at the present time, on experiments. The application of the principle of linear free energy relations to the prediction of the constants of the two principal equilibria indicated above (P_0 and K) is examined successively below.

1. Equilibria in Extraction Processes Not Involving the Formation of New Compounds ("Physical" Partition)

A partition of this type depends on the hydrophobic properties of the substances extracted and the overall absolute free energy of the process (and hence $\lg P_0$) increases with decrease of the absolute free energy of hydration of the partitioned compound. The influence of the increments characterising the structural components of the molecules of the partitioned compounds on $\lg P_0$ has been found to be additive for such compounds. For example, the introduction of each new CH_2 unit into the extractant molecule increases $\lg P_0$ by 0.4–0.5. A detailed scale of the increments π (Table 1),¶ characterising the structural elements and permitting the prediction[46–50] of the physical partition constants for members of each homologous series of extractants in terms of the equation

$$\lg P_0 = a + b\Sigma\pi \qquad (11)$$

The determination of the activity coefficients, which are necessary for calculations by equations of type (5), is an independent problem. The methods used for such calculations have been surveyed in a monograph.[10]

§ The history of the application of the principle of the linear free energy relations to extraction has been briefly surveyed.[14]

¶ A more detailed compilation of the parameters π may be found in a monograph.[45]

has been developed. Here a and b are coefficients which remain constants within the limits of a series of extractable substances with different structures (the nature of the aqueous phase and that of the organic solvent immiscible with it remains unchanged within the limits of the series).

Table 1. The increments π characterising the hydrophobic properties of the structural groups of the extractant in relation to physical partition.[46,47]*

Group	π	Group	π	Group	π
$-CH_2$	0.52	OH	−1.20	$-C\genfrac{}{}{0pt}{}{/\!\!/O}{\backslash H}$	−1.10
$-CH_3$	0.69	Br	1.01	$-C\genfrac{}{}{0pt}{}{/\!\!/O}{\backslash NH_2}$	−3.10
$\stackrel{\backslash}{\underset{/}{-}}N$	−2.50	I	1.30	$\genfrac{}{}{0pt}{}{\backslash}{/}C\genfrac{}{}{0pt}{}{/}{\backslash}$	0.18
$\genfrac{}{}{0pt}{}{\backslash}{/}NH$	−2.30	—COOH	−0 93	$\stackrel{\backslash}{\underset{/}{-}}CH$	0.32
Cl	0.92	—COO—	−1.01	$-NH_2$	−2.25
$\genfrac{}{}{0pt}{}{\backslash}{/}S{=}O$	(−3.8)	$\stackrel{\backslash}{\underset{/}{-}}P{=}O$	(−0.7)	$-C_6H_5$	(4.40)
HPO_3^-	(−5.2)	$\stackrel{\backslash}{\underset{/}{-}}\underset{\vert}{NH^+}$	(−3.5)	$\stackrel{\backslash}{\underset{/}{-}}PO_4$	(−0.80)

*In this and other tables, the values shown in brackets were obtained by treating limited sets of data; they may be revised as these sets are increased.

The parameters π for a series of structural elements of the partitioned compound, the elements in a pure state being capable of dissolving in an aqueous phase, vary in parallel with the variation of the free energy of hydration of these groups and linearly as a function of the empirical parameter $\Delta G^*_{\mathrm{hydr}}$ related to it (Table 2).[51,52] For this reason, for example for a series of amine salts having the same cation but different anions, the quantity $\lg P_0$ increases linearly with increase of $\Delta G^*_{\mathrm{hydr}}$ for these anions. Thus the partition of a series of tri-n-butylammonium salts with different anions between water and chloroform[54] can be described by the equation $\lg P_0 = 2.28 + 0.02\,\Delta G^*_{\mathrm{hydr}}$. For amine salts of different structure, incorporating both different cations and different anions, the partition in the system involving $CHCl_3$ can be calculated from the formula $\lg P_0 = -3.52 + 0.48n_C + 0.02\,\Delta G^*_{\mathrm{hydr}}$, where n_C is the number of carbon atoms in the alkyl chains of the amine, $\Delta G^*_{\mathrm{hydr}}$ the parameter of the hydration of the anion, and the coefficient 0.48 corresponds to π for the CH_2 group of the amine.

The changes in $\lg P_0$ occurring on changing the nature of the organic solvent in which extraction takes place for systems where the interaction between the diluent and the compound extracted has the character of non-specific solvation (without the formation of donor–acceptor and hydrogen bonds) may be predicted on the basis of the principle of linear free energy relations using the parameters ID* ("influence of the diluent")[55–57] listed in Table 3. It has been shown[55] for a large number of examples that, within the limits of each series of systems including the given partitioned compound and different diluents, $\lg P_0$ increases linearly with increase of ID* in accordance with an equation of the type $\lg P_0 = a + b\mathrm{ID}^*$.

Together with the ID* scale, one can apparently also use for the prediction of $\lg P_0$ the "polarity-polarisability" π^* scale, developed subsequently,[58] which is effectively correlated with the ID* scale. The authors,[58] who developed the π^* scale, demonstrated convincingly that it is possible to construct a scale describing the influence of non-specific solvation alone and a wide range of different phenomena.

Table 2. The average values of $\Delta G^*_{\mathrm{hydr}}$ for different anions.[53]

Anion	$-\Delta G^*_{\mathrm{hydr}}$, J mol^{-1}	Anion	$-\Delta G^*_{\mathrm{hydr}}$, J mol^{-1}

Brilliant Red A anion	175		
$TlBr_4^-$	154		

This is fully consistent with the treatment, published earlier,[51] of the physical significance of the ID* scale and the ideas concerning the role of non-specific and specific solvation in extraction processes.[16,51,59] The present author and his co-workers[66] also showed that, when solvents interacting with the solute solely via the non-specific solvation mechanism are chosen, then a satisfactory linear correlation of the parameters of the π^* scale with those of a number of other scales known in organic chemistry, namely the E_T,[60] Z,[61] χ_R,[62] S,[64] θ,[65] etc. scales obtains for all these solvents. We have shown[66] that the ID* scale is well correlated with the parameters π^* and satisfactorily correlated with the parameters of the other scales indicated above for solvents chosen in this way, provided that corrections are applied for the differences between the molar volumes. A linear correlation between the ID* scale and the ε^0 scale[68] has been established.[67]

*The values of ID* obtained with the aid of correlation equations from the parameters of the π^* and lg k_i scales are given in square brackets.[66]

In comparing the different scales for the influence of diluents, it is essential to note that the ID* scale provides the most accurate correlation with lg P_0, because it has been derived directly from extraction data and already includes allowance for the differences between the molar volumes of the solvents. Furthermore, the other scales have been constructed for anhydrous solvents, while the ID* scale applies to diluents in equilibrium with the aqueous phase, i.e. under conditions closest to those which exist in real extraction systems. Moreover, the ID* scale is specially designed to describe extraction equilibria and applies to solvents which can be used as diluents; the other scales apply mainly to solvents miscible with water and to a lesser extent to hydrophobic solvents. Nevertheless, in those cases where the parameter ID* has not been determined for a particular solvent, approximate estimates may be made in terms of the π^* or lg k_i scales, whose parameters are also listed in Table 3, or on the basis of the approximate values of ID* calculated from them and indicated in Table 3 in square brackets.

The joint influence of the nature of the diluent and of the structure of the partitioned compound can be expressed by a single two-parameter equation[52] of the type

$$\lg P_0 = a + b\Sigma\pi_i + a\text{ID}^*, \qquad (12)$$

where a, b, and c are constant coefficients within the limits of a series of systems differing only in the nature of the diluent and the structure of the extractant. Thus the partition of trialkylamines is described by the equations lg $P_0 = -2.48 + 0.48n_C + 0.36\text{ID}^*$. A similar equation has been found[56] also for trialkyl phosphates.

In order to estimate the partition of trialkylammonium salts incorporating different anions in extraction by different diluents, we may employ the equation[69] lg $P_0 = a + 0.48n_C + 0.02\Delta G^*_{\text{hydr}} + 0.36\text{ID}^*$. The optimum length of the alkyl chain can also be selected on the basis of this equation for the practical employment of the amine salt as a function of the nature of this anion. It follows from the equation that, in order to maintain a sufficiently low solubility of the salt in the aqueous phase on passing from the anion NO_3^- to SO_4^{2-}

(ΔG^*_{hydr} then diminishes by ~200 kg g-ion^{-1}), it is necessary to increase the length of the alkyl chains in the amine salt by ~10 CH_2 groups (overall).

It follows from the data presented above that, in order to ensure the minimum contamination of the surrounding medium (the liquid waste or the solutions of the final products) by the dissolved extractant, one can increase the length of the alkyl chains or employ diluents with higher parameters ID*. Examples of the employment of extractants with lengthened alkyl chains to diminish their solubility in the aqueous phase have been described in a number of communications[70–73] dealing with studies of extractants with chains longer than in tributyl phosphate as possible substitutes for the latter in the extraction processing of the irradiated fuel from atomic power stations. A preliminary quantitative estimate of the expected decrease of the solubility was then obtained from an equation of type (11) and the parameters π. If it is nevertheless necessary to employ a relatively hydrophilic extractant, then the admixture of the latter can be washed out of the aqueous waste by fresh solvent; the effectiveness of the washing will then evidently increase with increase of ID* for the diluent. This makes it possible to select a suitable diluent from Table 2.

Since one can use in principle aqueous solutions containing hydrophilic organic additives in extraction schemes (sometimes a polar organic liquid immiscible with the non-polar organic solvent can also play the role of the aqueous phase), the results of studies of partition in such systems too are of interest. The applicability to systems of this kind of equations based on the principle of the linear free energy relations has been demonstrated[74] and for each new type of polar phase it is possible to set up a special scale of parameters of type characterising the contribution to lg P_0 of individual structural units of the substance passing to the non-polar phase. With decreased polarity of the polar phase, the quantities π diminish. We have found that in such systems the linear relations between lg P_0 and the ID* for the non-polar phase also hold, provided that the polar phase remains unchanged within the limits of the series.

The π_i, ID*, and ΔG^*_{hydr} scales have been created on the basis of a statistical treatment of large sets of extraction equilibrium data. For the treatment of such sets with the aid of a computer, the "OPAG" program has been developed.[53] It makes it possible to calculate not only the value of each parameter but also to obtain its statistical characteristics, which serve for the quantitative estimation of the accuracy of the prediction based on this parameter in each specific extraction system for a specified fiducial probability. Studies designed to expand and refine the scales indicated are being continued as interest grows in new diluents, extractants, and anions. The "OPAG" program makes it possible to introduce into the computer memory new additional data and to recalculate the entire set accumulated in the memory with a small consumption of computer time.

As mentioned above, the ID* scale (as well as the π^* scale) describes the influence of the nature of the diluent in systems where there is no specific solvation. For systems with specific solvation, whose influence on the extraction was first analysed in detail by the present author and his co-workers,[16,59] one may perhaps usefully employ an equation of type (11) including an additional term (increment) characterising the capacity of the diluent for the formation of donor or acceptor bonds. A scale based on such a series of increments has been developed in relation to solvatochromic effects.[95,96] A similar increment scale, reflecting the influence of specific solvation on physical partition, can probably be devised also on the basis of extraction data. The scale of ID parameters described below can be used for the combined allowance for the joint influence of non-specific and specific solvation in cases where the diluent exhibits electron-accepting properties.

Overall, the use of the tabulated values of ID*, π_i, and ΔG^*_{hydr} in combination with an equation of type (12) permits the reliable prediction of important characteristics of extractants associated with physical partition.

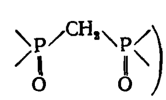
2. Equilibria In Extraction Processes Involving the Formation of Hydrophobic Compounds

Equilibrium systems of this type are most often used in technology and were therefore investigated in the first place (only recently has such attention been devoted to physical partition).

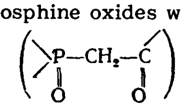
The Influence of the Structure of the Extractant

A preliminary estimation of the extraction capacity of a nucleophilic extractant (and hence of the constant K) is usually made on the basis of the available information about the capacity of its functional group for complex formation via a reaction of type (1). For example, if it is necessary to extract and separate palladium(II) from uranium(VI) in a nitric acid medium, then evidently one can use as the extractant a hydrophobic compound in which the functional group consists of the atom S, which is capable of forming coordinate bonds with the "soft" Pd^{2+} cations[97] but not with the "hard" UO_2^{2+} cations.[98]

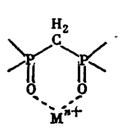
In selecting the functional group of the extractant, account must also be taken of the capacity of the cation extracted via reaction (1) for the formation of neutral complexes. Constants for extraction via the type (1) reactions are known[5,9–14] to increase with increase in the ability of the M^{n+} cations to coordinate the A^- anions. Therefore, for the extraction from nitrate solutions of, for example, plutonium(IV) or uranium(VI), whose cations form relatively readily neutral complexes with nitrate ions,[98] it is sufficient to employ monodentate extractants[99] incorporating one phosphoryl ($>P{=}O$) or sulphoxide ($>S{=}O$) functional group, such as tributyl phosphate or dioctyl sulphoxide. For extraction from nitric acid solution of tervalent lanthanide elements, which show a smaller tendency towards complex formation with NO_3^- ions, one has to employ bidentate extractants, for example, diphosphine oxide, with the functional group



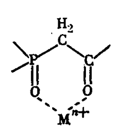
or carbamoylmethylphosphine oxides with the group[100–102]



which form more stable solvates with metal salts as a result of the formation of six-membered rings of type (I) or (II):

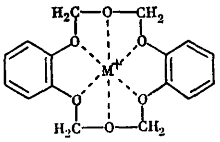


(I)



(II)

The extraction from nitric acid solutions of alkaline earth or alkali metals, which show an even smaller tendency to form complexes with NO_3^- ions, requires the use of polydentate extractants, incorporating more than two electron-donating groups or atoms, arranged in the form of a ring in order to render sterically feasible the simultaneous formation of a large number of bonds with the cation extracted. "Crown" ethers, for example dibenzylcrown-6 ether (III), belong to extractants of this type:[103,104]



(III)

The preliminary selection of acid extractants is made taking into account the fact that constants for extraction via reactions of type (3) increase with increase of the dissociation constants of the extractant. After the type of functional groups or group of the extractant has been chosen, the structures of the substituents attached to these groups are optimised[105] in order to achieve the best extraction and selectivity and also the greatest compatibility of the extractant and the compounds extracted with the diluent.[16] The most suitable diluent, into which the extractant and solvate will be effectively extracted as a result of physical partition, is also chosen.

As stated above, not only qualitative but also quantitative prediction of the influence of various factors on K is frequently needed at the optimisation stage. In both cases the prediction can be based on the use of the principles of linear free energy relations (LFE).

Starting from 1964–1965, the possibility of predicting the equilibrium constants of extraction processes of type (1) with the aid of parameters familiar from organic chemistry, namely the Hammett (σ), Kabachnik (σ_ϕ), Taft (σ^*), etc. constants,[17,74,75] for the substituents attached to the functional group of the extractant and included in equations of the type $\lg K = a + b\Sigma\sigma$ based on the LFE principle has been established for reactions of types (1)–(3). However, such equations are inapplicable to organic series of extractants where the steric factors governing the influence of substituents vary insignificantly. The need to take account also of the steric factors by employing equations of the type

$$\lg K = a + b\sum\sigma^* + c\sum E_S^* , \tag{13}$$

where σ^* are the induction constants (Taft constants) and E_S^* the steric parameters of the substituents at the functional groups of the extractants, has been demonstrated for the general case.[19,76] In order to describe the large sets of extraction data, it was necessary to develop the E_S^* scale, differing somewhat from the familiar Taft (E_S) scale.[17,74,75] The equation found[19,76] for the extraction of nitric acid by the nitrates of 16 tertiary amines of different structure dissolved in xylene, namely $\lg K_{HNO_3} = -0.20 - 0.28\Sigma\sigma^* + 0.79\Sigma E_S^*$, may serve as an example of the exact description of a large set of values of K.

Similar analysis of the factors influencing the sensitivity coefficients b and c in equations of type (13) using different types of extractants and also a detailed compilation of the correlation equations of type (13) for different systems may be found in a review.[17]

The equation without the term including the constants E_S^* may be applicable to phosphoryl-containing extractants, provided that the Kabachnik parameters σ_ϕ are used. The quantitative relation between the structure and extracting power of organoelemental extractants has been analysed recently.[78]

The approach to the quantitative description of the influence of the structure of extractants and of the nature of the compound extracted developed in recent years is also of interest. It is based on the use of two-parameter equations incorporating terms which take into account the ability of the components to form both polar and covalent bonds. The principles of this approach have been described in detail.[77]

The Influence of the Nature of the Diluent

It has been established[24] that, for the series of systems where extraction is determined by type (1) reactions, the LFE principle holds when the nature of the diluents is altered. An ID scale[12] (Table 4), reflecting[55,57] the joint influence of the non-specific and specific solvation of the nucleophilic functional groups of the extractant by diluent molecules, has been developed on the basis of the statistical treatment of a large set of extraction data. It has also been shown that equations of the type

$$\lg K = a + b\text{ID}. \tag{14}$$

hold for a large series of extraction systems in which only the nature of the diluents is varied.

Table 4. The parameters ID of the diluents.[12]

Diluent	ID	Diluent	ID
n-Octane	(0.20)	1,2-Dichloroethane	−0.16
Cyclohexane	0.50	Nitrobenzene	(−0.03)
Butylbenzene	(0.23)	Chloroform	−1.52
p-Xylene	0.10	Cyclohexane + benzene (1 : 1)	0.20
o-Xylene	0.10	*p*-$(C_2H_5)_2C_6H_4$	0.12
Benzene	0.0	$(C_2H_5)_3C_6H_3$	(−0.26)
Chlorobenzene	−0.15	*o*-(iso-$C_3H_7)_2C_6H_4$	0.35
Bromobenzene	−0.30	Toluene	0.03
Anisole	(0.18)	85% Decane + 15% chloroform	−1.12
Bromobenzene + CCl_4 (1 : 1)	−0.50	90% Tetradecane + 10% chloroform	−0.75
CCl_4	−0.60	85% Tetradecane + 15% chloroform	−1.12
Bromocyclohexane	(−0.45)	99% Cyclohexane + 1% octanol	(0.53)
95% Benzene + 5% decanol	(−0.20)	98% Cyclohexane + 2% octanol	(0.53)
Cyclohexanone	(0.30)	97% Cyclohexane + 3% octanol	(0.43)
80% Octane + 20% chloroform	−1.40	96% Cyclohexane + 4% octanol	(0.38)
80% Decane + 20% chloroform	−1.47	94% Cyclohexane + 6% octanol	(0.30)
80% Decane + 20% octanol	(−2.20)	90% Cyclohexane + 10% octanol	(0.23)
95% Benzene + 5% chloroform	−0.40	96% n-Hexane + 4% octanol	(0.12)
90% Benzene + 10% chloroform	−0.65	95% Benzene + 5% n-decane	(−0.20)
85% Benzene + 15% chloroform	−0.80		
80% Benzene + 20% chloroform	−1.20		
90% Octane + 10% chloroform	−0.77		
85% Octane + 15% chloroform	−1.23		
90% Decane + 10% chloroform	−0.80		

Examples of linear relations of this type for the extraction of HNO_3 by ammonium nitrates and the extraction of plutonium(IV) nitrates and HNO_3 by neutral phosphoryl-containing extractants have been published.[50,106]

In those cases where the extraction proceeds via reactions (2) and (3), leading to appreciable changes in the polarity of the components of the organic phase, the influence of the diluent is determined to a large extent by the non-specific solvation of the extractant molecules by the diluent. For these systems, the influence of the diluent is determined by an equation of type (14), but, instead of the parameters ID, it is necessary to employ in this instance the parameters ID*, i.e. those which describe the corresponding effects in physical partition.

Detailed compilations of the dependence of $\lg K$ on ID and ID* have been published[17] and an analysis separating the regions in which these parameters are applicable has been carried out.[55,57] The applicability of the parameters ID* has been recently confirmed.[67,72]

The Joint Influence of the Structure of the Extractant and of the Nature of the Diluent

It was found for the first time in 1970[12] that electrophilic diluents, solvating specifically the nucleophilic group of the extractant, have a levelling effect on the extracting power of nucleophilic extractants of different structures. This effect can be expressed quantitatively by a linear relation, which makes it possible to describe[80,107] the sets of data for systems in which the structure of the extractant and the nature of the diluent are varied simultaneously by equations with a "cross" term of the type

$$\lg K = a + b\mathrm{ID} + \rho\Sigma\sigma + d\mathrm{ID}\Sigma\sigma. \tag{15}$$

For example, the set of constants for the extraction of plutonium(IV) nitrate by neutral organophosphorus compounds (NOPC) is described[106,107] with a high accuracy by the equation $\lg K_{\mathrm{Pu}} = -0.18 + 3.03\Sigma\sigma_{\phi} + 0.30\ \mathrm{ID} - 0.33\ \mathrm{ID}\Sigma\sigma_{\phi}$. Equations of a similar type also describe the large set of constants for the extraction of nitric acid and uranyl nitrate by NOPC, sulphoxides, and arsine oxides of different structure in different diluents[80] and also the extraction of HNO_3 by substituted ammonium salts.[19,50]

The use of Eqns.(13)–(15) makes it possible to predict reliably the extracting power of extractants of different structure in various diluents using tabulated values of σ_{ϕ}, σ^*, E_S^*, and ID, which is done for the selection of extraction systems with optimum composition as regards extractant and diluent.[70,82–84] Such prediction has been adequately achieved for a series with a constant functional group of the extractant. When the functional groups are varied, the changes in the sensitivity coefficients in equations of types (13)–(15) have so far been understood only qualitatively. The task of the future development of a theory is the development of methods for the quantitative estimation of the influence of the replacement of the functional groups of the extractants themselves on the coefficients of Eqns.(13)–(15).

The Influence of the Nature of the Anions and Cations Participating in the Extraction

It has been established that the extraction by amines of anions in the form of acids via the neutralisation reaction[85] or in the form of ionic associated species when quaternary ammonium salts or complexes of metal salts of crown ethers are extracted depends on the parameters of the hydration of anions $\Delta G^*_{\mathrm{hydr}}$ in accordance with the equation $\lg K = a + \Delta G^*_{\mathrm{hydr}}$. The quantities $\Delta G^*_{\mathrm{hydr}}$ for ~80 different anions have been evaluated by the appropriate treatment of a large set of extraction data[27,53] (Table 2). Using the parameters in Table 2, it is possible to predict the influence of the changes in the nature of the anion on the extraction constants.

When the anions A^- and X^- are exchanged, i.e. in extraction via reaction (5), the extraction constant can be expressed by the equation

$$\lg K = \varkappa(\Delta G^*_{\mathrm{A}} - \Delta G^*_{\mathrm{X}}) \tag{16}$$

The correlation equations of type (16) have been compiled and the factors influencing the selectivity coefficient κ have been analysed.[52,53] Numerous examples of the use of equations of type (16) have been published.[86–90]

In order to estimate the influence of the nature of the anionic ligands on the extraction of salts of "hard" cations and acids via addition reactions of type (1), it has been suggested[92] that the Edwards nucleophilicity parameters H be used in combination with equations of the type $\lg K = a + bH$, where a and b are sensitivity coefficients which are constant within the limits of a series of extraction systems differing only in the nature of the anionic ligands. Examples of such relations for the extraction of acids and uranium(VI) salts (from solutions in identical acids) by substituted ammonium salts and also the parameters H have been published in reviews.[14,17]

It has also been found that the LFE principle holds for the extraction of "hard" cations via type (1) reactions by nucleophilic extractants[93] and the possibility of predicting in a number of instances the extraction constants with the aid of an equation of the type $\lg K = a + b\mathrm{IE}$, where IE are empirical parameters (the "influence of the element") characterising the "hard" cations, has been demonstrated. This approach agrees with the ideas developed independently in a study[94] where it was suggested that the parameters of the empirical f_{M} scale be used as parameters characterising the cations. The possibility of this application of the parameters E_{M}, calculated by Petrukhin and Borshch,[108] characterising "soft" cations has been recently demonstrated for the extraction of such cations.

The Joint Influence of the Nature of the Anions and Diluents

In the absence of specific solvation, the values of lg K for the extraction of acids via neutralisation reactions vary linearly with the parameters ID^*. For systems of this type, the slope of the plot of lg K against $\Delta G^*_{\mathrm{hydr}}$ is almost independent of ID^*, which makes it possible to describe large sets of data with the aid of two-parameter linear equations without cross terms. For example, the equation

$$\lg K_{\mathrm{HA}} = 16.51 + 1.196\mathrm{ID}^* + 0.181\Delta G^*_{\mathrm{hydr}}$$

is valid[90] for the extraction of acids incorporating different anions by solutions of trioctylamine (TOA) in different diluents. Equations of this type are valid in the absence of appreciable specific solvation (ID $\geqq -0.6$). When specifically solvating diluents are used, the coefficient of $\Delta G^*_{\mathrm{hydr}}$ may decrease on passing to the most electrophilic diluents—alcohols, chloroform, etc.[52]

The Influence of the Quantitative Composition of the Aqueous Phase

Such influence can be described with the aid of equations of the type $\lg D = a + b\mathrm{IAP}$, where a and b are coefficients which remain constant within the limits of a series of systems differing only in the composition indicated and IAP is a parameter characterising the composition of the aqueous phase.[17] Examples of the employment of the parameters IAP for the calculation of partition coefficients have been published.[109–115]

All the equations examined above, which make it possible not only to predict the extraction constants for different systems but also to describe with the aid of a small number of equations large sets of data, which is only important in connection with the continuing increase in the volume of information on extraction equilibria.

Equilibrium Partition in Extraction by Mixtures of Extractants

In order to enhance the extraction properties, synergistic mixtures are sometimes used. Mixtures of acids and neutral extractants are commonest. The increased extracting power of such mixtures is explained by the formation of adducts of the neutral extractants with the hydrophobic metal salts formed by the acid extractant. Many investigators still continue to carry out laborious experiments in order to determine the influence of the nature of the diluent on extraction constants by such mixtures disregarding the fact that simple relations have been established whereby one can predict the positions of such equilibria without carrying out experiments or with a minimal number of experiments. It has been established that lg K usually decreases linearly with increase in ID* for the diluent, falling more steeply than for the individual acid extractants:[116] the fall is determined by the sum of the effect of the diluent on lg K for the acid extractant and lg Q (the formation constant of the adduct), which also decreases linearly with increased ID*. As for acid extractants, the slope of the dependence of lg K on ID* diminishes as the extractant becomes more hydrophilic, because the contribution of the changes in P_0 increases in this case.

A change in the nature of the neutral extractant forming part of the composition of the mixture influences the synergism as well as the extracting power of the extractant itself, i.e. this influence can be predicted with the aid of the parameters σ_ϕ, σ^*, and E^*_S.

3. The Selectivity in the Separation by Extraction of Elements Having Similar Properties

The survey of a large number of data on the practical application of extraction shows that the factors influencing the separation of elements with relatively similar properties are frequently not the same as the factors influencing the thorough elimination of poorly extractable impurities from readily extractable elements. For this reason, in these two cases it is desirable to carry out separately the analysis of the factors influencing the selectivity of the extraction.

The problem of the separation of elements with similar properties preceded historically a second problem, which might have been solved by a simple repetition of the extraction cycles and has arisen solely because of the requirement for economy.

On the other hand, the separation of elements with relatively similar properties has engaged the attention of chemists over several decades.

As noted above, the first step in choosing a selective system involves the choice of the functional group of the extractant and the composition of the aqueous phase on the basis of the available information about the complex formation. The next step is to optimise the structure of the extractant and the nature of the diluent in order to increase the separation factor, which is especially important when the elements to be separated have similar properties. For this purpose, the extraction equilibria are analysed with the aid of the Law of Mass Action (LMA) and LFE.

It follows from the LMA that the partition coefficient of the extracted element is proportional to the concentration of the extractant raised to a power equal to the solvation number. For this reason, as the concentration of the extractant rises, the value of D for the element forming the higher solvate increases faster than that for the element which forms the lower solvate. Therefore, if the first element is extracted no less effectively than the second, it is evident that the separation factor will increase with increasing extractant concentration, while in the opposite case it will fall. For example, plutonium(IV) is extracted in the form of a disolvate by an amine in nitrate systems, while uranium(VI) is extracted as the monosolvate, plutonium(IV) being extracted more effectively than uranium(VI). The separation factor Pu(IV)/U(VI) in this system can therefore be appreciably improved by increasing the extractant concentration. This is also characteristic of the extraction of plutonium(IV) and uranium(VI) by acid extractants of the type of thenoyltrifluoroacetone with which plutinium(IV) reacts to form 1:4 compounds, while uranium(VI) forms 1:2 compounds.

Next, for the same solvation numbers and for approximately equal capacities for being extracted, the separation factor can be increased by saturating the extractant with the main element present in excess. The concentration of the free extractant then diminishes and the degree of extraction of the impurity element diminishes correspondingly according to the LMA. If the excess of the main element is small, it can be generated artificially by devising an appropriate arrangement of flows ensuring the return of part of this element to the cycle after purification. The effectiveness of this procedure, referred to as the reflux process, has been demonstrated[117,119] etc. The data presented demonstrate the fruitfulness of the application of the LMA to the selection of the optimum conditions in extraction purification. The use of the LMA for the analysis of extraction conditions was initiated in our country by Fomin[9] who, starting in 1955, has used and vigorously advocated this procedure which has been adopted by many investigators.

The employment of equations based on the LFE principle is also very fruitful. Thus, when the structure of the extractant is altered, it is necessary to analyse the influence of various factors in terms of the expression

$$\beta_{1,2} = a + b\Sigma\sigma^* + c\Sigma E^*_S,$$

where $\beta_{1,2}$ is the separation factor for the elements (1) and (2). This expression can be obtained from Eqn.(13) bearing in mind that lg $\beta_{1,2}$ = lg D_1−lg D_2. Analysis with the aid of this expression, for example, of conditions governing the separation of the tervalent actinides, which have similar properties, in extraction by substituted ammonium nitrate has demonstrated[120] a relatively high and positive value of the coefficient of $\Sigma\sigma^*$ and a low value of the coefficient of ΣE^*_S. This led to the conclusion[120] that extractants with (as far as possible) a positive value of $\Sigma\sigma^*$ should be used and at the same time one should have an amine with a high value of $|\Sigma E^*_S|$ in order to attain a fairly high value of D. Indeed, among tertiary amines, methyldioctylamine is more selective than trioctylamine, whereas for trialkylamines with a longer chain $\Sigma\sigma^* \cong$ const. while ΣE^*_S diminishes and the values of $\beta_{1,2}$ therefore differ little.

In certain systems where only one structural factor is varied, an increase in the partition coefficient is observed following an increase of steric hindrance. For example, the separation factor Pu(IV)/Th(IV) increases on extraction with trialkylamines[50] in accordance with the equation

$$\lg \beta = a - b\Sigma E^*_S.$$

However, this is true for identical solvation numbers. For different solvation numbers, analysis of the data on the basis of the LFE principle and the finding that for each compound the slope of the dependence of lg β on the parameters σ^* and E^*_S increases with increasing solvation number enabled us in 1978 to formulate the following rules[17] which determine the influence of the structure of the extractant, the nature of the diluent, and the nature of the anionic ligand on the selectivity of the extraction process.

1. For a series of extraction systems differing solely in the nature of the metals extracted but characterised by the same solvation numbers, the same composition of the complex extracted, and the same type of nucleophilic extractant, the selectivity in the extraction of these metals increases following the changes in the inductive and steric effects of the substituent† associated with the increase in $\Sigma\sigma^*$ or the decrease in ΣE^*_S.

---

†This rule has been formulated earlier also in other studies.[121,122]

2. If the complexes of two elements extracted in the given extraction system have different solvation numbers, then the change in the nature of the substituent leading to an overall decrease of the extracting power (increase of $\Sigma\sigma^*$, decrease of ΣE_S^*) entails a fall in the selectivity of the extraction if the element whose complex has the smallest solvation number differs also by having a smaller capacity for being extracted and increases if the element is extracted more effectively than the element whose complex has the higher solvation number.

3. For systems in which the influence of the diluent can be expressed by the dependence on ID for identical solvation numbers of the two elements extracted, the selectivity of the extraction by the given nucleophilic extractant increases with decrease in the parameter ID for the diluent, i.e. with increase in the ability of the diluent to solvate the nucleophilic functional group of the extractant.

4. If the compounds of the salts of the two metals are characterised by different solvation numbers, then the selectivity increases with increase in ID, provided that the complex with the higher solvation number corresponds to the more effectively extracted element.

5. In cation exchange reactions, the increase in ID^* hinders the reactions involving the conversion of acids into metal salts and reduces the selectivity of the extraction of the latter (for equal solvation numbers).

6. In an anion exchange reaction, the increase in ID^* favours to a greater extent the occurrence of reactions leading to the formation of more polar compounds in the organic phase, i.e. the increase of ID^* tends to increase the selectivity of the extraction of the anions of the stronger monobasic acids from a medium comprising weaker acids and of the extraction of singly charged ions from a medium comprising doubly charged and multicharged anions.

7. The selectivity of the extraction for a pair of elements where the cation of one element is "hard" while the other is a "soft" Lewis acid, can be increased by going over to anions with a higher value of H in those cases where the "hard" element is extracted more effectively or by going over to anions with a low H where the "soft" element is more readily extracted.

When the two anions to be separated are extracted by the anion exchange mechanism, the selectivity is determined by the anion exchange extraction constant for the given pair of anions, which is determined by Eqn.(16). It has been established that the coefficient κ in Eqn.(16) depends on the nature of the extractant cation and in a non-specifically solvating diluent is 0.235 for quaternary ammonium bases; for tertiary amines, it amounts to 0.16–0.18. The selectivity of the extraction of anions falls sharply when a specifically solvating electrophilic diluent is employed, because, as mentioned above, when highly solvating diluents such as octyl alcohol are employed, the dependence of lg K or ΔG^*_{hydr} is weak and the selectivity of the separation of singly charged anions is correspondingly low.[52]

Using Eqn.(16), the ΔG^*_{hydr} scale, which is known for ~80 anions, and the coefficients κ determined for ~80 series of systems, it is possible to predict the selectivity in the extraction of anions for different combinations of 80 anions in 80 series, i.e. for ~7.5×10^5 different extraction systems. It has been shown[27,53] that, with the aid of the "OPAG" program, it is possible to determine not only the 7.5×10^5 anion exchange extraction constants but also the accuracy of each prediction for a specified fiducial probability. This result[53] is apparently the most striking example of the effectiveness of the application of the LFE principle to the prediction of extraction constants.

4. Properties Associated with the Interaction at the Interface and Determining the Extensive Separation of Elements Having Different Properties

The principles governing the prediction of the extracting power examined above have proved applicable to the prediction of the surface-active properties of extractants and diluents at the interface[123–127] and to the estimation of the optimum conditions governing the extensive separation of elements with different properties.

The interfacial tension is a property on which depends the rate of separation of two phase systems into different layers in extraction apparatus, which determines the productivity of the extraction equipment. It has been established that the interfacial tension γ at the water–diluent interface decreases with increase in the parameter ID^* for the diluent. For solutions of nucleophilic extractants, γ increases with increase in the above parameter.[126,127] All the nucleophilic extractants are surfactants. The energy of their adsorption at the interface W, which determines the interfacial tension γ, varies linearly under these conditions with the sum of the Kabachnik parameters for the substituents at the nucleophilic centre, for example at the P=O group.[125] If the extractant is a salt of an amine or a quaternary ammonium base, W varies linearly with $\Sigma\sigma^*$ and ΣE_S^* for the substituent and, when the nature of the anion is altered, then W varies linearly with the parameter ΔG^*_{hydr} for the anion of the substituted ammonium salt.[128]

The above findings can be understood if account is taken of the fact that the surface activity of the nucleophilic extractant, expressed by its adsorption at the interface, is determined by the same factors as its extracting power, i.e. the basicity of its functional group. Any factors which reduce this basicity (the replacement of the substituents at the functional group, its solvation by the diluent, and the change in the nature of the anion of the substituted ammonium salt, which is itself a functional group) reduce also the surface activity. The binding of the nucleophilic functional group on formation of the solvate via a type (1) reaction has a particularly marked influence. For example, it has been shown[129–131] that the formation of the disolvates $UO_2(NO_3)_2 \cdot (TBP)_2$, $Th(NO_3)_4(TBP)_2$, and $Pu(NO_3)_4(TBP)_2$ in the extraction of the nitrates of these elements by tributyl phosphate (TBP) very greatly reduces the interfacial activity in the corresponding extraction system.

These findings, combined with the parameters ID^*, σ, E_S^*, and ΔG^*_{hydr} are also used to optimise the structure of the extractant and the nature of the diluent in order to take into account the changes in the surface properties occurring under these conditions.[69,132] The equations based on the LFE principle for the prediction of the interfacial activity and the factors governing the separation of extraction emulsions into layers have been surveyed.[123] The possibility of predicting the interfacial tension confirms the effectiveness of the LFE concept as a means whereby the properties of extraction systems can be predicted.

The application of external electrical and magnetic fields influences markedly the properties of the interface. These phenomena, which may be employed in the extraction technology of the future, are at present in the initial stage of their investigation.[133,134]

If two elements have markedly different partition coefficients then, in principle, having ensured a sufficient number of stages in the washing of the extract under conditions where the extraction coefficient of the valuable element is greater than unity and that of the impurity element is much less than unity, one can expect the attainment of separation (purification) factors as large as may be desired. In reality, the purification coefficient attainable in practice is usually limited to 10^5–10^6 even when the impurity element virtually is unextractable under the selected condition. The explanation is that, after the separation of the main bulk of the impurity, a small proportion of the latter remaining in the extract (10^{-4}–10^{-5}) is retained by it and cannot be washed out.

This may be caused by the mechanical entrainment of this part of the impurity in the form of a microemulsion of the aqueous phase in the organic phase, in the form sorbed on some kind of entrained solid microparticles, in the form of a complex with a microimpurity in the extractant capable of extracting the impurity element, and in the form of a complex with some kind of anion present as a microimpurity in the aqueous phase and forming an extractable compound with the impurity element.

The probability of the formation of microemulsions as well as the entrainment of solid microparticles increases with decrease in the interfacial tension, i.e. with increase in the surface activity of the component of the extraction system at the interface. For this reason, an increased degree of purification is promoted by any measures which reduce the interfacial surface activity. We shall consider this postulate in relation to extraction by trialkyl phosphates. When account is taken of the characteristics of the influence of the structure of the extractant on the interfacial activity, mentioned in Section I, the parameters σ_ϕ of the substituents (Table 3) permit the conclusion that an increase in the length of the alkyl chain of trialkyl phosphates (TAP) entails an increase in the interfacial tension. This factor, together with those examined above (Section II, 1), must be taken into account in selecting the optimum chain length. Evidently the increase in the length of the alkyl chain should improve the conditions for extensive purification at the extractant stage. At the same time, an unduly great increase in the length of the alkyl chains of the TAP can give rise to difficulties in other operations in technological schemes, for example in the washing out of the products of the hydrolysis of the TAP by alkaline solutions.[135] The optimum length of the alkyl chain of the TAP is chosen[69] in such a way that the best extraction conditions are ensured simultaneously with sufficiently effective remaining operations of the extraction cycle.

It is useful to employ a diluent with a high ID^*, other conditions being equal, because it has been shown[126,127] that this tends to reduce the interfacial activity.

Systematic investigation of the influence of various factors on the interfacial activity has shown[129–131] that the binding of the extractant in a solvate complex with a metal salt reduces its surface activity to that of the pure diluent and the overall surface activity is determined by the presence of the free extractant. From this, it follows that the saturation of the extractant by the salt of the metal extracted is essential not only for the suppression of the extraction of impurity elements with similar properties (see above) but also for the attainment of a high degree of elimination of mechanically entrained non-extractable impurities (in the form of microemulsions or solid particles). It is noteworthy that the removal of mechanically entrained impurities—elements incapable of forming stable complexes—can increase the degree of purification not only in the extraction stage but also in the course of subsequent operations, provided that the latter are based on complex formation, extraction, or ion-exchange sorption of the impurity element.

In view of the strong influence of the formation of an emulsion on purification during extraction, increasing attention is being devoted to this problem. Interesting results have been obtained by Moyer and McDowell[136] and Yagodin and Tarasov.[137] Ideas concerning the factors influencing emulsification, developed initially for petrochemical processes and the protection of the environment and surveyed in a number of communications,[138–140] are fully applicable to extraction processes.

The type of emulsion has a marked influence on the emulsification and on the separation of the emulsion into layers. The formation of a microemulsion is more probable in the continuous phase and is less likely in the disperse phase. On the other hand, if the microparticles entrained by the organic phase or concentrated at the interface are more effectively wetted by the aqueous solution, then they are more effectively separated if the organic phase is the continuous phase in the extraction process. Useful data about the factors influencing the rate of separation of the phases into layers as a function of the type of emulsion, the hydrophilic properties of the solid particles present in the system, and the length and the degree of branching of the alkyl chains of the extractant have been published.[136]

Microimpurities in the extractant, which, as stated above, can be the second cause limiting a high degree of purification, may be formed following the slight decomposition of the extractant in the cycle and are usually removed in one of the operations of the cycle as a result of dissolution in the aqueous phase. In order to assess the possibility of removing the microimpurity, one can employ equations relating P_0 to the structure of these compounds and the nature of the diluent. For example, it is possible to assess in this way the possibility of the "automatic" removal in the given cycle of admixtures, harmful to the purification process, of acid alkyl phosphates formed as a result of the hydrolysis of trialkyl phosphates or salts of primary amines which are produced on decomposition of extractants of the type of trialkylamines. Evidently the chain length of the nucleophilic extractants should be optimal, i.e. such that its solubility in water is sufficiently low and the solubility of the harmful decomposition product sufficiently high for removal from the organic phase during the operation of the extraction cycle.

These considerations are used in selecting the optimum structure of the extractant, the nature of the diluent, and the extraction conditions in order to obtain especially high purification coefficients in extraction cycles. As the technology develops, the requirements for the preparation of ultrapure materials will probably increase and an increase in the separation factors to 10^9 and above will be needed. For this reason, further search for methods whereby the degree of separation of elements with different properties can be increased for a minimal number of operations should remain of crucial importance in the future.

III. OPTIMISATION OF THE STRUCTURE OF EXTRACTION SCHEMES

1. Schemes With a Countercurrent (Structure, Modelling, and Regulation)

Schemes with a multistage countercurrent of aqueous and organic phases satisfy most completely the requirements for a high degree of extraction. Modern technological schemes are frequently characterised by a complex structure of the flows, organised in such a way that a high degree of saturation of the extractant by the target element can be achieved when necessary (as mentioned above, this is essential for the improvement of purification) or the part of the valuable component washed out together with the impurities during the washing of the extractant can be returned to the system for re-extraction.

The boundary conditions governing the operation of any scheme consist in the requirement that the concentration of the metal extracted in the organic phase should not exceed the capacity of the extractant and that the concentration in the discarded solution should not exceed the specified losses. Furthermore, as a rule the process should be stationary, i.e. there should be no changes in the accumulation of the element in any part of the countercurrent apparatus as a function of time. To test that these conditions are maintained and that the optimum current scheme can be selected, it is necessary to calculate the distribution of all the components among the different stages of the scheme in the steady-state regime; it is frequently essential to estimate the redistribution of the components among the stages for particular deviations from the nominal regime (in order to develop control and regulation systems). In certain instances, it is preferable to employ semicontinuous schemes in which the valuable component is deliberately accumulated (as a function of time) in a particular stage of the countercurrent apparatus.[141] It is then also necessary to estimate the distribution of the element or compound extracted among the stages taking into account in addition also the process time.

All the calculations indicated are carried out with the iterative formulation of the material balance equations at each stage taking into account the partition coefficients among the stages at the concentrations of the components yielded by the calculation. The use of mathematical modelling for calculations on countercurrent extraction processes was initiated in the USSR approximately 25 years ago by Fomin and Rozen and co-workers[142,143] and at the present time this field has been greatly improved as a result of the efforts of a large number of investigators—both chemists and mathematicians.[144–151] When the number of stages is large, the calculations are laborious, but nowadays they can be successfully performed with the aid of computers. For example, calculation on a computer of type EC-1055 sometimes takes several tens of minutes, a period which is acceptable for the calculation of particular regimes in the planning or development of the process but is much too long if the calculation is performed in order to control the process. For this reason, the construction of high-speed computational schemes constitutes an urgent task for the further development of models. An example of the creation of a high-speed algorithm for calculations on countercurrent extraction is provided by the study of Rozen and Zel'venskii.[152]

The first models included partition data obtained on the basis of the LMA; they require the knowledge of a large number of constants (the extraction constants and the stability constants of all the complexes in the aqueous phase) and the activity coefficients of all the compounds present in the system. Subsequently much attention was devoted to the creation of purely empirical models with the smallest number of constants requiring determination. For the distribution of microconcentrations, the model consists of the IAP function (see above) to which the partition coefficients D are linked (on the basis of the LFE principle) by a simple linear relation. A characteristic feature of the IAP function is that it is the same for a series of elements with similar properties, for example, for the extraction of UO_2^{2+}, WO_2^{2+}, MoO_2^{2+}, PuO_2^{2+}, and NpO_2^{2+} or for U^{4+}, Pu^{4+}, Np^{4+}, Th^{4+}, and Hf^{4+}. In all complex cases, for example, in the case of the simultaneous extraction of several elements at macroconcentrations, one can employ purely empirical formulae fitted to the dependence of D on the contents of different components in the solutions. These relations frequently proved to be simpler and more accurate than those based on the LMA. The countercurrent distribution models, constructed using these formulae, made it possible to devise algorithms and programs for computer calculations which are very fast to execute.[1]

In systems for which there are large sets of experimental data, the "formally rigorous" descriptions of the equilibrium, having the form of the LMA but including a number of assumptions based on empirical relations, are also used. Such successfully realised models include those taking into account the surface density of the hydration of cations, a concept developed in a number of studies,[40,153,154] or including the extraction "constants" expressed by an empirically fitted function of the composition of the aqueous phase.[43,44]

The use of mathematical models for apparatus with discrete stages makes it possible to determine the structure of the control system on the basis of the measurement of the location of the front of the extracted element in the countercurrent apparatus choosing for this point the stages between which the concentration gradient is greatest.

The use of mathematical models for apparatus with discrete stages permits the calculation of the concentration at each stage under different conditions,[154,155] including those where the normal process conditions are infringed, and thus permits the estimation of the results of possible infringements.

For column (non-discrete) countercurrent extractors, the creation of a mathematical model for the distribution along the height of the apparatus is more complicated, because such distribution is much more subject to the influence of both kinetic and hydrodynamic factors, such as the possible changes in the "arrest" of the disperse phase, when the flow rate of the solutions and the supply of external energy for the dispersion of the phases are altered. The development of models for such apparatus is an important task, because column extractors, together with extractors of the mixing-settling type, are widely used in practice.[1,156]

An important task in the field of the modelling of countercurrent extraction is as far as possible a more accurate quantitative description of the dependence of the distribution of all the components of the system of interest to technology on its composition. This requires further study and description with the aid of suitable empirical formulae of the experimental data obtained for the distribution of different elements which are of interest and which are re-extracted as the technology develops. The most detailed studies on these lines have been carried out for the description of the distribution of actinide elements and elements which are fission products.

2. Periodic Extraction, Membrane Extraction, and Extraction Chromatography

Countercurrent extraction is not the only possible extraction scheme. In certain cases it may prove useful to employ also other schemes for extraction processes. If it is necessary to employ an extractant with a comparatively high solubility in the aqueous phase or one which is particularly scarce, whose losses must be reduced to a minimum, and also in the case where it is necessary to reduce to a minimum the access of the extractant to the aqueous solution (for example, in extraction from biological liquids), one can employ membrane extraction.[157] In this variant, the extractant is separated from the aqueous solution by a thin semipermeable partition. To accelerate the process, whose characteristic features hardly differ as regards partition from those of the usual extraction, an electrical potential difference is applied to the system. The development of the theoretical principles of this process is of great interest.

A novel method, called "emulsion membrane extraction", began to be developed during the last decade.[158,159] It makes it possible to combine extraction with re-extraction. The method consists in incorporating initially the solution to be re-extracted in the extractant phase in the form of a stabilised emulsion of the water/oil type. The resulting mass is then dispersed in the aqueous phase to form an emulsion comprising drops of the extractant with smaller drops of the re-extractant incorporated in them. As a result of this, extraction and re-extraction take place simultaneously, which ensures a high extraction coefficient per extraction stage. The possibilities of this method are still being investigated[159] and will probably be limited by the requirement that sufficiently stable emulsions of the re-extractant in the extractant be obtained. The choice of the appropriate emulsifying agent is apparently the main problem. The growing interest in emulsion membrane extraction is indicated by the appreciable growth of the number of publications on this question during recent years.[160-163]

Extraction chromatography, a method in which the extractant is deposited on a solid carrier, occupies the boundary between extraction and sorption.[164] Here the characteristics of the partition are the same as in extraction. The factors influencing the equilibrium partition quoted above are applicable to this process. As regards kinetics and apparatus, the method is closer to sorption processes.

3. The Choice of the Composition of the Aqueous and Organic Phases for a Waste Free Technology

As noted above, a characteristic feature of extraction methods is the almost complete absence of the consumption of the reagent and hence of salt waste. For this purpose, one selects extractants which possess a sufficient but moderate extraction power so that re-extraction can be carried out with water without using complex-forming agents and other reagents. The extracting power must be such that there is no need to employ a salting-out agent in the extraction stage. For example, very weak extractants—carboxylic acid esters—require the addition of salting-out agents (nitrate salts) in order to extract uranyl nitrate, although the re-extraction is carried out with water.[165] On the other hand, trioctylphosphine oxide extracts uranyl nitrate effectively from dilute nitrate acid but the re-extraction with water is impossible; it is necessary to employ a solution of complex-forming agents.[166] The optimum extractant is in this case TBP—the extraction is from a 2–3 M HNO_3 solution and the re-extraction is carried out with water. There are no reagents other than HNO_3, which can be concentrated (distilled) from the refined product and returned to the cycle.

Similar approaches are necessary also in the extraction of other elements: this is achieved by selecting extractants of appropriate strengths. Thus the introduction of salting-out agents is necessary to extract americium or the lanthanides from nitrate solutions by tributyl phosphate. However, stronger bidentate extractants[101-105] or phosphoric triamides[167] extract these elements from 2–3 M HNO_3 and permit re-extraction into water.

The extraction of elements such as caesium is still more difficult. As mentioned above, a solution involves the employment of polydentate extractants in which the simultaneous operation of all the functional groups is ensured by the cyclic structure of the extractant skeleton (crown). These extractants are able to extract caesium and strontium from nitric acid solutions without the use of salting-out agents in re-extraction with water.[168,169]

In the specific selection of the optimum structure of the bidentate extractant and of the diluent, one can be guided by the rules described above (Section II).

A promising method for the removal of reagents involves the use of electrochemical re-extraction methods, which are at present in the stage of intense research, where the element is converted into a non-extractable valence state by passing an electric current through the solution.[1] The use (in order to change the valence of the extractable elements or the degree of formation of their complexes) of gaseous reagents or reagents which would decompose into gaseous products as a result of the reactions is of interest.[170-174]

Although extraction systems as a whole are usually almost reagent free, a small source of salts which might then be transferred to the waste is the operation involving the regeneration of the extractant; this is sometimes carried out to eliminate the microimpurities accumulated after the prolonged use of the extractants, consisting of the products of the decomposition of the extractants which might interfere with the high degree of purification of the valuable elements. A traditional procedure for the elimination of traces of acid decomposition products from NOPC involves washing with solutions of sodium carbonate and alkaline–salt reagents. There has been a growth of interest in the replacement of these operations by sorption or the use of reagents which decompose to gaseous products.[170] In the development of methods for the removal of such impurities, the ideas, considered above, concerning the factors influencing physical partition and the stability of the complexes in extraction systems are employed.

4. The Use of Kinetic Factors. Reactions in the Organic Phase

During the last 10–15 years, the kinetics of extraction have been the subject of numerous studies, which have been surveyed in greatest detail in the monograph of Yagodin and co-workers.[174] The main results of the research into the kinetics has been the discovery of new characteristics of the mechanisms of the processes. For example, it has been shown[175] that one of the causes of the formation of microemulsions of water in the surface layer of the organic phase is the faster mass transfer of the extractable compounds from the aqueous to the organic phase than their dehydration, which then occurs in the surface layer and leads to the liberation of water in the form of the microemulsion. The discovery of the mechanism of the catalytic action of certain impurities or additives on the rate of extraction, which makes it possible to find ways for accelerating the processes, is of great importance.[174,176] Without repeating the numerous examples of the employment of data for the kinetics of extraction in technological schemes, quoted by Yagodin and co-workers,[174] we may note certain additional factors stimulating the development of kinetic studies.

(a) Relatively slow processes occurring when the phases are allowed to stand, for example, the decomposition of reductants when extracts are allowed to stand, which lowers the efficiency of the reductive extraction of plutonium in the scheme designed to separate it from uranium, have been observed.[177]

(b) A greater degree of decomposition of the extractant has been found when the extract was allowed to stand in contact with highly radioactive solutions.[178]

(c) The impurity element is slowly converted into an extractable form on standing in the aqueous phase.[179]

In these cases it is useful to employ types of apparatus with an increased rate of phase separation even if this entails some increase in the complexity of their design or operating costs.

It has been established that, when phosphoryl-containing extractants or substituted ammonium salts are used, the rate of mass transfer under the conditions of vigorous stirring of the phases is sufficiently high and the time required to attain a degree of completion of the process of 90–95% does not usually exceed 1–2 s, i.e. the required phase contact time is short compared with the phase separation time in the gravitional or even in a centrifugal field and no measures are required to accelerate the mass transfer in such systems using apparatus with discrete stages. The kinetics of mass transfer in systems of this kind require investigation mainly in relation to column extractors where additional process acceleration would reduce the height of the equivalent theoretical plate and hence the size of the apparatus. This field of extraction kinetics has so far been little developed and apparently requires more attention in the future.

In a number of instances the slowness of the mass transfer processes also in apparatus with discrete stages has been demonstrated. For example, the extraction by acid reactants is relatively slow. The studies on the use of added "catalysts" accelerating this process, which have been initiated, are of interest for such systems.[180] Sometimes the reason why the process is slow is the low interfacial surface activity of the extractant. For example, the extraction of palladium(II) by dialkyl sulphides is a slow process, because an extractant of this kind is hardly sorbed at the interface, as a result of which its concentration in the reaction zone is very low.[176] In this case the catalyst may even consist of a weak but surface-active extractant, which transfers the palladium(II) compounds into the bulk of the organic phase, where rapid reaction with the dialkyl sulphide can take place.

In most cases the rate of extraction depends on the ratio of the interfacial activities of the extractant and the extractable compound. Nucleophilic extractants are adsorbed from the organic phase at the interface and such adsorption, the extent of which increases with increase in the interfacial activity (as noted above, this has been predicted), accelerates the formation of the extractable solvate. Since metal salts solvated by the nucleophilic extractant are usually surface-inactive, they are readily desorbed from the interface and pass into the bulk of the organic phase. This explains the relatively high rate of extraction of metal salts by the nucleophilic extractant already noted. If the extractant is associated in the organic phase, the degree of its adsorption at the interface is reduced and there is a corresponding decrease of the rate of extraction. Thus the rate of extraction by associated substituted ammonium salts is somewhat lower than the rate of extraction with, for example, tributyl phosphate. The rate of re-extraction of metal salts in such systems is usually somewhat lower than the rate of extraction, probably because the concentration of the surface-inactive solvate at the interface is very low.

The extraction of nucleophilic extractants from the aqueous phase by surface-inactive solvents is a relatively slow process, because, although the adsorption from the aqueous phase at the interface is appreciable, the desorption of the surface-active extractant molecules from the interface to the bulk of the organic phase is hindered.

The slowness of the extraction of many elements by acid extractants may be accounted for qualitatively by the low degree of adsorption of these extractants at the interface as a consequence of the formation of stable associated species and the weak desorption of the extractable compounds from the interface into the bulk of the extractant, because such compounds frequently exhibit a high interfacial activity.[123]

Thus, to a first approximation, the influence of the interfacial properties predicted with the aid of the LFE principle, can be used to explain the characteristic features of the extraction and re-extraction in various technological systems.

The removal of the microimpurity entrained in the extract by washing with an aqueous solution of a complex-forming agent or a reductant is sometimes a slow process. The process is slow because the impurity is wholly in the organic phase, while the reagent is in the aqueous phase. The traditional solution is to increase the phase contact time or the number of stages and the concentration of the reagent. We have shown[181] that the employment of reactions in the organic phase by introducing a reagent soluble in it (before washing) is very effective in such cases. In a homogeneous phase the process involving preparation for washing is much faster than in a heterogeneous system, which in many instances[182] makes it possible to increase the separation factors compared with those obtained as a result of traditional washing by 1–2 orders of magnitude without increasing the contact time or the reagent concentration.

The use of kinetic factors to increase the degree of separation of elements in extraction when there is a significant difference between the rates of their extraction after the appropriate choice of conditions has also attracted the attention of investigators.[33]

Advances in Catalysis by Heteropolyacids

I.V.Kozhevnikov

The advances in acid catalysis by heteropolyacids are examined and data on the acidity of heteropolyacids are surveyed. The characteristics of homogeneous and heterogeneous acid catalysis by heteropolyacids are discussed and its applied aspects are noted.
The bibliography includes 116 references.

CONTENTS

I. Introduction 811
II. Structural characteristics of heteropolyacids in the solid state and in solution 812

IV. Acid catalysis by heteropolyacids 816

I. INTRODUCTION

Heteropolycompounds (HPC) have come to be widely used as homogeneous and heterogeneous acid and oxidative catalysts by virtue of their unique physicochemical properties.[1-8] They are also of great interest as model systems for the study of fundamental problems of catalysis.[1,4,5] This is due to the available of reliable data on the structure of the HPC, the possibility of the specific variation of their acidity and oxidation potentials, and the similarity of their catalytic action in solution and in the solid state ("pseudo-liquid phase"[1,5]). As a results of studies carried out in the last decade in the USSR and abroad, the scientific principles of the selection of effective HPC catalysts have been formulated. The high Brønsted acidity of heteropolyacids (HPA), greatly surpassing in this respect the usual inorganic acids[4] and traditional acid catalysts,[5] is of fundamental importance for catalysis. The use of HPC as catalysts of oxidation processes is based on the reversibility of their redox reactions and their ability to enter into many-electron oxidation-reduction reactions.[4] Many new catalytic processes in which they participate have been developed, including amongst others a wide variety of processes involving fundamental and fine organic synthesis,[3,4,8] the preparation of hydrocarbons from methanol,[2,7] the photochemical liberation of hydrogen from water.[6] Some of them have already begun to be used in industry abroad, for example, the liquid-phase hydration of propene in the presence of tungsten HPA[9] and the vapour-phase oxidation of methacrolein to methacrylic acid on molybdenum HPC.[5] In the future the number of such processes will undoubtedly increase. Catalysts based on HPC are characterised by a higher activity compared with their existing traditional analogues. With their aid, it is frequently possible to achieve a higher selectivity and also to solve successfully environmental problems.

This communication is devoted to the consideration of the present state of one of the most important aspects of catalysis by HPC—acid catalysis by HPA. Attention is concentrated on the discussion of the acid properties of HPA in solutions and in the solid state, their proton structure, and the characteristic features of the homogeneous and heterogeneous acid catalysis. The use of HPC as oxidation catalysts has been considered in a number of reviews.[3–6]

II. STRUCTURAL CHARACTERISTICS OF HETEROPOLY-ACIDS IN THE SOLID STATE AND IN SOLUTION

HPA and their salts are polyoxo-compounds incorporating anions (heteropolyanions) having metal–oxygen ocathedra MO_6 as the basic structural units. They contain one or several heteroatoms X, which are usually located at the centre of the anion (central atoms). The MO_6 octahedra are linked together and form an extremely stable and compact skeleton of the heteropolyanion (HPAN). The cations may be hydrogen, alkali metal, and other metal ions.[10–12] More than twenty types of structures, incorporating from 4 to 40 metal atoms and from 1 to 9 heteroatoms, are now known for molybdenum, tungsten, vanadium, and niobium HPAN.[12] The commonest compounds, belonging to the saturated 12th series (M : X = 12) are of greatest importance for catalysis. They contain HPAN having Keggin's structure

$$XM_{12}O_{40}^{x-8},$$

where X is the central atom (Si^{IV}, Ge^{IV}, P^{V}, As^{V}, etc.), x the degree of its oxidation, and M is molybdenum or tungsten, which can be partly replaced by other metals. HPA and their acid salts are mainly used in acid catalysis and the neutral salts capable of generating strong acid centres on interaction with the reaction medium are more rarely employed.[7]

The compounds considered are usually obtained by acidifying an aqueous solution containing the salt of the heteroelement and the alkali metal molybdate or tungstate with subsequent isolation of the HPA salt as the hydrate. The acids can be obtained by extracting with ether acidified solutions of the salts and also by ion exchange.[10]

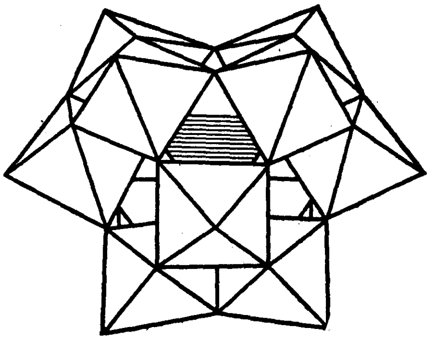

Figure 1. The structure of the heteropolyanion $XM_{12}O^{x-8}$ (α-isomer).[13]

The molecular structure of the 12th series HPC was established by Keggin as early as 1934 by the X-ray diffraction analysis of the hydrates of 12-tungstophosphoric acid.[13] This study played the most important role in the understanding of the laws governing the formation of the HPC structure.[10–12] Keggin's structure for the $XM_{12}O_{40}^{x-8}$ anion (α-isomer) is illustrated in Fig.1. It incorporates the central XO_4 tetrahedron surrounded by 12 MO_6 octahedra having common vertices and edges. The MO_6 octahedra are grouped in four M_3O_{13} triads, which are connected by common vertices. The radius of the HPAN is ~0.6 nm. The anion contains 12 quasi-linear M–O–M linkages between the octahedra forming part of different M_3O_{13} triads, 12 angular $M\overset{O}{\diagup\;\diagdown}M$ bonds between the octahedra within a single triad, 4 X–O–M bonds whereby the triads are joined to the central atom, and 12 terminal M=O bonds. These bonds exhibit characteristic vibration frequencies in the IR spectrum in the range 600–1100 cm^{-1}.[10–12,14]

Keggin's structure is fairly stable. It is preserved in HPC hydration–dehydration and dissolution processes and also on substitution of the metal in the HPAN, on replacement of the outer-sphere cations, and in not too extensive oxidation-reduction reactions.[4,5,10–12]

A less common type of 12th series HPC consists of compounds containing the anions $XM_{12}O_{42}^{x-12}$, where M is molybdenum and X is cerium(IV), uranium(IV), or thorium(IV). They have the Dexter–Silverton structure (Fig.2).[10] The central atom in these compounds is surrounded by 12 oxygen atoms and is located at the centre of the eicosahedron. The MO_6 octahedra are located in pairs on the common face.

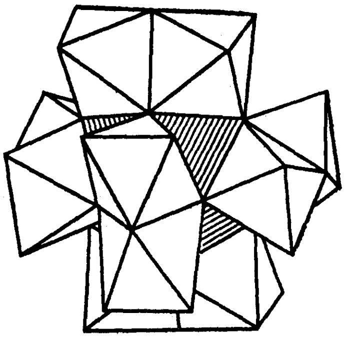

Figure 2. The structure of the hetropolyanion $XM_{12}O_{42}^{x-12}$.[10]

Together with the saturated 12th series HPC, a wide variety of derivatives of unsaturated series are known; the 11th series HPC XM_{11} have a defective Keggin's structure, in which one metal atom is missing, while the 9th series compounds XM_9 are obtained from the 12th series compounds by removing the M_3O_{13} fragment. They dimerise with formation of dinuclear derivatives $X_2M_{18}O_{62}^{x-16}$, having the Dawson structure (Fig.3).[10] The X_2Mo_{18} structure is chiral as a consequence of the slight shift of the Mo atoms relative to one another in two XMo_9 fragments (D_3 symmetry). As a result of this, the X_2Mo_{18} compounds can be used as catalysts in asymmetric synthesis (see below). In contrast to X_2Mo_{18}, the compounds X_2W_{18} possess no chirality and their symmetry is higher, close to the D_{3h} symmetry.[10]

The crystal structure of HPC consists of a three-dimensional lattice made up of HPAN, the cations, and the molecules of the water of crystallisation. In contrast to the rigid molecular structure of the 12-heteropolyanions, it varies within wide limits when their chemical composition and also the conditions of their synthesis and heat treatment are varied.[5,14]

Water-soluble HPC (the acids and salts of many metals) crystallise as hydrates containing a variable number of water molecules (up to 30 and above). Most of the water of crystallisation is readily removed on heating to 100–150 °C.[14]

This process is reversible. It is usually assumed that the main bulk of the water of crystallisation is within the pores of the HPC, as happens in zeolites.[12] The HPAN in the hydrates are not linked to one another and their packing is achieved as a result of the formation of hydrogen bonds with the molecules of the water of crystallisation.[10-12] As a result of this, the HPAN exhibits an appreciable mobility in the crystal matrix.[15] The water molecules in the crystal unit cell form clusters, because the hydrogen bonds between them are stronger than those between the water molecules and the oxygen atoms of the HPAN.[12]

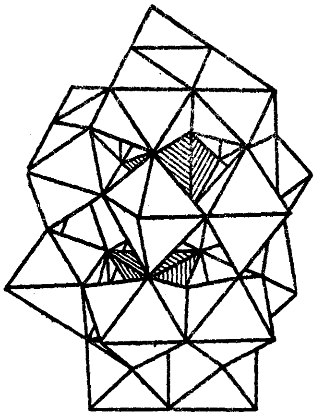

Figure 3. The structure of the heteropolyanion $X_2M_{18}O_{62}^{2x-16}$.[10]

In the dehydration process Keggin's structure of the 12-heteropolyanions is retained, as has been confirmed by the invariance of the IR spectra, but the cell parameters change significantly. Thus, according to X-ray diffraction data, the lattice constant of $H_3[PW_{12}O_{40}].29H_2O$ is 2.33 nm, while $H_3[PW_{12}O_{40}].6H_2O$ has a constant of 1.25 nm.[14] Thus, on dehydration, the unit cell contracts and the distance between neighbouring HPAN diminishes. Consequently, in this case one cannot assume that the water of crystallisation is "zeolitic" in nature. However, the removal of water from the insoluble salts of the acid $H_3[PW_{12}O_{40}]$ hardly alters their crystal structure and in this case the water of crystallisation can be assumed to be "zeolitic".[14]

Like hydrates, HPC form crystalline solvates with molecules of polar organic substances such as alcohols, ethers, ketones, amines, etc. This property plays an important role in heterogeneous catalysis and is manifested in the behaviour of HPA as the "pseudo-liquid phase"[5,7] (see below). The nature of the solvates and the products of their thermal decomposition have been investigated.[16]

The thermal stability of HPC is fairly high. For acids with Keggin's structure, it increases in the sequence $H_4[SiMo_{12}O_{40}]$ < $H_3[PMo_{12}O_{40}]$ < $H_4[SiW_{12}O_{40}]$ < $H_3[PW_{12}O_{40}]$, so that the last acid decomposes at a temperature in excess of 400 °C.[17] The salts are usually more stable than the acids. The thermal stability of the HPC increases in the presence of water vapour.[18]

HPA are as a rule readily soluble in water and water-containing solvents. For example, the solubility of the acid $H_4[SiMo_{12}O_{40}].8H_2O$ at 25 °C is 88 wt.% in water, 86 wt.% in ethyl acetate, and 85 wt.% in diethyl ether.[11] The solubility falls sharply when dehydrated HPA and thoroughly dried non-aqueous solvents are used.[19] HPA do not dissolve in solvents such as benzene, petroleum ether, and chloroform.

The state of the HPC in solution depends on the acidity of the medium, the composition and concentration of the compound, and the nature of the solvent.[4,10,11] Keggin's structure is retained in fairly concentrated solutions but in dilute solutions account must be taken of the possibility of the destruction of the HPAN. The HPAN exist in moderately acid solutions, while in a stronger acid medium they undergo acid hydrolysis with formation of metal oxo-cations. In an alkaline medium hydrolysis with formation of the anions of simple acids of the corresponding heteroatoms and metals takes place. The resistance of the HPAN to hydrolysis in aqueous solutions decreases in the series of metals W > Mo > V [11] and increases in organic media.[4] Recently, significant progress has been achieved in the study of the state of HPC in solutions as a result of the application of ^{31}P, ^{51}V, ^{17}O, ^{183}W, ^{95}Mo, etc. NMR.[10] The NMR method makes it possible to identify HPAN of different structural types and also to detect geometrical isomers without disturbing the equilibrium in the system.

By virtue of their large size, HPAN have a low surface charge density. For this reason, HPA and their salts are almost fully dissociated in aqueous solution and the HPAN are weakly solvated. Nevertheless, saturated HPAN can function as ligands and can give rise to extremely stable complexes with transition and lanthanide metal ions. Several conveniently disposed peripheral M=O groups participate simultaneously in the formation of such complexes. For example, the stability constants of the complexes of anions having the Dexter–Silverton structure, namely $CeMo_{12}O_{42}^{8-}$ and $UMo_{12}O_{42}^{8-}$, with the cations Cu^{2+} and Er^{3+} are 10^5–10^6 litre mol^{-1}.[20,21] The metal cations in these complexes are linked to three oxygen atoms of the HPAN at once, and the HPAN is thus a tridentate macroligand. Heteropolytungstates having Keggin's structure form complexes with the cations Fe^{2+}, Fe^{3+}, MoO_2^{2+}, VO^{2+}, and VO_2^+, characterised by a stability constant of ~10^2 litre mol^{-1}.[22] The complexes of heteropolytungstates with hydrogen peroxide have been discovered and characterised.[23] The complexes of metal cations with defective anions of the type XM_{11} and X_2M_{17},[10] which have a vacancy in Keggin's or Dawson's structure and exhibit a high coordinating capacity, are well known.

The individual metal–oxygen fragments of the compact structure of the HPAN are appreciably mobile and therefore each can be regarded as a discrete ligand. The mobility of the ligands in the HPAN has been established by studying the ^{99}Mo, ^{185}W, and ^{17}O isotope exchange.[24-27] It has been demonstrated with the aid of the ^{32}P isotope that there is no exchange of the central atom in $PMo_{12}O_{40}^{3-}$.[24] The kinetics and mechanism of the substitution of W(VI) in the $SiW_{12}O_{40}^{4-}$ and $PW_{12}O_{40}^{3-}$ anions by the VO^{2+}, VO_2^+, MoO_2^{2+}, Fe^{2+}, and Fe^{3+} cations have been investigated.[22]

III. ACID PROPERTIES OF HETEROPOLYACIDS

Heteropolyacids are strong polybasic acids, greatly surpassing in strength the usual inorganic acids.[4] The basicity of the heteropolyacids $H_{8-x}[X^{x}M_{12}^{VI}O_{40}]$, where M = Mo of W, follows from Keggin's structure and has been demonstrated by numerous direct measurements.[4,11,12]

1. The Acidity of Solid Heteropolyacids

Two types of protons have been found in crystalline HPA:[12,28-30] (1) non-localised hydrated protons bound to one HPAN as a whole and rapidly exchanging with the protons of the water molecules in the hydration shell of the acid; (2) non-hydrated protons localised at the peripheral oxygen atoms of the polyanion. When the water of crystallisation is removed, dehydration takes place and all the protons become localised. Thus water plays an important role in the formation of the proton structure of crystalline HPA.[12] It has been suggested[31] that the oxygen atoms of the angular groups $\mathrm{M}\overset{\mathrm{O}}{\diagup\,\diagdown}\mathrm{M}$ serve as the proton localisation centres because the greatest electron density is concentrated on these particular groups as a consequence of the weaker reversed $d_\pi-p_\pi$ interaction. The majority of the spectroscopic (broad band ^1H NMR and IR) and structural methods do not allow an unambiguous solution of the problem of the site where the protons are localised in polyanions.[12] The ^{17}O NMR method is promising in this respect. Data[26,32] obtained by this method confirm that the O atoms of the angular bridges are protonated in solution. However, one should note that different centres may protonated in crystalline and dissolved HPA.

The hydrated protons in HPA hydrates with a high water content exist in the form of dioxonium ions $H_5O_2^+$ and more complex hydrates $H^+(H_2O)_n$.[12,33,34] This has been established by ^1H NMR and neutron diffraction methods in relation to the hexahydrates of the acids PMo_{12} and PW_{12}. The ion $H_5O_2^+$ appears as a result of the formation of the strong quasi-symmetrical hydrogen bond $H_2O...H^+...OH_2$. In the acid $H_3[PW_{12}O_{40}].6H_2O$, it has an almost planar structure. The O–O distance in the dioxonium ion is significantly reduced owing to the formation of a strong hydrogen bond and amounts to 0.237 nm. The dioxonium ion is linked by hydrogen bonds via the protons of the water molecules to the terminal oxygen atoms of the M=O groups in the HPAN.[34] We may note that, according to the available data,[35] in aqueous solutions of strong acids the simplest stable hydrate is also the dioxonium ion and not H_3O^+. The difference between the H_3O^+ and $H_5O_2^+$ ions is very small and is determined solely by the degree of asymmetry of the $H_2O...H^+...OH_2$ hydrogen bond. If this bond is symmetrical, then the $H_5O_2^+$ complex must be regarded as the dixonium ion and if it is assymetric it should be regarded as the hydroxonium hydrate $(H_3O)^+H_2O$. Apparently such fine differences are not very significant for acid catalysis.

The nature of the acid centres in solid HPA has been established by the method involving the adsorption of bases, mainly pyridine.[1,14,18] Pyridine is adsorbed on strong Brønsted acid centres in the form of the pyridinium ion $C_5H_5NH^+$, while on the Lewis centres it is adsorbed in the form of a complex with a donor–acceptor bond. The difference between the IR spectra of these forms made it possible to establish that the entire pyridine adsorbed on the HPA exists in the form of the pyridinium ion, i.e. the acidity of the HPA is of the Brønsted type.[1,14,18]

The following sequence of crystalline HPA in terms of acid strength has been established by ^1H NMR [30] and pyridine and ammonia thermal desorption[1,14,18,36] methods (the ammonia desorption temperatures in degrees C are indicated under the formulae):

$$\underset{592}{H_3[PW_{12}O_{40}]} > \underset{532}{H_4[SiW_{12}O_{40}]} > \underset{463}{H_3[PMo_{12}O_{40}]} > \underset{423}{H_4[SiMo_{12}O_{40}]}\,.$$

The acidity of phosphoric acids is greater than that of silicic acids and that of tungstic acids is greater than the acidity of molybdic acids. This agrees with the higher negative charge on the oxygen atoms in molybdic acids compared with tungstic acids. The effective charges on the oxygen atoms of the HPA have been determined by X-ray photoelectron spectroscopy.[12] Quantum-chemical calculations have also shown that the charge on the peripheral oxygen atoms increases when W is replaced by Mo.[37]

Crystalline HPA have a stronger acidity than traditional solid acids such as aluminosilicates, H_3PO_4/SiO_2, etc. Thus pyridine adsorbed on $SiO_2-Al_2O_3$ is fully desorbed at 300 °C, while on $H_3[PW_{12}O_{40}]$ it is strongly retained even at a higher temperature in the form of the pyridinium ion.[14] At the same time the number of Brønsted acid centres per unit area of the $H_3[PW_{12}O_{40}]$ and $SiO_2-Al_2O_3$ surfaces is approximately the same.[14]

In many respects, crystalline HPA behave like solutions. This is manifested primarily by the mobility of the elements of their structure. As already mentioned, the HPAN exhibits an appreciable mobility.[15] The HPA protons exchange rapidly with the protons of the molecules of the water of crystallisation.[28,29] Anhydrous HPA exhibit proton conductivity and water vapour accelerates the diffusion of H^+.[30] As in solution, the oxygen atoms of crystalline HPA exchange with the oxygen of water.[1] The rate of such exchange in HPA is much higher than in metal oxides. Crystalline HPA also exchange ^{18}O oxygen with CO_2 and O_2, the rate of exchange diminishing in the sequence $H_2O \gg CO_2 \gg O_2$.[14] The similarity between the molecular structures and the types of behaviour in the crystalline state and in solution makes it possible to treat the mechanisms of homogeneous and heterogeneous catalytic reactions involving them from a single standpoint.

2. The Acidity of Heteropolyacids in Solution

In aqueous solutions there is no adequate justification for subdividing the HPA protons into localised and non-localised. It is more correct to treat HPA as the usual polybasic Brønsted acids in which all the protons are hydrated and equivalent and are linked to the anion as a whole and not to individual basic centres. In solutions all the acid protons are capable of being substituted by other cations, provided that the HPAN is sufficiently stable with respect to alkaline hydrolysis.

Table 1. The dissociation constants of heteropolyacids in water at 25 °C.

*At 20 °C.

In aqueous solution, HPA are strong acids in which the first three protons are fully dissociated. The stepwise character of the dissociation is not observable as a consequence of the levelling influence of the solvent. The subsequent dissociation proceeds stepwise as the pH of the solution is raised. The dissociation constants, starting with K_4, have been measured for certain acids with the Keggin and Dexter-Silverton structures in aqueous solution[38–40] (Table 1).

Non-aqueous solvents have a differentiating effect on the dissociation of the acids. They are more suitable for the investigation of the stepwise dissociation of polybasic acids. It is also significant that in non-aqueous media the HPA are much more stable towards degradation than in aqueous solutions.[4] In ethanol and acetone the first proton and to a large extent also the second proton are fully dissociated in Keggin's structures, while the first and second protons in acids such as $H_3[PW_{12}O_{40}]$ and $H_4[PW_{11}VO_{40}]$ are fully dissociated and the third proton is partly dissociated. In the less polar acetic acid, the HPA behave as comparatively weak 1–1 electrolytes.[4,41,42] Table 2 presents the stepwise dissociation constants of the HPA in acetone and acetic acid and for comparison also the dissociation constants of the usual inorganic acids. Evidently, the HPA are much stronger than the usual inorganic acids such as H_2SO_4, HBr, HCl, HNO_3, and even $HClO_4$. This is of fundamental importance for the application of HPA in acid catalysis. Attention should be drawn to the fact that, in terms of acidity, sulphuric acid, which is a traditional acid catalyst, is inferior to HPA by 2–5 p*K* units. The dependence of the acidity of HPA on their composition is strikingly weak. It is remarkable that the nature of the central atom has almost no influence despite the fact that the strengths of the corresponding simple acids differ appreciably (thus H_3PO_4 and H_4SiO_4 have $pK_1 = 2.12$ and 9.7 respectively in water[45]). Heteropolyacids are significantly stronger than the corresponding simple acids, which are weak or moderately strong.

*From Pawlak et al.[43]

**From Polotebnova et al.[44]

***From Porcham and Engelbrecht.[46] The p*K* not marked with asterisks were taken from Kozhevnikov and co-workers.[41,42]

The difference between the strengths of the HPA and the usual acids can be most simply explained within the framework of the electrostatic theory taking into account the size of the anions and the number of oxygen atoms available for the delocalisation of the charge of the anion.[4,41,42] Since the HPAN are much larger than the anions of the usual acids, the energy of the proton bond in the HPA should be lower and their dissociation constants should be higher compared with the usual acids. Furthermore, the greater the degree of delocalisation of the charge of the anion, the smaller the effective negative charge on its individual basic proton-accepting centres, and hence the weaker the attraction of the proton to the acid anion. The formal negative charges of the HPAN $PM_{12}O_{40}^{3-}$ and $SiM_{12}O_{40}^{4-}$ are identical with the charges on the anions of the corresponding simple acids PO_4^{3-} and SiO_4^{4-}, but the charge per outer oxygen atom is 9 times smaller in the HPA than in the phosphate and silicate ions. As a result of this, the acids $H_{8-x}[XM_{12}O_{40}]$ are much stronger than $H_{8-x}[XO_4]$. An interesting analogy between the properties of the HPA and inorganic acids having the general formula $XO_n(OH)_m$, where X is a group IVA–VIIA element, is noteworthy. These acids are remarkable because their strength increases with increase in *n* and depends little on *m* for constant *n*.[47]

The weak influence of the composition of the HPA on their acidity nevertheless obeys a definite rule, which is clearer in polar solvents. In solvents of low polarity, for example, in acetic acid, there is a possibility of the influence by ion association. The series based on the acid strengths of the HPA in acetone is:[4,42]

$$H_3[PW_{12}O_{40}] > H_4[PW_{11}VO_{40}] > H_4[SiW_{12}O_{40}] \simeq H_3[PMo_{12}O_{40}] >$$
$$> H_4[PMo_{11}^{VI}Mo^{V}O_{40}] \simeq H_4[PMo_{11}VO_{40}] > H_4[SiMo_{12}O_{40}]\ .$$

A similar sequence has been observed from the variation of the chemical shifts of the proton of chloral hydrate in the presence of HPA, obtained using nitrobenzene as the solvent. Thus the acidity series in solutions agrees well with the series found for solid acid hydrates. This agreement is reasonable, because the HPA behave in approximately the same way in the solid state and in solution.

The acidity diminishes when the HPA is reduced and when Mo or W is replaced by V and also on replacement of the central P atom by Si.

In all the cases enumerated, the decrease in acidity when the composition of the HPA is altered is accompanied by an increase in its basicity (the number of equivalent protons bound to the HPAN). The above dependence of the dissociation constants of HPA on their basicity agrees with the prediction of the electrostatic theory. By treating the HPAN as conducting spheres, with a charge equal to the basicity of the HPA, and the protons as positive point charges, it can be shown that any change in composition leading to an increase in the basicity of the HPA entails a decrease in the dissociation constants.[42] We may note that the substitution of Mo by W in the HPAN increases the dissociation constant but does not alter the basicity of the acid. However, in this case there is a correlation between the acidity and the effective charge on the peripheral oxygen atoms of the anion.

The splitting off of a proton from the acid can be represented as an ionisation process—dissociation with the intermediate formation of an ion pair:[48]

$$HPA \overset{K_i}{\rightleftarrows} HPAN^- \| H^+ \overset{K_d}{\rightleftarrows} HPAN^- + H^+\ .$$

It has been established that the HPA in solution are almost fully ionised ($K_i \gg 1$) and exist in the form of solvate-separated ion pairs.[41,42] Thus the specific features of the acid properties of the HPA are determined by the weak electrostatic bond between the proton and the anion in the ion pair. The fruitfulness of electrostatic ideas in the chemistry of HPC, owing to the large amount of ionic character in the bond between the cations and the polyanions and the weak solvation of the HPC, must be emphasised.

Concentrated HPA solutions are of great interest for catalysis. The acidity of concentrated $H_3[PW_{12}O_{40}]$ solutions is greater than the acidity of solutions of sulphuric and perchloric acids having the same concentration. The difference between the H_0 is 1–1.5 units.[49] Presumably the values of *H* are similar for acids of different composition, because in dilute solutions the dissociation constants of HPA depend only slightly on composition.

Using the concepts of hard and soft acids and bases, one can say that the HPAN are soft bases, which interact weakly with the hard acid H^+. According to Izumi et al.,[19] acids can be arranged in the following sequence in terms of their softness:

$$SiW_{12}O_{40}^{4-} > GeW_{12}O_{40}^{4-} > PW_{12}O_{40}^{3-} > PMo_{12}O_{40}^{3-} >$$
$$> SiMo_{12}O_{40}^{4-} > NO_3^- > p\text{-}MeC_6H_4SO_3^- > SO_4^{2-}.$$

3. Relation between the Oxidative and Acid Properties of Heteropolycompounds

HPC are many-electron oxidants. The addition of electrons increases the basicity of the HPAN and may be accompanied by protonation. The reduction of the Mo and W HPAN can be represented by the following equation taking into account protonation:

$$XM_{12}^{VI}O_{40}^{x-8} + ne^- + mH^+ \rightarrow H_mXM_{12-n}^{VI}M_n^VO_{40}^{x+m-n-8}$$

where $m \leq n$.[4,10,50] Hence the oxidation potential of the HPAN is

$$E = E_0 + \frac{RT}{nF} \ln \{XM_{12}^{VI}O_{40}^{x-8}\}\{H^+\}^m/\{H_mXM_{12-n}^{VI}M_n^VO_{40}^{x+m-n-8}\},$$

where E_0 is the standard redox potential, F is the Faraday, and the formulae in braces represent the ionic activities.

Table 3. The redox potentials of Keggin's structure of heteropolycompounds in aqueous solution.

Redox system	n_e	E_0, V	Refs.
	V (V) → V (IV)		
$PV^VW_{11}/PV^{IV}W_{11}$	1	0.78	[53]
$PV^VMo_{11}/PV^{IV}Mo_{11}$	1	0.68	[54]
$PV_2^VMo_{10}/PV_2^{IV}Mo_{10}$	2	0.71	[54]
$PV_3^VMo_9/PV_3^{IV}Mo_9$	3	0.71	[54]
$PV_4^VMo_8/PV_4^{IV}Mo_8$	4	0.71	[54]
	Mo (VI) → Mo (V)		
$PMo_{12}^{VI}/PMo_9^{VI}Mo_3^V$	3	0.65	[55]
$SiMo_{12}^{VI}/SiMo_9^{VI}Mo_3^V$	3	0.63	[55]
	W (VI) → W (V)		
$BW_{12}^{VI}/BW_{11}^{VI}W^V$	1	−0.36	[56]
$GeW_{12}^{VI}/GeW_{11}^{VI}W^V$	1	−0.02	[56]
$SiW_{12}^{VI}/SiW_{11}^{VI}W^V$	1	−0.05	[56]
$PW_{12}^{VI}/PW_{11}^{VI}W^V$	1	0.15	[56]
	Co (III) → Co (II)		
$Co^{III}W_{12}/Co^{II}W_{12}$	1	1.0	[57]

Remarks. The O atoms and charges have been omitted from the formulae; n_e is the number of electrons transferred and E_0 is expressed relative to the normal hydrogen electrode.

The quantities E_0 are as a rule unknown owing to the lack of data on the HPAN equilibria in solution. One uses instead the corresponding formal redox potentials, which depend on the pH and the HPAN concentration.[50] It is seen from the last equation that the oxidation potential of the HPAN depends on the acidity of the medium, at least in the pH range where the anion is protonated on reduction. Tungsten anions with Keggin's structure may have a charge up to −6 without the addition of protons on reduction in an acid aqueous solution (pH ≤ 1) by virtue of the high acidity of the corresponding acids.[51] In non-aqueous media, their charge is much smaller.

The oxidation potential of the HPC depends on the nature of both the metals and the central atom[4,50,52] (Table 3). The oxidation potential diminishes in the series of metals V > Mo > W. The central atom (a constant electrovalence ion) influences the redox potential via the change in the charge of the HPAN: the higher the charge of the anion, the lower the oxidation potential.[4,50,52] The dependence of the redox potential on the charge of the anion is frequencly linear and can be predicted with the aid of electrostatic theory.[52]

It has been demonstrated by the temperature-programmed reduction method that the ease of reduction of solid HPA by hydrogen diminishes in the sequence $PmO_{10}V_2 \cong SiMo_{12} \geqq PmO_{12} \cong PmO_6W_6 > PmO_2W_{10} > PW_{12} \cong SiW_{12}$, and the ease of reduction of salts of 12-molybdophosphoric acid diminishes in the sequence $Ag^+ > Cu^{2+} > Ni^{2+}$.[5,58] The process is appreciably facilitated if a mixture of the acids with the Pd/C catalyst is reduced. Thus the capacity of solid HPA for reduction is fairly well correlated with the redox potentials in solution.

The question of the relation between the oxidative and acid properties of HPA is important for their use as acid catalysts. Comparison of the dissociation constants and oxidation potentials of HPA (Tables 2 and 3) shows that there is no correlation between them. At the same time, one must bear in mind that the dissociation constants of HPA diminish when they are reduced. Thus the catalytic activity of HPA should depend on the reducing capacity of the reaction medium.

Data on the kinetics of the redox reactions of HPAN with various one-electron reductants and oxidants are of interest in this connection. It has been established[59] that the observed kinetics agree satisfactorily with the Marcus theory. Thus this theory can be used to predict the stability of HPA in a reducing medium under the conditions of acid catalysis.

IV. ACID CATALYSIS BY HETEROPOLYACIDS

Heteropolyacids have long been used in catalysis,[3,10,11] but systematic studies in this field began comparatively recently. The likely usefulness of HPA as acid catalysts is due to their high Brønsted acidity, which is superior to that of the usual catalysts. Since HPA are readily soluble in water and oxygen-containing solvents and their stability in the solid state is fairly high, they are used as both homogeneous and heterogeneous catalysts. The W and Mo HPA have acceptable technological characteristics. In contrast to the usual inorganic acids, they are non-toxic and involatile, have no smell, and are stable on prolonged storage. Although HPA are much more expensive than acids such as sulphuric and hydrochloric, their use is frequently economically justified because of the high efficiency of their catalytic action.

Tungstic acids are the preferred catalyst in the series of HPA[4] because of their higher acidity, hydrolytic and thermal stability, and lower oxidation potentials compared with the Mo and V acids. In heterogeneous catalysis, one uses, together with HPA, their salts with cations such as Ag^+, Cu^{2+}, Pd^{2+}, Al^{3+}, etc.[7] The mechanism of the formation of acid centres in such systems is examined below. The strength and number of acid centres of HPA catalysts can be regulated by selecting the outer-sphere cation, by replacing the central atom and the metal in the structure of the polyanion, and also by employing carriers of different nature and by varying the concentration of the acid on the carrier.[5] In both homogeneous and heterogeneous catalysis by heteropolyacids, the

Brønsted rule usually holds satisfactorily: the catalytic activity is correlated with the strength of the acid centres of the catalyst.

Table 4 presents examples of reactions catalysed by HPA, many of which are of practical interest. HPA are frequently superior to the traditional acid catalysts as regards not only activity but also selectivity. This is because they make it possible to carry out the process under milder conditions. Furthermore, by virtue of the inertness of the anion, HPA do not enter into side reactions with organic reagents, in the manner characteristic of the usual inorganic acids (sulphonation, chlorination, etc.).[4]

Table 4. Acid catalystis by heteropolyacids.

Reaction	Catalyst	T, °C	α, %	A	Refs.
Hydration–dehydration					
$RCH{=}CH_2 + H_2O \rightarrow RCH(OH)CH_3$	PW_{12}, SiW_{12}, PMo (hom.)	170—350	95—99	2—4	[9]

Notation: XM_{12} are the heteropolyacids $H_{8-x}[XM_{12}O_{40}]$ and in certain cases their salts; hom. = homogeneous catalytic systems and het. = heterogeneous catalytic systems; T is the temperature; A is the ratio of the catalytic activity of the HPA to the activity of an inorganic acid (H_2SO_4) in homogeneous reactions or of aluminosilicate in heterogeneous reactions; α is the selectivity.

*The aluminosilicate exhibits an appreciable activity only above 400 °C.[5,72]

**The activity of the HPA in relation to toluene-p-sulphonic acid.

***Together with the acids, the Ag^+, Cu^{2+}, and Al^{3+} salts are active.

1. Homogeneous Acid Catalysis

In this Section attention is concentrated on the following questions: (a) comparison of HPA and the usual inorganic acids in terms of their catalytic activity and selectivity; (b) dependence of the activity of HPA on their composition; (c) relation between the activity of HPA and their acidity; (d) the influence of the oxidative properties of HPA on their catalytic action.

The hydration of lower olefins is the first example of the practical application of HPA in an acid catalysed process.[9] The application of HPA on carriers as heterogeneous catalysts of the hydration of olefins has been known for a long time. They are more active than the industrial H_3PO_4/SiO_2 catalyst and are not removed by entrainment.[83] In the homogeneous process developed comparatively recently,[9] olefins ranging from ethylene to butene are converted into alcohols with a selectivity of 95–99% at 170–350 °C and pressures in the range 10–30 MPa in the presence of 10^{-5}–10^{-3} M aqueous solutions of $H_4[SiW_{12}O_{40}]$, $H_3[PW_{12}O_{40}]$, $H_5[BW_{12}O_{40}]$, $H_3[PMo_{12}O_{40}]$, $H_4[SiMo_{12}O_{40}]$, and their soluble salts. In conformity with their strength, the catalytic activity of HPA is higher than those of sulphuric and nitric acids.[79] The main advantage of the homogeneous hydration of olefins compared with the heterogeneous process is the attainment of higher degrees of conversion of the olefin as a result of the increased concentration of water and the use of a higher pressure. Data concerning industrial liquid-phase hydration of propene under the influence of HPA have been published recently.[9]

The addition of carboxylic acids to olefins (esterification of olefins) proceeds smoothly in solution in the presence of 10^{-4}–10^{-2} M tungsten and molybdenum HPA at 20–140 °C with a selectivity of ~100% in relation to esters of secondary alcohols.[4,62] Sulphuric acid, whose acidity is lower, is less active than HPA by a factor of 30–90.[62] The activity of tungstic acid is higher by a factor of 2–2.5 than that of molybdic acids, despite the virtual identity of their dissociation constants, which is due to the difference between the oxidation potentials of the acids. Molybdic acids, which are stronger oxidants, are reduced during the reaction by the components of the reaction mixture and lose their acidity, while tungstic acids are not reduced, because their oxidation potentials are significantly lower.

The dealkylation of derivatives of 2,6-di-t-butylphenol to 2-t-butylphenols is a key stage in the synthesis of widely used phenolic antioxidants. The acids PW_{12} and SiW_{12} are highly active homogeneous and heterogeneous catalysts of this reaction.[73,84,85] The heterogeneous process proceeds at 130–150 °C in the presence of the catalyst (less than 1%) in the melt of the substrate.[84,85] Molybdic acids are raidly deactivated as a result of their reduction by the reaction medium. HPA are tens of times more active than heterogeneous catalysts such as ion-exchange resins, aluminosilicates, aluminium sulphate, etc. The homogeneous process is even more effective. In solutions in acetic acid, dealkylation takes place already at 80 °C.[73] The catalytic activity of HPA is correlated with the acidity and exceeds by a factor greater than 100 the activity of sulphuric acid.

The transesterification of butyl acetate to form ethyl acetate takes place in solution in ethanol at 110–130 °C in the presence of 10^{-4}–10^{-2} M tungsten or molybdenum HPA.[67] In this reaction, the HPA is 4–10 times more active than sulphuric acid. Contrary to expectation, molybdic acids proved to be more active in this instance than tungstic acids. In the course of the reaction, the Mo acids are reduced and probably partly decompose. The true catalyst apparently consists of alkoxide complexes of molybdenum formed on decomposition of the HPA. In conformity with this hypothesis, the order of the reaction with respect to the molybdenum HPA is less than unity (the order with respect to tungstic acids is unity). We may note that titanium and zirconium alkoxide complexes are known to catalyse effectively esterification reactions.[86] The reduction and decomposition of molybdic acids have also been observed in the acetolysis reactions of esters.[19]

The acid decomposition of cumenyl hydroperoxide is the basis of the commonest industrial method of synthesis of phenol and acetone. Many homogeneous and heterogeneous catalysts have been proposed for this reaction, but only sulphuric acid has found practical application, although in its presence the process is insufficiently selective and yields phenolic waste water.[87] HPA are very active and selective homogeneous catalysts of the decomposition of cumenyl hydroperoxide.[68,88] Compared with sulphuric acid, they reduce the yield of the phenolic resin and the amount of waste water and increase the quality of the phenol obtained. The reaction rate constants k is correlated with the acidity of the HPA (in acetone at 25 °C [68]):

Catalyst	PW_{12}	$PW_{11}V$	PMo_{12}	SiW_{12}	$PMo_{11}V$	$SiMo_{12}$
$10^4 k$, s^{-1}	8.0	6.4	6.3	5.8	4.2	3.5
pK_a	3.0	3.2	3.6	3.6	3.7	3.9

Sulphuric acid is less active by 2–3 orders of magnitude than HPA.

The most selective catalyst of the decomposition of cumenyl hydroperoxide is 12-molybdophosphoric acid.[88] Tungstic acids are significantly less selective. It is most probable that this is due to the difference between the oxidative properties of the molybdic and tungstic acids. The point is that, in the presence of the hydroperoxide, which is a powerful oxidant, the HPA are in the oxidised state. After the completion of the decomposition of the hydroperoxide, the reaction medium becomes reducing and the molybdenum HPA are rapidly reduced in it and lose their catalytic activity. Tungsten HPA and the usual inorganic acids are not reduced and continue to catalyse side condensation reactions after the decomposition of the hydroperoxide has been completed. Thus the oxidative properties of HPA may also play a positive role in acid catalysis under certain conditions.

A selective semi-industrial method of synthesis of methyl methacrylate by the homogeneous esterification of methacrylic acid with t-butyl methyl ether (TBME) in the presence of Mo and W heteropolyacids at 110–150 °C has been developed:[89]

$$H_2C{=}C(CH)_3COOH + (CH_3)_3COCH_3 \rightarrow$$
$$\rightarrow H_2C{=}C(CH_3)COOCH_3 + H_2C{=}C(CH_3)_2\ ,$$

The initial stage is the decomposition of TBME to methanol and isobutene. The isobutene dimer is formed as a side product, but its yield can be appreciably reduced by the continuous removal of isobutene from the reactor.

A new interesting aspect of catalysis by HPA is asymmetric synthesis. It has been found recently that the chiral acid $H_6[P_2Mo_{18}O_{62}]$ can be used as the catalyst of the asymmetric polycondensation of benzyl alcohol.[90] In the presence of the l-brucine-$H_6[P_2Mo_{18}O_{62}]$ homogeneous system, benzyl alcohol is converted into an optically active polybenzyl:

$$nC_6H_5CH_2OH \rightarrow -(-C_6H_4CH_2-)_n- + (n-1)H_2O.$$

In the presence of the non-chiral acid $H_6[P_2W_{18}O_{62}]$, an optically inactive polybenzyl is formed.

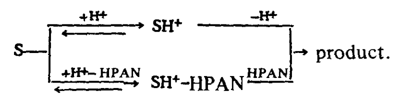
The homogeneous reactions catalysed by HPA are usually of first order with respect to the substrate S. The order with respect to the catalyst depends on the ionising capacity of the solvent. Thus, in media where the degree of dissociation of the HPA is low, the reactions are of first order. For example, the rates of the reactions involving the esterification of olefins and the dealkylation of derivatives of 2,6-di-t-butylphenol in acetic acid[62,73] are described by the expression:

$$v = k[\mathrm{HPA}][\mathrm{S}].$$

In more polar solvents, where the degree of dissociation of the HPA is appreciable, the process frequently takes place in accordance with the kinetic equation

$$v=(k_1[\mathrm{H}^+]+k_2[\mathrm{H}^+\text{—HPAN}])[\mathrm{S}],$$

where H^+–HPAN is the acid heteropolyanion. Examples of such reactions are the decomposition of cumenyl hydroperoxide into phenol and acetone in acetone (H^+–HPA = $H_2PMo_{12}O_{40}^-$),[68] the hydration of isobutene,[3,79] and the cyclisation of butane-1,4-diol to tetrahydrofuran[66] in aqueous solution (H^+–HPA = $HSiW_{12}O_{40}^{3-}$). In this case, the reaction proceeds via two pathways: specific catalysis by the H^+ ion and general catalysis by the HPAN:



Thus HPA are more active as homogeneous catalysts than the usual acids, especially sulphuric acid. This makes it possible to carry out the catalytic processes at a lower catalyst concentration, which frequently increases the selectivity and makes it possible to reduce the amount of waste water in the neutralisation of the catalyst.

2. Heterogeneous Catalysis

(a) *General characteristics.* In heterogeneous catalysis, HPA and their salts are used as massive and deposited catalysts. The best carriers are neutral supports—silica gel and activated charcoal. Basic carriers, such as Al_2O_3 and MgO, are unsuitable, because they neutralise the HPA.[36] The properties of catalysts based on the salts depend significantly on the nature of the metal cation, the degree of substitution of hydrogen in the acid by the metal, and the solubility of the salt. The temperature at which the HPA catalysts are used does not as a rule exceed 300–350 °C, which is within the limits of the thermal stability of tungstic acids. Since HPA and the water soluble salts are highly hydrated, they are subjected to a preliminary heat treatment *in vacuo* at 100° to 300 °C in order to remove the water of crystallisation. Such heat treatment does not disrupt the structure of the HPAN. Evacuation of the HPC at 130 °C for 1 h lowers the amount of water to 1–2 molecules per HPAN.[69] The insoluble salts are hydrated to a much lesser extent. Their water is zeolitic in character and is readily removed by evacuation at 25 °C.[14]

The acids in massive form and their soluble salts are characterised by a low specific surface (1–5 $m^2\ g^{-1}$), which depends little on the heat treatment conditions.[69,91] The specific surface of insoluble caesium salts reaches 100–200 $m^2\ g^{-1}$ The acid caesium salts $Cs_{3-x}H_x[PW_{12}O_{40}]$ (x = 0.15 to 0.5), which have a large surface area, are of interest as insoluble acid catalysts.[5,92] They are distinguished by a higher thermal stability than the initial acids.[5]

The porosity of massive specimens of the PmO_{12} and PW_{12} acids is insignificant. Thus $H_3[PMo_{12}O_{40}]$ has a pore volume of 0.026 $cm^3\ g^{-1}$ at 25 °C and a wide distribution of the pore sizes with respect to radius. After vacuum treatment at 110 °C, the pore volume remains unchanged but a narrow peak, corresponding to a radius of ~2 nm, appears on the pore size distribution curve. Such pores are formed as a result of the change in the crystal structure of the acid on dehydration, which leads to the appearance of cavities and the contraction of the unit cell. After evacuation at 450 °C, the peak vanishes; the pore distribution again becomes broad, which can be accounted for by the further mutual approach of the HPAN.[93]

The study of the PW_{12} and SiW_{12} acids deposited on silica gel by X-ray diffraction showed that the HPA phase on the carrier surface is formed when its content is ~20 wt.%.[36] According to ammonia thermal desorption data, the strength of the HPA on silica gel diminishes, as for the massive acids, on passing from PW_{12} to SiW_{12}, and is independent of its concentration on the carrier.[36] HPA on activated charcoal exhibit high activity and are not washed off by water and organic solvents.[65] Such catalysts are promising for processes in suspension. The decomposition of tungsten HPA was observed when these were deposited on alumina even when the basicity of the Al_2O_3 had been reduced by preliminary treatment with HCl.[36]

The activity of deposited catalysts usually increases with increase in the content of the HPA to 15–30 wt.% (which corresponds to approximately monolayer coverage) and is subsequently independent of the latter.[36,66] The activity of the deposited catalysts calculated per acid molecule is much lower than the activity of the massive acid specimens. This applies to reactions such as the alkylation of benzene with ethylene, the esterification of acetic acid with ethanol, the dehydration of 2-propanol,[36] the vapour-phase nitration of benzene,[66] etc.

(b) *The "pseudo-liquid phase".* The water-soluble HPC exhibit a high affinity for the molecules of polar substances such as alcohols, ketones, ethers, esters, amines, etc. Large amounts of these substances are sorbed in the bulk of the crystalline HPC with formation of solvates. This phenomenon should not be confused with adsorption in the micropores of the usual sorbents.[1,5,7] Table 5 presents data for the absorption and adsorption of polar and non-polar substances by the acid $H_3[PW_{12}O_{40}]$. The total degree of sorption of the substance at 25 °C and the amount which is irreversibly retained after evacuation at 25 °C are indicated. For polar molecules, the latter corresponds to the presence of 50–100 layers of the sorbate on the $H_3[PW_{12}O_{40}]$ surface. Oxygen-containing compounds are almost fully desorbed at 100–150 °C, while nitrogen derivatives require the use of higher temperatures. The degree of sorption of non-polar hydrocarbons (alkanes, olefins, arenes) is insignificant. They are adsorbed only on the HPA surface.

Table 5. The sorption of different substances by the acid $H_3[PW_{12}O_{40}]$ at 25 °C.[5]

Substance	Sorption*	
	irreversible	total
Pyridine	6.0	9
Ammonia	3.2	4.3
Methanol	2.2	>10
Isopropyl alcohol	6.3	>10
Ethylene	0,03	0.04
But-1-ene	0.2	0.25
Benzene	0,1	0.5

*The number of sorbed molecules of the given substance per HPA molecule.

By virtue of the rapid absorption of polar molecules, the catalytic reactions can occur not only on the surface but also on the bulk of the massive HPA. In relation to polar substances, solid HPA behave similarly to highly concentrated solutions, i.e. all the acid protons and not only the surface protons participate in the catalytic reaction. This phenomenon, which is unusual for heterogeneous acid catalysis and is characteristic of massive HPA, is described by the term "pseudo-liquid phase".[1,5] The ability of crystalline HPA to effect the catalytic reactions of polar substances in the bulk of the catalyst, like the reactions in homogeneous systems, is implied.

In contrast to polar molecules, non-polar reagents are incapable of being absorbed in the bulk of the HPA; they interact only with the surface of the catalyst. Soluble salts of HPA also possess the property of the "pseudo-liquid phase". Insoluble salts, which do not absorb polar molecules, possess no such property.

In terms of the catalytic properties in relation to the molecules of polar substances, massive HPA resemble zeolites to some extent. In both cases, virtually all the acid centres of the catalyst are accessible: in the HPA as a result of the absorption of the substrate in the bulk phase and in zeolites as a result of the high internal surface area. However, whereas in the case of HPA this is true only of polar molecules, in a zeolite this is true of any molecules whose dimensions do not exceed the diameter of the zeolite channels. In contrast to zeolites, HPA do not have sufficiently pronounced molecular-sieve properties, because they do not have a rigorously ordered porous structure.

Several studies have been devoted to the "pseudo-liquid phase".[1,5,7,94–98] The dehydration of alcohols (ethanol, 2-propanol, 2-butanol),[69,94] the conversion of methanol into hydrocarbons,[7,95] the decomposition of formic acid,[69] and other reactions have been included amongst pseudo-homogeneous reactions. The "pseudo-liquid phase" is manifested kinetically by the fact that the rate of the reaction catalysed by the deposited HPA is proportional to the concentration of the active component and not its surface area. Such relations have been found in the study of the conversion of methanol on deposited silver and copper salts of PW_{12}.[97,98] However, in the case of the HPA themselves, the rate, which initially increases with increase of the amount of acid on the carrier, subsequently reaches a plateau; thus the specific catalytic activity calculated per HPA molecule diminishes. This can be explained by the fact that, on increasing the amount of deposited acid, the absorption of the substrate in the bulk of the catalyst becomes the rate-limiting stage of the catalytic process. The latter is analogous to the internal diffusion inhibition in the case of the usual porous catalysts. Another possible explanation is a considerable contribution of the surface reaction.

The correlation of the catalytic activity with the acidity of the massive HPA specimens may serve as evidence for pseudohomogeneity. Thus the rates of the above reactions decrease almost linearly as the H^+ in $H_3[PW_{12}O_{40}]$ is substituted by sodium or pyridine is added, falling almost to zero after the introduction of three pyridine molecules or three sodium ions per PW_{12} anion.[7,69,94,95] In the case of surface reactions, the specific surface of the catalyst plays a decisive role. For example, in the conversion of dimethyl ether into hydrocarbons, the insoluble salt $Cs_{2.5}H_{0.5}[PW_{12}O_{40}]$ (specific surface 101 $m^2\ g^{-1}$) shows a higher activity per unit mass of the catalyst than $H_3[PW_{12}O_{40}]$ (specific surface 5 $m^2\ g^{-1}$).[92]

By virtue of the similarity of the properties of crystalline and dissolved HPA, their acidities in the solid state and in solution depend on the composition of the acid in virtually the same way. As a result of this, the rates of pseudohomogeneous reactions catalysed by solid HPA are usually well correlated with the dissociation constants of the acids in solution and with the strengths of the solid acids measured by the method involving the thermal desorption of ammonia or pyridine. Thus the activity of massive HPA in the dehydration of 2-propanol at 100 °C diminishes in the sequence $PW_{12} > SiW_{12} > PW_{10}P_2 > PMo_{12} \approxeq PMo_{10}V_2 \approxeq SiMo_{12}$,[1,5] which is close to the acidity series in solution (Table 2). The lower activity of PMo_{12} compared with SiW_{12} can be explained by the reduction of PMo_{12} during the reaction.[5]

The absorption of 2-propanol in the bulk of the catalyst during dehydration on $H_3[PW_{12}O_{40}]$ has been demonstrated by the rapid replacement of 2-propanol-d_0 in the gas stream by 2-propanol-d_8.[94] In the absence of the catalyst, the d_0 molecules were rapidly (in the course of 2 min) replaced by the d_8 molecules at the outlet from the reactor. In the presence of the catalyst, the exchange took a much longer time (~20 min) which confirms the sorption of the alcohol in the bulk of the HPA. These data made it possible to estimate the amount of alcohol in the catalyst, which was ~7 molecules per anion, corresponding to the coverage of the $H_3[PW_{12}O_{40}]$ surface by approximately 100 alcohol monolayers. This demonstrates convincingly the presence of 2-propanol in the bulk of the catalyst. It has also been found that the rate of absorption is 50 times higher than the rate of dehydration of propanol and absorption does not therefore limit the rate of the catalytic reaction under these conditions (80 °C).

The question of the relative contributions of the bulk and surface reactions to the observed catalytic activity of HPA catalysts naturally arises. It can be answered by comparing the activities of massive specimens of the acids and the dispersed acids on carriers with respect to reactions characterised by pseudo-homogeneity. As already mentioned, in many reactions the catalytic activity of HPA deposited on inert carriers, calculated per acid molecule, is much higher than for massive specimens of the acids. This has been observed both in surface reactions (alkylation of benzene by ethylene,[36] isomerisation of but-1-ene [94]) and in the typical bulk-phase 2-propanol dehydration reaction.[36] The specific catalytic activity is independent of the concentration of deposited HPC only in the conversion of methanol on the silver and copper salts of PW_{12}.[97,98] However, this may be associated with the characteristic features of the formation of the acid centres in the HPA salts (see below). Thus the impression is created that in pseudo-homogeneous reactions the activity of solid HPA catalysts is determined to a larger extent by the degree of dispersion of the acid than by its bulk-phase properties. This may be associated with the difference between the strengths of the surface and bulk-phase protic centres of the HPA (see below) or with the slow course of absorption, as a result of which the reaction proceeds preferentially in the layer near the surface.

Pseudo-homogeneity apparently plays a significant role in low-temperature reactions of polar substances, i.e. under conditions where the degree of sorption of the substrate in the bulk of the catalyst is high. In high-temperature reactions, the contribution of the bulk-phase reaction is probably not so great. However, the available data are still too few to reach a final conclusion. Detailed kinetic studies of catalysis by deposited HPA are necessary.

The practical value of the phenomenon of the "pseudo-liquid phase" arises because it becomes possible to regulate specifically the selectivity of the catalytic process by differentiating the acid reactions of polar and non-polar substances on coarsely dispersed soluble and finely dispersed insoluble HPC—for example, $H_3[PW_{12}O_{40}]$ and $Cs_{3-x}H_x[PW_{12}O_{40}]$.[55,99] The selectivity can also be altered by employing the difference between the rate of desorption of the intermediates from the surface of the catalyst and from its bulk phase.

An example of such regulation of selectivity is provided by the conversion of dimethyl ether into a mixture of C_1–C_6 alkenes and alkanes on massive PW_{12} HPC at 290 °C.[99] The alkenes are the primary products from which alkanes are formed. The alkene/alkane ratio is clearly correlated with the absorption capacity of the catalyst. Thus, in the case of the acid $H_3[PW_{12}O_{40}]$, which absorbs the ether in an amount corresponding to approximately 40 monolayers (28 °C), the propene/propane ratio is approximately unity. The salt $Cs_{2.5}H_{0.5}[PW_{12}O_{40}]$ sorbs less than one monolayer and we have the ratio propane/propane ≈ 12. These data have been explained as follows.[97] The alkenes formed on the surface of the $Cs_{2.5}H_{0.5}[PW_{12}O_{40}]$ catalyst are readily desorbed. The alkenes obtained in the bulk of the catalyst, namely the acid $H_3[PW_{12}O_{40}]$, its sodium salts, etc. undergo hydrogen transfer reactions with formation of alkanes before being desorbed. Other examples of the regulation of selectivity have been published.[69]

Theoretically the HPA capable of behaving as a "pseudo-liquid phase" are unique objects for the study of one of the main problems of catalysis—the relation between homogeneous and heterogeneous catalysis.

(c) *The acid centres of heteropolyacid catalysts.* As already mentioned, massive HPA exhibit purely Brønsted acidity.[1,5,7] In terms of its strength, they are superior to aluminosilicates[5] and are much more active than the zeolite HY in the dehydration of 2-propanol.[100] It is believed that the protic centres of the HPA are fairly uniform, at least as regards the bases sorbed in the bulk phase (ammonia, pyridine).[93] These conclusions can be extended also to HPA on inert carriers.

Data on the crystal and proton structures of HPA permit a series of hypotheses about the structure of the acid centres of the catalyst considered. The protons in the free HPA molecules (in solution and probably on the surface of the inert carrier for a low coverage) are localised predominantly at the oxygen atoms of the angular bridges  $M\overset{O}{\diagup\diagdown}M$.[12] In massive acids, the protons participate in the formation of the crystal structure, linking together the HPAN by hydrogen bonds.[12] In the crystals, the positions of the protons may be different because they are determined not only by the negative charge on the oxygen atoms of the polyanion but also by the character of the packing and the unit cell parameters. Indeed, a structural study[34] has shown that the protons in the hexahydrate $H_3[PW_{12}O_{40}]$ enter into the composition of the dioxonium ions $H_2O...H^+...OH_2$, each of which links four neighbouring HPAN by forming hydrogen bonds between the protons of the water molecules and the terminal oxygen atoms of the W=O group. On dehydration, the size of the unit cell diminishes.[14] The exact data concerning the positions of the protons in the dehydrated acids are lacking, but, by analogy with hydrates, one may assume that the crystal structure is determined by the presence of a hydrogen bond between the HPAN via the terminal oxygen atoms, $M{=}O...H^+...O{=}M$, where the non-hydrated proton assumes the role of the binder.

Thus the structure of the Brønsted acid centres in HPA catalysts should depend on their phase state (homogeneous, heterogeneous, massive, or deposited) and the degree of hydration. On the basis of the available structural data, we shall now attempt to represent the structure of the proton centres of the main types of catalysts of this kind (Table 6).

In homogeneous systems the HPA molecules exist in a free state in solution. Their acid centres are homogeneous; they include hydrated (solvated) protons, which are most probably localised at the oxygen atoms of the angular bridges  $M\overset{O}{\diagup\diagdown}M$, linking the metal atoms in the M_3O_{13} triads. The structure of such centres can be represented as structure (I), where three equivalent bridging oxygen atoms in the six-membered metallocycle serve as centres at which the hydrated protons are localised. In the middle of the skeleton of the triad there is an internal oxygen atom through which the triad is linked to the heteroatom.

The heterogeneous catalysts include bulk-phase and surface acid centres. Their structures may be different for the massive and deposited forms. According to some data,[34] the bulk-phase proton centres of the massive hexahydrate of the PW_{12} acid have the structure (II), which incorporates a dioxonium ion linked via hydrogen bonds to the terminal oxygen atoms of the four anions in the unit cell. In highly hydrated acids, the $H_5O_2^+$ ion may be additionally hydrated and the water molecules can also participate in the formation of hydrogen bonds between the anions.[12,34] Such protons centres are apparently responsible for the occurrence of the low-temperature psuedo-homogeneous reactions involving the liberation of water, for example, the dehydration of 2-propanol at 80–150 °C. In vapour-phase reactions at a higher temperature, they are hardly retained as a consequence of the dehydration of the acid.

Table 6. The proton centres of catalysts based on heteropolyacids.

No.	Structure of proton centre*	Type of catalyst	Characteristics of the proton centre
(I)		Homogeneous	Centre in isolated HPA molecule in solution
(II)		Massive heterogeneous	Bulk-phase centre in highly hydrated HPA
(III)	M=O···H⁺···O=M	Massive heterogeneous	Bulk-phase centre in dehydrated HPA
(IV)		Deposited heterogeneous	Centre in highly dispersed acid on a carrier or surface centre in the massive acid

*M = Mo or W.

The bulk-phase centres of the dehydrated HPA can be represented by the structure (III). It is natural to suppose that the structures (II) and (III) can be reversibly interconverted in the course of the acid hydration–dehydration process. The bulk-phase proton centres (III) probably play a significant role in high-temperature pseudo-homogeneous reactions such as the conversion of methanol and dimethyl ether into hydrocarbons at 250–350 °C.

The structural characteristics of the deposited HPA have so far been inadequately investigated. The structure (IV) may be adopted for the proton centres of highly dispersed HPA on the surfaces of inert carriers. It is analogous to the structure of the HPA centres in solution. The difference consists only in the fact that in the deposited catalyst the water content has been reduced to a minimum as a result of heat treatment. If the HPA concentration on the carrier is sufficient for the formation of a two-dimensional or three-dimensional phase, the proton centres of the deposited catalyst may be represented by the set of structures (II)–(IV) depending on the degree of hydration. As regards the surface proton centres of massive HPA, the structure (IV) can be adopted for them although one cannot rule out the additional involvement in the surface reactions of the bulk-phase centres (II) and (III) in the layer near the surface.

The ideas about the structure of the acid centres of the HPA examined may be extended also to acid alkali metal salts.

The question of the realtive activities of different acid centres is very important. Unfortunately, there are as yet insufficient data for a detailed comparison, but certain estimates are possible. It has been found that the activity of the surface acid centres of massive $H_3[PW_{12}O_{40}]$ in the heterogeneous dealkylation of 2,6-di-t-butyl-4-methylphenol in the substrate melt is close to the activity of the centres in the corresponding homogeneous process in solution in acetic acid.[73] This result appears to be entirely natural, since the structures of the centres (I) and (IV) are identical, but it would be too early to treat it as a general rule.

There are not yet any reliable experimental data for the comparison of the activities of the bulk-phase centres (II) and (III), but they can be compared with the centres (IV) in highly dispersed acids on the surface of an inert carrier. As already mentioned, the deposited acids are a little more active than the massive specimens per one acid molecule in typical bulk-phase reactions such as the dehydration of 2-propanol and the esterification of acetic acid by ethanol.[36] This shows that the surface centres (IV) are more active than the bulk-phase centres (II) and (III). This is evidently caused by their different strengths and accessibilities. The more accessible centres (IV), incorporating isolated protons, undoubtedly exhibit a stronger protonating capacity than the centres (II) and (III) in which the protons are bound more strongly, because they participate in the formation of the crystal structure. The surface centres (IV) apparently play the main role in heterogeneous catalysis in many instances.

The structure may be refined and the strength of various proton centres may be estimated in principle by quantum-chemical methods. A semi-empirical calculation has been carried out for the cluster $M_3O_{16}X$ modelling the acid centre (IV), within the framework of the extended Hückel method.[37] The electronic structure of $PMo_{12}O_{40}^{3-}$ has been calculated in terms of the LCAO-MO approximation.[101]

(d) *The formation of acid centres in the salts of heteropolyacids.* Many neutral HPA salts catalyse reactions occurring on Brønsted acid centres and the activity of the salts of certain metals greatly exceeds the activity of the initial acids.[7,64,76,102,103] The neutral salts themselves do not possess an appreciable acidity. This is evident, for example, from the fact that, when pyridine is adsorbed on them, pyridinium ions are not formed and they totally fail to catalyse reactions such as the cracking of cumene and the isomerisation of *o*-xylene, which occur on proton centres, including HPA.[76] It has been established that the salts acquire a strong Brønsted acidity and a high catalytic activity on interaction with the reaction medium. Depending on the nature of the metal cation, one of two mechanisms of the generation of acid centres operates: the hydrolytic[104] or oxidation-reduction[76] mechanisms.

The hydrolytic mechanism is characteristic of metal cations with a high electronegativity (Al^{3+}, La^{3+}, Zn^{2+}, etc.). The Brønsted acid centres are formed as a result of the dissociation of water molecules in the coordination sphere of the metal ion in accordance with the equation

$$M^{n+} + H_2O \rightleftharpoons M(H_2O)^{n+} \rightleftharpoons M(OH)^{(n-1)+} + H^+.$$

The correlation between the catalytic activity and the electronegativity of the metal cation is a sign of the hydrolytic mechanism because the acid dissociation constants of the aquo-complexes are well correlated with the electronegativities.[105] Such correlation has been found in the dehydration of 2-propanol on PMo_{12} salts.[104]

The oxidation-reduction mechanism predominates for salts with metal cations having a fairly high oxidation potential (Ag^+, Cu^{2+}, Pd^{2+}, Pt^{4+}, etc.).[7,76] The acid centres are formed as a result of the reduction of the metal cations by the components of the reaction medium. A typical example is provided by the conversion of methanol into hydrocarbons in the presence of the silver and copper salts of PW_{12}.[7,103] The hydrogen formed as a result of the dehydrogenation of the alcohol then plays the role of the reductant. Traces of H_2 have indeed been detected in the methanol conversion products. The proton centres are formed in accordance with the equations

$$Ag^+ + {}^1/_2H_2 \rightarrow Ag^0 + H^+ ,$$
$$Cu^{2+} + {}^1/_2H_2 \rightarrow Cu^+ + H^+ .$$

The conversion of methanol in the presence of PW_{12} salts has a long induction period, during which the acid centres are produced. When H_2 is introduced into the system, the induction period vanishes. The activity of the salts after treatment with hydrogen at 300 °C exceeds the activity of the initial acid. Small amounts of added O_2 reversibly suppress the catalytic activity of the salt, probably as a result of the reaction:

$$2Ag^0 + 2H + {}^1/_2O_2 \rightarrow 2Ag^+ + H_2O .$$

We may note that, in the hydrolytic formation of acid centres, the catalytic activity of the salts is independent of the presence of H_2 in the system. It is not yet clear why the salts reduced with hydrogen are more active than the initial acids. In our view, this may be accounted for by the activation of the substrate by metal cations or other metal species.

Active catalysts of the conversion of methanol have been prepared by treating with hydrogen the silver salt of PW_{12} deposited on Pd/SiO_2.[66] The mechanism of the formation of the acid catalyst probably involves the dissociation of the hydrogen molecule by metallic palladium. Next, the H atoms, migrating on the surface as a result of spill-over, reduce the silver salt of PW_{12}.

After treatment with hydrogen, the silver and copper salts of PW_{12} catalyse the cracking of cumene and the isomerisation of *o*-xylene.[76] The palladium salt of PW_{12} reduced with hydrogen is an active catalyst of the isomerisation of alkanes.[77] A bifunctional catalyst, incorporating zerovalent palladium and the HPA, is formed in this system via the oxidation-reduction mechanism. The catalytic process involves the dehydrogenation of the alkane on the zerovalent palladium and the subsequent acid skeletal isomerisation. An analogous catalyst has been obtained from a platinum(IV) salt.[66]

(e) *Certain catalytic reactions with participation of heteropolyacids and their salts.* Recently, much attention has been devoted to the synthesis of hydrocarbons from coal in connection with the limited availability of petroleum resources. One of the main aspects of the solution of this problem is the synthesis of hydrocarbons from methanol. Methods have been developed for the conversion of methanol into an artificial liquid fuel containing paraffinic and aromatic hydrocarbons, ranging from C_7 and above, using high-silicon zeolites as catalysts.[106] However, the HPA PW_{12} and SiW_{12} as well as their salts also catalyse the conversion of methanol into hydrocarbons.[2,95,102] A mixture of olefins and alkanes ranging from C_1 to C_7 as well as water and dimethyl ether are formed in the reaction occurring at atmospheric pressure and 250–350°C.

The C_3–C_5 compounds predominate among the hydrocarbons. In contrast to the reaction on zeolites, the yield of compounds above C_7 and aromatic hydrocarbons is very low. This difference is probably due to the molecular sieve effect of zeolites, as a result of which the reaction of hydrocarbons within the zeolite pores is more extensive than on the HPA.

The composition of the products renders HPA unsuitable for the synthesis of motor fuel. However, they are of interest for the selective synthesis from methanol of hydrocarbons such as ethylene and propene. The preferred catalysts for this purpose are the insoluble PW_{12} salts with organic and inorganic cations, which have a large surface area.[99] Vigorous research is being prosecuted on these lines.

The activity of PW_{12} salts in the conversion of methanol decreases in the following sequence (the yields of hydrocarbons, expressed as percentages, at 300 °C are indicated in brackets):[102] Ag(98) > Cu(60) ≅ H(60) > Fe(48) > Al(36) > Pd(26) > La(24) > Zn(13). An analogous series has been obtained for the SiW_{12} salts: Ag(79) > Cu(61) > H(39) > Fe(24) > Al(15) > Zn(7) > La(2). The proportions of different hydrocarbons in the methanol conversion products on HPA and their salts are the same,[102] which indicates that a common mechanism of the catalytic process operates. It has been suggested that the conversion of methanol occurs in the bulk of the catalyst via a carbonium ion mechanism.[2,95]

The alkylation of aromatic compounds by olefins is a large-scale industrial process. Tungsten HPA, which catalyse this reaction, are much more active than the usual heterogeneous catalysts (aluminosilicates, H_3PO_4/SiO_2, etc.). The optimum efficiency in the alkylation of benzene by propene has been achieved when the HPA was used at 150 °C and a pressure of 15 atm, while in the case of the aluminosilicate catalyst the highest efficiency was at 300 °C and 30 atm.[71]

The industrial synthesis of t-butyl methyl ether, an additive which increases the octane number of motor fuel, is carried out by the reaction of isobutene with methanol in the liquid phase in the presence of a cation-exchange resin:[107]

$$(CH_3)_2C{=}CH_2+CH_3OH\rightarrow(CH_3)_3COCH_3\ .$$

HPA catalyse this reaction in both liquid and vapour phases.[63, 108–110] The activity of solid acids in the vapour-phase synthesis of TBME at 90 °C decreases in the sequence $H_3[PW_{12}O_{40}] \cong H_4[SiW_{12}O_{40}] > H_3[PMo_{12}O_{40}] \cong$ zeolite HY > SiO_2–Al_2O_3 > $H_4[SiMo_{12}O_{40}]$. Alumina is completely inactive.[110]

The PW_{12} and SiW_{12} acids and their silver and copper salts, deposited on activated charcoal (30 wt.%), ensure a process selectivity of 100% at 50–110 °C for degrees of conversion of isobutene in the range 30–40%.[64] The activity of the salts increases after treatment with hydrogen. The salt $Ag_3[PW_{12}.O_{40}]$, reduced with hydrogen at 200–300 °C, is more active than $H_3[PW_{12}O_{40}]$. The rate of reaction increases with increase in the concentration of $Ag_3[PW_{12}O_{40}]$ on the carrier to 50 wt.% and then remains constant. The yield of TBME increases with decrease of temperature as a consequence of the displacement of the reaction equilibrium towards the product. At 50 °C and for the volume ratio methanol/isobutene = 1, the yield of TBME on the 30% $Ag_3[PW_{12}O_{40}]/C$ catalyst was 76% for a selectivity of 100%. This catalyst is three times more active than the industrial catalyst (the Amberlite 15 cation-exchange resin)[64] and 100 times more active than aluminosilicates.[5]

Using solid HPA, certain traditional liquid-phase processes can be carried out in the vapour phase. An excellent example is provided by the nitration of benzene. The industrial process involving nitration with a mixture of concentrated nitric and sulphuric acids was developed a very long time ago but hitherto problems of the processing of the acid employed and of the waste water have not been finally solved. In the presence of the $H_3[PW_{12}O_{40}]/SiO_2$ catalyst benzene is nitrated with nitrogen dioxide in the vapour phase at 270 °C.[66] The reaction takes place in accordance with the equation

$$C_6H_6+NO_2\rightarrow C_6H_5NO_2+NO+H_2O\ .$$

Dinitrobenzene is not formed. The rate of the process increases with increase in the $H_3[PW_{12}O_{40}]$ content to 30% and then remains constant. The yield of nitrobenzene, reaching 56%, increases in the presence of water vapour, which probable stabilises the HPA structure.

The number of examples illustrating the high efficiency of HPA catalysts could be greatly increased. In many instances they are more active than the usual acid catalysts and satisfy to a greater extent the energy and ecological requirements which must be met by modern chemical industry.

---o0o---

Extensive information about the catalytic properties of HPA has now accumulated. Many new catalytic processes have been developed and some of them have already begun to be used in industry. However, much still remains to be done both as regards the development of the theoretical principles of catalysis by HPA and as regards its practical application.

HPA are extremely interesting as model objects for the study of the elementary steps in heterogeneous acid catalysis. Together with the experimental methods, quantum-chemical calculations in terms of the cluster approximation can be used effectively for this purpose. The behaviour of solid HPA as the "pseudo-liquid phase" leads to unique possibilities for the study of the relation between homogeneous and heterogeneous catalysis.

The synthesis and study of the catalytic properties of new HPC, incorporating different elements as central atoms, ligands, and outer-sphere cations, constitutes an urgent problem. An interesting application of HPC is bifunctional catalysis with simultaneous transfer of protons and electrons, which has so far been little investigated. The employment of HPC as catalysts of a wide variety of processes in fine organic synthesis, including asymmetric synthesis, is promising. Because of the high price of the products, the gain in selectivity in this instance as a result of the introduction of the more effective catalyst frequently greatly exceeds the expenditure on the catalyst.

During the preparation of the review for the press, the VIIIth Japanese–Soviet Seminar on Catalysis, "Catalysis by New Materials", was held in Tokyo. Studies on catalysis by HPA, including the practical utilisation of these catalysts, were widely represented.[111–116] At the present time, tungsten HPA are used in Japan in the industrial manufacture of 2-propanol, 2-butanol, and t-butyl alcohol by the liquid-phase hydration of the corresponding olefins. A process leading to the polymerisation of tetrahydrofuran in the presence of $H_3PW_{12}O_{40}$ has been developed:[115]

n  $+ H_2O \rightarrow HO{-}[{-}(CH_2)_4{-}O{-}]_n{-}H$.

The construction of a factory in Japan for the application of this process is being completed.

The vapour-phase oxidation of methacrolein to methacrylic acid in the presence of a heterogeneous catalyst based on PMo_{12} is used on a large scale (80 000 tonnes annually).[111] Thus the industrial application of HPA catalysts abroad is increasing at a high rate, which confirms the urgent need to develop this field in our country.

Organic Compounds of Polyvalent Iodine-Derivatives of Iodosobenzene

E.B.Merkushev (deceased)

The review describes the latest advances in the chemistry of aliphatic and aromatic iodoso-compounds, iodosohalides, iodosocarboxylates, and the derivatives of μ-oxobisacyloxy(aryl)iodine. A separate section is devoted to polymers with tervalent iodine.

The bibliography includes 300 references.

I. INTRODUCTION

Having passed chlorine through a solution of iodobenzene in chloroform in 1886, Willgerodt[1,2] obtained, instead of the expected substitution product, the addition product $PhICl_2$, which was called phenyl iodosochloride in accordance with one of the then current nomenclatures. During the period which has elapsed since then, a wide variety of organic compounds containing iodine in the tervalent or quinquevalent state have been synthesised and their chemical properties have been investigated.

During the 1950's–1960's extensive studies were carried out on iodonium salts by Beringer in the USA and Nesmeyanov, Vanags, and Neilands in the USSR. Since the 1970's, the chemistry of aryl iodosocarboxylates has been developing successfully as a result of the efforts of scientists from many countries.

Despite the fact that the number of publications on the chemistry of organic compounds of polyvalent iodine is relatively small, nevertheless they have been covered in chronological order by fairly large numbers of periodically published reviews. The studies up to 1914 have been described in Willgerodt's monograph,[3] those published up to 1942 are dealt with in Sandin's review[2] already mentioned, and the studies up to 1965 are surveyed in Banks's review.[4] The data on all organic compounds of polyvalent iodine known up to 1955 are presented in the form of Tables in the review by Beringer and Gindler.[5] At the present time this field of chemistry has developed so widely that it is not possible to describe its present state in a single journal publication. There exists a brief review on iodonium salts[6] and one of the chapters of a monograph[7] is devoted to organic compounds of polyvalent iodine—mainly iodonium salts. The chemistry of aryl iodosocarboxylates is dealt with in a recently published review[8] and their application as oxidants is described in a monograph.[9] A review[10] is devoted to the use of polyvalent iodine compounds (mainly organic compounds) in organic chemistry. Interesting data on the chemistry of iodonium salts can be found also in other communications[11,12] and information about the chemistry of aryl iodosocarboxylates is available in books.[13,14]

The majority of organic compounds of polyvalent iodine belong to one of three large groups: the iodonium salts $R_2I^+X^-$, the iodonium ylides $R-\overset{+}{I}-\overset{-}{E}$ ($E = C$ or N), and derivatives of iodosobenzene PIY_2 ($Y_2 = O$ or $Y = Cl$, F, or RCO_2).† The present review is devoted to the last group of compounds. The relation between various organic compounds of polyvalent iodine is illustrated in Scheme 1 for phenyl derivatives.

II. IODOSO-COMPOUNDS

1. Synthesis

Usually only the iodoso-derivatives of aromatic and heteroaromatic compounds and to a lesser extent vinyliodoso-compounds are relatively stable.[2] Among derivatives containing an iodine atom linked to an *sp*^{3}-carbon atom, only perfluoroalkyliodoso-derivatives are stable.

The iodoso-group can be introduced into certain arenes with electron-accepting substituents using the reaction of the latter with iodosyl sulphate:[16,17]

$$ArH \xrightarrow{(IO)_2SO_4/H_2SO_4} ArIO$$

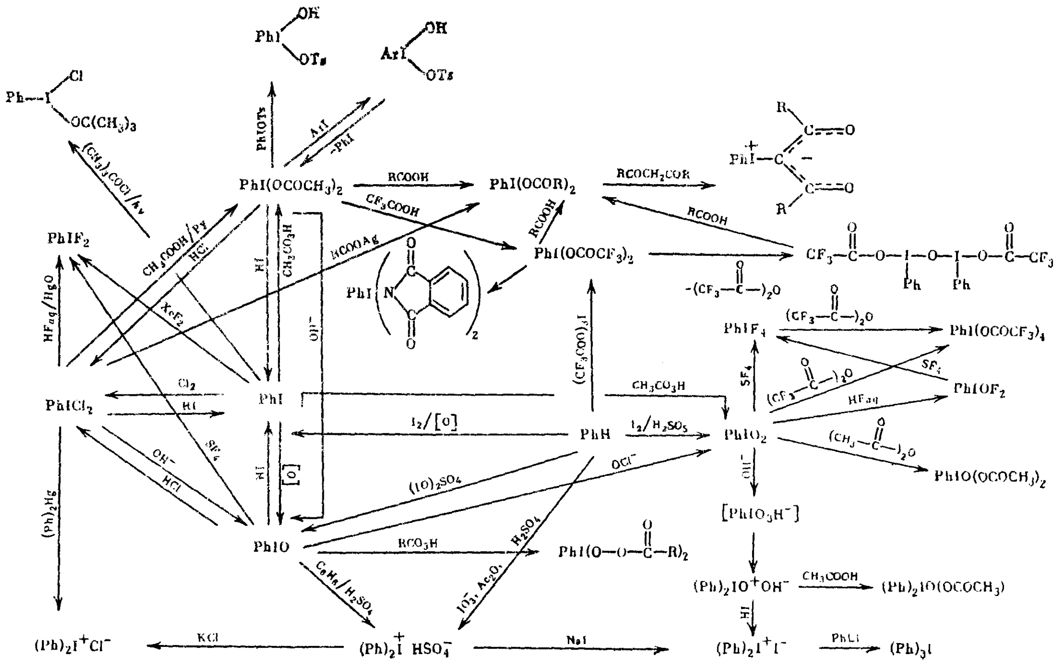
Among the methods based on the hydrolysis of phenyl iodosochloride or phenyl iodosoacetate,[18,19] preference should be given to the latter because it is less laborious and the initial compound is stable on storage. Iodosobenzene can be prepared by the reaction of phenyl iodosochloride with silver oxalate, carbonate, or nitrate in acetonitrile.[20]

A number of specific methods for the synthesis of perfluoroalkyliodoso-derivatives have been proposed—for example the ozonolysis of perfluoroiodoalkanes,[21] the hydrolysis of the trifluoroacetates of iodosoperfluoroalkanes,[22] or

---

†The existence of iodosobenzene in the polymeric form $(PhIO)_n$ has been reported.[15]

Scheme 1



the interaction of perfluoroalkyl iodosofluorides with silicon dioxide.[21]

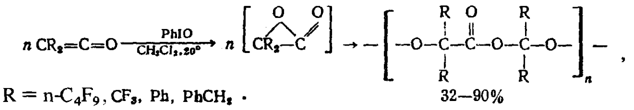
The stability of the iodoso-compounds of all classes is low; they disproportionate on storage:[4,21]

$$2R{-}IO \rightarrow R{-}I + R{-}IO_2\ ,$$
$$R = Ar,\ C_nF_{2n-1}\ .$$

2. Properties

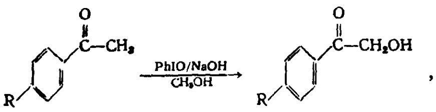
Iodoso-compounds have been used mainly as oxidants. Scant information about the early studies may be found in reviews.[2,4] A number of new reactions involving oxidation by iodosobenzene have been described in a series of communications.[23–25]

Fruitful researches into the oxidation of compounds of a wide variety of classes by iodosobenzene in an alkaline medium were initiated in the 1980's. Ketens give rise to unstable α-lactones, which polymerise at the instant of formation:[26]



R = n-C_4F_9, CF_3, Ph, $PhCH_2$. 32—90%

Acetophenones (I) are oxidised to ω-hydroxyacetophenones (II):[27]

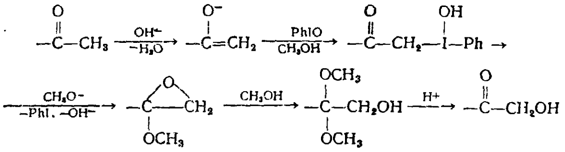


(I) (II), 45—71%

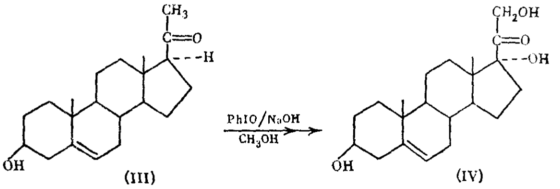
R=H, CH_3, OCH_3, F, Cl, Br, I, NO_2 .

2,6-Diacetylpyridine is oxidised by phenyl iodosoacetate (PIA) in an alkaline medium to 2,6-di(hydroxyacetyl)pyridine in 63% yield.[27]

The acetyl group can be converted to the hydroxy-acetyl group via the following scheme:[28,29]



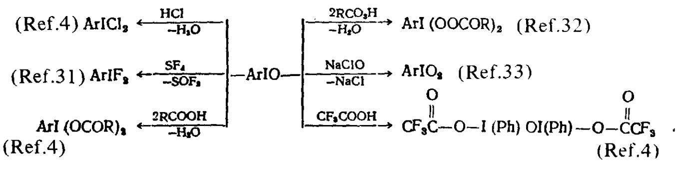
The reaction discovered made it possible to transform the steriod derivative (III) into the derivative (IV) with a high yield:[29,30]



(III) (IV)

Iodosobenzene converts tetracyanoethylene into the corresponding epoxide in 74% yield.[26]

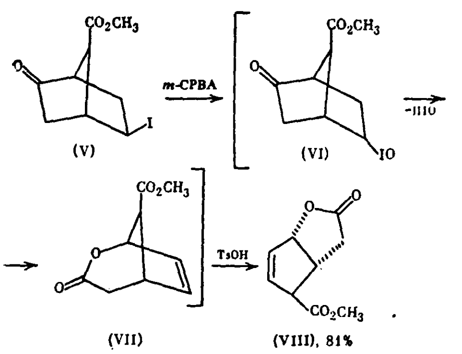
Iodosoarenes can be readily converted into organic compounds of polyvalent iodine belonging to different classes:[4,31–33]



(a) Oxidation Reactions of Alkyl Iodides#, §

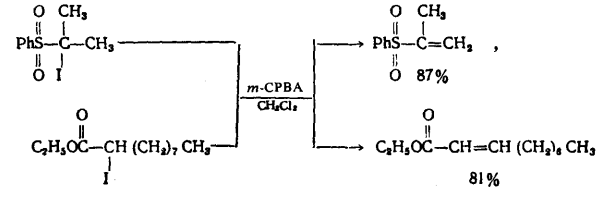
Alkyl iodides are resistant to the action of $KMnO_4$, H_2O_2, or O_3 but under the influence of certain oxidants, usually peracids, they are converted into esters or ethers, vicinal diesters, α-iodoesters, alcohols, ketones, or oxirans.[37–40] The mechanisms of these reactions have not so far been ultimately elucidated but the intermediate formation of aliphatic iodoso-derivatives is usually postulated.

The reaction involving the conversion of the bicyclic iodide (V) under the influence of *m*-chloroperbenzoic acid (m-CPBA) to the lactone (VIII) was described in 1977. The lactone is probably formed via the iodoso-derivative (VI) which is converted into the unsaturated bicyclic lactone (VII) by splitting off HIO:[41]

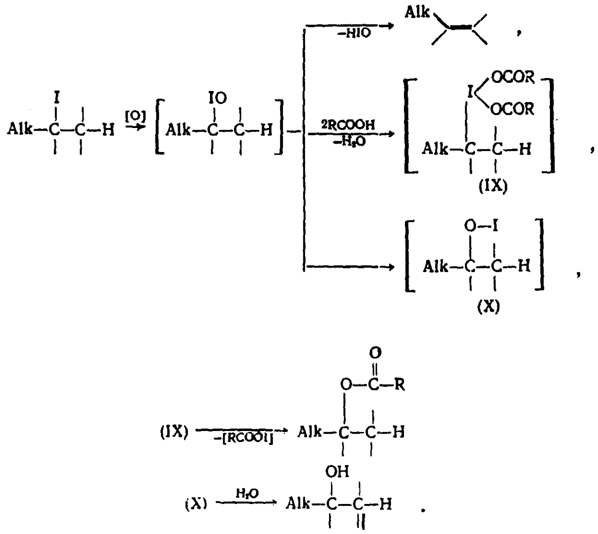


(V) (VI) (VII) (VIII), 81%

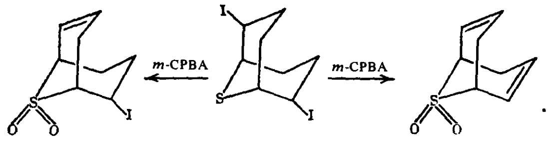
Many details of the reaction of alkyl iodides with peracid were elucidated by Reich and Peake.[42] In a neutral medium, primary alkyl iodides are oxidised by *m*-CPBA to alcohols with a satisfactory yield. Alkyl iodides having electron-accepting groups in the α-position converted into alkenes:



In all cases the initial oxidation products are iodoso-compounds whose subsequent fate depends on the structure of the alkyl iodide. The iodoso-compound can split off hypoiodous acid (*syn*-elimination) or can react with the organic acid to form the iodosocarboxylate (IX), which is not isolated and is converted further into an ester. A rearrangement of the iodoso-compound via a radical or ion pair into the alkyl hypoiodite (X) with subsequent hydrolysis to an alcohol is also possible:

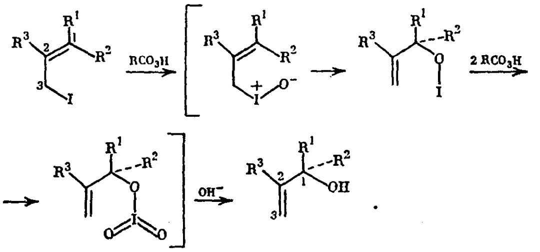


On oxidation with *m*-CPBA, the bicyclic sulphide (XI) gives rise to the unsaturated sulphones (XII) or (XIII) depending on the reaction conditions:[43]

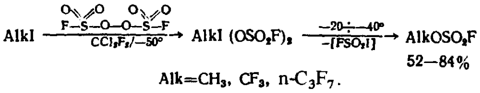


(XII), 62% (XI) (XIII), 70%

Allyl iodides are oxidised by peracids to allyl alcohol via the intermediate formation of derivatives of tervalent and quinquevalent iodine {the reaction involves a [2,3]sigmatropic rearrangement}:[44]



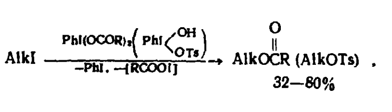
Alkyl iodides are converted into alkyl fluorosulphates under the influence of peroxydisulphuryl difluoride:[45]



$$AlkI \xrightarrow[CCl_2F_2/-50^\circ]{F-SO_2-O-O-SO_2-F} AlkI(OSO_2F)_2 \xrightarrow[-[FSO_2I]]{-20 \div -40^\circ} \underset{52-84\%}{AlkOSO_2F} ;$$

$$Alk=CH_3,\ CF_3,\ n\text{-}C_3F_7.$$

The reactions of alkyl iodide with phenyl iodosocarboxylates or phenyl iodosohydroxytosylate lead to esters:[46,47]



$$AlkI \xrightarrow[-PhI,\ -[RCOOI]]{PhI(OCOR)_2\left(PhI\begin{smallmatrix}OH\\OTs\end{smallmatrix}\right)} \underset{32-80\%}{AlkOC(=O)R\ (AlkOTs)} .$$

Esters are also formed when alkyl iodides are oxidised by derivatives of μ-oxobisacyloxy(aryl)iodine.[33,47]

#See Zefirov and co-workers.[34–36]

§In certain studies such reactions are referred to by the term "oxidative deiodination". It cannot be regarded as apt since the reaction RI → RH is usually associated with the term "deiodination". It is probably better to call these reactions "oxidative substitution of an iodine atom".

When alkyl iodides are oxidised with iodine pentafluoride, aldehydes are produced,[48] oxidation with phenyl iodosochloride affords alkyl chlorides,[1] and oxidation with iodine tris(trifluoroacetate) gives rise to alkyl trifluoroacetates.[49]

Alkenes interact with iodine trichloride to form 1,2-dichloroalkanes, which are probably formed via unstable alkyl iodosochlorides.[50]

The oxidation of alkyl iodides in the presence of salts of acids whose anions are superweak nucleophiles leads to the replacement of iodine by the anion of these acids. The reaction described probably proceeds via a stage involving the formation of carbonium ion intermediates:[51,52]

$$\mathrm{CH_3(CH_2)_nI} \xrightarrow[\mathrm{CH_2Cl_2,\ -78\div+50^\circ}]{[\text{oxidant}]/\mathrm{M^+OR^-}} \underset{20\text{—}70\%}{\mathrm{CH_3(CH_2)_nOR}}\ ;$$

$\mathrm{R{=}CH_3,\ CF_3,\ }p\text{-}\mathrm{CH_3C_6H_4}.$

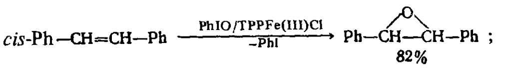
It is at present difficult to estimate the synthetic value of reactions involving the oxidative substitution of the iodine atom in alkyl iodides, because many communications are only preliminary and do not give experimental details. However, the value of such reactions is apparently very high; for example, the reaction of methylene iodide with nitronium fluoroborate in the presence of tetrabutylammonium perchlorate results in the formation of methylene bisperchlorate, otherwise difficult to obtain, in nearly quantitative yield.[34]

For the biological oxidation of alkyl halides, including alkyl iodides, see Macdonald et al.[53]

(b) Catalytic Oxidation¶

There exists a large group of oxidation reactions in which iodosobenzene is smoothly involved only in the presence of various metal-containing catalysts.

The ability of iodosobenzene to hydroxylate organic compounds in the presence of cytochrome P-450 has been demonstrated.[55,56] Various metal-containing porphyrins are simple models of the active centre of cytochrome P-450. The ease of oxygen transfer from iodosobenzene to organic substrates in the presence of porphyrins containing iron, chromium, or manganese has been demonstrated.[57-61] It is difficult to predict whether these reactions will find applications in preparative organic chemistry, because studies carried out hitherto have been devoted mainly to the elucidation of the mechanism of the enzyme action. However, many reactions take place extremely stereoselectively; for example *cis*-stilbene is epoxidised in a high yield, while the *trans*-isomer is almost inert:



$$cis\text{-}\mathrm{Ph{-}CH{=}CH{-}Ph} \xrightarrow[\mathrm{-PhI}]{\mathrm{PhIO/TPPFe(III)Cl}} \underset{82\%}{\mathrm{Ph{-}\overset{\frown O\frown}{CH{-}CH}{-}Ph}}\ ;$$

TPPFe(III)Cl = chloro(5,10,15,20-tetraphenylprophyrinato)iron.

There is apparently no need to use the fairly complex catalysts mentioned above. The ability of iodosobenzene to oxidise readily alcohols to aldehydes and ketones and disubstituted alkynes to α-dicarbonyl compounds at room temperature in methylenechloride in the presence of $\mathrm{RuCl_2{-}P(Ph)_3}$ has been demonstrated.[62-64]

In the presence of iron-containing porphyrins, iodosobenzene oxidises sulphides to sulphoxides.[65,66] Certain sulphoxides can be oxidised by this system to the corresponding sulphones.

III. IODOSOHALIDES

1. Iodosochlorides

(a) Synthesis

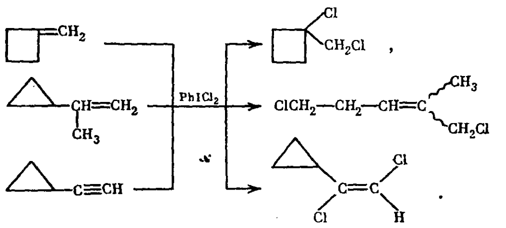
On treatment with chlorine in a solvent, aryl iodides give rise to aryl iodosochlorides.[4] Vinyl iodides are also capable of forming vinyl iodosochlorides. For example, *trans*-diiodoethylene is converted into *trans*-iodovinyl iodosochloride.[67] *trans*-Chlorovinyl iodosochloride can be obtained in a high yield from acetylene.[67-69]

Aliphatic iodosochlorides are as a rule unstable and can be obtained only at low temperatures.[67] The iodosochlorides derived from alkyl iodomethyl sulphones proved to be unexpectedly stable.[70,71]

(b) Chlorination

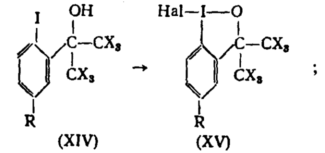
Aryl iodosochlorides are mild chlorinating agents and in solution are able to chlorinate alkenes on thermal or photochemical initiation with formation of vicinal chloride. The reaction mechanism is complex. The reaction can proceed via both radical and ionic mechanisms.[72,73] When alkanes are chlorinated, the tertiary carbon atom is attacked preferentially.[74]

Unsaturated hydrocarbons with cycloalkyl substituents produce high yields of dichlorides.[75,76] It is of interest to note that the trimethylene ring is attacked preferentially in 2-cyclopropylpropene:



Steroid derivatives are also chlorinated by phenyl iodosochloride.[77-79] It has been shown that there is a possibility of the selective halogenation of steroid alcohols with subsequent introduction of a double bond using iodosochlorides based on carboxylic acids having the general formula $\mathrm{Cl_2I.(C_6H_4)_nCOOH}$ (n = 0–4), joined to the steroid molecules by ester linkages.[80] The reaction of ethers with phenyl iodosochloride affords the α-chloro-derivatives, while molecular chlorine usually leads to αα′-dichloro-derivatives.[81] Molecular chlorine converts diazoketones into resins, but phenyl iodosochlorine produces geminal dichlorides.[82] The use of phenyl iodosochloride for the chlorination of triphenylphosphine-acylmethylenes has been described.[83,84]

The iodine-containing alcohols (XIV) have been converted into halogeno-iodinanes (XV),[85] which are convenient reagents for benzyl and allyl halogenation:[85]



(XIV) (XV)

R=H, CH₃; X=H, F; Hal=Br, Cl, F .

Numerous studies have been made of the influence of polar effects on radical chlorination by aryl iodosochlorides,[86-95] but unfortunately much still remains obscure in this problem.

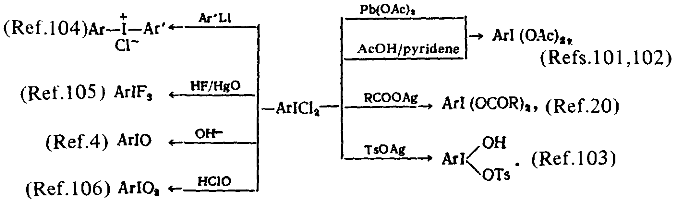
¶For a brief review, see Meunier.[54]

(c) Oxidation

Phenyl iodosochloride in aqueous pyridine converts sulphides and selenides into sulphoxides and selenoxides.[96,97] Phenyl diphenylmethyl sulphide is cleaved by phenyl iodosochloride to benzenesulphenyl chloride and diphenylmethyl chloride.[98] Secondary steroid alcohols are converted into the corresponding ketones in good yields on treatment with the phenyl iodosochloride–pyridine system.[99] The iodosochloride based on 3-iodopyridine is capable of oxidising selectively secondary alcoholic groups in steroid polyalcohols.[100]

(d) Different Reactions

Like iodoso-compounds, aryl iodosochlorides are widely used in the synthesis of various derivatives of polyvalent iodine:[4,20,101–106]

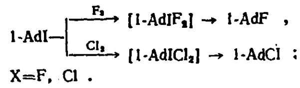


Aryl iodosochlorides are unstable substances which decompose on storage.[4] The main product of the decomposition of phenyl iodosochloride is *p*-chloroiodobenzene.[107]

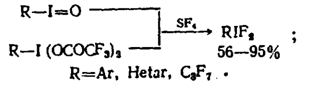
2. Iodosofluorides

(a) Synthesis

They can be obtained from derivatives of univalent or tervalent iodine. Iodosofluorides can be synthesised by fluorinating iodides with elemental fluorine,[108] chlorine trifluoride,[109,110] or xenon difluoride.[111,112] On treatment with molecular fluorine or chlorine, 1-iodoadamantane is converted into 1-fluoro or 1-chloroadamantane via the intermediate formation of iodosohalides, which are not isolated:[113]



Phenyl iodosofluoride was obtained in a high yield by the electrolysis of silver fluorine in acetonitrile in the presence of iodobenzene.[114] Aryl iodosofluorides can be prepared by condensing iodoso-compounds with 48% hydrofluoric acid[115–117] or by treating iodosochlorides with hydrogen fluoride in the presence of mercury(II) oxide.[105] Iodosofluorides can be synthesised most conveniently by the interaction of iodoso-compounds or iodosotrifluoroacetates with sulphur tetrafluoride:[22]

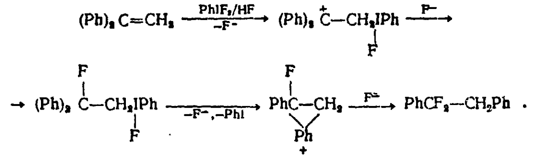


(b) Fluorination

The reaction of 1,1-diphenylethylene with phenyl iodosofluoride affords 1,1-difluoro-1,2-diphenylethane.[105] 3,3-Diphenylprop-2-ene behaves analogously:[118,119]

$$(Ph)_2C{=}CH{-}CH_3 \xrightarrow[CHCl_3,\ -20°]{PhIF_2} PhCF_2{-}CH(Ph){-}CH_3 \ .$$

These reactions probably proceed via a stage involving the formation of a phenonium ion:[120]



Ketones are fluorinated by phenyl iodosofluoride in the α-position.[121] The fluorination of compounds of different classes by methyl iodosofluoride and aryl iodosofluorides has been investigated in a number of studies.[122–125]

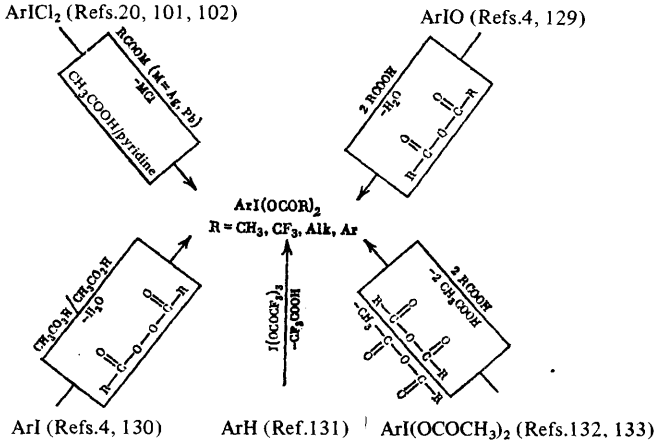
IV. IODOSOCARBOXYLATES

While the nomenclature† of iodonium salts is identical in different countries, the nomenclature of organic compounds of quinquevalent iodine is still in a state of constant development; one would think therefore that the time had come to adopt an unambiguous nomenclature for aryl iodosocarboxylates. For example, more than a dozen different names may be found in the chemical literature of different countries during the last 25 years for the compound $PhI(OCOCH_3)_2$, first synthesised by Willgerodt and called by him phenyl iodoacetate ("Phenyliodacetat").[3] Aryl iodosocarboxylates can probably be named as iodosoesters—derivatives of hydrated iodosoarenes $ArI(OH)_2$, i.e. the compound $PhI.(OCOCF_3)_2$ can be called phenyl iodosotrifluoroacetate, while in the case of partial esters the prefix "hydroxy" is used, for example, the compound PhI(OH)Ts would be called phenyl iodosohydroxytosylate.[127] In the case of mixed iodosoesters, the acid residues forming part of their composition are named alphabetically, i.e. the compound $PhI.(OCOCH_2Br)(OCOCH_2Cl)$ is called phenyliodosobromoacetate-chloroacetate.[128]

1. Synthesis

The scheme presented below illustrates different methods of synthesis of aryl iodosocarboxylates:

Scheme 2

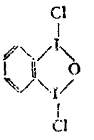


---

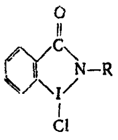
†For the IUPAC recommendations concerning the nomenclature of organic compounds of polyvalent iodine, see Ref.126.

The reaction of arenes with iodine tris(trifluoroacetate) in trifluoroacetic acid or methylene chloride leads to aryl iodosotrifluoroacetates.[131]

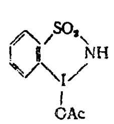
The oxidation of *o*-substituted aryl iodides sometimes leads to the formation of heterocyclic compounds containing tervalent iodine in the ring, for example compounds (XVI)–(XX):[134–139]



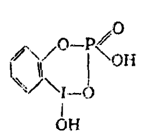
(XVI)



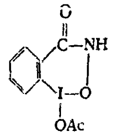
(XVII)



(XVIII)



(XIX)



(XX)

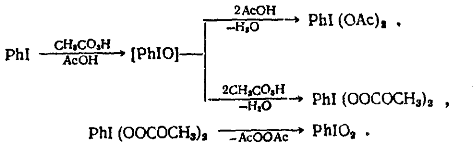
R=CH_3, CH_2CH_2Cl, $CH_2CO_2CH_3$.

It is of interest to note that phenyl iodoso-*p*-nitrophenylbenzoate is formed on decomposition of *p*-nitrophenylbenzoyl peroxide in iodobenzene.[130] Although this reaction takes place at high temperatures, where aryl iodosocarboxylates usually decompose, it is apparently pssible to select mild conditions for the decomposition of acyl peroxides, whereupon these reactions can become a good preparative method of synthesis of aryl iodosocarboxylates.

Phenyl iodosochloride reacts with lead diacetate or silver salts of carboxylic acids to form phenyl iodosocarboxylates in high yields.[20,101] Aryl iodosochlorides with electron-donating substituents give rise to aryl iodosoacetates on treatment with acetic acid in the presence of pyridine.[102]

The condensation of iodoso-compounds with carboxylic acids also leads to aryl iodosocarboxylates.[4] This reaction is complicated by the instability and poor solubility of iodoso-compounds in the usual organic solvents; it is normally carried out in liquid carboxylic acids, whose excess serves as the solvent (the attempts to condense iodosobenzene with solid carboxylic acids in organic solvents were unsuccessful[140,141]). In these reactions the carboxylic acids can be successfully replaced by their anhydrides.[129,142,143]

The availability of aryl iodosoacetates, their stability on storage, and their ready solubility have made these compounds key reagents in the synthesis of various aryl iodosocarboxylates. Aryl iodosoacetates can be prepared in high yields by oxidising aryl iodides with 30% H_2O_2 in acetic anhydride[144] or with 40% peracetic acid and acetic acid.[145] When iodobenzene is oxidised with the latter reagent, iodoxybenzene may be formed.[146] The mechanism of this process is not entirely clear; iodoxybenzene may be formed on decomposition of the peroxy-compound arising as a result of the condensation of iodosobenzene with peracetic acid:[147]



The exchange reaction of aryl iodosoacetates with substituted benzoic acids can serve as a preparative method of synthesis of the corresponding benzoates.[148,149] Phenyl iodosocarboxylates can be obtained by the exchange reaction between the phenyl iodoso-trifluoroacetate (PITFA) and the sodium salts of carboxylic acid in acetonitrile.[150]

When the exchange reaction between aryl iodosoacetates or aryl iodosotrifluoroacetates and carboxylic acids was carried out in high-boiling solvents at a reduced pressure, it became a universal procedure, which permitted the synthesis of a large series of iodosocarboxylates containing the residues of aliphatic, aromatic, and heterocyclic acids as well as the residues of acylated aminoacids[132] (Table 1):

$$PhI(OAc)_2 \xrightarrow[-2AcOH]{2RCOOH/C_6H_4Cl} PhI(OCOR)_2 .$$

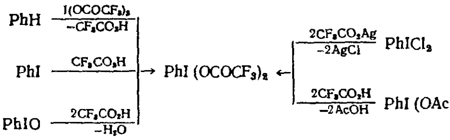
Table 1. Phenyl iodosocarboxylates $PhI(OCOR)_2$.[132]

R	Yield, %	R	Yield, %
Ethyl	72	*o*-Iodophenyl	32
Propyl	81	*o*-Phenylphenyl*	96
Isopropyl	82	*p*-Methoxyphenyl*	83
t-Butyl	82	*p*-Nitrophenyl	96
Diphenylmethyl	85	3,5-Dinitrophenyl	98
Fluoromethyl	91	*o*-Acetoxyphenyl**	62
Chloromethyl	94	*o*-(2-Formylphenyl)phenyl**	58
Trichloromethyl	82	4-Fluorenonyl**	98
2,4-Dichlorophenoxymethyl	92	2-Furyl	60
Phenyl	96	*N*-Benzoylglycyl	92
o-Bromophenyl	66	*N*-Benzoyl-DL-alanyl	96

*The solvent used for the exchange reaction was o-dichlorobenzene.

**Solvent–nitrobenzene.

The methods of synthesis of two phenyl iodosocarboxylates, namely $PhI(OCOCF_3)_2$ and PhI(OH)OTs, which have become in recent years multipurpose reagents for organic synthesis, merit special consideration. Phenyl iodosotrifluoroacetate can be prepared from benzene, iodobenzene, phenyl iodosochloride, and phenyl iodosoacetate (PIA):[4,20,131,132,151]



The best of these methods involves the exchange reaction of phenyl iodosoacetate with trifluoroacetic acid. It occurs on simple recrystallisation of PIA from warm (but not boiling) trifluoroacetic acid.[132,151]

Phenyl iodosohydroxytosylate (PIHT) can be prepared by condensing silver tosylate with phenyl iodosochloride or by the exchange reaction of toluene-*p*-sulphonic acid with phenyl iodosoacetate.[103,127] The latter method is more convenient.

2. Oxidation Reactions

All the numerous reactions of aryl iodosocarboxylates with organic compounds can be divided into two large groups. The first group embraces reactions during which aryl iodosocarboxylates are reduced to iodoarenes and various oxidation products not containing iodine are formed from organic substrates. Reactions during which aryl iodosocarboxylates are not reduced and the compounds formed contain a tervalent iodine atom may be assigned to the second group.

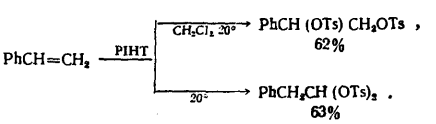
Almost all the oxidation reactions in the first group can be subdivided into three subgroups. The first includes reactions of aryl iodosocarboxylates with various acids (OH, NH, and SH- etc. acids). Reactions of aryl iodosocarboxylates with unsaturated compounds, usually leading to acyloxylation products, belong to the second sub-group. The third subgroup comprises the oxidation reactions of compounds containing heteroatoms (S, P, Se) with formation of the corresponding oxides.

The reactions of the second group are subdivided into two subgroups: the formation of iodonium salts and iodonium ylides.

(a) Alkenes

When alkenes react with PIA, PITFA, or PIHT, vicinal diesters are formed.[140,152–154]

On treatment with PIHT, styrene is converted either into 1-phenyl-1,2-di(tosyloxy)ethane or into 2-phenyl-1,1-di(tosyloxy)ethane depending on the reaction conditions:[154]



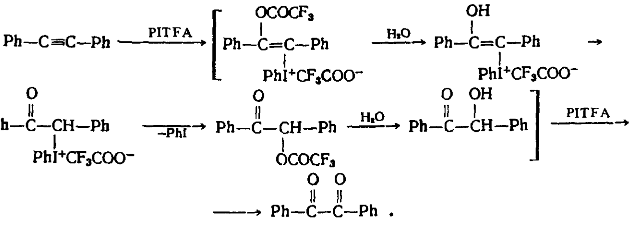
$$\mathrm{PhCH{=}CH_2} \xrightarrow{\text{PIHT}} \begin{cases} \xrightarrow{\mathrm{CH_2Cl_2},\ 20^\circ} \mathrm{PhCH(OTs)CH_2OTs}\ , & 62\% \\ \xrightarrow{20^\circ} \mathrm{PhCH_2CH(OTs)_2}\ . & 63\% \end{cases}$$

Propene reacts with the PIA/I_2 system to form 2-acetoxy-1-iodopropane in a high yield.[24] The reaction of this system with keten leads to the mixed anhydride of acetic and iodoacetic acids, which can be converted into iodoacetic acid or its anhydride.[155] On treatment with the PIA/$(CH_2)_3SiN_3$ system, styrene is converted into an azide:[156]

$$\mathrm{Ph{-}CH{=}CH_2 \xrightarrow{PIA/(CH_3)_3SiN_3} Ph{-}\overset{\overset{O}{\|}}{C}{-}CH_2N_3}\ .$$

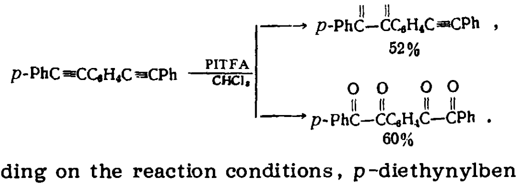
(b) Alkynes

Diarylacetylenes are inert when acted upon by both PIA and lead tetraacetate.[157] However, PITFA oxidises tolanes with electron-donating and not very strong electron-accepting substituents in moist chloroform to the corresponding benzils in good yields.[158] The reaction probably proceeds with the intermediate formation of vinyl- and alkyl-iodonium salts:[158]



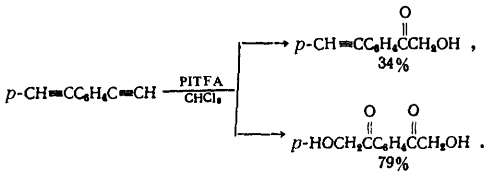
$$\mathrm{Ph{-}C{\equiv}C{-}Ph \xrightarrow{PITFA} \left[Ph{-}\overset{OCOCF_3}{\overset{|}{C}}{=}\underset{\underset{PhI^+CF_3COO^-}{|}}{C}{-}Ph \xrightarrow{H_2O} Ph{-}\overset{OH}{\overset{|}{C}}{=}\underset{\underset{PhI^+CF_3COO^-}{|}}{C}{-}Ph \rightarrow Ph{-}\overset{O}{\overset{\|}{C}}{-}\underset{\underset{PhI^+CF_3COO^-}{|}}{CH}{-}Ph \xrightarrow{-PhI} Ph{-}\overset{O}{\overset{\|}{C}}{-}\underset{\underset{OCOCF_3}{|}}{CH}{-}Ph \xrightarrow{H_2O} Ph{-}\overset{O}{\overset{\|}{C}}{-}\overset{OH}{\overset{|}{CH}}{-}Ph \right] \xrightarrow{PITFA} Ph{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}Ph}\ .$$

We have shown that PITFA oxidises 1,4-di(phenylethynyl)benzene to 4-phenylglyoxaloyltolane or to 1,4-di(phenylglyoxaloyl)benzene:[159]



$$p\text{-}\mathrm{PhC{\equiv}CC_6H_4C{\equiv}CPh} \xrightarrow[\mathrm{CHCl_3}]{\text{PITFA}} \begin{cases} p\text{-}\mathrm{Ph\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}C_6H_4C{\equiv}CPh}\ , & 52\% \\ p\text{-}\mathrm{Ph\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}C_6H_4\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}Ph}\ . & 60\% \end{cases}$$

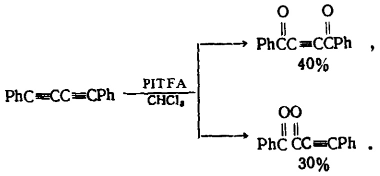
Depending on the reaction conditions, *p*-diethynylbenzene is converted into 1-ethynyl-4-hydroxyacetylbenzene or into 1,4-di(hydroxyacetyl)benzene:[160]



$$p\text{-}\mathrm{CH{\equiv}CC_6H_4C{\equiv}CH} \xrightarrow[\mathrm{CHCl_3}]{\text{PITFA}} \begin{cases} p\text{-}\mathrm{CH{\equiv}CC_6H_4\overset{O}{\overset{\|}{C}}CH_2OH}\ , & 34\% \\ p\text{-}\mathrm{HOCH_2\overset{O}{\overset{\|}{C}}C_6H_4\overset{O}{\overset{\|}{C}}CH_2OH}\ . & 79\% \end{cases}$$

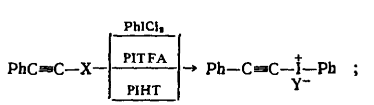
It must be emphasised that at present PITFA is the only reagent capable of oxidising selectively one triple bond in the molecules of polyacetylenic compounds.

Diphenylbutadiyne is oxidised by PITFA to a mixture of dibenzoylacetylene and phenyl(phenylglyoxaloyl)acetylene:[161]



$$\mathrm{PhC{\equiv}CC{\equiv}CPh} \xrightarrow[\mathrm{CHCl_3}]{\text{PITFA}} \begin{cases} \mathrm{Ph\overset{O}{\overset{\|}{C}}C{\equiv}C\overset{O}{\overset{\|}{C}}Ph}\ , & 40\% \\ \mathrm{Ph\overset{O}{\overset{\|}{C}}\overset{O}{\overset{\|}{C}}C{\equiv}CPh}\ . & 30\% \end{cases}$$

Phenylacetylene reacts with phenyl iodosochloride, PITFA, or PIHT to form acetylenic iodonium salts:[159,162,163]



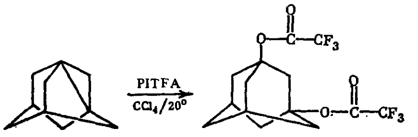
$$\mathrm{PhC{\equiv}C{-}X} \xrightarrow{\mathrm{PhICl_2}\ /\ \text{PITFA}\ /\ \text{PIHT}} \mathrm{Ph{-}C{\equiv}C{-}\overset{+}{I}{-}Ph\ ;}\quad \mathrm{Y^-}$$

X=Li, Y=Cl; X=H, Y=CF_3CO_2; X=H, Y=TsO .

The stability of such salts increases with decrease of the nucleophilicity of the anion. Disubstituted acetylenes react with the PIA/I_2 system to form *trans*-β-acetoxy-α-iodoalkenes, which readily hydrolyse to α-hydroxyketones.[164]

(c) Cyclopropanes

Various cyclopropylphenyl iodosoacetates were synthesised for the first time in 1979.[165] The three-membered ring in phenylcyclopropane is opened by PITFA with formation of 1-phenyl-1,3-bis(trifluoroacetoxy)propanes.[166] The same reaction takes place also with PIA in a chloroform–trifluoroacetic acid mixture, in which PITFA is formed *in situ*.[167] The strained 1,3-dehydroadamantane (XXI) interacts with PITFA to form the unstrained 1,3-bis-(trifluoroacetoxy)-adamantane (XXII) in a high yield:[168]



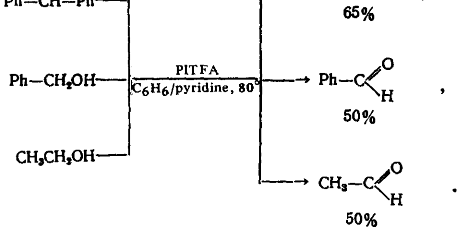
(XXI) (XXII)

(d) Polynuclear Condensed Hydrocarbons

9,10-Dihydroanthracene is dehydrogenated by PITFA or phenyl iodosophthalimidate to anthracene.[151,169] PITFA can oxidise anthracene further to a mixture of 1,2- and 9,10-anthraquinones.[170]

(e) Alcohols, Glycols, Phenols, and Hydroperoxides

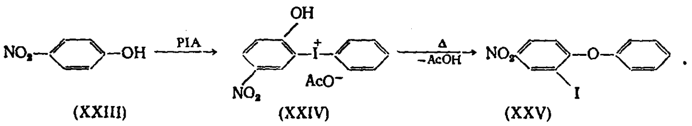
Alcohols of different classes react with PIA or PITFA, being oxidised to carbonyl compounds:[4,151]



$$\left.\begin{matrix} \mathrm{Ph{-}\overset{OH}{\overset{|}{C}H}{-}Ph} \\ \mathrm{Ph{-}CH_2OH} \\ \mathrm{CH_3CH_2OH} \end{matrix}\right\} \xrightarrow[\mathrm{C_6H_6/pyridine},\ 80^\circ]{\text{PITFA}} \begin{cases} \mathrm{Ph{-}\overset{O}{\overset{\|}{C}}{-}Ph}\ , & 65\% \\ \mathrm{Ph{-}CHO}\ , & 50\% \\ \mathrm{CH_3{-}CHO}\ . & 50\% \end{cases}$$

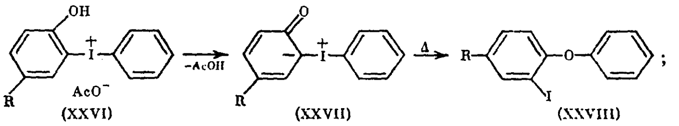
Phenyl iodosoacetate oxidises alcohols in the form of halogenomagnesium alkoxides generated *in situ* from the alcohols and n-propylmagnesium bromide.[171]

The reaction involving the oxidation of phenols by PIA yields a complex mixture of products, in which quinones and o-acetoxyphenols predominate.[172] 4-Nitrophenol (XXIII) is converted into 2-hydroxy-5-nitrodiphenyliodonium acetate (XXIV), which can rearrange on heating via a reaction having an unknown mechanism into 2-iodo-4-nitrophenyl phenyl ether (XXV):[148]



(XXIII) (XXIV) (XXV)

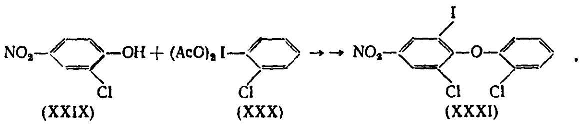
The oxidation of p-ethoxycarbonyl-, p-formyl-, or p-acetylphenols proceeds analogously. The iodonium salts (XXVI), formed initially, split off an acetic acid molecule and are converted into the iodonium ylides (XXVII), which can rearrange to the diphenyl ethers (XXVIII):[173]



(XXVI) (XXVII) (XXVIII)

R = NO_2, $COOC_2H_5$, CHO, $COCH_3$.

2-Chloro-4-nitrophenol (XXIX) is oxidised by 2-chlorophenyl iodosoacetate (XXX), forming 2-chlorophenyl 2-chloro-6-iodo-4-nitrophenyl ether (XXXI):[174]

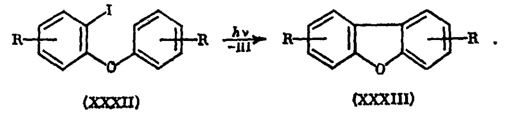


(XXIX) (XXX) (XXXI)

However, 2,6-dichloro-4-nitrophenol is oxidised by PIA to 2,6-dichloro-1,4-benzoquinone.[148]

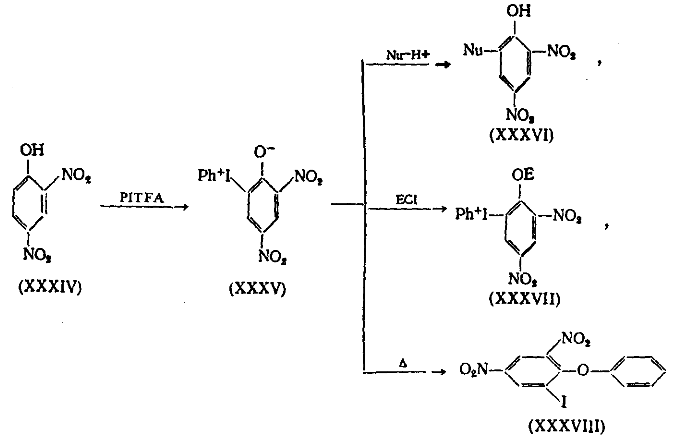
The facts presented permit the conclusion that this interesting reaction is probably general among phenols having an electron-accepting group in the p-position and at least one free o-position.

Photochemical syntheses based on 2-iodo-substituted diphenyl ethers (XXXII) lead to a simple way of preparing substituted dibenzofurans (XXXIII) (see, for example, Kappe et al.[175]):



(XXXII) (XXXIII)

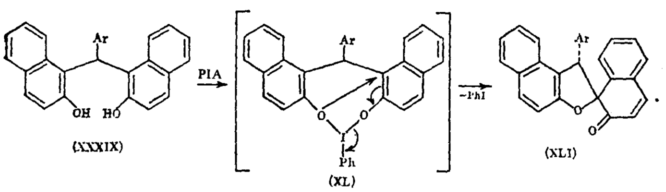
2,4-Dinitrophenol (XXXIV) is oxidised by PITFA to the iodonium salt (XXXV); the latter can react with both nucleophiles and electrophiles, forming the products (XXXVI) and (XXXVII); on heating, compound (XXXV) rearranges to 6-iodo-2,4-dinitrophenyl phenyl ether (XXXVIII):[176]



(XXXIV) (XXXV) (XXXVI) (XXXVII) (XXXVIII)

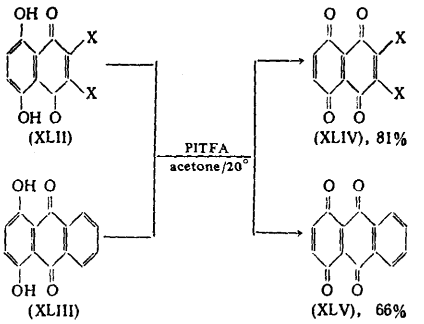
Nu=OH, OCH_3, n-C_4H_9NH; E=H, PCl_2, $Si(CH_3)_3$.

The bisnaphthols (XXXIX) rearrange under the influence of PIA into the spiro-compounds (XLI) via the iodosoethers (XL):[177,178]



(XXXIX) (XL) (XLI)

The reaction of catechol with PIA affords o-benzoquinone in 90% yield.[179] PITFA oxidises 2,3-dichloro-5,6-dicyanohydroquinone to 2,3-dichloro-5,6-dicyanoquinone in 90% yield.[151] PITFA converts the anhydride of hydroquinone-2,3-dicarboxylic acid quantitatively into the anhydride of p-benzoquinone-2,3-dicarboxylic acid.[180] The oxidation of the dihydroxyquinones (XLII) and (XLIII), derived from naphthalene and anthracene, by treatment with PITFA results in the formation of the corresponding diquinones (XLIV) and (XLV):[181]



(XLII) (XLIII) (XLIV), 81% (XLV), 66%

X=H, Cl .

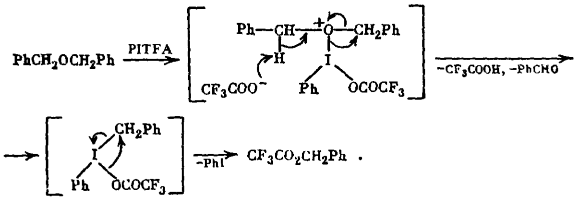
t-Butyl hydroperoxide interacts with PIA at a low temperature to form a new peroxide, which decomposes on raising the temperature:[182]

$$PhI(OAc)_2 \xrightarrow[-2AcOH]{2\ t\text{-}BuOOH} [PhI(OOBu\text{-}t)_2] \rightarrow PhI + O_2 + (t\text{-}BuO)_2 .$$

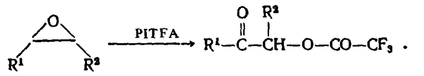
(f) Ethers

On treatment with PITFA, alkyl aryl ethers are converted into iodonium salts.[183] Benzyl ethers are cleaved by PITFA to carbonyl compounds and benzyl or alkyl trifluoroacetate.

This reaction proceeds via the intermediate formation of an oxonium complex, which is converted, with formation of a carbonyl compound, into a tervalent iodine derivative, which then decomposes to iodobenzene and trifluoroacetate:[184]



Oxirans are converted by PITFA into the trifluoroacetate of α-hydroxyketones:[185]



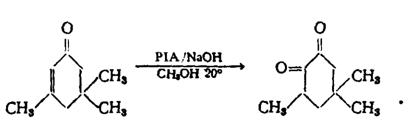
On reaction with trimethyl orthoformate, PIHT is converted into phenyl iodosomethoxytosylate:[186]

(g) Aldehydes and Ketones

After prolonged contact with PITFA, benzaldehyde is oxidised to benzoic acid. This reaction probably proceeds via the intermediate formation of the mixed anhydride of benzoic and trifluoroacetic acids.[187]

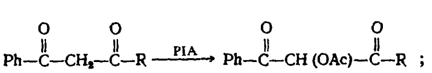
Cyclohexanone reacts with PIA to form 2-hydroxycyclohexanone in 80% yield.[26]

On treatment with PIA, isophorone (XLVI) is converted into 3,5,5-trimethylcyclohexane-1,2-dione (XLVII):[26]



(XLVI) (XLVII)

The reaction of acetophenones with PIA in the presence of sulphuric acid leads to products of the acetoxylation of the methyl group.[188] Benzil is cleaved by PITFA to benzoic acid. This reaction probably also takes place via a stage involving the formation of the mixed anhydride of benzoic and trifluoroacetic acids.[160] Dibenzoylmethane and 4,4,4-trifluoro-1-phenylbutane-1,3-dione are acetoxylated on treatment with PIA:[188,189]

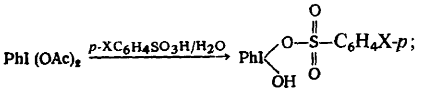


$R=Ph, CF_3$.

Polycarbonyl compounds are cleaved by PIA to carboxylic acids in aqueous acetic acid.[190]

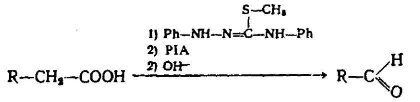
(h) Carboxylic Acids and Water

Aryl iodosocarboxylates enter into exchange reactions with carboxylic acids.[4] The reactions of PIA with substituted benzenesulphonic acid lead to the corresponding phenyl iodosohydroxybenzenesulphonates:[127]



$X=H, CH_3, Cl, NO_2$.

Carboxylic acids having the methylene group in the α-position react with S-methyl-1,4-diphenylisothiosemicarbazide, forming the salts of 5-substituted 3-methylthio-1,4-diphenyl-1,2,4-triazoles. The latter are acetoxylated by PIA at the methylene group and the hydrolysis of the resulting derivative affords aldehydes containing one carbon atom less than the initial acid:[191,192]



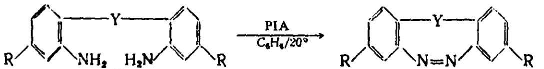
$R=CH_3, C_2H_5, n\text{-}C_7H_{15}$.

The hydrolysis of PIA is the best preparative method of synthesis of iodosobenzene.[19] This reaction proceeds via hydrated iodosobenzene, which loses a water molecule. Under the usual conditions, the reaction requires alkaline catalysts but at elevated temperatures it can take place even under the influence of the traces of moisture present in the solvent (see, for example, Hey et al.[193]).

(i) Primary Aromatic Amines

These are oxidised by aryl iodosocarboxylates to azo-compounds under mild conditions with yields ranging from low to excellent. The reaction takes place via a free-radical mechanism.[194–196]

The amino-derivatives (XLVIII) cyclise under the influence of PIA to diazepines (XLIX):[197,199]

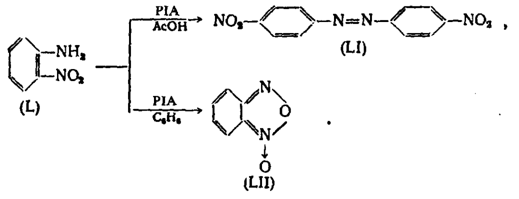


(XLVIII) (XLIX), 35–71%

$Y=CH_2, SO_2$; $R=H, Cl$.

The remarkable reaction involving the oxidation of 4-iodoaniline to 4,4′-diiodoazobenzene by chlorine or peracetic acid can be explained by the intermediate formation of iodosochlorides and iodosoacetates.[199,200]

o-Nitroaniline (L) can be oxidised both to 4,4′-dinitroazobenzene (LI) and to benzofuroxan (LII):[196]

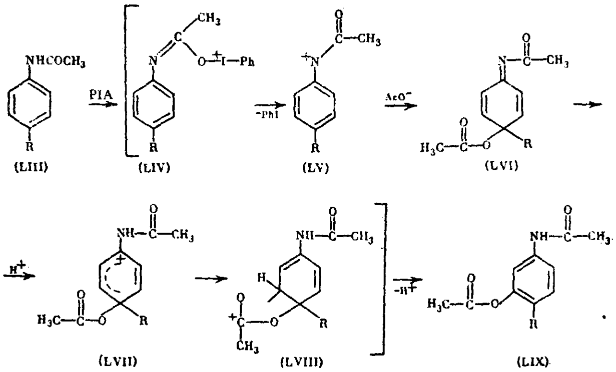


(L) (LI) (LII)

2-Amino-3-nitrobiphenylene is converted into the corresponding furoxan in 70% yield.[201] The oxidative cyclisation reaction is common to anilines having in the o-position a substituent capable of forming a heterocyclic ring.[202]

The reactions of the acetanilides (LIII), having electron-donating groups in the 4-position, with PIA proceed in accordance with the heterocyclic mechanism via the iodonium salt (LIV), the nitrenium cation (LV), and the dienoneimine (LVI).

The protonated form of the latter (LVII) rearranges intramolecularly via compound (LVIII) to the 3-acetoxy-derivative (LIX):[203]

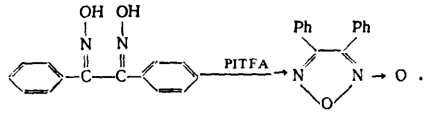


(j) Carboxylic Acid Amides

On reaction with aryl iodosocarboxylates, they are decarbonylated.[204–206] PITFA is a convenient reagent for the stepwise degradation of peptides attached to an insoluble polymeric support.[207]

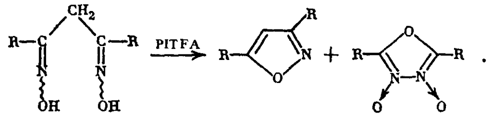
(k) Oximes

α-Dioximes react with PITFA to form mixtures of aldazine di-*N*-oxides and nitrile oxides. The benzil dioxime (LX) is converted into the corresponding furoxan (LXI):[151]



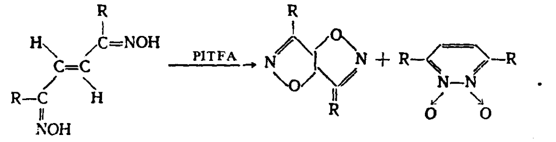
(LX) (LXI), 91%

The β-dioximes (LVII) give rise to mixtures of isoxazoles (LXIII) and 4-oxa-4*H*-pyrazole di-*N*-oxides (LXIV):[208,209]



(LXII) (LXIII) (LXIV)

trans-2-Unsaturated 1,4-dioximes (LXV) react with PITFA to form a mixture of 3a,6a-dihydroisoxazolo[5,4-*d*]isoxazoles (LXVI) and pyridazine 1,2-dioxides (LXVII):[210]



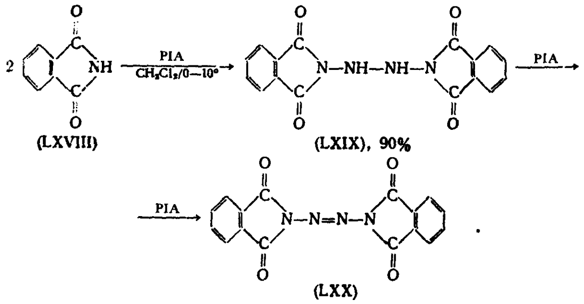
(LXV) (LXVI) (LXVII)

(l) Various Nitrogen-containing Compounds

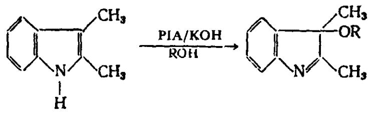
Hydrazobenzene is dehydrogenated quantitatively by PIA to azobenzene.[194] PITFA converts diethyl hydrazodicarboxylate into diethyl azodicarboxylate;[151] PIA is ineffective in this reaction.

Schiff bases are oxidised by PIA with formation of aldehydes and azo-compounds.[211] The interaction of *NN*-dibenzylhydroxylamines with PIA leads to nitrones.[212]

Phthalimide (LXVIII) is oxidised by PIA to the tetrazane (LXIX), which can be converted further into the tetrazene (LXX):[213]



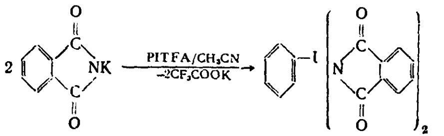
4-Amino-3,5-diphenyl-1,2,4-triazole reacts with PIA to form benzonitrile; in the presence of alkenes, this reaction can lead to aziridines.[214] The reactions of PIA with aryldiazomethanes or 1-aryl-1-diazoethanes affords complex mixtures of products, the main components of which are the trifluoroacetates $ArCH_2OCOCF_3$ or $ArCH(CH_3)OCOCF_3$.[215] On treatment with PIA in the presence of alkali in alcohols, 2,3-dimethylindole (LXXI) gives rise to 3-alkoxyindolenine (LXXII):[216]



(LXXI) (LXXII)

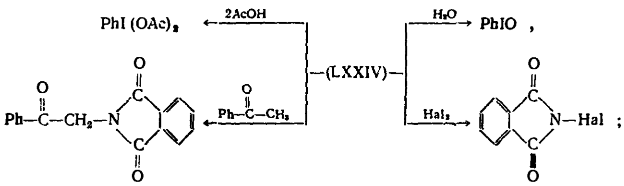
R=CH_3, C_2H_5 .

Phenyl iodosophthalimidate (LXXIV) is obtained by the reaction of potassium phthalimide (LXXIII) with PITFA:[169]



(LXXIII) (LXXIV), 74%

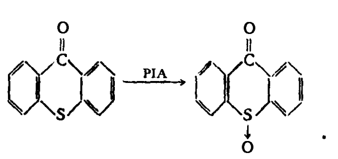
Compound (LXXIV) enters into a series of reactions:[169]



Hal=I, Br .

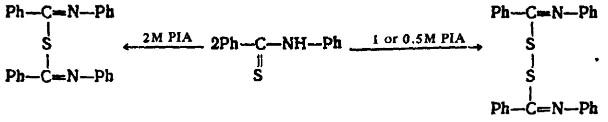
(m) Sulphur-containing Compounds

Thiophenols are oxidised to disulphides on treatment with both PIA [217] and PITFA.[151] The oxidation of sulphides by PIA leads to sulphoxides.[218,219] When the thiaxanthone (LXXV) is treated with PIA, it is converted into the corresponding sulphoxide (LXXVI) in a high yield:[220]



(LXXV) (LXXVI)

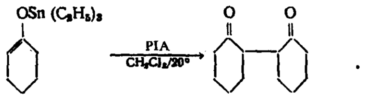
It is of interest to note that phenyl trityl and benzyl trityl sulphides are not oxidised by PIA to the corresponding sulphoxides but are cleaved with formation of diphenylmethanol and probably compounds containing bivalent sulphur.[221] The oxidative elimination of sulphur from various sulphur-containing compounds is possible. On treatment with PIA, thiobenzanilide is converted into benzanilide in aqueous ether.[222] Depending on the reaction conditions, in absolute ether thiobenzanilide is converted into di(α-phenyliminobenzyl) sulphide or into di(α-phenyliminobenzyl) disulphide:[222]



(n) Compounds Containing Phosphorus, Selenium, Boron, and Tin

The reaction of triphenylphosphine with PITFA leads to triphenylphosphine oxide.[8] Selenazines react with PIA to form the corresponding selenazine oxides.[223]

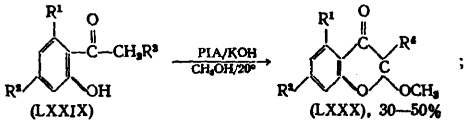
Phenyl iodosoacetate is capable of oxidising boron compounds.[224,225] The triethylstannyl enolate of cyclohexanone (LXXVII) is converted on treatment with PIA into 2,2′-dioxo-1,1′-bicyclohexyl (LXXVIII):[226]



(LXXVII) (LXXVIII), 61%

(o) Polyfunctional Compounds

The reaction of benzoin with PITFA results in the formation of benzil in a high yield.[158] The interaction of *o*-hydroxyacetophenones (LXXIX) with PIA in the presence of KOH affords coumaran-3-ones (LXXX):[227]

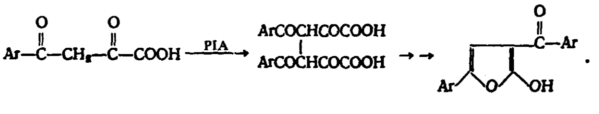


(LXXIX) (LXXX), 30–50%

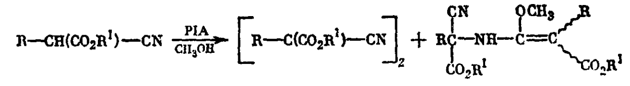
$R^1=R^2=R^3=H$, $R^4=OCH_3$; $R^1=R^2=H$, $R^3=R^4=CH_3$; $R^1=R^2=CH_3$, $R^3=H$, $R^4=OCH_3$; $R^1=R^2=H$, $R^3=R^4=PhCH_2$.

The oxidation of 3-cyanopyrrolidine-2,5-diones with PIA leads to the formation of ring opening products.[228] *NN*-Dialkyl-2-aminoalcohols are cleaved by PIA to aldehydes and iminium salts; the latter hydrolyse to amines and formaldehyde.[229] On treatment with PIA or iodosobenzene, α-ketoacids are decarbonylated.[26,140,230]

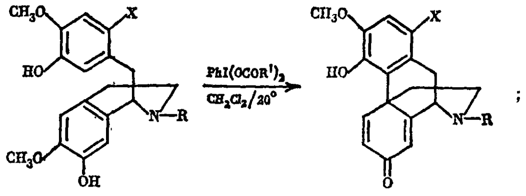
α-Hydroxyacid esters are oxidised by PIA to α-ketoacid esters.[231] 4-Aryl-2,4-dioxobutanoic acids are cyclised by PIA to 4-aroyl-2-aryl-5-hydroxyfurans:[232]



When α-cyanocarboxylates are treated with PIA, they dimerise:[233]



Reticuline (LXXXI) is cyclised by phenyl iodosocarboxylates to salutaridine (LXXXII):[133]



(LXXXI) (LXXXII), 14-32%

X=H, Br, Cl; R=CH$_3$, CHO, CO$_2$C$_2$H$_5$; R^1=CH$_3$, CCl$_3$, CF$_3$.

The PIA/cyanamide system converts the penicilloic acid derivative (LXXXIII) into the derivative (LXXXIV):[234]

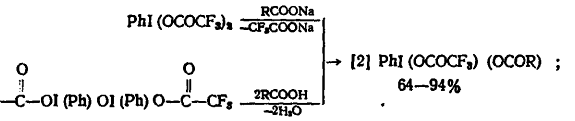
(LXXXIII) (LXXXIV)

(p) Mixed Iodosocarboxylates

For a long time, the sole representative of these compounds was phenyl iodosobromoacetate-chloroacetate synthesised from PIA:[128]

$$PhI(OAc)_2 \xrightarrow[-AcOH]{CH_2ClCOOH} \left[PhI\begin{matrix}OAc\\OCOCH_2Cl\end{matrix}\right] \xrightarrow[-AcOH]{CH_2BrCOOH} PhI\begin{matrix}OCOCH_2Br\\OCOCH_2Cl\end{matrix}.$$

Iodosocarboxylates contain the residues of various acids, one of which is trifluoroacetic acid, and can be conveniently obtained from PITFA[150] or from μ-oxobis(trifluoroacetoxy)(phenyl)iodine:[33]



$$PhI(OCOCF_3)_2 \xrightarrow[-CF_3COONa]{RCOONa} [2]\ PhI(OCOCF_3)(OCOR);\ 64–94\%$$

$$CF_3\overset{O}{\overset{\|}{C}}-OI(Ph)OI(Ph)O-\overset{O}{\overset{\|}{C}}-CF_3 \xrightarrow[-2H_2O]{2RCOOH} [2]\ PhI(OCOCF_3)(OCOR)$$

R=CH$_3$, CH$_2$Cl, CHCl$_2$.

Cyclohexene reacts with phenyl iodosoacetate-trifluoroacetate to form 1-acetoxy-2-trifluoroacetoxycyclohexane, which readily hydrolyses to 2-acetoxycyclohexanol.[150]

(r) Catalytic Oxidation

Like iodosobenzene, aryl iodosocarboxylates are able to hydroxylate organic compounds in the presence of cytochrome P-450.[235] Tolan is oxidised by the PIA/RuCl$_2$–P(Ph)$_3$ system to benzil[63] and 1-octanol is oxidised to 1-octanal.[62] PIA in aqueous acetic acid containing RuCl$_3$ cleaves fumaric, maleic, arylic, and cinnamic acid as well as styrene at the carbon–carbon double bonds.[236] It has recently been possible to isolate the complex formed in the reaction of PIA with the manganese-containing porphyrin: PhI(OAc)–O–Mn(IV)–O–I(OAc)Ph. This complex hydroxylates organic compounds.[237]

3. Direct Halogenation of Aromatic and Heteroaromatic Compounds

The possibility, in principle, of iodinating *m*-xylene in warm acetic acid by the I_2/PIA or I_2/PhIO system was demonstrated in 1963.[238] Azobenzene is iodinated by the I_2/PIA system in boiling acetic acid, forming 4-iodoazobenzene in a low yield.[239] These iodinating systems have not found extensive application in synthetic organic chemistry. The observation of a fairly unexpected iodination of iodobenzene to *p*-diiodobenzene in a high yield by the I_2/PITFA system in carbon tetrachloride at room temperature[160] led the authors[170,240,241] to investigate the preparative possibilities of this reaction.

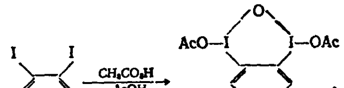
The iodination takes place readily at room temperature when equimolar amounts of PITFA and iodine are mixed with the organic substrate in methylene chloride, chloroform, carbon tetrachloride, or 1,2-dichloroethane:

$$\text{R—H} \xrightarrow[\text{–PhI, –CF}_3\text{COOH}]{\text{I}_2\text{/PITFA}} \text{R—I} \; ; \quad \text{R=Ar, Hetar} \; .$$

This system iodinates compounds which are more reactive in electrophilic substitution reactions than iodobenzene. There is no need to employ PITFA which is unstable on storage—it can be generated in situ from PIA and trifluoroacetic acid.[170] This method is effective for the direct iodination of arylcyclopropanes.[242] The Br_2/PITFA system is convenient for bromination of arenes,[243,244] while the $AlCl_3$/PITFA system is convenient for chlorination.[244] Because of its experimental simplicity, the possibility of carrying out the halogenation at room temperature, and the ease with which the target products can be isolated, the above halogenation method can find extensive application in fine organic synthesis. Certain data on these processes are presented in Table 2.

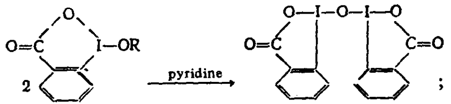
V. DERIVATIVES OF µ-OXOBISACYLOXY(ARYL)IODINE

Although these compounds have been known for a long time, it is noteworthy that until recently there was no convenient method of their synthesis. The oxidation of *o*-diiodobenzene (LXXXV) with peracetic acid yields the µ-oxo-compound (LXXXVI):[134]



(LXXXV) (LXXXVI)

On treatment with pyridine, derivatives of *o*-iodosobenzoic acid (LXXXVII) give rise to the µ-oxo-compound (LXXXVIII):[141]



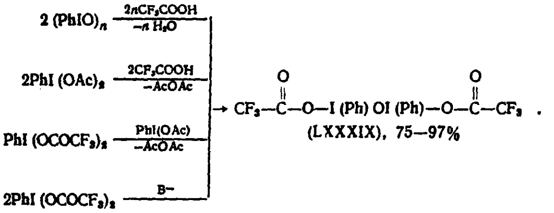
(LXXXVII) (LXXXVIII)
R=CH_3, Ac .

µ-Oxo-compounds can be obtained from PIA:[245]

$$2\text{PhI(OAc)}_2 \xrightarrow{2\text{RCOOH}} \text{R—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—OI(Ph)OI(Ph)O—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—R} \; ;$$

R=CH_2Cl, CH_2Br, CCl_3 .

A series of effective approaches to the synthesis of µ-oxobis(trifluoroacetoxy)(phenyl)iodine (LXXXIX) have been proposed:[33]



$$\left.\begin{array}{l} 2\,(\text{PhIO})_n \xrightarrow[-n\,\text{H}_2\text{O}]{2n\text{CF}_3\text{COOH}} \\ 2\text{PhI(OAc)}_2 \xrightarrow[-\text{AcOAc}]{2\text{CF}_3\text{COOH}} \\ \text{PhI(OCOCF}_3)_2 \xrightarrow[-\text{AcOAc}]{\text{PhI(OAc)}} \\ 2\text{PhI(OCOCF}_3)_2 \xrightarrow{\text{B}^-} \end{array}\right| \rightarrow \text{CF}_3\text{—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—O—I(Ph)OI(Ph)—O—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—CF}_3 \; .$$

(LXXXIX), 75—97%

Table 2. The synthesis of halogeno-derivatives by halogenation in the presence of PITFA.

Organic substrate	Halogeno-derivative	Yield, %	Refs.
Benzene*	iodobenzene	72	[170]

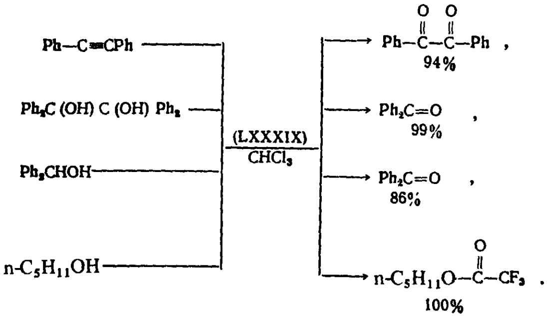
Mesitylene	trichloromesitylene	63	[244]
Durene	dichlorodurene	38	[244]
Fluorenone	2,7-dichlorofluorenone	93	[244]

*The reaction was carried out in an excess of the aromatic substrate.

Certain data on the oxidative properties of the compounds obtained are illustrated by the equations presented below:[33]

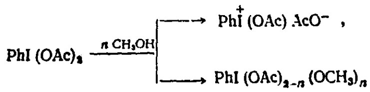


$$\left.\begin{array}{l} \text{Ph—C}\equiv\text{CPh} \\ \text{Ph}_2\text{C(OH)C(OH)Ph}_2 \\ \text{Ph}_2\text{CHOH} \\ n\text{-C}_5\text{H}_{11}\text{OH} \end{array}\right| \xrightarrow[\text{CHCl}_3]{\text{(LXXXIX)}} \left|\begin{array}{l} \rightarrow \text{Ph—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—Ph}\,,\ 94\% \\ \rightarrow \text{Ph}_2\text{C=O}\,,\ 99\% \\ \rightarrow \text{Ph}_2\text{C=O}\,,\ 86\% \\ \rightarrow n\text{-C}_5\text{H}_{11}\text{O—}\overset{\text{O}}{\overset{\|}{\text{C}}}\text{—CF}_3\,.\ 100\% \end{array}\right.$$

On treatment with like carboxylic acids, the μ-oxo-compounds are converted into phenyl iodosocarboxylates, while unlike carboxylic acids convert them into mixed iodosoesters.[245] Treatment of alkenes with the μ-oxo-compounds results in the formation of vicinal diesters.[246]

VI. SPECTROSCOPIC DATA

X-Ray diffraction data have been obtained for phenyl iodosochloride,[247] PIA,[248] phenyl iodosodichloroacetate,[249] μ-oxobis(trifluoroacetoxy)(aryl)iodine,[33] and 1-hydroxy-3-oxo-3*H*-benzoiodoxole (the cyclic form of *o*-iodosobenzoic acid).[250] ^1H, ^{13}C, and ^{19}F NMR data have been published for various organic compounds of polyvalent iodine;[31,33,136,251,252] the ^{19}F NMR spectra of perfluoroalkyliodoso-compounds have been discussed.[21,253] The observed splitting of the PIA signal in the ^1H NMR spectrum on reducing the temperature in solution in methanol has been interpreted as evidence for the existence of the ionic and covalent forms of PIA at a low temperature.[254] However, it has been shown[233] that PIA interacts with methanol even at very low temperatures and thus the problem has remained open:

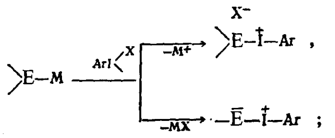


$$PhI(OAc)_2 \xrightarrow{n\,CH_3OH} \begin{cases} Ph\overset{+}{I}(OAc)\,AcO^- , \\ PhI(OAc)_{2-n}(OCH_3)_n . \end{cases}$$

The IR spectra of various polyvalent iodine compounds have been discussed in a series of studies[141,255–257] and the IR and Raman spectra have been described.[15] For data on the dipole moments of aryl iodosocarboxylates, see Exner and Plesnicar.[258] The results of conductimetric studies of solutions of phenyl iodosochloride have been published by Zappi and Cortelezzi[259] and those for PIA solutions can be found in the paper of Johnson and co-workers.[260,261] Erlich and Kaplan[262]# published the Mössbauer spectra for different polyvalent iodine compounds.

VII. IODONIUM ION AND IODONIUM YLIDE FORMATION REACTIONS

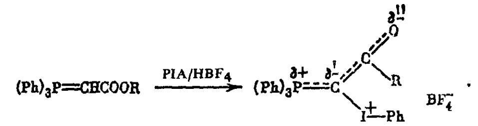
So many different methods of synthesis of iodonium salts and iodonium ylides have now been developed that they cannot be represented simply by any one scheme. However, most of them can be described by the equation given below:



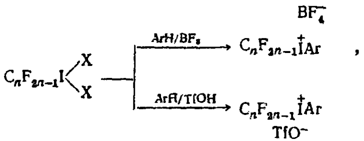
M=Li, Na; E = C, N.

In principle, any polyvalent iodine compounds can be used in iodonium ion formation reactions, but aryl iodosoacetates or iodoso-compounds are most frequently employed.[17] They can be generated *in situ* by oxidising aryl iodides.[263,264]

When the phosphonium ylide is treated with PIA in the presence of HBF_4, a double iodonium salt is obtained[265] (see also Moriarty et al.[266]):

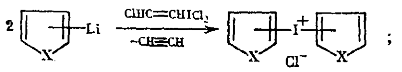


Derivatives of perfluoroiodosoalkanes were found to be extremely useful reagents for the synthesis of iodonium salts:[267–272]



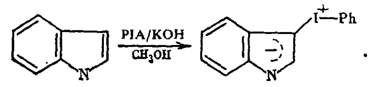
X=F, CF_3CO_2; Tf=CF_3SO_2 .

A unique iodonium ion forming agent is PIHT,[163,273–276] which can condense with trimethylsilyl derivatives of furan under neutral conditions to form furylphenyliodonium salts.[274] *trans*-Chlorovinyl iodosochloride is a convenient reagent for the synthesis of heterocyclic iodonium salts:[277–279]



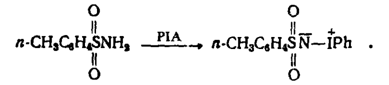
X=S, O, Cl

The reaction of PIA with indole (XC) leads to the formation of an ylide (XCI) with a carbon–iodine bond:[280]



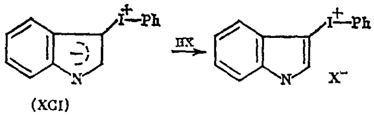
(XC) (XCI)

The interaction of PIA with toluene-p-sulphonamide affords an ylide with a nitrogen–iodine bond:[281]



$$n\text{-}CH_3C_6H_4\overset{O}{\underset{O}{\overset{\|}{\underset{\|}{S}}}}NH_2 \xrightarrow{PIA} n\text{-}CH_3C_6H_4\overset{O}{\underset{O}{\overset{\|}{\underset{\|}{S}}}}\bar{N}-\overset{+}{I}Ph .$$

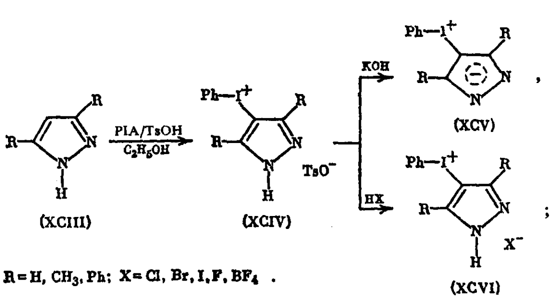
Iodonium salts are most closely related to iodonium ylides and they can sometimes be interconverted. The iodonium ylide (XCI) can be converted into the iodonium salts (XCII):[280]



(XCI)

X = TsO, BF_4, ClO_4 .

The iodonium salts (XCIV), obtained from pyrazoles (XCIII), give rise to the iodonium ylides (XCV) or the new iodonium salts (XCVI):[282]



(XCIII) (XCIV) (XCV) (XCVI)

R=H, CH_3, Ph; X=Cl, Br, I, F, BF_4 .

#According to these data,[262] the chlorine atoms in the molecule of phenyl iodosochloride are entirely equivalent, which fails to provide any kind of justification for the use of the term "aryliodonium chlorides" for aryl iodosochlorides, which can be encountered in some communications.

VIII. POLYMERS WITH TERVALENT IODINE

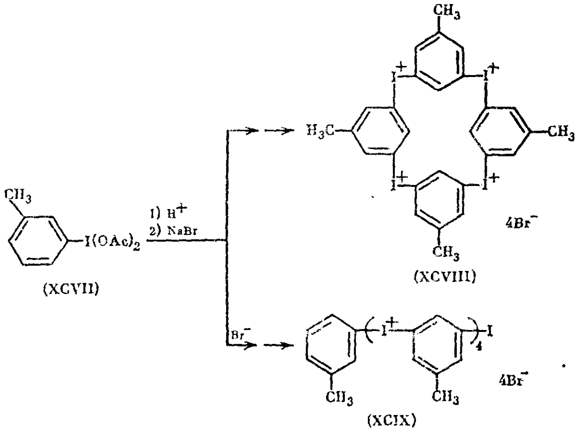
All these polymers can be arbitrarily divided into two groups. The first includes those in the molecules of which the tervalent iodine atom is used to link individual monomer units, while the second group comprises polymers whose monomer units are linked via other atoms and the polyvalent iodine atom enters into the composition of the macromolecule as a functional group.

Condensation of iodosobenzene with succinic anhydride, of PIA with adipic acid, and of phenyl iodosochloride with the silver salt of sebacic acid made it possible to obtain polymers in which the monomer units are linked by a tervalent iodine atom. They are solid brittle substances, insoluble in all the usual organic solvents under the normal conditions, but soluble on heating in some solvents, the dissolution being accompanied by degradation.[283] Unfortunately no data could be obtained about the structure of such polymers.

Polymers in which the monomer units are joined together with $-\overset{+}{I}-$groups have been synthesised:[284]

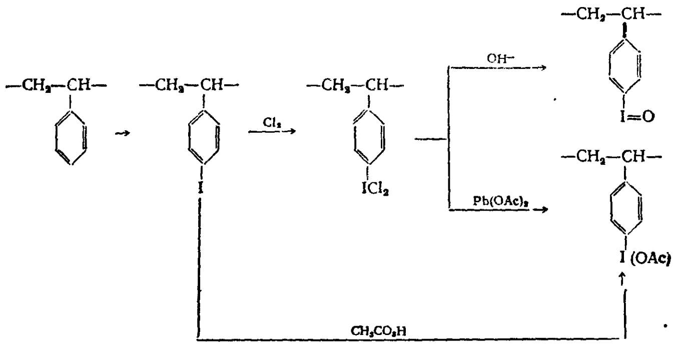
$$n\,\mathrm{Ph(CH_2)_3Ph}\xrightarrow[2)\ \mathrm{NaBr/H_2O}]{1)\ n(\mathrm{AcO})_2\mathrm{IC_6H_4I(OAc)_2}}-\left[-\overset{\mathrm{Br^-}}{\overset{+}{I}}-\mathrm{C_6H_4}-\overset{\mathrm{Br^-}}{\overset{+}{I}}-\mathrm{C_6H_4(CH_2)_3-C_6H_4}-\right]_n- .$$

m-Tolyl iodosoacetate (XCVII) forms cyclic or linear tetrameric iodonium ions (XCVIII) and (XCIX) in sulphuric acid:[284]

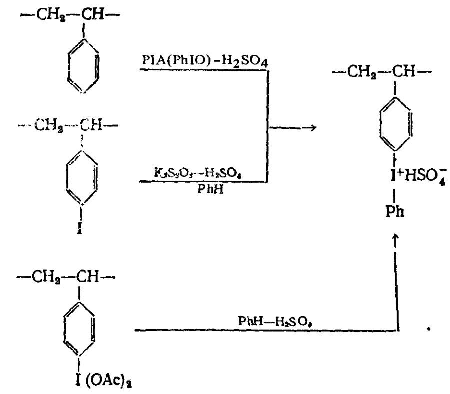


(XCVII) (XCVIII) (XCIX)

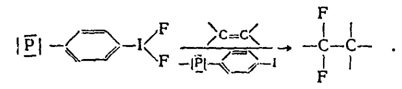
A series of polymers with polyvalent iodine, prepared on the basis of both linear and cross-linked polymers, are known.[285–296] The linear polystyrene can be iodinated in the presence of the oxidants P_2O_5–H_2SO_4 and HIO_3–H_2SO_4 on heating in nitrobenzene[288,289] in the presence of PITFA at room temperature in chloroform.[291] Poly(*p*-iodostyrene) can be converted into a polymer with polyvalent iodine by the same procedures as iodobenzene:



Polymeric iodonium salts based on linear polystyrene can be obtained with the aid of the reactions given below:[289]

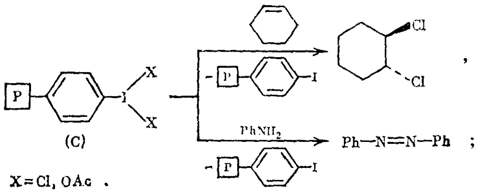


The cross-linked iodinated divyinylbenzene–styrene copolymer produces, on treatment with xenon difluoride, a polymeric reagent with iodosofluoride groups, which fluorinates olefins at room temperature with rearrangement:[292]



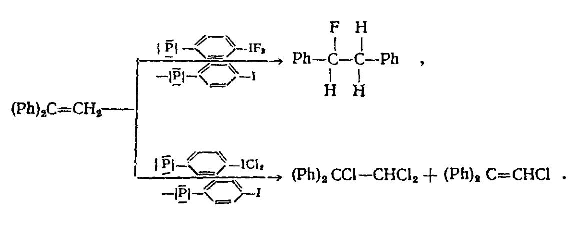
The spent polymer can be separated from the reaction product by simple filtration and can be reused after regeneration.[292]

The iodosochloride (C), obtained from the iodinated cross-linked divinylbenzene–styrene copolymer, reacts with cyclohexene to form *trans*-1,2-dichlorocyclohexane. The polymeric iodosoacetate (C) oxidises aniline to *trans*-azobenzene:[293]



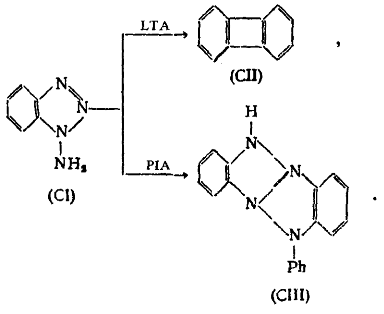
(C)

The reaction of 1,1-diphenylethylene with polymeric reagents based on cross-linked iodopolystyrene leads to various halogeno-derivatives:[294]

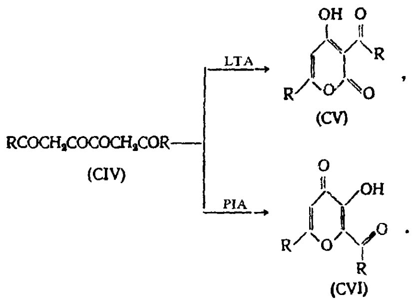


IX. CONCLUSION

Many chemists are under the impression that aryl iodosocarboxylates as oxidants are entirely similar to the popular reagent lead tetraacetate (LTA) (see, for example, Varvoglis[8]). However, in the 1980's a series of oxidation reactions were discovered, which proceed in a fundamentally different way, depending on whether the oxidant is LTA or PIA. For example, the oxidation of 1-aminobenzotriazole (CI) with LTA leads to the biphenylene (CII) in a high yield,[297] while in the oxidation of compound (CI) by PIA biphenylene is not formed at all and the main product is compound (CIII):[298]



By oxidising the tetraketone (CIV) with LTA or PIA, it is possible to obtain two isomeric pyrones (CV) and (CVI):[299]

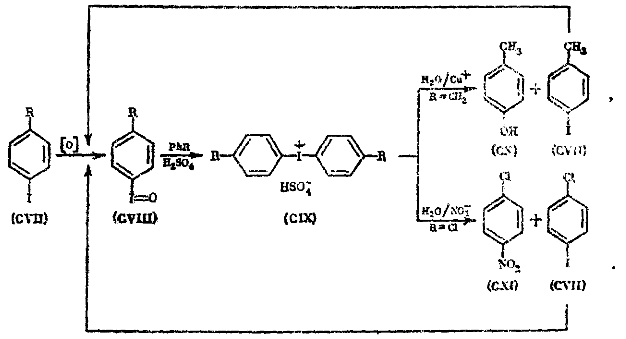


Bearing in mind the definite similarity between LTA and PIA in oxidation reactions, one should note one fundamental difference between these reagents. Their reduction products are lead diacetate in the former case and iodobenzene in the latter and to this day it is definitely easier to separate organic oxidation products from lead diacetate than from iodobenzene. It is noteworthy that PIA, in particular, and phenyl iodosocarboxylates in general can enter into the composition of polymers which are both soluble (for example, iodinated polystyrene) and insoluble (for example, the iodinated divinylbenzene–styrene copolymer). At the present time lead-containing polymers are not used in organic synthesis. These facts suggest that in the future the chemistry of polymeric iodosocarboxylate oxidants will develop. The products of the reduction of such reagents will be polymeric iodoarenes and they can be separated without special difficulty from reaction mixtures by simple filtration.

It is noteworthy that, as a chlorinating agent effecting the addition of chlorine to alkenes via an ionic mechanism, the polymeric iodosochloride resembles molecular chlorine rather than phenyl iodosochloride.[294]

Most attention should be devoted to multipurpose reagents for organic synthesis such as PITFA and PIHT.

There has been a remarkable study which demonstrated the possibility of obtaining p-cresol (CX) and p-chloronitrobenzene (CXI) by the iodonium ion formation reaction using iodo-derivatives of toluene or chlorobenzene (CVII), which proceeds via the corresponding iodo-derivatives (CVIII) and iodonium salts (CIX):[300]



Taking into account all the foregoing factors, one may conclude that, together with iodonium salts, the most important representative of organic compounds of tervalent iodine are aryl iodosocarboxylates and that new major discoveries are to be expected in the first place in these two fields.

The σ Constants of Substituents Containing Silicon Subgroup Elements

A.N.Egorochkin and G.A.Razuvaev

The general aspects of the correlation equations linking the structure and reactivity of compounds of silicon subgroup elements are examined. Taking into account the specific features of the intramolecular interactions in the organoelemental compounds, the σ constants of substituents containing silicon, germanium, and tin atoms have been analysed.
The bibliography includes 138 references.

I. INTRODUCTION

The search for and investigation of the relations between the chemical structure of molecules and their reactivity is one of the fundamental problems in chemistry. The most significant advances in physical organic chemistry, achieved in this field during the last few decades, are associated with the use of the so called correlation equations based on the principle of the linear relation between the free energy changes (LFE).[1-18] The essential feature of the LFE principle is as follows.[1,4] If the molecule consists of the reacting group A and the non-reacting substituent X, then (a) the change in the logarithm of the rate constant *k* induced by the influence of X is linearly related to the change in the logarithm of the equilibrium constant *K* for the same reaction [Eqn.(1)]:

$$\delta_X \lg k_1 = a_1 \delta_X \lg K\,, \qquad (1)$$

and (b) the changes in lg *k* and lg *K* induced by the influence of X, for a reaction I with participation of the group A_1 are linearly related to the corresponding changes for another reaction II with participation of the same group A_1 and also for reaction II with participation of another group A_2:

$$\delta_X \lg k_1 = b_{12} \delta_X \lg k_2 = a_2 b_{12} \delta_X \lg K_2\,, \qquad (2)$$

where k_1 and K_1 refer to reaction I and k_2 and K_2 refer to reaction II, a_1, a_2, and b_{12} are independent of X but do depend on the reactions considered, and δ_X is an operator reflecting the influence of the change in the substituent X on *k* and *K*.

Experimental data on the basis of which the LFE principle has been formulated have been analysed in a number of studies.[1,5,6,9,18,19] By comparing the ionisation constants of substituted benzoic acids K_a with the constant for the unsubstituted acid K_0 in water at 25 °C, it is possible to obtain from Eqn.(1) the constants σ characterising the substituents

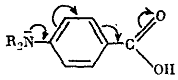
$$\sigma = \lg K_a - \lg K_0 \qquad (3)$$

and then the familiar Hammett equation:[1]

$$\lg k - \lg k_0 = \rho\sigma, \qquad (4)$$

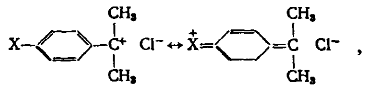
The reaction constant ρ in Eqn.(4) characterises the sensitivity of the reaction to the electronic effects of the substituents compared with the constant 1.00 adopted for the dissociation of benzoic acids.

Thus the first method of determining the Hammett σ_m and σ_p constants for *meta*- and *para*-substituents (including organoelemental substituents) in the benzene ring involves the study of the ionisation constants of benzoic acids or the rate constants *k* for the reaction involving the side chain of benzene derivatives. However, this procedure cannot be used to calculate the σ constants for *ortho*-substituents, since their influence on the reaction centre is determined not only by electronic effects but also by steric effects. An important characteristic feature of the Hammett σ_p constants (in contrast to the σ_m constants) for π-electron-donating substituents (the *+M* types of substituents NR_2, OR, and $CH_2.EP_3$, where *E* is a silicon subgroup element) is their dependence on the direct polar conjugation between these substituents and their reaction centres, which can be described, for example, by the following schemes:



Therefore, in order to estimate the degree of interaction between the substituent and the ring, it is essential to disrupt in such cases the direct polar conjugation system. For example, one can use data for the ionisation constants of the acids $XC_6H_4CH_2COOH$. Similar procedures have been used in a number of investigations.[20-24]

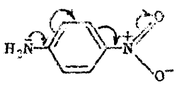
As a result, the constants σ^0 have been obtained for *+M* type *para*-substituents.[11,13] The σ_p^+ constants have been introduced[15,25] to characterise *para*-substituents of the *+M* type which are involved in direct polar conjugation with the electron-deficient reaction centre. Thus the stabilisation of the transition state in the reaction involving the solvolysis of cumenyl chlorides by substituents X of this kind (for example, the group CH_3O), i.e.



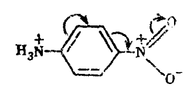
,

is associated mainly with the enhancement of the electron-donating properties of the group X, i.e. with the increase of the absolute values of the constants σ_p^+ for these substituents compared with the Hammett σ_p constants. The constants σ_m^+ and σ_m for the *meta*-substituents are virtually identical.

In order to characterise the electron-accepting substituents of the *−M* type (NO_2, CN, CHO, etc.), which are involved in direct polar conjugation with the reaction centre, σ_p^- constants have been introduced.[1,18,19] The enhancement of the electron-accepting properties of the NO_2 group as a substituent ($\sigma_p^- > \sigma_p$), manifested in the ionisation of aniline derivatives, can be accounted for by direct polar conjugation:



which leads to a decrease of the basicity of *p*-nitroaniline. There is no direct polar conjugation in the *p*-nitroanilinium ion:[10]



The constants σ_m^- and σ_m for *meta*-substituents are virtually identical. The σ constants discussed above are represented by the sum of the inductive (σ_I) and resonance (σ_R) contributions: $\sigma = \sigma_I + \sigma_R$. In order to estimate the inductive effect and hence resolve σ into its components, methods based on the LFE principle and the hypothesis that the free energy of activation can be represented by the sum of independent contributions due to the inductive, resonance, and steric effects have been developed.[2] For quantitative estimates of the inductive effects, the following factors were studied: the ionisation of bicyclo[2.2.2]octane-1-carboxylic acids;[11,26,27] the hydrolysis of the aliphatic acid esters XCH_2COOR;[2,3] the ionisation of substituted aliphatic acids;[28] the reactivity of aromatic compounds;[29,30] the chemical shifts of the signals of the ^{19}F nuclei in the NMR spectra of *meta*-substituted fluorobenzenes.[16,31] The constants σ_I, or quantities proportional to them, were obtained in the above studies for a large number of substituents, including those containing silicon subgroup elements.

The problem of the quantitative estimation of the inductive effect has been discussed in greater detail in a number of studies,[9-12,19] in which the possibility of resolving the σ constants into the inductive (σ_I) and resonance (σ_R) components was also analysed:

$$\sigma_R = \sigma_p - \sigma_I\,, \tag{5}$$

$$\sigma_R^0 = \sigma_p^0 - \sigma_I\,, \tag{6}$$

$$\sigma_R^+ = \sigma_p^+ - \sigma_I\,, \tag{7}$$

$$\sigma_R^- = \sigma_p^- - \sigma_I\,. \tag{8}$$

It has been emphasised[11] that the resonance constants of type σ_R, determined from Eqns.(5)–(8), are least accurate, since they depend on the errors in the determination of the constants σ_p and σ_I. The constants σ_R^0 are calculated from NMR and IR spectroscopic data.[16,31-33] A series of physicochemical and physical methods for the determination of the σ constants of substituents have been described in the review literature[11-13] and certain methods will be considered below.

We may note that, despite the wide variety of methods for the determination of σ constants and the use of different scales for the latter, when account is taken of the electronic effects of substituents, only the constants defined by Eqns.(5)–(8) are usually employed. This group of relations does not include the constants for complex aromatic systems and *ortho*-substituents and also constants characterising the steric effects of substituents. It is clear from the foregoing that the correlation equations relating the chemical structure and reactivity of compounds, based on the LFE principle, are empirical. For this reason, since the publication of the first[1] and subsequent studies[34,35] (see also the relevant reviews[8,12,19,36,37]), attempts have been frequently made to secure a justification of the system of Hammett–Taft constants. As early as the 1950's, it was established[34,35] with the aid of approximate quantum-chemical methods that the σ constants of substituents in the benzene ring are proportional to the change, induced by these substituents, in electron density on the carbon atoms in the *meta*- and *para*-positions in the ring and hence also on the reaction centre linked to these carbon atoms. On the one hand, these studies fundamentally clarified the physical significance of the σ constants, and, on the other hand, they served as the basis for an enormous number of investigations devoted to the analysis of the relations between the σ constants and various physical properties of organic and organoelemental compounds.

The results of some of these studies, which can be treated as sources of useful information about the σ constants of substituents incorporating the silicon subgroup elements and also about the specific features of the intermolecular interactions in organoelemental compounds of Group IVB elements, will be considered below in greater detail. In recent years, additional data, confirming the interpretation of the physical significance of the σ constants formulated in the 1950's, have been obtained with the aid of modern non-empirical quantum-chemical methods. It has been established for benzene derivatives[37,38] and ethylene and acetylene derivatives[39,40] that the π-electronic charge on the substituent is linearly related to the corresponding σ_R^0 constants.

However, the theoretical justification of both the correlation equations and of the LFE principle itself is inadequate. Furthermore, there exist a number of experimental limitations. For this reason, the σ constants can be used only with a certain degree of caution. The present review does not discuss the contradictions between the LFE principle and Hammond's postulate[6,9,10] and the influence of the field effects and bond polarisation on the σ_I constants is not dealt with in detail.[41,42] We may note that, in choosing the most reliable values of the σ constants (see below), account was taken of the dependence of the constant σ on temperature,[43] the solvent, the type of conducting system, and the nature of the reaction centre. Furthermore the hyperconjugation effects,[44] which are more important for organoelemental compounds than for organic compounds, and also the specific features of the steric effects in compounds of silicon subgroup elements[45] were taken into account.

It is essential to note that the limited amount of the available literature data and also in many instances the inadequate reliability (see below) of some of the σ constants preclude so far the formulation of reliable (statistical) values[11] for these quantities referring to substituents containing silicon subgroup elements. Therefore, our choice of the most and least reliable σ constants was made taking into account the views of the authors of the original publications and our own. As literature data accumulate and methods for the determination of σ constants develop and improve, a correction of many of their values will become inevitable.

II. METHODS FOR THE DETERMINATION OF THE σ CONSTANTS OF ORGANOELEMENTAL GROUP IVB SUBSTITUENTS

The methods for the determination of the σ constants of organoelemental substituents can be divided into two groups. The first group includes the physical (mainly spectroscopic) methods for the determination of σ constants. Different versions of NMR,[16,31,44-59] the IR spectroscopy of individual compounds and molecular complexes,[32,33,60–64] the UV spectroscopy of charge-transfer complexes (CTC),[38,65–67] the ionisation potentials[66] and dipole moments[68] of compounds with organoelemental substituents, as well as many other less common physical methods have been employed. The second group includes methods for the determination of the σ constants of organoelemental compounds based on the study of the chemical properties of various compounds containing such substituents.

Overall, the use of physical methods is preferable. The errors of the determination associated with the possibility of the involvement in the reaction of not only the main reaction centre but also of the organoelemental substituents ER_3 (E is a silicon subgroup element), whose E atom may be solvated in consequence of the high reactivity of organoelemental compounds and E–C bonds may be cleaved, are reduced to a minimum in this instance. The values of σ found without a sufficiently correct estimation of such complicating factors cannot therefore be regarded as fully reliable.

The Tables presented below indicate, together with the values of the σ constants, also the methods of their determination and (in the footnotes to the Tables) a brief description of the characteristics of the methods. In the Tables, the most reliable σ constants are included in square brackets and the least reliable ones are in round brackets. If experimental literature data were used to calculate the σ constants, the number of the corresponding literature reference in the Table is followed by an asterisk.

III. ANALYSIS OF THE σ CONSTANTS

The σ constants are a source of quantitative information about the electronic effects of substituents containing the elements E. The tasks dealt with in this Section are a systematic arrangement and analysis of such information and also the selection (in accordance with the principles indicated above) of the most and least reliable values of σ.

Table 1. The constants σ_I of silicon-containing substituents.

Substituent	σ_I	Method of determination	Refs.

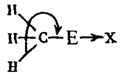
Table 1 (continued).

Notation: NMR-C-B—analysis of the chemical shifts of the signals of the *meta*- and *para*-carbon atoms in the ^{13}C-derivatives of benzene. The specific form of the relations between the chemical shifts or their differences and the constants σ, σ_R^0, and ρ^* has been indicated in a series of communications;[44–55] NMR-F-B—analysis of the chemical shifts δ in the ^{19}F NMR spectra of the *meta*-substituted (δ_m) and *para*-substituted (δ_p) fluorobenzenes. The most widely used is the method of Taft and co-workers[16,31] using the relations $\delta_m = -7.1\ \sigma_I + 0.60$ and $\delta_p = 7.1\ \sigma_I - 29.5\ \sigma_R^0 + 0.60$. The chemical shifts are measured relative to the shift of fluorobenzene for solutions in chloroform; IR-SiH—analysis of the stretching vibration frequency of the Si–H bond in the IR spectra of silane derivatives;[64] X-1–the study of the p*K* of substituted benzoic acids;[69,70] X-2–the study of the p*K* of substituted acetic acids;[28] X—on the basis of reactivity data but using less common methods; IR-M-H—analysis of the vibrational spectra and force constants of the M–H bonds (M = silicon subgroup element);[62] NMR-C-S—analysis of the chemical shifts of the signals of the carbon atoms in the vinyl group and the benzene ring in the ^{13}C NMR spectra of 4-substituted styrenes $XC_6H_4.CH{=}CH_2$;[56,57] NMR-H-S—analysis of the chemical shifts in the ^1H NMR spectra of 4-substituted styrenes $XC_6H_4.CH{=}CH_2$;[56,57] NMR-F-N—analysis of the chemical shifts in the ^{19}F NMR spectra of β-fluoronaphthalenes;[46] Ph—on the basis of physical research methods but using less common procedures.

1. The Inductive Constants σ_I

The constants σ_I characterise quantitatively the inductive effects of the substituents EX_3, where X are various groups. The changes in the values of σ_I for EX_3 and CX_3 with fixed X and variable E reflect the changes in the electronegativities of the Group IV elements E. However, the electronegativities of the Group IV elements E have not been generally accepted. Thus, according to Marrot and Maire,[75] the electronegativities of the elements E and groups of the type $E(C_2H_5)_nCl_{3-n}$ diminish in the sequence C > Ge > Si > Sn. However, according to other data,[76] the character in the changes in the electronegativities is different: C(2.55) > Pb(2.33) > Ge(2.01) > Sn(1.96) > Si(1.90) (the numerical values are given in brackets). The differences between these two series are caused not only by the different accuracies of the methods for the determination of electronegativity but also by more profound causes.[44,77] One of these is the effect (together with the inductive effect) of the σ,σ conjugation, whose influence increases in the sequence C < Si < Ge < Sn < Pb and depends on the type of substituents linked to E. For this reason, both inductive and hyperconjugation contributions are significant for the constants of certain substituents EX_3.[78] We may note that, in systems of the type



the contribution of σ,σ conjugation increases with the increase of the atomic number of E and with enhancement of the electron-accepting properties of X.[44]

The second cause is the conjugation within the substituent EX_3, which influences its electronegativity. If X is an atom or fragment with unshared electron pairs or an αβ-unsaturated hydrocarbon group, then, as will be shown in greater detail in the analysis of the constants σ_R, resonance effects arise. The role of the latter increases with increase of the σ_R for the groups X and also in the sequence Sn < Ge < Si and with increase of the effective positive charge on E, which depends on the fourth substituent linked to E.[79]

Notation: The solvents are indicated in brackets; for the significance of the designation of the methods, see the footnote to Table 1.

Ultimately the effective charge on the atom E changes in a complex manner and the electronegativity of the group EX_3 depends not only on the atom E but also on the type of substituent X and the organoelemental molecule as a whole. For this reason, the constants σ_I for organoelemental substituents (Tables 1 and 2) can be regarded as constants only by convention. As experimental data accumulate, a subsystem of σ_I constants will apparently be created for each comparatively narrow type of compounds.

On the basis of the data in Tables 1 and 2, one may reach several conclusions of a general character. For a fixed atom E, the constants σ_I of substituents of the type EX_3 vary in parallel with the enhancement of the electron-accepting properties of the group X: Alk < C_6H_5 < OAlk < Br < Cl < F. A higher value of σ_I corresponds to the substituent CH_2EX_3 than to the substituent EX_3. This is associated primarily with the electronegativity of the carbon atom, which exceeds the electronegativity of other Group IVB elements, which also agrees with the higher values of σ_I for $CAlk_3$ compared with $EAlk_3$. For example, the values of σ_I for $E(CH_3)_3$ are −0.07 (E = C[11]), −0.15 (E = Si), −0.11 (E = Ge), and −0.13 (E = Sn). However, constants σ_I which in many cases appreciably exceed the analogous values for carbon compounds correspond to the substituents $EHal_3$; 0.41–0.45 (CF_3); 0.30–0.41 (CCl_3); 0.26 (CBr_3).[11] We may note that, among the constants σ_I for halogenoalkyl groups, appreciable anomalies are also observed which cannot be accounted for solely from the standpoint of electronegativity. It is believed[101] that these anomalies are caused by the field effect, which has also been confirmed by data[42] indicating the predominance of the field effect over electronegativity for substituents of this type.

Smaller σ_I constants correspond to the silantranyl and germantranyl groups than to the corresponding trialkoxy-derivatives, which may be associated with the decrease of the electronegativity of the central atom owing to the partial electron transfer to this atom from nitrogen. The constants σ_I for the substituents $OEAlk_3$ and $SSnAlk_3$ are lower than the corresponding values for the analogous carbon derivatives apparently mainly owing to the more pronounced electron-donating properties of the groups $EAlk_3$ (compared with alkyl groups) (the constants σ_I for OAlk and SAlk are 0.3–0.2).[11]

2. The Resonance Constants σ_R^0

The constants σ_R^0 characterise the ability of substituents to be conjugated with n-donor groups or π-systems. Being involved in conjugation, the substituents EX_3 are electron donors (negative σ_R^0) (Tables 3 and 4). In this respect, the substituents EX_3 differ sharply from their carbon analogues CX_3. On the other hand, weakly electron-donating properties, arising in consequence of hyperconjugation, are typical for the substituents CX_3. Electronegative groups X can exhibit weak electron accepting properties.

The traditional interpretation of the resonance electron-accepting properties of EX_3 is based on the idea that the unoccupied *nd* orbitals of the atoms E participate in conjugation with *n*- or π-donor fragments D in compounds of the type $D{-}EX_3$ [$(p-d)\pi$ interaction]. This problem has been discussed in greater detail by Egorochkin and Khorshev.[79] Clearly the resonance interactions between the fragments D and EX_3 are determined both by the electron-donating properties of D and the electron-accepting properties of EX_3. Therefore, by fixing the fragment EX_3 and varying the fragment D, it is possible to vary the degrees of resonance interactions between EX_3 and D. It follows from the general theory[111] and experimental studies on organosilicon and organogermanium compounds[77,79] that the character of the variation of the degree of the $(p-d)\pi$ interaction between the fixed fragment EX_3 and the variable fragment D is determined by the σ_R constants of D. On the other hand, if both fragments EX_3 and D, vary, then the effective positive charge on the atom E becomes decisive. The constants σ_R^0 can therefore be regarded as characteristics of substituents of type EX_3 only for a fixed fragment D; an analogous situation obtains also for the constants σ_I.

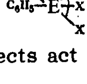
Notation: IR-B—analysis of the intensities of the *A* absorption band in the region of 1600 cm^{-1} in the IR spectra of monosubstituted benzenes using the relation $\sigma_R^0 = 0.0075 (A-100)^{1/2}$; [32,33,60] NMR-C-S1—analysis of the chemical shifts in the ^{13}C NMR spectra of the β-substituted styrenes $C_6H_5CH{=}CHX$; [50] IR-HB-A—IR spectroscopic study of the hydrogen bond formed by acetylene derivatives with phenol; [63] IR-E—analysis of the intensity of the *A* stretching vibration band of the double bond in the IR spectra of monosubstituted ethylenes using the relation $\sigma_R^0 = 0.0060 (A-80)^{1/2}$; [60] IR-A—analysis of the intensity of the *A* stretching vibration band of the triple bond in the IR spectra of monosubstituted acetylenes using the relation $\sigma_R^0 = 0.0046 A^{1/2} - 0.05$; [60] for the significance of the remaining designations of the methods, see the footnote to Table 1.

In this respect, the groups EX_3 resemble organic substituents for which the values of σ_R are likewise not invariant; when the electronic characteristics of the reaction centre are changed significantly, the sign of the constants may also change.[112] The condition that the fragment D is invariant holds for the majority of studies in which the σ_R^0 constants have been obtained for the substituents EX_3. These constants have been determined mainly for benzene derivatives. Almost all the values of σ_R^0 presented in Tables 3 and 4 characterise the resonance properties of the substituents EX_3 in relation to the benzene ring ($D = C_6H_5$). (See below, for the acetylene derivatives).

Another feature of the constants σ_R^0 (Tables 3 and 4) is that their values reflect not only the effects due to the (p–d)π interaction but also the σ, π conjugation



$C_6H_5{-}EX_3$ [113].

These two resonance effects act in opposite directions.

Notation: NMR-C-N—analysis of the chemical shifts in the ^{13}C NMR spectra of naphthalene derivatives; [58] for the significance of the remaining designations of the methods, see the footnotes to Tables 1 and 3.
Note: The solvents are indicated in brackets.

Although a series of quantum-chemical[113–115] and experimental[44,88,116] studies have been devoted to the characteristics of σ, π conjugation, there are many unsolved problems as regards the estimation of the relative contributions of the (p–d)π interaction and the σ, π conjugation to the overall resonance effect of EX_3 relative to the benzene ring. Some of these will be considered below in the analysis of the σ_p

and σ_p^+ constants of EX$_3$. Here we may note that the $(p-d)\pi$ interaction is weakened as the atomic number of E increases, while the σ,π conjugation actually becomes more intense. Therefore, for isostructural compounds, the contribution of the $(p-d)\pi$ interaction to the overall resonance effect of EX$_3$ relative to the aromatic ring is most significant when E = Si and the contribution of the σ,π conjugation is greatest when E = Pb. The stronger σ,π conjugation in acetylene derivatives[44,63] leads to negative values of σ_R^0 for E = Ge, Sn and to low values of σ_p (see below) for EX$_3$ linked by a triple bond.

As noted above, the constants σ_R^0 of the substituents EX$_3$ in CH$_2$EX$_3$ have different signs. The negative signs of the constants σ_R^0 for the groups CH$_2$EX$_3$ are due to the σ,π conjugation in benzyl derivatives:

$C_6H_5-CH_2-EX_3$

There is no effect of the $(p-d)\pi$ interaction in these compounds.

We may note certain features in the way the constants σ_R^0 of the substituents EX$_3$ vary as a function of the nature of E and X. For the substituents E(CH$_3$)$_3$, the constants σ_R^0 decrease with increase of the atomic number of E, which corresponds to the maximum degree of the $(p-d)\pi$ interaction in silicon compounds. The low values of σ_R^0 for the substituents PbAlk$_3$ are caused by the maximum degree of the σ,π conjugation and the minimum degree of the $(p-d)\pi$ interaction for lead compounds. For constant E, the enhancement of the electron-accepting properties of X and EX$_3$ increases the effective positive charge on E and intensifies the resonance electron-accepting properties of the substituents EX$_3$ (i.e. increases their σ_R^0 constants) for the following sequence of X: Alk < AlkO < Hal. For the same reason, the constants σ_R^0 increase with increase of n in the groups E(CH$_3$)$_{3-n}$Hal. The constants σ_R^0 of the substituents CH$_2$EX$_3$ show a tendency to decrease following the enhancement of the electron-accepting properties of X and to increase with increase of the atomic number of E, i.e. with increase of the polarisability of the E–C bonds.

3. The Hammett Constants σ_p and σ_m

These constants characterise quantitatively the overall electronic effect (inductive and resonance) of the substituents EX$_3$. Approximate values of σ_p can be obtained, using the relation $\sigma_p = \sigma_I + \sigma_R$, from the approximate estimate $\sigma_m \cong \sigma_I$; the difficulties arising in this procedure have been described.[11] In interpreting the constants σ_p, one should bear in mind the problems discussed in the analysis of the constants σ_I and σ_R^0. Furthermore, a considerable proportion of the constants σ_m and σ_p have been determined by chemical methods (Tables 5 and 6), which might have led to the appearance of appreciable non-controllable errors. Therefore, a non-critical application of these constants entails inevitably large errors and it is difficult to avoid subjectivity in estimating the most and least reliable values of the constants.

Note: The solvents are indicated in brackets; for the significance of the designations of the methods, see the footnotes to Tables 1, 3, and 5.

However, one should note that the constants σ_p and σ_m carry nevertheless important qualitative information about the electronic effects of EX_3. Thus the constants σ_p for $E(CH_3)_3$ are larger (−0.06– −0.13) than for the group $C(CH_3)_3$ (−0.20[11]). These estimates show that the resonance electron-accepting properties of organoelemental substituents must be more significant. The above conclusion has also been confirmed by the fact that the constants σ_p are larger than σ_m. The higher values of the constants σ_p for the substituents EX_3 than the corresponding values of σ_m are due to the presence in the former of a considerable resonance component, which is always positive. When this resonance component is negative, then $\sigma_p < \sigma_m$, which has in fact been observed for the substituent $CH_2Si(CH_3)_3$. It was noted above that, following the enhancement of the electron-accepting properties of X and EX_3, the constants σ_I and σ_R^0 increase; naturally, this also entails an increase of the constants σ_p.

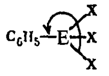
4. The Electrophilic Constants σ_p^+

The constants σ_p^+ reflect the overall influence of the electronic structure of the substituents EX_3 or CH_2EX_3 on the electron-deficient reaction centre. For the majority of the systems investigated hitherto (Tables 7 and 8), such a centre is the benzene ring, which has a positive charge. Analysis of the values of these constants constitutes an even more complex task than the interpretation of the Hammett constants σ_p. At first sight, it may turn out that there is altogether no correspondence between the values of the constants σ_p and σ_p^+ for organoelemental substituents (in contrast to organic substituents). For example, it is known[19] that, in the presence of a positive charge on the benzene ring, the p,π conjugation of the electron-donating organic substituents of the $+M$ type with the ring intensifies (the constants σ_p^+ and σ_p are negative and $\sigma_p^+ > \sigma_p$), while the conjugation remains unchanged for the electron-accepting substituents of the $-M$ type (the constants σ_p^+ and σ_p are positive and $\sigma_p^+ \cong \sigma_p$).

The values of σ_p^+ found for organoelemental compounds show that any groups EX_3 should exhibit stronger electron-donating properties (or weaker electron-accepting properties) than would follow from the estimates based on the σ_p constants. This is caused by the enhancement of the σ,π conjugation



when a positive charge arises on the ring.[116] [The second resonance effect—the $(p-d)\pi$ interaction—hardly depends on the charge on the ring.]

Table 8. The constants σ_p^+ of germanium-, tin-, and lead-containing substituents.

Substituent	σ_p^+	Method of determination	Refs.

Notation: IR-NB—analysis of the intensities of the stretching vibration bands of the NO_2 group in the IR spectra of *para*-substituted nitrobenzenes;[61] for the significance of the remaining designations of the methods, see the footnotes to Tables 1 and 7.

Note: The solvents are indicated in brackets.

[a] Taking into account the data in Refs.65, 113, 131, and 132.

The enhancement of the σ,π conjugation, characterised by the difference $\sigma_p^+ - \sigma_p$ is greater the greater the polarisability of the chemical bonds of the $C_{Ar}EX_3$ fragment of the $C_6H_5EX_3$ fragment of the $C_6H_5EX_3$ molecule and hence the greater the bond refraction ΣR_D, which is a quantitative measure of the polarisability. Therefore linear relations between $\sigma_p^+ - \sigma_p$ and ΣR_D hold for silicon and the germanium compounds and also for any other phenyl derivatives of non-transition Group II–V elements.[116]

The constants σ_p^+ of the groups $E(CH_3)_3$ reflect the influence of oppositely directed effects—the $(p-d)\pi$ interaction and the σ,π conjugation. The former effect is most significant for E = Si or Ge and the corresponding values of σ_p^+ (−0.13 and −0.21) are therefore greater than for $C(CH_3)_3$ (−0.26). On passing to $Sn(CH_3)_3$, the σ,π conjugation intensifies and σ_p^+ diminishes (to −0.34). With enhancement of the electron-accepting properties of X in EX_3, the constants σ_p^+ increase.

On passing from EX_3 to the substituents CH_2EX_3, the constants σ_p^+ diminish sharply, i.e. the negative values of these constants are significantly greater than the corresponding values of σ_p. This is caused by the intensification of the σ,π conjugation

$C_6H_5-CH_2-EX_3$

in the present of a positive charge on the ring. The linear relation between $\sigma_p^+ - \sigma_p$ and $\sum R_D$, which holds for $C_6H_5.CH_2EX_3$, is also valid for alkylbenzenes, although the σ,π conjugation in the latter is comparatively weak.[116] It follows from the analysis of the values of σ_p^+ that the electron-donating properties of the substituents CH_2EX weaken following the enhancement of the electron-accepting properties of X and intensify with increase of the atomic number of E. These features of the σ,π conjugation have been discussed in greater detail in other communications.[44,67,116]

The properties of the σ_p^+ constants of organoelemental substituents reflect the dependence of σ_p^+ on the type of reaction series and on the degree of conjugation between the substituent and the reaction centre, which is familiar[19] for carbon compounds. Comparison of the constants σ_p^+, determined for the same substituent by methods based on the NMR and UV spectroscopy of CTC, indicates a marked discrepancy between the results. According to the UV spectroscopic data for CTC, the substituents $CH_2E(CH_3)_3$ are much stronger electron donors, the discrepancy between the results obtained by the two methods increasing with increase of the atomic number of E. Under the experimental conditions of the UV spectroscopic measurements for CTC, there is an appreciable positive charge on the aromatic ring, which leads to an increase of the degree of σ,π conjugation. The constants σ_p^+ then reach high negative values, which is inconsistent with the data obtained by the NMR method, where there is no positive charge on the ring in the ground electronic state.

Thus in the experiments involving the NMR and UV spectroscopic measurements for CTC, the substituent $CH_2E(CH_3)_3$ is in essence linked to different reaction centres (neutral and positively charged). The constants σ_p^+ therefore do not remain invariant, reflecting the unequal degrees of conjugation of the substituent $CH_2E(CH_3)_3$ with different reaction centres. Analogous situations have been discussed for organic compounds.[112,116]

5. Other σ Constants

Systematic studies of other constants of organoelemental substituents are only just beginning. Only scattered data are available on the constants σ_p^- of the substituents $Si_n.(CH_3)_{2n+1}$ (where $n = 1,2,3$),[59,69,121,136] $Si(C_6H_5)_3$, and $Ge(C_6H_5)_3$;[73] the constants σ_R^- and σ_R^+ of the silantranyl and trialkoxysilyl groups[52] and $COOCH_2SiF_3$,[83] $OE(C_6H_5)_3$, and $SE(C_6H_5)_3$, where E = Sn or Pb,[61] have also been obtained.

The steric effects in organoelemental compounds[45] are distinguished by a number of features. Therefore, together with the accumulation of data on the steric constants E_S of silyl substituents,[137] the constants $E_S(Si)$,[138] reflecting the specific features of the steric effects of the alkyl groups linked to the silicon atom, have also been introduced.

---o0o---

In conclusion we may note that the correlation equations linking structure and reactivity have been developed for silicon subgroup compounds to a lesser extent than for carbon derivatives, which can be explained not only by the inadequate extent to which the organoelemental compounds have been investigated and the experimental difficulties in the determination of the σ constants of the element-containing substituents but also by the marked, even more pronounced than for carbon compounds, dependence of these constants on the type of reaction centre. Although, on the one hand, this factor does hold back the use of the σ constants as universal characteristics of the donor–acceptor properties of element-containing substituents, on the other hand, the correlation equations constitute an effective means for the investigation of intramolecular interactions between the silicon subgroup element and the variable reaction centre. Analysis of the accumulated information about the σ constants is therefore of independent interest and leads to prospects for further study of urgent theoretical problems in the organoelemental chemistry of non-transition elements.

The Phosphorus Analogues of Aminocarboxylic Acids

V.P.Kukhar' and V.A.Solodenko

The review is devoted to aminophosphonic, aminophosphinic, and aminophosphonous acids and their derivatives. The interest in these compounds is in many respects because some of them have been detected in Nature and have an appreciable bioactivity. The review deals with the methods of synthesis of aminophosphonic, aminophosphinic, and aminophosphonous acids and with the properties of these compounds, attention being specially concentrated on the phosphorus analogues of natural α-aminocarboxylic acids.

The bibliography includes 258 references.

III. The properties of aminophosphonic, aminophosphinic, and aminophosphonous acids 866

I. INTRODUCTION

β-Aminoethylphosphonic acid (ciliatine)—the first natural product with a P–C bond—was isolated from natural sources in 1959.[1] Subsequently other natural aminophosphonic, aminophosphinic, and aminophosphonous acids and their derivatives were discovered.[2–10] The appreciable bioactivity of these compounds stimulated interest in the study of their chemistry and bioreactions. The phosphorus analogues of natural aminocarboxylic acids have attracted special attention. These compounds belong to the class of aminoalkyl organophosphorus compounds, whose chemistry has been considered in a number of reviews.[11–13] At the same time, the presence in their structure of the free amino-group, frequently in combination with other functional groups (hydroxy-, mercapto-, etc.), imposes definite limitations on the choice of methods and frequently requires special approaches to their synthesis. Stereochemical aspects are also important.

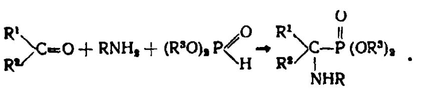
The chemistry of α-aminophosphonic acids has been examined in a review[14] published in 1975, but during the intervening period has been significantly supplemented by new results. A later review[15] on the chemistry of aminophosphinic acids is extremely concise.

This review deals with the methods of synthesis of aminophosphonic, aminophosphinic, and aminophosphonous acids (APA) and their properties. Attention is concentrated on the phosphorus analogues of natural α-aminocarboxylic acids.

II. METHODS OF SYNTHESIS OF AMINOPHOSPHONIC, AMINOPHOSPHINIC, AND AMINOPHOSPHONOUS ACIDS

1. Amino- and Amido-alkylation of Hydrophosphoryl Compounds; the Kabachnik–Fields Reaction

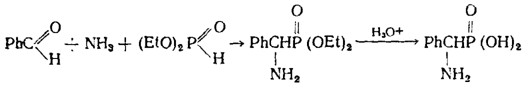
At the beginning of the 1950's, Kabachnik and co-workers[16–21] and independently the American investigator Fields[22] showed that the interaction of ammmonia (or an amine), a carbonyl compound, and a dialkyl phosphite leads to the formation of α-aminophosphonic acid esters (the Kabachnik–Fields reaction):



$$R^1R^2C{=}O + RNH_2 + (R^3O)_2P(O)H \rightarrow R^1R^2C(NHR){-}P(O)(OR^3)_2 \,.$$

It has been suggested that the reaction mechanism involves the initial formation of an α-hydroxyalkylphosphonic acid ester with the subsequent replacement of the hydroxy-group by the amino-group.[23] Another view on the mechanism of this reaction has been described in a monograph,[24] where the reaction is treated as aminoalkylation of a hydrophosphoryl compound (HPC) by an electrophilic intermediate formed form the carbonyl compound and the amine.

The range of compounds which can be involved in this process is extremely large.[23,24] We shall deal only with studies where the synthesis of α-APA† with an unsubstituted amino-group has been described. The most convenient method for the synthesis of these compounds uses ammonia as the amino-component.[16–21,25] When benzaldehyde, an alcoholic ammonia solution, and diethyl phosphite are heated in a sealed tube at 100 °C, diethyl α-aminobenzylphosphonate is formed, its hydrolysis leading to free α-aminobenzylphosphonic acid:[16,18]



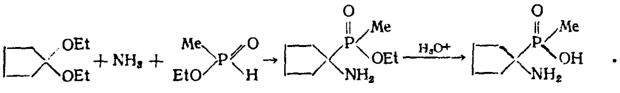
$$PhC(O)H + NH_3 + (EtO)_2P(O)H \rightarrow PhCH(NH_2)P(O)(OEt)_2 \xrightarrow{H_3O^+} PhCH(NH_2)P(O)(OH)_2 \,.$$

Phosphonic analogues of alanine (Ala^P) and phenylalanine (Phe^P) have been obtained by this method.[26] The yields of α-aminophosphonic acid esters synthesised in this way do not usually exceed 45%. Diethyl α-aminoethylphosphonate has been obtained in 76% yield by a somewhat modified method (stirring of a mixture of acetaldehyde–ammonia, diethyl phosphite, and ammonia in a sealed tube at room temperature).[27] The use of acid esters of phosphonous acids makes it possible to obtain derivatives of α-aminophosphinic acid.[20] The phosphonic and phosphinic analogues of cycloleucine were obtained in this way, starting from the diethylketal of cyclopentanone

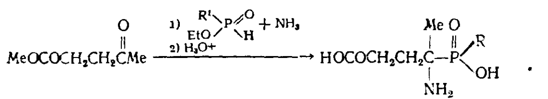
---

†The APA which are analogues of natural aminocarboxylic acids are designated by the generally accepted three letter abbreviations with the superscript P. For the phosphorus analogues of aspartic and glutamic acids, the additional subscripts α, β, and γ, denoting the position of the phosphorus-containing group, are introduced. For the phosphine analogues, a superscript indicating the position of the substituent at the phosphorus atom is added.

and diethyl phosphite or ethyl methylphosphonite respectively:[28]



The α-phosphonic and α-phosphinic analogues of α-methylglutamic acid has been synthesised analogously by the aminoalkylation of diethyl phosphite and ethyl methylphosphonite:[29]

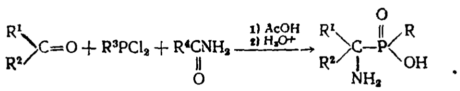


R = OH, Me

Overall, the Kabachnik–Fields reaction is a convenient general method for synthesis of α-aminophosphonic and α-aminophosphinic acids; the important advantages of the method are a single-stage process and the availability of the starting compounds.

The aminoalkylation of HPC has been extended to tervalent phosphorus acids—hypophosphorus, phosphorous, and phosphonous acids, which made it possible to obtain directly free α-aminophosphonous,[30,31] α-aminophosphonic,[32] and α-aminophosphinic,[33,34] acids. However, this approach has not found extensive application in the synthesis of α-APA with a free amino-group because it is restricted almost exclusively to the aminoethylation reaction. The report[35] of the synthesis of a series of α-(*N*-benzylamino)alkylphosphonic acids by the aminoalkylation of phosphorous acid was subsequently judged to be erroneous.[36] It is noteworthy that the aminoalkylation of phosphorous acid is used extremely widely for the synthesis of APA derivatives with valuable complex-forming properties.[12,13]

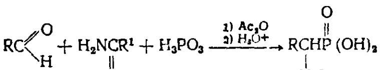
The reaction involving the amidoalkylation of tervalent phosphorus halides has found very extensive application in the synthesis of α-APA. When a carbonyl compound, phosphorus trichloride [or an alkyl(aryl)dichlorophosphine], and a compound containing the amide group interact in acetic acid, an intermediate is formed, whose hydrolysis leads to the formation of α-aminophosphonic or α-aminophosphinic acid in 40–60% yield:[37]



R^3 = Cl, Alk, Ar; R^4 = EtO, $PhCH_2O$;
R = OH, Alk, Ar

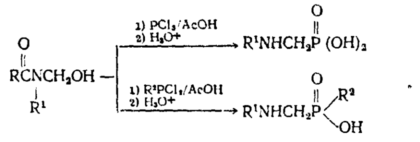
The use of acetals instead of carbonyl compounds and of carboxylic acid amides (acetamide, benzamide) instead of carbamates lowers the yield of α-APA. It is of course not permissible to employ amines and ammonia in this reaction.[37] The process can be carried out successfully also in trimethylacetic acid.[38] Aminomethylphosphonic acid (Gly^P) [39] as well as the phosphonic and phosphinic analogues of cycloleucine,[28] proline,[40] serine,[41] α-methylaspartic, α-methylpyroglutamic, glutamic, and pyroglutamic acids,[42] and ornithine[43] have been obtained by this method. The use of *N*-alkylbenzylcarbamates as the amide components makes it possible to synthesise α-(*N*-alkylamino)alkylphosphonic and the corresponding phosphinic acids.[44] The attempts to employ *NN'*-dialkylbenzylcarbamates in the reaction were unsuccessful.[44]

The amidoalkylation of phosphorous acid in acetic anhydride has been used to obtain phosphonic analogues of alanine, valine, and also other α-aminophosphonic acids (yields from 10 to 75%):[45]



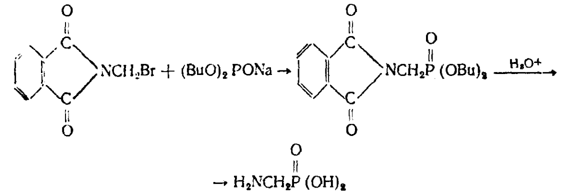
R = Me, iso-Pr, Ar; R^1 = $PhCH_2O$, Ph, Me

The interaction of *N*-hydroxymethylamides with phosphorus trichloride or alkyl(aryl)dichlorophosphines in acetic acid leads to the formation of aminomethylphosphonic or aminomethylphosphinic acid, including *N*-alkylated derivatives, in 25–80% yield:[46–48]



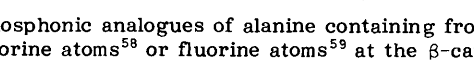
2. The Arbuzov and Michaelis–Becker Reaction

The Arbuzov and Michaelis–Becker reactions have been of fundamental importance for the chemistry of organophosphorus compounds and historically were the first methods of synthesis of aminomethylphosphonic acid—the phosphonic analogue of glycine (Gly^P):[26,49]



The use of dialkyl phosphonites makes it possible to obtain aminophosphinic acids.[50] The use of the Arbuzov and Michaelis–Becker reactions for the synthesis of β-, γ-, and ω-APA has been described.[49,51–55]

For example, the Arbuzov reaction has been the key stage in the first synthesis of phosphinothricin—a phosphinic analogue of glutamic acid (Glu$^{\gamma\text{-}PMe}$):[9]

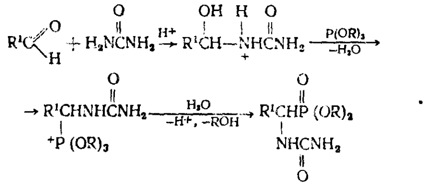


Diethyl α-ethoxycarbonylaminomethylphosphonate—an important intermediate in the synthesis of cephalosporin—has been obtained by the reaction of the ethyl ester α-bromo-*N*-t-butoxycarbonylglycine with triethyl phosphite:[56,57]

$$\underset{\displaystyle Br}{\text{t-BuOCONHCHCOOEt}} \xrightarrow[2)\ HCl/EtOH]{1)\ P(OEt)_3} \underset{\displaystyle COOEt}{H_2NCH\overset{O}{\overset{\|}{P}}(OEt)_2}$$

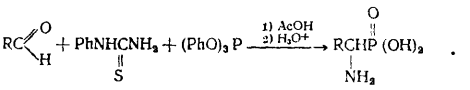
The phosphonic analogues of alanine containing from one to three chlorine atoms[58] or fluorine atoms[59] at the β-carbon atom have been obtained by the Arbuzov reaction.[59] The long duration and relatively severe reaction conditions can be regarded as disadvantages of the Arbuzov reaction as a method of synthesis of APA. In certain cases this method does not yield satisfactory results. Thus the phosphinic analogue of alanine (Ala^{P-Ph}) has been obtained by the Arbuzov reaction in only 5% yield.[50]

The Arbuzov reaction in its classical form is used for the synthesis of α-APA as a rule only in order to obtain aminomethylphosphonic and aminomethylphosphinic acids and their derivatives. On the other hand, the non-classical variants of the Arbuzov reaction, where electrophiles other than alkyl halides are introduced into the reaction with tervalent phosphorus acid esters, have found extremely extensive applications in the synthesis of phosphonic and phosphinic analogues of α-aminocarboxylic acids. Thus it has been found that, on heating with aldehydes and ureas, phosphites and phosphonites give rise to esters of α-ureidophosphonic and the corresponding phosphinic acids. Mono- and di-substituted ureas produce only monophosphonates, while unsubstituted urea gives rise to a mixture of mono- and di-phosphonates. Instead of urea, thiourea may be employed. The reaction is facilitated in the presence of acid catalysts. The following process mechanism has been discussed:[60]



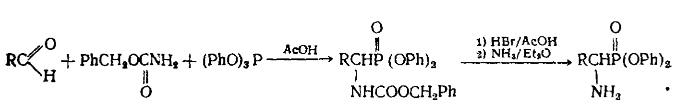
$$\mathrm{R^1CHO} + \mathrm{H_2NC(O)NH_2} \xrightarrow{H^+} \mathrm{R^1CH(OH)-\overset{+}{N}H-C(O)NH_2} \xrightarrow[-H_2O]{P(OR)_3} \mathrm{R^1CH(\overset{+}{P}(OR)_3)NHC(O)NH_2} \xrightarrow[-H^+,\,-ROH]{H_2O} \mathrm{R^1CH(NHC(O)NH_2)P(O)(OR)_2}\ .$$

This process is the basis of a series of methods of synthesis of α-APA and their derivatives. Thus, when an aldehyde, *N*-phenylthiourea, and triphenyl phosphite are heated in acetic acid, the diphenyl esters of α-thioureidoalkylphosphonic acid esters are formed and their hydrolysis leads to the free α-aminoalkylphosphonic acids:



$$\mathrm{RCHO} + \mathrm{PhNHC(S)NH_2} + \mathrm{(PhO)_3P} \xrightarrow[2)\ H_3O^+]{1)\ AcOH} \mathrm{RCH(NH_2)P(O)(OH)_2}\ .$$

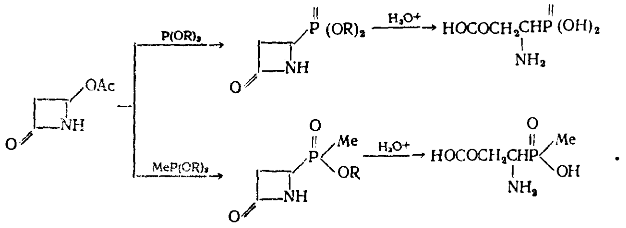
A series of α-APA, including the phosphonic analogues of alanine, valine, phenylalanine,[61] methionine,[62,63] cysteine, and cystine,[64] have been obtained by this method. Instead of *N*-phenylthiourea, unsubstituted thiourea,[61] *N*-(α-phenylethyl)thiourea,[61] and ethyl- or benzyl-carbamates[65] can be used in the reaction. The *N*-benzyloxycarbonyl derivatives of α-APA formed when benzylcarbamate is used are smoothly converted into the diphenyl esters of α-aminophosphonic acids on treatment with hydrogen bromide in glacial acetic acid, which constitutes a convenient method of synthesis of these compounds:[66]



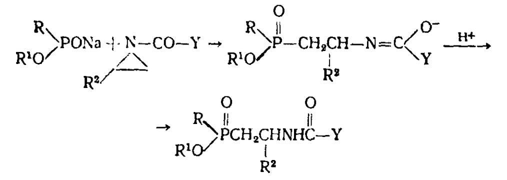
$$\mathrm{RCHO} + \mathrm{PhCH_2OC(O)NH_2} + \mathrm{(PhO)_3P} \xrightarrow{AcOH} \mathrm{RCH(NHCOOCH_2Ph)P(O)(OPh)_2} \xrightarrow[2)\ NH_3/Et_2O]{1)\ HBr/AcOH} \mathrm{RCH(NH_2)P(O)(OPh)_2}\ .$$

The phosphonic analogues of valine and phenylglycine have been obtained by the hydrolysis of α-ureidoalkylphosphonates, formed on heating a mixture of *N*-phenylurea, triethyl phosphite, and the corresponding aldehyde in toluene in the presence of boron trifluoride etherate.[67] When an *N*-monosubstituted urea, obtained from the optically active α-phenylethylamine, is used in this reaction, asymmetric induction is observed and the optically active α-aminophosphonic acid is formed (but the enantiomeric excess is small).[68]

4-Acetoxyazetidin-2-ones readily react with phosphites and phosphonites to form 2-oxoazetidin-4-ylphosphonates and the corresponding phosphinates; the acid hydrolysis of the resulting compounds affords the phosphonic and phosphinic analogues of aspartic acid ($Asp^{\alpha-P}$ and $Asp^{\alpha-P-Me}$):[69-71]



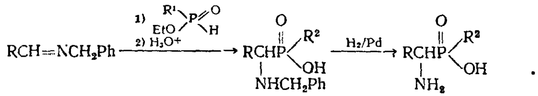
The esters of tervalent phosphorus acids enter into the Arbuzov and Michaelis–Becker reactions with *N*-acyl- or *N*-sulphonyl-aziridines to form derivatives of α-aminoethylphosphonic and the corresponding phosphinic acid:[72-74]



On interaction with phosphites, *N*-(trimethylammoniamethyl)-formamide gives rise to esters of *N*-formylaminomethylphosphonic acid.[75] The reaction of diethyl methylphosphonite proceeds analogously.[15]

3. The Addition of Hydrophosphoryl Compounds to Carbon–Nitrogen and Carbon–Carbon Multiple Bonds

The addition of HPC to the carbon–nitrogen double bond is an important general method for the formation of the P–C–N bond system.[11,13,24] The addition of HPC to Schiff bases, choosing a substituent at the nitrogen atom which can be removed with formation of a free amino-group, is most often employed for the synthesis of α-APA. Many α-aminophosphonic and α-aminophosphinic acids, for example, have been obtained by the addition of acid phosphites and phosphonites to aldimines based on benzylamine, since the *N*-benzyl group is readily removed by hydrogenolysis in the presence of the palladium catalyst:[76,77]



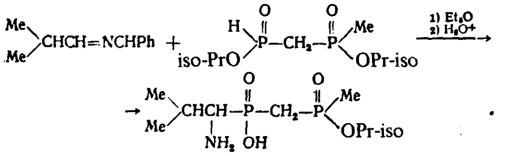
$$\mathrm{RCH{=}NCH_2Ph} \xrightarrow[2)\ H_3O^+]{1)\ R^1(EtO)P(O)H} \mathrm{RCH(NHCH_2Ph)P(O)(R^2)(OH)} \xrightarrow{H_2/Pd} \mathrm{RCH(NH_2)P(O)(R^2)(OH)}\ .$$

R^1 = OAlk, Alk, Ar; R^2 = OH, Alk, Ar

The *N*-α-phenylethyl group is also removed by catalytic hydrogenolysis.[78-80] The addition of dialkyl phosphites to aldimines, obtained from the optically active α-phenylethylamine, is accompanied by appreciable asymmetric induction, which has been used for the asymmetric synthesis of α-aminophosphonic acids.[78,79,81] The highest degree of asymmetric induction (up to 80% optical purity) has been observed in acid catalysis (HCl, AcOH); with increase of temperature, the stereoselectivity of the addition diminishes appreciably. Diethyl phosphite can be replaced in this reaction successfully by tris(trimethylsilyl) phosphite.[80]

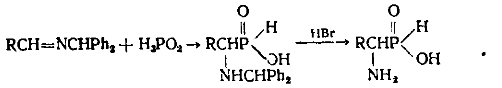
Together with dialkyl phosphites, mono-, bis-,[82] and tris-(trimethylsilyl) phosphites[80] also add to Schiff bases. The silyl esters of α-aminophosphonic acids formed are readily hydrolysed under neutral conditions (on heating with water or alcohol) to the free acids, which facilitates the isolation of the latter.

The addition of acid esters of methylenediphosphonic acids to Schiff bases has been described:[83]



$$\mathrm{Me_2CHCH{=}NCHPh + H(iso\text{-}PrO)P(O){-}CH_2{-}P(O)(Me)(OPr\text{-}iso) \xrightarrow{1)\,Et_2O;\ 2)\,H_3O^+} Me_2CH\underset{NH_2}{CH}{-}\underset{OH}{P}(O){-}CH_2{-}P(O)(Me)(OPr\text{-}iso)}$$

Phosphorous acid usually reduces Schiff bases to secondary amines and products of addition to the C=N bonds can be obtained in satisfactory yields only in isolated instances.[84] In contrast to phosphorous acid, hypophosphorous acid adds fairly smoothly to Schiff bases with formation of *N*-substituted α-aminophosphonous acids.[85] Many α-aminophosphonous acids, including the phosphonous analogues of all the most important natural α-aminocarboxylic acids, have been obtained in this way:[86–89]



$$\mathrm{RCH{=}NCHPh_2 + H_3PO_2 \rightarrow \underset{NHCHPh_2}{RCH}P(O)(H)(OH) \xrightarrow{HBr} \underset{NH_2}{RCH}P(O)(H)(OH)}$$

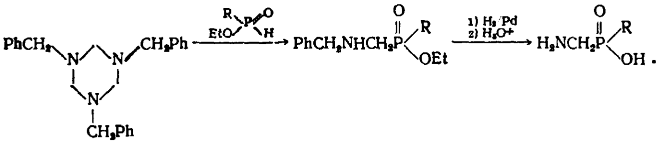
Catalytic hydrogenolysis is unsuitable in this instance for the removal of the protecting group owing to the poisoning of the catalyst by the hydrophosphoryl compound and for this reason azomethines with the *N*-diphenylmethyl substituent, which is readily removed in an acid medium, are employed.

The addition of dialkyl phosphites to azomethines with the acid-removable *N*-diphenylmethyl substituent has been used to synthesise phosphonic analogues of alanine, valine, phenylalanine, and cycloleucine;[90] mono- and di-aminodiphosphonic acids, including the diphosphonic analogues of aspartic and glutamic acids, have been synthesised in this manner.[91]

The application of other *N*-protecting groups, removable by acid hydrolysis, for the synthesis of α-APA has been described, namely the t-butyl,[92] 1-phenylcyclopentyl,[93,94] and αα-disubstituted benzyl[95] groups.

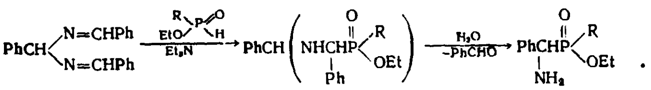
The addition of HPC to azomethines has been used widely in the synthesis of various α-APA, in particular potential bacteriostatic compounds,[96] analogues of morphactins (plant growth regulators),[97–100] phosphorus analogues of penicillamine,[101] and spin-labelled compounds.[102]

Hexahydrotriazines react with acid phosphites and phosphonites to form esters of *N*-substituted α-aminophosphonic and the corresponding phosphinic acids:[15,33,92,103]



Phosphinic analogues of glycine ($\mathrm{Gly^{P-R}}$) (R = Me or Et)[15] as well as the phosphonic analogue of proline[104] have been obtained by this method. The latter compound has also been synthesised by the addition of diphenyl phosphite to monomeric 1-pyrroline.[77] Aminomethylphosphonous acid ($\mathrm{Gly^{P-H}}$) has been synthesised by adding hypophosphorous acid to 1,3,5-tris(diphenylmethyl)hexahydrotriazine in 10% yield.[88]

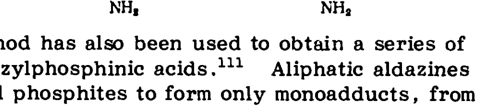
Hydrobenzamide combines with two equivalents of dialkyl phosphite or a monoester of phenylphosphonous acid to form phosphorus-containing aminals, the controlled hydrolysis of which affords the esters of α-aminobenzylphosphonic and the corresponding phosphinic acids:[105,106]



$$\mathrm{PhCH(N{=}CHPh)_2 \xrightarrow[Et_3N]{R(EtO)P(O)H} PhCH\left(NH\underset{Ph}{CH}P(O)(R)(OEt)\right)_2 \xrightarrow[-PhCHO]{H_2O} Ph\underset{NH_2}{CH}P(O)(R)(OEt)}$$

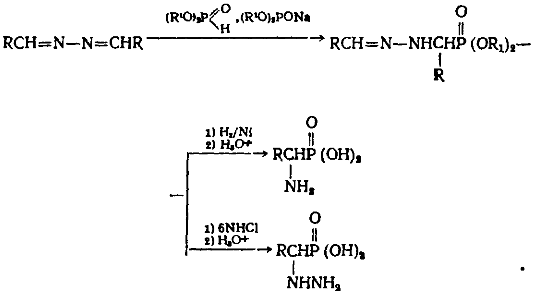
NN'-Dialkylidene-1,2-diaminoalkanes, formed from ammonia and aliphatic aldehydes, behave similarly, which has been used to obtain the esters of certain α-aminophosphonic acids, including the dialkyl esters of the phosphonic analogues of valine.[107]

α-Aminophosphonic acid can be obtained also from aldazines by adding HPC to the C=N bond with subsequent reductive cleavage of the nitrogen–nitrogen bond. Aromatic aldazines combine with two equivalents of dialkyl phosphite and the resulting adducts are reduced with an excess of sodium dialkyl phosphite to esters of α-aminobenzylphosphonic acids:[108–110]



$$\mathrm{XC_6H_4{-}CH{=}N{-}N{=}CH{-}C_6H_4X \xrightarrow{(RO)_2P(O)H,\ (RO)_2PONa} XC_6H_4{-}\underset{NH_2}{CH}P(O)(OR)_2 \xrightarrow{H_3O^+} XC_6H_4{-}\underset{NH_2}{CH}P(O)(OH)_2}$$

This method has also been used to obtain a series of α-aminobenzylphosphinic acids.[111] Aliphatic aldazines react with dialkyl phosphites to form only monoadducts, from which α-hydrazinophosphonic acids can be obtained by acid hydrolysis[112] or α-aminophosphonic acids can be produced by hydrogenation on Raney nickel:[112,113]



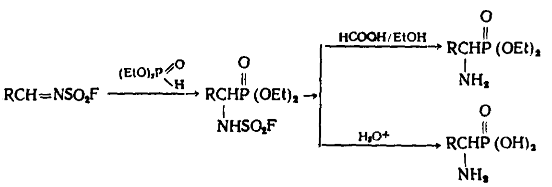
$$\mathrm{RCH{=}N{-}N{=}CHR \xrightarrow{(R'O)_2P(O)H,\ (R'O)_2PONa} RCH{=}N{-}NH\underset{R}{CH}P(O)(OR_1)_2}$$

$$\mathrm{\xrightarrow{1)\,H_2/Ni;\ 2)\,H_3O^+} \underset{NH_2}{RCH}P(O)(OH)_2 \qquad \xrightarrow{1)\,6N\,HCl;\ 2)\,H_3O^+} \underset{NHNH_2}{RCH}P(O)(OH)_2}$$

Acid phosphonites interact similarly with aliphatic aldazines, which makes it possible to obtain α-aminophosphinic acids.[114] This method has been used to obtain phosphonic and phosphinic analogues of alanine, valine, and leucine. The phosphonic and phosphinic analogues of cycloleucine have been synthesised analogously by adding one mole of diethyl phosphite or ethyl methylphosphonite respectively to the ketazine based on cyclopentanone.[28]

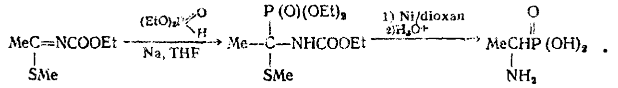
HPC can also be added to a series of other compounds with a C=N bond, which has been employed to synthesise α-APA. For example, benziminoethyl ether combines with two equivalents of dialkyl phosphite to form the ester of the N-phosphorylated α-aminobenzylphosphonic acid.[115] It has been suggested that iminoesters are intermediates in the reaction of orthoformate, a primary amine, and a dialkyl phosphite (or a monoalkyl phosphonite), which results in the formation of aminomethylenebis(phosphonates) or aminomethylenebis(phosphinates).[15,116]

Dialkyl phosphites add to *N*-acylimines to form the esters of *N*-acylated α-aminophosphonic acids.[117,118] Hydrolysis of these compounds leads to α-aminophosphonic acids; it is sometimes possible to remove selectively the *N*-acyl group with formation of esters of α-aminophosphonic acid:[119]



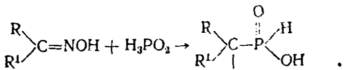
$$\mathrm{RCH{=}NSO_2F \xrightarrow{(EtO)_2P(O)H} \underset{NHSO_2F}{RCH}P(O)(OEt)_2 \rightarrow \left\{ \xrightarrow{HCOOH/EtOH} \underset{NH_2}{RCH}P(O)(OEt)_2 ;\ \xrightarrow{H_3O^+} \underset{NH_2}{RCH}P(O)(OH)_2 \right.}$$

N-Acyliminothioesters are capable of reacting with dialkyl phosphites analogously to *N*-acylimines. The reductive elimination of alkylthio-groups from the adducts and subsequent hydrolysis lead to α-aminophosphonic acids:[126]



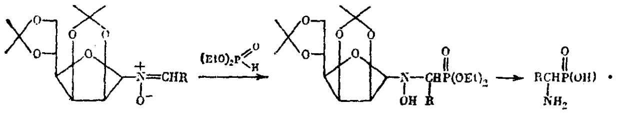
This method has been used to synthesise the enantiomers of the phosphonic analogue of phenylalanine.[121]

Under the conditions of alkaline catalysis, oximes combine with two equivalents of dialkyl phosphite to form *N*-phosphorylated α-aminophosphonates as a result of the postulated aminophosphonate–amidophosphate [phosphoramidate?] rearrangement.[122] The addition of hypophosphorous acid to oximes, which leads to the formation of α-aminophosphonous acids, is of considerable interest. The phosphonous analogues of alanine, valine, and glutamic acid ($\mathrm{Glu}^{\alpha-\mathrm{P-H}}$) have been obtained by this method:[123]



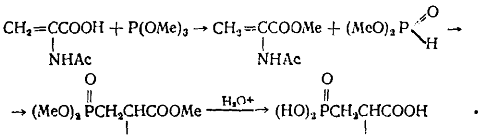
The mechanism of this reaction has not been elucidated.

The addition of dialkyl phosphites to *N*-glycosylnitrones has been used for the asymmetric synthesis of dextrorotatory phosphonic analogues of serine, valine, and alanine:[124]

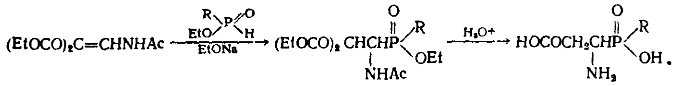


Dialkyl phosphites[125] and phosphorous acid[126,127] add to nitriles with formation of aminomethylenediphosphonic acids or their esters. Under the conditions of base catalysis, dialkyl phosphites react with arylisonitriles to form *N*-arylaminomethylenediphosphonates.[128]

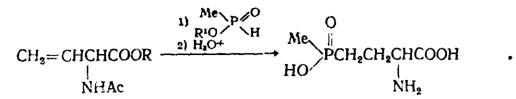
The ability of HPC to undergo Michael addition to activated carbon–carbon double bonds has also been used to synthesise α-, β-, and γ-APA. The phosphonic analogue of aspartic acid $\mathrm{Asp}^{\beta-\mathrm{P}}$, where the β-carboxy-group has been replaced by the phosphono-group, has been obtained by the interaction of α-acetamidoacrylic acid with phosphite:[129]



The addition of esters of methyl- and ethyl-phosphonous acids to α-acetamidoacrylic acid proceeds with formation of the corresponding phosphonic analogue of aspartic acid ($\mathrm{Asp}^{\beta-\mathrm{P-Me}}$ and $\mathrm{Asp}^{\beta-\mathrm{P-Et}}$).[130] The phosphonic and phosphinic analogues of aspartic acids, in which the phosphono- or phosphino-group replaces the α-carboxy-group, have been obtained by the addition of dialkyl phosphites or acid phosphonites to acetamidomethylenemalonate with subsequent hydrolysis and decarboxylation of the adducts:[130,131]

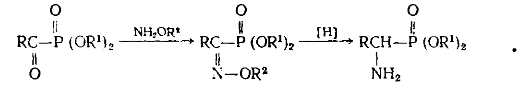


The esterification of the carboxy-groups in these compounds with subsequent ammonolysis leads to the formation of the phosphonic and phosphinic analogues of asparagine.[130,131] The phosphonic and phosphinic analogues of α-methylaspartic acid have been obtained by adding the corresponding HPC to β-aminocrotonate.[29] The same approach has been used to obtain the phosphinic analogue of glutamic acid—phosphinothricin ($\mathrm{Glu}^{\gamma-\mathrm{P-Me}}$):[15]



4. Amination of α-Oxophosphonates (The Oxime Method)

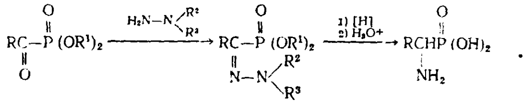
A number of methods of synthesis of α-aminophosphonic and α-aminophosphinic acids are based on the use of α-oxoalkylphosphonates and the corresponding phosphinates, which are converted into oximes and then reduced (the oxime method):



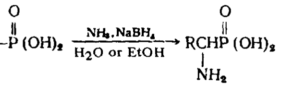
The oxime group can be reduced by a wide variety of reductants. Thus α-aminobenzylphosphonic acid and its derivatives[132] and also the phosphonic analogue of dihydroxyphenylalanine (DOPA) [133] have been obtained by the reduction of the corresponding oximes with aluminium amalgam. Diborane has also been used as the reductant;[134] the phosphonic analogues of alanine, valine, leucine, and isoleucine have been obtained in this way. The oximes can be reduced by hydrogenation on Raney nickel,[135,136] which has been used in the synthesis of the phosphonic analogues of tryptophan.[136]

In the reduction of oximes with zinc in formic acid, the amino-group formed is partly formylated; to achieve deformylation, the reaction mixture is treated with hydrogen chloride in methanol.[137] The esters of phosphonic analogues of alanine, valine, leucine, phenylalanine, glutamic acid, and methionine,[137] as well as the phosphonic analogue of cysteine[138] have been synthesised by this procedure. The reduction of oximes with zinc in formic acid has also been employed for the synthesis of α-aminophosphonic acids.[42]

α-Oxophosphonates can be converted into hydrazones, whose reduction with aluminium amalgam[139] or zinc in a mixture of acetic and trifluoroacetic acids[140] as well as catalytic hydrogenation[139,140] lead to α-aminophosphonates:



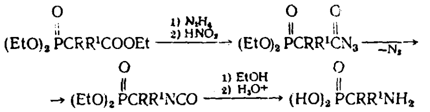
The single-stage method for the direct conversion of α-oxophosphonic acids into α-aminophosphonic acids on treatment with ammonia and sodium tetrahydroborate[141] is undoubtedly attractive:



The phosphonic analogues of alanine, valine, leucine, phenylalanine, and glutamic acid ($\mathrm{Glu}^{\alpha-\mathrm{P}}$) have been obtained in this way. Instead of ammonia, primary amines can be used in the reaction. It is of interest that the mono- and di-esters of α-oxophosphonic acids do not enter into this reaction. The use of $\mathrm{NaB}^3\mathrm{H}_4$ makes it possible to obtain tritium-labelled α-aminophosphonic acids.[142]

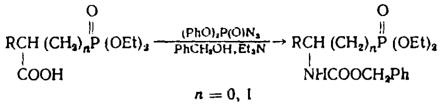
5. Synthesis of Aminophosphonic Acids using the Curtius and Hofmann Rearrangements

One of the most frequently employed methods of synthesis of α-APA is that from the esters of α-phosphonocarboxylic acids, whose key stage is the Curtius rearrangement of the corresponding phosphonocarboxylic acid azides. The general scheme of this multistage synthesis, which is usually carried out as a "single flask" process, i.e. without the isolation of intermediates, is presented below:[129,143]



The phosphonic analogues of glycine, alanine, phenylalanine, valine, α-methylalanine, tyrosine, lysine, ornithine, etc. have been obtained by this procedure.[129,143–145] The method has also been used to synthesise α-aminoethylphosphonic acid (ciliatine) and γ-aminopropylphosphonic acid (the phosphine analogue of γ-aminobutyric acid [146]). The broad limits of its applicability, in particular the possibility of synthesising α-, β-, γ-, and ω-APA as well as αω-diaminophosphonic acids must be regarded as advantages of the methods. Its disadvantage is its multistage nature, which is frequently the reason for the moderate overall yields of the aminophosphonic acids.

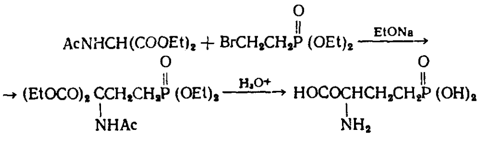
If the rearrangement of the phosphonocarboxylic acid azides is carried out in the presence of alcohols, it is possible to isolate the corresponding carbamates derived from the aminophosphonic acids, which has been used to synthesise N-benzyloxycarbonyl derivatives of α- and β-aminophosphonates:[147]



The Hofmann degradation of phosphonocarboxylic acid amides can also be used to synthesise aminophosphonic acids. This method has been used successfully to obtain β-aminoethylphosphonic acid[148] and its derivatives.[149,150] On the other hand, there are contradictory literature data concerning the possibility of using the Hofmann degradation for the synthesis of α-aminophosphonic acids. The successful preparation by this method of a series of α-aminophosphonic acids, including the phosphonic analogues of α-alanine, has been reported.[151] However, it has been shown that, depending on the structure, the phosphonoacetamides $(EtO_2)P(O)CHRC(O).NH_2$ either undergo the Hofmann rearrangement with formation of α-APA (for R = Et or Ph) or are brominated at the α-carbon atom (for R = Me or $PhCH_2$). The phosphonic analogue of α-alanine could not be obtained by this method.[152]

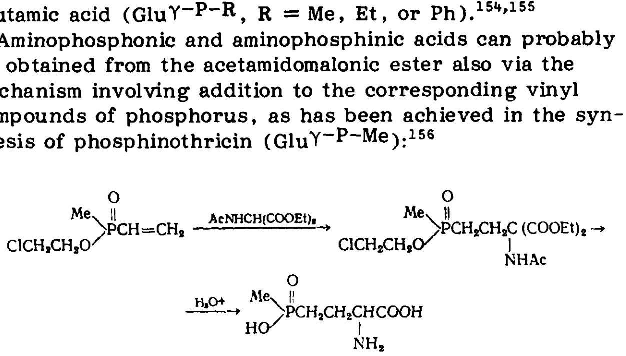
6. Syntheses Using Acetamidomalonic Ester and Vinylphosphonates or Vinylphosphinates

In one of the first specific syntheses of phosphonic analogues of natural aminoacids, the alkylation of acetamidomalonic ester with β-bromoethylphosphonate was used to obtain the analogue of glutamic acid ($Glu^{\gamma-P}$):[153]

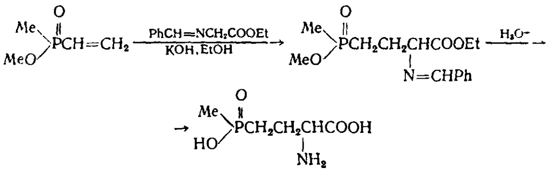


The introduction of β-bromoethylphosphonates into this reaction entailed the formation of phosphinic analogues of glutamic acid ($Glu^{\gamma-P-R}$, R = Me, Et, or Ph).[154,155]

Aminophosphonic and aminophosphinic acids can probably be obtained from the acetamidomalonic ester also via the mechanism involving addition to the corresponding vinyl compounds of phosphorus, as has been achieved in the synthesis of phosphinothricin ($Glu^{\gamma-P-Me}$):[156]

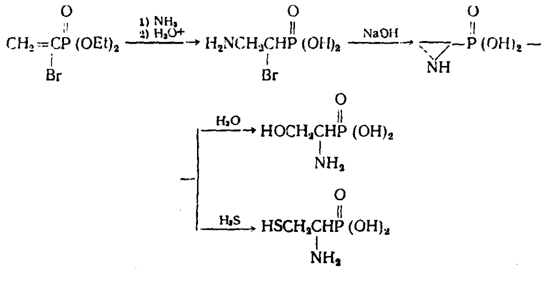


The same method has been used to obtain phosphinic analogues of glutamic acids containing various substituents at the phosphorus atom, including functional groups [$Glu^{\gamma-P-R}$, where R = CH_2COOMe, CH_2COOH, $CH_2CH_2CH(NH_2)COOH$, $CH_2C_6H_4Br$-p, or $PhCH_2$].[115] Certain Schiff bases also undergo Michael addition to methylvinylphosphinate, which has been used successfully to synthesise phosphinothricin:[157]



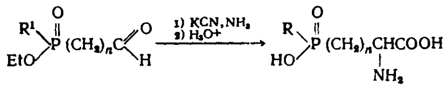
The addition of chiral Schiff bases to vinylphosphonates and vinylphosphinates has been used for the asymmetric synthesis of α-amino-γ-phosphonobutyric acid [(+)-$Glu^{\gamma-P}$] and (+)-phosphinothricin [(+)-$Glu^{\gamma-P-Me}$], as well as their (−)-enantiomers.[158]

Ammonia adds to α-bromovinylphosphonate with formation of β-amino-α-bromoethylphosphonic acid, which cyclises in an alkaline medium to aziridinylphosphonic acid. The opening of the aziridine ring in this acid by treatment with water or hydrogen sulphide leads to the formation of the phosphonic analogues of serine[159,160] and cysteine[138] respectively:



7. Other Methods of Synthesis of Aminophosphonic, Aminophosphinic, and Aminophosphonous Acids

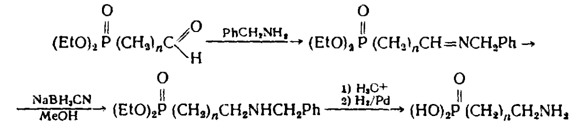
The traditional methodology for the synthesis of aminocarboxylic acids has also been applied to the synthesis of APA. For example, the phosphonic and phosphinic analogues of aspartic and glutamic acids ($Asp^{\beta-P}$ and $Glu^{\gamma-P}$) have been synthesised from β- and γ-oxophosphonates and the corresponding phosphinates using the Strecker reaction:[161,162]



R = OH, Me, Et; n = 1, 2

The phosphonic and phosphinic analogues of α-methylaspartic and α-methylglutamic acids can be obtained in the same way.[29] The use of (−)-α-phenylethylamine in the Strecker synthesis makes it possible to obtain phosphonic analogues of aspartic and glutamic acids enriched in the (+)-enantiomers.[163]

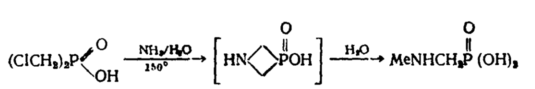
β- and γ-Aminophosphonic acids have been synthesised by condensing benzylamines with β- and γ-oxophosphonates with subsequent reduction of the resulting azomethines with sodium cyanohydroborate and the removal of the P-ester and N-benzyl groups by acid hydrolysis and hydrogenation over a palladium catalyst respectively:[164]



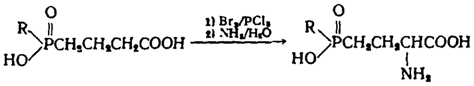
n=1,2

α-Aminophosphonic acids can also be synthesised by the direct substitution of the halogen atoms in α-halogenoalkylphosphonic acids or their derivatives by the amino-group. However, this method is not used frequently, possibly because the substitution by the amino-group in chloromethylphosphonate on treatment with ammonia proceeds under extremely severe conditions and aminomethylphosphonic acid is formed in a moderate yield (20–48%):[165,166]

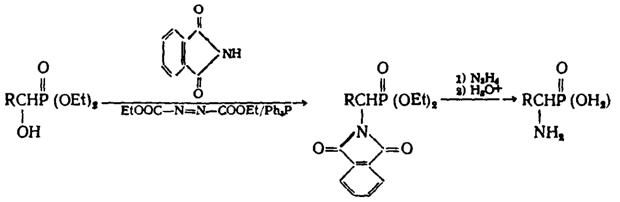
Aminomethylphosphonous acid has been obtained analogously by the reaction of chloromethylphosphonous acid with ammonia.[167] The interaction of ammonia and amines with di(chloromethyl)phosphinic acid has been investigated in a number of studies.[168–171] The products of the reaction of this acid with aqueous ammonia proved to be N-methylaminomethylphosphonic acid, which has been explained by the initial formation of the azaphosphetidine oxide ring, which is cleaved by water at the P–C bond:[168]



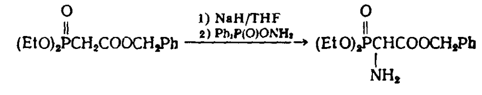
On reaction with di(chloromethyl)phosphinic acid, benzylamine gives rise to di(benzylaminomethyl)phosphinic acid, the catalytic hydrogenolysis of which affords di(aminomethyl)phosphinic acid.[168] The substitution of a halogen atom by the amino-group has been used in the synthesis of phosphonic and phosphinic analogues of glutamic acid (Glu$^{\gamma-P}$ and Glu$^{\gamma-P-Me}$):[172]



α-Aminoalkylphosphonic acids can be obtained from the readily available α-hydroxyphosphonic acids, which are formed from carbonyl compounds and HPC. The substitution of the hydroxy-group by the amino-group is achieved by means of the Mitsunobu reaction between the α-hydroxyphosphonate and phthalimide in the presence of triphenylphosphine and diethyl azodicarboxylate and subsequent removal of the phthalimide group by the standard treatment with hydrazine:[173]

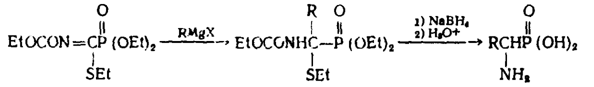


The amino-group can be introduced directly into the α-position in the molecules of phosphonoacetates, which produce stabilised carbanions, by treatment with reagents such as O-(mesitylenesulphonyl)hydroxylamine [174] and O-(diphenylphosphinoyl)hydroxylamine.[175] The α-aminophosphonoacetates formed are important intermediates in the synthesis of cephalosporins:

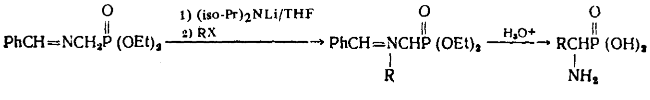


Treatment with trifluoromethanesulphonyl azide results in the introduction in the α-position of phosphonoacetates of the azido-group, whose reduction by catalytic hydrogenation affords α-aminophosphonoacetates.[176]

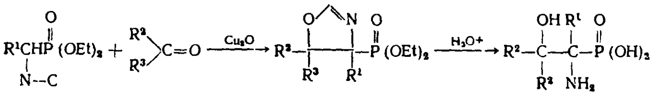
Approaches based on the modification of the P–C–N bond system already formed can also be used in the synthesis of α-aminophosphonic acids. Thus the reaction of a Grignard reagent with α-(N-ethoxycarbonylimino)-α-(ethylthio)methylphosphonate leads to the formation of an adduct, which is converted into an α-aminoalkylphosphonic acid after the reductive elimination of the ethylthio-group and hydrolysis.[177] The phosphonic analogues of alanine, valine, and phenylalanine have been synthesised in this way:



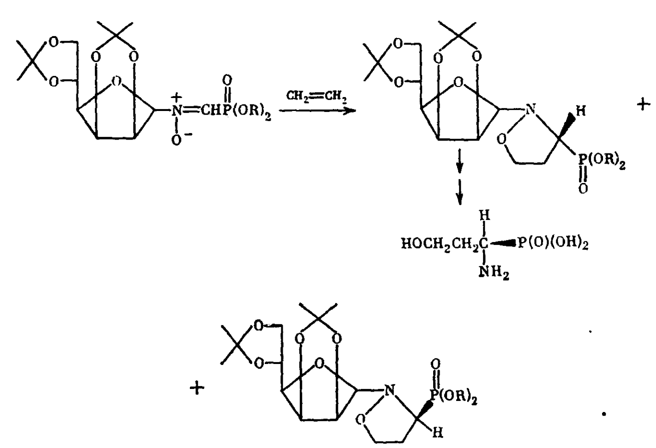
The aldimine obtained from aminomethylphosphonate can be alkylated by halogenoalkanes; the hydrolysis of the resulting compounds leads to the α-aminophosphonic acids Ala^P, Phe^P, and As-$^{\alpha-P}$:[178]



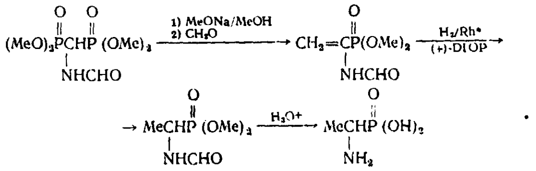
The oxazoline method of synthesis of α-aminoacids has been applied to the synthesis of the phosphonic analogues of derivatives of serine, the oxazolinylphosphonates necessary for this purpose being formed as a result of the addition of carbonyl compounds to isocyanomethylphosphonates:[179]



The cycloaddition of ethylene to C-dialkoxy-N-glycosylphosphonoylnitrones, which proceeds with appreciable stereoselectivity, has been used to synthesise laevorotatory phosphonic analogues of homoserine, aspartic acid, and asparagine:[180]



α-(*N*-Formylamino)vinylphosphonate, obtained by the Horner–Wittig reaction from *N*-formylaminomethylenediphosphonate and paraformaldehyde, gives rise to α-(*N*-formylamino)ethylphosphonate as a result of hydrogenation on a complex rhodium catalyst (Rh*) in the presence of the chiral ligand (+)-2,3-dihydroxy-2,3-*O*-isopropylidene-1,4-bis(diphenylphosphino)butane (DIOP). Hydrolysis of the product leads to the optically active (–)-α-aminoethylphosphonic acid (with an enantiomeric excess of 76%):[181]



$$\underset{NHCHO}{(MeO)_2\overset{O}{\overset{\|}{P}}CH\overset{O}{\overset{\|}{P}}(OMe)_2} \xrightarrow[\;]{1)\,MeONa/MeOH \atop 2)\,CH_2O} \underset{NHCHO}{CH_2{=}C\overset{O}{\overset{\|}{P}}(OMe)_2} \xrightarrow[(+)\text{-}DIOP]{H_2/Rh^*}$$

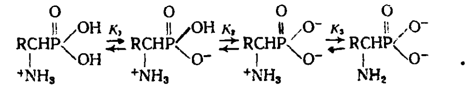
$$\rightarrow \underset{NHCHO}{MeCH\overset{O}{\overset{\|}{P}}(OMe)_2} \xrightarrow{H_3O^+} \underset{NH_2}{MeCH\overset{O}{\overset{\|}{P}}(OH)_2}\,.$$

Many aminophosphonic acids have been obtained by modifying particular functional groups present in the phosphonates. For example, the phosphonic analogue of arginine has been obtained from the phosphonic analogue of ornithine by converting the δ-amino-group into the guanidino-group.[182] Derivatives of β-aminoethylphosphonic acid have been obtained by reducing the nitro-group in β-nitroethylphosphonates[183,184] and the nitrile group in phosphonoacetonitriles.[185] Catalytic hydrogenation of α-hydroxy-β-nitroethylphosphonates has been used to obtain derivatives of β-amino-α-hydroxyethylphosphonic acid.[186,187] This acid is also formed on ammonolysis of oxiranylphosphonates.[188]

As can be seen from the foregoing, there is at present a fairly wide set of methods of synthesis of APA based both on the specific properties of individual phosphorus-containing reagents and on the application of the "standard" methodology for the synthesis of aminocarboxylic acids. Phosphorus analogues of many natural α-aminocarboxylic acids have been obtained by these methods. However, one should note that α-APA containing additional functional groups (analogues of serine, threonine, lysine, etc.) are still difficult to obtain and the phosphorus analogues of certain important natural aminoacids have not been described hitherto. The problem of the asymmetric synthesis of α-APA also remains urgent and requires new solutions.

III. THE PROPERTIES OF AMINOPHOSPHONIC, AMINOPHOSPHINIC, AND AMINOPHOSPHONOUS ACIDS

Aminophosphonic, aminophosphinic, and aminophosphonous acids are white high-melting crystalline substances, soluble in water and sparingly soluble in ethanol and other organic solvents. On recrystallisation from aqueous solvents, some of them are isolated as hydrates.[51,189] The potentiometric titration curves for aminophosphonic acids have three breaks corresponding to the three ionisation constants of these compounds:[129,190]



The ionisation constants and isoelectric points of valine and its phosphonic and phosphonous analogues are presented in Table 1.

Table 1. The ionisation constants and isoelectric points of valine and its phosphorus analogues.[88]

Acid	pK_1	pK_2	pK_3	p*I*
$\underset{NH_2}{Me_2CHCHCOOH}$	2.28	9.36	–	5.82
$\underset{NH_2}{Me_2CHCH\overset{O}{\overset{\|}{P}}(OH)_2}$	1.23	5.68	10.46	3.46
$\underset{NH_2}{Me_2CHCH\overset{O}{\overset{\|}{P}}}(H)(OH)$	1.19	7.79	–	4.49

The ionisation constants of α-aminophosphonic acids in water[143,190] indicate the greater acidity of the phosphonic acid group in these compounds compared with the corresponding phosphonic acids themselves,[191] which is due to the influence of the amino-group. As was to be expected, aminophosphonic, aminophosphinic, and aminophosphonous acids have a zwitter-ionic structure, which has been confirmed by the NMR study of their aqueous solutions[88,192] and an X-ray diffraction study of crystalline specimens.[189]

Like aminocarboxylic acids, α-aminophosphonic acids are able to form complexes with many metal cations, in particular with Ni^{2+} and Cu^{2+}.[193] In their chelating capacity, α-aminophosphonic acids are close to aminocarboxylic acids and, with increase of the number of phosphono-groups in the molecule, the complex-forming capacity also increases, polyaminopolyalkylphosphonic acids being effective complexones.[194,195] Aminomethylphosphonic acid reacts with the Co^{2+} ion to form the compound $[Co(H_2NCH_2PO_3H_2)_2.2H_2O]H_2O$, which crystallises in the monoclinic system and is a coordination polymer produced as a result of the formation of –O–P–O bridge bonds between the cobalt atoms.[196]

The IR spectra of the APA and their esters have characteristic absorption bands due to the P=O (1150–1250 cm^{-1}), P–O–C (1040–1060, 1165 cm^{-1}), and $P–O^-$ (1000–1100 cm^{-1}) groups.[88,197] The IR spectra of aminophosphonous acids also contain the absorption band due to the P–H group (2300 to 2400 cm^{-1}).[88] The amino-group in free APA is protonated, as a result of which the IR spectrum exhibits broad absorption bands due to the $^+NH_3$ group (2000–3200 cm^{-1}, 1560 to 1600 cm^{-1}), which usually overlap in the region of approximately 3000 cm^{-1} with the absorption due to the stretching vibrations of the C–H and O–H bonds.[37,198] The IR spectra of APA esters show absorption bands due to the NH_2 group (3280–3380 cm^{-1}, 1500–1620 cm^{-1}).[66]

The ^{31}P NMR chemical shifts for certain APA and their esters are presented in Table 2. The table shows that these chemical shifts depend on the pH of the medium, which can be explained by the formation of protonated forms of these compounds in an acid medium and the deprotonated forms in an alkaline medium.[33,88,168,199]

Table 2. The chemical shifts and spin–spin coupling constants for the ^{31}P NMR spectra of certain aminophosphonic, aminophosphinic, and aminophosphonous acids.

α-Aminophosphonic, α-aminophosphinic, and α-aminophosphonous acids contain a chiral centre—the α-carbon atom—and exist in the form of two enantiomers. Almost all the methods of synthesis examined above lead to racemic mixtures with the exception of the instances of asymmetric synthesis where one of the enantiomers predominates in the product.[68,78–81,124,158,163,180,181] In order to obtain optically active α-APA, mixtures of diastereoisomers, formed on treatment of the racemate with an optically reactive reagent, are separated by repeated recrystallisation. The reagent of this kind most often employed is dibenzoyl-L-(+)-tartaric acid, which forms mixtures of diastereoisomeric salts on reaction with esters of α-aminophosphonic and the corresponding phosphinic acids. The (–)-diethyl ester of α-aminobenzylphosphonic acid with an optical purity in excess of 97%,[106,200] the (+)- and (–)-diethyl esters of the phosphonic analogue of phenylalanine, formed on hydrolysis of the enantiomeric Phe^P,[189] other optically active α-aminophosphonates,[25,201] and also the (+)-ethyl ester of α-aminobenzylphenylphosphinic acid[202] have been obtained in this way. On reaction with the diphenyl esters of α-aminophosphonic acids, the anhydride of dibenzoyl-L-(+)-tartaric acid gives rise to mixtures of diastereoisomeric amides (or imides), which afford optically active α-aminophosphonic acids after separation and hydrolysis. The enantiomers of the phosphonic analogues of alanine, valine, leucine, phenylalanine, phenylglycine,[203,204] and serine[41] have been synthesised by this procedure. The monoalkyl esters of *N*-acylated α-aminobenzylphosphonic acid have been separated into their enantiomers via the diastereoisomeric salts with *R*-(+)- and *S*-(–)-α-phenylethylamines [205] and (–)-ephedrine.[206] The (+)- and (–)-α-phenylethylamines have also been used to obtain optically active α-aminophosphonous acids.[88]

The acylation of the amino-group in racemic α-aminophosphonates by derivatives of optically active α-aminocarboxylic acids gives rise to diastereoisomeric phosphonodipeptides, which can be separated by chromatography on ion-exchange resins[200,207] or silica gel;[208] a method based on the separation by column chromatography for unprotected or fully protected phosphonodipeptides with subsequent acid hydrolysis of the resulting diastereoisomers has been proposed for the synthesis of optically active α-aminophosphonic acids.[203] The possibility of the enzymic separation of *N*-acyl derivatives of α-aminophosphonic acids has also been reported.[209]

The absolute configuration of certain optically active α-aminophosphonic acids has been determined by X-ray diffraction. The *S*-configuration of the chiral centre has been observed for (–)-Val^P and (–)-α-aminobenzylphosphonic acid;[78,79] (+)-Phe^P also has the *S*-configuration and the bond lengths and angles do not differ significantly from the usual values and are close to the analogous parameters of phenylalanine derivatives;[189] (+)-Ala^P likewise has the *S*-configuration.[210]

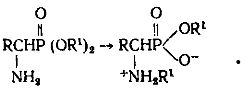
Comparative analysis of the NMR data and of the specific rotations of the glycosidic precursors made it possible to attribute the *R*-configuration to the laevorotatory enantiomers of the phosphonic analogues of homoserine, asparagine, and aspartic acid [(–)-Asp$^{\alpha-P}$].[180] From the chromatographic behaviour of diastereoisomeric phosphonodipeptides containing the *N*-terminal L-Phe residue and the P-terminal Leu^P, Met^P, and Phe^P residues, the *R*-configuration was also attributed to the laevorotatory enantiomers of these α-aminophosphonic acids.[208] The absolute configurations of a series of optically active α-aminophosphonic acids, namely *S*-(+)-Ser^P, *S*-(+)-aziridinylphosphonic acid, *S*-(+)-α-amino-β-chloroethylphosphonic acid, R-(–)-Phe^P, and R-(–)-Tyr^P, have been established by means of chemical correlation with α-aminophosphonic acids having known configurations.[201] The laevorotatory enantiomer of the phosphonous analogue of alanine has the *R*-configuration, because it is oxidised to R-(–)-Ala^P.[88]

The asymmetric esters of α-aminophosphonic acids contain two asymmetric centres, C_α and P, and exist in the form of diastereoisomers which are clearly distinguishable by the NMR spectra.[206,211,212] Mixtures of diastereoisomers are formed similarly in the case of α-aminophosphinic acid esters. It has been established by X-ray diffraction that the asymmetric centres of the (+)-isomer of ethyl α-aminobenzylphenylphosphinate have the absolute *R*(C_α), *S*(P)-configuration.[202]

1. Reactions of the Amino-group in Aminophosphonic, Aminophosphinic, and Aminophosphonous Acids

α-Aminophosphonic acids are protonated at the amino-group in acid media, but it is not possible to isolate the salts, in particular the hydrochlorides, in a pure state, since the ratio α-APA/HCl is greater than unity.[146] After prolonged heating of the hydrochlorides of aminophosphonic acids, hydrogen chloride is fully eliminated with formation of free aminophosphonic acids, which can be accounted for by the appreciable acidity of the phosphono-group.[18,129] α-Aminophosphonic acid esters form hydrochlorides,[103,197] picrates,[197] and acid oxalates[136,137,175] with characteristic melting points, which are used for their isolation, purification, and identification. Racemic α-aminophosphonates and the corresponding phosphinates react with optically active acids to form diastereoisomeric salts, which are used for their resolution into enantiomers.[25,106,189,200,201]

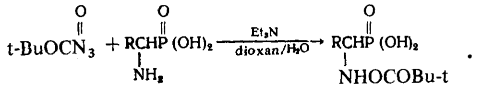
α-Aminophosphonic acids and their esters are alkylated at the amino-group on treatment with methyl iodide or dimethyl sulphate; exhaustive alkylation of α-APA leads to the formation of "phosphonobetaines".[213-215] The full esters of α-aminophosphonic acids are gradually converted into the monoesters even at room temperature:



$$RCH(NH_2)P(O)(OR^1)_2 \rightarrow RCH(\overset{+}{N}H_2R^1)P(O)(OR^1)O^- .$$

The rate of this process depends on the nature of the group R^1 and diminishes in the sequence Me > Et > n-Pr > iso-Pr.[107] The *N*-arylation of α-aminophosphonic acids by 1-nitro-9-phenoxyacridine has been described.[216]

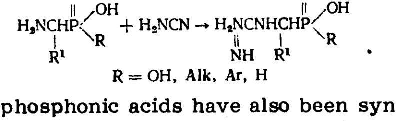
On interaction with an excess of acetic anhydride, α-aminophosphonic acid esters give rise to *N*-acetyl derivatives, while their reaction with benzoyl chloride or tosyl chloride in the presence of pyridine affords *N*-benzoyl and *N*-tosyl derivatives respectively.[217,218] *N*-Benzyloxycarbonyl derivatives of α-aminophosphonic acid esters have been obtained by the Schotten–Baumann acylation,[219] by reaction with *N*-(*O*-benzyloxycarbonyl) hydroxysuccinimide,[206] and by acylation with benzyloxycarbonyl chloride in chloroform in the presence of triethylamine.[220,221] On heating with acetic anhydride, the free α-aminophosphonic acids produce *N*-acetyl derivatives;[115,217] *N*-chloroacetyl,[215] *N*-benzoyl,[129,143,217] *N*-tosyl,[222] and *N*-benzyloxycarbonyl derivatives[222-224] of α-APA have been obtained by the Schotten–Baumann acylation with the corresponding acid chlorides in aqueous alkaline media. α-Aminophosphonic acids are formylated by 100% formic acid in acetic anhydride and are converted into *N*-trifluoroacetyl derivatives on interaction with trifluoroacetic acid anhydride.[141] On fusion with phthalic anhydride, *N*-phthaloyl derivatives of α-aminophosphonic acids are formed.[215,222] The interaction of α-aminophosphonic acids with t-butoxycarbonyl azide in aqueous dioxan in the presence of triethylamine leads to the formation of *N*-t-butoxycarbonyl derivatives:[225]



$$t\text{-BuOC(O)N}_3 + RCH(NH_2)P(O)(OH)_2 \xrightarrow[\text{dioxan/H}_2\text{O}]{\text{Et}_3\text{N}} RCH(NHCOBu\text{-}t)P(O)(OH)_2 .$$

The amino-group in α-aminophosphonic acids[226] and their esters[227] condenses with aldehydes to form the corresponding aldimines.

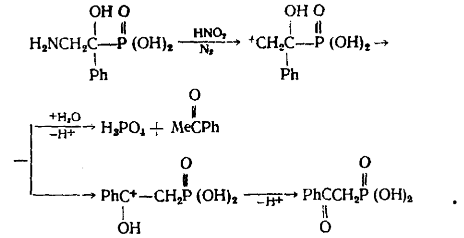
On interaction with cyanamide, α-aminophosphonic, α-aminophosphinic and α-aminophosphonous acids give rise to α-guanidinophosphonic,[228] α-guanidinophosphinic,[229] and α-guanidinophosphonous[228] acids:



$$H_2NCH(R^1)P(O)(OH)R + H_2NCN \rightarrow H_2NC(=NH)NHCH(R^1)P(O)(OH)R .$$

R = OH, Alk, Ar, H

α-Guanidinophosphonic acids have also been synthesised by the reaction of α-aminophosphonic acids with *S*-ethylisothiourea.[230] α-Aminoalkylphosphonates can be oxidised to the corresponding α-nitroalkylphosphonates.[231] The diazotisation of aminophosphonic and aminophosphinic acids leads to the formation of carbonium ions, which fragment or rearrange depending on their structure:[51,198,232]

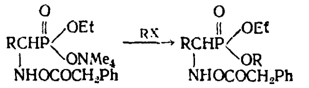


$$H_2NCH_2C(OH)(Ph)P(O)(OH)_2 \xrightarrow[N_2]{HNO_2} {}^+CH_2C(OH)(Ph)P(O)(OH)_2 \rightarrow$$
$$\xrightarrow[-H^+]{+H_2O} H_3PO_4 + MeC(O)Ph$$
$$\rightarrow PhC^+(OH)-CH_2P(O)(OH)_2 \xrightarrow{-H^+} PhC(O)CH_2P(O)(OH)_2 .$$

Like aminocarboxylic acids, α-APA produce a characteristic purple-violet colour on interaction with ninhydrin, which is used for their detection.[15,88,129,233]

2. Reactions of the Phosphorus-containing Fragments of Aminophosphonic, Aminophosphinic, and Aminophosphonous Acids

The di- and mono-esters of α-aminophosphinic acids can be obtained by the esterification of the phosphono-group in *N*-protected α-aminophosphonic acids. The dimethyl esters are formed when *N*-acylated *N*-aminophosphonic acids are treated with diazomethane.[222,225] The interaction of diazomethane with the monoesters of *N*-acylaminophosphonic acids affords asymmetric esters.[205,211,222,234,235] Diazoethane[205] and diphenyldiazomethane[236,237] interact with *N*-acylated α-aminophosphonic acids and their monoesters like diazomethane. In the presence of [tritiated? (Ed.of Translation)] ultra-heavy water, diazoethane esterifies the monoethyl esters of *N*-benzyloxycarbonylaminophosphonic acids with formation of tritium-labelled diethyl esters.[238] Ethyl orthoformate is used to introduce the ethyl group in the synthesis of diethyl and asymmetric alkyl ethyl esters.[206,211,224,234] Asymmetric ethyl methyl, benzyl ethyl, and cyanomethyl ethyl esters have been obtained by the reaction of the tetramethylammonium salts of the monoethyl esters of *N*-acylated α-aminophosphonic acids with corresponding alkylating agents:[239]

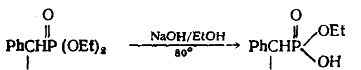


$$RCH(NHCOCH_2Ph)P(O)(OEt)(ONMe_4) \xrightarrow{RX} RCH(NHCOCH_2Ph)P(O)(OEt)(OR)$$

$RX = MeI, PhCH_2Br, NCCH_2OSO_2Ph$.

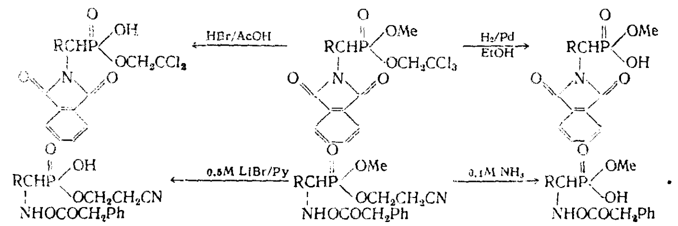
N-Acylated α-aminophosphonic acids give rise to monoesters on esterification with hydroxy-compounds in the presence of pyridine in trichloroacetonitrile[211,234,235,240,241] and on condensation with alcohols in the presence of dicyclohexylcarbodiimide (DCC).[141,242]

Another approach to the synthesis of the monoesters of α-aminophosphonic acids involves the partial hydrolysis of the diesters. When the diethyl ester of the phosphono-analogue of phenylalanine was heated with 80% acetic acid, the monoethyl ester was obtained in 10% yield.[141] The alkaline hydrolysis of *N*-acylated dialkyl aminophosphonates proceeds more successfully:[221,243]



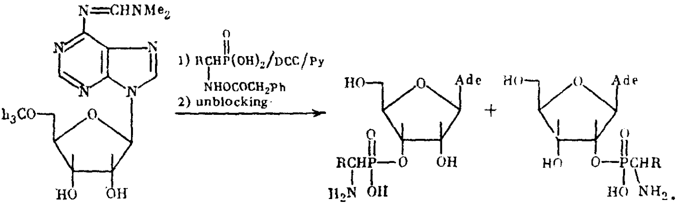
$$PhCH(NHCOCH_2Ph)P(O)(OEt)_2 \xrightarrow[80°]{\text{NaOH/EtOH}} PhCH(NHCOCH_2Ph)P(O)(OEt)(OH) .$$

In many instances, the monoesters of *N*-acylated α-aminophosphonic acids can be obtained by the non-hydrolytic cleavage of the diesters by treating the latter with reagents such as boron tribromide in methylene chloride, lithium bromide in pyridine, sodium thiophenoxide in ethanol, or a 45% solution of HBr in glacial acetic acid.[244] The monoesters of *N*-acylated α-aminophosphonic acid are also formed when the ester groups in asymmetric diesters are removed selectively:[206,211,234,235]



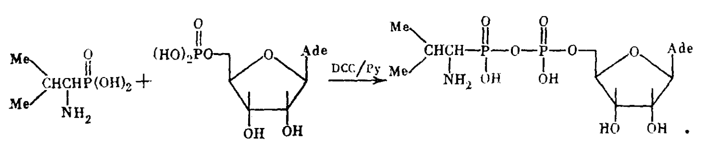
The monoethyl ester of the phosphonic analogue of valine has been obtained by heating the hydrochloride of its diethyl ester.[141] The monoethyl ester of *N*-phthaloylaminomethylphosphonic acid is formed on hydrolysis of the corresponding chlorophosphonate obtained on treatment of the diethyl ester with phorphorus pentachloride.[243]

α-Aminophosphonic acids have been made to react with nucleosides and nucleotides. The *N*-benzyloxycarbonyl derivatives of $\mathrm{Ala^P}$ and $\mathrm{Phe^P}$ (in the form of pyridinium salts) condense with the free 2'- or 3'-hydroxy-groups of *N*-dimethylaminomethylene-5'-*O*-trityladenosine in the presence of DCC. After the removel of the protecting groups and chromatographic purification on DEAE-cellulose, adenosine derivatives phosphorylated in the 2'- and 3'-position by the corresponding α-aminophosphonic acids were obtained in 20–38% yield:[245]



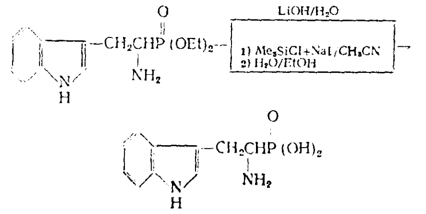
R = Me, PhCH$_2$; Ade = 9-adeninyl.

N-Benzyloxycarbonyl-$\mathrm{Ala^P}$ interacts with 2',3'-*O*-isopropylideneuridine or the corresponding adenosine derivative in the presence of mesitylenesulphonyltriazole as the condensing agent with formation of the corresponding 5'-*O*-(α-aminoethylphosphonoyl) ribonucleosides in 40–50% yield.[246] When 2,4,6-triisopropylbenzenesulphonyl chloride is used as the condensing agent, the yield of the phosphorylated ribonucleosides is low; only traces of the target product are formed in the presence of DCC.[246] $\mathrm{Val^P}$ condenses with adenosine monophosphate (AMP) in the presence of DCC to form a mixed anhydride (in 20% yield):[142]



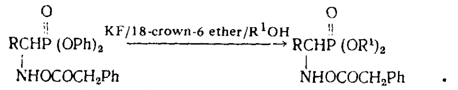
The mixed anhydrides of AMP with $\mathrm{Phe^P}$ and $\mathrm{Met^P}$ were obtained analogously (in yields of 17–24%).[247] In the condensation of the trioctylammonium salts of AMP with the imidazolides of α-aminophosphonic acids, the yield of the corresponding mixed anhydrides is somewhat higher (26–35%). The highest yields of the mixed anhydrides (50–62%) were attained in the reaction of *N*-protected α-aminophosphonic acids with AMP imidazolides.[247] In the condensation of AMP with the monoethyl ester of the phosphonic analogue of valine, the phosphono-group of the latter was activated by treatment with phosgene; the yield of the condensation products was 45%.[247] The chemical and enzymic syntheses of the mixed anhydride of β-aminoethyl phosphonic acid and cytidine 5'-phosphate have also been described.[248]

The esters of α-aminophosphonic and the corresponding phosphinic acids are converted into the free acids usually by hydrolysis in acid media. The rate of hydrolysis depends on the nature of the *O*-alkyl (*O*-aryl) groups split off (for example, in acid hydrolysis the *C*-isopropyl groups are eliminated much more readily than the *O*-ethyl groups[109]) and the character of the acid employed (the rate of hydrolysis falls in the sequence HI > HBr > HCl [143]). In those cases where the aminophosphonate is unstable in an acid medium, the hydrolysis is carried out with alkalies[136] or the compound is *O*-dealkylated by treatment with halogenosilanes in acetonitrile:[136,159]



Phenyl,[249] benzyl,[250] diphenylmethyl,[236,237] and trichloroethyl[211] P-ester groups can be removed by catalytic hydrogenolysis. The diphenylmethyl group is eliminated also on refluxing with ethanol or on treatment with trifluoroacetic acid at room temperature.[237] The *p*-methylbenzyl group is eliinated by treatment with 98% formic acid.[251] *OO*-Disilylaminophosphonates are converted into free aminophosphonic acids after prolonged heating with alcohols or a water–alcohol mixture.[80,82] The diethyl esters of *N*-alkylaminophosphonic acids, which are extremely resistant to hydrolysis by aqueous solutions of acids and bases, have been converted into the free acids by treatment with dry hydrogen chloride at an elevated temperature.[197,152]

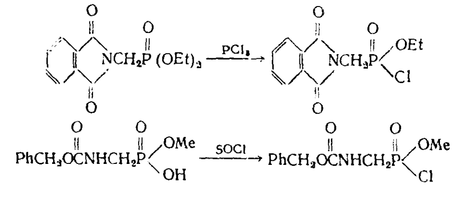
The diphenyl esters of *N*-acylated α-aminophosphonic acids can be converted into the dialkyl esters by transesterification in the fluoride–crown ether–alcohol system:[204,253]



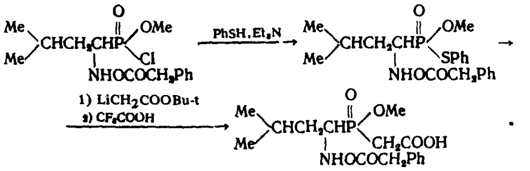
$$\underset{\mathrm{NHCOCH_2Ph}}{\mathrm{RCH}}\overset{\mathrm{O}}{\mathrm{P}}\mathrm{(OPh)_2} \xrightarrow{\mathrm{KF/18\text{-}crown\text{-}6\ ether/R^1OH}} \underset{\mathrm{NHCOCH_2Ph}}{\mathrm{RCH}}\overset{\mathrm{O}}{\mathrm{P}}\mathrm{(OR^1)_2}$$

R = Me, Et, Pr, Bu, CH$_2$CH=CH$_2$

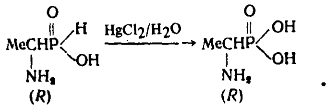
The *N*-protecting groups and peptide bonds are not involved in such transesterification, which makes it possible to employ this process for the modification of phosphonopeptides.[249] *N*-Protected aminophosphonates can be converted into the corresponding aminophosphonochloridates by treatment with phosphorus pentachloride[243,250,254] or thionyl chloride:[220,221]



These phosphonochloridates interact readily with nucleophiles and are used for the synthesis of phosphonopeptides and other derivatives of aminophosphonic acids. For example, the α-aminophosphonic acid $\mathrm{Leu^P}$ has been converted into the α-aminophosphinic acid with a carboxymethyl substituent at the phosphorus atom ($\mathrm{Leu}^{P-CH_2COOH}$) in accordance with the following scheme:[255]

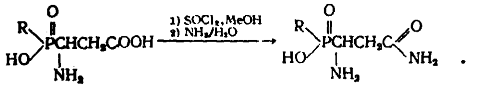


α-Aminophosphonous acids are oxidised with mercury(II) chloride or bromine water to the corresponding α-aminophosphonic acids with retention of the configuration of the chiral α-carbon atom:[86,88,123]



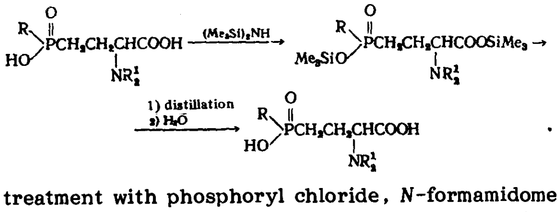
3. Reactions of Other Groups Present in Aminophosphonic and Aminophosphinic Acids

The carboxy-group in carboxylated aminophosphonic and aminophosphinic acids can be esterified without involving the phosphorus-containing fragment.[33,42,199] Such esterification of the carboxy-group in $\mathrm{Asp}^{\alpha-P}$ with subsequent ammonolysis has been used to obtain the phosphonic and phosphinic analogues of asparagine:[130,131]



R=OH, Me, Et

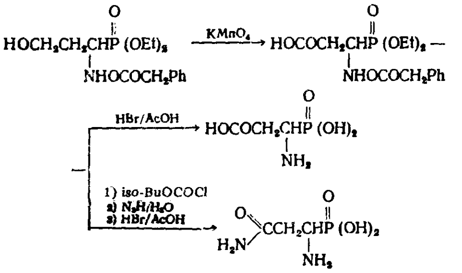
In the presence of diazabicycloundecene and alkyl halides or diazomethane the carboxy- and phosphono-groups in carboxylated aminophosphonic acid are esterified simultaneously.[163] When aminophosphonic and aminophosphonic acids are heated with an excess of hexamethyldisilanzane, the trimethylsilyl derivatives are formed.[100] A method has been proposed for the purification of APA, consisting in their silylation with subsequent distillation and removal of silyl groups by hydrolysis or alcoholysis:[15,256]



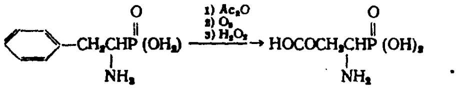
On treatment with phosphoryl chloride, *N*-formamidomethylphosphonates are converted into isocyanomethylphosphonates containing the readily metallated methylene group:[75]

The interaction of the resulting anion with electrophiles leads to the heterocyclic P–C–N systems: the esters of oxazolylphosphonic acids (reactions with acid chlorides and carbonyl compounds) and the ester of mercaptothiazolylphosphonic acid (reaction with carbon disulphide).[75,257,258] Analogous reactions have been described for *N*-formamidomethylphosphinates.[15]

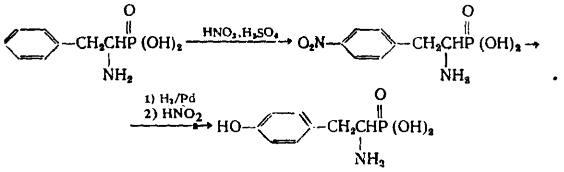
On treatment with a mixture of acetic and hydrobromic acids, the phosphonic analogues of serine and isoserine give rise to the O-acetyl derivatives without affecting the amino-group.[159] The oxidation of the β-hydroxymethylene fragment of the phosphonic analogue of homoserine has been used to synthesise the phosphonic analogues of asparagine (Asn^{P}) and aspartic acid ($\mathrm{Asp}^{\alpha-P}$):[180]



The ozonolysis of the phosphonic analogue of phenylalanine followed by oxidative treatment results in the decomposition of the benzene ring and the formation of the phosphonic analogue of aspartic acid ($\mathrm{Asp}^{\alpha-P}$):[201]



The phosphonic analogue of phenylalanine has been converted into the phosphonic analogue of tyrosine via the following scheme:[201]



Since these reactions do not involve the chiral centre, they have been used to determine the absolute configurations of the optically active aminophosphonic acids $\mathrm{Asp}^{\alpha-P}$, $\mathrm{Asn}^{\alpha-P}$, Phe^{P}, and Tyr^{P}.[180,201]

As can be seen from the foregoing, the chemistry of APA constitutes at the present time an independent chapter in the chemistry of organophosphorus compounds with its own tasks and approaches to their solution. Both traditional methods of synthesis of OPC and the "phosphorus" versions of the classical methods of synthesis of aminocarboxylic acids are widely used in the chemistry of APA. The advances in the chemistry of APA have made available a wide range of phosphorus analogues of natural aminoacids, although many problems, for example the synthesis of polyfunctional and optically active APA, have still not had optimal solutions.

A characteristic feature of this field of HPC is that it adjoins closely bio-organic chemistry and biochemistry. This is related not only to the structural similarity of the aminoacids and APA but also to the existence of natural APA, which confirms their definite biological role. The development of research into the field of APA has already led to the creation of highly active herbicides (glyphosphate, phosphinothricin) and promising medicinal drugs (the antibiotic alaphosphin).

Presumably further studies in the field of APA will involve primarily the development of methods of synthesis of APA and the complex analogues of the most important biologically active natural products containing APA fragments. Secondly, they will involve the wide-scale employment of these compounds in bio-organic research and, finally, they will be associated with the search for new substances of practical use in medicine and agriculture.

Platinum(II) Complexes of Purine and Pyrimidine Bases and Their Nucleosides

A.I.Stetsenko, K.I.Yakovlev, and S.A.D'yachenko

The results of studies on the synthesis, structure, and physicochemical properties and reactivities of platinum(II) complexes of purine and pyrimidine bases and their nucleosides, carried out mainly during the last decade, are summarised. Attention is directed to the characteristic features of these compounds as ambident and bridging ligands. The methods of study are characterised and the influence of coordination on the physicochemical characteristics of the purine and pyrimidine ligands and the effect of the mutual influence of the ligands in the platinum(II) complexes are analysed. The data concerning the ways in which the purine and pyrimidine ligands are bound in the platinum(II) complexes are compared with the manifestation of the antitumour activity by these complexes.
The bibliography includes 216 references.

I. INTRODUCTION

The antiblastoma activity of *cis*-dichlorodiammineplatinum-(II), i.e. *cis*-[Pt$(NH_3)_2Cl_2$] (*cis*-DDP) was discovered in 1969.[1] At the present time this compound is used as an effective antitumour agent with a broad spectrum of activity.[2,3] Under the names "Platind", "*cis*-Platina", Neoplatin", and "Platidiam", *cis*-DDP is manufactured in the USA, England, Czechoslovakia, Finland, and certain other countries.

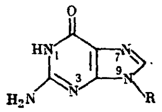
Other platinum complexes are also being vigorously investigated in the search for active water-soluble compounds with a low toxicity. Complexes of chelating dicarboxylate dianions having the *cis*-structure and constituting the so-called second generation of cytostatic platinum(II) complexes are in the stage of clinical tests. They include cyclobutane-1,1-dicarboxylatodiammineplatinum(II), a series of platinum(II) complexes of diaminocyclohexane (malonates and substituted malonates as well as 4-carboxyphthalate), and a platinum(IV) complex—*cis*-dichlorodiisopropyl-*trans*-dihydroxoplatinum-(IV).[4-7] The antitumour activity of the platinum complexes depends on many factors—the charge on the complex, the degree of oxidation of the central atom, the nature of the neutral and acido-ligands, and the kinetic and thermodynamic stability of the complexes.[4] One of the main factors is the geometrical configuration of the complexes: only the *cis*-isomers are active, the *trans*-isomers being inactive.

The mechanism of the antitumour action of the platinum complexes has so far been inadequately investigated. It has been established that the active complexes inhibit the synthesis of DNA *in vitro* and *in vivo* via reactions with heterocyclic DNA bases.[8-13] Among the DNA bases, the purine base guanine and the pyrimidine base cytosine show the greatest tendency to react with *cis*-DDP.[14-19] The specific action of *cis*-DDP on tumour cells is caused both by the faster division of these cells compared with normal cells and by the fact that the damage induced by *cis*-DDP is made good faster in normal cells than in tumour cells.[12]

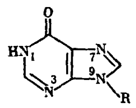
cis-DDP can interact with DNA bases in different strands of the double helix, effecting the so-called intercross-linking,[20-22] for example, with the complementary bases—guanine and cytosine. However, this type of linkage is not dominant, since only 1% of the total amount of the platinum bound to DNA participates in intercross-linking.[23,24] The binding of *cis*-DDP by the molecules of the bases of a single DNA strand, the so-called intracross-linking, is more probable.[25-27] Nor can one rule out also the reactions of *cis*-DDP with the same DNA base via a chelating mechanism.[28-31] Intracross-linking can in fact explain the dependence of the antitumour activity on the geometrical configuration of the complexes: (1) the distance between the planes of the bases in DNA is 3.4 Å, which corresponds to the distance between the chlorine atoms in DDP (3.3 Å) and differs from the distance in the *trans*-isomer (4.66 Å); (2) only the *cis*-isomers are capable of forming chelate bonds. Apart from the direct interaction with DNA, the active complexes can influence the bond between DNA and proteins.[32-34]

II. METHODS OF STUDY, SYNTHESIS, STRUCTURE, AND PROPERTIES OF PLATINUM(II) COMPLEXES OF PURINE BASES AND THEIR NUCLEOSIDES

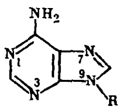
The purine bases with R = H include guanine (Gu) (I), hypoxanthine (Hyp) (II), and adenine (Ad) (III). Their nucleosides (with R = β-D-ribofuranosyl) are guanosine (Gua), inosine (Ino), and adenosine (Ado).



(I)



(II)



(III)

The presence of several endocyclic nitrogen atoms and also of the potentially electron-donating exocyclic groups and atoms (NH_2, O) is responsible for the ambident nature of the ligands and complicates the determination of the structure of their complexes. Physical, mainly spectroscopic, methods are used for this purpose: UV, IR, and Raman spectroscopy, X-ray electronic spectroscopy, circular dichroism, fluorescence analysis, atomic absorption, and, to the greatest extent, ^1H, ^{13}C, ^{15}N, and ^{195}Pt ($I = 1/2$) microwave spectroscopy. The complexity of the IR spectra of the ligands and the low sensitivity of the UV spectra to changes in the type of bond limit the application of these methods to the determination of the structures of the complexes. The NMR methods are most informative and unambiguous. In many studies spectroscopic methods have been used to investigate the formation of complexes between platinum(II) and purine and pyrimidine bases in solutions. However, under these conditions there is a possibility of the existence of a series of complexes. More definite information about the compositions and structures of the complexes can be obtained by means of spectroscopic study of the complexes isolated. X-Ray diffraction studies lead to final conclusions about the structures of the complexes, but they cannot always be carried out owing to the difficulty of growing single crystals. Potentiometric titration with alkali is used to detect protonated NH groups in the coordinated ligands, to characterise the influence of coordination on the acidity of the ligands, and to investigate the state of the complexes in different media—pH and [Cl^-] determinations. The conductimetric method is used to study the kinetics of the substitution of chloride ions in the reactions of *cis*-DDP with purine and pyrimidine bases and their nucleosides. The NMR methods play the main role in the determination of the structures of the complexes. Here we shall indicate in greater detail the possibility of the use of proton magnetic resonance (^1H NMR). Comparison of the ^1H NMR spectra of free and coordinated ligands in D_2O can yield information about the non-labile protons [for example H(2) and H(8) in the adenosine molecule]. Coordination induces changes in the ^1H NMR spectra of the ligand. As a consequence of the decrease of electron density on formation of the donor–acceptor bond, the deshielding of the proton near the electron-donating atom and the downfield shift of its signal are observed. Furthermore, owing to the spin–spin coupling with the ^{195}Pt magnetic nucleus (nuclear spin $I = 1/2$), the signal of the nearest proton becomes a triplet with the intensity ratios 1:4:1 in conformity with the content of the ^{195}Pt isotope in natural platinum (34%). The spin–spin coupling constant $J_{^{195}Pt-^1H}$ depends on the distance between the ^1H and ^{195}Pt nuclei: thus, in the platinum(II) complexes with the thymine anion, we have $^3J = 38$ Hz, $^4J = 4–15$ Hz, and $^5J \cong 0$. The study of the ^1H NMR spectra in DMSO-d_6 makes it possible to characterise also the distance between the labile protons of the NH_2, OH, and SH groups in the coordinated ligands.

Examples of the application also of other microwave spectroscopic methods to the study of the structures of the platinum(II) complexes of purine and pyrimidine bases will be given below.

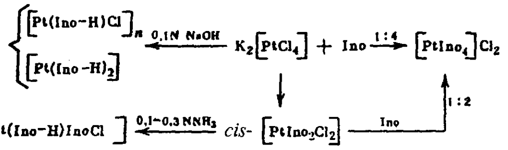
1. Platinum(II) Complexes of 6-Oxopurines and Their Nucleosides

Since *cis*-DDP is bound preferentially by the guanine in DNA, the interaction of guanine and guanosine with platinum(II) complexes has been investigated in most studies. Fewer studies have been devoted to the reactions with their antimetabolites—hypoxanthine and inosine. Guanine, hypoxanthine, and their nucleosides can be coordinated both in the form of neutral molecules and in the form of anions via different electron-donating atoms. There is a possibility of the following main types of coordination under these conditions: (a) monodentate—via the N(7), N(1), and N(9) heteroatoms (for the bases); (b) bidentate—via the N(7) and O(6) atoms; (c) bridged—with participation of the N(7) and N(1) or O(6) atoms.

(a) The Monodentate Type of Bond

The interaction of *cis*-DDP and *trans*-$[Pt(NH_3)_2Cl_2]$ with guanosine and inosine in solutions at different pH has been investigated by a differential spectrophotometric method.[13] It has been shown that the *cis*- and *trans*-isomers react with oxopurines in the same way, the latter being coordinated as monodentate species. At low pH, the bond is formed via the N(7) atom, while at high pH (pH > 9) it is formed via the deprotonated N(1) atom. The conclusion that this type of binding obtains has been confirmed by data for 7- and 1-methyl-substituted inosine and guanosine. The bonding of platinum(II) via N(7) has been established spectrophotometrically also for hypoxanthine.[35,36] However, the spectrophotometric method, especially when applied to solutions containing mixtures of products, cannot provide an exact answer about the ligand binding site. Studies in which the complexes are isolated are more promising. Platinum complexes of different types have been obtained with guanosine and inosine—neutral, cationic, and anionic with different numbers of purine molecules. The reaction of nucleosides with *cis*-$[Pt(NH_3)_2Cl_2]$ and $[PtenCl_2]$ (en = ethylenediamine) lead to the formation of mixed tetrammines having the composition $[PtA_2L_2]Cl_2$, where L = guanosine, inosine, and xanthine.[37] The reactions of $K_2[PtX_4]$ with nucleosides for a nucleoside to platinum ratio of 2, are accompanied by the formation of the *cis*-nonelectrolytes $[PtL_2X_2]$ (X = Cl or Br; L = Ino or Gua).[38] When the ratio is unity, the anionic complexes $K[PtLCl_3]$ are formed.[39] Cationic complexes with four nucleoside molecules have been isolated—$[PtIno_4]Cl_2$, $[PtGua_4]Cl_2$, and *cis*-$[PtIno_2Gua_2]Cl_2$.[40,41] All these compounds contain nucleoside molecules bound as monodentate species.

The reactions of inosine with platinum(II) complexes can be represented by the scheme



The coordination site in inosine has been determined by ^1H NMR. The signal of the H(8) proton in the ^1H NMR spectra of the compounds isolated by Kong and Theophanides[37] shifted downfield by 0.8 p.p.m. and that of the H(2) proton shifted by only 0.4 p.p.m. The H(2) signal in the spectra of the complexes remained as a singlet, while the H(8) signal was a triplet as a result of spin–spin splitting by the ^{195}Pt nucleus. These data enabled the authors to conclude that inosine is linked to platinum(II) via N(7). A similar type of bonding occurs also in other platinum(II) complexes with inosine and guanosine coordinated as monodentate species.[38–41] The ^1H and ^{13}C NMR methods, with the aid of which the occurrence of Pt–N(7) coordination was demonstrated,[2] were used to determine the donor atom of guanosine:

The H(8) signal is a triplet with $^3J[^{195}Pt - ^1H(8)] = 24$ Hz; in the ^{13}C NMR spectrum, $\Delta\delta[C(5)]$ and $\Delta\delta[C(9)]$ exceed on coordination the changes in the chemical shifts of signals due to other carbon atoms. X-Ray diffraction studies confirmed the monodentate mode of binding of guanosine and inosine via the N(7) atom in the complexes $[Pt(NH_3)_2Gua_2].Cl_{3/2}(ClO_4)_{1/2}$,[42] $[PtenGua_2]Cl_{3/2}I_{1/2}.2H_2O$,[43] and $[PtdienGua].(ClO_4)_2$ (dien = diethylenetriamine).[44] The same type of binding has been observed in the complexes of 9-methylguanine $[Pt(9\text{-}CH_3Gu)_4]Cl_2$ [45] and with the inosine nucleotide $[Pt(NH_3)_2(5'\text{-}IMP)_2]$ (5′-IMP = inosine 5′-monophosphate).[29]

Among the platinum(II) complexes with monodentate coordination of 6-oxopurines, almost no isomeric triammines of the type $[PtA_2LCl]Cl$, where A = NH_3 or ½en and L = Gu, Gua, Hyp, or Ino, have been isolated. Complexes of this type can be formed in the first stage of the interaction of DDP with DNA bases. They are of interest as objects to be used in tests for antitumour activity, since they contain one labile Cl^- ion together with the molecule of a lipophilic ligand and are readily soluble in water. The isomeric triammine complexes $[Pt(NH_3)_2LCl]Cl$ and *cis*-[PtenLCl]Cl (L = inosine or hypoxanthine) have been synthesised[46,47] by treating the isomeric non-electrolytes $[Pt(NH_3)_2Cl_2]$ and *cis*-$[PtenCl_2]$ with inosine or hypoxanthine in 1:1 proportions. The type of ionic decomposition and the inner-sphere location of the chloride ions have been established conductimetrically (Λ = 110–120 Ω^{-1} cm^2 mol^{-1}) and by IR spectroscopy $\nu(Pt-Cl)$ = 328–337 cm^{-1}. The $\nu(C=O)$ frequency changes little on coordination. The acid properties of the complexes and their hydrolytic stability have been investigated. Coordination leads to an appreciable intensification of the acid properties of inosine: the pK_a of free inosine is 8.9 [dissociation of N(1)H], while for certain isomeric triammines $[Pt(NH_3)_2InoCl]Cl$ the pK_a is 7.18 (*trans*-form) and 7.85 (*cis*-form) at an ionic strength of 0.3 (0.3 M KCl). Isomeric complexes of the tetrammine type, namely $[Pt(NH_3)_2.Ino_2]Cl_2$ and *cis*-$[PtenIno_2]Cl$, have been isolated and their acid properties have been investigated. The tetrammine complexes exhibit the properties of weak dibasic acids with similar dissociation constants: the pK_a^1 and pK_a^2 are 7.00 and 9.1 for the *cis*-form and 6.65 and 8.0 for the *trans*-form. The lower acidity of the *cis*-isomer reflects the greater *trans*-influence of NH_3 compared with inosine.

In relation to hydrolysis, the *cis*-triammine $[Pt(NH_3)_2.InoCl]Cl$ is less stable: the stability constant (0.1 M KNO_3, 25 °C) is 7.1 × 10^2 litre mol^{-1}, while the value for the *trans*-form is 1.4 × 10^3 litre mol^{-1}.[46,47] The same behaviour has been observed also for isomeric adenosine-containing triammines. Apparently the disposition of the cumbersome nucleoside molecule next to the chlorine ion decreases the stability of the Pt–Cl bond.

It is noteworthy that the synthesis of the triammines involves certain difficulties as a consequence of the possible admixture of complexes of the tetrammine type. These compounds are obtained more readily when substituted ligands are employed. Thus a chloride complex of N^2N^2-dimethyl-9-methylguanine of the triammine type has been isolated. Investigation of its geometry made it possible to attribute a smaller structural *trans*-effect to the N(7)-coordinated purine base compared with the Cl^- ion; the length of the Pt–N bond along the *trans*-coordinate $H_3N-Pt-Cl$ exceeds by 0.3 Å the length of the bond along the *trans*-coordinate H_3N–Pt–purine.[48]

On the basis of the available data, it can be regarded as established that the preferred site where guanosine, inosine, and hypoxanthine are bound to the central platinum(II) is the N(7) atom despite the fact that its basicity is extremely low {pK_b[N(7)] is 11.9 for Gua, 12.1 for Hyp, and 13.0 for Ino}, while the capacity of N(1)H for acid dissociation is appreciable {pK_a[N(1)H] is 8.7 for Ino, 8.8 for Hyp, and 9.2 for Gua},[49] so that it would seem that anionic complexes involving the substitution of the N(1)H proton should be formed rather than complexes with neutral nucleosides. Apparently the basicity of the N(7) nitrogen atom and the acidity of the N(1)H group are not factors determining the stability of the bond between nucleosides and the acid $[Pt(NH_3)_2]^{2+}$, which is much softer than the proton.

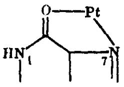
The coordination of guanosine via the N(7) atom in a neutral medium is characteristic also of another "soft" acid, namely CH_3^+Hg.[49]

The monodentate coordination of guanine via the N(7) atom is observed also in reactions of *cis*-DDP with DNA involving the intrastrand binding of *cis*-DDP to the N(7) atoms of neighbouring guanine molecules.[50–52]

In an alkaline medium, one may expect the binding of $Pt(NH_3)_2^{2+}$ and CH_3^+Hg to nucleosides as a result of the dissociation of the proton from N(1)H. The water-insoluble non-electrolytes $[Pt(Ino - H)_2]$ and $[Pt(Gua - H)_2]$,[38] isolated under these conditions, are polymers according to Raman and spectroscopic and ^1H NMR data[53,54] and contain bridging nucleoside anions linked to platinum(II) atoms not only via the deprotonated N(1)H group but also via coordination involving the N(7) atom. The monodentate binding of nucleosides via the protonated N(1)H group is not characteristic of platinum(II) complexes. Only when the N(7) and N(9) atoms in 7,9-dimethylguanine and 7,9-dimethylhypoxanthine are blocked by a methyl group, is it possible to achieve the monodentate coordination of guanine and hypoxanthine via the N(1)H groups. Thus studies have been made of the crystal structures of the following complexes which have been isolated: $[Ptdien7,9\text{-}(CH_3)_2Hyp](PF_6)_2$, $\{Pten[7,9\text{-}(CH_3)_2Hyp]_2\}(PF_6)_2$, and $\{Pt(NH_3)_2[7,9\text{-}(CH_3)_2Hyp]_2\}(NO_3)_2.2H_2O$.[55,57] These complexes are of interest also because their structures are to some extent analogous to those of platinum(II) complexes of cyclic amides—α-pyrrolidinone and α-pyridone,[58,59] containing the NHCO fragment.

(b) Bidentate Binding

The bidentate binding of 6-oxopurines and their nucleosides to platinum(II) of the N(7)–O(6) chelate type has been the subject of numerous discussions and has still not been demonstrated directly by X-ray diffraction. A chelate of this type is possible only for the *cis*-isomer.

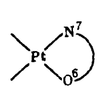


Since only the *cis*-isomer exhibits antitumour activity, many investigators see the cause of the difference between the activities of the $[Pt(NH_3)_2Cl_2]$ isomers in the fact that the *cis*-isomer forms a perfect chelate with the guanine of DNA, while the *trans*-isomer does not.[29,30,31,38,60,61]

In order to model the formation of this type of chelate in the interaction of DDP with DNA, a study has been made of the reaction of DDP with 6-oxopurines. The compounds isolated, whose composition corresponds formally to the bidentate binding of 6-oxopurines and their nucleosides, such as *cis*-$[PtA_2L]^{2+}$ and *cis*-$[PtA_2(L - H)]^+$, where $(L - H)^-$ is the ligand anion, as well as the complexes formed in solutions have been investigated. The following structural formulae can be proposed for the complexes having this composition.

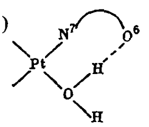
Monomeric complexes:

(a)



direct bidentate chelate bond

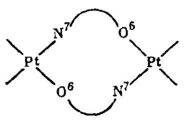
(b)



indirect chelation via the H bond between the O(6) atom and the proton of the coordinated water molecule.

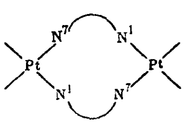
Dinuclear and polynuclear complexes with a bridge bond,

(c)



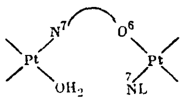
N(7)–O(6) bridge

(d)



N(7)–N(1) bridge

(e)



N(7)–Pt–O(6) bridge with monodentate H_2O and 6-oxopurine molecules.

Analogous bond types have been postulated also for coordinated 6-oxopurine anions. A direct answer to the question concerning their structure can be obtained by the X-ray diffraction method, but this is not always possible owing to the difficulty of isolating crystals suitable for analysis by X-ray diffraction. The possibility of chelation has therefore been investigated mainly by spectroscopic methods—IR, Raman, NMR, fluorescence, and atomic-absorption methods, X-ray electronic spectroscopy, etc. However, under these conditions one obtains at best information about the involvement of the O(6) atom of the oxopurine in the coordinate bond with platinum(II) but not about the mononuclear or polynuclear structure of the complexes. Measurements of the molecular weight are necessary for this purpose, which is hindered by the electrolytic character of the compounds and their poor solubility in non-polar solvents. Owing to the differential binding of *cis*-DDP by the DNA guanine, most of the studies have been devoted to the elucidation of the mode of binding of guanine, guanosine, and their derivatives in platinum(II) complexes.

Complexes whose composition corresponds to bidentate coordination have been isolated and investigated in a number of studies:[62] [PtdatGua]Cl_2, where dat = 3,4-diaminotoluene. The reaction of [PtdatCl$_2$] with guanosine was carried out in dimethylformamide (DMF), the complexes being isolated by adding the 1:1 acetone–ether mixture. Recrystallisation of the complex [PtdatGua]Cl_2 from a methanol–ether mixture leads to the formation of a complex of the triammine type with guanosine bound as a monodentate species, namely [PtdatGuaCl]Cl. The stretching vibration frequency $\nu(C{=}O) = 1645$ cm^{-1} in the complex [PtdatGua]$^{2+}$ is appreciably smaller than in the complex containing guanosine coordinated as a monodentate species, i.e. [PtdatGuaCl]$^+$ (1685 cm^{-1}) and in free guanosine; on this basis, the authors concluded that an unstable chelate of the N(7)–Pt–O(6) type is formed in the first compound. The change in the N(1)H chemical shift in the spectra of the complexes [in hexadeuteriated dimethyl sulphoxide (DMSO-d_6)] is also consistent with this hypothesis: the shifts are 10.82 p.p.m. for [PtdatGua]Cl_2 and 10.70 p.p.m. for [PtdatGuaCl]Cl; in the first complex, deshielding increases owing to the involvement of O(6) in coordination.

It has been demonstrated by X-ray electronic spectroscopy that in the solid complexes of *cis*-DDP with DNA which have been isolated the 1s[O(6)] ionisation energy of guanine is reduced by 0.5–0.7 eV, whereas no such decrease is observed in the binding of the *trans*-isomer.[63] The DDP and [PtenCl$_2$] complexes, which are capable of chelation, as well as their aquo-forms greatly reduce the intensity of the fluorescence in the DNA–ethidium bromide system.[64] It has been observed by the atomic absorption method that the absorption intensity in the complexes with the postulated chelate linkage, i.e. [Pt$(NH_3)_2$Gua]Cl_2 and [PtenGua]Cl_2, is smaller by a factor of two than in the complexes with the monodentate coordination of guanosine.[65] It has been established by potentiometric measurements that the reaction of DDP with DNA guanine is accompanied by the elimination of two chloride ions per molecule of the complex, while in the reaction with the *trans*-isomer one such ion is removed.[31] The conclusion that a platinum(II) chelate complex with guanine is formed via the N(7) and O(6) atoms was also reached on the basis of circular dichroism spectra.[66]

Complexes in which the bidentate coordination of the neutral guanosine molecule, namely [PtenGua]$(NO_3)_2$.$2H_2O$ and [PtenGua]$(ClO_4)_2$, synthesised by treating a solution of *cis*-[Pten$(H_2O)_2$]$^{2+}$ with guanosine in 1:1 proportions at 40 °C for 1 day, have been described.[67] The outer-sphere position of the NO_3^- and ClO_4^- ions follows from IR spectra [$\nu(NO_3^-) = 1380$ cm^{-1} and $\nu(ClO_4^-) = 1100$ cm^{-1}] and conductimetric data, which correspond to the decomposition of complexes of the type characteristic of 1:2 electrolytes. Comparative study of the IR spectra in the $\nu(C{=}O)$ region for complexes with monodentate and postulated bidentate coordination of guanosine showed that in the latter the $\nu(C{=}O)$ frequency is reduced by 20 cm^{-1}. When 1 equivalent of NaOH is added to aqueous solutions of the complexes, the pH increases from 4.5 to 7.2, but, as the reaction proceeds, it falls to 6.9. The addition of alcohol entails the formation of the compounds [Pten(Gua – H)]X.$2H_2O$, where X = ClO_4^- or NO_3^-, and [Pten(Gua – H)]I.$3H_2O$. As a result, the authors assume the possibility of the formation of a chelate especially for the anion (Gua – H)$^-$, but in concentrated solutions they do not rule out the possibility of the existence also of polymeric species with bridging anions.

The bidentate coordination of the anions of 6-oxopurines in platinum(II) complexes has been postulated.[38,67,68,69] Dilute solutions (10^{-4} M) of the complexes [Pten(Gua – H)]$(ClO_4)_2$.$2H_2O$, [Pten(Gua – H)Cl], and [PtenGua]$(NO_3)_2$ contain no polymers judging from circular dichroism spectra: the spectra of these complexes are analogous to those of free guanosine and its anion but differ from the spectra of [PtenGua$_2$].Cl_2, where the interaction of two neighbouring guanosine molecules leads to a two-phase signal.[67,70] The ^{195}Pt and ^{15}N NMR methods have been applied to solve the problem of the possible chelation of inosine in reactions with platinum(II) complexes.[71] The ^{195}Pt NMR spectra yield valuable information about the structure of the platinum complexes. The chemical shift of the ^{195}Pt nuclei changes appreciably as a function of the nature of the donor atoms in the coordination unit and the geometrical configuration of the complex. For example, the chemical shifts in the spectra of the isomeric aquo-complexes $[Pt(NH_3)_2(H_2O)_2]^{2+}$ differ by 209 p.p.m. The ^{195}Pt NMR spectra are usually recorded for specimens enriched in ^{15}N, since the ^{14}N nuclei, which possess a quadrupole moment, broaden the signals. The spin–spin coupling constant $^1J(^{195}Pt-{}^{15}N)$ is sensitive to the nature of the *trans*-ligand and can be used in its turn for the determination of the donor atoms and for the estimation of the *trans*-influence. The formation of polymeric hydroxo-complexes when solutions of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ are allowed to stand, can be followed clearly on the basis of the ^{195}Pt NMR spectra: the chemical shift in the specially prepared solutions is −1593 p.p.m. (using Na_2PtCl_6 as the external standard) and, when the solution is allowed to stand, new signals appear at −1161.8 p.p.m and −1520 p.p.m., referring respectively to $[Pt(NH_3)_2OH]_2^{2+}$ and $[Pt(NH_3)_2.OH]_3^{3+}$.[30,72–74]

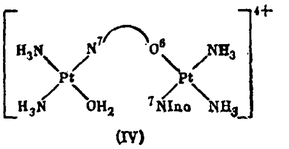
Signals of the initial complex [a triplet with $^1J(^{195}Pt-{}^{15}N) = 312$ Hz] and broad signals due to the formation of complexes of the triammine and tetrammine types with inosine were observed in the $\{^1H\}-{}^{195}Pt$ NMR spectra, with suppressed resonance of the protons, of the 1 : 1 mixture of *cis*-$[Pt(^{15}NH_3)_2Cl_2]$ and inosine, but signals corresponding to the $^{195}Pt-O(6)$ bond, which should have been present in the chelate, were not found.[71] However, the authors assume the formation of the N(7)–Pt–O(6) chelate in the 1 : 1 mixture of *cis*-$[Pt(^{15}NH_3)_2(H_2O)_2]^{2+}$ with inosine, because the $\{^1H\}-{}^{15}N$ NMR spectrum of this system contains an additional signal displaced by 2 p.p.m. towards higher frequencies compared with the spectrum of the monoaquotriammine complex. The signal was absent from the spectrum of a solution of *cis*-$[Pt.(^{15}NH_3)_2(H_2O)_2]^{2+}$ containing adenosine 5′-monophosphate.

Chelation has been observed indirectly in the cobalt(II),[75] copper(II),[76] and nickel(II) [77] complexes of guanosine. Direct chelation has been demonstrated by X-ray diffraction in the copper(II) complexes of theophylline, which is a structural analogue of guanine.[78] It has been established by the same method that the DDP–*cis*-$Pt(NH_3)_2^{2+}$ fragment bound to DNA is located in the vicinity of the N(7) and O(6) atoms of guanine.[79] Quantum-chemical calculations agree with the occurrence of chelation.[80] Complexes of palladium with the chelated anions, namely $[Pd(Ino-H)_2]$ and $[Pd(Gua-H)_2]$, have been isolated.[81] The coordination of the guanosine anion via the deprotonated N(1) atom has been observed in the reaction of *cis*-$[Pt(DMSO)_2Cl_2]$ with inosine in an alkaline medium.[82]

Stereochemical relations more favourable for chelation obtain for 6-mercaptopurines, since the increase of the C–S bond length promotes the decrease of the strain on formation of the S(6)–N(7) chelate. Palladium(II) complexes with this type of bond have been observed.[83–85] Cationic, anionic, and non-electrolytic platinum(II) and palladium(II) complexes of 6-mercaptopurine bound as a bidentate species have been described.[86] The isomeric diamines $[Pt(NH_3)_2Cl_2]$ react differently with 6-mercaptopurine (6-mp): all the ligands are substituted in the *cis*-isomer and the complex $[Pt(6\text{-mp}-H)_2]$ is formed, while in the *trans*-isomer only two Cl^- ions are substituted, which is caused by the strong *trans*-influence of 6-mercaptopurine. The formation of the Pt–S and Pt–N bonds in the chelate has been confirmed by the EXAFS method.[87]

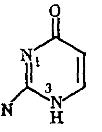
Experimental and theoretical studies, whose results conflict with the hypothesis of the formation of a direct chelate of the N(7)–O(6) type, have been carried out. Stereochemical objections have been raised by Sletten.[76] The interaction of the complexes $[Pten(H_2O)_2]^{2+}$ and $[PtenCl_2]$ with inosine and its derivatives at different pH has been investigated by the Raman spectroscopic and ^1H NMR methods.[53,54] For the ratio Ino/Pt ≤ 2, complexes with one or two inosine anions are formed in an alkaline medium. The H(8) and H(2) signals undergo an upfield displacement under these conditions. With increase of the Pt/Ino ratio from 1 to 4, the ^1H NMR spectra change qualitatively—the signals become broad, which has been attributed to the formation of polymeric species containing bridging inosine anions with participation of the N(1) and N(7) atoms.

In order to investigate the possible chelation reaction between *cis*-DDP and inosine and hypoxanthine, we investigated the complexes *cis*-$[PtA_2L](NO_3)_2$ (A = NH_3 or ½en and L = inosine or hypoxanthine), whose composition corresponds to bidentate binding, and the spectroscopic characteristics and acid properties of these compounds and the complexes of the triammine type $[PtA_2LCl]Cl$ with monodentate coordination of the ligands were compared. The complexes *cis*-$[PtA_2L](NO_3)_2$ were obtained by treating a solution of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with an equimolar amount of the ligand and were precipitated with acetone.[47] The acid titration curves for the complexes obtained differ sharply from the titration curves for the complexes with ligands bound as monodentate species: the acidity of the complexes *cis*-$[Pt.(NH_3)_2L](NO_3)_2$ is appreciably greater and the curves consist of a short initial section corresponding to the titration of a strong acid (0.20–0.25 equiv.of OH^- per mole) and a second section in the pH range 6–8. From the pH values in this section, one may conclude that it corresponds to the titration of a coordinated water molecule in the complex *cis*-$[PtA_2LH_2O]^{2+}$. Comparison of the titration curves for the complex *cis*-$[Pt(NH_3)_2Ino](NO_3)_2$ and the isomeric monoaquo-ions $[Pt(NH_3)_2InoH_2O]^{2+}$, prepared from the corresponding triammines by removing the Cl^- ion by treatment with $AgNO_3$, leads to the following conclusions: (1) the titration curves for *cis*- and *trans*-$[Pt(NH_3)_2InoH_2O]^{2+}$ differ little from one another; this conflicts with the hypothesis of the existence of the N(7)–Pt–O(6) chelate in solutions, since the capacity for chelation is characteristic only of the *cis*-isomer, which would have led to a difference between the titration curves; (2) the titration curves for the isomeric monoaquo-cations and *cis*-$[Pt(NH_3)_2Ino](NO_3)_2$ are also similar. Hence one may conclude that solutions of these compounds contain species with analogous compositions and structures. These can be (1) the monomeric aquo-cations *cis*-$[Pt(NH_3)_2InoH_2O]^{2+}$ and (2) the dimeric and polymeric cations linked by bridging inosine molecules via the N(7) and O(6) atoms in which the acid dissociation of N(1)H is enhanced. The contents of these species can be estimated from the relative sizes of the corresponding sections of the titration curves: 75% of platinum exists as the monoaquo-cation and 25% as the dimer. The participation of the O(6) atom in the coordinate bond follows from the ^{13}C NMR spectra of the complex $[Pt(NH_3)_2.Ino](NO_3)_2$ in D_2O: (1) the C(5) and C(8) signals of inosine in the complex undergo the greatest downfield shift, which indicates the presence of the Pt–N(7) bond; (2) the C(2) signal changes little under these conditions, i.e. there is no Pt–N(1) bond; (3) the form of the C(6) signal differs sharply from that of the signal in the spectra of complexes with monodentate coordination of inosine—it has a multiplet structure, is appreciably broadened, and has been displaced downfield. Comparison of the X-ray emission spectra of the complexes *cis*-$[Pt(NH_3)_2Hyp]\{B(C_6H_5)_4\}_2$ and *cis*-$[Pt(NH_3)_2.(Hyp)_2]\{B(C_6H_5)_4\}_2$ indicates a decrease of electron density at the O(6) atom in the first compound, which agrees with the involvement of the atom in the coordinate bond. The circular dichroism spectra of these compounds are of the single-phase character (like the spectra of free inosine and the complexes having the *trans*-configuration), in contrast to *cis*-$[Pt(NH_3)_2Ino_2]Cl_2$, where there is a possibility of band splitting owing to the π-interaction of inosine molecules in close proximity. This set of data has led us to the conclusion that formula (IV) may be attributed to the cationic complex.



(IV)

A paper published a year and a half after our communication[88] also described the application of the method involving the acid titration of the isomers $[Pt(NH_3)_2(9\text{-}C_2H_5Gu)H_2O]^{2+}$ in order to detect chelation. On the basis of the similarity of the titration curves for the isomers, it was concluded that there are no chelates with a N(7)–Pt–O(6) bond. The consumption of alkali in the titration after the jump at pH 8 was in our case 1 equiv. per mole of platinum; a strongly acidic section, corresponding to the consumption of 0.25 equiv. of OH^- per mole, was also observed. The character of the titration curve was likewise explained by the acid dissociation of H_2O in *cis*-$[Pt(NH_3)_2(9\text{-}C_2H_5Gu)H_2O]^{2+}$ and a dimer containing bridging and terminal 9-ethylguanine molecules. It has been suggested that the bridge bonds are formed via the N(7) and N(1) atoms of 9-ethylguanine and that the strong acid properties are due to the dissociation of N(3)H in an unusual tautomeric form of 9-ethylguanine. We believe that the involvement of the N(1) atom in the bridge bond is less probable than the involvement of the O(6) atom. In the analogous complexes of inosine, the presence of the Pt–O(6) bond has been confirmed by a number of methods; furthermore, the unusual tautomeric form of 9-ethylguanine with a proton at N(3) corresponds to one of the tautomeric forms of isocytosine:



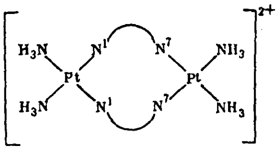
(V)

However, isocytosine has weak acid properties ($K_a = 3.2 \times 10^{-10}$) and K_a for the complex *cis*-$[Pt(NH_3)_2(\text{iso-Cyt})Cl]Cl$ which we synthesised is 1.3×10^{-7}. The strong acidity along the first section of the titration curve is therefore hardly likely to be associated with the formation of such a tautomer.

A combination of the most modern research techniques has been used by Raudashl-Siever et al.[89], namely high-performance liquid chromatography (HPLQ) and ^{195}Pt NMR, for the investigation of the nature of the products formed in the reaction of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with guanine and its methyl-substituted derivative for different ratios and concentrations of the components, different pH (2 and 7), and different contact times (temperature 60 °C). The HPLQ method makes it possible to detect the formation of a number of compounds in solution. The predominant complexes were isolated on the preparative scale and analysed. They include dinuclear complexes with one or two bridging guanine anions—$[Pt_2(NH_3)_4(Gu-H)](NO_3)_3.2H_2O$ and $[Pt_2(NH_3)_4.(Gu-H)_2](NO_3)_2.2H_2O$—and the monomeric complex $[Pt(NH_3)_2(Gu-H)Gu]NO_3$. The formation of complexes with chelated molecules or anions of guanine has not been observed.

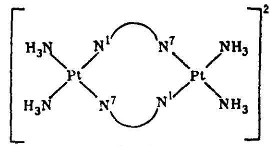
(c) Bridge Type Coordination of Purines and their Nucleosides

Complexes of this type include the dinuclear complexes with bridging guanine anions. The complex $[Pt_2(NH_3)_4(Gu-H)_2].(NO_3)_2.2H_2O$ contains the coordination unit PtN_4 according to ^{195}Pt NMR spectra; two ^{195}Pt signals (−2416 and −2468 p.p.m.) indicate the presence of two isomers:



(VI)

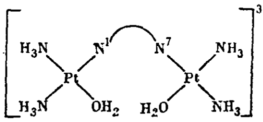
and



(VII)

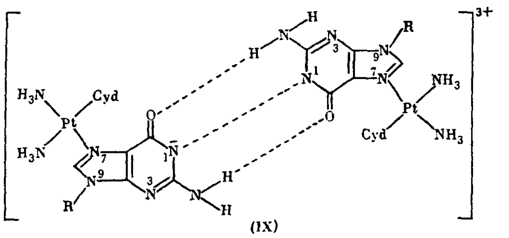
"head to head" "head to tail"

The ^{195}Pt NMR spectra of the dimer $[Pt_2(NH_3)_4(Gu-H)].(NO_3)_3.2H_2O$ contains one signal at −1015 p.p.m., which corresponds to the PtN_3O unit and the coordination formula



(VIII)

In both compounds the bridge is formed via the N(1) and N(7) atoms of the guanine anion. We explain the acid properties of the complexes $[PtA_2L](NO_3)_2$ (A = NH_3 or ½Eu; L = Ino or Gua) by the formation of dimers with an inosine and guanosine bridge bond via the N(7) and O(6) atoms.[47,90] This type of bonding had been postulated earlier in the polymeric platinum(II) and palladium(II) complexes with these ligands.[91,92] The bridge bond via the N(3) and N(9) atoms becomes possible for guanine derivatives dimethylated at N(1) and N(7).[89] The binding of two platinum(II) atoms by the neutral hypoxanthine molecule via N(3) and N(9) has been established in the complex $[Pt_2Gly_2Cl_4Hyp]$, where Gly = glycine, formed in the reaction of $K_2[PtGly_2Cl_2]$ with hypoxanthine, in view of the identical shifts of the H(2) and H(8) signals on coordination.[93] Yet another type of binding, via three hydrogen bonds between guanine and its anion, has been indicated in the dimeric complex $[Pt_2(NH_3)_4.Cyd_2Gu(Gu-H)]^{3+}$, where Cyd = cytidine:[94]

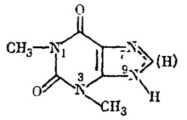


(IX)

In conclusion of this Section, one may say that the presence of the N(7)–Pt–O(6) chelate in the complexes with the ratio L/Pt = 1, where L = 6-oxopurines or their nucleosides, does not follow self-evidently from spectroscopic and physicochemical studies of these compounds and has not been confirmed by X-ray diffraction. The existence of these compounds, especially in solutions, as mixtures of mononuclear monoaquo-complexes and dimeric or polymeric species containing bridging nucleoside ligands with participation of the O(6) atom in the bridge bonds appears more likely. The ratios of these forms depend on the concentration and pH of the solution: in an alkaline medium, the probability of the formation of polymeric structures with bridging anions increases and one cannot rule out the existence of chelates with the anion. Investigation of the structures of these compounds by X-ray diffraction and the determination of their molecular weight in solution are undoubtedly required.

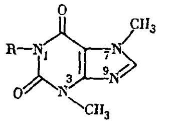
2. Platinum(II) Complexes of 2,6-Dioxopurines

The platinum(II) and platinum(IV) complexes of methylated 2,6-dioxopurines have been investigated:



(X)

N-1,3-dimethylxanthine, theophylline (Thp)



(XI)

R = H: *N*-3,7-dimethylxanthine, theobromine (TeO); R = CH_3: *N*-1,3,7-trimethylxanthine, caffeine (Caf)

Tautomerism is possible for theophylline [the proton is located at the N(7) or N(9) atom]. These ligands are biologically active. Caffeine enhances the antitumour activity of DDP.[95] The ligands contain various nitrogen atoms in the heterocycle blocked by methyl groups, which makes it possible to investigate the bond between the metal and a definite nitrogen atom. By treating a solution of $K_2[PtCl_4]$ in 0.5 *N* HCl with theophylline, it was possible to isolate complexes having the composition $(ThpH)_2[PtCl_4]$ and $(ThpH)[PtThp.Cl_3]$, the former with an outer theophyllinium cation and the latter with an outer cation and coordinated theophylline molecule linked by a bond via the N(9) atom.[96,97] The theophylline anion is coordinated to platinum(IV):[98] the reaction of $[Pt(CH_3)_3(H_2O)_3]^+$ with sodium theophyllinate leads to the formation of the complex $[Pt(CH_3)_3(Thp-H)]$, containing the anion (Thp - H) and the Pt(IV)–N(7) bond. The compound is monomeric in solutions in DMSO and C_2H_5OH. The molecular weight of the complex in $CHCl_3$ and CH_2Cl_2 corresponds to the trimer. On the basis of the $^1H-^{195}Pt$ and $^{13}C-^{195}Pt$ spin–spin coupling constants, it has been established that the theophylline anion plays the role of a tridentate ligand, forming a chelate bond via the N(7) and O(6) atoms with platinum(II) and a bridge bond via N(9) with another platinum(II) atom.

The caffeine complex $(PPh_3CH_3)[PtCafCl_3]$, where $(PPh_3.CH_3)^+$ is the triphenylmethylphosphonium cation, has been isolated and its structure investigated; the bond between caffeine and platinum(II) is formed via the N(9) atom.[99] The anionic complex $K[PtCafCl_3]$ was found to possess antitumour activity: towards lymphocytoleukaemia P-388, the inhibition coefficient was 150%. Mixed non-electrolytes having the composition $(MCafLCl_2)$ [M = Pt(II) or Pd(II); L = Ado, Ino, or Gua] were isolated following the interaction of equimolar amounts of nucleosides and $K[PtCafCl_3]$ in an aqueous DMSO solution.[100] The coordination of caffeine via the N(9) atom and of nucleosides via the N(7) atom has been established by the ^1H and ^{13}C NMR methods. The *cis*-structure of the non-electrolyte follows from the presence of two absorption bands in the Pt–Cl region. Treatment of the complexes with alkaline solutions leads to the isolation of complexes with nucleoside anions: [MCaf.(Ino - H)Cl] and [MCaf(Gua - H)Cl]. The decrease of $\nu(C{=}O)$ in the spectra of the inosine and guanosine anions compared with the free ligand has been interpreted by the authors as a result of the formation of a Pt–O(6) bond, either of the N(7)–Pt–O(6) chelate type or the bridge type.

The product $[Pt(Caf-H)Cl]_2$, isolated in small amounts in the reaction of $K_2[PtCl_4]$ with caffeine (1:1) in 0.5 *N* HCl at 50 °C, is extremely unusual.[100] Its dimeric structure has been confirmed by measurement of its molecular weight. The far IR spectrum shows a $\nu(Pt-Cl)$ band at 305 cm^{-1}, corresponding to the Pt–Cl–Pt bridge bond. The signal of the H(8) proton is absent from the ^1H NMR spectrum of the complex, which has been explained by the formation of the Pt–C(8) σ-bond. However, the proposed structure requires further confirmation, since the presence of the Pt–C(8) σ-bond has not been demonstrated directly by the ^{13}C NMR method and the heterolytic cleavage of the C(8)–H bond in an acid medium is unlikely. It is also noteworthy that not one complex with the caffeine anion has been described hitherto.

A σ-bond of the ylide, carbene type is formed between Ru(III) and the caffeine C(8) atom in the reaction with $[Ru(NH_3)_3(H_2O)_3]^{3+}$.[101] The complex $[Ru(NH_3)_3Cl_2Caf]Cl.H_2O$ with a neutral caffeine molecule, in which the presence of the Ru(III)–C(8) bond has been established by X-ray diffraction, has been isolated. The Ru–C(8) distance (2.03 Å) corresponds to a strong, short bond. Complexes with this type of bond, namely $[Ru(NH_3)_4CafCl]Cl_2.2H_2O$ and $[Ru(NH_3)_4TeoCl]Cl_2.2H_2O$, have been described.[102] In both complexes the Ru(III)–N(9) bond is sterically hindered by the $N(7)CH_3$ group. Theophylline, in which the group is absent, is capable of binding both via the N(7) atom and the O(6) atom.

As a consequence of acid dissociation at N(7) and N(1)H, theophylline and theobromine are able to form complexes with coordinated anions, both Ru(III)–N(9) and Ru(III)–C(8) bonds being formed in the case of theophylline. A bond of the M–C(8) type is also present in the complexes of $HgCH_3^+$ with xanthine.[103]

Non-electrolytes having the composition $[PtThp_2Cl_2].2H_2O$ and $[PtCaf_2Cl]$ have been obtained in the reactions of $K_2[PtCl_4]$.[104] The isomeric triammines $[Pt(NH_3)_2LCl]Cl$ and the *cis*-tetrammines $[Pt(NH_3)_2(Thp)_2](NO_3)_2$ have been isolated after reactions involving *cis*- and *trans*-$[Pt(NH_3)_2.Cl_2]$. According to ^{13}C NMR data, the greatest downfield shift relative to the proton-donating ligands is observed on coordination for the signals due to the C(4) and C(8) atoms (4–7 p.p.m.), which indicates the presence of the Pt–N(9) bond. In the spectra of isomeric complexes having two theophylline molecules, two sets of ^{13}C signals are observed: one corresponding to coordination via the N(9) atom and the other, with an appreciable shift of the C(5) signal, which justifies the conclusion that the bond linking the second theophylline molecule is formed via the N(7) atom. The signals of the H(8) proton and of the methyl groups are also doubled in these compounds, which agrees with the hypothesis that the theophylline molecules are bound via both the N(9) and N(7) atoms.

3. Platinum(II) Complexes of Adenine and Adenosine

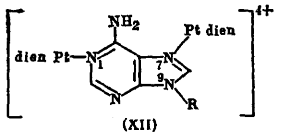
Adenine and its nucleoside adenosine (III) are 6-aminopurines. Adenine and adenosine possess weak basic properties, owing to the possibility of protonation at the N(1) atom: $pK_a[N(1)H^+] = 4.1$ (Ad) and 3.6 (Ado). The N(9)H group in adenine is capable of weak acid dissociation: $pK_a = 9.8$.[49] The following main types of coordinate bonds can be postulated for these ligands: (1) a monodentate bond via the N(1) or N(7) atoms; (2) a bridge bond in which the adenosine molecule binds two platinum atoms via the N(1) and N(7) atoms; (3) a bidentate bond via the N(1) [or N(7)] atom and the NH_2 group.

The monodentate coordination of adenine and adenosine via the NH_2 group is probable owing to the p,π-conjugation of the unshared electron pair of the NH_2 group with the ring.

The involvement in the bonds of the atom N(3), which is blocked by the D-ribose residue in close proximity, is just as unlikely. In addition to these types of bonding, adenine is capable of being coordinated in the form of an anion as a result of the acid dissociation of the HN(9) groups.

The principal conclusions about the interaction of adenine and adenosine with platinum(II) complexes have been reached by Theophanides and co-workers.[37,105] The non-electrolytic complexes $[PtL_2X_2]$ ($X = Cl^-$ or Br^-) were isolated after treating a solution of $K_2[PtCl_4]$ with adenine, adenosine, and tri- and tetra-acetyladenosine. The signal of the H(8) proton undergoes the greatest downfield shift in the ^1H NMR spectra of the complexes: $\Delta\delta_{H(8)} = 0.92$ p.p.m. and $\Delta\delta_{H(2)} = 0.21$ p.p.m.; this indicates the coordination of the ligand via the N(7) atom. The monodentate coordination of adenosine was observed also by Ettore.[106] Adenosine and 9-methyladenine protonated at N(1) are also capable of such coordination: the complexes $[Pt(AdoH)Cl_3]$ and $[Pt(9\text{-}CH_3.$ $.AdH)Cl_3]$ are formed in 3 *N* HCl.[107] Other adenosine complexes containing the Pt–N(7) bond have also been isolated: the isomeric $[Pt(NH_3)_2Ado_2]Cl_2$ [108] and $[PtAdo_4]Cl_2$.[109] At the same time, for adenine there is much more evidence than for oxopurines and their nucleosides indicating the involvement of the N(1) atom in the monodentate bond with platinum(II). The coordination of adenosine via the N(7) atoms is promoted by an acid medium. It has been shown in relation to the reaction of $[PtdienH_2O]^{2+}$ with adenosine that in a neutral medium there is also a possibility of the formation of complexes with a Pt–N(1) bond.[37,110] The complexity of the ^1H NMR spectrum of the complex $[Pt(TAA)_2Cl_2]$ (TAA = triacetyladenosine), which has four signals instead of two for H(2) and H(8), was explained by the formation of complexes with three bond types:[105] N(7)–Pt–N(7), N(1)–Pt–N(1), and N(7)–Pt–N(1). The same three types of monodentate binding of adenosine were observed in the reactions of $[Pt(NH_3)_3Cl]Cl$ with adenosine with the ratio Ado/Pt = 2.[111] The products were separated by high performance liquid chromatography and their structure was demonstrated by spectrophotometric measurements at different pH. The double binding via the N(1) and N(7) atoms was observed also in the platinum(II) complexes of 9-methyladenine.[112]

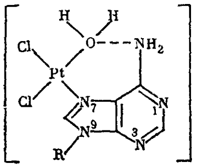
The formation of dinuclear complexes with a bridge type coordination of adenosine was first observed in solutions by the isomolar series (continuous variations) spectrophotometric method.[113] An analogous result was obtained in the study of the ^1H NMR spectra of solutions of [PtdienCl]Cl containing adenosine and an excess of the platinum(II) complexes, i.e. for a ratio Pt/L > 2.[37] Under these conditions, approximately equal downfield shifts of the signals of the H(2) and H(8) protons, amounting to 0.9–1 p.p.m., are observed. Both signals acquire the triplet form as a result of the spin–spin interaction with the ^{195}Pt nucleus [with the constant $^3J_{^{195}Pt^1-{}^1H(2,8)} = 26$ Hz]. The authors believe that the dinuclear complexes (XII) with a bridge type coordination of adenosine are formed in solution:



(XII)

The presence in solutions of complexes containing the Pt–N(1)–N(7)–Pt linkage as a result of the reactions of $[PtacacCl_2]^-$ (acac = acetylacetone) and *cis*-$[PtDMSOCl_3]^-$ with adenosine has been demonstrated by ^1H NMR.[114] Isomeric *cis*- and *trans*-complexes with a similar bond have been isolated in a pure state: $[Pt(NH_3)_2ClAdoPt(NH_3)_2Cl]Cl_2$ and $[Pt(NH_3)_2ClAdPt(NH_3)_2Cl]Cl_2$.[115,116] Anionic dinuclear complexes $K_2[PtCl_3AdoPtCl_3]$ with bridging adenosine molecules have also been described.[39] The tendency of adenine and adenosine molecules towards the bridge type of binding is manifested by the formation of polymeric complexes. Polynuclear complexes with 9-methyladenine having the composition $[Pt(9\text{-}CH_3Ad)Cl_2]$ have been described.[105] The formation of a series of polymeric complexes in the reaction of $K_2[PtCl_4]$ with adenine has been indicated.[117] A trinuclear complex with adenine anions $(Ad-H)^-$ having the composition $[Pt_2Ad(Ad-H)_2C_2H_5OH][PtI_4]$ has been isolated.[118]

The bidentate binding of adenine and adenosine to platinum(II) presupposes the involvement in the coordination of the NH_2 group and one of the nitrogen heteroatoms—N(1) or N(7) (most probably). The hypothesis of the bidentate binding of these ligands has been put forward on the basis of spectrophotometric measurements.[13,113] Complexes whose composition corresponds to this coordination have been isolated: $[PtAdX_2].2H_2O$ ($X = Cl^-$ or Br^-) and $[PtAdoI_2]$. $.2H_2O$.[119] A strong downfield shift of the signal of the NH_2 group is observed in the ^1H NMR spectra of these compounds in DMSO-d_6, which is regarded as evidence for its involvement in binding. The complexes $[PtAdoCl_2]$, $[PtAdCl_2H_2O]$, and $[PtAdCl_2]$ have been isolated.[120] The complex [PtAdo. $.Cl_2]$ is anhydrous and monomeric and frequencies characteristic of Pt–Cl–Pt bridge bonds are absent from its IR spectrum; according to far IR spectroscopic data, it has the *cis*-configuration. A chelate structure involving the NH_2 group and the N(7) atom has been proposed for this complex. The formation of a chelate in which the NH_2 group of the adenine molecule is bound by a hydrogen bond to the oxygen atom of a water molecule is more probable for the hydrated complex:



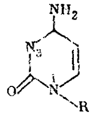
(XIII)

The insoluble complex $[PtAdCl_2]$ is apparently polymeric. Solutions of the non-electrolytic complexes $[PtAdCl_2H_2O]$ and $[PtAdoCl_2]$ in DMSO exhibit an inhibiting effect amounting to 50–60% on four strains of tumours[121] and at the same time they are less toxic than *cis*-DDP. The cationic complexes *cis*-$[Pt(NH_3)_2Ado](NO_3)_2$, in which the formation of a chelate involving N(7) and the NH_2 group can also be postulated, have been described.[115,116] The complexes differ from compounds with monodentate coordination of adenosine in their ^1H NMR spectra and acid properties. However, a final conclusion about the structure can be reached on the basis of X-ray diffraction analysis, which so far has not been possible owing to the lack of crystals suitable for this purpose.

III. THE SYNTHESIS, STRUCTURE, AND PROPERTIES OF PLATINUM(II) COMPLEXES OF PYRIMIDINE BASES AND THEIR NUCLEOSIDES

1. Complexes of Cytosine and Its Derivatives

Cytosine [Cyt, (XIV), R = H] together with guanine belong to the class of DNA bases which react preferentially with platinum complexes. In terms of their ability to interact with DDP, cytosine is in the second place after guanine and among pyrimidine bases it is in the first place. The keto-amino-form is most characteristic of cytosine and its nucleoside cytidine [Cyd, (XIV), R = β-D-ribosofuranosyl]:[122]



(XIV)

Cytosine and cytidine are ambident ligands, since they contain several potential donor atoms. They can be the heterocyclic N(3) and N(1) atoms, the exocyclic NH_2 group, and the exocyclic oxygen atom.

The binding of cytosine and its derivatives via the exocyclic amino-group is unlikely for the same reason as in the case of adenosine. The binding of metal ions via the amino-group becomes possible after its deprotonation. In the free ligands, the acid properties of the NH_2 group are extremely weak ($pK_a = 16$),[125] but coordination enhances them. The ribose residue of cytidine is not involved in the coordinate bond.

The principal site of the coordination of cytosine and cytidine to metal ions is one of the heterocyclic nitrogen atoms. In order to determine which particular atom, it is useful to compare the capacities of these atoms for protonation. It follows from spectroscopic (IR and ^1H NMR) and X-ray diffraction studies and also calculations of electron density that cytosine and cytidine are protonated in the N(3) position.[124–126] The pK_a are 4.6 for Cyt $N(3)H^+$ and 4.2 for Cyd $N(3)H^+$.[127] On this basis, one can postulate that cytosine and cytidine are also coordinated in the platinum(II) sphere via the N(3) atom. The formation of complexes of cytosine and its derivatives with platinum(II) has been investigated in most cases in solutions with the aid of ^1H NMR. Studies in which individual complexes with these ligands were isolated and their structure demonstrated are less common in the literature.

In one of the first investigations[13] by differential spectrophotometry at different pH, a study was made of the interaction of cytidine with the geometrical isomers of $[Pt(NH_3)_2 . Cl_2]$ at 37 °C. Analysis of the absorption spectra of the equilibrium mixture led the authors to the conclusion that a chelate is formed with participation of N(3) and the $4\text{-}NH_2$ group in the reaction with the *cis*-isomer and that there is monodentate binding via the N(3) atom in the reaction with the *trans*-isomer. However, further studies failed to confirm the formation of the chelate.

Studies have been made[37,128] of the ^1H NMR spectra of solutions of the platinum(II) complexes of cytosine and cytidine. Two doublet signals of the H(6) (7.35 p.p.m.) and H(5) (5.60 p.p.m.) protons and also a broad signal of the NH_2 group at 7.1 p.p.m. were observed in the ^1H NMR spectrum of free cytosine in DMSO-d_6.[129] The spin–spin coupling constant $^3J_{H(5)-H(6)} = 7$ Hz. On formation of the cytidine complex in the reaction with [PtdienCl]Cl, the signal of the H(5) proton undergoes a downfield shift of 0.13 p.p.m., which is somewhat greater than the shift of the H(6) proton (0.11 p.p.m.). Spin–spin interaction with the ^{195}Pt nucleus has been observed for the H(5) atom: instead of a doublet, two triplets with the intensity ratios 1:4:1 were produced. The spin–spin coupling constant is $^4J_{^{195}Pt-^1H(5)} = 8$ Hz, which is close to the value observed for the *meta*-proton in the platinum(II) complexes of pyridine.[130] The splitting of the signal of the H(6) proton by the ^{195}Pt nucleus was not observed. These data led the authors to the conclusion that cytidine is coordinated via the N(3) atom. A similar bond is formed also in the coordination of the 5-mononucleotide of cytidine (cytidine 5′-monophosphate or 5′-CMP).[128]

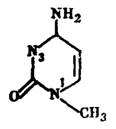
The ^1H and ^{13}C NMR spectra of the complexes of $PtCl_2 . 2DMSO$ and $PdCl_2 . 2DMSO$ with cytosine and cytidine in solutions in DMSO-d_6 have been thoroughly investigated.[129] In these systems too, $\Delta\delta[H(5)] = 0.18$ p.p.m. $> \Delta\delta[H(6)] = 0.11$ p.p.m. In the solutions of cytosine in DMSO-d_6, the signal of the proton in the NH_2 group is at 6.91 p.p.m. and is remote from the signal of N(1)H (10.27 p.p.m.). Coordination leads to a downfield shift of the signal of the NH_2 proton and to its splitting into two components: 8.59 and 8.25 p.p.m., because the rotation about the C–N bond in the complex is hindered. In the ^{13}C NMR spectra, the greatest shift has been observed for the C(2) and C(4) signals, both undergoing an upfield shift: $\Delta\delta[C(4)] = 1.3$ Hz and $\Delta\delta[C(2)] = 3.1$ Hz (WH90 Bruker spectrometer with a field strength of 21.14 kG under pulsed Fourier conditions). Coordination influences also the spin–spin coupling constant $^1J_{^{13}C-^1H}$, which changes to a greater extent for the carbon atoms located nearer the coordination centre: $\Delta\,^1J_{^{13}C(5)-^1H(5)} = 10$ Hz $> \Delta\,^1J_{^{13}C(6)-^1H(6)} = 3$ Hz. Thus the results of our study demonstrate convincingly the involvement of the N(3) atom in coordination. The complexity of the spectra due to the fact that the reaction does not go to completion (~80%) and because the solution contains the free ligand is one of the methodological disadvantages of the above study. The authors were also unable to observe the $^{195}Pt-^1H$ spin–spin interaction. It has been stated[131] that one of the causes hindering the manifestation of the spin–spin splitting may be the anisotropy of the relaxation of the chemical shifts arising in recording at high frequencies (~100 MHz).

The formation of chelates of the type $N(3)-Pt-NH_2$ in reactions with platinum(II) complexes is not characteristic of cytosine and cytidine. A similar relationship has been proposed for $[Pt\,Cyt\,I_2]$ complexes,[119] but without a convincing proof.

Cytosine- and cytidine-containing platinum(II) complexes of the triammine type, namely *cis*-$[PtA_2LX]X$ (A = NH_3 or ½en), are of great interest. These compounds can be formed in the first stage of the reaction of DDP and $[PtenCl_2]$ with the pyrimidine bases in DNA. The triammines *cis*-$[PtA_2LX]X$ (L = Cyt or Cyd; A = NH_3 or ½en; X = Cl^-, Br^-, or NO_2^-) have been synthesised.[132,133] The complexes have been obtained on heating *cis*-$[PtA_2X_2]$ with an equimolar amount of the ligand, evaporation, and precipitation with acetone. Their structure was demonstrated by measuring the electrical conductivity (100–120 Ω^{-1} cm^2 mol^{-1}) and by the presence of the $\nu(Pt-X)$ absorption band in the long-wavelength absorption spectra. The ^1H NMR spectra of the triammines in D_2O and DMSO-d_6 indicate the coordination of cytosine and cytidine via the N(3) atom: for all the compounds, $\Delta\delta[H(5)] > \Delta\delta[H(6)]$. This conclusion also follows from the ^{13}C NMR spectra: the greatest shift in coordination has been observed for the C(2) and C(4) carbon atoms, which are in neighbouring positions relative to N(3): $\Delta\delta[C(2)] = 8.9$ p.p.m. and $\Delta\delta[C(4)] = 5.6$ p.p.m. in the spectrum of *cis*-$[Pt(NH_3)_2 . CytCl]Cl$, while the chemical shifts for the C(5) and C(6) atoms differ by 0.7 and 1.5 p.p.m. respectively. Coordination in the platinum(II) sphere greatly enhances the acid properties of cytosine as a result of the dissociation of N(1)H: $K_a = 6.1 \times 10^{-13}$ for cytosine[127] and $K_a = 5.0 \times 10^{-10}$ for *cis*-$[Pt(NH_3)_2CytCl]Cl$. The replacement of Cl^- by Br^- and NO_2^- leads to some decrease of acidity, apparently a result of the enhancement of the σ-donor properties of the acido-ligands. The hydrolytic stability of the bond in the complex *cis*-$[Pt(NH_3)_2CytCl]Cl$ has also been characterised: $K_{inst} = (4.0 \pm 0.5) \times 10^{-4}$.[134]

The communications examined contain the results of the investigation of the reactions of cytosine and cytidine with platinum(II) complexes having two or one chloride ions. The interaction of these ligands with $K_2[PtCl_4]$ is much more complex. In this case the nucleophilic substitution of the chloride ions is accompanied by the formation of polymeric products—the so-called "platinum pyrimidine blues".[135] The "blues" are obtained in an alkaline medium; their formation is apparently associated with the deprotonation of the ligands. A solid diamagnetic amorphous blue product having the composition $K_{0.2}PtCydCl_{1.5}(OH)_x(OH_2)_y$ has been isolated. On the basis of the ^1H NMR spectra and reactions with reductants ($NaBH_4$), the authors assume that the "blue" contains partially oxidised platinum and the cytosine anion, formed as a result of the deprotonation of the amino-group, is bound to platinum(II) by means of a chelate or bridge type bond via this group and the N(3) atom.

Among cytosine derivatives, the formation of platinum(II) complexes with methylcytosine (XV) ($1\text{-}CH_3Cyt$) has been studied to the greatest extent.

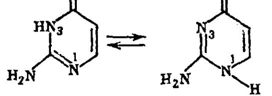


(XV)

Cationic complexes with the *cis*-structure have been isolated—the tetrammines $[Pt(NH_3)_2]$ $(1\text{-}CH_3Cyt)_2(NO_3)_2.$ $.1\text{-}CH_3Cyt$ [136,137] and the triammines *cis*-$[Pt(NH_3)_2(1\text{-}CH_3.$ $.Cyt)Cl]X$ ($X = Cl^-$ or NO_3^-).[138] It was established by ^1H NMR, on the basis of the greater shift of the signal of the H(5) proton than the shift of the H(6) proton signal on coordination and the triplet splitting of the H(5) proton signal, that the coordination is via the N(3) atom; it was confirmed for the tetrammine by X-ray diffraction. The triammines are unstable both in aqueous solution and on heating. In the latter case NH_2 is split off and *trans*-$[PtNH_3Cl_2(1\text{-}CH_3Cyt)]$ is formed.[139] A tetrammine with three molecules of 1-methylcytosine, namely $[Pt(NH_3).$ $.(1\text{-}CH_3Cyt)_3](ClO_4)_2$, was isolated after starting with the *trans*-non-electrolyte $[PtNH_3Cl_2(1\text{-}CH_3Cyt)]$.[140] The authors regard the formation of this compound as evidence for yet another pathway leading to the interaction between the DDP and DNA bases, namely one involving the displacement of NH_3 and the binding of three DNA bases. However, the elimination of NH_3 from *cis*-DDP under conditions simulating cytoplasm has not been demonstrated experimentally and there are no data indicating the presence of antitumour activity in the mixed *trans*-non-electrolyte $[PtNH_3ACl_2]$.

Among the platinum(II) complexes containing the neutral 1-methylcytosine molecule, there are also rarely encountered monomeric complexes with the terminal ligands OH^- and H_2O, namely $[Pt(NH_3)_2(1\text{-}CH_3Cyt)OH]NO_3.2H_2O$ and $[Pt(NH_3)_2.$ $.(1\text{-}CH_3Cyt)H_2O](NO_3)_2.H_2O$.[141] In contrast to cytosine, 1-methylcytosine is capable of being coordinated in the form of an anion via a bridge-type bond involving the N(3) atom and the deprotonated NH_2 group. It has been demonstrated by X-ray diffraction that such a bond occurs in the complex $[Pt(NH_3)_2(1\text{-}CH_3Cyt)_2Pt(NH_3)_2](NO_3)_2$.[142] The complex was isolated after treating the dimer $[Pt(NH_3)_2OH]_2(NO_3)_2$ with 1-methylcytosine in proportions of 2 : 1. In the same communication it is stated that there is a possibility of obtaining complexes in which platinum has the formal oxidation state of 2.5+: the complex $(H_2O_2)[Pt(NH_3)_2NO_2(1\text{-}CH_3.$ $.Cyt\text{-}H)_2Pt(NH_3)_2NO_2](NO_3)_2$, with an octahedral environment around the platinum atoms, has been obtained in small amounts—yield 2%. Structural data confirm the presence of the Pt–Pt bond for atoms in an oxidation state higher than 2+; thus the Pt–Pt distance in this complex is 2.584 Å, while in the platinum(II) and platinum(III) dimers these distances are respectively 2.970 Å and 2.466 Å.[143,144] In our view, the properties of this compound and the conditions governing its formation require further study, since there has been no full analysis of the complex, its yield is very low, and finally the formation of the $H_5O_2^+$ cation at pH 6 is unlikely.

The complexes (III) of platinum(II) with isocytosine (iso-Cyt), a cytosine isomer, have been described:[133,145]



(a) (b)

(XVI)

Isocytosine exists mainly in the form of two tautomeric forms (a) and (b).[146] Complexes of this ligand of the triammine and tetrammine types having the *cis*-structure have been isolated: $[PtA_2(iso\text{-}Cyt)Cl]Cl$ and $[PtA_2(iso\text{-}Cyt)_2]Cl_2$ ($A = NH_2$ or $\frac{1}{2}en$).[145] Coordination is accompanied by a hypsochromic shift of the ring vibrations and a large downfield shift of the signal of the H(5) proton in the ^1H NMR spectra of the complexes in DMSO-d_6, which suggests the formation of a coordinate bond via the N(3) atom of the tautomeric form (XVIb). Isocytosine is characterised by much more pronounced acid properties than cytosine: $K_a = 3.2 \times 10^{-10}$.[127] The same also applies to platinum(II) complexes of isocytosine: $K_a = 5.0 \times 10^{-10}$ for *cis*-$[Pt(NH_3)_2.$ $.LCl]Cl$ ($L = Cyt$) and 1.3×10^{-7} for the same complex with $L = iso\text{-}Cyt$; $K_a^1 = 4.3 \times 10^{-10}$ for *cis*-$[Pt(NH_3)_2L_2]Cl_2$ when $L = Cyt$ and 3.2×10^{-7} when $L = iso\text{-}Cyt$.[133,145]

2. Platinum(II) Complexes of Aminopyrimidines

Apart from the formation of platinum(II) complexes of natural aminopyrimidines (cytosine and cytidine), studies have also been made of the formation of complexes with other aminopyridimidines. The platinum(II) complexes of 2-aminopyrimidine (2-Apm) and its substituted derivatives (XVII) have been most thoroughly investigated:[116,147–150]

(XVII)

where $R = H$, CH_3, OCH_3, or C_6H_5.

The presence of several potential donor atoms and groups in aminopyrimidine molecules suggests different types of binding of these ligands to platinum(II). Two main types of coordination—monodentate and bridge type—have been established.

In the reactions of 2-aminopyrimidine with $K_2[PtX_4]$ ($X = Cl^-$, Br^-, or I^-), non-electrolytic complexes with ligands involved in monodentate coordination, i.e. $[PtL_2X_2]$ with L = 2-Apm, 4-phenyl-2-aminopyrimidine (4-Ph-2-Apm), 4-methyl-2-aminopyrimidine ($4\text{-}CH_3\text{-}2\text{-}Apm$), and 4-methoxy-2-aminopyrimidine ($4\text{-}CH_3O\text{-}2\text{-}Apm$), have been isolated.[116,147,150,151] The non-electrolytic character of the complexes has been demonstrated by measuring the molar conductances of their dimethylformamide (DMF) solutions (13 to

15 Ω^{-1} cm^2 mol^{-1}).[147] The far IR spectra show two absorption bands in the region of Pt–X stretching vibrations: 330–340 cm^{-1} (Cl), 231–249 cm^{-1} (Br), and 202–218 cm^{-1} (I), as well as two bands in the Pt–N region (257–290 cm^{-1}), which led to the conclusion that the complexes have the *cis*-configuration. On heating, the complexes isomerise to the *trans*-forms, whose spectra have a single narrow absorption band in the ν_{as}(Pt–X) and ν_{as}(Pt–N) regions. The *cis*-isomers exhibit a definite antitumour effect: in relation to adenocarcinoma AK-755, the inhibition of tumour growth was ~60%.[152] There exist divergent views about the geometrical structure of the non-electrolytic platinum(II) complexes of aminopyrimidines of analogous composition apparently due to the lability of these compounds.[153–155]

Charged complexes with monodentate coordination of 2-aminopyrimidine have been described: the isomeric $[Pt(NH_3)_2L_2]X_2$ and *cis*-$[PtenL_2]X_2$, where L = 2-Apm or 4-Ph-2-Apm and X = Cl^-, NO_3^-, or $\frac{1}{2}[PtCl_4]^{2-}$.[147,148] In order to synthesise chloride complexes with 2-Apm, the isomeric $[Pt(NH_3)_2Cl_2]$ and $[PtenCl_2]$ complexes were dissolved in an aqueous solution of the ligand, while the nitrate complexes were synthesised by treating the aquo-complexes $[Pt(NH_3)_2(H_2O)_2]^{2+}$ and $[Pten(H_2O)_2]^{2+}$ with the ligands; the platinites were precipitated with a $K_2[PtCl_4]$ solution. In order to determine the structure of the complexes, their IR and ^1H and ^{13}C NMR spectra were investigated. Coordination leads to an increase of the stretching vibration frequencies of the pyrimidine ring, which indicates the involvement of one of the heterocyclic nitrogen atoms in binding. Comparison of the ^1H NMR spectra of the ligands and complexes (Table 1) finally demonstrates this. The ^1H NMR spectrum of 2-aminopyrimidine shows a triplet signal due to the H(5) proton and a doublet signal due to the equivalent H(4) and H(6) protons. On coordination, the signals of all the protons undergo a downfield shift owing to deshielding.[148,149] The H(5) triplet signal shifts only slightly under these conditions, while the equivalence of the H(4) and H(6) protons breaks down and their signals become of the doublet of doublets type, which is due to the spin–spin interaction of the H(4) and H(6) nuclei both with H(5) and with one another. Such changes in the ^1H NMR spectra of the complexes agree with the formation of monodentate bonds by one of the heterocyclic nitrogen atoms, because, on coordination via the NH_2 group, the equivalence of the H(4) and H(6) protons would have been retained. The involvement of a heterocyclic nitrogen atom in binding is confirmed by the occurrence of the spin–spin interaction of the nearest proton with the ^{195}Pt nucleus. The ^1H NMR spectrum of 4-Ph-2-Apm in DMSO contains two doublets of equal intensity due to the non-equivalent H(5) and H(6) protons with a spin–spin coupling constant of 5 Hz (see Table 1), a singlet signal due to the NH_2 group (6.50 p.p.m.), and complex signals due to the protons of the phenyl group (7.40 and 7.94 p.p.m.). The coordination of 4-Ph-2-Apm in the platinum(II) sphere entails a downfield shift of the signals of the H(5) and H(6) protons, the H(6) doublet being displaced to a greater extent than the H(5) doublet. This permits the conclusion that the coordinate bond of 4-Ph-2-Apm is formed via the ring N(1) atom. An analogous conclusion has been reached on the basis of the ^{13}C NMR spectra of the platinum(II) complexes of 2,6-dimethyl-4-aminopyrimidine.[156–158] The signals of the C(6) carbon atoms ($\Delta\delta$ = 8–12 p.p.m.) and of the methyl groups in the vicinity of the N(1) atom, namely $C(2)H_3$ and $C(6)H_3$ ($\Delta\delta$ = 4–6 p.p.m.) undergo the greatest shift on coordination. The signal due to the protons of the NH_2 group undergoes a downfield shift (1.5–2.3 p.p.m.) and is broadened to a doublet. As in the complexes with cytosine,[129] this is explained by the partial double bond character of the  bond in the complex and the hindered nature of the rotation of the protons about this bond.

Table 1. The chemical shifts and the spin–spin coupling (SSC) constants of the protons of 2-aminopyrimidines in the free and coordinated states (X = Cl^- and NO_3^-)*.

Compound	Solvent	δ, p.p.m.				SSC constants, Hz		
		H (5)	H (4)	H (6)	$^3J_{5-6}$	$^3J_{5-4}$	$^4J_{4-6}$	$^3J_{^{195}Pt-^1H}$

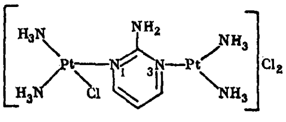
---

*The chemical shifts listed in the Table refer to the average positions of the proton signals.

Monodentate coordination via one of the heterocyclic nitrogen atoms is possible also for the aminopyrimidinium cation LH^+ protonated at the amino-group: the compounds $[MLHX_3]$ (X = Cl^- or Br^-; L = 2,6-dimethyl-4-aminopyrimidine or thiamine; M = Pt(II) or Pd(II)] have been isolated.[156–158]

Comparison of the spectroscopic (^1H NMR and electronic spectra) characteristics of the isomeric tetrammines $[PtA_2L_2]$.Cl_2 (A = NH_3; L = 2-Apm, 4-Ph-2-Apm, 4-CH_3-2-Apm, or 4-OCH_3-2-Apm) is of interest. It has been shown[159] that the downfield shift of the signal due to the non-labile H(4), H(5), and H(6) protons on coordination is greater for the *trans*-isomer than for the *cis*-isomer. The hyperchromic effect involving the absorption band of the ligands, observed on coordination, is also more pronounced for the *trans*-form. On this basis, it has been concluded that the *trans*-influence of 2-Apm and of its 4-substituted derivatives is smaller than that of NH_3. The explanation of this phenomenon may be sought in the lower stability of the bonds between aminopyrimidines and platinum(II).

The reactions between the platinum(II) complexes and 2-aminopyrimidines for the ratio Pt/L = 2 are accompanied by the formation of dinuclear complexes with a bridging aminopyrimidine molecule.[149,160] Thus complexes with the *cis*-structure and the composition $[PtA_2ClLPtA_2Cl]Cl_2$ (A = NH_3 or $\frac{1}{2}$en; L = 2-aminopyrimidine) have been isolated. Comparison of the ^1H NMR spectra of the ligands and the complexes showed that the signals of all the non-labile protons undergo a downfield shift on coordination and to a greater extent for the H(4) and H(6) protons [$\Delta\delta(4,6)$ = 0.6 p.p.m.]. The equivalence of the protons in the complex is maintained, since they give rise to one doublet signal with doubled intensity. This finding indicates the symmetrical binding of the 2-aminopyrimidine molecules to platinum atoms via the N(1) and N(2) atoms:



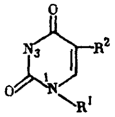
(XVIII)

The amino-group of the ligand in the complexes with bridge type coordination manifests weak acid properties [K_a = (1.8 ± 0.3) × 10^{-10}] as a consequence of the polarising influence of two neighbouring platinum(II) ions.[147]

The bidentate coordination of 2-aminopyrimidines with oxidation of the NH_2 group and the heterocyclic nitrogen atom is not characteristic of the platinum(II) complexes. The reactions of the platinum(II) complexes with 2-Apm in proportions of 1:1 lead to the formation of mixtures of compounds containing a dinuclear and a triammine complex.[159,161] On reaction with palladium (II), the compounds PdX_2.2-Apm (X = Cl^- or SCN^-), in which a chelate bond is postulated, were isolated.[162] In our view the formation of this bond is unlikely owing to the instability and strain of the four-membered ring. The molecular weights of the complexes should be measured, since they could have a dimeric structure with two bridging 2-aminopyrimidine molecules, i.e. $[PdX_2 2\text{-Apm}]_2$. The chelate coordination of 2-hydrazino-4,6-dimethylpyrimidine (2-hd-4,6-dmpm), observed by Saha et al.[163], is more probable, since this entails the formation of stable five-membered rings.

3. Platinum(II) Complexes of 2,4-Dioxopyrimidines

Among compounds of this class, the platinum(II) complexes of uracil (Ur), its nucleoside uridine (Urd), 5-methyluracil (thymine) (Th), its nucleoside thymidine (Thd), and also certain other 5- and 6-substituted uracils have been most thoroughly investigated.

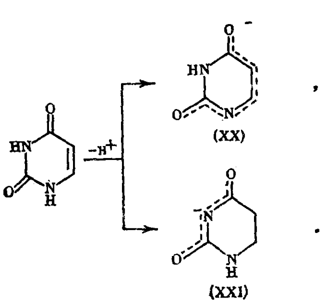


(XIX)

R^2 = H and R^1 = H(Ur) or β-D-ribofuranosyl (Urd); R^2 = CH_3 and R^1 = H(Th) or β-D-ribofuranosyl (Thd)

Uracil and thymine enter into the composition of natural biopolymers—RNA (Ur) and DNA (Th)—and can react with the antitumour complex *cis*-DDP. Active antitumour platinum complexes containing these ligands and other 2,4-dioxopyrimidines—the so called "platinum pyrimidine blues"—have been isolated.[164,165,166] The "blues" are more soluble in water and are less toxic than *cis*-DDP: LD_{50} is 200 to 500 mg kg^{-1} for the "blues" and 12 mg kg^{-1} for *cis*-DDP. The structure of the "blues" has not been fully established but it has been shown by the electrophoretic, chromatographic, and spectroscopic ("EXAFS") methods that they are cationic oligomeric platinum complexes with a molecular weight of 1000–3000 and a mixed oxidation state of platinum (2+ and 3+).[164,167] The ligands play the role of a bridge and join together the platinum atoms via heterocyclic atoms and O(4).

Uracil and its analogues exist in various tautomeric forms and exhibit ambident properties; for example, the two tautomeric forms (XX) and (XXI) are possible for the uracil anion:



The determination of the structure of the complexes with these ligands is therefore complicated and requires the application of a series of physical methods. In the absence of direct X-ray diffraction data, the most reliable information about the mode of coordination of these ligands can be obtained by NMR methods.

(a) Platinum(II) Complexes of Uracil, Thymine, and Their Nucleosides

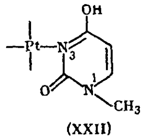
In contrast to the nucleic acid bases determined previously, uracil, thymine, and their nucleosides do not react with *cis*-DDP in a neutral medium.[13,26,37,168] The ability to be coordinated in the platinum(II) sphere is characteristic solely of the uracil and thymine anions and is associated with the manifestation by the latter of acid properties, which cytosine does not possess. The pK_a are 9.4 for uracil, 9.2 for uridine, 9.8 for thymine, and 9.7 for thymidine. The uracil and thymine monoanions consist of approximately equal amounts of forms dissociated at N(3)H and N(1)H.[169,170] As a result of tautomerism, the coordinate bonds linking uracil and thymine are formed both via the N(3) atom and the N(1) atom. Thus the reaction of the cation $[Pt(NH_3)_2.(H_2O)_2]^{2+}$ with uracil in a neutral medium leads to the formation of complexes with both types of bonds, via the N(3) and N(1) atoms, and having the composition $[Pt(NH_3)_2(Ur-H).NO_3]$.[171] The uridine and 6-uracil anions, in which the N(1) atoms is either linked to D-ribose or is blocked by the neighbouring methyl group, are coordinated solely via the N(3) atom.[110,163]

Complexes with the thymidine anions having the composition $[Pt(NH_3)_3(Thd-H)]NO_3$ and $[Pten(Thd-H)_2]$ have been isolated in reactions of thymidine with the corresponding aquo-complexes.[172] Thymidine is coordinated via the N(3) atom, which is accompanied, analogously to the behaviour observed in the complexes with the uracil and uridine anions,[171] by an upfield shift of the H(6) proton signal. The authors determined the formation constant of $[Pt(NH_3)_3(Thd-H)]^+$ ($\lg K_{form}$ = 10.4 ± 0.1) and the successive formation constants of $[Pten(Thd-H)_2]$ ($\lg K^1$ = 10.3 ± 0.1 and $\lg K^2$ = 7.4 ± 0.1) from the dependence of the intensity of the H(6) signal on the pH. The ^{13}C NMR method was used to determine the donor atom in solutions of $[PtenCl_2]$ with an excess of uridine or thymidine.[173] Two sets of signals due to carbon atoms can be observed in these systems, one referring to non-coordinated uridine or thymidine and the other to the complexes $[Pt(L-H)_2]$, where (L − H) are the uridine and thymidine anions. The greatest shift on coordination of uridine (compared with the non-bonded neutral molecule) is observed for the C(2) and C(4) atoms: their signals have undergone downfield shifts of 5.3 and 8.0 p.p.m. respectively. The C(5) and C(6) signals are displaced to a lesser extent and in the opposite direction—upfield.

A large series of studies on the platinum complexes of uracil and its derivatives have been carried out by Lippert and co-workers. The difficulty of determining the structure of the platinum complexes of unsubstituted uracil and thymidine, for which there is a possibility of the coordination of both tautomeric forms, was noted. In order to determine the type of coordination, IR and NMR spectroscopy are used.[174-177] Thus the stretching vibration frequency $\nu(C-O)$ for the complexes with the Pt–N(1) bond is characterised by an intense band at 1640 cm^{-1} with shoulders in close proximity to regions at lower and higher frequencies, while the Pt–N(3) bond is characterised by a band at 1550 cm^{-1} and another at 1650 cm^{-1}. The ^1H NMR spectra of the tautomeric complexes differ by the triplet splitting of the H(6) proton signal on formation of the Pt–N(1) bond ($^3J_{^1H-^{195}Pt}$ = 38–40 Hz), while in the spectra of the complexes with the Pt–N(3) bond the H(6) signal is not split while the H(5) signal is split but has a smaller spin–spin coupling constant ($^4J_{^1H-^{195}Pt}$ = 4–15 Hz). It has also been stated that the tautomers have different reactivities—the complexes with the Pt–N(1) bond are stable in an acid medium but at the same time they exchange the H(5) proton for deuterium, while the complexes with the Pt–N(3) bond split off the free ligand on heating in an acid medium. The exchange of H(5) with deuterium is observed in an alkaline medium in this case.[110] Factors influencing the formation of a particular tautomeric complex are said to include the nature of the solvent, the pH of the aqueous solution, the solubility of the reaction products, the capacity of the ligands for participation in a hydrogen bond, and even the reaction conditions.

(b) Platinum(II) Complexes of N(1)-Substituted Uracil and Thymine

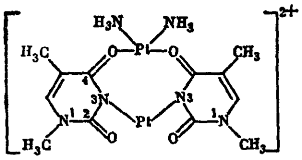
This class of compounds includes the uracil and thymine nucleosides and N(1)-methyl-substituted compounds. In many cases studies have been made of the reactions of 1-methyluracil and 1-methylthymine with platinum(II) complexes. The structure of these compounds can be established more readily than that of the complexes with unsubstituted ligands—the Pt–N(3) bond is formed in all cases. The reactions of the anions of 1-methyluracil and 1-methylthymine led to the isolation of the non-electrolytic complexes cis-$[Pt(NH_3)_2(1\text{-}CH_3Ur\text{-}H)_2].4H_2O$ and cis-$[Pt(NH_3)_2.(1\text{-}CH_3Th-H)_2]$,[176-178] the mixed type cationic complexes cis-$[Pt(NH_3)_2(1\text{-}CH_3Th-H)L]ClO_4$ (L = cytosine, guanine, or adenine),[179,180] and even complexes containing not only ligand anions but also ligand molecules—cis-$[Pt(NH_3)_2.(1\text{-}CH_3Ur)(1\text{-}CH_3Ur-H)]X.H_2O$.[181] It is suggested that the neutral ligand is coordinated in an unusual tautomeric form (XXII):



(XXII)

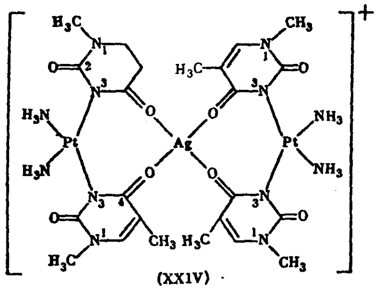
The Pt–N(3) bond with a neutral ligand is unstable, the ligand is readily split off, and X^- enters into the composition of the complex.

Polynuclear complexes with 1-methyluracil and 1-methylthymine can be formed via bridging hydroxo-groups or ligand anions. Dimers of the first type, namely cis-$[Pt.(NH_3)_2(L-H)]_2OH$, are formed in an alkaline solution. It has been suggested that the cis-Pt–OH–Pt group is capable of interacting with DNA bases, cross linking them via intrastrand or interstrand mechanisms.[180] Polymerisation via bridging 1-methyluracil and 1-methylthymine anions leads to the formation of homopolynuclear and heteropolynuclear complexes.[181-188] Exocyclic oxygen atoms participate in the bridge bond together with the heterocyclic nitrogen atoms. An example of a homonuclear polymer is the dimer cis-$[Pt(NH_3)_2(1\text{-}CH_3Th-H)]_2(NO_3)_2$ [182-184] with electron-donating N(3) and O(4) atoms [compound (XXIII)]:



(XXIII)

The bidentate bridge bond via the 1-methylthymine and 1-methyluracil anions exists also in heteronuclear complexes of the type Pt_2M, where M = Ag^+,[186] Mn^{2+},[187] or Cu^{2+},[188] for example in cis-$[Pt(NH_3)_2(1\text{-}CH_3Th-H)_2Ag(1\text{-}CH_3Th-H)_2.Pt(NH_3)_2]NO_3$ (XXIV):



(XXIV)

More complex polymeric structures occur when the 1-methyluracil anions exhibit the properties of tridentate ligands being coordinated via the N(3) atom and both exocyclic O(4) and O(2) atoms. An example is provided by the pentanuclear heteronuclear complex of the type Pt_4A_9 – $[Pt_4(NH_3)_8(1\text{-}CH_3Ur-H)_4Ag](NO_3)_5$.[189] After slight heating, the complex gives rise to the blue product $[Pt_4.(NH_3)_8(1\text{-}CH_3Ur-H)_4](NO_3)_5.5H_2O$, in which platinum is in the 2.25+ oxidation state. This product may be formed as a result of the intermolecular oxidation-reduction reaction

$$Ag^{+1}+e\rightarrow Ag^0,\ Pt_4^{8+}-e\rightarrow Pt_4^{9+}$$

The platinum "blues" incorporating the 1-methyluracil anions are obtained also after cautious oxidation of the "head to head" dimer $[Pt(NH_3)_2(1\text{-}CH_3Ur-H)]_2(NO_3)_2$ with nitric acid.[183,185] After more far reaching oxidation, yellow-orange diamagnetic complexes, resembling the platinum(III) dimers with α-pyridone, are formed.[190-192] Platinum "blues' with the thymine anion have also been described.[193]

The ^{195}Pt NMR method combined with high performance liquid chromatography has been used to determine the structure of the platinum(II) complexes of 1-methyluracil [89,194] (Table 2). The spectra of the mononuclear complexes show a single signal whose position is determined by the nature of the electron-donating atoms. Thus the replacement of two H_2O molecules by two Cl^- ions leads to an upfield shift c 500 p.p.m. An even greater upfield shift (820 p.p.m.) is observed after the replacement of two H_2O molecules by two 1-methyluracil anions. Complexes with the PtN_4 coordinatio unit, namely cis-$[Pt(NH_3)_2(1\text{-}CH_3Ur-H)_2]$ (–2407 p.p.m.) and $[Pt(NH_3)_4]^{2+}$ (–2579 p.p.m.) are characterised by the greatest upfield chemical shifts. The dimer cis-$[Pt(NH_3)_2.(1\text{-}CH_3Ur-H)]_2^{2+}$ with an asymmetric "head to head" structure, in which one of the platinum atoms is involved in the

PtN_4 coordination unit while the other is in the PtN_2O_2 group, gives rise to two signals in the ^{195}Pt spectrum, i.e. at −2210 and −1267 p.p.m., which correspond to two types of coordination.

Table 2. The ^{195}Pt NMR spectra of platinum(II) 1-methyluracilate complexes in D_2O (external standard—Na_2PtCl_6).[89]

Complexes with *cis*-structure	^{195}Pt chemical shift, p.p.m.
cis-DDP	−2097
$[Pt(NH_3)_2(H_2O)_2]^{2+}$	−1588
$[Pt(NH_3)_2(1\text{-}CH_3Ur\text{—}H)_2]$	−2407
$[Pt(NH_3)_2(1\text{-}CH_3Ur\text{—}H)(H_2O)]^+$	−1999
$[Pt(NH_3)_2(1\text{-}CH_3Ur\text{—}H)Cl]$	−2261
$[Pt(NH_3)_2(1\text{-}CH_3Ur\text{—}H)]_2^{2+}$	−2210, −1267

(c) Platinum(II) Complexes of 5-substituted Uracils

In the reactions of *cis*-DDP and its aquo-form with the sodium and lithium salts of 5-substituted uracil, complexes having the *cis*-structure with one and two ligand anions were isolated: $[Pt(NH_3)_2(5\text{-RUr}-H)Cl]$ (R = H, Br, or NO_2) and $[Pt(NH_3)_2(5\text{-RUr}-H)_2]$ (R = H, F, Cl, Br, I, or NO_2).[195] The anionic form of the ligand in the complexes follows from their composition and has been confirmed by the similarity of the UV and IR spectra of the complexes in the initial salt. The type of coordination was determined by the ^1H and ^{13}C NMR methods in relation to complexes with two anions. In the spectrum of the complex with uridine—*cis*-$[Pt(NH_3)_2.(Urd-H)_2]$—in which coordination is possible only via the N(3) atom, the H(6) proton signal is a doublet, as in the free ligand, and has undergone an upfield displacement of 0.2 p.p.m. compared with uridine. Analogous ^1H NMR spectra have been observed also for *cis*-$[Pt(NH_3)_2(Ur-H)_2]$, *cis*-$[Pt(NH_3)_2(5\text{-FUr}-H)_2]$, and *cis*-$[Pt(NH_3)_2(5\text{-BrUr}-H)_2]$, for which coordination of the anions by the N(3) atom is also suggested. The ^1H NMR spectrum of the complex *cis*-$[Pt.(NH_3)_2(5\text{-}NO_2Ur-H)_2]$ has a different form: the H(6) signal is a triplet as a result of the spin–spin interaction with the ^{195}Pt nucleus and its upfield shift is 0.1 p.p.m. In the spectrum of the complex of 5-chlorouracil, two H(6) signals are observed—a singlet with $\Delta\delta$ = 0.32 p.p.m. and a triplet for which $\Delta\delta$ = 0.10 p.p.m. Both forms of coordination of the ligand, via the N(3) and N(1) atoms, have been proposed for this complex. The conclusions reached have also been confirmed by ^{13}C NMR:[196] in the complexes with the Pt–N(3) bond, the greatest downfield shifts on coordination are observed for the C(2) and C(4) atoms, while in those with the Pt–N(1) bond, the greatest shifts are for C(2) and C(6).

IV. KINETICS OF THE REACTIONS OF PURINE AND PYRIMIDINE BASES AND THEIR NUCLEOSIDES WITH PLATINUM(II) COMPLEXES

In order to characterise the reactivity of the platinum(II) complexes, it is of interest to investigate the kinetics of the reactions of these compounds with the purine and pyrimidine DNA bases and as well as their antimetabolites and nucleosides. Such a study has been carried out for the reactions of the diammines $[Pt(NH_3)_2Cl_2]$ and the isomeric triammines $[(PtNH_3)_2InoCl]Cl$ with inosine and cytidine.[197,198] The interaction of *cis*-DDP with inosine incudes two stages:

$$cis\text{-}[Pt(NH_3)_2Cl_2] + L \xrightarrow{k^1} cis\text{-}[Pt(NH_3)_2LCl]^+ + Cl^- , \qquad (1)$$

$$cis\text{-}[Pt(NH_3)_2LCl]^+ + L \xrightarrow{k^2} cis\text{-}[Pt(NH_3)_2L_2]^{2+} + Cl^- . \qquad (2)$$

The kinetics of the second stage were investigated initially, because it proceeds with substitution of only one chloride ion by inosine. The conductimetric method was used and the reaction was carried out under pseudo-first-order conditions in an excess of the entering ligand at 50 °C. The constant k^2_{obs} was calculated from the first-order kinetic equation and its dependence on the concentrations of the ligand and the Cl^- ions was determined. Analysis of the data permits a series of conclusions: (1) the reactions of the cytidine complexes are faster than those of the inosine complexes; (2) the incorporation of inosine in the platinum(II) complexes obeys a kinetic equation which differs from the equation for the insertion of NH_3 or amine: for inosine there is no linear relation between k_{obs} and the inosine concentration and k_{obs} diminishes with increase of the concentration of Cl^- ions. This type of dependence has been explained by the fact that inosine is inserted mainly in the hydrolysis product *cis*-$[Pt(NH_3)_2InoH_2O]^{2+}$ and that the reverse insertion of Cl^- ions in the monoaquo-complex competes with this process. The characteristic feature of inosine is manifested by the fact that the rate constant for the insertion of the bulky ligand is lower than the rate constant for the incorporation of Cl^- ions in the monoaquo-complex; (3) the quantity k^2_{obs} depends on the geometrical structure of the triammine: the substitution of the Cl^- ion in the *cis*-triammine is faster than in the *trans*-isomer, which indicates a weaker *trans*-influence of inosine than that of NH_3. The reactions of guanosine with the triammines $[Pt(NH_3)_3Cl]Cl$ and *cis*-$[Pt(NH_3)_2CytCl]Cl$ proceed analogously.[145,199]

The rate constant for the first stage k^1_{obs} was estimated on the basis of the experimental study of the rate of reaction of the isomeric platinum(II) diammines with inosine and the known constants k^2_{obs} for the second stage. The quantity k^1_{obs} was found by solving the kinetic equation for two consecutive irreversible first-order reactions by means of a program specially devised for the CM-4 computer. The quantity k^1_{obs} varies linearly in this instance with the concentration of inosine, which is associated with the greater contribution of the mechanism involving the direct nucleophilic substitution in stage 1. The ratio of the constants k^1_{obs} for the isomeric diammines is the reverse of the ratio of the constants k^2_{obs} for the triammines: $k^1_{obs}(trans) > k^1_{obs}(cis)$ as a consequence of the greater *trans*-influence of Cl^- compared with NH_3.

It has been shown by the spectrophotometric method that the interaction of labile and less stable palladium(II) triammines [PddienBr]Br with inosine proceeds via a more complex mechanism,[200] including not only the stage involving the reversible hydrolysis of Br^- ions but also the reversible substitution of Br^- ions and water molecules by inosine. The conclusions reached in a conductimetric study of the kinetics of the reaction of [PtdienBr]Br with inosine[201] are close to ours. The kinetics of the reaction of $[PdenCl_2]$ with inosine have been studied by the stopped flow method with spectrophotometric measurements.[202] Hydrolytic and direct substitution processes were taken into account in the reaction mechanism, but the formation of complexes with two inosine molecules, which is extremely probable in the presence of a (10–20)-fold excess of the ligand, was not considered.

A conductimetric kinetic study at 50 °C of the interaction of cytidine with the platinum(II) triammine *cis*-$[Pt(NH_3)_2.CydCl]Cl$, the isomeric $[Pt(NH_3)_2InoCl]Cl$ complexes, and the *cis*-non-electrolyte $[Pt(NH_3)_2Cl_2]$ has been carried out.[197,198] The insertion of cytidine in the complexes obeys, in contrast to inosine and guanosine, the rules observed for other ligands L in the reactions with platinum(II) complexes; $k_{obs} = k_1 + k_2[L]$, where k_{obs} is the pseudo-first order rate constant, k^1 the hydrolysis rate constant, and k^2 the rate constant for direct substitution. It follows from a comparison of the quantities k_{obs} for the same complexes at the same concentrations of the entering ligand that the reactions with cytidine are faster than those with inosine and are somewhat slower than the reactions with guanosine.[197,199] The constant k_{obs} for the reaction of cytidine with *cis*-$[Pt(NH_3)_2.$ $.InoCl]Cl$ is greater than for the reaction with the *trans*-isomer, which has been explained by the weaker *trans*-influence of inosine compared with NH_3. The interaction of cytidine with *cis*-$[Pt(NH_3)_2Cl_2]$ follows an analogous law, but is somewhat faster. The kinetic parameters of the first stage exceed by factors of 3 for k_1^1 and 200 for k_2^1 the corresponding values for the second stage. The interaction of bifunctional mono- and di-nuclear platinum(II) complexes with oligo- and poly-nucleotides has been investigated.[203,204] The complex *cis*-$[Pt(NH_3)_2(H_2O)(OH)]^+$ binds oligocytidine via the N(3) atom; the reaction product then forms interstrand bonds with the inosine polynucleotide (polyI) via the substitution of the OH^- group by the inosine molecule deprotonated at N(1).[204] The kinetics of the reactions of $[XPt\ dien-(CH_2)_6-dienPtY](NO_3)_n$ (n = 2–4, $X = H_2O$, $Y = H_2O$ or Br^-, or $X = Y = Br^-$) with inosine monophosphate (IMP) and polyI have been investigated spectrophotometrically.[205] The decrease of the reaction rate in the presence of Br^- ions indicates the dominant role of the hydrolytic mechanism. The increase of the rate constant on passing from IMP to polyI has been explained by the increased contribution of the S_N2 mechanism in the latter case.

New data on the problems dealt with in this review have been communicated in the reports at the XIVth International Conference on Coordination Chemistry in 1986. The necessity for a comparative study of the interaction of the isomeric dichlorodiammineplatinum(II) complexes with DNA and oligo- and polynucleotides was pointed out.[206–208] A number of studies were devoted to the synthesis and investigation of the structure and kinetics of the formation of "platinum blues" with 1-methyluracil and its derivatives.[209–211] Dinuclear platinum(III) complexes with bridging anions of uracil and its derivatives have been isolated.[177] Treatment of these compounds with an excess of 1-methyluracil and also oxidation of the dimeric platinum(II) complexes of this ligand with nitric acid led to the isolation of the unusual platinum(III) complexes $[Pt_2(NH_3)_4(C_5H_5N_2O_2)_3]Si_6NO_3.7H_2O$, in which the third 1-methyluracil anion is linked to platinum(III) via the C_5 atom.[212] A chelate platinum(IV) complex of cytosine has been isolated.[213] The platinum(II) complex of guanosine $[PtGuaCl_2H_2O]$ was found to exhibit anticancer activity.[214] The stabilities of the bonds of purine and pyrimidine nucleosides and their mononucleotides with palladium(II) via various electron-donating heterocyclic nitrogen atoms [N(7), N(1), and N(3)] have been compared using the ^1H NMR method.[215] The kinetics of the reactions of *cis*-$[Pt(NH_3)_2(H_2O)_2]^{2+}$ with nucleic acid bases have been studied and it has been shown that the rate of insertion of the bases varies in the sequence guanine > adenine ≅ cytosine > thymine.[216]

In conclusion, we may note that the results of the study of the structure and properties of the platinum(II) complexes of the purine and pyrimidine bases and their nucleosides and antimetabolites can be used to establish a correlation between the structure of the platinum(II) complexes, their reactivity in relation to DNA, and their antitumour activity. The characteristics of the purine and pyrimidine bases and their derivatives as ligands are manifested in their ambident character and in their tendency to form homo- and hetero-polynuclear complexes with bridge bonds and metal–metal bonds. The data on the acid–base properties and the kinetic and thermodynamic stabilities of the platinum(II) complexes of the above ligands make it possible to characterise their behaviour in biological media with different acidities and chloride ion concentrations and to estimate the influence of coordination on the properties of these ligands and the effects of their mutual influence in the platinum(II) coordination sphere.

Acyclic Alkoxy- and Aryloxy-phosphoranes

L.N.Markovskii, N.P.Kolesnik, and Yu.G.Shermolovich

The review gives a systematic account of the methods of synthesis, physical properties, structure, and reactivity of pentacoordinate phosphorus compounds having an acyclic structure and containing alkoxy- and aryloxy-substituents. The bibliography includes 91 references.

I. INTRODUCTION

Phosphorus is undoubtedly outstanding among other Group V elements of the Periodic System as regards the number of compounds with different coordinations of the central atom which really exist and are being investigated. The compounds of pentacoordinate phosphorus (phosphoranes) occupy a special place in organophosphorus chemistry. Fundamental research into the mechanisms of the reactions of organophosphorus compounds has yielded convincing evidence for the existence of intermediates with pentacoordinate phosphorus in reactions of compounds of tricoordinate and tetracoordinate phosphorus.[1–6] The concept of metastable hydroxyphosphorane derivatives $(RO)_{5-n}P(OH)_n$, formed as intermediates, has been dominant in the study of the biochemical role of phosphate-containing coenzymes, for example ATP.[7–10]

The ability of the phosphorus atom to form covalent bonds with five ligands has long been known in the inorganic chemistry of phosphorus. The high stability of PF_5 and other fluorophosphoranes has received a detailed theoretical justification.[11–13] On the other hand, the chemistry of stable pentaorganophosphoranes, i.e. compounds in which the phosphorus atom is linked by σ-bonds to five organic substituents, has been developing vigorously only during the last 25 years. Among the studies which have stimulated the detailed investigation of organophosphoranes, mention must be made of the investigation of the mechanism of the hydrolysis of cyclic phosphates,[14] which made it possible for the first time to discover the important role which the presence of a cyclic fragment in the molecule plays in the stabilisation of organophosphoranes. Ramirez[1,15] established the rules governing the formation of cyclic alkoxyphosphoranes and the principles of their molecular structure and pointed out the possibility of their synthetic employment.

Until recently, much less was known about pentaorganophosphoranes with an acyclic structure despite the fact that the closest models of the intermediates in the majority of the reactions of organophosphorus compounds (OPC), including biochemical processes, are precisely phosphoranes with a phosphorus atom not involved in a ring.

In the series of acyclic pentaorganophosphoranes, alkoxy- and aryloxy-phosphoranes are best known. Several relatively unstable acyclic alkoxyphosphoranes with arylthio-groups[16,17] or dialkylamino-groups[18] as well as several penta(perfluoroalkyl)phosphoranes[19,20] and penta-arylphosphoranes[21] are known.

The increased stability of acyclic alkoxy- and aryloxyphosphoranes compared with their thia- and aza-analogues can apparently be explained by the greater electronegativity of the oxygen atom compared with the oxygen atoms attached to sulphur and nitrogen atoms. On the other hand, the electronic and steric properties of the substituents at the oxygen atoms could influence the stability and reactivity of the same phosphoranes. In order to elucidate the factors influencing the properties of acyclic alkoxyphosphoranes, methods have been developed in recent years for the synthesis of a wide variety of compounds of this type and their reactivity has been investigated in reactions with organic compounds of different classes. The results of these studies are surveyed in the present review.

II. METHODS OF SYNTHESIS

The methods of synthesis of alicyclic penta-alkoxy- and penta-aryloxy-phosphoranes, as well as alicyclic alkoxy- and aryloxy-organophosphoranes, can be usefully divided into three groups in terms of the coordination of the phosphorus in the initial compounds used for the synthesis. Many of these phosphoranes have been obtained from compounds of pentacoordinate and tricoordinate phosphorus and many fewer from compounds of tetracoordinate phosphorus.

1. Synthesis from Halogenophosphoranes

The reaction of phosphorus pentachloride and phenol proceeds, according to Anshutz[22] and Zhmurova and Kirsanov,[23] via a stage involving the formation of dichlorotriphenoxyphosphorane (I) and leads to an organophosphorus compound of a new type—pentaphenoxyphosphorane (II):

$$3C_6H_5OH + PCl_5 \xrightarrow[-3HCl]{} \underset{(I)}{(C_6H_5O)_3PCl_2}$$

$$(C_6H_5O)_3PCl_2 + 2C_6H_5OH \xrightarrow[-2HCl]{} \underset{(II)}{(C_6H_5O)_5P} \quad .$$

However, ^{31}P NMR [24] showed that these reactions yield not compound (II) but a mixture of dichlorotriphenoxyphosphorane (I) and other compounds.

Analytically pure pentaphenoxyphosphorane (II) was obtained only in the presence of a base—γ-collidine:[24]

$$PCl_5 \xrightarrow[2)\ 5C_6H_5OH]{1)\ 5(CH_3)_3C_5H_2N,0°C} \underset{(II)}{(C_6H_5O)_5P} + 5(CH_3)_3C_5H_2N \cdot HCl \quad .$$

Other substituted pentaphenoxyphosphoranes $(ArO)_5P$ with $Ar = o\text{-}CH_3C_6H_4$, $p\text{-}CH_3C_6H_4$, $o\text{-}ClC_6H_4$, or $p\text{-}ClC_6H_4$,[25] as well as penta(perfluorophenoxy)phosphoranes [26] have been obtained analogously.

A method consisting in the reaction of halogenophosphoranes with alcohols or phenols in the presence of bases and also with alkoxides, phenoxides, or alkoxy- and aryloxy-silanes has been used successfully for the synthesis of a whole series of acyclic alkoxy- and aryloxy-phosphoranes. Apart from PCl_5, the halogenophosphoranes employed were PF_5, alkyl-, and aryl-fluoro-phosphoranes,[27,28] alkoxychloro- and alkoxyfluoro-phosphoranes,[27,29–32] dibromotriphenyl- or dibromotributyl-phosphoranes,[33,34] and tris(trifluoromethyl)-fluoro- or tris(trifluoromethyl)chloro-phosphoranes [35,36] (Table 1):

$$(CH_3)(CF_3)_3PF + CH_3OSi(CH_3)_3 \xrightarrow[-(CH_3)_3SiF]{} \underset{(III)}{(CH_3)(CF_3)_3POCH_3}$$

$$R^1R^2_2PX_2 + 2R^3OM \xrightarrow[-2MX]{} \underset{(IV)-(XIX)}{R^1R^2_2P(OR^3)_2} \quad .$$

When phosphorus pentachloride is treated with perfluoro-t-butyl hypochlorite penta(perfluoro-t-butoxy)phosphorane is formed in a quantitative yield.[37]

2. Synthesis from Compounds of Tetracoordinate Phosphorus

There are very few methods of synthesis of acyclic alkoxy- or aryloxy-phosphoranes from compounds of tetracoordinate phosphorus. Methyl- or aryl-aryloxy-phosphoranes containing two, three, or four aryloxy-groups [compounds (XX)–(XXVI) and (XXIX)] are formed, for example, when methyl- or aryl-aryloxyphosphoniatrifluoromethanesulphonates (XXVII) [38–40] or trichlorophenylphosphonium chloride (XXVIII) [39] are treated with the corresponding phenoxides:

$$\underset{(XXVII)}{R_n\overset{+}{P}(OAr)_{4-n}\overline{S}O_3CF_3} + ArOM \xrightarrow[-CF_3SO_3M]{} \underset{(XX)-(XXIV)}{R_nP(OAr)_{5-n}}$$

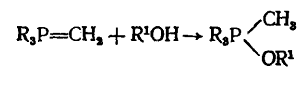
$R{=}CH_3$, $n = 1$, $Ar{=}C_6H_5$ (XX), $2,6\text{-}(CH_3)_2C_6H_3$ (XXI), $2\text{-}CH_3C_6H_4$ (XXII), $4\text{-}CH_3C_6H_4$ (XXIII); $R{=}CH_3$, $n = 2$, $Ar{=}2\text{-}CH_3C_6H_4$ (XXIV)

$$CH_3(C_6H_5)_n\overset{+}{P}(OC_6H_5)_{3-n}\overline{O}SO_2CF_3 \xrightarrow[-CF_3SO_3M]{C_6H_5OM} \underset{(XXV),\ (XXVI)}{CH_3(C_6H_5)_nP(OC_6H_5)_{4-n}}$$

$n = 1$ (XXV), 2 (XXVI)

$$\underset{(XXVIII)}{C_6H_5\overset{+}{P}Cl_3Cl^-} + 4C_6H_5OH \xrightarrow{2,6\text{-lutidine}} \underset{(XXIX)}{C_6H_5P(OC_6H_5)_4} \quad .$$

It has been established[41] that the alkoxytetramethylphosphoranes (XXX) and (XXXI) and the alkoxymethyltriphenylphosphoranes (XXXII)–(XXXIV) are formed as a result of the addition of alcohols to trimethylphosphinomethylene (XXXV) or triphenylphosphinomethylene (XXXVI) respectively:



$$R_3P{=}CH_2 + R^1OH \rightarrow R_3P\begin{matrix}\diagup CH_3\\ \diagdown OR^1\end{matrix}$$

$R{=}CH_3$ (XXXV), C_6H_5 (XXXVI)

$R{=}CH_3$, $R^1{=}CH_3$ (XXX), C_2H_5 (XXXI);
$R{=}C_6H_5$, $R^1{=}CH_3$ (XXXII),
C_2H_5 (XXXIII), $(CH_3)_2CH$ (XXXIV) .

The formation of acyclic alkoxy- and aryloxy-phosphoranes is possible in principle also as a result of the addition of suitable reagents to the P=O double bond. However, although several examples of addition to the phosphoryl group, involving both an increase of the coordination number of phosphorus[42] and proceeding without change in coordination,[43–48] are known at present in the chemistry of organophosphorus compounds, the only rigorously demonstrated instance of the synthesis of a pentacovalent phosphorane structure among

---

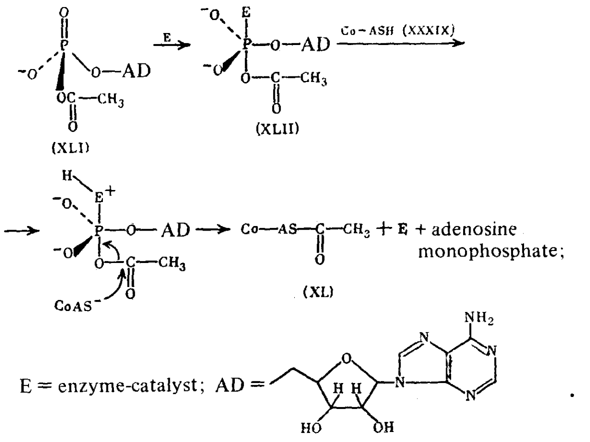
[a] Not isolated in a pure state. [b] Data quoted by Denney et al.[16] [c] In ^{31}P NMR (relative to 85% H_3PO_4).

the acyclic compounds is the reaction of tris(trifluoromethyl)-phosphine oxide (XXXVII) with hexamethyldisiloxane:[49,50]

$$\underset{\text{(XXXVII)}}{(CF_3)_3P{=}O} + (CH_3)_3SiOSi(CH_3)_3 \rightarrow \underset{\text{(XXXVIII)}}{(CF_3)_3P[OSi(CH_3)_3]_2}$$

The phosphorane (XXXVIII) formed under these conditions is a low-boiling liquid, which has been isolated in a pure state by vacuum distillation.

It is noteworthy that the hydroxyphosphorane concept, based on the hypothesis that processes involving adenosine triphosphate proceed via an intermediate with a pentacoordinate phosphorus atom,[8,9] formed as a result of the addition of the enzyme to the P=O bond, has become widely adopted at the present time in biochemistry. For example, in the conversion of the coenzyme A (CoASH) (XXXIX) into the acetylcoenzyme A (XL), the adenyl acetate (XLI) formed initially reacts with the enzyme E catalysing this process and is converted into the pentacoordinate intermediate (XLII). As a result of proton transfer from the mercapto-group of coenzyme A (XXXIX) to the apical atom through which the enzyme is linked to the phosphorus followed by attack on the carbonyl group by the coenzyme anion, acetylcoenzyme A (XL) is subsequently obtained:[9]



3. Synthesis from Compounds of Tricoordinate Phosphorus

As a result of the studies of Denney and co-workers, the method of synthesis of acyclic alkoxyphosphoranes from compounds of tervalent phosphorus and dialkyl peroxides has come to be widely known since 1964. The first representative of acyclic penta-alkoxyphosphoranes, namely pentaethoxyphosphorane (XLIII), was obtained by the reaction of triethyl phosphite with diethyl peroxide.[51] Subsequently pentamethoxyphosphorane (XLIV) was also obtained by the same method.[52] However, these compounds were not isolated in a pure state—they contained an admixture of trialkyl phosphates:

$$(AlkO)_3P + AlkOOAlk \rightarrow (AlkO)_5P;\ Alk{=}C_2H_5\ \text{(XLIII)},\ CH_3\ \text{(XLIV)}\ .$$

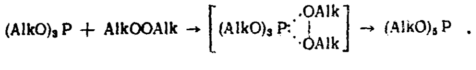
Having studied systematically the reaction of diethyl peroxide with compounds of tervalent phosphorus, Denney and co-workers[53-55] found the optimum conditions for the synthesis and isolation of a whole series of diethoxyphosphoranes (XLV)-(LIII):

$$R^1R^2_2P + C_2H_5OOC_2H_5 \rightarrow \underset{\text{(XLV)}-\text{(LIII)}}{R^1R^2_2P(OC_2H_5)_2}$$

$$R^1{=}R^2{=}C_6H_5\ \text{(XLV)},\ C_4H_9\ \text{(XLVI)},\ CH_3\ \text{(XLVII)},$$
$$(CH_3)_2CH\ \text{(XLVIII)},\ CH_3O\ \text{(XLIX)};\ R^1{=}C_2H_5O,\ R^2{=}C_6H_5\ \text{(L)};$$
$$R^1{=}CH_3,\quad R^2{=}C_6H_5\ \text{(LI)};\quad R^1{=}C_6H_5,$$
$$R^2{=}C_2H_5O\ \text{(LII)},\ CH_3\ \text{(LIII)}\ .$$

Denney and Jones[55] suggest two possible mechanisms for the formation of phosphoranes from dialkyl peroxides.

The direct formation of alkoxyphoshorane in a single stage via a transition state in which both oxygen atoms are linked to the phosphorus atom:



$$(AlkO)_3P + AlkOOAlk \rightarrow \left[(AlkO)_3P\begin{matrix}\cdot OAlk\\ |\\ \cdot OAlk\end{matrix}\right] \rightarrow (AlkO)_5P\ .$$

A two-stage mechanism involving substitution at the oxygen atom of the dialkyl peroxide with formation of the tetra-alkoxyphosphonium cation–alkoxide anion ion pair, which is subsequently converted into the penta-alkoxyphosphorane:

$$(AlkO)_3P + AlkOOAlk \rightarrow (AlkO)_4\overset{+}{P}AlkO^- \rightarrow (AlkO)_5P$$

The reactivity of phosphites and phosphines in relation to diethyl peroxide is the opposite of their reactivity in nucleophilic substitution reactions with C_2H_5L.[55] These data make it possible to give preference to the single-stage mechanism of the formation of the phosphorane in which the tervalent phosphorus atom is inserted, as a biphilic reagent, in the oxygen–oxygen bond.

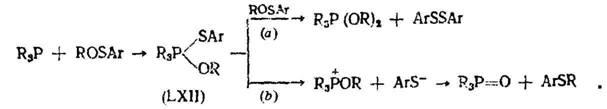
The disadvantages of using dialkyl peroxides are the difficulty of obtaining them, their explosive nature, and also the limited set of such compounds. The reactions with dialkyl peroxide take place slowly [for example, in the synthesis of pentaethoxyphosphorane (XLIII) the reaction lasts 20 days at room temperature[55]] and the phosphoranes are always formed not in a pure state but in a mixture with the oxidation products of the initial organophosphorus compound: phosphates, phosphonates, phosphinates, or tertiary phosphine oxides.[51-55]

The method of synthesis of acyclic alkoxyphosphoranes involving the reaction of derivatives of tervalent phosphorus with alkyl benzenesulphenates is free from many of these disadvantages. When this method involving the reaction of two moles of alkyl benzenesulphenate with tervalent phosphosus compounds under mild conditions is used, the corresponding alkoxyphosphoranes (IV), (XI), (XV), (XLIII)-(XLV), (L), (LII), and (LIV)-(LXI) are formed in high yields:[16,56-59]

$$(C_6H_5)_{3-n}P(OAlk)_n + 2AlkOSC_6H_5 \rightarrow \underset{\text{(IV), (XI), (XV), (XLIII)}-\text{(XLV), (L), (LII), (LIV)}-\text{(LXI)}}{(C_6H_5)_{3-n}P(OAlk)_{n+2}} + (C_6H_5S)_2$$

$$n=0,\ Alk{=}CF_3CH_2\ \text{(IV)},\ CH_3CH_2\ \text{(XLV)};$$
$$n=1,\ Alk{=}CH_3CH_2\ \text{(L)},\ CF_3CH_2\ \text{(LXI)};$$
$$n=2,\ Alk{=}CF_3CH_2\ \text{(XI)},\ CH_3CH_2\ \text{(LII)},\ \text{cyclo-}C_5H_9\ \text{(LIX)},\ (CH_3)_3CCH_2\ \text{(LX)};$$
$$n=3,\ Alk{=}CF_3CH_2\ \text{(XV)},\ CH_3CH_2\ \text{(XLIII)},\ CH_3\ \text{(XLIV)},\ (CH_3)_2CH\ \text{(LIX)},$$
$$(CH_3)_3CCH_2\ \text{(IV)},\ \text{cyclo-}C_5H_9\ \text{(LVI)},\ \text{cyclo-}C_6H_{11}\ \text{(LVII)},\ C_6H_5CH_2\ \text{(LVIII)}\ .$$

It has been suggested[56-60] that the mechanism of this reaction involves the direct insertion of phosphorus in the S–O bond analogous to the reaction with dialkyl peroxides[55,61] with a certain degree of donation of the free electron pair of sulphur to the phosphorus orbitals in the transition state and the formation of alkoxyarylthiophosphorane (LXII) as an intermediate. Such mixed alkoxyarylthiophosphoranes have been isolated in the reactions of alkyl benzenesulphenates with cyclic phosphites[56,62] and in other cases in reactions with acyclic tris(2,2,2-trifluoroethyl)[16] and tris(1-trifluoromethyl-2,2,2-trifluoroethyl) phosphites.[63] The alkoxyarylthiophosphorane (LXII) then reacts with another molecule of benzenesulphenate to form a dialkoxyphosphorane and diphenyl disulphide (pathway *a*):



(LXII)

The other pathway in the reactions of tervalent phosphorus compounds with alkyl benzenesulphenates involves the formation of a phosphoryl compound and an alkyl aryl sulphide, apparently as a result of the dissociation of the mixed alkoxyarylthiophosphorane (LXII) into an ion pair and its subsequent reactions (pathway *b*). For example, diethoxyphenylphosphine reacts with ethyl benzenesulphenate to form 65% of tetraethoxyphenylphosphorane (LXII) and 35% of diethyl phenylphosphonate.[59] On the other hand, the reactions of mixed alkylarylphosphines[55] and tributylphosphine[60] with alkyl benzenesulphenates proceed only via pathway *b*. Apparently, the presence of electron-donating alkyl groups promotes the stabilisation of the phosphonium cation.[54] If, on the other hand, the rate of the reaction of the mixed alkoxyarylthiophosphorane with another molecule of alkyl benzenesulphenate is higher than the rate of its dissociation, pathway *a* operates.

Apart from the two general methods of synthesis of acyclic alkoxyphosphoranes from tricoordinate phosphorus compounds described above, several individual instances of the synthesis of phosphoranes of this type are also known.

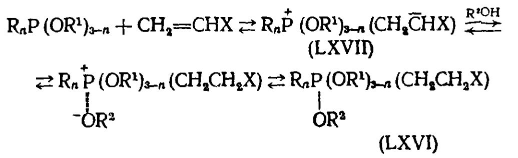
Pentakis(2,2,2-trifluoroethoxy-1-trifluoromethyl)phosphorane (XIV) has been obtained by the reaction of the phosphite (LXIII) with the bis(1,1,1,3,3,3-hexafluoroisopropyl) ester of sulphoxylic acid (LXIV):[64]

$$\underset{\text{(LXIII)}}{4\,[(CF_3)_2CHO]_3P} + \underset{\text{(LXIV)}}{S[OCH(CF_3)_2]_2} \rightarrow \underset{\text{(XIV)}}{[(CF_3)_2CHO]_5P} +$$
$$+ 2\,[(CF_3)_2CHO]_3P{=}S + [(CF_3)_2CHO]_3P{=}O + (CF_3)_2CHOCH(CF_3)_2 \ .$$

The reaction of chloroform with sodium methoxide and trimethyl phosphite leads to the formation of tetramethoxydimethoxymethylphosphorane (LXV):[65]

$$(CH_3O)_3P + CHCl_3 + 3CH_3ONa \rightarrow \underset{\text{(LXV)}}{(CH_3O)_4PCH(OCH_3)_2} + 3NaCl \ .$$

Aryl phosphonites and aryl phosphinates react with derivatives of acrylic acid in the presence of alcohols to form alkoxyphosphoranes (LXVI):[66]



$$R_nP(OR^1)_{3-n} + CH_2{=}CHX \rightleftarrows \underset{\text{(LXVII)}}{R_n\overset{+}{P}(OR^1)_{3-n}(CH_2\overset{-}{C}HX)} \xrightleftharpoons{R^2OH}$$
$$\rightleftarrows R_n\underset{\underset{-OR^2}{\vdots}}{\overset{+}{P}}(OR^1)_{3-n}(CH_2CH_2X) \rightleftarrows R_n\underset{\underset{OR^2}{|}}{P}(OR^1)_{3-n}(CH_2CH_2X)$$

(LXVI)

$n = 1, 2$; $R{=}C_6H_5$; $R^1 = CH_3$, C_2H_5;
$R^2 = CH_3$, C_2H_5, $(CH_3)_3C$;
$X{=}COOC_2H_5$, CN
$n = 2$; $R{=}n\text{-}(CH_3)_3COC_6H_4$; $R^1{=}R^2{=}(CH_3)_3C$; $X{=}COOC_2H_5$.

It has been suggested[66] that the betaine (LXVII) formed as an intermediate is protonated by alcohol and the alkoxide anion then carries out a nucleophilic attack on the positively charged phosphorus atom with formation of the phosphoranes (LXVI).

III. NMR SPECTRA AND STRUCTURE

The signals of the phosphorus nuclei in the ^{31}P NMR spectra of acyclic alkoxy- and aryloxy-phosphoranes are in the range δ_P = −20.3−−92.0 p.p.m. (relative to 85% H_3PO_4). The chemical shifts at the highest fields are characteristic of penta-alkoxy- and penta-aryloxy-phosphoranes. When one, two, or three alkoxy-groups are replaced by an aryl group and especially by the methyl group, the chemical shift undergoes an appreciable downfield displacement (Table 2). It may be that such displacement is caused by the distortion of the symmetry of the electron distribution around the pentacoordinate phosphorus induced by the difference between the electronegativities of the alkyl(aryl) and alkoxy-substituents. With a decrease in the difference between the electronegativities of the substituents—in the case of the phosphoranes (VII), (IX), and (XXXVIII) containing CF_3 groups at the phosphorus atom—there is almost no downfield displacement of the signal. A similar hypothesis has been used to account for the downfield displacement of the signals in the ^{31}P NMR spectra of tetracoordinate phosphorus compounds.[67] An exception in the series considered is that of alkoxytetramethylphosphoranes (XXX) and (XXXI), whose chemical shifts occur at the lowest fields (Table 2).

---

[a] In the solid state.

It has been suggested that penta-alkoxyphosphoranes have the structure of a trigonal bipyramid (TBP). However, ^{1}H, ^{13}C, and ^{19}F NMR studies of a series of these compounds [compounds (IV)–(VII), (XV), and (XVIII)] [26,57,68,69] demonstrated the equivalence of the alkoxy-groups even at low temperatures. This has been explained[57] by the very low barrier to permutational isomerisation of the phosphoranes investigated.

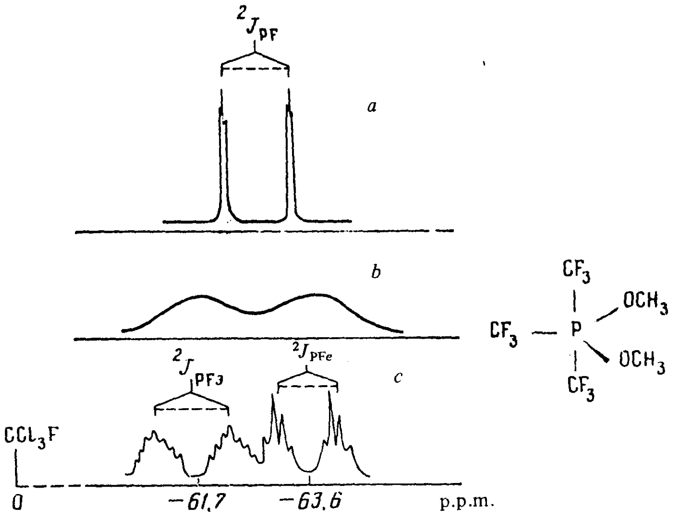
It has been established by X-ray diffraction [71] that pentaphenoxyphosphorane in the crystalline state has the structure of a TBP with the phosphorus atom at the centre. The two axial P–O bonds (1.602, 1.596, and 1.600 Å). It has been suggested that the electrons of the apical oxygen atoms are less involved in the p, d_π conjugation with the phosphorus atom than the electrons of the equatorial oxygen atoms and are mainly delocalised over the benzene rings. The five benzene rings are distributed in the TBP in such a way that the intramolecular repulsion is a minimum.

In the case of tetrakix(2,6-dimethylphenoxy)methylphosphorane (XXI) [38] and tetrakis(1,1,1,3,3,3-hexafluoroisopropoxy)methylphosphorane (XII), [30] the rate of pseudorotation is reduced to such an extent that, in the ^{1}H NMR spectra of the phosphorane (XXI) at −65 °C and in the ^{1}H and ^{19}F NMR spectra of the phosphorane (XII) even at 25 °C, the alkoxy-substituents are found to be non-equivalent owing to their location in the axial or equatorial positions.

The study of the ^{1}H and ^{19}F NMR spectra of a series of alkyl- and aryl-phosphoranes (XLV), (XLVI), and (L) at different temperatures showed that the rate of the pseudotransformation is a function of the number of alkyl or aryl groups linked directly to the phosphorus. The pseudotransformation is retarded when the number of these groups increases. [55]

The trigonal-bipyramidal structure of trialkoxy- and triaryloxy-phosphoranes, in which two alkoxy- or aryloxy-groups occupy axial positions and one occupies an equatorial position, has been established spectroscopically for triethoxydiphenylphosphorane (L) at −60 °C, [56] dimethyltri(2-methylphenoxy)phosphorane (XXIV) at −95 °C, [38] diphenyltris(2,2,2-trifluoro-1-trifluoromethylethoxy)phosphorane (VIII) at 25 °C. [30]

The activation energies for the intramolecular pseudorotation of the ligands are 5.8, 12.0, and 14.0 kcal mol^{-1} respectively for the phosphoranes (XXIV), (L), and (LXI).



^{19}F NMR spectra of dimethoxytris(trifluoromethyl)phosphorane (VII) in CCl$_3$F: [35] *a*) $t = 33°$, $^2J_{PF} = 96$ Hz; *b*) $t = -60$ °C; *c*) $t = -80$ °C, $^2J_{PF_e} = 108$ Hz and $^2J_{PF_a} = 88$ Hz.

Dimethyltris(2,2,2-trifluoro-1-trifluoromethylethoxy)phosphorane (VIII) has apparently an even higher isomerisation barrier, because the coalescence temperature for this compound is 60 °C. [30] The ^{1}H NMR spectra of the phosphoranes (XLV) and (LI) (Table 2) do not change in the temperature range from −60° to 120 °C or to 60° respectively. It has been suggested [54] that in these compounds and also in the phosphorane $(C_6H_5)_3(OCH_2CF_3)_2$ (V) [34] the alkoxy-groups occupy axial positions and the phenyl and alkyl groups occupy equatorial positions. The invariance of the NMR spectra over a wide temperature range can apparently be explained by the high energy barrier to pseudorotation.

In contrast to the phosphoranes (IV), (XLV), and (LI), the alkoxy-groups in dimethoxytris(trifluoromethyl)phosphorane (VII) are in the equatorial positions, which follows from the analysis of the ^{19}F NMR spectra (see Figure). At room temperature, the CF$_3$ groups are equivalent and appear in the ^{19}F NMR spectrum as a doublet of heptets. When the temperature is reduced to −80 °C, two signals with an intensity ratio of 2 : 1 are observed in the ^{19}F NMR spectrum—a doublet of quartets with $\delta_F = -63.6$ p.p.m. and relatively small spin–spin coupling constants ($^2J_{PF} = 88$ Hz), which are characteristic of axial CF$_3$ groups, and a doublet of heptets with $\delta_F = -61.7$ p.p.m. and relatively higher values of the spin–spin coupling constants ($^2J_{PF} = 108$ Hz) characteristic of equatorial CF$_3$ groups. [35]

An analogous trigonal bipyramidal structure with two axial CF$_3$ groups has been determined by ^{19}F NMR also for tris(trifluoromethyl)bis(trimethylsiloxy)phosphorane (XXXVIII) [49,50] and also for methoxymethyltris(trifluoromethyl)phosphorane (III). [36]

Analysis of the ^{13}C and ^{1}H NMR spectra of methoxytetramethylphosphorane (XXX) [41,72] at different temperatures enabled the authors to demonstrate that this compound has a trigonal bipyramidal structure in which the methoxy-group and one of the methyl groups occupy axial positions and the remaining three methyl groups occupy equatorial positions.

IV. CHEMICAL PROPERTIES

1. Thermal Stability

The majority of acyclic penta-alkoxyphosphoranes containing alkyl substituents with the normal structure are liquids which have not been isolated in a pure state. Heating or an attempt to distil them *in vacuo* lead to decomposition. [51,52,54,57] Penta-alkoxyphosphoranes decompose slowly also at room temperature. Thus pentaethoxyphosphorane (XLIII) does not change during storage in a refrigerator for 7 days [57] but decomposes at 20 °C with formation of triethyl phosphate, ethanol, diethyl ether and probably ethylene: [51]

$$\underset{\text{(XLIII)}}{(C_2H_5O)_5P} \xrightarrow{20^\circ C} (C_2H_5O)_3P{=}O + C_2H_5OH + C_2H_5OC_2H_5 + CH_2{=}CH_2\ .$$

Among the penta-alkoxyphosphoranes investigated, pentabenzyloxyphosphorane (LVIII) shows the lowest stability, decomposing fully in the course of two days at room temperature. [57]

The stability of acyclic penta-alkoxyphosphoranes increases somewhat for compounds with branched alkyl substituents. Crystalline pentaneopentyloxyphosphorane (LV), pentacyclopentyloxyphosphorane (LVI), and pentacyclohexyloxyphosphorane (LVII), which are stable for several months at temperatures in the range 0–10 °C, have been isolated in a pure state. [57]

The thermal stability of penta-alkoxyphosphoranes increases to a much greater extent following the enhancement of the electron-accepting properties of the alkyl substituents. Thus pentakis(2,2,2-trifluoro-1-trifluoromethylethoxy)phosphorane (XIV), [29] pentakis(2,2,2-trifluoroethoxy)phosphorane (XV), [27] and pentakis(ααω-trihydropolyfluoroalkoxy)phosphoranes (XVI) and (XVII) [32] distil *in vacuo* without decomposition, while pentakis(2,2,2-trichloroethoxy)phosphorane (XVIII) is a crystalline substance stable on heating to 130 °C in the course of 1 h.[31] All the known penta-aryloxyphosphoranes as well as the alkyl- and aryl-aryloxyphosphoranes (XX), (XXIII)–(XXVI), and (XXIX) are thermally stable, which is apparently also caused by the electron-accepting properties of the aryloxy substituents. In solutions, these phosphoranes are weakly dissociated (the equilibrium constant is less than 10^{-7}):[40,73]

$$(ArO)_5P \rightleftarrows (ArO)_4\overset{+}{P} + ArO^- \ .$$

The replacement of one, two, or three alkoxy-groups by alkyl or aryl-groups as a rule diminishes the thermal stability of the alkoxy-phosphoranes. Thus tributylbis(2,2,2-trifluoroethoxy)phosphoranes (VI) decomposes even at room temperature in 24 h with formation of 20% of bis(2,2,2-trifluoroethyl) ether.[34]

It has been shown by ^1H and ^{31}P NMR [54] that the phosphoranes (XLVI), (XLVII), and (LIII) exist in solutions even at 20 °C in equilibrium with the phosphonium form. The equilibrium has been explained[54] by the fact that the alkyl and aryl substituents at the phosphorus atom stabilise the phosphonium cation:

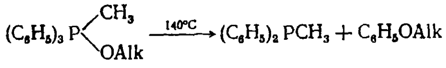
$$R_nP(CH_3)_{3-n}(OC_2H_5)_2 \rightleftarrows R_n\overset{+}{P}(CH_3)_{3-n}(OC_2H_5) + C_2H_5O^-$$
$$R = n\text{-}C_4H_9,\ n = 3\ (XLVI);$$
$$R{=}C_6H_5,\ n = 1\ (LIII),\ n = 0\ (XLVII) \ .$$

The high thermal stability of dimethoxymethyltetramethoxyphosphorane (LV), which does not decompose until 125 °C via a mechanism unusual for acyclic alkoxyphosphoranes (involving the formation of a tervalent phosphorus compound), is noteworthy:[65]

$$(CH_3O)_4PCH(OCH_3)_2 \xrightarrow{\Delta} (CH_3O)_3P + HC(OCH_3)_3 \ .$$
$$(LXV)$$

The thermal stability increases most significantly on passing to phosphoranes containing only one alkoxy-group. The alkoxytetramethylphosphoranes (XXX) and (XXXI) [41] and the alkoxymethyltriphenylphosphoranes (XXXII)–(XXXIV) have been isolated pure by vacuum distillation or crystallisation. They do not decompose until 130–140 °C:[74]

$$(CH_3)_4P(OAlk) \xrightarrow{130°C} (CH_3)_3P{=}O + AlkCH_3$$
$$(XXX),\ (XXXI)$$



$$(C_6H_5)_3P\begin{matrix}\diagup CH_3\\ \diagdown OAlk\end{matrix} \xrightarrow{140°C} (C_6H_5)_2PCH_3 + C_6H_5OAlk$$

(XXXII) — (XXXIV) .

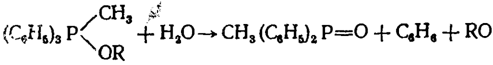
2. Hydrolysis

All the acyclic penta-alkoxy- and penta-aryloxy-phosphoranes as well as alkoxy- or aryloxy-organylphosphoranes, with the exception of $(C_6H_5)_3P[OC(CF_3)_2C_6H_5]_2$ (V),[33] are extremely readily hydrolysed by atmospheric moisture with dissociation of the P–O bond. The hydrolysis of penta-alkoxy- and penta-aryloxy-phosphoranes leads to the formation of alcohols and phenols and phosphates:[9,25,29,32,37,75,76]

$$(RO)_5P + H_2O \rightarrow (RO)_3P{=}O + 2ROH$$
$$R{=}(CF_3)_3CH\ (XIV);\ H(CF_2)_nCH_2,\ n = 2\ (XVI),$$
$$4\ (XVII);\ C_6H_5\ (II);\ CH_3\ (XLIV);\ C_2H_5\ (XLIII) \ .$$

The products of the hydrolysis of the alkoxy- or aryloxyalkyl(aryl)phosphoranes (IV), (XXI), (XLV), (L), and (LII), containing four, three, or two alkoxy-groups, are phosphonates, phosphinates, or tertiary phosphine oxides respectively.[34,38,54,56] The hydrolysis of methoxytetramethylphosphorane (XXX) and the alkoxymethyltriphenylphosphoranes (XXXII)–(XXXIV), containing only one alkoxy-group, proceeds with the dissociation of both P–O and P–C bonds:[41]

$$(CH_3)_4POCH_3 + H_2O \rightarrow (CH_3)_3P{=}O + CH_4 + CH_3OH$$
$$(XXX)$$



$$(C_6H_5)_3P\begin{matrix}\diagup CH_3\\ \diagdown OR\end{matrix} + H_2O \rightarrow CH_3(C_6H_5)_2P{=}O + C_6H_6 + ROH$$

(XXXII)—(XXXIV) .

The P–C bond is ruptured also on hydrolysis of the phosphoranes (VII) (XXXVIII) containing trifluoromethyl groups at the phosphorus atom:[35,50]

$$(CF_3)_3P(OCH_3)_2 + 2H_2O \rightarrow (CF_3)_2PO_2H + CF_3H + 2CH_3OH$$
$$(VII)$$
$$(CF_3)_3P[OSi(CH_3)_3]_2 + H_2O \rightarrow (CF_3)_2PO_2H + CF_3H + [(CH_3)_3Si]_2O \ .$$
$$(XXXVIII)$$

The kinetics and mechanism of the hydrolysis of acyclic alkoxy- and aryloxy-phosphoranes have been investigated[25] in relation to pentaphenoxyphorane (III) and certain substituted penta-aryloxyphosphoranes. The rate of reaction in neutral and alkaline media depends greatly on the electronic and steric properties of the substituents in the aromatic ring (Table 3).

Table 3. The influence of substituents on the rate of hydrolysis of penta-aryloxyphosphoranes at 25 °C in 75% aqueous dimethoxyethane.[25]

Rate constant, s^{-1}	$P(OC_6H_5)_5$	$P(OC_4H_4CH_3\text{-}o)_5$	$P(OC_6H_4CH_3\text{-}n)_5$	$P(OC_6H_4Cl\text{-}o)_5$	$P(OC_6H_4Cl\text{-}n)_5$
k_{H_2O}	0.202	$1.1 \cdot 10^{-5}$	0.0197	0.106	390
k_{H^+}	16.4	1.3	79	—	—
k_{OH^-}	11.4	$7.5 \cdot 10^{-4}$	3.4	—	—

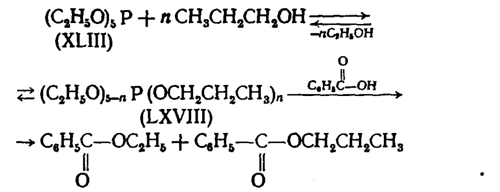
These effects are less pronounced in an acid medium. Kinetic data and especially the appreciable steric effects enabled the authors to suggest that the hydrolysis of pentaphenoxyphosphoranes in neutral and alkaline media also takes place via an intermediate in which the coordination number of phosphorus rises to six:[25]

$$(C_6H_5O)_5P + H_2O \xrightarrow{k_1} (C_6H_5O)_5\overline{P}OH + H^+$$
$$(II)$$
$$(C_6H_5O)_5\overline{P}OH \xrightarrow{k_2} (C_6H_5O)_3P{=}O + C_6H_5OH + C_6H_5O^- \ .$$

The entropies (–188 J mol^{-1} K^{-1}) and enthalpies (22.5 kJ mol^{-1} of activation obtained for the hydrolysis of pentaphenoxyphosphorane (II) in 25% aqueous dioxan also led the authors[75] to the conclusion that this is a multistage process involving the formation of a hexacoordinate intermediate.

3. Reactions with Alcohols

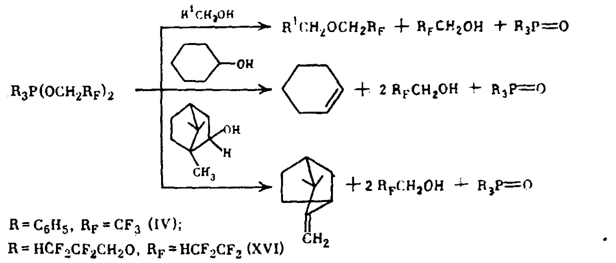
The mode of reaction of alkoxyphosphoranes with alcohols is determined by the nature of the substituents both in the phosphorane and alcohol molecules. In the reaction of pentaethoxy phosphorane (XLIII) with five moles of propyl alcohol, the exchange of ethoxy-groups for propoxy-groups is observed. This apparently results in the formation of the mixed phosphoranes (LXVIII), since treatment of the reaction mixture with benzoic acid entails the formation of ethyl benzoate and propyl benzoate in equal amounts:[76]



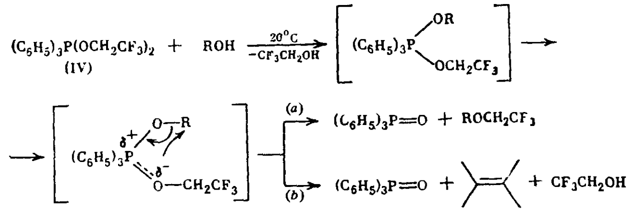
$$(C_2H_5O)_5P + n\,CH_3CH_2CH_2OH \underset{-nC_2H_5OH}{\rightleftarrows} (C_2H_5O)_{5-n}P(OCH_2CH_2CH_3)_n \xrightarrow{C_6H_5\overset{O}{\overset{\|}{C}}-OH} C_6H_5\underset{\overset{\|}{O}}{C}-OC_2H_5 + C_6H_5-\underset{\overset{\|}{O}}{C}-OCH_2CH_2CH_3 .$$

(XLIII) (LXVIII)

With enhancement of the electron-accepting properties of the substituents in ethoxyphosphoranes, their tendency to alkylate alcohols also increases. The ethers $ROCH_2P_F$ ($R = C_4H_9$, C_5H_{11}, C_8H_{17}, $C_6H_5CH_2$, or $C_6H_5CH_2CH_2$) are formed when bis(2,2,2-trifluoroethoxy)triphenylphosphorane (IV) [33,34] and pentakis(2,2,3,3-tetrafluoropropoxy)phosphorane (XVI) [69] react with the corresponding primary alcohols. In their reactions with cyclic secondary alcohols (cyclohexanol or borneol), the phosphoranes (IV) and (XVI) exhibit dehydrating properties, as a result of which one observes the preferential formation of olefins:[33,34,69]



2-Phenylethanol interacts with the phosphorane (IV) to form 70% of the ether $C_6H_5CH_2CH_2OCH_2CF_3$ and 11% of styrene:[33,34]



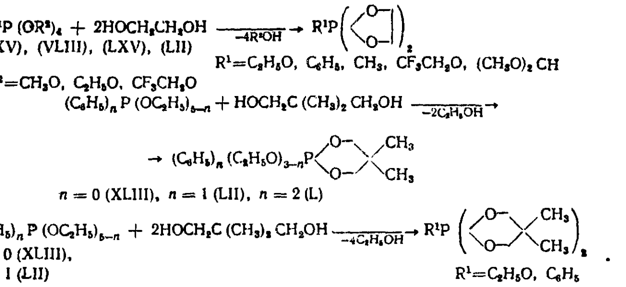
It has been suggested[33,34] that, as a result of attack on the phosphorus atom, one of the trifluoroethoxy-groups is exchanged in the first stage for an alkoxy-group. Then, as a result of nucleophilic attack by the trifluoroethoxide anion on the α-carbon atom of the alkyl group (pathway *a*), ethers are produced. In the cyclic secondary alcohols, the trifluoroethoxide anion apparently attacks the β-carbon atom (pathway *b*), which leads to the formation of olefins.

The possibility of the initial attack by the alkoxide anion on the alkoxyphosphorane molecule precisely at the phosphorus atom has been demonstrated by the formation of compounds of hexacoordinate phosphorus in the reactions of phosphoranes (II), (XI), (XV), (XLIII), (XLIV), and (LXX) with alkoxides or phenoxides:[16,39,69,77]

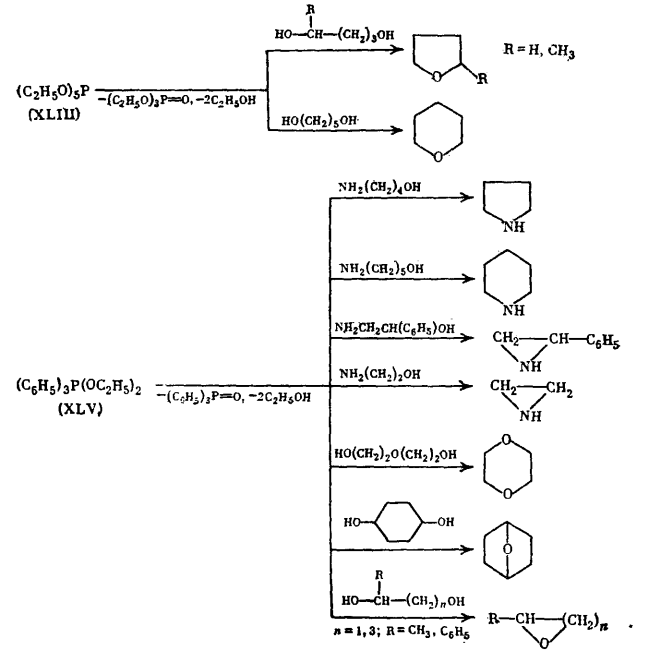
$$(C_6H_5)_nP(OR)_{5-n} + ROM \rightarrow (C_6H_5)_n\bar{P}(OR)_{6-n}\,M^-$$

$n = 0$, $R{=}CH_3$ (XLIV), C_2H_5 (XLIII), C_6H_5 (II), CF_3CH_2 (XV);
$n = 1$, $R{=}CF_3CH_2$ (XI);
$n = 2$, $R{=}CF_3CH_2$ (LXI);
$M^+ = K^+$, Na^+, $(C_2H_5)_3\overset{+}{N}H$.

Acyclic phosphoranes containing at least two alkoxy-groups react with 1,2-glycols to form phosphoranes containing one or two five-membered or six-membered rings.[16,65,69,78] This mode of reaction is apparently associated with the stabilising influence of these rings on the phosphorane structure:[79,80]



The reactions of the alkoxyphosphoranes (XLIII) and (XLV) with diols containing more than three methylene groups and also with aminoalcohols entail the dehydration of the latter and the formation of heterocycles, probably as a result of the decomposition of the intermediate unstable phosphoranes:[78,81-83]



Reactions are rapid at room temperature and can serve as a convenient preparative method for the synthesis of simple heterocycles.

4. Reactions with Phenols

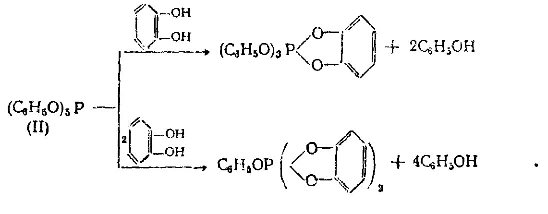
Pentamethoxy- and pentaethoxy-phosphoranes (XLIV) and (XLLIII) react with various phenols at room temperature, as a result of which phenol ethers are formed in high yields:[76,84]

$$(RO)_5P + ArOH \rightarrow (RO)_3P{=}O + ArOR + ROH$$

$R{=}CH_3$ (XLIV), C_2H_5 (XLIII)

Pentakis(polyfluoroalkoxy)phosphoranes (XVI) and (XVII) interact with phenols only at 150–160 °C, but phenol alkylation products are not then formed. According to ^{31}P NMR data, when equimolar amounts of the phosphorane (XVII) and phenol are heated, nucleophilic substitution of the polyfluoroalkoxy-group by the phenoxy-group takes place and an equilibrium mixture of the initial phosphorane (XVII) and a mixed phenoxytetrakis(polyfluoroalkoxy)phosphorane is formed.[59]

In the reaction of pentaphenoxyphosphorane (II) with catechol, the phenoxy-groups are substituted and cyclic phosphoranes are formed:[85]

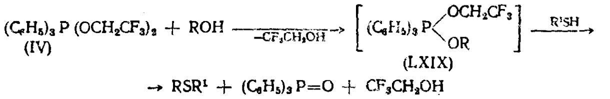


5. Reactions with Thiophenols and Mercaptans

Acyclic alkoxyphosphoranes alkylate thiophenols and mercaptans at room temperature. The product of the alkylation of thiophenol by pentamethoxyphosphorane (XLIV), namely methyl phenyl sulphide, is formed in 90% yield:[84]

$$\underset{\text{(XLIV)}}{(CH_3O)_5P} + C_6H_5SH \rightarrow C_6H_5SCH_3 + (CH_3O)_3P{=}O + CH_3OH$$

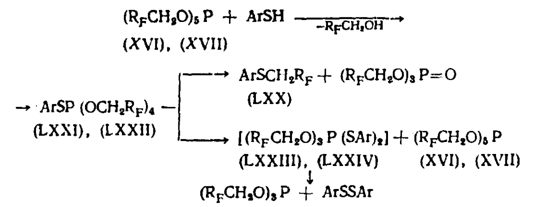
The alkoxy(2,2,2-trifluoroethoxy)triphenylphosphoranes (LXIX), formed as intermediates in the reactions of the phosphorane (IV) with alcohols, are also convenient alkylating agents for thiophenols and mercaptans:[34,86]



$$\underset{\text{(IV)}}{(C_6H_5)_3P(OCH_2CF_3)_2} + ROH \xrightarrow[-CF_3CH_2OH]{} \underset{\text{(LXIX)}}{\left[(C_6H_5)_3P\begin{smallmatrix}OCH_2CF_3\\ OR\end{smallmatrix}\right]} \xrightarrow{R^1SH} RSR^1 + (C_6H_5)_3P{=}O + CF_3CH_2OH$$

$R{=}C_2H_5$, $CH_3CH_2CH_2$, $C_6H_5CH_2$,
$C_6H_5CH_2CH_2$, *cis*-$CH_3CH{=}CH{-}CH_2$,
trans-$CH_3CH{=}CHCH_2$ $CH_2{=}CHCH(CH_3)$,
trans-$C_6H_5CH{=}CHCH_2$;
$R^1{=}C_6H_5$, $C_6H_5CH_2$, $CH_3(CH_2)_3$, C_2H_5 .

In contrast to compound (IV), pentakis(polyfluoroalkoxy)phosphoranes (XVI) and (XVII) react with thiophenols only on heating. The yields of the alkylation products, i.e. aryl polyfluoroalkyl sulphides (LXX), then diminish with increase of the length of the polyfluoroalkyl chain.[17] The reactions of the phosphoranes (XVI) and (XVII) with thiophenols take place as a result of the initial attack by the thiophenol on the phosphorus atom with formation of arylthiotetrakis(polyfluoroalkoxy)phosphoranes (LXXI) and (LXXII).[17] The way subsequent reactions take place depends on the length of the polyfluoroalkyl chain of the substituent.

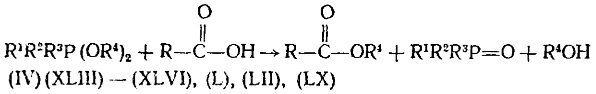


$R_F{=}HCF_2CF_2$ (XVI), (LXXI), (LXXIII)
$R_F{=}H(CF_2CF_2)_2$ (XVII), (LXXII), (LXXIV) .

The arylthiophosphorane (LXXI) is largely converted into the sulphide (LXX) and phosphate via the mechanism of the second stage of the Arbuzov reaction and disproportionates to the phosphoranes (XVI) and (LXXIII) only to a slight extent. However, the arylthiophosphorane (LXXII) is to a considerable extent converted into the di(arylthio)phosphorane (LXXIV) together with decomposition via the mechanism of the Arbuzov rearrangement. Compound (LXXIV) is unstable and decomposes under the reaction conditions to a phosphite and a disulphide, which has been confirmed by a special experiment.[17,69]

Reactions with Acids

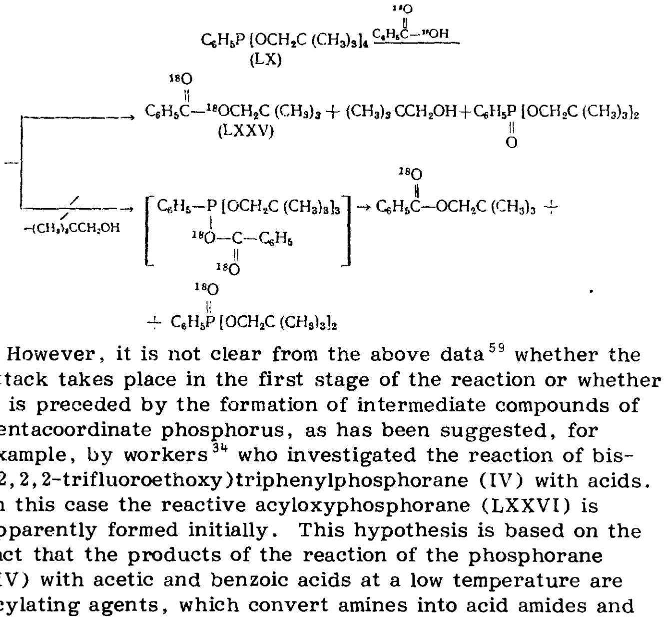
Acyclic alkoxyphosphoranes react vigorously with carboxylic acids at room temperature to form products of the alkylation of the latter—esters:[33,34,53,54,59,76,84]



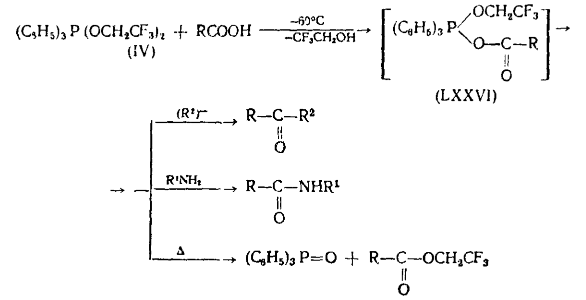
$$R^1R^2R^3P(OR^4)_2 + R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}OH \rightarrow R{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}OR^4 + R^1R^2R^3P{=}O + R^4OH$$

(IV)(XLIII) – (XLVI), (L), (LII), (LX)

It has been shown[59] that in the reaction of tetraneopentylphenylphosphorane (LX) with [^{18}O]-labelled benzoic acid, both isotopic ^{18}O atoms are located in the molecule of the ester (LXXV), i.e. the acid attackes the α-carbon atom of the alkoxy-substituent:



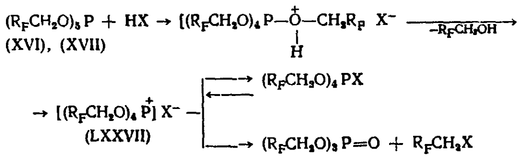
However, it is not clear from the above data[59] whether the attack takes place in the first stage of the reaction or whether it is preceded by the formation of intermediate compounds of pentacoordinate phosphorus, as has been suggested, for example, by workers[34] who investigated the reaction of bis(2,2,2-trifluoroethoxy)triphenylphosphorane (IV) with acids. In this case the reactive acyloxyphosphorane (LXXVI) is apparently formed initially. This hypothesis is based on the fact that the products of the reaction of the phosphorane (IV) with acetic and benzoic acids at a low temperature are acylating agents, which convert amines into acid amides and alkyl or aryl anions into ketones:[34]



$R{=}CH_3$, C_6H_5
R^1, $R^2{=}$Alk, C_6H_5 .

On the other hand pentakis(polyfluoroalkoxy)phosphoranes (XVI) and (XVII) do not react with acetic and benzoic acids on heating to 100 °C in the course of 4 h. 2,2,3,3-Tetrafluoropropyl benzoate is formed only after prolonged heating of the reactants at 170 °C.[69]

Bearing in mind the ability of the oxygen atom in alkoxyphosphoranes to be protonated by acids,[87,88] one may put forward a general mechanism of the reactions of acyclic alkoxyphosphoranes with acids, consisting in the protonation of oxygen and subsequent splitting off of the alcohol and the formation of the phosphonium salt (LXXVII), which may exist in equilibrium with the acyloxyphosphorane. The decomposition of the salt (LXXVII) actually leads to the final reaction products:

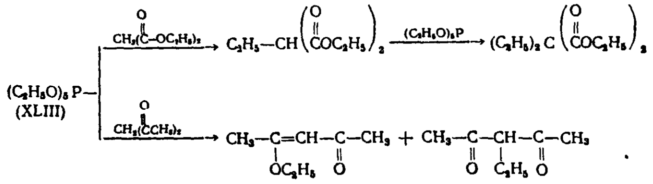


$R_F=H(CF_2)_n$, $n=2$ (XVI), 4 (XVII);
$X^-=C_6H_5COO^-$, Cl^- .

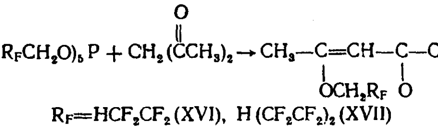
Evidently the difference between the reactivities of the alkoxyphosphoranes (IV), (XLIII), (XLVII), (L), (LII), and (LX) and of the polyfluoroalkoxyphosphoranes (XVI) and (XVII) in relation to acids is associated with the influence of the polyfluoroalkyl substituents, which weakens the nucleophilic properties of the oxygen, hindering its protonation.

7. Reactions with CH Acids

Pentaethoxyphosphorane (XLII) ethylates diethylmalonic ester at the carbon atom and acetylacetone at the oxygen atom. An insignificant amount of the *C*-alkylation product is also formed in the latter case:[76]



Pentakis(polyfluoroalkoxy)phosphoranes (XVI) and (XVII) react with acetylacetone to form vinyl ethers only:[89]

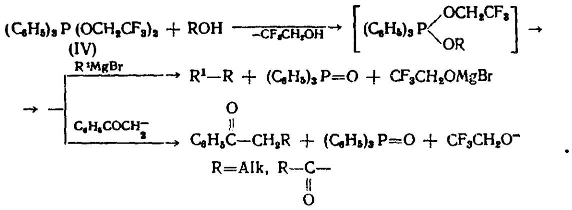


$$(R_FCH_2O)_5P + CH_2(\overset{O}{\overset{\|}{C}}CH_3)_2 \rightarrow CH_3-\underset{OCH_2R_F}{\underset{|}{C}}=CH-\underset{O}{\underset{\|}{C}}-CH_3$$

$R_F=HCF_2CF_2$ (XVI), $H(CF_2CF_2)_2$ (XVII) .

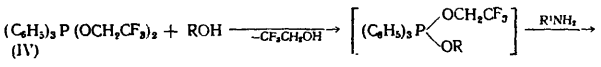
8. Reactions with Carbanions

Succesive treatment of bis(2,2,2-trifluoroethoxy)triphenylphosphorane (IV) with an alcohol or acid and then with a Grignard reagent or the enolate anion results in the formation of compounds with a C–C bond—alkanes or ketones. It is believed[34] that the carbanion executes a nucleophilic attack on the intermediate highly reactive alkoxy- or acyloxy-phosphorane:



9. Reactions with Amines and Carboxylic Acid Amides

The structure of the products of the reactions of alkoxyphosphoranes with primary amines is determined by the nature of the substituents at the phosphorus atom. When bis(2,2,2-trifluoroethoxy)triphenylphosphorane (IV) is treated with an alcohol and then a primary amine, the latter is alkylated and a secondary amine is formed:[34]

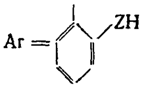


$\rightarrow RR^1NH + CF_3CH_2OH + (C_6H_5)_3P{=}O$

$R = n\text{-}C_8H_{17}$, $C_6H_5CH(CH_3)$, $C_6H_5CH_2$,
trans-$CH_3CH{=}CHCH_2$, $CH_2{=}CHCH(CH_3)$;
$R^1{=}CH_3(CH_2)_3$, $CH_3(CH_2)_2$, C_6H_5 .

Primary arylamines are alkylated also in the reaction with bis(2,2,2-trifluoro-1-trifluoromethylethoxy)triphenylphosphorane (LXXVIII):[90]

$$\underset{\text{(LXXVIII)}}{(C_6H_5)_3P[OCH(CF_3)_2]_2} + ArNH_2 \rightarrow \underset{\text{(LXXIX)}}{ArNH-CH(CF_3)_2} + HOCH(CF_3)_2 + (C_6H_5)_3P{=}O$$



Ar = ; Z=O, S, NH .

The secondary amines (LXXIX) thus produced have been used successfully for the synthesis of heterocyclic systems.[90]

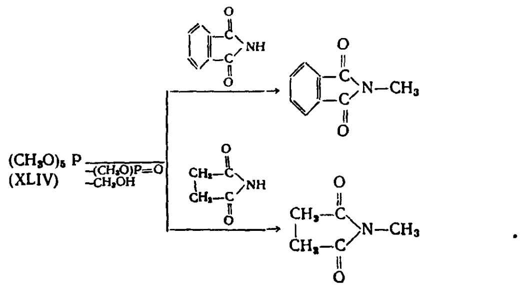
In contrast to the examples quoted above, the reactions of pentakis(polyfluoroalkoxy)phosphoranes (XVI) and (XVII) with primary arylamines lead to tris(polyfluoroalkoxy)phosphazobenzenes (LXXX):[69]

$$[H(CF_2)_nCH_2O]_5P + ArNH_2 \rightarrow \underset{\text{(LXXX)}}{[H(CF_2)_nCH_2O]_3P{=}NAr} + 2H(CF_2)_nCH_2OH$$

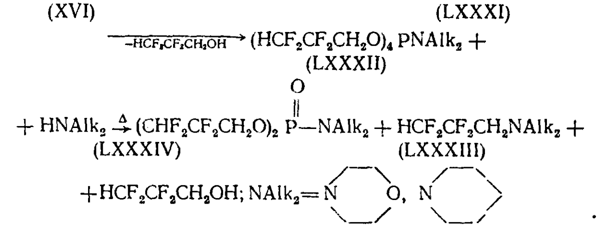
$n=2$ (XVI), 4 (XVII) .

There are very few data on the reactions of acyclic alkoxyphosphoranes with compounds containing a secondary aminogroup.

Pentamethoxyphosphorane (LXIV) reacts with phthalimide and succinimide to form *N*-methylated compounds:[84]



Detailed study of the reaction of pentakis(2,2,3,3-tetrafluoropropoxy)phosphorane (XVI) with secondary amines[91] showed that a compound of hexacoordinate phosphorus with an acyclic structure, namely dialkylammonium pentakis(2,2,3,3-tetrafluoropropoxy)piperidino(morpholino)phosphorate (LXXXI), is formed initially even at 20 °C as a result of the attack by the amine on the phosphorus atom. The phosphorates (LXXXI) are crystalline compounds stable at 20 °C. When they are heated to 150 °C, the nucleophilic substitution of the 2,2,3,3-tetrafluoropropoxy-group takes place and the mixed piperidino(morpholino)tetrakis(2,2,3,3-tetrafluoropropoxy)phosphorane (LXXXII) is produced. The latter alkylates a second amine molecule and the final products of the reaction of the phosphorane (XVI) with piperidine or morpholine on heating are therefore the tertiary amine (LXXXIII), the phosphoramidate (LXXXIV), and tetrafluoropropanol:



$$\underset{\text{(XVI)}}{(HCF_2CF_2CH_2O)_5P} + 2Alk_2NH \xrightarrow{20^\circ C} \underset{\text{(LXXXI)}}{(HCF_2CF_3CH_2O)_5\,\bar{P}NAlk_2H_2\overset{+}{N}Alk_2} \xrightarrow{\Delta}$$

$$\xrightarrow[-HCF_2CF_2CH_2OH]{} \underset{\text{(LXXXII)}}{(HCF_2CF_2CH_2O)_4PNAlk_2} +$$

$$+ HNAlk_2 \xrightarrow{\Delta} \underset{\text{(LXXXIV)}}{(CHF_2CF_2CH_2O)_2\overset{O}{\overset{\|}{P}}{-}NAlk_2} + \underset{\text{(LXXXIII)}}{HCF_2CF_2CH_2NAlk_2} +$$

$$+ HCF_2CF_2CH_2OH;\ NAlk_2 =$$

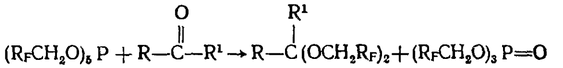
10. Reactions with Aldehydes and Ketones

Bis(2,2,2-trifluoroethoxy)triphenylphosphorane (IV) reacts with aliphatic aldehydes at room temperature to form bis(2,2,2-trifluoroethyl)acetals:[31]

$$\underset{\text{(IV)}}{(C_6H_5)_3P(OCH_2CF_3)_2} + RCHO \rightarrow (C_6H_5)_3P{=}O + RCH(OCH_2CF_3)_2$$

$$R{=}(CH_3)_2CH,\ n\text{-}C_5H_{11},\ n\text{-}C_6H_{13}.$$

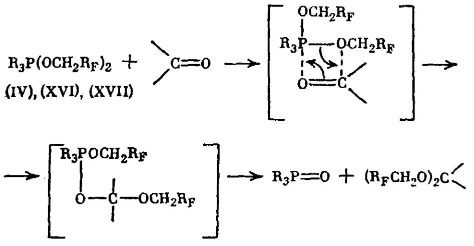
Pentakis(polyfluoroalkoxy)phosphoranes (XVI) and (XVII) alkylate on heating formaldehyde and also aldehydes and ketones with electron-accepting substituents but do not react with the usual aliphatic aldehydes and ketones even at 200 °C:[89]



$$(R_FCH_2O)_5P + R{-}\overset{O}{\overset{\|}{C}}{-}R^1 \rightarrow R{-}\overset{R^1}{\overset{|}{C}}(OCH_2R_F)_2 + (R_FCH_2O)_3P{=}O$$

$$R_F{=}HCF_2CF_2\ \text{(XVI)},$$
$$H(CF_2CF_2)_2\ \text{(XVII)}$$
$$R{=}R^1{=}H;\ R{=}Ar,\ R^1{=}H;\ R{=}C_6H_5CH{=}CH,\ R^1{=}H;$$
$$R{=}CH_3CH{=}CH,\ R^1{=}H;\ R{=}R^1{=}CF_3.$$

It has been suggested[34,89] that the alkylation proceeds via a four-membered cyclic transition state, which is produced as a result of the initial attack by the positively charged carbon atom of the carbonyl group on the oxygen atom of the polyfluoroalkoxyphosphorane:



$R = C_6H_5$, $R_F = CF_3$ (IV); $R = H(CF_2CF_2)_nCH_2O$, $R_F = H(CF_2CF_2)_n$, $n = 1$ (XVI), $n = 2$ (XVII)

The significant difference between the reactivities of the phosphorane (IV), on the one hand, and the phosphoranes (XVI) and (XVII), on the other, can apparently be explained by the weakening of the nucleophilic properties of the oxygen of the polyfluoroalkoxy-group in the molecules of compounds (XVI) and (XVII), as a result of which the attack on the carbon atom of the carbonyl group is possible only after an increase of the positive charge on the latter.

The literature data examined show that the methods of synthesis of derivatives of acyclic hydroxyphosphoranes known at present make it possible to obtain compounds containing substituents with different electronic and steric properties at the phosphorus atom; this alters in its turn their chemical properties within extremely wide limits.

Acyclic alkoxyphosphoranes are extremely reactive reagents, suitable for the synthesis of various classes of organic compounds. Special mention should be made of the advantages of alkoxyphosphoranes as alkylating agents: the alkylation takes place under mild conditions in the absence of basic or acid catalysts and does not require the use of protecting groups; the reaction does not result in the formation of acids or bases, which are in many instances undesirable.

Since vigorous investigation of the chemical properties of acyclic alkoxyphosphoranes began only recently, many reactions have been examined in relation to a limited number of examples. There is no doubt that further study of acyclic alkoxy- and aryloxy-phosphoranes will greatly expand the range of synthetic applications of these reactive compounds and will also lead to the discovery of new facts, which will extend our understanding of the nature of phosphorus compounds.

I. CHEMICAL PHYSICS IN MODERN CHEMISTRY

Modern chemistry has become a high risk science. Progress in engineering and technology requires from chemistry the creation of new substances and materials with extreme and frequently contradictory and at first sight incompatible properties, the development of economical efficient technologies based on new non-traditional principles, the creation of new means for the control and diagnostics of processes and materials, and the development of new principles of chemical energetics. Under these conditions, scientific research along traditional lines of trial and error has become very refined, laborious, and expensive and the risk of unsuccessful research, the risk of invalid trials, and the risk of errors have increased. The more complex the problem, the greater the risk of failure and of fruitless expenditure of labour, materials, and time.

The degree of risk can be reduced only on the basis of a profound knowledge of the physics of chemical processes, the theory of structure, molecular organisation, the functioning and transformation of chemical systems, and a profound analysis of the predictions following from such knowledge and understanding, i.e. on the basis of the principles constituting chemical physics. The level of this science and its state determine the horizons of chemical materials science, chemical synthesis, chemical technology and power generation, chemical diagnostics, and environmental chemistry. Naturally, each of these fields develops as a result of its intrinsic internal potential frequently entirely without being based (or not knowingly based) on chemical physics, but the increase of the complexity of chemical problems, which can be seen objectively to arise from scientific and technical progress, inevitably makes it necessary to resort to chemical physics, its corollaries and predictions, and its growing predictive power.

The aim of this article is to analyse the concerns of modern chemical physics, its present level, its aims, its ability to reduce the risks discussed above, and its growing points and prospects.

II. STRUCTURE OF MATTER

The atomic-molecular and electronic structures of chemical species and substances constitute the classical problem of chemical physics. Structure is the first, key element in the series structure–property–function. The determination of relations in this series is a problem of fundamental importance; its solution makes it possible to predict on the basis of the structure of the substance its function and purpose and its likely usefulness and applications.

Traditionally chemical physics has been concerned with the direct problem—the determination of structure and then the investigation of properties, which resulted in the determination of the field in which the given substance can be used and can function. However, the converse problem has become increasingly acute in modern chemistry—the creation of chemical structures with a specified atomic-molecular architecture in order to ensure specified properties and functions of these structures. This is important in the creation of purpose-designed drugs, semiconducting materials with specified conducting properties, alloys with specified corrosion resistance, ceramic materials with definite thermal and mechanical stabilities, optical glasses with specified electrochromism, etc.—the generality of this problem is universal.

This Section deals with the level and style in which modern chemical physics solves structural problems and the characteristics, trends, methods, and means used in such solutions. They are different for structures with different scales and levels of organisation and we shall therefore immediately introduce the following classification: isolated species (atom, molecule, ion, and radical), small assemblies (van der Waals molecule, complex, macromolecule, micelle, cluster), and large assemblies (crystal, liquid, amorphous body, membrane, etc.).

1. Isolated Species

The determination of the structural-chemical and structural-physical parameters of isolated species is the traditional task of chemical physics; these parameters characterise the electron shell and nuclear skeleton of the species (the angles and distances between atoms and bonds, the frequencies and amplitudes of vibrations, internal rotations, inversions, and conformational transitions, the energies and symmetries of the electronic, vibrational, and rotational states, ionisation potentials, electron affinities and bond energies, the polarisability tensor, the magnetic and electrical dipole moments, the charge and spin distributions, the dipole moments of electronic transitions, the oscillator strengths, the electron delocalisation frequencies, the energies of quadrupole and electron-nucleus magnetic interactions, etc.). They are required for calculations on the thermodynamics of gases and plasma, for the calculation of the composition of species and their state, for the prediction of properties, stability, and conditions governing the existence and the reactions of chemical systems (especially at high and ultrahigh temperatures). They are needed in chemical energetics (emissive power of high-temperature gases under non-equilibrium conditions, the functioning of gas lasers, etc.).

Three new features have imparted a modern "aspect" to this traditional task of chemical physics: intense efforts to attain highly excited states, the endeavour to characterise "exotic" species, and finally, the very high (sometimes close to the limit) metrological accuracy.

The very marked tendency to specify the structural and spectroscopic characteristics of excited states—just as complete as for the ground state—has arisen for a number of reasons. Firstly, this is associated with the search for new laser systems and the choice of species (emitters) suitable for generation. For this purpose, one needs knowledge of the spectroscopy of the species which is as complete as possible—the energy and symmetry of the excited levels, the radiative lifetimes, the probabilities of the radiative and non-radiative transitions, etc.

Secondly, it is needed as an analytical means for the identification and recognition of excited species in processes induced by electron impact, photo-excitation, and powerful collisions (the chemistry and optics of the atmosphere, space chemistry and plasma, high-temperature chemistry, combustion and explosion, shock waves, etc.).

Thirdly, the properties of excited states and their potential energy surfaces are needed for the prediction of reaction pathways, for the prediction of orbital symmetry-dependent prohibitions, for the assessment of the adiabatic nature of reactions and calculations on the chemical dynamics of elementary processes, for the analysis of ways of transforming chemical energy and procedures for the chemical pumping of the reaction products. An enormous amount of work has already been carried out on the characteristics of the excited state of atoms and diatomic and triatomic molecules and radicals and this "energy programme" in chemical physics has been extended increasingly to polyatomic molecules and radicals; the principal research techniques are laser and microwave spectroscopy in different versions and combinations. The "energy programme" in chemical physics is characterised most strikingly by the enormous range of the states of atoms investigated—from hot, Rydberg atoms to ultracold atoms.

When the valence electron is excited to high orbitals with large values of the principal quantum number n (n reaches values of several tens up to 100) and is remote from the nucleus, its energy levels are described by the familiar simple Rydberg formula and such excited atoms are referred to as Rydberg atoms. The energy transitions between levels with high values of n correspond to millimetre waves; the energy of the levels is altered by an external electric field, which can even induce the ionisation of the Rydberg atoms; one method for their detection is based on this phenomenon.

The properties and energetics of Rydberg atoms have been investigated quite widely and in fair detail. For example, even the isotopic shifts in the energy of the atoms, caused by the magnetic electron–nucleus interaction, have been measured. Thus the difference between the energies of the ^{86}Sr (nuclear spin $I = 0$) and ^{87}Sr ($I = 9/2$) isotopes and its dependence on n have been measured for the Sr ($5sns$) atoms. The difference ΔE is 0.4 GHz for $n = 35$, 0.9 GHz for $n = 50$, and 1.7 GHz for $n = 70$; in the limit at $n \to \infty$, ΔE tends to 2.8 GHz—the energy of the hyperfine interaction of the 5s electron with the ^{87}Sr nucleus.

One of the remarkable properties of Rydberg atoms is as follows. In a resonator with a very high Q-factor, the photon emitted by a Rydberg atom is retained for a fairly long time, so that it can be recaptured by the same atom. Hence arises the possibility of constructing a single-atom laser, in which a two-level atom interacts with a single-frequency electromagnetic field, which is accompanied by the absorption and emission of the same photon by the same atom. A system which will make it possible to test experimentally the postulates and predictions of quantum electrodynamics is being created at the present time. From this point, chemical physics is at the junction with atomic physics and quantum electrodynamics.

The preparation of ultracold atoms is based on the alteration of the velocity of an atom following the absorption of an optical quantum (laser cooling of atoms). If the atoms and laser photons are tuned in such a way that the absorption takes place in the low-frequency wing of the absorption line, then the resonance absorption by the atom moving towards the photons shifts to the centre of the line and intensifies by virtue of the Doppler shift, whereas for atoms moving in the same direction as the stream of photons the Doppler effect displaces the resonance from the centre of the line and decreases the absorption. As a result the atoms experience a retarding force directed along the stream of photons. If the atoms are now placed in opposed laser beams directed along three orthogonal axes, it is possible to ensure a comprehensive retardation of the atoms. In such a laser field, the movement of the atoms is retarded with a velocity decay time of $\sim 10^{-4}$ s as if they were in an optically viscous medium, which is referred to as "optical treacle". Thus Na atoms can be cooled to 2.4×10^{-4} K and in principle there is a possibility of cooling down to 10^{-6}–10^{-10} K.

Ultracold atoms, virtually lacking kinetic energy, are of interest in precision spectroscopy and in the probing of atom–atom and atom–surface potentials. They also lead to a unique possibility of an experimental test of the fundamental postulates of quantum mechanics, in particular of Bose condensation. Here again, chemical physics adjoins quantum physics.

The second feature of modern structural chemical physics involves a sharp and bold expansion of the assortment of species investigated, including the chemical bonds between the atoms of the elements of almost the entire Periodic System in various combinations, many of which were not so long ago regarded as exotic: Si_2H_2, AsH_2, AsN, CrO^+, PH, ZrO, BeTi, LiPd, Cd_2, CsH, BI, SeO^+, PCl^+, NaCr, HCr, ScLi, SrBr, Si_3, Si_2C, SeS, Li_3, MgC_2, CrN^+, CrC^+, muonium and muonium-containing molecules, ions, and radicals, etc.—the list of such species is becoming ever longer. The distances and angles between atoms, the vibration frequencies, the energies of the ground and excited states, the Coriolis constants, the spin-rotational and spin–spin interactions, potentials, etc. have been measured for them. These trends have been stimulated by the search for new laser systems, the research into the spectroscopic detection of high-energy processes in plasma, in flames, in interstellar space, and in the atmospheres of the stars and planets, and also the search for ways of synthesising new substances and materials. Earlier such exotic molecules were detected predominantly in space, whilst nowadays they are obtained and investigated in wide assortment under laboratory conditions.

The third feature is the extremely high metrological level of the structural information and its exact quantitative description, i.e. the high level of what can be designated in English by the simple word quantification (the corresponding Russian term "kolichestvennost'" is unusual and is hardly likely to be adopted in our language). Thus the hyperfine interaction energy in the Cs atom in the ground $^2S_{1/2}$ state is 9192631784 ± 31 Hz and has been measured with an accuracy of 1 part in 10^9. Furthermore, the dependence of this quantity a on the inert gas pressure p has been measured; the change amounts to approximately 10^{-6} of a. For He and Ne, $da/dp = +874$ and 450.2 Hz GPa^{-1}, while for Ar we have $da/dp = -146.7$ Hz GPa^{-1}, which means that the collisions of the Cs atom with He and Ne "clamp" the unpaired Cs electron to the nucleus and intensify the electron–nucleus interaction, while collisions with Ar move the electron away from the Cs nucleus and diminish this energy (probably as a result of the mutual "adhesion" of the Cs and Ar atoms and the partial, approximately 10^{-6}, electron transfer from Cs to Ar). In the excited state $^2P_{1/2}$, the hyperfine interaction energy is 1168 MHz, while in the $^2P_{3/2}$ state it is only 200 MHz. The latter values were obtained with coherent laser excitation of the D_1 and D_2 lines of the Cs atoms and from the observed quantum beats in the transitions between the levels of the hyperfine structure.

The molecular constants of MgO, PbO, and N_2O_3 have been measured with a high degree of accuracy for all the isotopic forms of these molecules and the quadrupole and magnetic interaction tensors and the spin-rotational coupling constants have been determined. The molecular constants for all the isotopic forms of O_2 [including the constants of the magnetic spin-Hamiltonian and among these the constant for the hyperfine interaction with the ^{17}O nucleus: $a(^{17}O) = -54.758$ MHz] have been determined. Measurements have been made with a high degree of accuracy for the hyperfine interactions (both isotropic and anisotropic) of the radical-cation $Cr(CO)_4^+$ with the ^{53}Cr and ^{13}C nuclei and on their basis it was concluded that the above radical-cation has the T_d symmetry and that the unpaired electron is localised in the pure σ orbital. These are only a few instances demonstrating how the high metrological level of the structural information ensures the reliability and non-ambiguity of the conclusions concerning the chemical structure of the species.

The high degree of "quantification" of structural chemical physics reflects, on the one hand, the high metrological level of the modern physical research methods—magnetic resonance in its different versions, Mössbauer, microwave, laser, X-ray, and photoelectron spectroscopy, mass spectrometry, and their numerous "hybrid" combinations. On the other hand, it is of practical value for quantum magnetometry with its frequency standards—it ensures the "raising" of the accuracy and reliability of quantum chemistry as well as the improvement of its computational methods and schemes.

2. Small Assemblies

Small assemblies occupy a position intermediate between individual molecules and continuous systems constituting a phase (liquid, crystal, amorphous glass, etc.). They represent a bridge between the individual molecules and their infinitely large assembly, where intermolecular interactions arise and the characteristics of matter are manifested.

Depending on the character and strength of the intermolecular interactions in the substance, either the properties and features of individual molecules are retained or they are completely lost.

In chemical physics there is an old problem which has now got, as it were, a new lease of life by virtue of advances in the study of the structure and properties of small assemblies. This is the problem of how the hierarchy based on composition (ranging from an individual molecule to a substance) is related to the hierarchy based on properties and functions in a given series, for which quantitative compositions are the qualitative features of a substance (or a phase) manifested, and for what number of individual species does the combined assembly of the latter become a substance and does this occur gradually or is there a "critical" threshold mass.

Van Der Waals Molecules and Complexes. The term van der Waals molecules is given to weakly bound complexes of atoms, radicals, or molecules which exist by virtue of intermolecular attraction. They are observed in rarefied molecular beams, gas streams expanding at ultrasonic velocities, in solid inert gas matrices, and in liquids, and are investigated by laser and microwave spectroscopic methods. An enormous number of such species are known: He_2, Xe_2, $(H_2)_2$, Hd.Ar, $(HF)_2$, Hg.He, $C_6H_6.CH_4$, ICl.Ne, HF.CO, $(N_2O)_2$, $(CO_2)_2$, $(SF_6)_2$, $OCS.CH_4$, Mg.Ca, $H_2S.Ar$, $C_2H_4.Ar$, $C_2H_4.NO$, CO.He, HCl.Xe, $(C_2H_2)_2$, etc. The completeness, reliability, and "quantification" of the structural information for such molecules and complexes is not inferior to that for isolated species. For van der Waals molecules, measurements are made of the symmetry and geometry (on the basis of the rotational spectra and moments of inertia), the quadrupole and spin–spin interaction constants, the rotational g-factors, the magnetic susceptibility and its anisotropy, the dipole and quadrupole moments, the vibration frequencies, the dissociation energies, the lifetimes, etc.

Thus $HCl.C_2H_4$ and $HCl.C_2H_2$ have the T-form: the axis of HCl passes through the centre of the partner molecule and is perpendicular to its axis. The distance from the Cl atom (it is the more remote) to the centre of the partner molecule is 3.724 and 3.699 Å for C_2H_4 and C_2H_2 respectively. In the van der Waals molecules $HCl.C_3H_6$ and $HCl.C_6H_6$, the HCl axis is perpendicular to the planes of the cyclopropane and benzene molecules and coincides with the C_{3v} and C_{6v} symmetry axes of these molecules. The distances from the remote Cl atom to the C_3H_6 and C_6H_6 planes are 3.567 and 3.629 Å. The molecules Kr.HCl and Kr.DCl are linear and their dissociation energies are 179 and 200 cm^{-1}, i.e. even a negligible isotope effect in the dissociation energies is readily measurable. The partner molecules CO and HF are organised into a linear complex with $C_{\infty v}$ symmetry, in which the H atom is "stuck" to the C atom; the dipole moment of the complex, measured on the basis of the Stark effect in the ground vibrational state for the rotational transition $J = 1 \rightarrow 2$, amounts to 2.352 D. The complex of N_2 with HF is linear, i.e. N(1)–N(2).HF; for this complex, the components of the quadrupole interaction tensor involving both ^{14}N nuclei have been measured and it has been found that the addition of the HF molecule induces a shift of electron density from N(1) to N(2), amounting to 0.03 of an electron.

In the NaK molecules, the partners are held together by long-range van der Waals forces and the two electronic states differing in spin ($^1\Sigma^+$ and $^3\Sigma^+$) are therefore energetically equivalent with a dissociation energy $D_e = 203.1$ cm^{-1} and an interatomic distance of 5.457 Å. For NaLi($X^1\Sigma^+$), we have $D_e = 6850$ cm^{-1} and in the excited state ($B^1\Pi$) the corresponding value is $D_e = 1758$ cm^{-1}. In the LiLi, LiNa, LiK, LiRb, and LiCs series, the vibration frequency decreases linearly from 350 to 180 cm^{-1} as a function of $m^{1/2}$, where m is the reduced mass of these van der Waals molecules (these results have been obtained in molecular beams using the laser-induced fluorescence of these molecules).

The dynamics of the van der Waals molecules, namely the lifetime in the ground state, the lifetimes in the excited and dissociative states, the distribution of the energy among the fragments after dissociation, etc., has been studied in detail. Thus the $He.I_2$ molecule exists for ~100 ps, while the lifetime of $H_2.Ar$ is three times longer; in both cases τ decreases with increase of the excess energy. The energetics and "energy problems" of the van der Waals molecules are examined in greater detail in Section IV.

In a liquid, the shifts of the lines in the electronic absorption spectra and their dependence on the polarisability of the solvents are believed to indicate the presence of van der Waals molecules. Thus the combination of the partner molecules in the species $C_6H_6.He$, $C_6H_6.Ar$, $C_6H_6.CH_4$, CH_4.toluene, CH_4.aniline, Ar.toluene, etc. has been identified.

The question arises why there is so much interest in the van der Waals molecules and why they are needed. The van der Waals molecules are the most reliable and the richest source of information about the intermolecular atom–atom pair potentials—their form and parameters; by virtue of these molecules, intermolecular potentials have now entered the age of high spectroscopic accuracy. Furthermore, a reduced potential has been found for inert gas atom pairs which is universal for these pairs and describes the interaction of the atoms with an accuracy better than to within 1%. One of the important questions is whether this universality is a common property of any pairs of atoms or whether it applies only to pairs of inert gas atoms and this question still awaits an answer.

Intermolecular potentials are reference quantities in problems of molecular dynamics in liquids, glasses, and macromolecules, in problems of chemical dynamics (calculation of the trajectories traversed by the reacting systems on the potential energy surface), in problems concerning intermolecular energy transfer and energy relaxation (in this case the efficiency of the transfer or relaxation is determined by the Fourier component of the potential and the frequency of the energy transition).

Interatomic and intramolecular potentials are responsible for the molecular organisation of crystals and large molecules, the packing of molecules in liquids, glasses, etc. A high accuracy of the potentials over all distances is required for such purposes and potentials of different interactions are needed: atom–atom, atom–non-spherical molecule, molecule–molecule, molecule–ion, etc.

The formation of van der Waals molecules is manifested in the macroscopic properties of gases—it alters the form of the pVT diagrams, the second virial coefficient, and the viscosity. These molecules induce the condensation of gases, crystallisation, and apparently other phase transitions. They are important at the critical points of the substances, where they determine the density fluctuations and the correlation radius. All these problems are within the sphere of the concerns of modern chemical physics.

The question arises whether van der Waals molecules play any significant role in chemical reactions. At first sight, the answer should be negative, because the bond energy between the partner species is low, frequently less than kT, so that collisions with extraneous molecules induce the decomposition of the van der Waals molecules. However, the angular distribution of the reaction products in molecular beams indicates unambiguously that many reactions are preceded by the formation of an intermediate complex, whose lifetime is longer or comparable to its rotation period ($\gtrsim 1$ ps) and is much longer than the duration of the collision of the reactants. Such reactions include $Cs + RbCl \rightarrow CsCl + Rb$, $Cl + I_2 \rightarrow ICl + I$, $D + H_2 \rightarrow DH + H$, etc. The intermediate complexes in these reactions can be regarded as van der Waals molecules, because they can hardly involve any specific interactions other than the van der Waals interactions (for example in $D.H_2$, in the reaction $D + H_2 \rightarrow DH + H$). In chemical dynamics, it is assumed that such reactions proceed via a statistical complex (see Section V). Van der Waals molecules and complexes are two concepts between which it is not possible to draw a boundary in the general case. There exist, however, two approximate criteria for their differentiation—the energy and structural criteria. A complex is assumed to be a species in which the bond energy between the partners exceeds kT and can reach considerable values; if, on the other hand, the bond energy is less than or comparable to kT, such a complex is regarded as a van der Waals molecule. Furthermore, in the van der Waals molecule the interactions between the partner species are universal and non-localised; on the other hand, in the complex the interactions between the partner species are specific and localised and one can rigorously specify and demonstrate the mutual orientation of the partner species, the atoms or atomic groups through which they are bound, and the electronic orbitals which they place at the disposal of one another on "contact". For other complexes (such as complexes of metal ions with organic and inorganic ligands included within the sphere of interest of inorganic and coordination chemistry), the solution of the problem of the organisation of the partner species has long been known. For weakly bound complexes in solutions and in gases, this problem has also been solved successfully by microwave and laser spectroscopy and magnetic resonance. For example, the characteristic features of the complex formation reactions of organic radicals and molecular oxygen with organic ligands, based on the magnetic properties of the complexes and their manifestations in magnetic resonance (EPR and NMR), have been found and the structure and dynamics of these complexes have been established.

Complex formation is an old, classical problem of chemical physics and two features impart to it its modern aspect: firstly, the high level of "quantification", characteristic, as mentioned above, of the entire chemical physics; secondly, definite structural characteristics of the organisation of the partner species—how they are oriented, which orbitals participate in complex formation, and what is the topography of the complex. Behind structural problems, there is another, more important functional problem—how does complex formation modify the electronic shells of the partner species and how does it alter their reactivities? Here chemical physics endeavours to achieve a *major* aim—to employ complex formation as a chemical principle for the control of the reactivity of species, to establish the general internal relations between structure and reactivity, and to extend them to the predictive level.

Particular attention is paid in modern chemical physics to complexes of excited molecules—excimers and exciplexes. Their characteristic feature is that the bonding in them is achieved only in the excited electronic state of one of the partner species; in the ground, unexcited state, there is no bonding and this state is dissociative. The interest in these complexes is partly associated with the investigation of the pathways leading to energy relaxation, but interest is mainly concentrated on excimer lasers in which the generation threshold is reduced as a result of the emptying of the lowest level (because it is dissociative) and a high generation power is attained.

Clusters. This term combines a wide set of species containing from several atoms or molecules to several tens or hundreds of atoms or molecules, for example $(H_2O)_n$, Cu_n, Na_n, Na_n^+, Ag_n, $(OCS)_n$, Cu_n^+, $(NH_3)_n$, Bi_n, $(CO_2)_n$, $(H_2)_n$, K_n, Mg_n, Pt_n, Al_n, $(H_2O)_n(NH_3)_mH^+$, He_n, $(N_2)_n(NO^+)$, Hg_n^+, K_n, Xe_n, In_n, $Cu_nBe_m^+$ $Pt_{38}(CO)_{44}$, etc. where n and m vary from several units to 1–2 tens and for certain clusters up to several tens and even hundreds. Clusters can be atomic, molecular (comprising atoms and molecules), and mixed–atomic-molecular, neutral, or charged. They are obtained and investigated in gases (for example, in streams expanding at ultrasonic velocities), in zeolite channels (the In_8 cluster has been obtained in this way), and in solid matrices (for example, in solid argon or xenon). Fig.1 illustrates the composition of the gas clusters formed by iodine in a helium–neon mixture; the great structural variety of these species is clearly seen. They differ in composition, properties, and in the nature of the forces retaining the species within the cluster.

Clusters are comparatively new species in chemistry and their appearance is due to advances in organoelemental and organometallic chemistry in the first place and also in chemical physics (for atomic and molecular clusters). An enormous number of studies are now being devoted to the methods of synthesis of clusters and their properties and structure. Their role in the physics of condensation, evaporation, and crystallisation, where they are precursors of a new phase, a kind of "protophase", has been clearly recognised. However, the greatest interest is associated with the chemistry of these species, their reactivity, their catalytic "potentials", and their direct use in chemical materials science.

The concerns of chemical physics are concentrated on the structure and properties of these species, their spectroscopy, energetics, dynamics, stability, and conditions governing their existence. The level of "quantification" is in this instance no worse than for individual species. For example, it is known that the Cu_3 cluster is a triangular Jahn–Teller molecule with a pseudorotation barrier of 111 cm^{-1}, which is only slightly less than the energy of the zero-point vibrations (118 cm^{-1}), and a symmetrical vibration frequency of 269.5 cm^{-1}. The electronic states of this cluster, the frequencies and intensities of their electronic transitions, their geometry, etc. are known. It has been demonstrated by time-of-flight mass spectrometry that the Xe_n clusters have a preferentially eicosahedral structure with stability maxima corresponding to certain coordination numbers under the conditions of maximum close packing (the "magic" numbers $n = 13$, 19, 55, 147).

However, the main, fundamental problem (with which we began this Section on small assemblies) concerns the question how the properties of individual species evolve on combination of the latter into the properties of a substance—the properties of a new phase. This is a problem of evolution of quantity into quality and is being vigorously developed in terms of two aspects—the structural-physical and purely chemical aspects.

In the structural-physical aspect, one establishes the dependence on the structure of the cluster of its physical parameters and properties: the symmetry and type of lattice the interatomic distances, the vibration frequencies and amplitudes, the bond energies, the ionisation potentials, the Debye temperatures, the heat capacities, and the dielectric constants, and, for metallic clusters, also the Fermi levels, the spin and charge densities and their distribution within the bulk of the cluster, the electrical resistance, magnetisation, etc.

Here are a few examples illustrating the level attained in the solution of the structural "cluster" problems. Among the charged molecular hydrogen clusters $(H_2)_n^+$, obtained by the photoionisation of the neutral clusters $(H_2)_n$, only the odd ions H_{2n-1}^+ have been detected but not the even ions. On the basis of experiments and calculations, it has been concluded that the odd clusters contain at the centre the skeleton of the triangular ion H_3^+ surrounded by hydrogen molecules. The adiabatic ionisation potentials of the water molecule, its dimer, and ice vary in the sequence 12.6, 11.1, and 8.8 eV, i.e. the change in potential on dimerisation is ~40% of its total change in the transition from an isolated molecule to a substance (ice). This is also valid for the vertical potential and means that the greatest changes in properties occur in the association of the first two—three molecules. On the other hand, the ionisation potential of the Na_n clusters diminishes slowly with increase of n and its fall is accompanied by oscillations; the even members of the series have a higher ionisation potential than the odd members, but even for the Na_{14} cluster the ionisation potential is still greater (appreciably greater—by a factor of 1.5) than electron work function of metallic sodium. In the Ag_n clusters, the characteristics of the transition from molecular properties to metallic properties are manifested already for $n = 6$ (they are observed in the electronic spectra from the excitation of the surface plasmons characteristic of the metallic state), while for $n = 10–15$ the cluster becomes purely metallic.

The Fe_{15} cluster has an average magnetic moment of 2.2 μ_B per atom, while in the metal this quantity is 2.7 μ_B. Theoretical estimates yield the following distribution of the magnetic moment with respect to the bulk of the cluster: 1.1 μ_B for the central atom, 2.7 μ_B for each of the first eight neighbours, and 2.8 μ_B for each of the six neighbours of the second "rank". The electrons are also distributed non-uniformly: the central atom of the cluster has 1.27 electrons more than the surface atoms. In terms of a number of properties (the structure of the electronic spectrum, magnetism), the Fe_{15} cluster is already fairly close to metallic iron, although certain differences from the metal are observed even for the Fe_n clusters with $n > 15$).

The Cr_{15} cluster has a magnetic moment (in contrast to the metal which is anti-ferromagnetic) and the distribution with respect to its bulk is as follows: −0.7 μ_B for the central atom, +4.1 μ_B for the first neighbours, and −3.4 μ_B for the second neighbours. In metallic chromium the magnetic moment of each atom is 0.7 μ_B, i.e. the magnetic state of the central atom in Cr_{15} is the same as in the metal, while the overall magnetic moment of the cluster is determined by the magnetism of the surface atoms (the non-equality of the magnetic moments of the first and second spheres).

The structural-physical studies embrace all types of clusters—atomic, molecular, purely metallic, and organometallic, whose nucleus consists of the metal atoms and the surround is made up of organic groups. The clusters in biomolecules (for example in nitrogenase and ferrodoxin), where they are responsible for the functioning of these biomolecules, merit special attention.

We shall now discuss the chemical behaviour of the clusters (we recall that this will be done in connection with the evolution of quantity into quality). The idea of the "chemical" approach will be illustrated in relation to the proton transfer reaction. In the $(HA)B_n$ cluster, the acid molecule HA is combined with n molecules of the base B. The proton transfer from HA to B via the reaction $(HA)B \rightarrow A^-(H^+B_n)$ is detected from the appearance of the anion A^-. The question is whether this reaction depends on n and whether there is a threshold value of n at which it begins. Experiments of this type have been performed with the aid of laser spectroscopy. In the α-naphthol (HA) clusters with ammonia (B), HA is excited to the singlet state S_1. In the ground state α-naphthol is a weak acid with $pK_\alpha = 9.4$, while in the excited S_1 state it is a strong acid with $pK_a = 0.5$. The proton transfer in the $(HA^*)B_n$ cluster does not occur for $n = 1–3$ (the A^- anion is not formed). The proton is transferred only in the clusters with $n \geq 4$. In the case of β-naphthol, whose $pK_a = 2.8$ in the excited S_1 state, the same reaction occurs only in clusters with $n \geq 10$. In the $(HA).(H_2O)_n$ clusters with α-naphthol in the S_1 state, proton transfer is detected only for $n \geq 20$. Thus the question whether the cluster acquires the properties of a "phase" has a clear-cut answer, but it is not as yet general. In the examples quoted above,

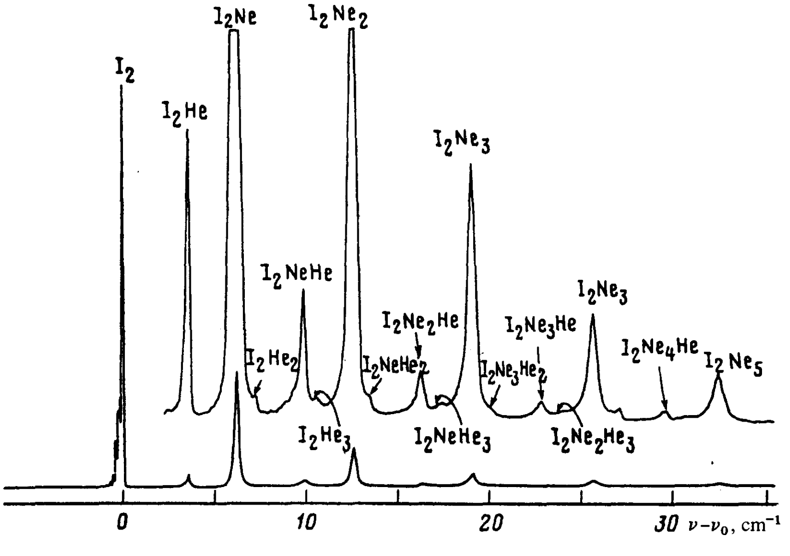

Figure 1. The fluorescence excitation spectrum of a stream of iodine vapour in a helium—neon mixture expanding at an ultrasonic velocity; the assignments of the lines to clusters having different compositions are illustrated; $\nu_0 = 17982$ cm^{-1}

the threshold value of n depends on the strength of the acid and base—the stronger the acid and base, the sooner does the cluster exhibit the features of a "phase".

For the same purpose, extensive studies have been made of the ion–molecule reactions in the clusters $(H_2O)_nH^+$, $(NH_3)_nH^+$, $(CH_3OH)_nH^+$, $(CH_3COCH_3)_nH^+$, and $(CH_3X)_n^+$ (X = F, Cl, Br, or I), and also in the mixed clusters $(CH_3X)_n^+\cdot(CO)_m$, $(CH_3X)_n^+(N_2)_m$, $(CH_3COCH_3)_n^+(CH_3OCH_3)_m$, etc. The aim of these studies was to find the characteristic features of the ion–molecule reactions (radical, nucleophilic, electrophilic) in such small assemblies, to create bridges between these reactions in gases and liquids, and to establish how the characteristics of the gas-phase reactions are transformed into those of liquid-phase processes and what is the size of the cluster when the latter begins to simulate the liquid or solid phase.

The answers to these questions are of special interest for catalysis—both homogeneous and heterogeneous. This is a problem of molecular organisation—how the atoms must be "arranged" on the surface of the catalyst and what should be their number in the cluster in order to ensure the activation of specified molecules and the catalysis of definite, selective reactions. For example, the catalytic activity of metallic gas-phase Nb_x clusters in the dehydrogenation of benzene has a threshold character: it is manifested for $x \geq 4$ and reaches a maximum for $x = 5$, 6, and 11, but it is found to be low for $x = 8$ and 10. The Nb_8 and Nb_{10} clusters also exhibit a low activity in the reactions with H_2 and N_2 and are distinguished among other clusters by their high ionisation potentials.

It is known that molecular hydrogen dissociates when it is adsorbed on metallic nickel and cobalt. However, calculations have shown that there is no dissociation in the interaction of nickel and cobalt atoms or of Ni_3 and Co_3 in the linear configuration with hydrogen. However, the Ni_3 and Co_3 triangular clusters as well as the Ni_{13} cluster do ensure dissociation. Thus the triatomic cluster with C_{3v} symmetry is the smallest, "threshold" structural element ensuring, for example, the catalysis of hydrogenation.

The problem of the evolution of quantity into quality has not so far had a general solution—neither in the structural-physical nor in the chemical aspect, but ways leading to the solution have already been found and progress on these lines constitutes one of the most important fields of chemical physics.

Special mention should be made of the chemical physics of metallic clusters in connection with the wide prospects for the application of these clusters in materials science and their use in optoelectronics and microelectronics (light filters, radiation receivers, solar batteries, composite materials, amorphous metals, new types of ferrites, etc.). [Isolated macromolecules must also be included among small assemblies. The concerns of chemical physics include the statistics of macro-molecules, internal rotation barriers, stereochemistry, optical isomerisms, the shape of macromolecules and the relative contributions of chaos and order to their organisation (coils, helices, linear chains, etc.), the interaction of macromolecules (the permeability and intertwining of coils, crystallisation, complex formation, and binding of macromolecules, including their binding to solid surfaces) "phase" transitions in isolated macromolecules (of the helix–coil type), etc. The aim of the studies of the structure and dynamics of macromolecules is to understand the principles governing the organisation of such macromolecules in block polymers, in blends, and in composite materials and to develop methods of controlling such organisation. These problems are important for ensuring the elasticity and strength of polymeric materials, for their rheology, and for the creation of new materials; here chemical physics adjoins the molecular physics of macromolecules.

3. Large Assemblies

The study of the structures of liquids and solids—amorphous and crystalline, individual components, and solutions—is the traditional task of chemical physics. The theories of liquids and solids (classical, semiclassical and quantum theories, statistical and dynamical theories), the short- and long-range order, the dynamics and the phonon spectra of crystals, the distribution function, and the computer simulation of structure and dynamics is a far from complete list of the traditional problems. The same problems are formulated in the study of disperse systems—suspensions, porous bodies, emulsions, aerosols, etc.

However, gradually the emphasis is shifting towards less traditional problems, among which most attention is being devoted to the structure of molecularly organised systems and the structure of defects and defective bodies. Thin films, adsorption layers, interfaces, liquid crystal formations, clathrates, "whiskers", monolayer and two-layer membranes, micelles, layer structures, intercalates, and Langmuir–Blodgett films—are examples of non-ideally organised structures (in contrast to crystals with their ideal organisation). The structure of these systems, their thermodynamics, the determination of the conditions governing their existence and their stability, and their behaviour in various external fields (electrical, mechanical, magnetic, and acoustic) are being investigated with the aim of deducing the principles governing the molecular organisation of such systems, the development of methods for controlling their organisation, and the prediction of the varied and useful functions of these systems.

Another modern aspect of structural chemical physics is the increasing interest in defects: impurity centres, dislocations, vacancies, molecular cavities, and local heterogeneities. New methods in chemical physics—high-resolution magnetic resonance, the annihilation of the positron and positronium, and the chemistry of muonium—are used together with traditional structural methods to analyse the defects, their nature, the structure and crystallographic environment in the vicinity of the defects, and the symmetry and amplitude of the distortions. Like isolated species, the defects are characterised by a high level of "quantification". For example, the irradiation-induced defect in zinc acetate is the radical $\dot{C}H_2CO_2(Zn)$, in which the CH_2 group executes complete rotations (jumps) around the CH_2–CO_2 bond with a barrier of 18.4 kJ mol^{-1}, while the torsional vibrations take place with an energy of 6.7 kJ mol^{-1}. This level of accuracy is typical also for the characteristics of other crystal defects.

The detection of structural heterogeneities and local cluster formation is very important for materials science; methods are being developed for non-disruptive detection. Thus the localisation of residual Si–H bonds of the cluster type has been observed in amorphous silicon (the importance of this material is generally known) by NMR. Atomic aggregates corresponding to Fe_n clusters with $n \cong 45$, in which the spin "ferromagnetic" correlation is retained at temperatures exceeding the macroscopic Curie temperature by 80 K, have been found in metallic iron from low-angle neutron scattering, i.e. the local Curie temperature is much higher than the average Curie temperature.

There is a growing interest in two extremes-completely ideal defect-free structures and highly defective structures; the latter is associated with the unusual effects and the unusual behaviour of substances under the conditions of shear deformation under pressure. In particular data are available concerning the appearance of strong paramagnetism in deformed diamagnetic metals and there has been a claim (which requires confirmation) that ferromagnetism appears in highly defective NaCl.

Structural chemical physics has self-evident aims: it "operates" on materials science—a large and most timely field of modern engineering, and is concerned with the development of principles governing the organisation of matter into specified structures and the principles used in controlling structure in order to create new generation materials with a predicted functional purpose. The strategy based on the transition from structure to properties and functions is the most reliable in modern materials science, on the basis of which considerable advances have already been achieved: new surfactants have been obtained for the large-scale removal of petroleum pollution from the surface of the sea and superconducting ceramics, organic metals, ferromagnetics, etc., have been created.

---o0o---

The structure of individual chemical species and their assemblies—large and small—belongs to the set of classical problems of chemical physics. While modern chemical physics is still concerned with the solution of this problem, nevertheless most attention (priority) is given to dynamic problems, which can be grouped to a first approximation into "four types of dynamics":

1) molecular dynamics, i.e. the dynamics of the movement and displacement of species;

2) the energy dynamics, characterising the time evolution of the energy in isolated molecules and their assemblies (migration, transformation, and relaxation of energy);

3) chemical dynamics, i.e. the development of the chemical interaction of species as a function of time (including chemical kinetics as a diagnostic method for the mechanisms of chemical reactions);

4) spin dynamics, i.e. the dynamics of the population and evolution of the spin states of the reacting species.

III. MOLECULAR DYNAMICS AND MOLECULAR ORGANISATION

The important position of molecular dynamics and chemical physics is due to the following factors. Firstly, molecular movements ensure the time modulation of intermolecular potentials, i.e. they create perturbed, random ("white") or correlated noise. The Fourier spectrum of this noise determines the energy dynamics of the molecules (energy transfer and quenching of excited states, energy pumping, and relaxation). Molecular movements modulate also the magnetic interactions and they are therefore responsible for the spin dynamics and magnetic relaxation.

Secondly, molecular dynamics ensures contact between the reacting species and their appropriate mutual orientation, namely their suitable "micro-organisation" in the transition state of the reaction—not noly for diffusion controlled reactions (this is self-evident and even trivial) but also for reactions occurring under kinetic conditions (especially in solids-see Section V).

Thirdly, molecular dynamics constitutes a pathway to molecular organisation; it is not fortuitous that both concepts are considered here together in a single Section. One cannot say that molecular organisation is a function of molecular dynamics alone, that only dynamics organises structures. Molecular organisation is determined primarily by thermodynamics and its laws. However, among molecularly organised systems (including biomolecules), non-equilibrium systems occupy a major place (they are in fact as a rule of greatest interest) and their formation, stability, and, what is still more important, their functioning are determined by molecular dynamics. Finally, the most important factor is that the dynamics of translational, rotational, and orientational movements of the structural elements of substances and materials (electrical and magnetic dipoles, electrons, ions, and molecular fragments) determines the properties of materials—mechanical strengths, elasticity and plasticity, rheology, electrical conductivity, magnetism, dielectric strength, etc.

1. Molecular Dynamics

The theoretical methods used in the analysis of molecular dynamics are just as varied as the experimental methods. The task of the theory is to find ways for the correct description of diffusion, to establish a relation between the "microscopic" dynamics and the transport macroproperties of the medium, and ultimately to impart a predictive power to the theory. A number of approaches have been developed for the solution of this problem. The self-diffusion coefficient D is expressed in terms of the autocorrelation velocity function $z(t) = \langle u_x(t).u_x(0)\rangle$, where u_x is the x component of the velocity of the selected species; in its turn, the function $z(t)$ is related to the radial distribution function and the frequencies of the harmonic oscillations of the given species in the medium. Its detailed behaviour is investigated by the computational methods of molecular dynamics based on the synthesis of the trajectories in the movement of the species by the numerical integration of the classical equations of motion. The validity of the approximations in the selection of the parameters and the function $z(t)$ is estimated by comparing the theoretical and experimental values of D. For low densities of the medium, $z(t)$ decreases as $t^{-3/2}$, while for high densities its behaviour is complex, oscillatory, and analytical predictions are difficult.

The dynamics of a Brownian particle (i.e. a large and heavy particle placed in a medium comprising small and light particles) constitutes a traditional problem. Such a particle does not respond to individual impacts by the molecules in the medium and its dynamics is controlled by the random fluctuations of the forces acting on its surface. The equation of motion has the classical form of Newton's second law:

$$mu = F\,[t, u(t')] \quad ,$$

where the velocity u and the force F at time t depends also on the velocity $u(t')$ in the preceding instant t'. Depending on whether there is a correlation between the past and the present (i.e. a correlation between t' and t) and its form, the solutions assume different forms. The search for these solutions at different correlation levels and comparison of their predictions with the experimental reality constitute in essence the subject with which the theory is concerned.

If the characteristic time of the fluctuations F is short compared with the velocity decay time, then F depends solely on $u(t)$ and there is no correlation between the past and the present. This situation is described by the familiar simple Langevin equation in which the force and the coefficient of friction are calculated. This problem is again solved at different approximation levels for the autocorrelation velocity function and the force, for the distribution of the initial velocity u_0, etc. In one of the approximations (u is small and the liquid is incompressible), one finds, in particular, the familiar Stokes–Einstein relation. For high velocities, the characteristic velocity decay time is $\sim 10^{-13}$ s, i.e. is of the same order of magnitude as the time taken by a sound wave to traverse the intermolecular distance. The Stokes approximation then fails and account must be taken of the elastic properties of the medium and the high-frequency spectrum of the elastic vibrations: this is the familiar Zwanzig–Bixon approximation.

The simple Langevin equation predicts an exponential decrease of the autocorrelation velocity function, which is not correct. This means that one cannot neglect the correlation between t and t'. The equation taking into account the correlation between the past and the present is known as the generalised Langevin equation, which includes the correlation time function—the memory function. It takes into account the fact that the species considered creates in the course of its movement a perturbation at time t', which extends in time and at the instant t returns to its source. The choice of the memory function, its various approximations, and the solutions of the generalised Langevin equation employing these functions constitutes one of the developing theoretical fields.

Another field is concerned with the development of the kinetic theory in which the probability density in the phase space of the coordinates and velocities and its time evolution are calculated. This density takes into account the correlation between the velocity and momentum. In the case of frequent but weak "soft" collisions, the movement of the species is described by the familiar Fokker–Planck equation, whose solutions are obtained and analysed at different approximation levels and subject to different initial conditions. In the case of infrequent and strong collisions with a large transfer of momentum, the movement is described by the Boltzmann equation (if it is assumed that there is no correlation with respect to the coordinates and velocities between the Brownian particles and the particles constituting the medium) or by the Enskog equation is a spatial correlation is retained.

The simple Langevin equation and the Fokker–Planck equation describe the behaviour of large particles for which the fluctuating driving force arises from the frequent and weak impacts by the species in the medium. The Boltzmann–Enskog equations describe the second limiting situation of the rare and strong binary collisions without any correlation between them. In a real situation, the theory cannot ignore the dynamic correlation between the collisions and in this sense the generalised Langevin equation with its memory function corresponds most adequately to reality. However, the difficulty is that the memory effects and the correlation between the past and the present are taken into account semiempirically with selected memory functions. The *ab initio* derivation of these functions from first principles is a difficult and unsolved part of the many-body problem. The task if theoretical molecular dynamics therefore remains the creation of bridges between the dynamics of an individual collision and the long-period dynamic behaviour of the species.

At the level of the theoretical approaches examined, solutions are being obtained to the problem of the Brownian movement with different dimensions—one-dimensional, two-dimensional, and three-dimensional—for the description of the behaviour of species in narrow channels and porous media, on surfaces within thin films and membranes, and in liquids and solids. Many studies have been devoted to the dynamics of pairs and to the calculation of the probability of their reaction or annihilation; this problem is particularly timely for radical pairs—neutral and charged, with and without allowance for spin evolution, with and without allowance for the acceptance and decomposition of radicals, with unrestricted diffusion and with diffusion limited by a closed volume with absorbing or reflecting walls. The solutions are used in photochemistry and in the chemical physics of magnetic-spin effects.

The generalised Langevin equation is solved in different versions, with different memory functions, and there exist classical and quantum solutions. The dynamic problems are solved for different intermolecular potentials and the effects of the anisotropy of the potential, the contribution of attraction and repulsion, and the role of short-range and long-range parts of the potential, its Coulombic and exchange branches, are analysed. Many problems are associated with the collective dynamics of crystal lattices, networks, liquid crystals, and membranes and with the dynamic behaviour of quasi-particles—phonons, solitons, magnons, plasmons, and excitons. Theoretical problems of molecular dynamics are frequently at the junction with the problems of contiguous fields of physics—the theory of elasticity and relaxation, plastic deformation, thermal conductivity, and rheology.

The scope of the experimental research into molecular dynamics is almost limitless; it refers to the transport of molecules in liquids, the transport of atoms in metals and alloys, the drift of electrons and ions in semiconductors and liquid and solid electrolytes, and diffusion in porous, microheterogeneous, and molecularly organised systems (micelles, clusters, adsorption layers, membranes, and Langmuir–Blodgett films). Studies on the dynamics of phase formation, especially in the early stages of this process under precritica conditions and at the critical points, and the dynamics of aggregation, coagulation, and cluster formation occupy an important place.

An independent field of study is associated with the dynamics of macromolecules—synthetic and biological: the conformational dynamics of neutral molecules and polyelectrolytes, the kinetics of helix–coil transitions, the "breathing" of macromolecular coils, the dynamics of the entanglement and disentanglement of coils, the untwisting of helices and of binding to substrates, the local dynamics of segments and the "macrodiffusion" of large molecules, etc. All these questions refer directly to polymer materials science, to the problems of the physics and mechanics of polymeric materials, and, for biomolecules, to the problems of their functioning (the synthesis of proteins, DNA, RNA, enzyme catalysis, muscle contraction, the permeability of membranes, bioenergetics, and immunological recognition).

Surface diffusion constitutes an important branch of dynamics associated with the problems of the growth and perfection of crystals, epitaxial layers, and films and with the problems of adsorption and heterogeneous catalysis. Appriciable advances in this field have been ensured by ion-field microscopy of surfaces whereby one can observe single atoms and follow events involving them. Thus the diffusion coefficient of Ba on tungsten changes by several orders of magnitude on different planes and the activation energies for diffusion on the (110), (111), and (112) planes differ sharply: 5.0, 11.5, and 17.5 kcal mol^{-1} respectively. On the face-centred lattice of rhodium, the atoms of the latter on the (111) plane migrate already at 55 K, while on the (110) plane they begin to move only at 300 K. The activation energies for diffusion also differ greatly: $\varepsilon(111) = 3.6$, $\varepsilon(311) = 12.4$, $\varepsilon(110) = 13.9$, and $\varepsilon(100) = 20.2$ kcal mol^{-1}. Under these conditions, the entire difference between the rates is determined by the energetics, the contribution of the entropy component being constant. On corrugated surfaces [of the (110), (311), and (331) types], the diffusion is directed strictly along definite channels—the potential energy ravines. The properties of the self-diffusion of platinum and tungsten are the same.

On the surface of body-centred lattices, new features appear in diffusion; in particular, along certain planes [for example, Rh (111)], the diffusional behaviour of a pair of atoms differs from the behaviour of a single atom, i.e. a correlated movement appears and gives rise to new problems concerning the ratio of the individual and collective movements and their contribution to diffusion. The W, Re, and Ir atoms on the W(211) surface move in pairs; the Pt_2, Pt_3, and Pt_4 clusters (which are linear) move on the W(110) plane via jumps of single atoms with retention of correlations in pairs and clusters.

Surface two-dimensional dynamics is an actively developing field in chemical physics. It refers not only to solid surfaces but also to monomolecular films on liquids (lateral diffusion), to membranes, and other two-dimensional systems. Here the main interest concerns the problem how the characteristics of two-dimensional dynamics are related to the atomic structure of the planes, to the molecular organisation of the two-dimensional systems, and to their thermodynamics and structure.

Excellent physical methods are used to investigate molecular dynamics: Rayleigh and Raman light scattering, acoustic and magnetic relaxation, the annihilation of positrons and positronium, coherent and non-coherent scattering of cold neutrons, laser picosecond and femtosecond spectroscopic methods, and also mathematical methods for the modelling of molecular dynamics. Laser picosecond holography merits special attention. The idea of this method involves the optical generation of a short-lived holographic lattice in a liquid or solid and subsequent observation of the dynamics of the "dissipation" of this lattice. The holographic lattice is created by passing through the liquid or crystal two picosecond pulses, coinciding in time, which cross in the specimen at an angle θ. Their interference creates in the specimen a holographic lattice with a constant $d = \lambda/2\sin(\theta/2)$, where λ is the wavelength of the laser emission generating the lattice. The principle governing the appearance of the holographic lattice involves the formation of electronically excited states, the excitation of intramolecular vibrations, and the generation of acoustic waves (phonons). Regardless of its specific cause, the holographic lattice constitutes a spatial-periodic change in the refractive index. Such a lattice "dissipates" after a time owing to molecular diffusion, the energy relaxation, or the decay of waves, while the dynamics of the dissipation can be detected by means of a delayed laser probe beam, which is diffracted by the holographic lattice. The intensity of the diffraction as a function of the delay of the probe beam yields the kinetics of the dissipation of the lattice on a picosecond scale. The characteristic dissipation times can be obtained from the time variation and the spatial scale of the dynamic processes responsible for the dissipation of the holographic lattice and the spatial averaging of the refractive index can be obtained from the frequency dependence (because d depends on λ).

The transport of excited molecules, their energy relaxation, the energy transfer (the transfer times and distances), the generation and detection of coherent acoustic phonons in crystals, and the rate at which they spread along different crystallographic axes are investigated in this way and the same procedure is used to observe the vibrational overtones and to measure the elastic and photoelastic constants of crystals. The method can be used for the non-disruptive monitoring of optical materials (including fibres) and for the analysis of the dynamics of membranes, liquid crystals, and amorphous bodies.

2. Molecular Organisation

Continued interest in molecularly organised systems has become a new feature of modern chemical physics. Molecular and supermolecular organisation of *ensembles* of species is an important principle governing the regulation of chemical processes and constituting a major resource in chemical technology and materials science. So far, this principle has been developed and adopted to only a slight extent, but its potential is exceptionally great and there are grounds for the claim that in the future "organised" chemistry will occupy a leading place in technology and materials science.

Studies on these lines are so wide in scope that it is impossible to analyse them fully. Even a cursory listing of selected examples gives an idea about the scale of such research at all levels—from molecular to macroscopic and supermolecular. The organisation of molecules into complexes, their incorporation in clathrates and micelles, immobilisation, the creation of organised systems simulating biochemical systems (biomimetic systems), the molecular organisation of active centres in metalloenzymes (nitrogenase, ferredoxin), clusters, intercalates, and layer structures—this is only a limited series of examples of organisation at the molecular level. The conformational organisation of macromolecules (helix, coil, extended chain, and their combinations) determine their packing in polymeric materials and specify the physicomechanical properties of fibres, block and regular copolymers, and blended compositions: the problem is how is this achieved, what is the form of the bridges between organisation and properties, and how their interrelation should be controlled.

Conformational dynamics, complex formation, and molecular organisation of polyelectrolytes, which have opened up major prospects for the creation of a new generation of immunogens and vaccines, in which it is possible to bypass even the genetic control of the immune response occupy a special place, i.e. it is possible to ensure that only B-lymphocytes are active, bypassing the T-lymphocytes responsible for the genetic prohibition of immunogenesis.

Phase organisation and phase transitions are traditional physicochemical problems which are still far from being solved. For example, it is known that there is a short-range order in the structure of simple liquids, in the organisation of which atomic configurations with odd (fifth) order symmetry elements predominate, while in a crystal lattice no matter how small, there should be symmetry elements with even orders only; there is virtually no understanding of the liquid–crystal transition with a rearrangement of the symmetry.

The answers to the following questions are of fundamental importance for the creation of materials with a regulated structure, with a specified combination of elastic and plastic properties, etc.: how to predict the fusion curve, the pVT diagram, and the thermodynamics of the phase transition from the intermolecular potentials; what is the microscopic mechanism of crystallisation, which factors control crystallisation, supercooling, and glass formation, what are the mechanisms of first- and second-order phase transitions and their relation with the short- and long-range order potentials; what are the contributions of the individual and collective molecular dynamics to phase transitions, and how is phase microheterogeneity created and how does it develop.

For example, the structure and organisation (both molecular and spin, magnetic organisation) of solid oxygen have attracted much attention. The existence of several phases in solid O_2 has been established experimentally and the reasons for their stability and magnetic properties have been determined: the orientationally disordered paramagnetic γ-phase; the antiferromagnetic β-phase with long-range orientational order and molecular axes parallel to the C_3 screw axis; the antiferromagnetic, monoclinic α-phase with two mirror magnetic sublattices. Theoretical analysis of the lattices with allowance for the magnetic component of the potential and the Heisenberg exchange spin–spin attraction predicted new stable phases with unusual magnetic properties. The importance of these studies does not lie merely in the prediction of new magnetic phases in solid O_2; it is much more important that the principles of molecular and spin organisation, which ensure specified magnetic properties, have been deduced in relation to this example. These principles are also important for the creation of organoferromagnetic materials, organic semiconductors, metals, and superconductors, ferromagnetic alloys, glasses, and various ceramics (including superconducting ceramics).

The phases and phase transitions in two-diemensional systems, especially in adsorbed layers, are even more varied. The ways in which the species on the surface are organised, the reorganisation of the two-dimensional structure to form a three-dimensional structure and conversely, the order–disorder transitions (fusion–crystallisation), the decomposition into domains and clusters, the dynamics of the surface migration of the domains, and the correspondence or lack of it between the organisation of the adsorption layers and the structure of the lattice of the solid (commensurate and non-commensurate phases) are important in this instance.

Many physical methods, including the diffraction of slow electrons and optical generation of the second harmonic are used to investigate the organisation and dynamics of a two-dimensional lattice gas and phase states and transitions. For example, it has been established on the basis of electron diffraction that hydrogen adsorbed on the Ni(111) plane forms an ordered two-dimensional phase for coverages of 0.3–0.5 and at a temperature below 250 K; for other coverages and for $T > 250$ K the adsorbed layer is disordered and non-organised.

The interest in two-dimensional organisation is targeted towards adsorption and adsorbents and heterogeneous catalysis and catalysts; but there is also another aim—the creation of surface layers with unusual properties by incorporating atoms in the upper layers of the lattice. For example, when a gold layer on silicon is bombarded with Ar^+ ions (100 keV), a mixed Au/Si layer is created and the intermettallic compound Au_3Si is formed. This is a non-equilibrium metastable phase which does not exist under equilibrium conditions. When titanium and zirconium phosphates are bombarded with Ar^+ ions, the surface layers are depleted in oxygen and phosphorus atoms, which are driven to the lower "levels" of the lattice.

The questions which fall within the range of concerns of chemical physics are how atoms are dislodged as a result of impact by an ion, how the electron shells are shaken in this process and how energy and momentum are lost, what are the secondary reactions of the hot atoms and electrons of the target, and how the atomic layers of the lattice are reorganised. The organisation and reorganisation of the surface layers of solids by ionic implantation of plasma and laser "microsurgical" methods constitute a promising pathway to the modification of the surface and the imparting of unusual mechanical, anticorrosion, magnetic, electrochemical, electrophysical, and photosensitive properties, which constitutes the principal stimulus of the research into this branch of chemical physics.

Numerous chemical and physicochemical processes occur at interfaces and the atomic-molecular organisation of the latter is associated with their functioning. The optical generation of the second harmonic is known to occur in non-centrosymmetric crystals, but the second-order optical non-linearity arises also at the boundary between two centrosymmetric media if a symmetry gap occurs in the interface. Since the thickness of the interface is much smaller than the optical wavelength, the dipoles induced at the interface form a polarised layer generating the second harmonic. This method is sensitive to the structure of the interfaces and ordered monolayers, to their dynamics with a small time resolution, to surface reconstruction, and to phase transitions. For example, Langmuir–Blodgett layers, their "evaporation" (liquid–gas-like two-dimensional state transition), and their "fusion" (two-dimensional "liquid"– two-dimensional "solid" transition) have been investigated by this method. The anisotropy of the polarisation tensor has been measured for a monolayer of pentadecanoic acid on water and it has been shown that, for low coverages, the molecules are inclined to the water surface at an angle of 30° while with increase of coverage they "straighten out" and in the limit lie along the normal to the surface.

The monolayers of docosanoic acid on aluminium and carbon form a two-dimensional hexagonal lattice, in which the molecules are perpendicular to the surface of the support and, when the number of monolayers increases to 7, the molecules are inclined and the hexagonal lattice is transformed into an orthorhombic lattice, whereupon one can observe the evolution of the phase transition. The phase transitions in biological membranes and their relation with the cooperative rotational movements of the hydrocarbon chains, the electrical double layers on electrode surfaces, etc. can be investigated in this same way. The first attempts have been made to create monolayers which are two-dimensional ferromagnetics.

Molecular and supermolecular organisation is a characteristic property of biochemical processes (the synthesis of proteins and nucleic acids, photosynthesis, ion transport, enzyme catalysis, immunological responses, electron transport, phosphorylation, etc.). Enzymes bind and orient reagents, organising the elementary chemical steps and ensuring a high stereoselectivity, as well as selectivity with respect to the reagent, the type of reaction, its localisation, temperature, pH, etc. Not only the elementary steps but whole sequences of reactions are organised in biochemical processes. The selectivity and productivity of biochemical processes reach a level which is only rarely attained in the usual chemistry (for example, polymerisation on immobilised catalysts) precisely by virtue of the high degree of organisation.

This situation is recognised with increasing clarity and there has been a sharp growth of interest in organised systems and their "chemical" functioning in recent years. The characteristics of chemical reactions in liquid crystals, layers, membranes, micelles, clathrates, clusters, etc. are being widely investigated. Organised catalytic systems are being constructed in accordance with the principles of enzyme catalysis and biomimetic processes simulating the operation of biosystems are being developed.

The self-organising systems in which the molecular organisation is induced by the chemical reaction are especially attractive. For example, the colourless molecule of a spiropyran dye with a long hydrocarbon "tail" is transformed photochemically into the merocyanine dipolar coloured form with separated charges, the molecules combining into micelles only in this form. The pohtochemical reaction functions in this instance as a trigger which "switches on" micelle formation.

The reaction can also "switch on" phase transitions (for example, the crystallisation of a solvent on nuclei—the molecules of the reaction product). This principle of the chemical trigger makes it possible, in particular, to increase by many orders of magnitude the sensitivity of the photodetecting systems (for example, in photography). An example of a "natural" chemical trigger is provided by the photoisomerisation of rhodopsin, which induces conformational transformations in the protein opsin, and the latter initiates a cascade of enzymic reactions, which ultimately lead to the generation of a membrane potential and the visual reception of light in the retina of the eye.

The most striking examples of supermolecular organisation have been observed in chemical reactions and crystals. For molecules organised into a crystal, their intrinsic reactivity, which is controlled by the structure of the electron shell, proved to be much less significant for the reaction than the mode of packing—the arrangement of the molecules in the crystal. The mode of reaction is determined by the intermolecular distances in the crystal, the mutual orientation of the molecules, and the spatial symmetry of the crystal. There are a number of examples of the unique selectivity and topological directionality of the reactions in crystals, which are atypical for the usual reactions in liquids or melts. Many organic substances have several (sometimes up to 10–12) crystal-chemical modifications. In fact, one can speak of the creation of a new branch of chemistry—the crystal-engineering chemistry, whose task is to construct crystals programmed for a specified type of chemistry.

Just as striking examples exist in heterogeneous reactions. Thus the Fe(111) plane is 430 times more effective in the synthesis of ammonia from H_2 and N_2 than the (110) plane and is 13 times more active than the (111) plane. On the Pt(111) plane, hexane is converted into benzene, while on the (100) plane cyclic and branched saturated hydrocarbons are formed from hexane. The molecular organisation of crystals or lattice atoms on the surface does indeed "write the script" of the chemical reaction in this instance.

IV. ENERGY DYNAMICS

In terms of the scale of research, energy dynamics occupies a leading place in chemical physics and such research has two major aims. The first aim is to create the theoretical foundations for and to develop the principles of selective, "non-statistical" chemistry ensuring a directed activity and specified reactions of the molecules (plasma-chemical activation, laser "surgery" of the molecules, energy stimulation of reactivity). The second aim is to search for ways of storing energy in the internal degree of freedom of molecules (electronic, vibrational, and rotational) in order to create new lasers, including lasers with solar pumping.

Energy dynamics includes a wide range of problems: selective population of rotational, vibrational, and electronic states, the exchange and transfer of energy between various states within the molecule and intermolecular exchange, and the relaxation of internal energy to kinetic and lattice energy. Here these problems will be considered briefly in terms of the following logical arrangement: the energy dynamics in gases and on the gas–solid surface, where it is possible to differentiate the individual contacts between species and to identify more reliably the physical interactions responsible for the fate of the energy; this is followed by the energy dynamics in van der Waals molecules and clusters as intermediate structures in which many-species interactions are switched on; finally, we have the energy dynamics in large assemblies—in liquids and solids.

1. Energy Dynamics in Gases

This is the most thoroughly developed and most vigorously developing field; the main cause of interest in it is the comparatively small number of contacts between energy-rich species (particularly at low pressures), their long lifetime, and hence good conditions for the storage, control, and utilisation of energy.

The exchange of the electronic energy (*E*) of excited atoms for the vibrational (*V*), rotational (*R*), and translational (*T*) energy of the molecules is a fundamental process in the energy dynamics of plasma, interstellar lasers, and many chemical gas-phase processes. The energy exchange via different channels (*E–V*, *E–R*, *E–T*) and different mechanisms, the time scale of the exchange, and the cross-sections of the channels depend on a multiplicity of causes, the most important of which is the mechanism of the exchange and the topology of the potential energy surface of the initial and final states of the system of interacting partners.

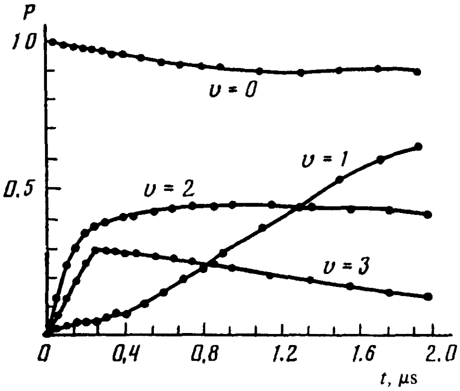

Figure 2. Dynamics of the population *P* of the vibrational states of the hydrogen molecule for $J = 1$ after the laser pumping of Na atoms (in relative units); 570 K, $p_{H_2} = 1$ bar, duration of laser pulse 0.2 μs.

The *E–V* exchange can proceed via a direct "physical" mechanism without the rupture of chemical bonds or via "chemical" mechanisms. Thus the Na($^2P_{1/2}$) atom, with a cross-section almost identical with the gas-kinetic cross-section, transfers its electronic energy to the vibrational-rotational levels of the H_2, N_2, CO, NO, O_2, I_2, C_2H_4, etc. molecules. These processes are investigated by laser spectroscopy: the pulse from one laser pumps the Na atoms (for example, in a mixture of sodium vapour and hydrogen) and the probing pulses of the second laser, with a variable time arrest, probe the populations of the vibrational-rotational states of the H_2 molecules and their time evolution. The Na($^2P_{1/2}$) atom pumps the vibrational state of H_2 with $\nu = 1, 2, 3$ (populations of 13, 61, and 26% respectively) in accordance with complex kinetics, which depend on ν, an example of which is illustrated in Fig.2. It constitutes a complex interplay of processes involving electronic-vibrational exchange between Na and H_2 and the migration of the *V*-energy via the vibrational reservoir of the H_2 molecules. The rotational distribution for different ν depends also on the rotational quantum number *J* (Fig.3), the states with odd *J* being populated to a greater extent than those with even *J*. In the *E–V* exchange between Na($^2P_{1/2}$), on the one hand, and N_2, CO, and NO, on the other, the high vibrational states up to $\nu = 3–5$ (in the interaction with N_2 and CO) and up to 7 (in the interaction with NO) are populated. The CO states with $\nu_{max} = 5$ are populated in the Hg($^3P_1$) + CO process.

It was assumed that the E–V exchange in the A + BC system proceeds via the ionic state $A^+ ... (BC)^-$ and that the ionic energy level intersects the energy levels of the initial and final states, the points of intersection ensuring the resonance energy transfer. However, *ab initio* calculations of the potential energy surfaces (PES) for Na + H_2, Na + N_2, and Na + CO have shown that this mechanism does not operate. The non-adiabatic transitions (the E–V exchange) occur in the region of the intersection of the ground ($^2A_1$) and excited ($^2B_1$) PES in the C_{2v} configuration for Na^*H_2 and Na^*N_2 (Na is attached at right angles in the middle of the H_2 and N_2 bond) and in the $C_{\infty v}$ configuration for Na*CO (linear configuration). In this region the molecules are in the extended phase and after decomposition of the complex remain vibrationally excited.

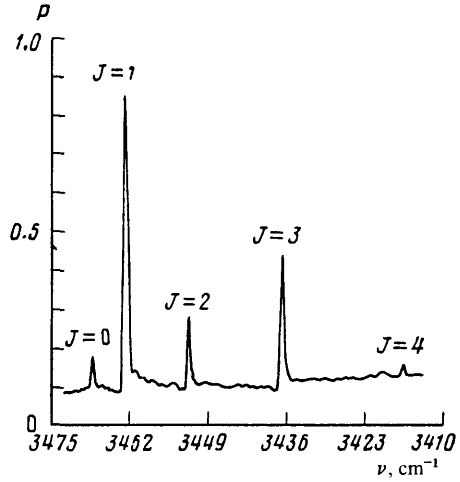

Figure 3. The spectrum of the rotational states of the hydrogen molecule for the $\nu = 3$ level after the laser pumping of Na atoms; delay time 0.5 µs, 500 K, $p_{H_2} = 300$ mbar (P = relative population).

For Na + H_2, the contribution of the "chemical" mechanism of the quenching of an electonically excited atom (via the formation of the hydride NaH) is not more than 0.5%. For the Mg(^{1,3}P), Ca(^{3}P), Sr(^{3}P), and Zn(^{1,3}P) atoms with energies in the range 2–5 eV, the chemical mechanisms involving the formation of the hydrides MH predominate, the reactions occurring via the insertion of the atom in the molecule in the C_{2v} configuration and with rotational excitation of the hydride MH (for example, the states with $J \geqq 30$ are populated in MgH).

The second chemical mechanism is dissociative:

$$Hg(^3P_1) + H_2 \rightarrow Hg(^1S_0) + H + H \ .$$

The energy transfer (the E–E process) makes an important contribution to the quenching, for example:

$$Hg(^3P_1) + Tl(^2P_{1/2}) \rightarrow Hg(^1S_0) + Tl(^2S_{1/2})$$

or

$$Hg(^3P_1) + C_2H_4 \rightarrow Hg(^1S_0) + C_2H_4(^3\Pi_1)$$

with transfer of angular momentum. The E–E processes are important for the pumping of lasers. For example, the functioning of the oxygen–iodine laser is based on the reactions

$$I_2(^1\Sigma_g^+) + O_2(^1\Delta_g, v \geqslant 3) \rightarrow 2I(^2P_{3/2}) + O_2(^3\Sigma_g^-) \ ,$$
$$I(^2P_{3/2}) + O_2(^1\Delta_g) \rightarrow I(^2P_{1/2}) + O_2(^3\Sigma_g^-) \ ,$$
$$I(^2P_{1/2}) \rightarrow I(^2P_{3/2}) + h\nu \ .$$

The conditions for energy resonance are critical for the transfer of the E-energy.

Rydberg atoms (see Section II) are attractive because the conditions for the resonance of small quanta of the E-energy with the V- and R-energies of the molecules are fulfilled in their collisions with molecules and the laws governing the E–E and E–R processes are conveniently investigated in relation to these atoms.

A Rydberg atom can be approximated by a model in which the Rydberg (excited) electron is so remote from the ionic residue of the atom that it can be regarded as a virtually free particle and the collision of the atom with the molecular target can be treated as the interaction of three particles—the Rydberg electron, the ionic residue, and the target particle. It can be accompanied either by the direct E–V or E–R transfer or by the reverse T–E,V–E, or R–E transfer, which increases the quantum number n of the Rydberg atom up to its ionisation threshold. The laser-induced fluorescence and selective-field ionisation methods have been developed for the investigation of these processes.

The interaction of the Xe(27f) atom, in which $n = 27$ for the f electron, with HF proceeds in accordance with the scheme:

$$Xe(27f) + HF(J) \rightarrow Xe(n, l) + HF(J-1)$$

i.e. the HF molecule loses a rotational quantum and the Rydberg atom is excited to the states with $n = 40$ and 41 and different values of l and $|m_l|$. This excitation is very selective: the Xe(n, l) states with $n = 39$ or 42 are absent, since the energy deficiency for them is approximately 5 cm^{-1}, while for $n = 40$ and 41 it is much less: ~1.2 and ~2.1 cm^{-1}.

The interaction of the Xe(27f) atom, in which $n = 27$ for the f electron, takes place for $J \leqq 3$. For $J \geqq 4$, i.e. for a larger store of the R-energy, the atom ionises:

$$Xe(27f) + HF(J) \rightarrow Xe^+ + HF(J-1) + e \ .$$

However, Xe(23f) behaves in a completely different way:

$$Xe(23f) + HF(J=0) \rightarrow Xe(21, l) + HF(J=1) \ .$$

Unlike the previous instance, here the electronic energy is transferred to the rotational levels of the target and the Rydberg atom undergoes partial deactivation with decrease of n. In this case the deficiency of energy resonance amounts to ~1.5 cm^{-1} and this process does not take place with the Xe(26f) and Xe(27f) atoms; although their energies are greater than that of Xe(23f), the resonance deficiency of ~2.6 cm^{-1} completely suppresses this process.

Together with the E–R processes, virtually isoenergetic processes involving no change in n and J also take place, for example:

$$Xe(27f) + HF(J) \rightarrow Xe(27, l) + HF(J)$$

in which the change in the orbital electronic momentum is compensated by the change in the translational energy.

The E–V transfer is a still more markedly resonance process. Thus the Na(ns) Rydberg atom induces a rigorously resonance-type vibrational excitation of CH_4 and CD_4: the transition $5s \rightarrow 4p$ (energy 2930 cm^{-1}) excites only the ν_3 vibration in CH_4 (2940 cm^{-1}), the $6s \rightarrow 4p$ transition (1331 cm^{-1}) induces the ν_4 vibration in CH_4 (1340 cm^{-1}), and the $7s \rightarrow 5d$ transition (975 cm^{-1}) excites the ν_4 vibration (965 cm^{-1}) in CD_4. The orbital angular momentum then changes by $\Delta l = 1$ or 2; processes with $\Delta l = 0$ do not occur. Thus the energy of the transition 8s → 7s coincides with that associated with the frequency ν_4 in CD_4, but this energy resonance is insufficient to effect the $E-V$ process.

These examples contain a small proportion of what is now known about the atomic-molecular energy dynamics and demonstrates merely the multiplicity of factors involved in this problem, the level of its solution, and the pathways leading to it. The same situation exists also in the energy dynamics of molecules: the examples quoted below give merely an idea about the current state of the problem and about the ways in which it is solved and the aims which have inspired the search for such solutions.

The relaxation of small molecules at low vibrational levels has been thoroughly investigated and has been incorporated in textbooks and monographs. Further progress in this field is being directed to complex molecules and high energies: the characteristic features of relaxation, the mechanisms, and the dynamics are being established. For example, Fig.4 shows how the vibrational energy of acetylene "descends" down the levels and is converted into kinetic energy: there is initially a rapid redistribution among the initial vibrational states (less than 15 collisions are necessary to achieve this), after which follows the slow relaxation of the symmetrical ν_2 stretching vibration (~650 collisions are required) to the ν_4 and ν_5 deformation vibrations, which slowly discard the V-energy into the R- and T-forms. A remarkable feature of this approximate picture is the "bottleneck" effect in the ν_2 vibrations, which can store energy for a long time.

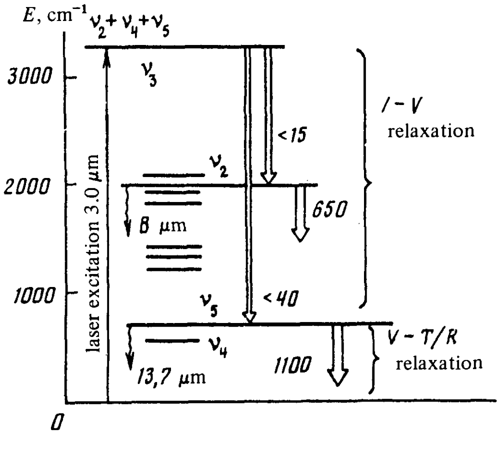

Figure 4. Pathways leading to the relaxation of the vibrational energy in the acetylene molecule among vibrational levels; the numerals against the arrows indicate the number of collisions of the excited molecule required for relaxation from the given level.

Molecules capable of retaining energy are needed for gas lasers and especially for lasers with solar pumping. Natural laser effects are known in the atmospheres of certain planets and the creation of solar lasers constitutes an attractive prospect. The principal requirements which must be met by gases to be used as media in solar lasers are as follows: wide and as far as possible continuous absorption bands to ensure effective pumping; the presence of metastable states and the occurrence of relaxation processes ensuring an inverted population; stability (or capacity for regeneration) of the chemical composition of the laser medium.

In order to find systems capable of transforming solar energy and storing it at excited levels with an adequate density, exceeding the generation threshold, it is essential to know not only the physicochemical structure of the molecules (see Section II), but also their energy dynamics—the lifetimes of the excited states, the mechanisms and cross-sections of the physical and chemical relaxation, and the ways of transforming energy. Examples of solar lasers based on Br_2, I_2, Na_2, Cs_2, IBr, etc. already exist, but their characteristics are far from perfect.

Rotational energy is known to be discarded rapidly, giving T-energy even in collisions with inert gas atoms, since the distances between the rotational levels are small compared with kT. However, for molecules with a small moment of inertia or with a large store of rotational energy (large J), the distances between the rotational levels are comparable to or exceed kT. Under these conditions, the molecule rotates so rapidly that its potential appears to be isotropic to the approaching atom. On the basis of this principle, the atom exhibits a weak perturbation and is ineffective in the $R-T$ relaxation. Because of this factor, the highly excited states of hydrogen halides survive many collisions and lasers based on rotational transitions have been devised using them.

Frequently such molecules with an inverse population of the R levels are formed in photochemical pumping. Thus the photolysis of BrCN at 193 nm yields CN with low E- and V-energies but with a large store of the R-energy (up to 1400 cm^{-1}); the states with J from 30 to 86 are populated under these conditions and the yield of molecules at the maximum of the distribution with respect to J ($J_{max} \cong 60$) is ~4%. These states are metastable (their relaxation by Kr, Ar, N_2, CO, and Xe is relatively inefficient) and are suitable for lasers.

For the majority of polyatomic molecules, the key problem is the intramolecular distribution of energy with respect to the vibrational reservoir. The intramolecular vibrational relaxation (IVR) is a collision-free process resulting from the intramolecular interaction of oscillators—vibrations of different types and having different frequencies. IVR determines the processes leading to the decomposition of molecules and ions on excitation by electron impact or photoexcitation, in chemical activation, and on multiphonon excitation; IVR influences strongly the vibrational and electronic-vibrational fluorescence spectra, chemiluminescence spectra, and the spectroscopy of laser systems.

Excellent methods (picosecond and femtosecond laser spectroscopy) for the generation of coherently pure vibrationally excited states in both electronic ground and electronically excited states have been developed.

A remarkable feature of IVR is the retention of coherence on redistribution and migration of energy among levels, which is manifested by quantum beats, observed on the kinetic luminescence decay curves. The frequencies of the quantum beats are related to the number of levels involved in the energy exchange and the coefficients of the basic vibrational wave functions, from which the overall vibrational wave function of the molecule is made up, can be found from the phase shifts and the amplitude of the modulation of the beats. Furthermore, the Hamiltonian matrix describing the interaction between the oscillators can be found, in principle, on the basis of these beat frequencies and coefficients.

For example, in the anthracene molecule for low vibrational energies (up to 1200 cm^{-1}) there is almost no energy redistribution, the quantum beats are missing, and the vibrational states generated by the laser excitation relax monoexponentially with $\tau \cong 20$ ns. When the vibrational energy store is 1380–1520 cm^{-1}, strong quantum beats appear with a frequency of ~5 GHz, indicating energy migration in which several levels with migration times of several hundreds of picoseconds are involved. For larger energies, rapid monoexponential loss of the coherence of the initial vibrational states takes place owing to the rapid migration of energy with $\tau \cong 20$ ps.

The redistribution of the V-energy is extremely selective: by no means all the vibrational states participate in the energy exchange. Thus, for a V-energy of 1380 cm^{-1}, only three vibrations interact strongly and participate in the energy exchange, while the density of the vibrational levels corresponding to this energy is ~25 per cm^{-1}, which is characteristic also of other energies in the vibrational reservoir. The number of levels participating in the exchange is much smaller than the density of the vibrational states. Such selectivity of the exchange is associated with the fact that the vibrational states are coupled via the anharmonicity of the vibrations and the latter can obey definite symmetry conditions. Thus, for anthracene (D_{2h} symmetry), this implies that the given vibrational state is coupled by anharmonicity to only $^1/_8$ of the total number of vibrational states.

The population of the rotational levels of the given vibrational state accelerates the vibrational migration and the IVR but does not alter the overall features—the coherence and quantum beats are retained. In principle, one may select on this basis the interaction responsible for the IVR—the anharmonicity of the Coriolis forces. Clearly, if the latter make the main contribution to the energy migration, then the beat frequencies must depend greatly on the rotational temperature and conversely, the absence of such dependence may imply a leading contribution by the anharmonicity.

The establishment of the IVR laws is one of the current growing points in energy dynamics. This problem has a direct bearing on the molecular mechanics of vibrations, namely on the question of the relation between coherence and chaos in the vibrational motion of molecules with different stores of vibrational energy. It adjoins the problem of the ergodic nature of molecular systems, which arises in the classical mechanics of Hamiltonian systems of coupled anharmonic oscillators. The famous KAM (Kolmogorv, Arnold, Moser) theorem demonstrates that, for small perturbations (and small energies), the classical movement of anharmonic oscillators is quasi-periodic and regular, whilst for high energies it becomes chaotic. Thus, for the Hamiltonian

$$H=\frac{1}{2}(p_x^2+p_y^2+\omega_x^2x^2+\omega_y^2y^2)+\lambda x(y^2+kx^2),$$

the trajectories (x, y) corresponding to small energies are periodic (Fig. 5b), while for high energies they become chaotic (Fig. 5a); here x and y are the coordinates, p_x and p_y the moments, and ω_x and ω_y the frequencies.

The relative contributions of order and chaos in IVR depend on the store of the vibrational energy, on the anharmonicity constants of the oscillators and their coupling, and on the density of the vibrational levels. The questions how IVR arises—coherently or chaotically—and at what rate are of fundamental importance for chemical dynamics. Both the pathways leading to the dissociative decomposition of the molecule and the energy pumping of the fragments depend on whether the IVR occurs before the decomposition or whether the decomposition overtakes IVR. In the former case the reaction is described by the statistical theory, while in the latter the reaction takes place "non-statistically", selectively.

As a rule IVR predominates in the competition between IVR and the dissociative decomposition. Thus, in the selective laser excitation of CH_2FCH_2Br, the yield of HBr and HF on decomposition of this molecule corresponds to a statistical distribution of the vibrational energy. In the selective pumping of the fifth overtone of the vibrations of the OH group in the $(CH_3)_3COOH$ molecule, the preferential breakdown of the O–O bond takes place; the energy transfer to this bond occurs over a period of ~2 ps, i.e. before the reaction via the O–H bond. In chemical activation via the exothermic addition of the carbene, i.e.

$$F_2C\!-\!CF\!-\!CF\!=\!CF_2 \ (CD_2) \xrightarrow{CH_2} F_2C\!-\!CF\!-\!FC\!-\!CF_2 \ (CD_2)(CH_2)$$

the vibrational energy, localised initially in the right-hand three-membered ring, is found in the left-hand ring after ~1 ps and the reactions of this molecule occur after IVR.

The number of examples of the non-statistical decomposition or vibrationally excited molecules is much smaller, but they open up pathways to photoselective chemistry, to the laser surgery of molecules, and to "non-statistical" chemistry. Naturally, there exist only limited possibilities for controlling the rate of IVR, but even the knowledge of the

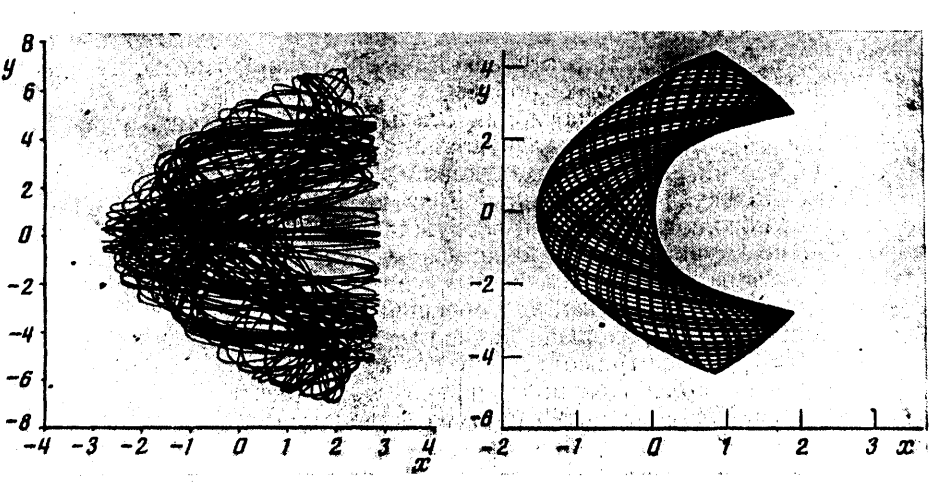

Figure 5. The chaotic (a) and quasi-periodic (b) trajectories $y(t)$ and $x(t)$ of the Hamiltonian H; $\omega_x = 2\omega_y$.

characteristic features of IVR is sufficient to be able to predict which molecules and in which processes are suitable for photoselective chemistry. The identification of the possibilities and principles of the molecular energy organisation of photoselective chemistry is one of the intriguing problems of chemical physics.

The advances in laser spectrocsopy have led to the possibility of investigating the vibrational relaxation of electronically excited states. The method of the ultrasonic expanding flow, in which the flux of molecules with rotational and vibrational temperatures close to the absolute zero is excited by the laser to specific vibrational levels of the electronically excited state and the fluorescence arising from these levels and its decay as a function of time are then detected, has been developed most thoroughly.

The width of the vibronic fluorescence bands increases sharply with increase in the store of the vibrational energy, starting from a certain threshold. This is evidence for a rapid intramolecular vibrational distribution—a rapid escape of vibrational energy from the populated level to a multiplicity of others as a consequence of the anharmonicity of the vibrations and Fermi resonance. When the number of coincident levels (and Fermi resonances) is small, coherent excitation results in the appearance of vibrational quantum beats corresponding to the oscillation of energy between the levels which modulates the decrease of the fluorescence intensity. Incidentally, such beats are also observed in intermolecular energy transfer. Thus, on excitation of HCl in argon, at an overall pressure of 3 bar and an HCl partial pressure of 29 mbar, the $H^{35}Cl$ vibration is pumped at 2963.3 cm^{-1}. Owing to the coherent energy transfer between $H^{35}Cl$ and $H^{37}Cl$ during the time decay of the signal of the trial pulse probing the population of the excited vibrational states, a periodicity (quantum beats) is observed with a period of 15 ps, which corresponds exactly to the difference between the vibration frequencies of the isotopic forms of HCl, amounting to 2.22 cm^{-1}. Under these conditions, the phase coherence is retained much longer, about 50 ps.

If the density of the Fermi resonances is large, there is a pronounced superposition of beats with a large set of frequencies and this situation is referred to as "Fermi bleeding" in IVR. Thus in naphthalene in the S_1 state in the presence of an excess vibrational energy $E_V = 3068$ cm^{-1}, the density of the vibrational levels is about 1600 per cm^{-1}, the distance between the levels involved in the "Fermi bleeding" is about 0.06 cm^{-1}, and the characteristic IVR time is 10–100 ps. In fluorobenzene the energy threshold of the intense IVR is much lower and begins at a density of levels amounting to 40 per cm^{-1}. In this case the Coriolis interaction, involving the rotational levels in IVR, which increases the density of the levels by the factor $2J$ (for rotational quantum number J), makes a significant contribution.

The role of the density of levels in IVR is illustrated by the popular example of molecules of the type

On excitation of the symmetrical vibration at 993 cm^{-1} of the electronically excited benzene ring, the time taken for the store of the V-energy to leak from the ring to the "tail" of the molecule depends on the density of the vibrational states of the "tail", i.e. on the value of n. Thus, for $n = 1$, this time is long, about 900 ns, whereas for $n \geqq 4$, it is reduced to 2–10 ps.

The electronic relaxation of even polyatomic molecules is a much slower process and it is investigated by laser spectroscopic methods with the same high level of "quantification" as the structure of the excited states (see Section II). Thus in benzophenone the electronic energy is lost from the S_1 state (the S_1–S_0 transition) over a period of 50 ps, the transition from the T state to the S_0 state via thermal excitation to S_1 (slow fluorescence) takes place in 1 μs, and the spin-prohibited direct T–S_0 relaxation requires a time of ~1 ms. The rate of relaxation of the E-energy then depends on the store of the vibrational energy in a complex manner. For example, in 9-cyanoanthracene in the presence of an excess of E_V up to 800 cm^{-1}, the quantum yield of the luminescence from S_1 and the luminescence time τ depend little on E_V: $\tau \cong 26$ to 28 ns. When $E_V \cong 1200$–1750 cm^{-1}, both the quantum yield and τ decrease sharply with increase of E_V and, when $E_V \cong 2000$–2500 cm^{-1}, the quantum yield diminishes to 0.1 and τ to 4 ns.

The energy dynamics of the molecules in the gas phase is a multifactorial, multiparameter problem in which none of the factors is of secondary importance: the type of molecules (diatomic, or polyatomic, linear or non-linear), the type of process (intramolecular or intermolecular), the type of energy (E-, V-, R-, or T-reservoir), and the sequence of the energy migration and escape processes (within one reservoir or between reservoirs), the mutual influence of the reservoirs, the anisotropy of the potential of the molecules and the processes ensuring its modulation, the limitations and prohibitions based on the angular momentum, the symmetry and deficiency of the energy, and the rate of movement of the partner species in the region of the overlap of their potentials. The theoretical solution of the problem requires the knowledge of the potential energy surfaces of the ground and excited states and calculations on the dynamics of the motion of the molecular system along the surface—both these problems refer to chemical dynamics (see Section V).

Analogous problems arise in the energy dynamics of the molecules on the surface—namely the problems of the rules governing the transfer of the vibrational, rotational, and electronic energy on impact of the excited molecule against the surface, of which phonons participate in the energy exchange processes (the collective lattice phonon or the localised high-frequency vibrations of the surface atoms), of the ways in which these processes depend on the velocities and masses of the molecules and on the potentials of the molecule and the target, and of the role played by the "roughness" of the surface on the atomic scale.

The greatest experimental progress has been achieved in this instance by the employment of the method of molecular beams, where a monochromatic stream of atoms or molecules in specified quantum states is directed onto the surface and the velocity and angular distribution of the reflected or desorbed species as well as their new distribution among quantum states are then determined. These studies have now assumed a large scale and they are aimed at the fundamental problems of heterogeneous catalysis, the chemistry and physics of surfaces, plasma chemistry, as well as the branches of thermophysics engaged in the questions of the thermal protection of space devices.

2. Migration of Energy in Clusters

The acquisition, storage, and utilisation of energy by molecular systems of finite dimensions (van der Waals molecules, clusters) have become the subject of vigorous investigations quite recently; the interest in this problem is associated with the fact that in such systems the energy spectrum can vary continuously as the dimensions are altered and this leads to the possibility of creating bridges between the energy dynamics of isolated species and the energy dynamics of species in large assemblies (liquids and solids).

The pumping of energy into clusters is achieved by electron impact, by electron capture, or by the laser excitation of one of the species in the cluster. For example, in the van der Waals complex $I_2.He$, the iodine molecule is promoted by the laser to an electronically excited state with an excess of vibrational energy and probe pulses then detect the fate of the energy and the dynamics of its migration. The principal migration pathway is the transition to the low-frequency vibration of the complex and dissociation, for example:

$$I_2 \cdot He(v=7) \rightarrow I_2(v=6) + He\ .$$

i.e. one vibrational quantum is sufficient for dissociation. The time taken for energy transfer from the high-frequency to the low-frequency vibration is fairly long but it decreases sharply with increase of the energy store. Thus, for $I_2.He$ with v = 12, 18, 23, and 25, the time taken for the escape of a vibrational quantum varies in the sequence 200, 100, 50, and 40 ps. Hence it follows that the anharmonicity of the vibrations, which is greater for larger amounts of vibrational energy, is responsible for the energy transfer.

However, this is not the only factor controlling the energy dynamics of clusters. The size of the vibrational quantum, the symmetry and structure of the cluster, the resonance deficiency, and the density of the vibrational states are also important. For example, the time of the vibrational relaxation to dissociative levels is ~100 ps in the $I_2.He$ cluster and ~100 ns in the H_2Ar cluster, i.e. is greater by three orders of magnitude; this is caused by the weaker interaction of the two types of vibrations in $H_2.Ar$ compared with $I_2.He$. For the same reason, the rate of dissociation in the $(HF)_n$ (n = 2 - 6) clusters (the rate at which HF is split off) in the presence of the enormous excess of vibrational energy of 3000 cm^{-1} amounts to only 10^6–10^7 s^{-1}. In the cluster of pentacene with Ar an energy of 300 cm^{-1} in the aromatic ring is converted slowly (over a period of 10–30 ns depending on the number of Ar atoms in the cluster) into the low-frequency vibration modes of the Ar atoms.

The intermolecular energy transfer and relaxation in gases are frequently preceded by the formation of van der Waals molecules or clusters whereupon new and unexpected features appear. Thus, in order to discard an energy quantum of the HCO deformation vibration, not less than 1500 collisions with the N_2 molecule are necessary but only 10 collisions with NO are sufficient. One might suspect that in the latter case a chemical reaction serves as a powerful relaxation channel, but this is not the case, since the reaction is slow and, furthermore, it is retarded on deformation-vibrational excitation of HCO. It is most likely that relaxation takes place in the complex HCO.NO in which the deformation vibration frequencies of HCO and the low-frequency vibrations of the complex itself do not differ greatly and the energy rapidly slows down to the dissociative levels of the complex.

The relaxation of the energy in clusters has begun to be investigated also by the theoretical methods of molecular dynamics. As an illustration of this approach, we shall consider the Ar_{13} clusters in which the electronic energy is "injected" into one of the central atoms. It organises a localised state—the Ar_2^* excimer, where one of the atoms is of the Rydberg type. The dissociation energy of the excimer, the equilibrium state, and the parameters of the Morse potential are known; next, its interatomic interaction with other atoms of the cluster is "switched on" and the molecular and energy evolutions of the cluster are analysed.

The redistribution of the vibrational energy in the cluster is hindered by two factors: (1) the marked difference between the vibrational frequencies of the excimer and the atoms in the cluster; (2) the local expansion of the cluster around the excimer, occurring when the intermolecular potential is switched on, because the repulsive branch of the excimer–argon atom potential is much steeper than the repulsive potential between the argon atoms. As a result of this, the first stage of the energy relaxation is the "explosion" of the cluster—its rapid expansion (over a period of ~200 fs) around the excimer. The second stage is the slow migration of energy to the vibrational mode of the cluster with its localisation at the predissociation levels of the surface atoms; as a result, the atoms "evaporate" from the cluster and the vibration energy is converted into the kinetic energy of the leaving atoms. This process takes place over a period of 10–100 ns.

The characteristic features of the relaxation of the highly excited (Rydberg) atoms in the lattice, the main one being the local "explosion" of the lattice, can be seen from this example; this is important for the problem of the interaction of strong radiations (laser, electronic, and X-ray) with solids (explosive evaporation, surface erosion, etc.).

The energy dynamics of the clusters aroused increasing interest and has been stimulated by the well-founded hope that the fundamental problems of energy relaxation in liquids and solids can be solved on the basis of the cluster energetics.

3. Energy Dynamics in Liquids

The fluxes of vibrational energy in a liquid are controlled by more complex laws than in a gas or a solid. In gases the vibrational pumping and relaxation are regulated by binary collisions—elastic (when the vibrational states of the partner species are not altered and there is only a shift of the phase of the vibrations) or inelastic (where both the vibrational states and phases change). The first process corresponds to phase relaxation, i.e. to the loss of phase coherence (characteristic time T_2); the second process involves energy relaxation—the removal of the energy to the lattice (characteristic time T_1). The T_1 process determines the escape of energy from the vibrational reservoir to the lattice, while the T_2 process constitutes the migration of energy within the vibrational reservoir without its loss to the lattice.

In a solid, both the phase and the energy relaxation can be interpreted as the interaction of a local vibration (or a vibrational exciton) with the phonon spectrum of the lattice (of a crystal or glass), whereupon the approximation of harmonic phonons is frequently satisfactory.

A liquid is too dense for the treatment to be restricted to the approximation of binary collisions but it is not sufficiently ideal to allow the phonon model to be employed. Furthermore, in a liquid there are low-frequency degrees of freedom (of rotation and of oscillation of the centre of gravity) for which $\hbar\omega \leq kT$ and which can be treated in classical terms as well as high-frequency degrees of freedom ($\hbar\omega \gg kT$), which must be treated only in quantum terms.

The phase coherence of the excited states assumes special importance for the energy dynamics in a liquid, where the density of oscillators is high. The rapid loss of phase coherence implies the rapid migration of the energy in the reservoir, whence $T_2 \ll T_1$. The ratio of T_1 to T_2 is important also for another reason—the energy can be extracted in the form of laser emission only under the conditions of high coherence. If the phase relaxation is limited by the escape of energy to the lattice, then $T_1 = T_2$; in this case, each step involving the removal of a quantum to the lattice also implies the loss of coherence.

For a set (packet) of oscillators of one kind (with one frequency and one phase), the absorption or emission line corresponding to the given vibrational transition is homogeneous (or homogeneously broadened) with a width T_2^{-1}. For a set of packets, the line constitutes a superposition of the lines of the individual packets; this is an inhomogeneous (or inhomogeneously broadened) line. The causes of the loss of phase coherence are various. Firstly, there is the microstructural inhomogeneity of the liquid when the oscillators in different local environments and the phases fall out of step at different rates under different conditions. This is especially significant for rapid phase relaxation, where molecular dynamics is incapable of averaging out the microstructural inhomogeneity during a period shorter than T_2. Secondly, there is the resonant transfer of vibrational quanta between oscillators; each step involving the migration of a quantum is accompanied by a loss of phase coherence. Thirdly, the intramolecular interaction of oscillators with anharmonic coupling between them can also become a cause of the system going out of phase: the excitation and relaxation of one oscillator modulate the frequency and phase of another oscillator. Other causes are the vibrational-rotational interaction, Fermi resonance, and the formation of clusters.

In the energy dynamics in a liquid, one can trace the same trend as in clusters: the greater the frequency isolation of the oscillator, the longer the period during which it retains the energy. A striking example is provided by the N_2 molecule in liquid nitrogen for which T_1 at 77 K has the record value of 45–60 s, while $T_2 \cong 150$ ps, i.e. $T_1/T_2 \gg 1$. In the presence of admixtures (CO, CO_2, CH_4, O_2), the relaxation of N_2 is directed to impurities and from them to the lattice. For SO_2 in liquid SO_2, we have $T_1 \cong 45$ ns and it is independent of temperature, while for HCl ($\nu = 1$), $T_1 \cong 1-2$ ns in liquefied HCl and decreases with increase of temperature. The HCl ($\nu = 1$) relaxation cross-section in liquid xenon is 3×10^{-8} and is almost the same as in a gas for collisions with argon atoms. In CH_3F, the ν_3 vibration has a relaxation time of 375 ns in liquid O_2 and 1300 ns in liquid argon.

In polyatomic and "low-frequency" molecules, the relaxation times are shorter by several orders of magnitude and lie in the picosecond range. Thus the CH stretching vibrations in CH_2Cl_2 and CH_3COCH_3 lose energy over periods of 50 and 65 ps and these are nevertheless long times, because the deformation vibrations are of the low-frequency type and the Fermi resonance is suppressed. In CH_3OH, the second overtone of the CH_3 deformation vibration has virtually the same frequency as the stretching vibration and the Fermi resonance shortens the relaxation time of the stretching vibration to 1.5 ps. In ethanol, the Fermi resonance is slightly weakened and T_1 increases to approximately 20 ps. In $CHCl_3$, $T_1 \cong 115-140$ ps and depends on temperature; for SF_6, $T_1 = 27$ ps in liquid oxygen and 160 ps in liquid argon.

The vibrational relaxation of polyatomic molecules as a rule takes place in two stages: (1) rapid redistribution of energy among the vibrational modes (or their combinations) within the molecule over a period of 1–2 ps and (2) slow escape of energy from the vibrational reservoir to the lattice over a period of tens or even several tens of picoseconds. For example, in anthracene and azulene, the intramolecular migration of energy via vibrations takes place over a period of 1–2 ps and the removal of energy to solvent molecules takes 20–40 ps.

Rapid intramolecular energy fluxes are associated with a high density of the vibrational states and a strong interaction (via anharmonicity and Fermi resonance). Thus, for molecules containing ~30 atoms, the density of the vibrational levels is ~10^6 per cm^{-1}. The slow relaxation is associated with the transfer of the *V*-energy to the librational and translational degrees of freedom of the solvent molecules and this reservoir is "disconnected" from the vibrational reservoir as regards frequencies.

The study of the energy relaxation in large molecules in both ground and excited states has steadily advanced to the femtosecond region; the aim of such advance is to find new possibilities for laser-coherent effects and for selective "non-statistical" chemistry.

The theory of vibrational relaxation in a liquid has developed predominantly in two directions. The first originated from the gas model of binary collisions into which "collective" elements are introduced—correlations of pairs, triplets, etc. The second direction employs the model of collective movements and the rate of relaxation is determined in terms of the Fourier components of the correlation functions of the non-diagonal matrix elements of the perturbing Hamiltonian. A purely hydrodynamic theory based on model representation of a species "trembling" in a viscoelastic medium has also been developing; the theory reproduces collectively the effects of viscosity and density, but it is too simplified to reproduce all the characteristic features of the relaxation. An approach based on the generalised Langevin equation (see Section III) has also been developed. In all cases the theory is based on intermolecular interactions and the relaxation is a result of a complex interplay of attractive and repulsive forces; the prediction of the result of this interplay and the determination of its rules and characteristics is a complex and serious combined problem in molecular and energy dynamics.

4. Energy Relaxation in Solids

The relaxation and transfer of electronic energy in solids (especially in crystals) is a thoroughly developed field of physics and chemical physics with long traditions. The principal laws governing the transfer and quenching of energy and the mechanisms of its degradation have been formulated, the dependences of the transfer cross-sections on the oscillator strengths, on the distances between the donor and the acceptor, and on the orientation of the dipole moments of the optical transitions of the donor and acceptor are being refined, and the characteristic features of the electronic relaxation in excimers and exciplexes are being investigated. The aspects of this problem associated with photosynthesis, phosphors, and solid lasers are developing particularly vigorously.

In vibrational relaxation, the main problem is the dynamics of phonon excitations and the relaxation of the vibrationally excited impurity centres as reflected in the phonon spectrum. The lifetimes of the optical phonons in crystals are measured by coherent laser spectroscopic methods; thus in diamond their lifetimes T_1 are 2.9 and 3.4 ps at 295 and 77 K respectively and the A_{1g} vibration of the CO_3^- anion in $CaCO_3$ relaxes over a period of ~3 ps.

The relaxation of impurity centres is of interest for the same reasons that the centres themselves are of interest (see Section II). The "burning of holes" in an inhomogeneously broadened spectrum (optical or vibrational), i.e. the saturation of optical or vibrational transitions for the given packet of centres of molecules, is used for their investigation. Conclusions about the rates and mechanisms of relaxation and about the contributions of the T_1 and T_2 processes to the relaxation are reached on the basis of the elemination of the "hole".

Direct results can be obtained from the spectroscopy of impurity centres in single crystals. For example, the width of the lines in the vibrational spectrum of SiF_6 in a xenon single crystal at 14 K is 0.028 cm^{-1}; it is homogeneously broadened, i.e. all the SiF_6 molecules in the xenon crystal are identical and constitute a single vibrational packet. The line width is determined by T_2, i.e. by the loss of phase coherence as a result of the phase falling out of step in the elastic scattering of the lattice phonons by the vibrations of the impurity centres (SiF_6 molecules).

Furthermore, it is possible to discover which phonos are responsible for the phase relaxation. At low temperatures (14–50 K), the temperature dependence of the line width (T_2^{-1}) is described satisfactorily on the assumption that the local phonons with the following parameters are responsible for the phase coherence: frequency 4 cm^{-1}, lifetime 8 ps, constant for the coupling of the SiF_6 vibrations to local phonons 0.08. At high temperatures (>50 K), the bulk-phase (Debye) phonons of the crystal play the main role with a coupling constant of 0.05 and a frequency maximum of 42 cm^{-1} (this corresponds to a Debye temperature of 62 K). For ReO_4^- in ionic crystals of alkalis, the line width is also determined by T_2^{-1} and the phase coherence is lost to Debye phonons.

One of the new aspects of the energy dynamics in solids is the relaxation of charge carriers and excitons in semiconductors. For example, the pulse excitation of carriers (duration of pulse 50 fs) in the GaAs superlattice (65 periods in GaAs having a thickness of 96 Å with barrier layers of $Al_{0.3}.Ga_{0.7}As$ having a thickness of 98 Å) generates a packet of excited carriers, whose relaxation takes place over a period shorter than 100 fs. The average energy of the carrier then remains unaltered, i.e. only energy exchange between the packet of excited carriers and the remaining carriers in the conductivity band takes place during 100 fs. The elimination of energy and the descent of the carriers to the bottom of the conductivity band take place over a period of the order of picoseconds (over a period of ~5 ps in GaAs) and the relaxation to the valence band requires ~7 ps.

The examples presented here are few in number but they demonstrate the high technical level of the experiments and the high time and frequency resolution. Little has been done as yet in energy dynamics in solids, but progress in this field is constantly accelerating.

V. REACTION DYNAMICS

This is the science of the development of chemical processes in time, which constitutes the central component of chemical physics. It answers or attempts to answer fundamentally important questions such as which reactions can occur and which are prohibited, in what ways and by what means is it possible to remove the prohibition, how chemical reactions can be controlled, and how the rate and direction of the reaction can be influenced. Chemical dynamics is the fundamental basis for the creation of new and the improvement of existing technologies. A second important aspect of chemical dynamics is analysis of the ways of transforming energy in elementary reactions in order to search for high quality chemical laser systems.

1. Potential Energy Surfaces and Theories of Reaction Dynamics

The task of the theory is the development of methods for the calculation of rate constant or cross-sections for specified quantum states of the reacting species; potential energy surfaces (PES), i.e. the dependence of the total energy of the reacting atomic-molecular system on the coordinates of the atoms, are needed for this purpose. The PES is the "conductor" of the chemical reaction, controlling the trajectories of the transitions from reactants to products and determining the reaction channels, the reaction cross-sections, and the distribution of energy in the product.

The calculation of PES is the first problem of chemical dynamics. Non-empirical (*ab initio*) computational methods are being developed; they are laborious, since they require the calculation of a large number points on the surface, but the main difficulties are associated with the correct allowance for the electronic correlation energy. Furthermore, subsequent employment of this PES in the calculation of trajectories requires an analytical, functional representation of the entire PES (which is virtually impossible) or of its section in the vicinity of the trajectory to be calculated. Semiempirical quantum-chemical methods are also being developed (for example, the method of diatomic complexes in the molecule—DCM), but the most popular are the even simpler methods based on the familiar London equation for the energy of a triatomic system. Among them, the LEPS (London–Eyring–Polanyi–Sato) PES is widely used. Semiempirical methods for the calculation of the one-dimensional profile of the reaction path from the reactants valley to the products valley are also known (for example, the "bond energy–bond order" method); it is useful in approximate calculations where only the rate constants are of interest and the entire PES need not be known.

Examples of PES for the $O + H_2$ reactions are presented in Fig.6. For linear $O(^3P) + H_2$ collisions, the forms of the PES obtained by the *ab initio* and DCM methods differ. The crossing point in the former is displaced towards the valley of the initial reactants and in the latter towards the valley of the products. This difference is of fundamental importance for the possibility of activating this reaction and the fate of the energy. It is seen from Fig.6*c* and 6*d* that the PES for the reaction $O(^1D) + H_2 \rightarrow OH + H$ with a linear configuration of the atoms and for the insertion reaction $O(^1D) + H_2 \rightarrow H_2O$ differ sharply from the PES for the $O(^3P) + H_2$ reactions.

The accuracy of the PES is a painfully acute problem in chemical dynamics: any errors in the calculation and distortions in the PES entail marked deformations of the trajectories. The reaction trajectories and cross-sections are so sensitive to the details of the PES that one frequently resorts to the solution of the converse problem: the trajectories and cross-sections are assumed on the basis of a calculated PES and then the results of the calculations are compared with reliable experimental data and the PES is "corrected" until "satisfactory" trajectories reproducing the experimental data are obtained.

The construction of the PES is the first part of chemical dynamics; the second part involves the calculation of the trajectories in the movement of the reaction system on the surface. If the calculation is based on the equations of classical mechanics, then the procedure is called the method of classical trajectories; if the quantum states of the internal degrees of freedom (rotations and vibrations) are taken into account in the equations, then the trajectories obtained are assumed to be quasi-classical in the sense that their initial conditions take into account the quantum character of the rotations and vibrations, but they do not represent rigorous solutions of the quantum equations of motion.

Examples of quasi-classical trajectories for the reactions $C(^1D) + HI \rightarrow CH + I$ and $C(^1D) + HI \rightarrow CI + H$ are presented in Figs.7*a* and 7*b*. Both trajectories describe the mutual approach of three atoms (the C atoms move along the normal to the centre of the H–I bond) with formation of a complex having a lifetime of ~0.8 ps along the first trajectory and ~0.4 ps along the second. The periodic changes in interatomic distances, i.e. bond vibrations (between 0.5 and 1.3 ps) are very marked in the complex; the highest frequency is that of the C–H vibration and the lowest frequency is that of the C–I vibration. The lifetime of the complex is comparable to the time required for the intramolecular migration of the vibrational energy (see Section IV) and its statistical distribution therefore holds in the reaction products.

The trajectories of the same reactions occurring in a linear collision do not reveal the existence of a complex. They have the form typical for the generalised reactions A + BC → AB + C (Fig. 7c). The absence of a long-lived bound state in such reactions is the cause of the non-statistical distribution of energy in the products.

The method of quasi-classical trajectories does not take into account the quantum effects of the motion and of the tunnelling under the barrier. Such problems do not arise in quantum calculations, being exotic rather than usual. The experience gained in the calculations has demonstrated that the introduction of quantum corrections to the quasi-classical trajectories with a one-dimensional potential barrier is insufficient and that it is necessary to solve the problem with a multidimensional barrier and that a method capable of describing the classical movement of the reactants along the PES over long distances and tunnelling over short distances is needed.

Definite advances have been made on these lines: a method of complex trajectories has been developed, within the framework of which it is possible to combine the mutually exclusive concepts of tunnel and classical trajectories. A complex trajectory becomes real when the real time is replaced by the imaginary time ($t \to it$) and the PES is replaced by the inverted PES ($U = -U$). In this method there are difficulties associated with the choice of the boundaries and contour of the trajectories, but overall it is an effective procedure whereby one can obtain "quantum" results from quasi-classical equations of motion.

Calculation of the trajectories on a single PES is frequently insufficient, since there are several PES in very close proximity in individual regions or even quasi-intersecting. The unusual problem of allowing for the non-adiabatic nature of the process, i.e. for the "jump" of the reaction system

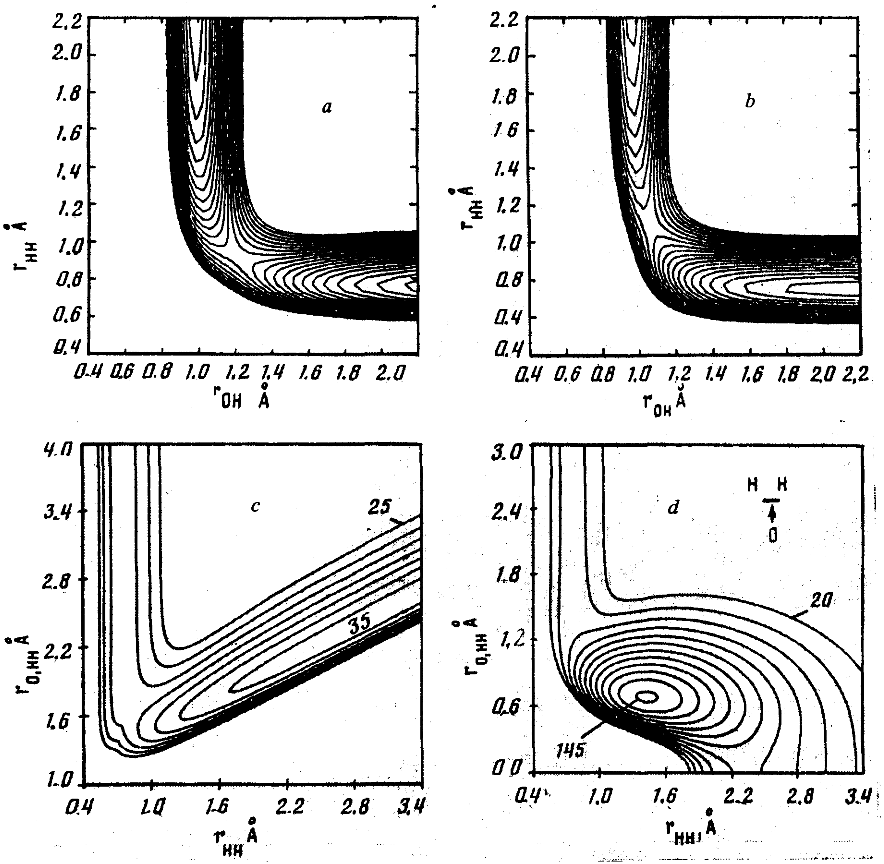

Figure 6. The potential energy surfaces for the O + H_2 reactions: *a*) non-empirical PES for $O(^3P)$ + $H_2 \to OH + H$ (linear complex, r^*_{OH} = 1.216 Å, $r^*_{H_2}$ = 0.920 Å, 12.58 kcal mol^{-1} barrier); *b*) PES obtained by the DCM method for $O(^3P) + H_2 \to OH + H$ (linear complex, r^*_{OH} = 1.061 Å, $r^*_{H_2}$ = 1.103 Å, 13.35 kcal mol^{-1} barrier); *c*) PES obtained by the DCM method for $O(^1D) + H_2 \to OH + H$ (linear complex, $r_{O,HH}$ = distance from O to the centre of the H–H bond, $r^*_{O,HH}$ = 1.66 Å, r^*_{HH} = 0.78 Å, 0.80 kcal mol^{-1} barrier); *d*) PES obtained by the DCM method for $O(^1D) + H_2 \to H_2O$ (complex with C_{2v} symmetry, reaction involving the insertion of O in the centre of the H–H bond, no barrier). Constant energy lines have been drawn from 1 to 20 kcal mol^{-1} at 1 kcal mol^{-1} intervals (for *a* and *b*), from 35 to 25 kcal mol^{-1} at 10 kcal mol^{-1} intervals (for *c*), and from −145 to 20 kcal mol^{-1} at 15 kcal mol^{-1} intervals (for *d*); r^* = coordinates of the apex of the barrier.

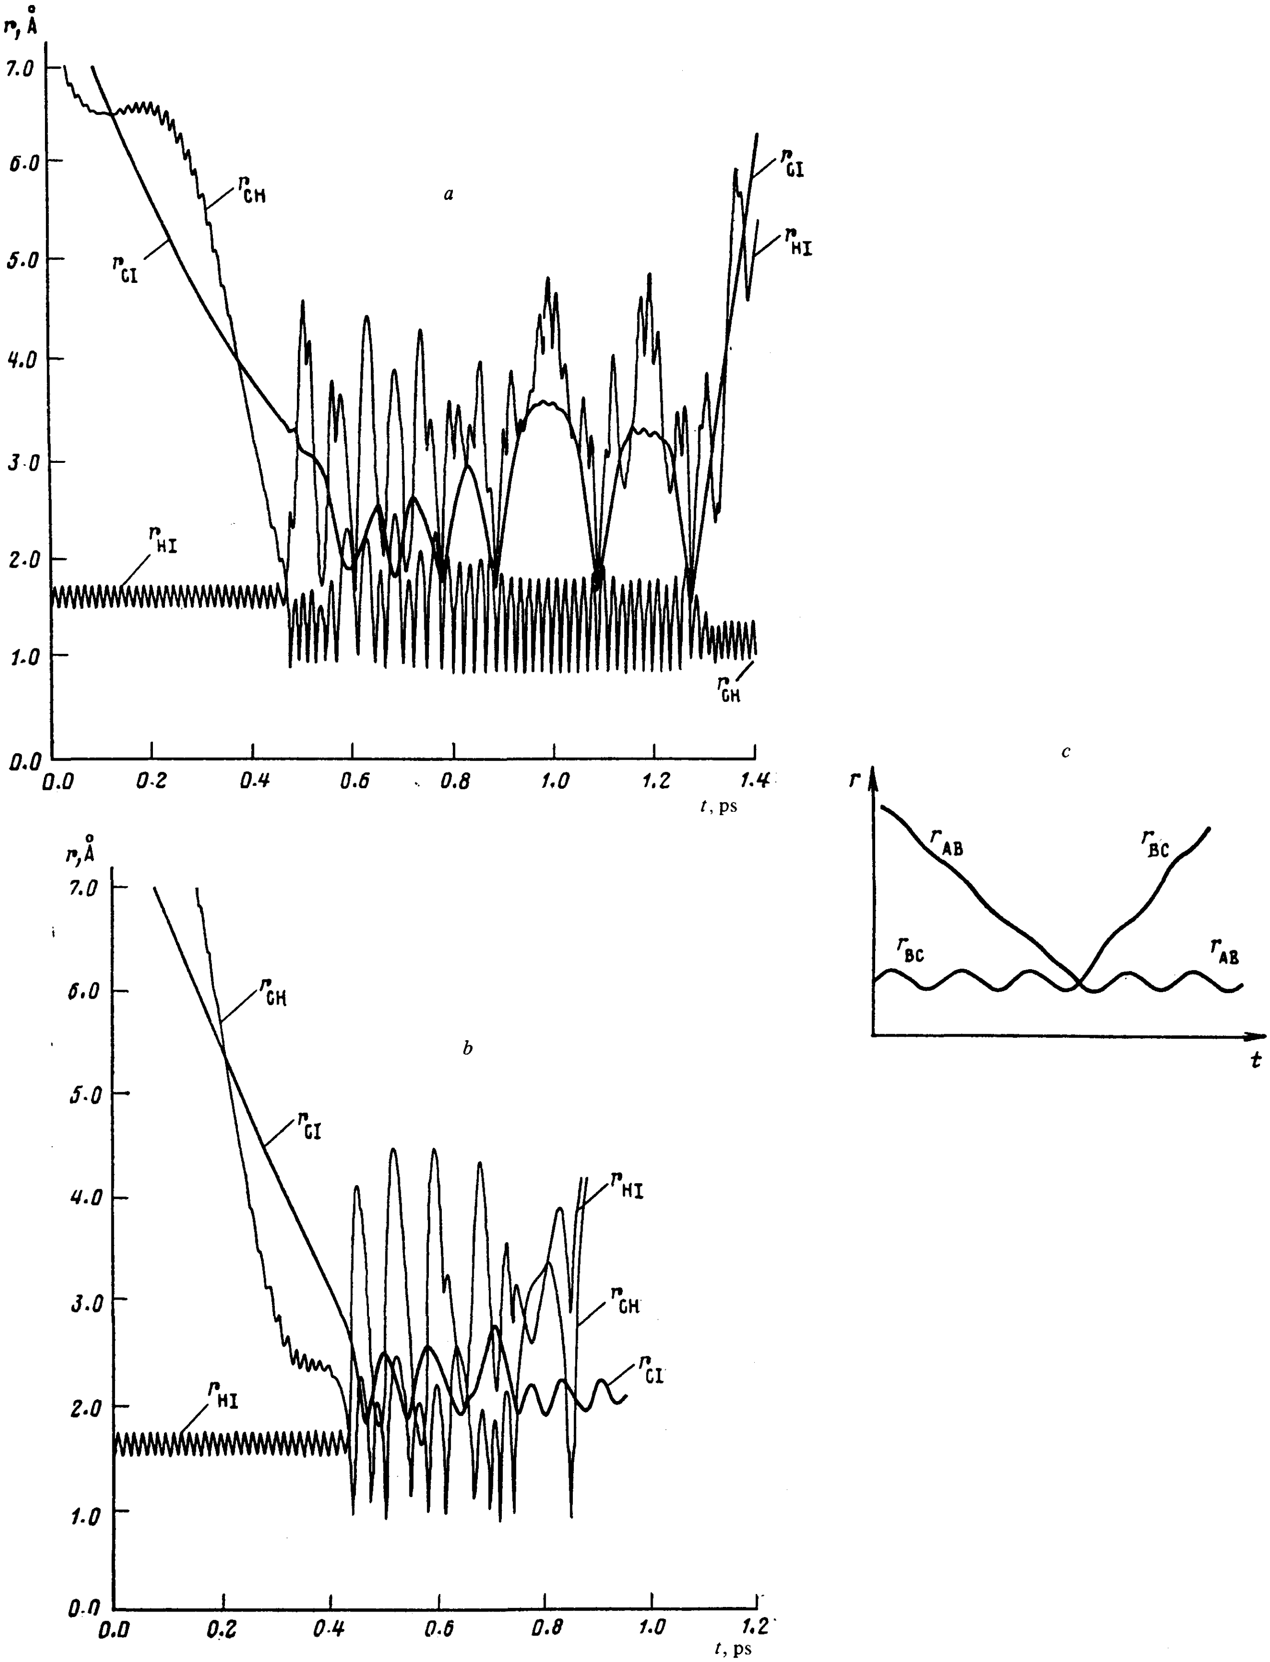

Figure 7. Examples of reaction trajectories: *a*) for $C(^1D)$ + HI → CH + I; *b*) for $C(^1D)$ + HI → CI + H; *c*) generalised trajectory for the forward reaction A + BC → AB + C.

between different PES in regions where they approach one another or quasi-intersect, then arises. Such jumps distort the reaction trajectories and allowance for them constitutes a serious problem in chemical dynamics.

In trajectory dynamics, account is taken of many trajectories for a given reaction (by no means all cross the bridge between the reactants valley and the products valley), and then the overall reaction cross-section in the specified states of the reactants is obtained by averaging the results with respect to the initial (starting) conditions governing the trajectories; one of the popular methods of selecting the initial conditions (but not the only one) is the Monte Carlo method.

Dynamic trajectory calculations yield the most complete information about the chemical reaction and provide answers to the following questions: what reaction channels exist, what are their probabilities, how is the energy of the reactants utilised in the reaction, how is it redistributed in the products, and at which modes of the motion is it localised. However, they are laborious and are by no means always fully realisable, being used predominantly for the simplest reactions. Simpler versions of the theory are therefore being developed, among which the method of the reaction pathway Hamiltonian merits special attention.

In this version of the theory, the classical Hamiltonian of the molecular reaction system is constructed and the reaction pathway as well as orthogonal oscillations (deviations from the reaction pathway in the closest regions of the PES along the pathway) are found. In principle, this approach makes it possible to carry out calculations for polyatomic systems and has definite practical advantages: the entire PES is not needed, only a small proportion of the latter being required (the region corresponding to the valley on the reaction pathway), but these advantages entail the sacrifice of the physical rigour and completeness of the calculation.

Together with dynamic trajectory theories, statistical theories are also being developed in chemical dynamics. They are suitable for reactions proceeding via a long-lived intermediate complex (resembling those which can be seen on the trajectories in Figs.7*a* and 7*b*). The formation of the complex and its decomposition are then independent events. If during the lifetime of the complex τ_c, a statistical distribution of the energy takes place (subject to the conservation of the energy and the momentum), then the reaction complex can be treated as a statistical system and its behaviour can be described in terms of statistical laws.

The criterion which determines whether the reaction can be described by the statistical theory is not always definite; it is frequently assumed to be represented by the condition $\tau_c \gg \tau_{rot}, \tau_{vib}$, i.e. the lifetime of the complex is longer than the rotational and vibrational relaxation times. However, this condition is not unambiguous and statistical theories are frequently applicable even if this condition is not fulfilled and, conversely, they are not applicable when it is fulfilled. In order to predict the properties of the reaction complex, it is important to know the behaviour of van der Waals molecules (Section II), while information derivable from energy dynamics is important for the prediction of its "statistical nature" (Section IV).

The transition state theory is frequently included among statistical theories; strictly speaking, this is not correct, because the configuration of the atoms at the top of the crossing ridge (it is referred to as the transition state or the activated complex) decomposes only via the direct channel and is not a statistical system. This is associated with the fact that one degree of freedom, corresponding to the reaction coordinate, has been differentiated in the method itself (in its physical aspect) and, by definition, it is isolated from the other degrees of freedom of the reaction system. On the other hand, in the transition state theory an equilibrium distribution is adopted, but it is a consequence of the equilibrium nature of the initial reactants. In other words, it leads to the activated complex together with the reactants but is not created in it and in this sense the claim that the transition state theory belongs to the class of statistical theories can be regarded as correct.

In the transition state theory, there is no dynamics of motion along the PES, only the knowledge of the energy spectrum of the reaction system moving along the PES being required. During its long history, the theory has received new formulations and justifications and many versions of this theory have been created: the canonic theory [calculation of the rate constants $k(T)$], the microcanonic theory [calculation of the cross-sections $\sigma(E)$], the variational theory (ensuring allowance for only the one-way reaction trajectories), the adiabatic transition state theory (it takes into account the quantum-mechanical partition functions and tunnel corrections), and, finally, the variational quantum-mechanical (or generalised) theory.

At the present time the transition state theories are the most productive, although they are more in the nature of recipes and not all their approximations are reliable. It has been demonstrated for a large number of collinear reactions over a wide temperature range that the rate constants usually agree with the quantum-mechanical calculations and with experiment to within an error not greater than 30%, although there are instances where the discrepancies in the constants amount to a factor of several tens and hundreds and it is not possible to estimate *a priori* this artibrary aspect.

The question when does the description of the reaction require dynamic trajectory calculations and when are statistical theories sufficient is a problem in statistical and non-statistical, selective chemistry. It is important especially in the chemistry of highly excited states; the emphasis laid on this problem is a tribute to technical progress. Hence follows the sharp increase of interest in ergodic systems. Chemical dynamics is beginning to adopt on a wide scale the approaches based on the ideas of the ergodic hypothesis, theories of order and chaos in chemical reaction systems are being developed, and problems of the chemical dynamics of periodic, oscillating reactions are being discussed. The endeavour to move outside the framework of adiabatic models and to develop effective methods whereby non-adiabatic conditions can be taken into account is associated with these factors.

The chemical dynamics of reactions in the condensed phase adds a new problem to all the difficulties and problems of gas-phase dynamics—that of allowing for the influence of the medium whose molecules act on the atomic-molecular reaction systems and are, strictly speaking, participants in the reaction and the question to what number of participants can the treatment be restricted has no definite answer. The first attempt to solve this problem arose in the familiar Kramers theory based on the solution of the equation of diffusional motion along the reaction coordinate. This theory introduced the concept of friction along the reaction pathway and was later developed in different versions—on the basis of the Fokker–Planck equation in terms of various approximations (Kramers himself obtained his initial equation in terms of the Stokes–Smoluchowski approximation—see Section III) and then on the basis of the Langevin equations. It was shown that the Kramers theory can also be obtained from the simple Langevin equation, i.e. subject to the condition that the random force acting from the direction of the molecules of the medium on the reaction system moving along the reaction coordinate is described by a Markov process. The generalised Kramers theory can be obtained from the generalised

Langevin equation and is equivalent to the problem of the attainment of the apex of a one-dimensional potential barrier by a Brownian particle when the random force is described by a non-Markov stationary Gaussian process. The generalised Kramers theory is then equivalent to the generalised transition state theory. The physical significance of the analogies is clear—the molecules of the medium (thermostat) act as a perturbing trajectory of the motion of the reaction medium along the reaction coordinate. The prospects for the development of a theory based on the quantum-mechanical version of the generalised Langevin equation have also been considered, but this is a difficult problem requiring the knowledge of the nature of the thermostat and of the details of the interaction of the reaction system with the thermostat at the quantum-mechanical level.

There have been definite advances in the development of theories of charge transfer reactions; they are based on the idea of the reorganisation of the medium as a result of fluctuations in dielectric polarisation. Such reorganisation produces potential wells and barriers, i.e. produces a potential surface, and this process is described by the classical theory, while movement along the reaction coordinate can be described within the framework of any dynamic theory (in particular, a purely tunnel version can be considered for electron transfer). A generalised quantum-mechanical-classical theory, in which the classical treatment of the movement of nuclei is combined with the quantum-mechanical description of the movement of electrons is also being developed.

The state of the theory of chemical reactions in the condensed phase is such that the theory and experiment are developing almost independently; the theory predicts merely general qualitative features but is incapable of making quantitative predictions. The difficulties are associated with the fact that many important details of the physics of the reactions are obscure—it is not clear what is the main factor which needs to be taken into account and what is of secondary importance and negligible in the theory.

2. Energetics in Reaction Dynamics

This problem has two aspects. The first involves the question of how the reacting molecules utilise the energy supplied to them, what energy is most effective and for what reactions, and under what conditions do the molecules employ their energy with the maximum benefit for the reaction. These questions have a direct bearing on the selective pumping of the energy to the degrees of freedom responsible for movement along the reaction coordinate—the control and stimulation of selected reactions. The second aspect involves the questions how energy is liberated in the chemical reaction, where it proceeds, where and in what forms it is localised, and how can it be concentrated and utilised. These questions have a bearing on the creation of laser media and effective pumping procedures in chemical lasers.

In principle, the answers to the majority of these questions are provided by trajectory calculations, but the laborious nature of the calculations and the limited accessibility of the PES has stimulated an alternative, experimental procedure, involving the use of modern laser spectroscopy, which makes it possible to produce and detect molecules in any quantum-mechanical states.

We shall deal first with the first set of questions—the ways of controlling reactions by pumping energy to the reacting species. These questions have no general answer; it depends on the type and topology of the PES, on the type of reaction, on the value of the energy, and on the type of the energy reservoir—*E*, *V*, *R*, or *T*.

When the electron reservoir is pumped up, electronically excited states are created, but even they exhibit a selectivity in reactions: each type of reaction is stimulated only by an electronic excitation of a definite type. The pumping of energy into the electron shell by no means stimulate every reaction despite the enormous amount of energy stored. One of the problems is to discover the nature of the selectivity, to learn how to predict it, and to employ it economically in the photostimulation, radiation-stimulation, and plasma-stimulation of processes.

The question of the relative contributions of the kinetic and vibrational energies to the activation of reactions is important. Thus, for reactions with a large barrier, there exists a kinetic energy threshold above which the reaction cross-section increases to a maximum and then diminishes. For endothermic reactions, the vibrational energy is much more effective than the kinetic energy, while for exothermic reactions the opposite situation obtains. The vibrational pumping of molecules is of special interest for two reasons: the vibrational energy relaxes with difficulty (at any rate much less easily than the kinetic and rotational energies) and should therefore be retained for a long time in the vibrational modes; the availability of powerful lasers operating in the vibrational-frequency range makes the question of practical significance.

The efficiency of vibrational energy in reactions depends on the heat of reaction, on the topology of the PES, on the height of the barrier, on the size of the vibrational quantum, on the adiabatic conditions, on the type of reactions (transfer of an atom, metathesis), on the complexity of the molecules, on the density of the vibrational states, on whether the reaction is of the direct, single-step type, or whether it proceeds via an intermediate statistical complex. Only one important feature has been reliably established and justified theoretically: the vibrational excitation is effective in overcoming the endothermic component of the potential barrier and hardly influences the overcoming of the barrier in thermally neutral and exothermic reactions. Its origin is inherent in the topology of the PES: for endothermic reactions, the barrier is encountered at an "early" stage, being displaced towards the initial reactants valley, while for exothermic reactions the barrier occurs at a "late" stage, being displaced towards the products valley.

For example, the reactions $Ca(Sr) + HF \rightarrow CaF(SrF) + H$ are accelerated by a factor of 10^4 already by the first vibrational quantum absorbed by HF, while the reaction $F + HCl \rightarrow HF + Cl$ with vibrationally excited HCl ($\nu = 1$) is accelerated only by a factor of 4. The reaction $CH_3 + H_2 \rightarrow CH_4 + H$ with participation of $H_2(\nu)$ is accelerated, while the excitation of CH_3 can accelerate, suppress, or altogether fail to influence the reaction, depending on the type of vibration excited. In the reaction $K + HCl \rightarrow KCl + H$, $HCl(\nu = 1)$ molecules react 100 times faster than $HCl(\nu = 0)$ and only 10 times faster if the same amount of energy is "thrown" into the kinetic degrees of freedom. In the reaction $OH + H_2 \rightarrow H_2O + H$, the $H_2(\nu = 1)$ molecules react 150 times faster than $H_2(\nu = 0)$, but the acceleration in the pumping of OH to the $\nu = 1$ state is only by a factor of 1.3. Neither the pumping of OH nor the pumping of CO alters significantly the rate of the reaction $OH + CO \rightarrow CO_2 + H$, while the reaction $O_2 + CN \rightarrow CO_2 + N$ is actually retarded by the pumping. The excitation of the HCO vibrations inhibits the HCO + NO reaction and this is evidence that it proceeds via a statistical complex.

An enormous number of such facts and observations exist for gas-phase reactions and by no means all have been explained satisfactorily. In the condensed phase the problem in activation is complicated by the rapid vibrational relaxation (see Section IV). There are very few data for reactions on solid surfaces (for example, it is known that the reaction $N_2O + Cu \rightarrow CuO + N_2$ is accelerated by a factor of 10^3-10^4 when vibrationally excited N_2O molecules participate in it), but this field will develop vigorously.

The influence of rotational pumping on reactions has been investigated mainly by the method involving the selection of rotational states in quadrupolar fields and by laser methods. The rate constants $k(J)$ for the reactions $Na + HF \rightarrow NaF + H$ and $Na + HCl \rightarrow NaCl + H$ decrease with increase in the rotational quantum number J to $J_{min} = 11$ (for the first reaction) and 7 (for the second), and then increase with increase in $J > J_{min}$. The reaction $K + RbF \rightarrow KF + Rb$ is exothermic, $k(J)$ falling with increased J; the reaction $H + OH \rightarrow H_2 + O(^1D)$ is also exothermic, but $k(J)$ increases with increased J. The rotation of OH accelerates the reaction $NO + OH \rightarrow NO_2 + H$, while the rotation of NO accelerates the reaction $NO + O_3 \rightarrow NO_2 + O_2$. In the reaction $H + HBr \rightarrow HBr + H$ with $v = 0$, J does not influence the reaction, but, when $v = 2$, the constant $k(J)$ increases with increasing J, i.e. the effect of the rotational R-energy depends on the vibrational state. The reaction $Br + HBr \rightarrow HBr + Br$ with HBr ($v = 0$) is insensitive to J up to $J \leq 10$, but is accelerated sharply for $J > 10$.

The influence of the R-energy depends on the kinetic energy: for a high kinetic energy (above the threshold), the influence of the R-energy is insignificant, which is understandable: for high rates, the time of contact between the species is much shorter than the period of the rotation and the rotational state of the reactant becomes insignificant for the reaction. The inhibition of the reaction by rotation, i.e. the decrease of $k(J)$ with increase of J, is also understandable to a first approximation: the reaction requires a definite orientation of the reactants, an appropriate orientation throughout the contact time, while rotation disrupts this arrangement. This is the effect involving the gyroscopic stabilisation of molecules: a rapidly rotating molecule averages out the perturbing potential of the incoming partner and this "saves it" from reaction.

However, these are only the few features which are understandable; much remains obscure and difficult to predict. The principal factor is apparently the ratio of the angular velocity of the rotating molecule to the relative velocity of the movement of the partners—it determines the efficiency of the R-energy in the reaction and so far there is no general solution to this problem.

An attractive problem involves the search for non-traditional and sometimes non-evident methods of controlling reactions using energetically weak influences. This is possible in systems with degenerate states, which, however, differ in reactivity. Then even weak influences induce almost isoenergetic transitions from one less reactive state to another, more reactive state. This is in fact the principle of magnetic influences on chemical reactions (see Section VI); this is also possible in laser chemistry, where the direction of the reaction can be altered by weak coherent radiation.

The idea can be illustrated by an example: suppose that the molecule decomposes into different products for a certain energy, which means that it possesses a series of degenerate continuous states, each of which is correlated with a definite composition of the products. The key question is how to intensify the selectivity of the molecules in relation to these states—how to achieve their selective population. This requires the control of the composition by a coherent linear superposition of these degenerate states. It can be achieved if the initial molecule is prepared by coherent irradiation with superposition of bound states and is then dissociated in a specified state. This idea has been realised experimentally in the photolysis of CH_3I via two channels:

$$CH_3I \rightarrow CH_3 + I(^2P_{1/2})$$
$$CH_3I \rightarrow CH_3 + I(^2P_{3/2})\,.$$

Using two-frequency laser irradiation (one frequency for the superposition of the coherently bound states and the other for photodissociation via one or other channel), it is possible to increase by a factor of two the quantum yield of the decomposition for an unchanged energy expenditure and to alter the competition between the channels. This is in essence the first example where energetic coherence has been manifested in chemical reactions.

We shall now turn to the second range of questions, concerning the fate of the heat of reaction. A most attractive procedure is to convert the heat (when it is sufficient) into an "intensive" form of energy—electronic energy. The efficiency of the electronic pumping into the reaction product depends on many factors—the magnitude of the heat of reaction, the orbital and spin prohibitions, the quasi-intersections of the PES, and the non-adiabatic nature of the trajectories on the PES. For these reasons, the quantum yield of the electronic pumping in different reactions (usually determined from the chemiluminescence yield) varies by many orders of magnitude—from 10^{-11} to ~1. It is important to establish the characteristics of the electronic pumping for the prediction of laser effects. They are widely investigated in the flames of metal vapours in CO, N_2O, O_2, O_3, etc. atmospheres, in the reactions of alkali metal atoms with halogen molecules, in the recombination of the N, O, etc. atoms on surfaces, etc. The search for chemical laser systems is one of the most vigorously developing fields of chemical physics.

The vibrational pumping of products is determined also by the topology of the PES: if there is an attractive potential between the reactants and the ridge separating the valleys occurs at an "early" stage, i.e. is displaced towards the reactants valley, the kinetic energy of the reactants is converted preferentially into the vibrational energy (V-energy) of the products; for a repulsive potential and a "late" ridge, the energy liberated remains in the kinetic form. Adiabatic conditions with respect to both ΔV and ΔR are frequently retained, i.e. the vibrational and rotational energies of the initial reactants are fully retained in the products. General characteristics have been scarcely established in this field hitherto, the adiabatic (or non-adiabatic) conditions, depending on the energy stored, the topology of the PES, and the vibrational-rotational coupling. For example, in the reaction $Cl + HD \rightarrow HCl + D$, the rotational energy is retained, while in the similar reaction $Cl + HD \rightarrow DCl + H$, the rotational energy of the initial molecule is converted almost fully into the kinetic energy of the products.

The energy pumping of the product frequently serves as the criterion of the reaction mechanism. Thus the reaction $Cs(7P_{1/2,\,3/2}) + H_2 \rightarrow CsH + H$ proceeds via the harpoon mechanism: the optical electron of the excited Cs atom is thrown like a harpoon from Cs to H_2 over long distances and the $Cs^+ + H_2^-$ ion pair is maintained as a result of the Coulombic potential and decomposes slowly into CsH and H. This mechanism agrees with the dynamic trajectory analysis of the PES on which the ionic and covalent energy levels "intersect". An important consequence of this mechanism is the strong rotational excitation of CsH: J_{max} reaches 17 and the maximum pumping has been achieved for $J = 10-12$.

The photolysis of H_2S in the gas phase at 193 nm leads to the formation of an H atom with an HS radical in the $^2\Pi_{3/2}$ or $^2\Pi_{1/2}$ states, their ratio being 3.75, which corresponds to an electronic temperature of 410 K. Vibrational excitation is almost completely absent and the rotational temperatures of the $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ states are 375 and 220 K, i.e. the electronic and rotational temperatures are close to the temperature of the photolysis, which means that the energy of the photolysing quantum is converted into the kinetic energy and the decomposition takes place non-statistically. The opposite case is represented by the decomposition reaction $CF_3NO \rightarrow CF_3 + NO$. The distribution of CF_3 and NO with respect to v is nearly statistical and the rotational temperature of NO ($^2\Pi_{1/2}$) is 900 K and is very close to the statistical limit of 1025 K; the *V*- and *R*-energies of CF_3 and NO are close to this limit. The times corresponding to the appearance of CF_3 and NO at 670, 640, and 500 nm are 18.5, 8.8, and 4.3 ns and agree with the lifetimes of the "energised" CF_3NO molecules measured independently. Clearly, CF_3NO decomposes via a long-lived statistical complex.

The present experimental level of research into pathways leading to energy pumping is demonstrated by the analysis of the energy states of the products in the following reactions:

$H+O_2 \rightarrow OH+O; \quad \Delta H = 16.6 \text{ kcal mol}^{-1};$
$H+CO_2 \rightarrow OH+CO; \quad \Delta H = 25.4 \text{ kcal mol}^{-1};$
$H+H_2O \rightarrow OH+H_2; \quad \Delta H = 14.8 \text{ kcal mol}^{-1}.$

All these reactions are endothermic, but the H atoms generated by the photolysis of HI are hot and the energy of the collision of H with its reaction partners (O_2, CO_2, H_2O) is 60 kcal mol^{-1}, which greatly exceeds the endothermicity. Despite the high collision energy in the $H + CO_2$ and $H + H_2O$ reactions, there is no vibrational excitation of OH (there are none in states with $v = 1$), but in the $H + O_2$ reaction there is significant vibrational pumping: the population of OH ($v = 1$) is only a factor of 2 smaller than the population of OH ($v = 0$).

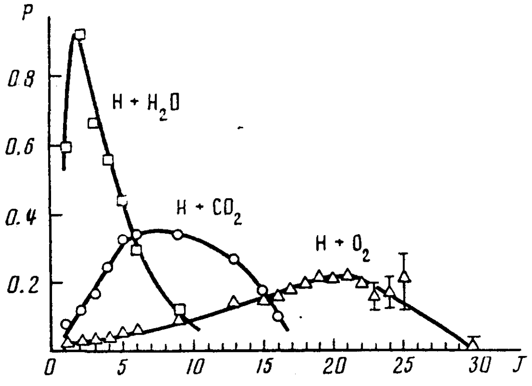

Figure 8. The populations *P* (in relative units) of the rotational states of OH ($v = 0$) in the reactions of a hydrogen atom with H_2O CO_2, and O_2 (pressure 0.2 mmHg, probing pulse delay time 100 ns).

The rotational excitation of OH in the $H + O_2$ reaction is very hot (*J* is large—Fig.8), while in the $H + H_2O$ reaction it is virtually absent, although the energetics are the same. In the $H + H_2O$ reaction the rotational distribution does not correspond to the statistical distribution, while in the $H + O_2$ reaction the statistical distribution obtains but this does not mean that the reaction can be treated statistically. This agreement is fotuitous: trajectory calculations have shown that the transition complex HO_2 on the non-empirical PES in the vicinity of the ridge has a lifetime of ~0.1 ps and the distribution of the rotational energy agrees with the experimental distribution in the absence of statistical equilibrium.

The spin-orbit doublets $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ are populated statistically, but the population of the Π^+ component of the Λ doublet takes place preferentially in all three reactions by a factor of 3–6. This means that an angular momentum is generated in all the reactions in the plane containing the bond undergoing dissociation, i.e. that the output channel in these reactions lies in a single plane. Otherwise, an angular momentum would have been created in the reaction around the bond being dissociated and this would have entailed the preferential population of the Π-component of the Λ doublet.

These features of the dynamics and energetics of all three reactions presented are associated with the characteristics of their PES and indicate how effectively the PES "conducts" both the chemical and energy dynamics.

3. Chemical Kinetics and Reaction Mechanisms

Chemical kinetics as the science of process rates and mechanisms is part of reaction dynamics; it has long outgrown their traditional framework and has reached a new level. Formal kinetics has been converted into a routine technique, the new level of modern kinetics being determined by the wide-scale application of a wide variety of physical methods permitting the reliable identification of the majority of intermediate species with a high time resolution (down to tens of femtoseconds). Reliable methods, characteristics, and criteria have been developed, whereby it is possible to achieve a sufficiently full determination of any mechanism.

The knowledge of the mechanism is not the ultimate aim; it is necessary to determine the rate-limiting stage, to establish the main and secondary pathways, and to select the method of controlling the process in order to increase its productivity and selectivity. The knowledge of the mechanism is the most important element on the way to creating intensive highly selective and energy saving chemical technologies.

A considerable proportion of chemical physics is devoted to kinetic studies and chemical mechanisms. It is concerned with the mechanisms of the reactions in molecular beams, ion-molecule reactions, the reactions of excited species, oxidation-reduction reactions, metal complex, acid–base, heterogeneous, micellar, and enzyme catalysis, and electrochemical reactions. Priority has been given to catalytic processes, plasma chemistry, combustion processes, reactions in solids, and processes associated with chemical energetics (new current sources, chemical methods for the accumulation and transformation of energy, etc.). Among them, we may mention the creation of new combustion regimes—the solid-phase oxygen-free combustion (self-propagating high-temperature synthesis), the creation of a "superadiabatic" regime with extremely high effeciencies approaching 100%, and combustion coupled with energy consuming processes. In the chemical physics of solid-phase reactions, valuable low-temperature chemical "explosions", induced by the mechanical stresses in strongly cooled glasses, and the quantum-mechanical limits of the rates of low-temperature reactions have been discovered and new types of mechanochemical processes, induced by shear deformation at high pressures and by shock waves, have been observed. There has been a sharp growth of interest in the problem of the macroscopic storage of mechanical energy and the utilisation of this store for the activation of chemical processes is a tentative basis of promising technologies.

A remarkable property of chemical reactions in solids has been established—even in the kinetic regime the reactions are controlled by the molecular dynamics of the solid so that the molecular organisation of the transition state and not the chemical step proper becomes the rate-limiting stage. This alters, in principle, the concept of the reactivity of species in a solid and leads to new ways of controlling reactions via the physics and mechanics of the solid.

VI. SPIN DYNAMICS

Spin dynamics includes the dynamics of the populations of the spin states of atomic-molecular species and matter, the dynamics and mechanisms of the pumping and relaxation of spin states, and the dynamics of the change of the angular momentum. It can be subdivided into two components—spin dynamics in systems without a chemical reaction and spin dynamics in reactive systems.

The first component is the traditional field adjoining magnetic resonances and magnetic resonance spectroscopy as a method in chemical physics. It includes an enormous number of problems—magnetic relaxation of electrons and nuclei, the dynamics of spin systems in UHF and microwave frequency fields, the exchange of magnetic energy between the Zeeman and magnetic-dipolar reservoirs, joint electronic-nuclear relaxation and the orientation of nuclei (dynamic nuclear polarisation), electron–electron relaxation and electron–electron double resonance, spin–orbit coupling and its contribution to the spin dynamics, and the spin relaxation and transition between the spin states of triplet moelcules, ions, carbenes, metal complexes, clusters, etc. A special branch of spin dynamics is associated with the optical orientation of electrons and nuclei: these phenomena are known in gases, in plasma, in molecular crystals, in impurity centres of a solid, and recently also in liquids.

Spin dynamics is controlled by magnetic perturbations and their time variation, being determined by the amplitude of the perturbation and the duration of its action and it therefore carries simultaneously information both about the structure and about the dynamics of the perturbations (molecular or chemical information). This is important for magnetic microwave spectroscopy as a physical method for structural analysis and for the identification of chemical species and substances and also for magnetometry (including quantum-mechanical magnetometry).

However, spin dynamics can be sensitive also to non-magnetic, purely electrostatic interactions. For example, the rate of singlet–triplet conversion in the carbene Ph_2C depends on the polarity of the solvent. This is possible owing to the Coulombic polarisation of the electron shell (on complex formation, solvation, etc.); this effect can alter the contribution of the spin–orbit coupling to the spin relaxation and can alter the spin dynamics. Another example: the electron-spin relaxation of the Na, K, Rb, and Cs atoms in the inversely populated state $^2S_{1/2}$ depends greatly on the nature of the "buffer" gas (He, Ne, H_2, CH_4, NH_3, C_6H_6, etc.). The cause of the effect is as follows: in the impact of an atom against the buffer molecule, Coulombic forces induce an orbital moment, while the spin–orbital coupling induces in its trun spin relaxation. Here not only the rate of relaxation but also the extent of the hyperfine magnetic interaction of the electron with its nucleus in the metal atom depends on the nature of the buffer gas. Thus highly polar molecules diminish the hyperfine interaction constant, because, in strong collisions between an atom and such molecules, the electron shell of the atom is polarised and a *p* orbital with a zero-point hyperfine interaction becomes mixed with the spherically symmetrical *s* orbital.

The dynamics of the exchange of the angular momenta (orbital and spin) between the molecules play a significant role in many processes, including the functioning of lasers. For example, in the iodine laser with emission based on the transition $I(5^2P_{1/2}) \rightarrow I(5^2P_{3/2}) + h\nu$, the inverse population is restored in the process $I(5^2P_{3/2}) + O_2(^1\Delta g) \rightarrow I(5^2P_{1/2}) + O_2(^3\Sigma_g^-)$, i.e. the electron-spin momentum is transferred from oxygen to the angular momentum of the iodine atom.

The spin dynamics in chemically reacting systems ensures an even greater richness of phenomena. In chemical reactions prohibitions based on the angular momentum (both orbital and, especially, spin momentum) are very strong, i.e. reactions requiring a change in the angular momentum are strictly prohibited; only reactions which are not accompanied by a change in momentum are allowed. The evidence for this postulate is numerous and reliable. Thus molecular, ion-molecule, and even radical substitution and addition reactions in solutions are not accompanied by the polarisation of the nuclear spins, which is a feature of the change in the electron spin. Even in reactions with participation of atoms with strong spin–orbit coupling, the spin is retained:

$$F(^2P_{1/2}) + Br_2 \rightarrow FBr + Br(^2P_{1/2})$$
$$F(^2P_{3/2}) + Br_2 \rightarrow FBr + Br(^2P_{3/2})$$
$$Br(^2P_{3/2}) + IBr \rightarrow Br_2 + I(^2P_{3/2})$$

(these reactions are significant in gas lasers based on halogen atoms).

The rigour with which the spin is retained and the rigour of the spin prohibitions of chemical reactions are evident from simple physical considerations alone. The intrinsic time of the elementary reaction is a fraction of a picosecond and magnetic or spin–orbit perturbations exerting an enormous force are necessary to alter the spin during this period. As a rule, such high-energy perturbations do not occur in the transition states of reactions. For this reason, spin is conserved in the vast majority of chemical reactions. Exceptions may be expected only in rare cases [for example, in reactions with a long-lived statistical complex (see Section V)]. The spin prohibitions in chemical reactions are stronger than the energy prohibitions: the latter are statistical in character (an energy fluctuation sufficient to overcome the barrier can always occur), while the former are absolute.

The existence of spin prohibitions has long been suspected, but their importance and scale have been estimated only recently and their consequences observed—magnetic effects in chemical reactions: the influence of weak magnetic fields on photophysical and photochemical processes in molecular solids, the influence of magnetic fields on chemical reactions, the dependence of the reaction rates on the magnetic moments of the nuclei of the reactants (the magnetic isotope effect), chemically induced dynamic nuclear polarisation, the microwave frequency maser-chemical effect, chemically induced magnetic electron polarisation, and the influence of high-frequency electromagnetic fields on chemical reactions. The discovery of these effects is a striking illustration of the definition of creativity as a way of converting the unpredictable into the inevitable. Fairly soon after their discovery, these effects passed from the class of intriguing incomprehensible phenomena to the class of self-evident phenomena with a simple and clear physics.

In order to remove the spin prohibition, i.e. in order to alter the spin, long-acting magnetic perturbations are needed. An example of long-lived states with magnetic interactions is provided by a pair of two radicals in which two unpaired electrons can exist in two spin states—singlet or triplet. The generation of molecules from the singlet pair is spin-allowed, while the generation from the triplet pair is prohibited. The reaction in the triplet pair stops and "waits" until magnetic interactions (Zeeman, hyperfine, or dipolar) alter the spin pairing and cause its transition from the triplet to the singlet states. In this spin-prepared pair prohibition of the reaction has been removed and reaction restarts. Thus the source of magnetic effects is the spin selectivity of chemical reactions.

Long-lived states with magnetic interactions are realised in pairs with participation of radicals, triplet molecules, electrons, paramagnetic holes, ions, and solitons—all are species with unpaired electrons. Magnetic interactions induce in these pairs transitions between various spin states and remove the prohibition of spin-selective chemical reactions in such pairs. Magnetic effects are therefore observed in varied processes—photoconductivity and photoluminescence, dark conductivity of organic semiconductors, the annihilation of broken bonds in mechanically deformed inorganic semiconductors, photosynthesis, changes in the rates of chemical reactions and product yields, etc.

Magnetic perturbations in pairs, which removes the spin prohibition, depend on the external magnetic field and are a source of magnetic field effects. They also depend on the magnetic electronic-nuclear interaction, on the magnetic moment of the nuclei, and on the magnetic spin and its projection—a dependence which leads to the magnetic isotope effect and to chemically induced nuclear polarisation. When the polarisation of the nuclei is high (and it can reach record values in the range 10^4–10^6 which are unobtainable in physics) and exceeds the generation threshold, the movement of the nuclear spins becomes coherent and a new property of chemical reactions is observed—the ability to generate a microwave frequency field, i.e. the chemical reaction becomes a kind of molecular quantum generator with chemical pumping—a chemical maser.

The spin state of the pairs and hence their reactivity can also be altered by the action of high-frequency fields. This leads to new possibilities for controlling chemical reactions and for developing new magnetic resonance methods; appreciable advances have already been made on these lines.

Quantum beats have been observed in the triplet–singlet conversion in the pairs and hence in the reactivity of these pairs and in the yields of the chemical products of their reactions. Ways of controlling the coherence of the spin dynamics of pairs with the aid of high-frequency fields have been found; this is the second example where coherence "operates" in chemistry (for the first, see Section V).

We may note a difference between the spin and magnetic effects. Spin effects, i.e. spin prohibitions, exist in all the states of matter—gases, liquids, solids, and plasma. However, in gases and plasma the duration of contact between the species is 10^{-13}–10^{-14} s and is too short for the occurrence of the magnetically induced spin conversion of the pairs. Only in liquids and solids are the spin effects accompanied by magnetic effects, since only under these conditions is the lifetime of the pairs of reacting species comparable to the spin evolution time and magnetic forces act for a sufficiently long time to alter the spin.

The spin evolution of pairs is induced via two channels. The "useful" channel includes evolution as a result of the Zeeman and hyperfine interactions and leads to all the magnetic effects enumerated above. The second channel includes the spin evolution induced by the dipolar interaction of the electrons and the spin–orbit coupling. It depends little on the magnetic field and involves the nuclear-spin system to only a slight extent and for this reason it makes possible the "leakage" of the spin states, lowers the scale of the magnetic effects and in this sense it is "harmful" and difficult to control.

Control of spin dynamics is one of the important problems of chemical physics: the scale of the magnetic effects depends on it. Thus the magnetic isotope effect and the efficiency of the separation of magnetic and non-magnetic isotopes in chemical reactions are determined by the spin, molecular, and chemical dynamics. In other words, they depend on the spin evolution and the competing processes involving the dissociation of pairs into isolated species (molecular dynamics) and the chemical reaction of the pairs, which restrict the spin evolution time. However, the problem is not only that of creating favourable "physical" conditions for spin evolution (adequate magnetic interactions, optimum lifetimes of the pairs, favourable molecular dynamics, minimum "leakage" via the harmful channel) but it is also necessary to "organise" chemistry and chemical reactions with respect to the specified physics (to create the required pairs with an intense Zeeman or hyperfine interaction, to specify a favourable starting spin state of the pairs, and to drive the reactions via the specified pathway). Clearly the problems of controlling spin dynamics are the problems of controlling the physics and chemistry of reactions.

Spin dynamics has two remarkable advantages: the first is that it reliably controls chemical reactions in the pairs and in its turn is itself controlled by weak magnetic interactions with negligibly small energies. This factor leads to non-traditional ways of controlling many physicochemical processes with the aid of weak magnetic and electromagnetic influences.

Pairs of spin-containing species, in which long-acting magnetic perturbations operate, altering the spin state of such pairs, are not the only type of magnetosensitive systems. Another type comprises electronically excited molecules or ions in which there is a set of energy states with different spin multiplicities. During the lifetime of these excited molecules, magnetically induced conversion takes place between these energy states, including conversion to predissociation levels at which the molecules decompose. This leads to a dependence of the luminescence and the decomposition of the molecules on the magnetic field. Effects of this type have been observed in the gas phase (where the lifetime of the excited molecules are sufficiently long) and they constitute one of the new fields in the chemical physics of gas-phase reactions.

VII. CONCLUSION

A reader with a rigorous viewpoint will say that the limits of chemical physics outlined in this article have been enormously extended, and he is right: in by no means all the fields and problems mentioned here has a leading position been attributed to chemical physics. Many of them are being worked out and solved in related chemical sciences—physical and quantum chemistry, the chemistry of high energies, electrochemistry, photochemistry and radiation chemistry, biochemistry, the chemistry of high-molecular-weight compounds, etc. Chemical physics overlaps (and this is natural) with solid state physics, molecular physics, biophysics and, to an especially great extent, physical and quantum chemistry. However, when one is dealing with the physics of chemical processes, the physics in chemistry, then one is concerned with chemical physics—it is its characteristic feature and reliable criterion.

There is an interesting feature in the development of chemistry. The traditional chemical and chemical engineering fields, which constitute the basis of chemical industry (petrochemistry, the manufacture of fertilisers, fundamental organic synthesis, etc.) have been established and have developed almost independently of chemical physics. However, new fields (microelectronics, laser and plasma chemical technologies, modern catalysis, chemical lasers, modern chemical materials science, modern analysis and diagnostics, etc.) are firmly based on chemical physics and the development of future or predicted fields (such as molecular electtronics, the new generation of superconducting materials, chemical bionics, organic ferromagnetics, etc.) is altogether unthinkable without chemical physics.

The current emphasis, priorities, and growing points in chemical physics have been noted in various sections of the present article; they can be generalised and grouped around the following principal fields:

Physical principles governing the creation of new materials with new or extreme properties;

control of chemical processes and the development of chemical and physical principles of the control of reactivity and chemical dynamics—the "tuning" of reacting species to a specified reaction and a specified rate;

energy dynamics, the creation of new chemolasers and methods for the transformation and accumulation of chemical energy;

the principles of molecular organisation, chemical dynamics, and the functioning of molecularly organised systems as a basis of a new generation technology.

Mössbauer Studies of Tunnel Phenomena in Chemical and Biological Physics

V.I.Gol'danskii

The combination of various methods based on the use of the Mössbauer effect, namely the traditional Mössbauer absorption spectroscopy, Mössbauer emission spectroscopy, and the Rayleigh scattering of Mössbauer emission, has made it possible to observe a series of characteristic features of the kinetics of intramolecular oxidation-reduction processes (in relation to the conversion of Turnbull's blue into Prussian blue) and to investigate the dynamic properties of biopolymers over a wide range of temperatures and degrees of hydration.

A very important role of tunnel processes was discovered in both cases—the intramolecular tunnel electron transfer (electronic-nuclear tunnelling) and the phonon-stimulated tunnelling of atoms and atomic groups respectively.

The bibliography includes 75 references.

I. INTRODUCTION

A characteristic feature of the current employment of isotopes in various natural sciences is the fact that not only the radioactivity itself but also the properties of the radioactive decomposition (its rate and mechanism) and of the radiation emitted (energy and hyperfine spectra, absorption and scattering, angular correlations etc.) serve as sources of physicochemical information.

Many types of transformations of atomic nuclei and elementary particles are known (they are listed in Table 1), in which various effects of the atomic, molecular, and crystal environment are manifested and all the effects can be used to study this environment, especially its structural and dynamic properties.

Table 1. The transformations of atomic nuclei and elementary particles observed with the aid of radioisotopes and the effects of the atomic, molecular, and crystalline environments manifested in such observations.

Transformation	Effect
Electron capture	Changes in lifetime
Isomeric transitions (with internal electronic conversion)	Changes in conversion coefficients and lifetime
Mössbauer isomeric transitions	Changes in structural and dynamic parameters of Mössbauer spectra
Cascade transitions ($\gamma\gamma$, $\beta\gamma$, etc)	Perturbation of angular correlations
Emission of γ-rays or particles by polarised nuclei	Perturbation of the angular distribution of the emitted γ-rays or particles relative to the direction of spin
Annihilation of positrons	Changes in the lifetime of positrons and of the number and the angular and energy correlations of the annihilated γ-quanta

Two phenomena in the physics of atomic nuclear and elementary particles where the influence of the properties of the environment—the Mössbauer effect and the annihilation of slow positrons—are strikingly observed, have been particularly vigorously investigated by the Structure of Matter Division of the Institute of Chemical Physics at the USSR Academy of Sciences.[1-4] A wide range of our investigations has been devoted to the development and application of chemical Mössbauer spectroscopy (MS). We began with the most traditional method—Mössbauer absorption spectroscopy (MAS), but subsequently the range of methods employed was extended and included also Mössbauer emission spectroscopy (MES), the Mössbauer spectroscopy of conversion electrons (MSCE), and the Rayleigh scattering of the Mössbauer emission (RSME).

In the present review we shall consider the application of MES and RSME to the study of tunnel phenomena in chemical and biological physics, namely the intramolecular tunnel electron transfer and the phonon-stimulated tunnelling of atoms and atomic groups in biopolymers. Thus we proceed from two directions—we apply various Mössbauer methods (MES and RSME in combination with MAS), investigate various objects, sometimes widely differing in their nature, namely inorganic coordination compounds and bio-organic macromolecules. Nevertheless the results obtained are closely related and supplement one another; they all deepen and extend our understanding of tunnelling processes and thus fall within the general range of studies of the tunnel effect in chemistry, electronic-nuclear and molecular tunnelling, and the low-temperature quantum limit of the rates of chemical reactions.[5-8]

II. STUDIES OF THE INTRAMOLECULAR TUNNEL ELECTRON TRANSFER BY THE MES METHOD

We shall begin with the use of Mössbauer spectroscopy (MES and MAS) in the study of the spatial and time delocalisation of electrons in molecules or more complex systems.[9] It is evident that, if we are dealing with a system of two potential wells separated by a barrier (Fig.1), then the electronic levels located above this barrier belong to neither the left-hand nor to the right-hand well and describe the system as a whole. For the sub-barrier levels, the situation is more complex.

We shall consider, for example, the simplest case of the behaviour of the electron in two identical potential wells, where it occupies one of the sub-barrier levels. It can be seen that in this case one could assume that the electron is either in the left-hand well (wave function ψ_l) or in the right-hand well (wave function ψ_r). However, neither of these positions of the electron (i.e. its spatial localisation) corresponds to the eigenstate of such a system. The eigenstates are symmetric $\psi_s = (1/\sqrt{2})(\psi_l + \psi_r)$ or antisymmetric $\psi_a = (1/\sqrt{2})(\psi_l - \psi_r)$ combinations of the wave functions ψ_l and ψ_r with energies differing by $\Delta E_{as} = \hbar/\tau$.

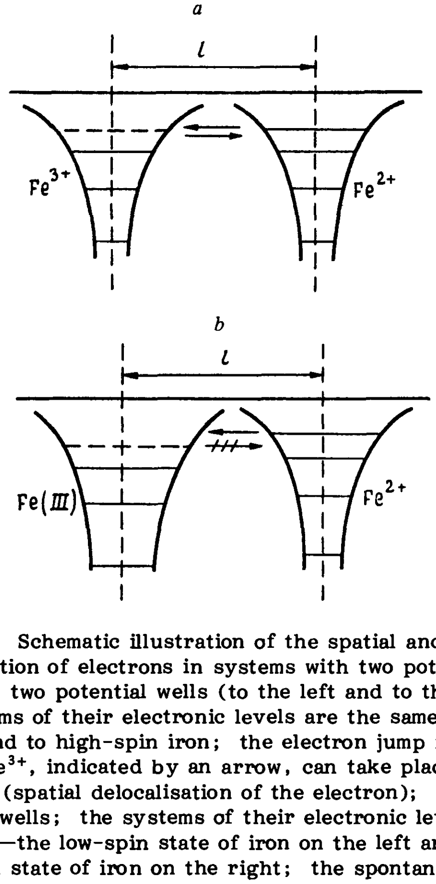

Figure 1. Schematic illustration of the spatial and time delocalisation of electrons in systems with two potential wells: *a*) two potential wells (to the left and to the right); the systems of their electronic levels are the same and correspond to high-spin iron; the electron jump from Fe^{2+} to Fe^{3+}, indicated by an arrow, can take place in either direction (spatial delocalisation of the electron); *b*) two potential wells; the systems of their electronic levels are different—the low-spin state of iron on the left and the high-spin state of iron on the right; the spontaneous electron transition from the upper level can take place only from right to left.

The energy splitting is thus related to the characteristic localisation time τ or, in other words, to the time required for the oscillation (jump) of the electron between the left-hand and right-hand wells. Only if the time τ is large compared with the characteristic time of the measurement by the given experimental method (τ_{exp}) is it possible to observe the spatial localisation of the states ψ_l and ψ_r.

For example, if the electron is in a system where two identical potential wells are represented by two high-spin tervalent iron ions Fe^{3+} (the ions *a* and *b*) then the wave function ψ_l will describe the Fe_a^{2+}–Fe_b^{3+} state, while the wave function ψ_r will describe the Fe_a^{3+}–Fe_b^{2+} state (Fig.1*a*). Each of these ions (*a* and *b*) spends 50% of time in the high-spin states of bivalent iron (Fe^{2+}) and tervalent iron (Fe^{3+}). The characteristic time of the measurement in Mössbauer spectroscopy is the average lifetime of the excited level $\tau_{exp} = \tau_M$, which is $\tau_M = 1.4 \times 10^{-7}$ s for ^{57}Fe. It the time taken for the electron jump between the two wells is greater than or comparable to the lifetime, $\tau \gtrsim \tau_M$, then two Mössbauer absorption spectra, representing both Fe^{2+} and Fe^{3+}, will be observed. If the jump time is much shorter than the time of the Mössbauer transition, $\tau \ll \tau_M$, only one Mössbauer spectrum, intermediate between those of Fe^{2+} and Fe^{3+}, will be observed. Thus MAS makes it possible not only to establish the very fact of the spatial delocalisation of electrons but also to investigate quantitatively the time scale characterising the electron jumps between different states.

The use of MES opens up new possibilities. Suppose that there are two different potential wells, for example, two tervalent iron ions, differing in their properties: we shall assume that one of them is in the high-spin (Fe^{3+}) state and the other is in the low-spin [Fe(III)] state (Fig.1*b*). In this case the presence of an additional electron in one of these potential wells is energetically more favourable than its presence in the other well and for this reason only one of the two possible states—the one with the lower energy—is represented in the usual (absorption) Mössbauer spectra.

However, we shall assume that at the instant of the formation of the Mössbauer nuclear level, the corresponding atom is in a higher, unstable electronic state of the system and that the system passes to a stable state only later, while the characteristic time of the transition is close to or greater than the lifetime of the Mössbauer level. In this case there is a possibility of noting the contribution of the initial unstable state of the system to the Mössbauer emission spectrum. This contribution may be especially significant for short time intervals immediately after the population of the Mössbauer level.

All these general considerations can be clearly illustrated in relation to compounds well known to chemists—the ferricyanide–ferrocyanide complexes called Prussian blue (PB) and Turnbull's blue (TB). The formation of these beautiful blue deposits is used to detect the high-spin Fe^{3+} or Fe^{2+} ions in solutions. The addition of potassium ferrocyanide $K_4[Fe^{II}(CN)_6]$, a salt of the low-spin bivalent iron, to Fe^{3+} salts causes the precipitation of PB, tentatively having the composition $Fe_4^{3+}[Fe^{II}(CN)_6]_3^{4-}$, while the addition of potassium ferricyanide $K_3[Fe^{III}(CN)_6]$. a salt of the low-spin tervalent iron, to Fe^{2+} salts leads to the formation of TB, which has the tentative composition $Fe_3^{2+}[Fe^{III}(CN)_6]_2^{3-}$.

All four forms of iron participating in these reactions—Fe^{3+}, Fe^{2+}, Fe(III), and Fe(II)—have different Mössbauer spectra (Fig.2); it is therefore not surprising that already in the very earliest stage of development of Mössbauer spectroscopy several laboratories in different countries (including our laboratory) began to investigate the absorption spectra of PB and TB in an attempt to identify both compounds. However, it was found that, whatever method used to prepare the compounds (Fig.2), only one resultant spectrum was always obtained, i.e. only one product, namely PB whose structure is illustrated in Fig.3, with low-spin bivalent iron Fe(II) ions adjoining carbon atoms, i.e. in an environment of ligands with a strong field, and high-spin tervalent iron (Fe^{3+}) ions adjoining nitrogen atoms, i.e. in an environment of ligands with a weak field; the additional Fe^{3+} ions occupy interstitial positions. The impression was created that TB does not exist at all and that the electron is always localised (in conformity with the situation illustrated in Fig.1*b*) at low-spin iron in all ferri-ferrocyanides.

The formation of precisely PB and not TB in all the procedures, listed above, for the preparation of iron cyanide complexes can be seen particularly clearly when the Mössbauer effect is used to analyse the position of the isotope label[10]—a method which is extremely convenient for the study of the structures, kinetics, and mechanisms of reactions of systems containing Mössbauer atoms in different functional states. In the instances described, the application of the Mössbauer effect involved the comparison of the absorption spectra with selective introduction of ^{57}Fe labels in the form of one of the four states of iron in one or both interacting compounds.[11]

Apart from the fact that the employment of the Mössbauer effect to analyse the state of the isotope labels confirmed the formation of Prussian blue and not Turnbull's blue in all the instances investigated, it also demonstrated that the sequence of the formation of the soluble and insoluble ferri-ferrocyanides differs significantly from, and sometimes is even completely opposed to, that adopted in the literature and that isotope exchange took place in solutions between different states of iron. However, these problems will not be discussed here and we shall proceed to experiments on Mössbauer emission spectroscopy (MES).

MES characterises the structural and dynamic properties of compounds containing emitters of resonance γ-quanta, i.e. atoms or nuclei in the highest excited Mössbauer level. The possibilities for the study of relaxation changes in such compounds are determined by the ratio of the lifetime of the Mössbauer level τ_M to the characteristic relaxation time τ_r. When $\tau_r \ll \tau_M$, relaxation takes place mainly before the nuclear transition and the emission spectra integrated with respect to time (IMES) therefore reflect principally the properties of emitters which have not undergone relaxation.

Nevertheless the use of delayed coincidences schemes with resolution time $\tau_{\text{coinc}} < \tau_M$, i.e. the study of the emission spectra differentiated with respect to time (DMES), leads to additional possibilities for the investigation of rapid relaxation processes. When $\tau_r \gg \tau_M$, predominantly atoms with unexcited nuclei, in the ground state, participate in the relaxation process and MES does not therefore carry any additional information.

Consequently the most favourable condition for the application of MES in its simplest (IMES) version is $\tau_r \sim \tau_M$. The usual values of τ_M are in the range 10^{-5}–10^{-10} s, while for ^{57}Fe (14.4 keV) we have $\tau_M \cong 1.4 \times 10^{-7}$ s and the emission of the resonance γ-quantum is in this case preceded by *K*-capture in ^{57}Co with formation of a short-lived ($\tau_0 \cong$ 12.5 ns) 136.4 keV excited state of ^{57}Fe and the subsequent emission of a non-Mössbauer 122 keV γ-quantum (Fig.4).

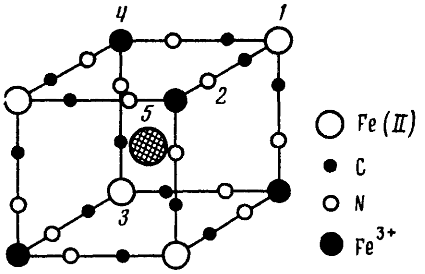

Figure 3. The structures of ferric ferrocyanides: *1*) C atom; *2*) N atom; *3*) low-spin iron atom at a lattice site; *4*) high-spin iron atom at a lattice site; *5*) high-spin iron atom in an interstitial position.

Thus the use of delayed ν (122 keV) and γ (14.4 keV) coincidences with a variable delay time (DMES) leads to the possibility of investigating relaxations with characteristic times ranging from $\tau_r \sim \tau_{\text{coinc}} \sim 10^{-9}$ s to $\tau_r \gtrsim \tau_M \cong 10^{-7}$ s.

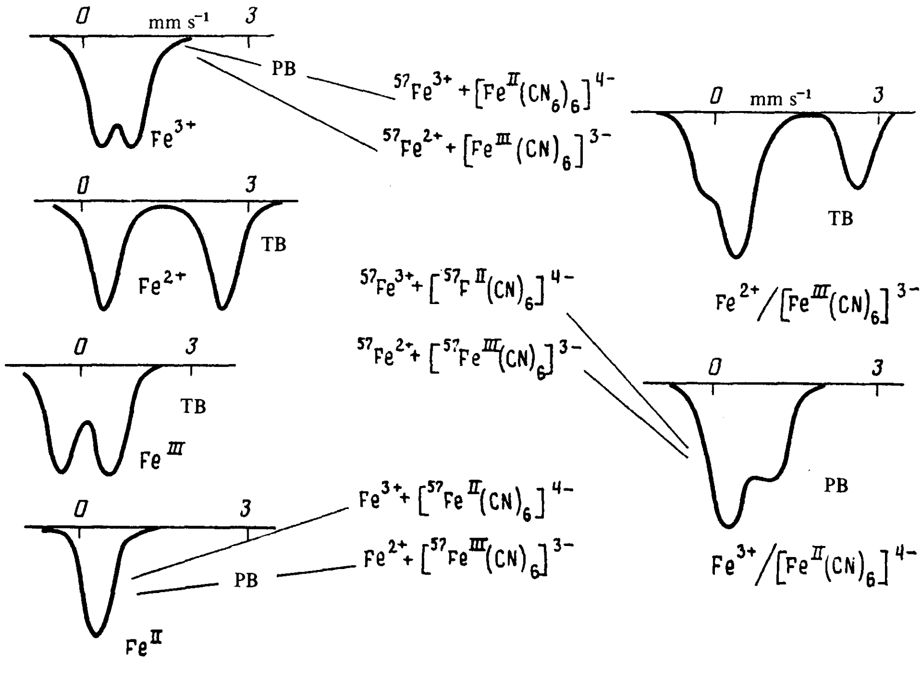

Figure 2. Mössbauer spectra of four different forms of iron.

Various chemical consequences of nuclear transformations, for example, the "shake-up" of the electronic shells as a result of the rapid change of nuclear charge and the subsequent Auger transitions, the Coulombic explosions of multiply ionised molecules, local heating, autoradiolysis, etc., are well known. Here we shall not discuss such processes (they are usually completed before the population of the 14.4 keV level of ^{57}Fe) and shall confine ourselves to chemical relaxation proper. This means, that we shall deal only with systems where the pre-Mössbauer nuclear transformation ^{57}Co → ^{57}Fe does not alone lead to an alteration of the ligand environment or the charge state of the daughter Mössbauer atoms (^{57}Fe), which are stabilised in the same environment and in the same valence state as the parent (^{57}Co) radioactive atoms. Since, however, certain chemical (valence and spin) states, which are entirely stable for the parent atom, prove to be unstable for the daughter atom (with an excited Mössbauer nucleus), the system will tend to a stable state, i.e. will undergo chemical relaxation.

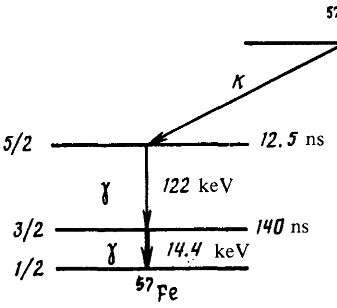

Figure 4. Schematic illustration of the radioactive decomposition (*K* capture) of ^{57}Co and subsequent γ-transitions for ^{57}Fe.

Precisely this situation has been observed[12–16] for ^{57}Co-labelled TB-like compounds of the kind of ferrous cobalticyanide $Fe^{2+}/[^{57}Co^{III}(CN)_6]$ and cobaltous ferricyanide $^{57}Co^{2+}/[Fe^{3+}(CN)_6]$. The decomposition of ^{57}Co is in this case followed by a kind of intramolecular oxidation-reduction reaction, in which the low-spin tervalent iron plays the role of the oxidant and the high-spin bivalent iron acts as the reductant. As a result, TB is rapidly converted into PB and is not therefore manifested in the usual absorption spectra, but it ultimately proved possible to demonstrate the initial formation of the short-lived TB with the aid of MES.

The search for the short-lived TB by MES methods was carried out using both the IMES and DMES (t = 0–60 ns) versions. The experiments with labelled cobalticyanide sources $M^{n+}/[^{57}Co^{III}(CN)_6]^{3-}$, where $M^{n+} = Ni^{2+}, Co^{2+}, Cu^{2+}$, and Fe^{3+} and with the $^{57}Co^{2+}/[Fe^{II}(CN)_6]$ source revealed the formation of daughter ^{57}Fe atoms in the same states as those in which the parent ^{57}Co atoms existed[17,18] and thus demonstrated the absence of appreciable chemical consequences in the emission spectra due to the effect of the *K*-capture in ^{57}Co. The cobaltous ferricyanide $^{57}Co^{2+}/[Fe^{III}.(CN)_6]^{3-}$ was used as the source, while potassium ferrocyanide $K_4Fe^{II}(CN)_6.3H_2O$ served as the absorber in the first MES experiments carried out at 77 K.[12] The results for the IMES and DMES (t = 0–60 ns) versions are presented in Fig.5.

Subsequent measurements[13] using the IMES version were performed on another source—of the type of cobaltous ferricyanide $Na^{57}Co/Fe^{III}(CN)_6$, and at lower temperatures, down to 12 K (Fig.6). It is evident that the contribution of the broad Fe^{2+} doublet (which is altogether absent from the absorption spectra owing to the instability of the TB) is in this case much greater than for IMES at 77 K. This fact reflects the retardation of the transformation TB → PB when the temperature is reduced from 77 to 12 K.

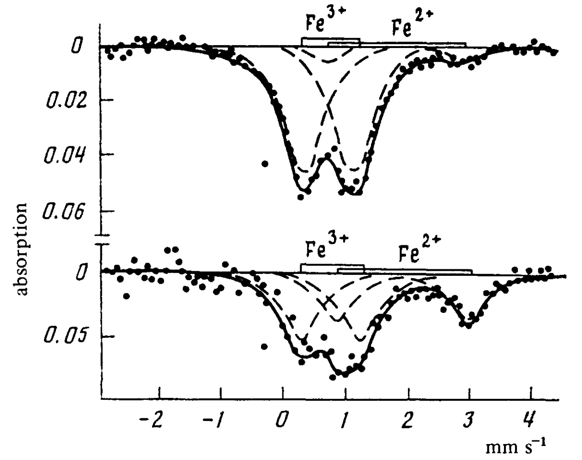

Figure 5. Mössbauer emission spectra of cobaltous ferricyanides $^{57}Co^{2+}/[Fe^{III}(CN)_6]$ at 77 K:[12] above—IMES; below—DMES (0–60 ns). The positions of the peaks of the narrow Fe^{3+} doublet and the broad Fe^{2+} doublet are indicated.

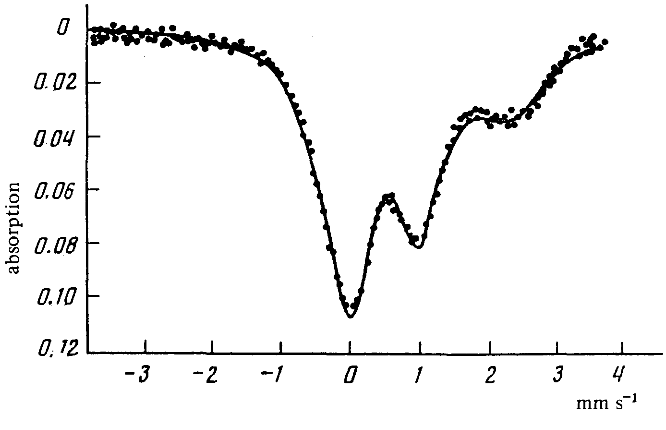

Figure 6. Mössbauer emission spectrum, integrated with respect to time (IMES), of $Na^{57}Co/[Fe^{III}(CN)_6]$ at 12 K.[13]

For an approximate (but sufficiently reliable) estimate of the rate of electron transfer in the transformation TB → PB, we shall employ a simplified representation of the observed emission spectra as a superposition of two undistorted components—the narrow Fe^{3+} (PB) and the broad Fe^{3+} (TB) symmetrical quadrupolar doublets (assuming that in this case

$f_{\mathrm{PB}} = f_{\mathrm{TB}}$). Under these conditions, the contribution of TB to the DMES spectra, obtained with a "window" of delayed $\gamma\gamma$-coincidences between $t = 0$ and $t = \tau$, should be given by

$$P_\tau = P_0\lambda\,[1 - \mathrm{e}^{-(\lambda+k)\tau}]/(\lambda + k)\,(1 - \mathrm{e}^{-\lambda\tau}),$$

where $\lambda = \tau_M^{-1}$, k the rate constant for the chemical transition (TB → PB), and P_0 the initial population of the TB state. With increase of τ, P_τ should diminish, approaching at $\tau \to \infty$ the value $P_\infty = P_0\lambda/(\lambda + k)$, characteristic of measurements by the IMES method.

The values of k obtained in this way in the range from 77 to 400 K are presented on the left-hand side of the curve in Fig. 7.[14] The right-hand side of the curve demonstrates the data obtained over the range 77–12 K with the aid of the IMES version in our joint study with the Helsinki group,[13] using the $\mathrm{Na^{57}Co/[Fe^{III}(CN)_6]}$ source. It follows from Fig. 7 that the temperature variation of the rate of electron transfer from $\mathrm{Fe^{2+}}$ to $\mathrm{[Fe^{III}(CN)_6]}$ gradually changes in accordance with a function of the Arrhenius type at temperatures above approximately 200 K (the activation energy E reaches here the value $E \cong 0.025$ eV) up to the low-temperature plateau at $T \lesssim 50$ K.

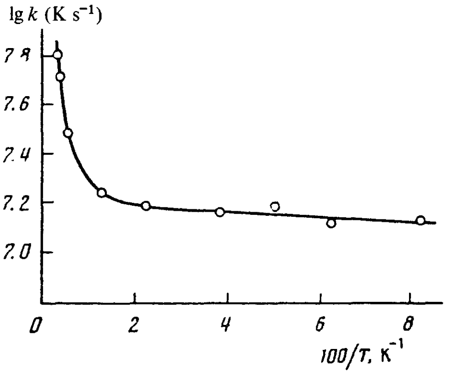

Figure 7. Temperature dependence of the rate constants for the TB → PB transition (data from Refs. 12 and 13 generalised and analysed in Ref. 14).

In this case the study of the rapid intramolecular transfer by the MES method came into contact with another field of our research—the problem of quantum (tunnel) chemical reactivity at low temperatures.

In our early theoretical studies on this problem,[19,20] the criterion of the "tunnel temperature" was introduced:

$$T_t = \frac{\hbar\sqrt{2}}{k_{\mathrm{B}}\pi d}\left(\frac{E}{m}\right)^{1/2}$$

where E is the height and d the width of the activation barrier and m is the mass of the tunnelling species. The high-temperature Arrhenius region is located above T_t, while below T_t is the region of the exponential predominance of tunnelling, which ultimately ensures the attainment of a plateau—the low-temperature quantum limit of the rate of the chemical reaction.

Within the framework of the theory of non-radiative transitions, two types of tunnelling, characteristic of different chemical reactions,[5] are considered and are usually referred to as the electronic-nuclear tunnelling and molecular tunnelling. Both these types of tunnelling lead to the appearance of a low-temperature plateau in the rate of reaction and the presence of such a plateau is regarded as proof that tunnelling predominates. The electronic-nuclear tunnelling was discovered in 1966 by Chance and de Vault in relation to the oxidation of cytochrome *c* by chlorophyll[21] and has also been observed, starting in 1971,[22] for many instances of the long-range electron transfer (over tens of angstroms) between donors and acceptors—variable valence ions.

Molecular tunnelling, observed in the form of a low-temperature plateau in the rate of the "true" chemical reaction in the full sense of these words (which rules out molecular rearrangement, steric rearrangement of atoms, and changes in valence bond lengths and angles) was discovered in 1973 in relation to the polymerisation of formaldehyde.[23]

The conversion of TB into PB was the first observed instance of intramolecular electron transfer via electronic-nuclear tunnelling. In contrast to the tunnelling of free electrons in solid-state physics, their "chemical" tunnelling is associated with the displacement of the nuclei and hence electronic-nuclear tunnelling is associated with a definite breakdown of the Franck–Condon principle.

The probability of a non-radiative electron transfer W_{if} is determined by the overlap of the electronic (ψ_e) and nuclear vibrational (ψ_v) wave functions in the initial (i) and final (f) states, described respectively by the electron transfer matrix element $L_e^2 = |\langle\psi_{e_i}|\hat{L}|\psi_{e_f}\rangle|^2$ and the Franck–Condon factor $F_V = |\langle\psi_{\nu_i}|\psi_{\nu_f}\rangle|^2$:

$$W_{if} = \frac{2\pi}{\hbar} L_e^2 F_v \rho_f,$$

where $\hat{L}$ is the transition operator of the type for non-abiabatic conditions and $\rho_f \sim (\hbar\omega)^{-1}$ the density of the vibrational levels in the final state (it is assumed that the dissipation of the heat of exothermic transitions in solids in the form of phonons occurs very rapidly and does not limit the observed rate of reaction).

The electronic-nuclear tunnelling is illustrated schematically on the left-hand side of Fig. 8. The penetration of the electron through the potential barrier (with a width l and a height E) is in this case accompanied by a much smaller barrier-free displacement (d) of nuclei. However, with increase of d whereupon the nuclear shift greatly exceeds the amplitude of the nuclear vibration Δ [for the nth vibration level of a harmonic oscillator, $\Delta_n = (2n+1)^{1/2}(\hbar/M\omega)^{1/2}$, where M is the nuclear mass and ω the characteristic vibration frequency], a potential barrier to nuclear transfer also appears (Fig. 8a) and the possibility of chemical reaction via molecular tunnelling arises. The wave functions $\psi_e(x)$ are proportional to $\exp(-x/\alpha)$ (for $x > \alpha$), where $\alpha = \hbar/(2mE_e)^{1/2}$, and for $l \gg \alpha$ the matrix element L_e^2 assumes the form of a tunnel factor of the Gamow type: $L_e^2 \sim \exp[-\beta l(m_eE_e)^{1/2}/\hbar]$, where $\beta \sim 1$ (and depends on the form of the barrier) and m_e is the mass of the electron.

This expression for L_e^2 is valid in the region of the low-temperature plateau, while above the "tunnelling temperature"

$$T_{te} = \frac{\hbar\sqrt{2}}{k_{\mathrm{B}}\pi l}\left(\frac{E_e}{m_e}\right)^{1/2} \cong 12\,000\,\frac{E_e^{1/2}}{l}$$

(Here E is expressed in eV, l in Å, and T_{te} in K) a temperature dependence of the Arrhenius type is valid:

$$L_e^2 \sim \exp(-E_e/k_{\mathrm{B}}T).$$

The wave functions $\psi_\nu(x)$ are proportional to $\exp[-(x/\Delta)^2]$ (for $x > \Delta$) and, for the Franck–Condon factor can therefore be represented by $F_\nu \sim [\exp -(\kappa d/\Delta)^2]$, where $\kappa \sim 1$. Since the statistically averaged vibration amplitude increases with temperature and for a harmonic oscillator $\langle\Delta^2\rangle$ is proportional to T for $k_{\mathrm{B}}T \gg \hbar\omega$, the behaviour of the Franck–Condon factors at high temperatures is of the Arrhenius type for both barrier-free and sub-barrier nuclear shifts.

With decrease in temperature, whereupon Δ approaches the amplitude of zero-point vibrations, Δ_0, the Franck–Condon factor reaches a minimal constant value (like also L_e^2), which leads to the appearance of a low-temperature plateau in the overall rate (W_{if}) of the non-radiative transition.

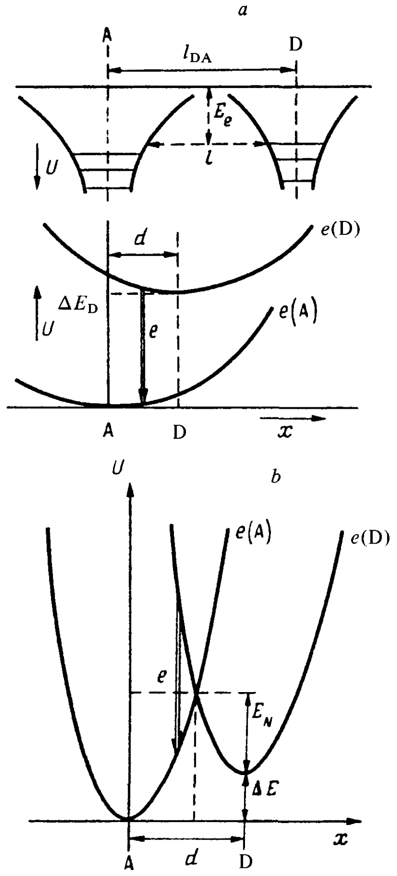

Figure 8. Schematic illustration of the electronic-nuclear tunnelling in electron transfer from a donor (D) to an acceptor (A): *a*) electron tunnelling over a distance l_{DA} through a barrier with a height E_e; such an electron transfer, symbolised below by a vertical arrow between two potential curves for internuclear interaction, corresponding to the states e(D) and e(A), is accompanied by a barrier-free shift of nuclei over a distance d; *b*) the nuclear shift d in the electron transfer from the donor to the acceptor is so great that the potential barrier with a height E_N and a width d arises between the two e(D) and e(A) potential curves (the heat of the transition is ΔE).

In the simplest case of resonance nuclear tunnelling, the Franck–Condon factor assumes the Gamow form (see, for example, Jortner and Ulstrup[24]) and the "tunnelling temperature" T_{tN} for the nuclear shift is

$$T_{tN}=\frac{\hbar}{k_B\pi\sqrt{2}d}\left(\frac{E_N}{M}\right)^{1/2}\cong 20\frac{E_N^{1/2}}{d}$$

(here E is expressed in eV, d in Å, and T_{tN} in K) for iron nuclei.

The structure of ferric ferrocyanide crystals is well known and corresponds to the interionic electron tunnelling distance $l \sim 5$ Å. The typical energy of charge transfer from the metal to the ligand in complexes of transition metals in the first row is $E_e \cong 4$ eV.[25] Consequently, the tunnelling factor of the Gamow type for a parabolic barrier ($\beta = \pi\sqrt{2}/2$) is close to 2.5×10^{-4}. The overall factor associated with the retardation of the transformation TB → PB on the low-temperature plateau, where the rate constant $k \sim 10^{-7}$ s^{-1}, amounts to $\sim 10^{-7}$, which means that the contribution of the nuclear shift (the Franck–Condon factor) to such retardation is virtually the same as for the tunnelling of the electron:

$$F_v \sim \exp[-(\varkappa d/\Delta_0)^2] \cong 4\cdot 10^{-4}.$$

The estimated value $\kappa d/\Delta_0 \sim 2.8$ can be compared with the probability of the Mössbauer effect for PB at low temperatures: $f' = \exp[-(\Delta_0/\lambda)^2] \cong 0.6$, where $\lambda = 0.14$ Å.

Thus $\Delta_0 \cong 0.1$ Å and $\kappa d \cong 0.3$ Å. Together with $E_A \cong 0.025$ eV, this reasonable estimate corresponds, in the case of a resonance nuclear shift, to $T_t \sim (10\kappa)$ K and thus confirms the conclusion that it is in fact the nuclear shift and not the electron transfer which is the process determining the appearance of the plateau in the rate of the transformation TB → PB, but only at $T \lesssim 50$ K and not at higher temperatures, where thermally activated electron tunnelling takes place.

Thus the combination of the experimental data for the rate of the chemical reaction on the low-temperature plateau ($\tau_r \cong \tau_M$), of the values of f' at $T \to 0$, and of the tunnelling temperature leads to fairly reliable estimates of both κ and d.

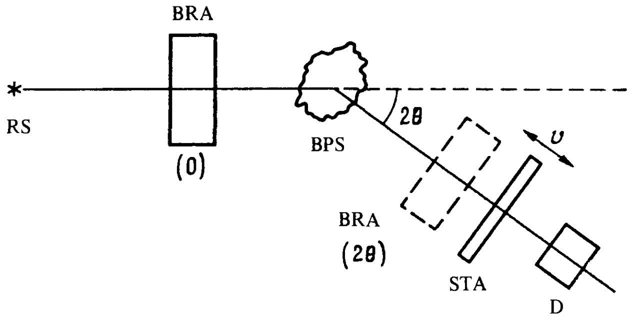

Figure 9. Schematic illustration of experimental observation of the RSME: RS—resonance source; BRA—"black" resonance absorber ensuring effective absorption throughout virtually the entire width of the Mössbauer line (it is placed either before the scatterer or beyond it—at an angle 2θ); BPS—biopolymeric scatterer; STA—standard thin absorber for the measurement of the line form by varying the rate of its movement ν; D—scintillation detector of γ-quanta, operating as the resonance detector together with the BRA.

III. STUDIES OF THE DYNAMIC PROPERTIES OF BIOPOLYMERS BY THE RSME METHOD

Extensive possibilities for the dynamic investigation of various chemical and especially biological systems have arisen as a result of another modern Mössbauer spectroscopic method—the observation of the Rayleigh scattering of the Mössbauer emission (RSME).[26–38] Leaving to one side its most informative (but also the most difficult to apply) version—coherent RSME, we shall consider only non-coherent scattering data.

The usual Mössbauer method involves the employment of a resonance source and a resonance absorber (or scatterer), while the detector is usually of the non-resonance type. The RSME method is based on the combination of the resonance source and the resonance detector for γ-rays (Fig.9). The exceptionally high energy resolution of the method (~10^{-9} eV) ensures the possibility of eliminating all non-elastic processes and a reliable determination of the contribution of elastic scattering against their background, where the elastic scattering itself is atomic and not nuclear in nature and takes place on the electron shells. In RSME observations there is therefore no need to have Mössbauer nuclei in the test specimens; Rayleigh scattering can be observed successfully and can yield valuable information for any substances in both solid and liquid phases, in the crystalline and amorphous states, and over wide ranges of temperatures, degrees of hydration, and other variables.

These features in fact determine the advantages of RSME in the study of biopolymers compared with other dynamic methods, the interpretation of the results of which also involves the use of Van Hove correlation functions, such as X-ray dynamic analysis (XDA) [39–41] and the usual MAS.[42–45]

*The information obtained represents the functional dependence of the probability of the elastic RSME (f_R) and of the width of the RSME resonance line (Γ_R) on the temperature T, the degree of hydration h (grammes of water per gramme of biopolymer), and the viscosity of the surrounding medium η. The viscosity was varied by adding glycerol (HSA, chromatophores) and glutaraldehyde (HSA).

A general description of the RSME theory and methods is available in a number of communications (see, for example, **Refs.26–28**), while our previous studies (for example, **Refs.29–38**) were concerned with both theoretical and experimental aspects of the application of incoherent RSME to the study of the dynamic properties of biopolymers. Here we shall confine ourselves to the description of certain typical results and the most important conclusions. The biopolymers investigated and the conditions in their study (temperature, degree of hydration) are listed in Table 2.

The probability f_R of the elastic RSME served as the fundamental initial dynamic characteristic of all the objects studied. This probability is proportional to the generalised Debye–Waller factor:

$$\exp(-2W)=\exp(-Q^2\langle x^2\rangle)$$

(here $Q = 4\pi \sin\theta/\lambda$ is the momentum transferred in scattering through an angle 2θ) and thus makes it possible to determine the averaged, generalised mean-square shift $\langle x^2\rangle$, which is assumed to be the same, in such general treatment, for all the atoms of the test specimens.

Additional dynamic information can be obtained by analysing the shape of the RSME spectral lines and by comparing the observed changes in this shape (or its constancy) with the expected increase of the line width Γ_R with decrease of f_R.[29–38]

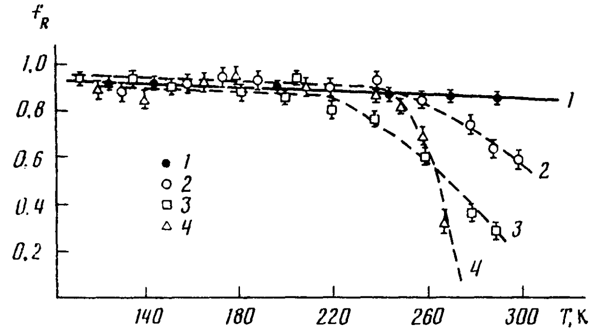

Figure 10. The contribution of elastic scattering as a function of temperature for different metmyoglobin specimens:[33] *1*) for P/P_S = 0.37 (h = 0.05); *2*) crystalline metmyoglobin; *3*) for P/P_S = 0.94 (h = 0.5); *4*) aqueous solution (26.6% metmyoglobin; h = 2.3).

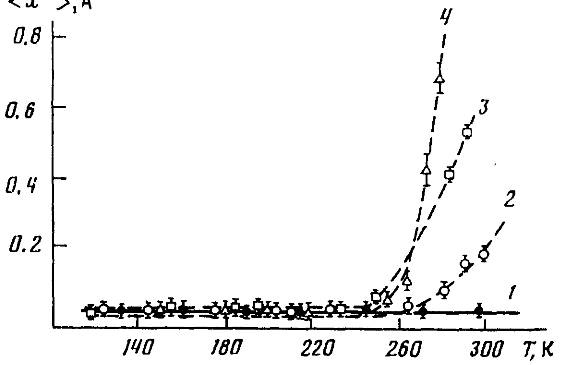

Figure 11. Generalised mean-square shift $\langle x^2\rangle$ as a function of temperature for different metmyoglobin specimens;[33] for the designation of the curves and points, see the legend to Fig.10.

A characteristic feature of the spectra of all the hydrated specimens (with a degree of hydration $h \gtrsim 0.3$ g of water per gramme of the biopolymer) was a sharp decrease of f_R at $T \gtrsim 220-230$ K, i.e. a sharp increase of the generalised mean-square shift, which reached extremely high values: $\langle x^2 \rangle \cong 1$ Å^2 for $h \cong 0.7$ and $T \cong 300$ K,[37] while the decrease of f_R at $T = 100-300$ K for dry specimens ($h \cong 0.05$) is linear and altogether insignificant: for example, $\langle x^2 \rangle \cong 0.05$ Å^2 at $T \cong 300$ K.[35]

The temperature variations of f_R and $\langle x^2 \rangle$ for metmyoglobin for different values of h [31] are presented in Figs.10 and 11. These data reveal a characteristic feature of the dynamics of biopolymers—a sharp decrease of f_r and a corresponding increase of $\langle x^2 \rangle$ in the high-temperature ($T \gtrsim 220$ K) region with increase of the degree of hydration h.

A typical example is provided by human serum albumin (HSA) at $T \cong 300$ K (Fig.12). The observed dependence of f_R on h is in this case much more pronounced than might have been expected if the mobilities of the protein as such and of the much more mobile solvent (water) had been additive. Even for high degrees of hydration ($h \cong 0.8$), the added portions of water continue to cause additional loosening of the proteins increasing the mobility of the protein globule.

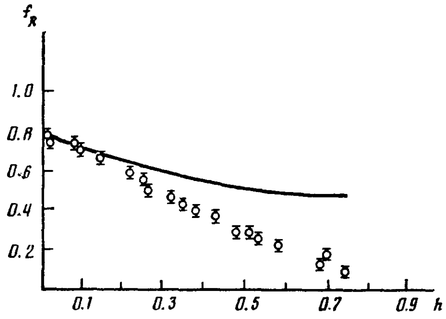

Figure 12. The contribution of elastic RSME as a function of the degree of hydration for human serum albumin at 300 K: symbols—experimental data; curve—calculation assuming simple additivity (without any correlations between the values of f_R for the protein and the solvent).[38]

The dependence of the generalised Debye–Waller factor for biopolymers on two parameters—temperature and degree of hydration—can be represented by a three-dimensional f_R (T, h) diagram, illustrated schematically in Fig.13.

The sharp decrease of the probability of the elastic RSME for biopolymers with increase of D and h is not accompanied by any serious broadening ($\Delta\Gamma$) of the spectral line. For example, the shapes of the RSME $g(\omega)$ lines for crystalline metmyoglobin at 240 and 300 K are virtually identical (Fig.14), while an almost fourfold decrease of f_R for HSA with increase of the degree of hydration (from $h = 0.05$ to $h = 0.73$) is accompanied by only a slight ($\Delta\Gamma \cong 0.10$ mm s^{-1}) broadening of the principal, "narrow" component of the RSME spectrum and by the appearance of a fairly weak broad component (Fig.15).

Such properties of the RSME spectra of biopolymers can be described by neither the Debye nor the Einstein models of the solid state nor by the picture representing a free liquid with spatially unlimited diffusion, to which the relation $f_R \cong \Gamma/(\Gamma + \Delta\Gamma)$ would have corresponded. Since the temperature dependence of the Debye–Waller factors and the line width for RSME is very similar to that for MAS (however, hydration effects have not been investigated by the MAS method), the RSME data can be interpreted by the procedures developed in recent years for the analysis of MAS results (see, for example, Refs.47–51) and based on the model representing continuous spatially limited diffusion, i.e. a Brownian harmonic oscillator with pronounced decay.

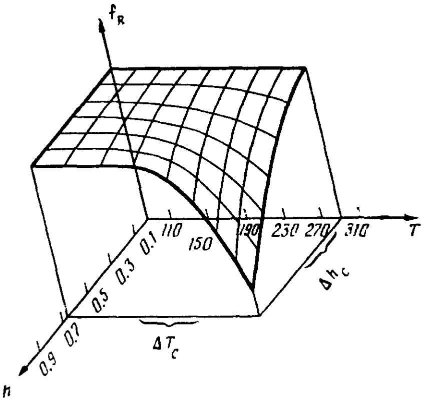

Figure 13. Three-dimensional diagram illustrating the dependence of the contribution by the elastic RSME on temperature and the degree of hydration.[46]

The physical foundations for such an approach appeared in 1973–1979 in the form of the idea of the existence of conformational substates (CSS) or, in other words, quasi-degenerate conformational states (QDCS) of protein globules, i.e. surfaces of a given macromolecule with the same overall structure which are almost degenerate in terms of energy and differ only slightly in terms of the local configurations.

Regardless of the approach to the treatment of QDCS [as "mobile defects",[52] treatment aided by the computer modelling of the dynamic properties of proteins[53] on the basis of the polychromatic kinetics of the Fe–CO recombination in haem-containing proteins,[54,55] or X-ray-dynamic analysis (XDA) [39–41]], the QDCS concept implies a definite modification of the understanding of protein structure (the structure of biopolymers in general) in the spirit of the scheme illustrated in Fig.16. Until the appearance of the QDCS concept, it was usually assumed that, in conformity with the familiar Schrödinger[56] definition of a protein as an aperiodic crystal, each individual biomacromolecule in its ground state is located in a global energy minimum and is characterised by a definite clearly fixed geometry. Within the framework of the QDCS concept, the global energy minimum for biomacromolecules is not realised at all, even as $T \to 0$, and the actual observed state is a spatially delocalised system with numerous local energy minima. The increase of the mobility of biopolymers with increase in temperature and in the degree of hydration can be described by the theoretical methods developed previously[47–51] by virtue of the stimulation of transitions between the QDCS.

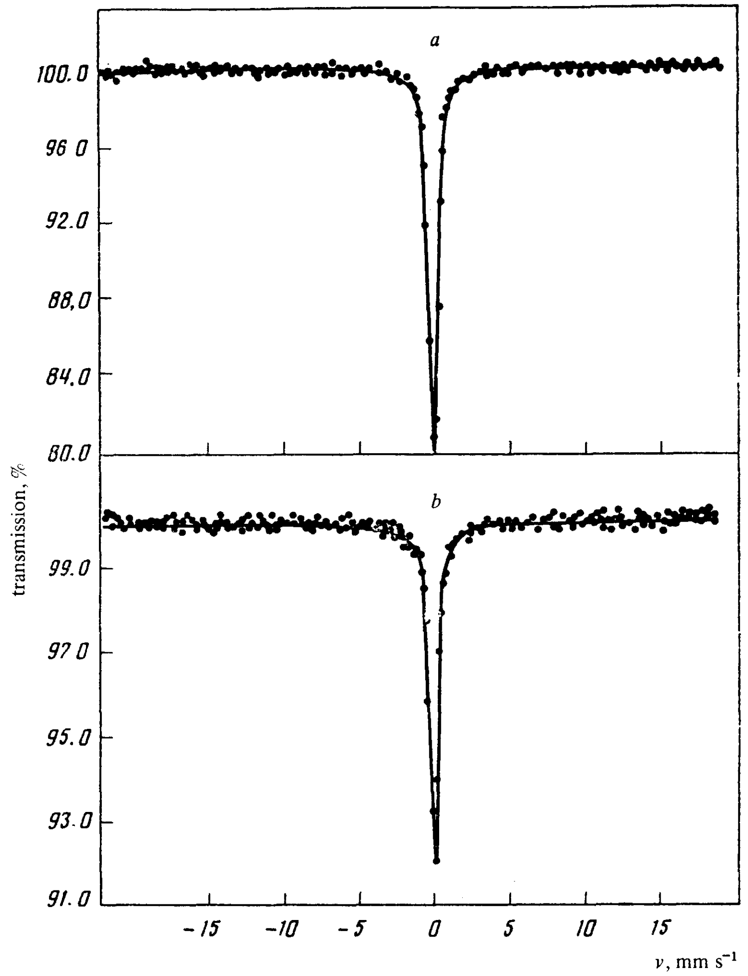

Figure 14. The RSME energy spectra for crystalline metmyoglobin at 240 K (*a*) and 300 K (*b*).[46]

The expansion of the variety of experimental MAS and RSME data necessitates further development of spatially limited diffusion models, namely a transition from the case of a single oscillator to a multimodal approximation, which presupposes the presence of at least two or three Brownian oscillators with pronounced decay. The conformational mobility of biopolymers at room temperature, determined by the MAS and RSME methods, is characterised by a fairly broad spectrum of correlation times τ_c—from 10^{-6} s (broadening of the principal, narrow, spectral line) to 10^{-9} s (contribution to the broad component) and further to even lower values of τ_c (decrease of the contribution of elastic scattering). According to data obtained by other methods (for example, the luminescence and spin label methods[57]), the range of correlation times embraces also much slower movements—down to $\tau_c \sim 1$ s. The hierarchy of the amplitudes and relaxation times of various internal motions in biopolymers is also manifested in the computer modelling of protein dynamics.[58]

A broad spectrum of relaxation times of motions is typical for the vitreous state—in contrast to the liquid and crystalline states.[59] That it is natural to compare the dynamic properties of biopolymers and glasses follows from the entire set of data for the dependence of the RSME spectra on temperature and the degree of hydration. The sharp increase of $\langle x^2 \rangle$ at the glass point T_g, similar to that observed for proteins above $T_c \cong 220$ K and also sometimes accompanied by a slight broadening of the spectral lines (when $f_R \lesssim 0.5$ to 0.1), is typical for supercooled organic liquids.[27,28] Our observations also demonstrated a clear correlation between the onset of the sharp decrease of f_R and the jump in the specific heat following an increase in temperature (DNA : $h \cong 0.6$; $T \cong 200$ K) and in the degree of hydration (lysozyme : $T \cong 300$ K; $h \cong 0.2$–0.3).[33,46] Such jumps in specific heat usually indicate the occurrence of glass points for polymers—they are absent only for a very high ($\gtrsim 75\%$) degree of crystallinity of the polymers. Additional experimental data, supporting the analogy between the dynamic properties of biopolymers and glasses, are presented and discussed in the present author's more detailed publications.[33,46]

Turning now to the three-dimensional diagram in Fig.13, it is natural to suppose that, below some kind of "critical" point (more correctly some kind of extended "critical" regions) in temperature and degree of hydration, the ground state of the biopolymer is more likely to resemble a heterogeneous glass than a crystal. As regards structural characteristics, this approach to biopolymers is consistent with Fig.16*b*—a system of local energy minima, which implies the absence of structural unambiguity in the biomacromolecule represented by a set of QDCS.

As regards the dynamic characteristics of biopolymers, we employed their heat capacity at very low temperatures as a test of dynamic vitreous properties.[46,64,65] The temperature dependence of the heat capacities of inorganic and organic dielectric glasses at low temperatures is given by

$$C_v(T) = C_1T + C_3T^3 + C_E\left(\frac{\theta_E}{T}\right)^2 \cdot \exp\left(\frac{\theta_E}{T}\right) \cdot \left[\exp\left(\frac{\theta_E}{T}\right) - 1\right]^{-2},$$

i.e., apart from the Debye (second) and Einstein (third) terms, it contains a linear term, which predominates as $T \to 0$.[60]

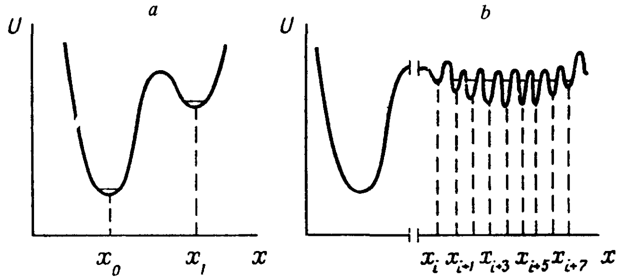

Figure 16. Potential energy curves for biomacromolecules: *a*) global energy minimum corresponds to the ground state (whose structure is unambiguously fixed as $T \to 0$), while the other minima (only one of these is shown) correspond to short-lived and weakly populated excited states; *b*) there is no global minimum at all and the system of local minima represents the spatially delocalised and energetically similar conformational substates (CSS) or quasi-degenerate conformational states (QDCS) whose populations are not unambiguously defined even as $T \to 0$.[46]

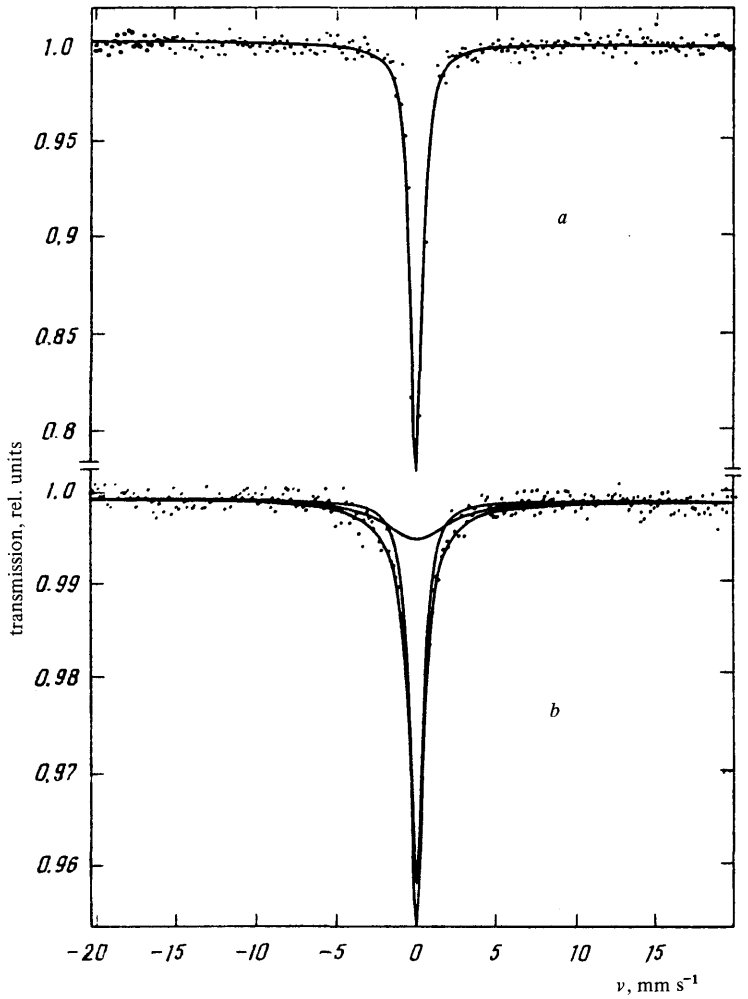

Figure 15. The energy spectra for HSA (300 K) at $h = 0.05$ (*a*) and $h = 0.73$ (*b*). For HAS with $h = 0.73$ (*b*), the overall spectrum represents a superposition of the "narrow" component (with the same line width as for $h = 0.05$) and the "broad" component, which are also illustrated in part *b* of the figure.[37]

This especially important linear contribution to the low-temperature heat capacity is associated with a fundamental property of the vitreous state—its non-equilibrium nature, the existence of a residual entropy as $T \to 0$. Its presence, magnitude, and physical significance have been explained[61,62] on the basis of the model of phonon-stimulated tunnelling (PST) in the so-called two-level (multilevel) systems, i.e. the tunnelling of atoms and atomic groups between two (or many) quasi-equilibrium positions (QEP), between two (or many) similar but non-equivalent potential wells by virtue of the adjustment of the transitional resonance between such QEP via the excitation (absorption or emission) of phonons (Fig.17).

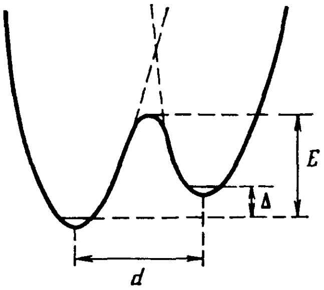

Figure 17. The simplest picture comprising two quasi-equilibrium positions (QEP) for atoms or atomic groups of biopolymer molecules (two-level system with two wells). Typical values: $E \cong 0.2$–0.4 eV, $d \cong 0.2$–0.4 Å. The resonance adjustment within the limits of the width of the energy gap Δ is ensured by phonons (phonon-stimulated tunnelling).[46]

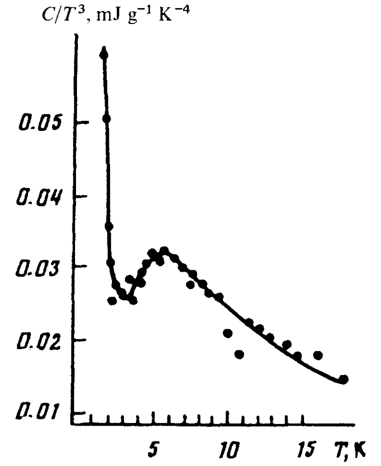

Figure 18. Experimental data[61] for the low-temperature heat capacity of HSA in terms of the function $C/T^3 = f(T)$, illustrating the presence of a linear term due to the phonon-stimulated tunnelling.

The dependence of the quantity C_1 on the spectral density of two-level states $n(\Delta)$ at $\Delta \to 0$ has the following form:[60]

$$C_1 = \frac{\pi^2}{6} k_B^2 n(0).$$

The local energy minima, illustrated in Fig.16*b* and characterising the QDCS of biomacromolecules, form precisely such a multilevel, multiwell system and it is natural to expect the occurrence of PST between QDCS playing the role of QEP.

We have analysed extensive experimental data for the low-temperature heat capacities of biopolymers (see the relevant review[63]) on the basis of the above three-term formula and observed[33,64,65] that the linear term C_1T for biomacromolecules is significant.

The results of our calculations and also of later direct experiments with HSA [66] (Fig.18) and metmyoglobin [67] are compiled in Table 3.

Table 3. Parameters of the low-temperature heat capacities of polymers and biopolymers.

The vitreous dynamic model of biopolymers proposed by the present author and his co-workers[33,64,65] presupposes the existence of internal mobility of the biomacromolecules even as $T \to 0$ by virtue of the PST of atoms and atomic groups.

Thus we have demonstrated yet again that the modern Mössbauer spectroscopic methods constitute an effective instrument in the study of tunnelling phenomena in chemical and biochemical physics—the quantum effects in the kinetics of chemical reactions and biomolecular dynamics, which are most pronounced at low temperatures.

The RSME data can yield fairly reliable estimates of the tunnelling parameters.[33,46] The maximum values of $\langle x^2 \rangle$ at 300 K reach almost 1 Å^2 and the contribution by elastic RSME is in this case smaller by a factor $N = 4$–5 than at low temperatures. According to Shaitan,[72] the factor N means simply the number of potential wells in the multiwell region of the delocalisation of certain atomic groups. The distance between the wells is then given by $d \cong \sqrt{\langle x^2 \rangle}/(N-1) \cong 0.25$ to 0.33 Å; subsequent analysis of the temperature dependence of the parameters of three-dimensional diffusion[47-51] yields the height of the energy barrier between the wells: $E \cong 0.2$ eV and the tunnelling temperature[19,20] for CH_2 groups is accordingly estimated at $T_t \cong 120$–160 K. Inspection of the multimodal Franck–Condon effects, i.e. allowance for the low-frequency vibrations of potential wells relative to one another[73-75] (apart from the high-frequency vibrations of the tunnelling groups within the limits of the occupied wells) leads to the conclusion that, even at the physiological temperatures, the contribution of tunnelling may be quite comparable to that of thermally activated transitions of atomic groups between QEP and that tunnelling induced by fluctuations can have a definite importance also for the functioning of proteins and other biopolymers.[33,46]

Thus RSME studies on biopolymers combined with MAS and XDA data as well as low-temperature heat capacities provide an adequate basis for treating natural biopolymers as special heterogeneous glasses incorporating regions with different glass points.[33,46,64,65]

At room temperature, a biomacromolecule contains regions whose properties resemble those of a crystal, a glass, a supercooled liquid, and an ordinary liquid. The principal physical parameter, chosen here for the purpose of the description and comparison of different states, is the free volume.

The $f_R(T, h)$ three dimensional diagram (Fig.13) demonstrates the existence of a transitional ΔT_c region in the vicinity of $T_c \cong 200-220$ K and a Δh_c region in the vicinity of $h_c \cong 0.1-0.3$. For $T < T_c$ and $h < h_c$, the dynamic properties of biopolymers combine the properties of a crystal and a glass, while above T_c and h_c they combine the properties of a crystal, a glass, and a supercooled liquid.

The temperature T_c plays the role of the usual glass point T_g and the degree of hydration h_c plays the role of a kind of hydration glass point h_g for those regions in biomacromolecules where the glass state is transformed into the highly elastic state. The increase of the specific volume (and also of the free volume) of the biopolymer and hence of its internal mobility with increase of temperature and of the degree of hydration accelerates appreciably at temperatures above T_c and for $h > h_c$.

All the above considerations are summarised in Table 4, where the plus and minus signs denote the presence or absence of the following four main properties: (a) order; (b) periodicity of the structure (for an individual biomacromolecule); (c) unambiguity of the structure (for an individual biomacromolecule) as $T \to 0$; here the plus sign denotes that $S_0 = 0$ at $T = 0$ and the minus sign denotes that $S_0 \neq 0$; (d) mobility as $T \to 0$.

Table **4**. Description of the parameters of the structural and dynamic properties of biopolymers.

Substance	Order	Periodicity	Unambiguity of structure*	Mobility*	Glass:IC number***
Ideal crystal	+	+	+	−	
Glass	−	−	−	+**	
Aperiodic crystal	+	−	+	−	1:3
Biopolymer (treatment after 1973-1979)	+	−	−	−	2:2
Biopolymer (treatment after 1983)	+	−	−	+	3:1

*As $T \to 0$.

**Treatment after 1972.

***Here IC = ideal crystal.

The ideal crystal (+++−) and glass (−−−+) (the plus sign denoting mobility in glasses has been generally accepted since 1972 [61,62]) are used in Table 4 as the principal comparison standards. The Schrödinger definition[46] of the protein as an aperiodic crystal is designated by the symbol (+−+−), the appearance of the concept of CSS (QDCS) (1973–1979) [39−41, 52−55] denotes the transition to (+−−−), and finally the vitreous dynamic model of proteins (1983) [33,64,65] corresponds to the formulation (+−−+). Thus the general ratio 3:1 in favour of the ideal crystal has gradually changed to 1:3 in favour of glass.

* * *

We have thus seen that gamma-resonance spectroscopy in its MAS and RSME versions has played a very notable role in the development of ideas about the structural and dynamic properties of biopolymers, i.e. in one of the most important problems of modern biochemical physics.

Chemical, Physical, and Biological Approaches to the Creation of Stabilised Enzyme Catalysts for Biotechnology

V.V.Mozhaev, K.Martinek, and I.V.Berezin (deceased)

The problem of the inter-relation between the structure and stability of proteins includes two main questions: firstly, how can we discover the molecular characteristics of the structure of proteins which are responsible for their stability? Secondly, how, knowing the general molecular causes of stability, can we alter the structure of a specific protein in order to increase its stability, i.e. to stabilise it? In the present review an attempt is made to present the current state of both the first (fundamental) and second (applied) aspects of this problem.
The bibliography includes 250 references.

I. INTRODUCTION

The problem of the inter-relation between the structure and stability of proteins is one of the key problems in modern protein chemistry.[1] Only its solution will permit a close approach to the realisation of the long-standing aim of investigators in the field of protein chemistry: to predict[1,2] the steric structure of the protein from its known aminoacid sequence and to attempt the synthesis[3] of a molecule of a protein type whose property is specified beforehand.

On the other hand, one of the central tasks of chemical (engineering) enzymology is to create stabilised enzyme preparations for various technological applications.[4-11] The pathway leading to the creation of stabilised enzymes was outlined several decades ago when many world laboratories began to elucidate and investigate the molecular mechanisms or at least the molecular causes of the inactivation of protein (see the relevant reviews[12,13]). Only after this "preparatory stage" did it become possible to proceed directly to the development of methods whereby the structure of enzymes could be influenced specifically in order to suppress the inactivation mechanisms established previously. The chemical and physical methods for the stabilisation of enzymes have so far been developed to the greatest extent (see the relevant reviews[14-19]). However, there is no doubt that the biological approach proposed recently (application of methods of genetic engineering)[20-22] merits no less attention.

The present review deals with the entire chemical-physico-biological set of inter-related problems. The data described have been divided into three somewhat separate sections. Firstly, there is a brief discussion of experimental and theoretical approaches used to establish the inter-relation between the stability of proteins and their structure. This is followed by the molecular causes of the stability of proteins themselves. This question has been frequently raised in the literature at least since the studies by Bressler and Talmud.[23] The current level of the problem has been fairly completely dealt with in recent publications, for example, in the monograph of Schultz and Schirmer.[1] We should therefore attempt here mainly to answer the following question: what must be done to the protein (how must its structure be altered) in order to impart to it greater stability. Finally, in the last Section it is shown how this can be achieved at the present time, i.e. the experimental methods for the preparation of highly stable biocatalysts are examined.

II. THEORETICAL AND EXPERIMENTAL APPROACHES TO THE ELUCIDATION OF THE INTER-RELATION BETWEEN THE STRUCTURE AND STABILITY OF PROTEINS

The solution of the problem of the inter-relation between the structure and stability of proteins in the most general form implies the calculation of the free energy of the protein from its steric structure. In principle, one could attempt to calculate separately for this purpose the energy of each of the stabilising (hydrogen bonding, hydrophobic, electrostatic, and dispersion interactions, etc.) and destabilising (in the first place the unfavourable entropy contribution by a strained conformation) factors and to add them up. Unfortunately, this cannot be carried out correctly.[1,24] The reason is that the contribution of each of the above components to the free energy of the protein amounts to tens and hundreds of kcal mol^{-1}.[25,26] This is a lot in view of the fact that proteins as a whole are characterised by a relatively low stability; the experimental free energy of stabilisation (of the native form relative to the denatured form) amounts to between 5 and 15 kcal mol^{-1} for the vast majority of globular proteins.[27]

Another general (experimental) way of solving the problem consists in the following procedure: one selects two proteins of different stability and by comparing their structures one attempts to elucidate how the structural characteristics are responsible for the increased stability of one of them. However, the following question arises: which pair of proteins should be chosen for such a comparison? If we select two arbitrary proteins, then in all probability their stabilities will be found to lie in the statistical average range of free energies: 5–15 kcal mol^{-1}. Consequently the differences in stability will be minute and it will be hardly possible to identify them with any definite structural characteristics, especially against the background of the large structural differences characteristic of functionally different proteins.

The same feature of protein structure (small differences in stability against the background of a great structural variety) lead apparently to a relatively low predictive value of studies of a generalised character.[28-31] In other words, the attempts to analyse the known structure of several tens of proteins in order to find a correlation between their stability and certain general structural parameters (hydrophobic nature,[28-30] volume,[30] or the content of particular aminoacid residues[31]) did not lead to unambiguous conclusions.

Comparison of the stabilities of proteins having fairly close structures proved to be most fruitful. Proteins having the same biological function are characterised by such structural kinship.

A typical experiment designed to elucidate the inter-relation between structure and stability consists of three stages. Firstly, two (or several) functionally related proteins from different sources are selected and are obtained in as pure a form as possible. Next, the following characteristics of the proteins are compared: (1) the aminoacid compositions and primary structures; (2) the steric three-dimensional structures and parameters of their conformational variability; (3) the resistance to the action of reversible denaturing agents and to irreversible investigation; (4) the temperathre dependence of the functional (catalytic) activity.

Finally, an attempt is made to correlate the quantitative stability characteristics obtained (such as the temperature of reversible denaturation, the optimum temperature of enzyme activity, and the equilibrium or kinetic denaturation parameters—ΔG, ΔH, ΔS, etc.) with the structural differences which it has been possible to discover.

The question arises of the origin of functionally related proteins having different stabilities. In the first place, they are found in nature. Firstly, these are related proteins from different mesophilic sources. Secondly, related proteins from thermophilic and mesophilic organisms are compared. Thirdly, proteins from wild strains are compared with proteins altered by mutation. The objects of such research are also obtained artificially. Three methods are used at present for this purpose: "site-directed" mutagenesis, immobilisation, and chemical modification. We shall consider what information can be obtained from the study of the inter-relation between the structure and stability of proteins by the application of each of these approaches.

1. Homologous Proteins of Mesophilic Organisms

Comparison of the structures of enzymes fulfilling identical functions in evolutionary remote organisms has long been used to elucidate the mechanisms of enzyme catalysis.[32] However, this approach is used much more rarely for the study of the inter-relation between the structure and stability of proteins. The point is that the differences between the primary structures of related mesophilic proteins can be extremely large. For example, in two of the most widely different proteins of the family of globins, only 16% of all the aminoacid residues occupy identical positions in the primary structures.[33] On the other hand, the differences between the stabilities of homologous proteins are as a rule very insignificant—not more than 1–3 kcal mol^{-1}. The insuperable problem discussed above therefore arises: how can one interpret the minute changes in stability against the background of large differences in structure?

Nevertheless, comparison of homologous proteins of mesophilic organisms yields some useful information about the inter-relation of their structures and stabilities.[33-36] Firstly, it is sometimes possible to find related proteins which differ only by 1–2 aminoacid residues, which naturally facilitates the problem of the elucidation of their role in the stability of the proteins being compared.[19] Secondly, it is frequently possible to discover "invariant positions" in proteins (the replacement of aminoacid residues in these positions is inadmissible, because it leads to the decomposition of the structure). As a rule, the invariant positions are located either in the inner regions of the globule[33-36] or in the regions corresponding to intersubunit contacts[36] and contacts between neighbouring α-helices.[33] The aminoacid involved in the coordination of haem[34] as well as the fragments of the active centres of the enzyme[36] are also invariant.

2. Comparison of Proteins from Thermophilic and Mesophilic Organisms

The existence of life under extreme conditions has long been known—for the history of the development of the problem, see Brock.[37] It was not until the middle 1960's that it became possible to demonstrate that the stability of microorganisms under extreme conditions is as a rule associated with the increased stability of their constituent biomacromolecules and in the first place proteins.[38]

The search for differences between the structures of related thermophilic and mesophilic proteins has the advantage over the comparison of mesophilic objects that the range of the differences between their stabilities is much wider and hence there is a greater probability of observing the structural differences which are significant for stability. Hitherto ~100 thermophilic proteins have been isolated in a highly pure form and their properties have been investigated. The molecular causes of the increased stability of thermophilic proteins have been discussed in a series of reviews and monographs.[19,37-49]

3. Proteins Modified by Mutation and Proteins from Wild Strains

Under the influence of unfavourable external influences, chemical agents, irradiation, and certain other factors in nature, the phenomenon of the so called mutagenesis takes place.[50] At the level of cells and whole organisms, mutagenesis is expressed by a change in morphology and functions and frequently leads to degeneracy. At the molecular level, nucleotides are replaced, new bases (or even whole sections of the genome) are incorporated or omitted. This results in the synthesis of proteins with a modified structure: with replacement of one (the most frequent case) or several aminoacid residues by different ones; with the polypeptide chain divided into a series of fragments not linked by covalent bonds or, conversely, with covalently cross-linked polypeptide chains.[50]

Comparison of the structures of mutant proteins and proteins from wild strains is actively employed for the elucidation of the mechanisms of enzyme catalysis,[51,52] in particular in order to discover the aminoacid residues significant for catalysis.[53] Using this approach, it has been possible to obtain also information about the role of individual aminoacids and of more complex structural factors in the stability of proteins some examples may be found in the review of Mozhaev and Martinek.[19]

4. Artificially Modified Proteins

There exist at least three ways of obtaining artificially modified proteins: site-directed mutagenesis (using the procedures of genetic engineering), immobilisation, and chemical modification.

(a) The Method of Site-Directed Mutagenesis

In this method manipulation at the level of genes yields analogues of proteins with a known tertiary structure differing by the replacement of only one aminoacid residue in a rigorously specified position.[54]† The latest advances in site-directed mutagenesis[20,55] have made the method available in many laboratories. Thus proteins of "aritificial origin" modified by mutation have come to be used for the study of the role of definite aminoacid residues in catalysis.[56] Enzymes with an improved activity and an altered substrate specificity have been obtained in this way.[57,58] As for mutants of natural origin, proteins with substituted aminoacid residues in specific positions, obtained artificially (by genetic engineering), can yield information about the role of individual structural elements also in the stability of proteins.

(b) Immobilisation of Enzymes

This should be understood in the first place as a method for the significant restriction of the mobility of protein molecules (or their fragments) in space or relative to one another.[59,61] In recent years this method has been used actively in biotechnology,[4–11] in particular for the stabilisation of enzymes.[14–19] However, sometimes one encounters the view that the immobilisation method is effective only for the solution of purely applied problems but does not yield new information for fundamental science. This view is based on the long-standing preconceived notion that immobilisation alters the structure of the enzyme compared with its native structure. However, it has been demonstrated in recent years by physical methods that this is by no means the case: in many instances immobilisation does not change the conformation of the enzyme at all or changes it only insignificantly (see the review of Martinek and Mozhaev[62]). Furthermore, having selected a suitable immobilisation method, one can be certain that the conformations of the native and immobilised enzymes are similar.[62] For this reason, immobilised enzymes have proved to be successful models in the study of a whole series of *in vivo* processes.[62,63] They also yield useful information about the inter-relation of the structure and stability of proteins. Thus the important role of fluctuations in the structure of the protein in its stability has been discovered with the aid of immobilisation.

(c) Chemical Modification of Proteins

This method is used as an approach not only to the stabilisation of enzymes[64–66] but also to the elucidation of the inter-relation between the structure and stability of proteins.[19,66]

The main problem involved in the use of the modification approach is that of obtaining a protein preparation in which only a specific functional group (or a specific series of groups) has been modified. The difficulty of specific modification lies in the fact that the functional groups of proteins exhibit the same type of reactivity: they are all potential nucleophiles and proton donors or acceptors (Table 1). For this reason, the "frontal" modification of proteins by an arbitrary reagent leads to competition between different functional groups of the protein for the reagent and usually ends in failure—non-specific modification. Nevertheless, advances in selective modification have led to the discovery of several reagents for virtually any functional group in proteins which involve only this particular group (for examples, see Table 1). Furthermore, even for reagents exhibiting group specificity, it is frequently possible to select conditions under which aminoacid residues of only one type are modified selectively. For this purpose, one varies either the pH (because as a rule only one of the forms—protonated or deprotonated—is reactive) or one employs reversible modification reactions (Table 2) with the aid of which other groups of the protein competing for the reagent can be subjected to preliminary blocking.

Table 1. The functional groups in proteins which can be subjected to specific modification.[72]

Group	Aminoacid residue	pK_a	Examples of selective reagents*
α-COOH	terminal aminoacid	<1—6.8	carbodiimide + nucleophile
β-COOH	Asp	<1—6.8	ditto
γ-COOH	Glu	<1—6.8	»
	His	6.4—7.5	diethyl pyrocarbonate
—SH	Cys	8.0—9.5	*N*-ethylmaleimide; disulphides
α-NH$_2$	terminal aminoacid	7.3—>12	dansyl chloride; methyl acetimidate
ε-NH$_2$	Lys	7.3—>12	ditto
	Tyr	9.4—>12	tetranitromethane, *N*-acetylimidazole
 $-NH-C(=NH)NH_2$	Arg	11.5—>12	butane-2,3-dione, phenylglyoxal
—OH	Ser, Thr	>12	—
	Trp	>12	*N*-bromosuccinimide
—S—CH$_3$	Met	—	chloramine T; H_2O_2

*Taken from Lundblad and Noyes.[89]

The potential value of the chemical modification method is truly enormous.[67–89] However, its application to the study of the inter-relation between the structure and stability of proteins encounters a series of methodological difficulties, which are frequently fundamental. We shall consider the most important of these difficulties and shall attempt to outline ways whereby they can be overcome.

1. There is a risk that modification will involve the invariant elements of the protein structure and will lead to undesirable conformational changes, up to the denaturation of the protein.[72,84] In order to test this possibility, the chemical modification product must be analysed by a physical method and it must be discovered whether the conformations of the native and modified proteins are different. If such differences exist, it is essential to alter the modifying agent.

---

†The methodological procedures of site-directed mutagenesis will be examined below.

2. Sometimes it is necessary to modify proteins under fairly severe conditions where undesirable side processes can take place (Table 3). In order to avoid secondary reactions, it is frequently necessary to resort to preliminary protection of the "vulnerable" functional groups (Table 2) and, after the modifications have been carried out, the "protecting groups" must be removed under mild conditions.

Table 2. Reactions leading to the reversible protection of the aminoacid residues in proteins.

Amino-acid	Reaction	Refs.
Met		[90]
Trp		[91]
Tyr		[92]
Ser, Thr		[93]
Arg		[94]
His		[95]
Cys		[96]
Lys		[97]

3. Only in rare cases is it possible to modify the protein in such a way that only a specific aminoacid residue in it is involved. Usually chemical modification results in a set of derivatives of the protein differing both in the number of modified groups and in the ordinal numbers of the residues affected by the modification in the primary structure. This naturally leads to a significant inhomogeneity of the products of the chemical modification of the proteins.[72,84] The difficulty of separating the product is inherent in the fact that the modified proteins frequently differ little in their physical properties (charge, molecular weight, molecular shape, etc.). High performance liquid chromatography proved to be especially useful in this field.[98]

4. Yet another serious problem is how to identify the product of the chemical modification of the protein. Aminoacid analysis is most often used for this purpose. However, the method suffers from the disadvantage that, before the direct determination of the aminoacid composition, the protein is subjected to a treatment under extremely severe conditions (concentrated HCl, temperature above 100 °C) in order to hydrolyse all the peptide bonds. This is naturally accompanied also by the rupture of other chemical bonds (weaker than the peptide bonds) and certain aminoacids undergo chemical decomposition. For this reason, the identification of many aminoacids (Cys, Trp, Met) and of the products of certain types of chemical modification (oxidation, acylation) is either altogether impossible by means of aminoacid analysis or inaccurate results are obtained.[85,86] Fortunately, this difficulty can be overcome[85] by employing certain methodological devices (for example, reactions competing for functional groups or the radioactive tracer method).

Table 3. Undesirable side reactions in the modification of the functional groups of proteins.[84]

Functional group	Conditions	Result
Peptide bond	pH 8—12	hydrolysis
ditto	pH 1—5	N-O acyl shift
SH group	oxidation	S-S bond, S-O acids
S-S bond	reduction	SH groups, new S-S bonds
ditto	pH 8—12	hydrolysis, β-elimination
S-CH_3 group of methionine	oxidation	hydroxy-derivative
Amide group	pH 8—12	hydrolysis
O-Glycosyl group	pH 8—12	β-elimination
O-Phosphate group	pH 8—12	β-elimination

Another way of overcoming this difficulty involves the determination of the degree of modification under mild conditions. This is effectively assisted by the reactions involved in the spectrophotometric titration of the residual unmodified functional groups of the proteins with the aid of chromophoric reagents (certain examples are presented in Table 4). The methods for the determination of the primary structure are used to determine the exact site where the modified aminoacid residue is located.[103]

Thus the difficulties arising can be overcome in principle and one can proceed to the search for the inter-relation between the stability and structure of the protein. The experiment must be begun with a comparison of the conformations of the native and modified proteins. The point is that sometimes the increase[104,105] or decrease[106,107] of the stability of proteins as a result of chemical modification is caused precisely by conformational changes. Such data are of limited value, because it is difficult to interpret them and even more difficult to predict them.

One usually has to deal with a chemical modification product which, while conformationally not different from the native protein, nevertheless has a lower or higher stability. In order to elucidate the molecular causes of stabilisation or destabilisation, the following methodological procedures are employed.

The increase of the degree of modification (of the number of modified functional groups). If the stabilising or destabilising effect changes monotonically (smoothly) under these conditions, the most likely implication is that specific interactions of any kind, for example, the formation of salt bridges or hydrogen bonds, do not arise (or vanish) in the protein on modification. Otherwise, the observed dependence would have been of a discrete type: indeed, it is difficult to imagine that the modification of each successive residue generates or destroys a salt bridge or hydrogen bond. It is more probable that the smooth type of dependence of the stabilising or destabilising effect on the degree of modification reflects a uniform alteration of some integral parameter of the globule (its hydrophobic property or surface charge).

A change in the chain length of the modifying agent for a specified degree of modification. For this purpose, it is convenient to employ homologous series of modifying agents: amines, aldehydes, imidates. Analysis of the type of dependence of the stabilising or destabilising effect on the chain length of the reagent has proved useful for the elucidation of the influence on the stability of proteins of integral parameters such as the surface hydrophobic character or surface charge.[66]

The influence of temperature on the stabilising or destabilising effects can sometimes help to elucidate[66] what type of interactions in the protein makes a decisive contribution to the stabilisation. In particular, if the stabilising effect increases with increase of temperature, then this is important evidence for the enhancement of hydrophobic interactions in the protein.

In conclusion of this Section of the review, we shall draw attention to the possibility of one fundamental error in the interpretation of experimental data. A particular mechanism of inactivation characteristic of the native protein can sometimes be significantly inhibited by chemical modification. For example, the thermal inactivation of bovine serum albumin in solution is sometimes caused mainly by its aggregation.[108] By introducing an excess negative charge on the protein surface (for example by citraconylation), aggregation can be fully prevented. The retardation of the inactivation observed experimentally in this case[108] is caused by a change in the inactivation mechanism and not by the internal stabilisation of the protein (due to its modification). In studies with modified and even with immobilised proteins or proteins modified by mutation, it is always important to make sure that the mechanisms of their inactivation are identical with the mechanisms for the native proteins.

III. MOLECULAR CAUSES OF THE STABILITY OF PROTEINS

The principal molecular causes of the stability of proteins were recently analysed by the present authors.[19] Here we shall consider them only in order to elucidate whether nature has left provision (and what kind of provision) for the artificial increase of the stability of proteins.

1. The Binding of Metal Cations, Substrates, Prosthetic Groups, and Other Low-Molecular-Weight Ligands

The most general explanation of the facts concerning the stabilisation of enzymes in their interaction with ligands was given by Schellman.[109] There exist at least two states of protein—native and denatured, and any compound is in principle capable of binding to either one. The preferential binding to one of the forms of the protein inevitably stabilises it in relation to the other by the amount equivalent to the free energy of formation of the corresponding complex. It is known that the effectors of enzyme activity are bound in the region of the active centre or near it. The formation of the enzyme—ligand complex therefore requires that the protein exist in the native conformation; there is as a rule no binding to the denatured form. This is precisely why specific low-molecular-weight ligands usually stabilise proteins.[109]

Table 4. Spectrophotometric determination of certain functional groups in proteins.

Reaction	λ, nm	Molar absorption	Refs.
	412	13 600	[99]
	410	18 000	[100]
	420	13 000	[101]
	550	13 800	[102]
	480	20 500	[102]

In connection with the preparation of artificially stabilised enzyme preparation by interaction with effectors, we draw attention to the fact that in such interactions proteins frequently undergo conformational changes,[110] i.e. are converted into other, sometimes more stable conformations. An attempt must be made to fix this stable conformation, for example with the aid of immobilisation;[111] a critical analysis of this approach has been carried out in a review.[62]

2. Protein–Protein and Protein–Lipid Interactions

In vivo proteins frequently interact with other protein molecules, lipids, and polysaccharides.[112] The structures then formed can be divided arbitrarily into two fundamentally different types: firstly, complexes with a small number of either protein–protein contacts (for example, subunit enzymes[113] or species comprising proteases associated with protein inhibitors[114]) or protein–lipid contacts (such as the complexes of albumin with aliphatic acids[115]) and secondly systems with a large number of inter-related concerted contacts of different types (protein–protein, protein–lipid, lipid–lipid) of the kind which obtain, for example, in biological membranes.[116] The interaction of the protein with other molecules in both these and other types of structures can significantly increase its stability.

The mechanism of stabilisation on formation of individual protein–protein or protein–lipid contacts has been in principle understood.[114] Together with polar and charged groups, there are "hydrophobic clusters" on the surface of proteins and their contact with water is thermodynamically unfavourable. On formation of the complex, the lipid or protein molecule "sits" on this cluster and thereby prevents its contact with the solvent.[117] The observed free energy of stabilisation amounts to several kcal mol^{-1} per protein–protein contact.[113,114]

Such protein–protein or protein–lipid contacts can also be created artificially: in the presence of lipids[118,119] or high concentrations of proteins (for example, albumin),[120,121] the stability of certain enzymes increases appreciably.

The mechanism of the stabilisation of enzymes when the latter are enclosed in biological membranes appears less unambiguous. Indeed, together with the "shielding effect" discussed above, many other factors should play an important role in this instance. Among them, we shall specify in the first place a change in the rigidity of the protein molecule as a result of its multipoint interaction with other proteins and lipids and we shall consider the influence of this factor on stability.

3. The Rigidity of the Protein Molecule

The rigidity determines the ability of the macromolecule to assume different states in conformational space[122] and is related directly to the stability of the protein. Indeed, both the protein denaturation process (the manifestation of the instability of the protein) and the fluctuations about a certain statistical average stage (the manifestation of the "non-rigidity" or flexibility of the protein) are based on the same molecular mechanisms: the vibrational and rotational movement in the macromolecule. The difference between these processes consists only in the fact that in denaturation a cooperative conformational transition of the entire globule takes place,[26] while local fluctuations in the structure involve only individual sections of the globule without a significant alteration of the overall conformation.[123]

In the present review we shall not attempt to give a rigorous thermodynamic definition of rigidity[122,123] or to relate it to the thermodynamic parameters of the stability of the protein.[124] Undoubtedly many factors which determine the stability of the protein (in the first place hydrophobic interactions) influence also its rigidity.[122,124] Here we shall consider only one question: how a factor such as immobilisation—natural or artificial—affects the rigidity and stability of the protein?

In nature proteins and membranes exist in a naturally immobilised state; this must be understood as having the consequence that, as a result of interaction with other proteins and lipids, their rotational diffusion as well as their vibrational and rotational movement are significantly restricted. The degree of immobilisation of proteins in a membrane depends in many respects on the integrity of the membrane and on the degree of structural formation in the latter. When the latter parameter is altered (for example, in a phase transition within the membrane), the "degree of immobilisation" of proteins changes significantly,[125] which entails changes in the catalytic properties of membrane enzymes.[125,126] However, until recently there have been virtually no data concerning the influence of structure formation in membranes on the stability of membrane enzymes.

A pioneering study on these lines was carried out by Welker.[127] He grew the obligatory thermophilic strain *Bacillus stearothermophilus* at temperatures ranging from 55° to 70 °C and observed that, with increase of the growing temperature, there is a significant increase of the stability of the cell membrane (which he inferred from the decomposition of cell protoplasts at elevated temperatures—Table 5). Simultaneously with the strengthening of the structure of the membrane, there is a significant increase in the thermal stability of membrane enzymes; this has been noted both for peripheral alkaline phosphatase and integral NADH-oxidase (Table 5). An increase of stability is observed only for enzymes forming part of the composition of the membrane. After extraction from the membrane, the stability of alkaline phosphatase first falls sharply and then becomes independent of the temperature at which the given culture of microorganisms has been grown (Table 5). Thus these data confirm the earlier hypothesis[128,129] of the stabilising influence of the membrane structure on proteins.

Table 5. The influence of the growth temperature (T_g) of the culture on the properties of the membranes of the cells of *Bacillus stearothermophilus* and the thermal stabilities of the enzymes.[127]

T_g, °C	Disruption of protoplasts, %				Degree of inactivation, %					
					free A.P.*		membrane A.P.		NADH-oxidase	
	65°	70°	75°	80°	65°	70°	65°	70°	75°	80°
55	0	100	100	100	100	100	87	100	100	100
60	0	80	100	100	100	100	0	92	90	100
65	0	0	70	100	100	100	0	20	75	84
70	0	0	10	100	100	100	0	5	0	10

*A.P. = alkaline phosphatase.

Comparison of the thermal stabilities of enzymes immobilised by natural (in a biomembrane) and artificial (on a polymeric carrier) procedures is extremely instructive. Fig.1 presents the temperature dependence of the catalytic activity of the integral membrane enzyme NADH-oxidase.[127] Evidently the stronger the membrane in which the enzyme has been incorporated (i.e. the higher the temperature at which the culture has been grown), the higher the temperature optimum of the catalytic activity. A similar family of experimental curves has been obtained[130] for artificially immobilised trypsin, whose molecules were attached to the carrier by different numbers of bonds (Fig.2). We believe that the identity of the forms of the temperature variations in Figs.1 and 2 is not fortuitous. Apparently it reflects the same trend: the increase of the stability of the enzyme as a result of the strengthening of its structure. The difference consists only in the fact that the strengthening is achieved either as a result of more pronounced structure formation in the natural protein-lipid membrane matrix *in vivo* or via an increase in the number of bonds between the enzyme molecule and the artificial polymer matrix *in vitro*

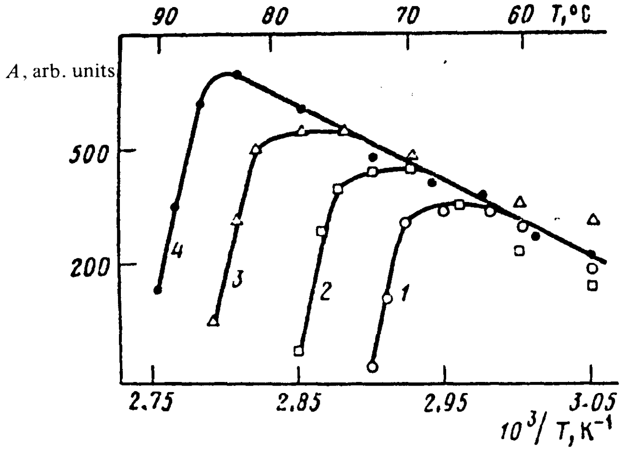

Figure 1. Temperature dependence of the catalytic activity (A) of a membrane enzyme (NADH-oxidase from the cells of *Bacillus stearothermophilus* grown at different temperatures): *1*) 55 °C; *2*) 60 °C; *3*) 65 °C; *3*) 65 °C; *4*) 70 °C.[127]

4. Salt Bridges

Among all the stabilising factors based on electrostatic interactions, ion pairs (or, in other words, salt bridges) make the greatest contribution to the stabilisation of protein.

There are relatively few ion pairs in proteins,[131,132] but they make a significant contribution to their stabilisation—up to 5 kcal mol^{-1} per ion pair if the latter is located within the globule and 1–2 kcal mol^{-1} if it is on the surface.[1,113] It is therefore not fortuitous that nature willingly makes use of them and creates thermophilic proteins with increased stability.[19]

We shall quote yet another example. Glyceraldehyde 3-phosphate dehydrogenase, from the moderate thermophile *Bacillus stearothermophilus* has a three-dimensional structure similar to that of the enzyme from rabbit muscle[133] with only a small but significant difference: in the region of subunit contacts, the thermophilic dehydrogenase has a cooperative system of additional salt bridges, which is missing from the mesophilic enzyme. This is in fact the main molecular reason why both the denaturation and the optimum catalytic activity of the thermophilic enzyme are observed at a higher temperature than for the enzyme from rabbit muscle.[133]

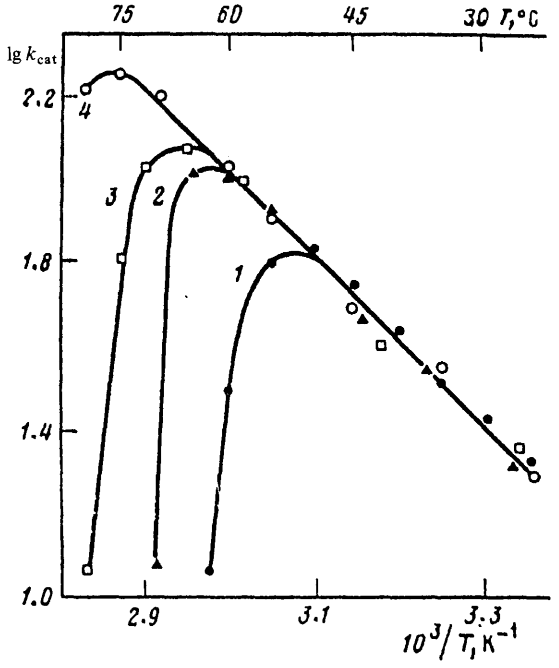

Figure 2. Temperature variation of the catalytic constants k_{cat} for the hydrolysis of the specific substrate catalysed by trypsin: *1*) free enzyme; *2–4*) enzyme immobilised covalently in polyacrylamide gel by 5, 8, and 15 bonds respectively.[130]

An attempt may be made to create in the protein additional ion pairs artificially, for example by site-specific mutagenesis or by chemical modification. However, success of such procedures, i.e. the appearance of a salt bridge, requires detailed knowledge about the steric structure of proteins. The likely usefulness of this approach will probably increase as more new information is obtained about the structure of proteins, in the first place by X-ray diffraction.[134]

5. Hydrogen Bonds

The hydrogen bonds in proteins play an important structural role; they maintain the spatial organisation in the secondary structures (α-helices, β-structures, rotations). It has come to be assumed that the formation of a hydrogen bond in proteins is an energetically favourable process. The energy of the hydrogen bond is frequently calculated as the result of two events: the dissociation of "old" hydrogen bonds between a polar atom (for example, the oxygen of the amide group) and a water molecule and the formation of "new" hydrogen bonds between the polar atoms in the protein molecule and has been estimated as 1–2 kcal mol^{-1}. However, in this treatment no account is taken of the fact that there is a parallel thermodynamically unfavourable process involving the immersion of the polar atom or group (for example, the amide group) within the hydrophobic nucleus of the globule. Allowance for the energetics of this process leads to the conclusion that[1] the free energy of formation of the hydrogen bond in the protein is close to zero. In other words, the hydrogen bond is the price which the protein has to pay for the characteristic features of its structure. In our view, there is therefore no point in attempting (for example, by methods of protein engineering) to introduce hydrogen bonds into the protein artificially.

6. Disulphide Bridges

The ideas about the stabilisation of proteins with S–S bonds arrived in protein chemistry from polymer chemistry. In the middle 1950's, it was shown that[135,136] the intramolecular cross-linking of macromolecules imparts to them additional rigidity and increases their stability. The nature of this stabilisation is entropic:[135] as a result of the appearance of a cross-link in the macromolecule (a S–S bond in a protein), there is a significant decrease in the entropy of the open-chain form, which entails an increase in the free energy difference between the native and denatured states of the protein. This stabilising contribution in proteins amounts to up to 4–5 kcal mol^{-1} per S–S bond.[137]

Modern methods of protein chemistry lead to extensive possibilities for the introduction of intramolecular cross links into proteins. Firstly, one can use bifunctional modifying agents.[133] The methods developed for the imposition of "molecular yokes" make it possible in the main to cross-link surface regions in the protein. Another approach involves the introduction of a cross link within the protein molecule. Here the method of site-directed mutagenesis can serve as the instrument. For example, it has been possible to introduce S–S bonds into lysozyme T4—a protein from which they are absent—by this method.[139]

7. The Low Content of Aminoacids Susceptible to Oxidative Modification

One of the common mechanisms of the inactivation of proteins involves the oxidation (for example, at an elevated temperature) of aminoacid residues important for the structure.[12,13] In the first place the SH group of cysteine and the indole ring of tryptophan undergo oxidative modification. It is therefore not fortuitous that the highly stable thermophilic proteins contain much smaller amounts of these labile aminoacids (in the first place Cys).[19]

Apparently there exist two pathways to the stabilisation of enzymes unstable with respect to oxidation. The first involves a copy of the procedure which nature has used in thermophilic enzymes: to decrease the number of SH groups. For this purpose, one has to attempt by the method of site-specific mutagenesis to replace the Cys residues, most susceptible to oxidation (provided of course that they are not involved in catalysis), by others less labile, but having similar properties (geometry, hydrophobic properties).[140] The other procedures are methodologically simpler: to create around the enzyme a microenvironment which would shield it from the inactivating factor (oxygen). For example, a charged polyelectrolyte can serve successfully as a shield of this kind: it "coats" the enzyme and significantly hinders the access of oxygen to it. The "salting out" of oxygen by the polyelectrolyte matrix made it possible to increase the stability of labile hydrogenases by a factor of thousands.[141]

8. Compact Packing of Aminoacid Residues

The protein molecule in solution represents a compactly packed structure; the packing density of aminoacid residues in the globule is close to that characteristic of crystals of organic molecules.[1] Nevertheless, there exist "cavities" within the protein which are filled with water molecules (5–15 molecules per protein with a molecular weight of 20 000–30 000). The contact between the polar water molecules and the hydrophobic nucleus of the protein is thermodynamically unfavourable and destabilises the protein.

The stability of the protein can be in principle increased by further compaction, i.e. by the "additional compression" of the protein structure with simultaneous removal of water molecules from the internal region. This type of procedure has been used by nature to create thermophilic enzymes; in their structures, certain internal aminoacid residues have been replaced (compared with the corresponding mesophilic analogues) by more bulky residues.[19] The idea of the compaction of the protein can also serve as the basis for artificial stabilisation if an attempt is made to replace suitable aminoacid residues, for example, by site-directed mutagenesis. It is then necessary to bear in mind that the replacement of aminoacid residues by certain others is impermissible, because it can lead to serious infringements of the protein structure.[142]

9. Hydrophobic Interactions

At the present time ideas about the nature of hydrophobic interactions and their role in the stability of proteins have been arranged to form an elegant system.[143–145] In proteins, about half of the entire volume is occupied by aminoacids with non-polar side groups. Their contact with water is thermodynamically unfavourable, because the introduction of a non-polar fragment into water makes the structure of the latter more ordered. Such structure formation in water diminishes the entropy of the system and hence increases its free energy.# Therefore, in the organisation of the structure of the protein (coiling), the following tendency is manifested: to remove from contact with water the greatest possible number of non-polar fragments in the protein and to hide them in the bulk of the globule.[147] The influence of the unfavourable entropy factor is thereby weakened, hydrophobic interactions are intensified, and the stability of the protein increases.§

As soon as the idea of hydrophobic interactions as a factor stabilising the protein arose, attempts were made to correlate the stability of the protein with its hydrophobic properties. For this purpose, it was natural to attempt the determination

---

#Structured clusters of water molecules were previously detected only around very small organic molecules.[143] In the X-ray diffraction analysis of the membrane protein crambin, it has recently been possible to observe a pentagonal cluster formed by water molecules around a non-polar fragment of the protein surface.[146] Thus it was demonstrated for the first time that the protein molecule does not alter qualitatively the character of the interaction of the non-polar fragments with water, i.e. the hydrophobic interactions have the same (entropic) nature for both small molecules and macromolecules.

§ This point of view on the entropic nature of hydrophobic interactions is dominant at the present time but is not the only one—see, for example, Hvidt's review.[148]

of a quantitative criterion of hydrophobic character. Tanford and co-workers suggested[149-150] that the free energy of the transfer of aminoacids from water to the organic phase be used. According to this classification, the more negative the ΔG of the transfer process for the aminoacid, the more hydrophobic it is (Table 6). The creation of a quantitative scale of hydrophobic character stimulated the search for correlations between the stability of the protein and its overall hydrophobic character, calculated as the sum of the hydrophobic character of all its constituent aminoacids. However, unambiguous conclusions could not be obtained from the correlations both for mesophilic proteins[28-30] and on comparing thermophilic and mesophilic proteins.[154,155]

Table 6. Indices of the hydrophobic character of aminoacids.

*The free energy of transfer from water to the organic solvent.[151]

**The fraction of the residues hidden within the globule.[152]

***The hydrophobic character of the environment in proteins.[153]

In the first part of the review, we already noted one of the causes of the failure of this approach: unduly small differences between the stabilities of the proteins against the background of large differences in their structures.

Another cause is that, when the aminoacid composition is determined by aminoacid analysis, one finds as a rule the overall contents of Asp + Asn and Glu + Gln, i.e. the acid and the corresponding amide, and one does not take into account the form in which these aminoacids are present. On the other hand, the differences between the hydrophobic properties of the acid and amide forms are large (cf. Asp and Asn, Glu and Gln in Table 6). For example, the highly stable ferredoxin *Clostridium thermosaccharolyticus* has a stability differing from that of the usual protein from *Clostridium tartarivorum*,[156] which has a normal stability, only by the fact that Glu residues are located in positions 31 and 44 and not Gln. With the aid of the usual amino-acid analysis, this difference could not be revealed. The comparison of X-ray diffraction data for the two proteins enabled the authors to resolve this problem.[156]

We may point to yet another source of error which arises in the analysis of correlations between the overall hydrophobic character and the stability of proteins. Sometimes the hydrophobic character of a stable thermophilic protein is compared with that of a statistical-average mesophilic protein and not a less stable mesophilic homologue.[157] This is methodologically absolutely incorrect; for a discussion of this question, see the review of Mozhaev and Martinek.[19]

The question arises whether there is any point (even when all the factors have been taken into account and a comparison made correctly) in seeking correlations between the stability and the overall hydrophobic character of proteins. Such a correlation would apparently be valid only for a certain "idealised" protein (it is sometimes represented by a drop of oil separated from contact with the solvent by a palisade of polar and charged groups[158]). Indeed, in such a hypothetical protein all the non-polar aminoacids would be involved in hydrophobic interactions. Although this simplified picture reproduces correctly the general trend towards the intensification of hydrophobic interactions in proteins, it is not observed in practice. According to X-ray diffraction data, approximately 50% of the area of real proteins is occupied by non-polar aminoacids.[114,145,147,159] They are frequently organised into surface hydrophobic clusters.[145] This has a functional importance because it enables proteins to bind via hydrophobic interactions to other proteins (polyenzyme complexes), lipids (biological membranes), polysaccharides (cell wall), and substrate effectors (enzyme catalysis and its regulation), i.e. ultimately it enables them to function correctly.[160,161] However, in proteins in the free, unbound state (enzymologists have to deal most often precisely with such objects), the disposition of non-polar aminoacids on the surface is "harmful" for stability, because it leads to the loss of free energy as a result of the weakening of hydrophobic interactions.

The non-ideality of protein structure (from the standpoint of the maximum realisation of hydrophobic interactions in them) necessitated the search for new approaches to the definition of a scale of the hydrophobic character of aminoacids. It became evident that the scale[149,150] established on the basis of the extraction model reflects incorrectly many trends in the coiling of the protein. It was therefore suggested that the hydrophobic character of aminoacids be estimated from statistical data for their distribution in the steric structure of proteins.[152,153,162,163]

Chothia's statistical scale[152] reflects the distribution of aminoacids in the bulk of the protein globule: the more frequently is the aminoacid encountered within protein globules and the more rarely on the surface, the more hydrophobic it is thought to be. Another statistical scale, set up by Ponnuswamy and co-workers,[153] is based on the fact that the hydrophobic character is determined by the microenvironment in which the given aminoacid residue is present. In this case the aminoacid which is surrounded by more hydrophobic neighbours in the protein globule is regarded as the more hydrophobic. The hydrophobic character of the microenvironment is then regarded as the sum of such characters[149,150] in the nearest neighbours in the tertiary structure of the aminoacids.

Comparison of these two statistical scales of the hydrophobic character[152,153] shows (Table 6) that they agree fairly well despite the fact that they are based on different principles. Thus in both scales Ile, Val, and Cys are the most hydrophobic and Lys, Arg, Asp, Glu, Asn, and Gln are the least hydrophobic. On the other hand, appreciable discrepancies between the data derived from the statistical scales and the extraction (Tanford) scale are observed. Thus Trp, which is the most hydrophobic on the extraction scale, occupies an intermediate position on the statistical scales and Tyr and Pro, which are closest to it in terms of their hydrophobic properties, should be more properly assigned to hydrophilic aminoacids in terms of the statistical scales.[152,153]

The causes of these discrepancies were first analysed by Chothia,[152,159] who concluded that the introduction of a polar atom into the aminoacid diminishes its hydrophobic character by 1–1.5 kcal mol^{-1}. It is therefore not fortuitous that the aminoacids which are most hydrophobic on the extraction scale (Trp and Tyr) do not belong to the most hydrophobic aminoacids on the statistical scales (Table 6). Although their large surface area ensures their high hydrophobic character, the presence of a polar atom makes their presence within the protein globule significantly less favourable.

There exist also other causes of the discrepancies between the extraction[149,150] and statistical scales of the hydrophobic property.[152,153] A classification based on the extraction properties has been established solely on the basis of model experiments (transfer of the given substance from the aqueous to the organic phase) and therefore it in no way takes into account the fact that the aminoacids considered in fact enter into the composition of the polypeptide chains. In other words, in real proteins they must adjoin other aminoacids which in principle influence the geometry and energy of their neighbours.[164] Furthermore, the principle of close packing is realised in proteins[1,140,147] and therefore on coiling the most bulky aminoacids (Trp and Tyr) they are forced to remain on the surface of the globule in order not to infringe the compactness of the structure.

Thus there are three main factors which prevent the realisation of hydrophobic interactions in the proteins with the maximum advantage for the stability of the steric structure. Firstly, there is the need to ensure a sufficiently close packing of the aminoacids in the protein. Secondly, the geometry and energy of aminoacids are influenced by the microenvironment, i.e. they are neighbours in the tertiary structure. Thirdly, hydrophobic clusters, which *in vivo* ensure the interaction of the protein with other molecules, should remain on the surface of the protein when it is coiled up. Consequently, there is hardly any point in attempting to find a correlation between the stability of the protein and its overall hydrophobic character. It has been suggested[154] that the content of aliphatic aminoacids be used as a more suitable parameter, because they are indeed more frequently encountered within the protein than on the surface. The so called aliphatic protein index has been defined:[165]

$$A = X_{\mathrm{Ala}} + aX_{\mathrm{Val}} + b(X_{\mathrm{Ile}} + X_{\mathrm{Leu}})\,.$$

where X_{ala}, X_{Val}, X_{Ile}, and X_{Leu} are the mole fractions of Ala, Val, Ile, and Leu in proteins and a and b are numerical coefficients determined by the size of the aminoacid residues. Fig.3 shows that the aliphatic index of the more stable proteins from thermophilic organisms is indeed higher than that of mesophilic proteins.

The following characteristics of the relation between the hydrophobic interactions in proteins with enhanced stability follow from the data considered. In the most general form, one may say that the increase of stability of proteins *in vivo* (for example of the stability of thermophilic enzymes) occurs not only and not so much at the expense of the increase of the overall hydrophobic character[166] as due to the more "correct" disposition of the non-polar aminoacids in the globule.[167] In other words, the greater the number of non-polar protein fragments are hidden in the interior of the globule and the smaller their number exposed to the solvent, the greater the stability of the protein. This picture has been described quantitatively by Lee and Richards,[147] who introduced the concept of the "surface area accessible (to the solvent)". It has been known that[159] the decrease of the overall free energy of the hydrophobic interactions in the protein ΔG_h depends on the change in the accessible surface area ΔA_s in the following manner:

$$\Delta G_h = \sigma\,\Delta A_s\,,$$

where σ is a proportionality coefficient numerically equal to approximately 25 kcal mol^{-1} A^{-2}. It follows from this equation that the decrease of the surface area of the hydrophobic contact with water should entail the intensification of the internal hydrophobic interactions in the protein and hence should stabilise the latter. This is indeed observed on comparing thermophilic enzymes with the corresponding mesophilic enzymes,[168,169] on comparing the structures of a series of mesophilic homologues,[170] and also from the analysis of the stability of proteins modified by mutation.[161,171]

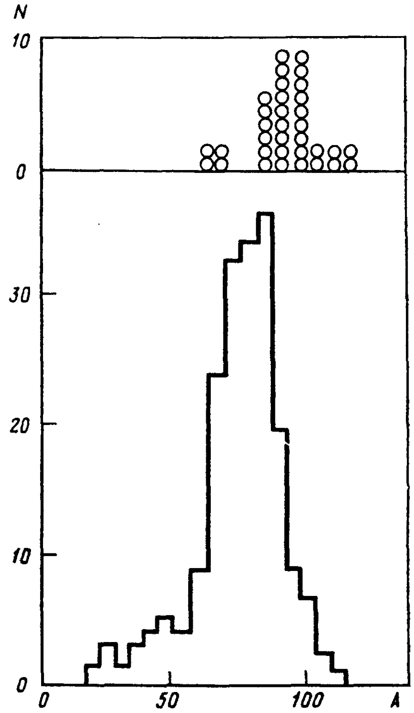

Figure 3. Distribution of the aliphatic index (A) among 34 proteins from thermophilic bacteria (upper section of the Figure) and 208 proteins from mesophilic organisms (lower section);[165] N = number of proteins.

Summarising this Section we may note that the stabilisation of proteins by the intensification of the hydrophobic interactions in them constitutes an extremely promising practical approach.[19,161] One should attempt either to decrease the hydrophobic character of the surface of the protein or to enhance its internal hydrophobic character.

IV. ARE THERMOSTABLE CATALYSTS NEEDED FOR BIOTECHNOLOGY?

The application of thermostable biocatalysts in biotechnolog has a number of advantages.[14-17,172]

The gain in the rates of processes. According to the van't Hoff rule, on raising the temperature by 10 K the rates of chemical, including enzyme-catalysed, reactions increase on average by a factor of 2–3.

The possibility of a shift of the thermodynamic equilibrium. The position of the chemical reaction equilibrium depends on temperature. According to the Le Chatelier principle, by raising the temperature, it is possible to displace the equilibrium towards synthesis for those reactions which take place with absorption of heat (endothermic reactions). Unfortunately, the thermochemistry of enzyme reactions which are of practical value has so far been studied in inadequate detail. As an example of an important reaction whose equilibrium shifts in an unfavourable direction on raising the temperature, we may quote the formation of a peptide bond.[173] Indeed, it has been shown that,[174] only by reducing the temperature for chymotrypsin-catalysed peptide synthesis, is it possible to increase the yield of the final product—the dipeptide.

The increase of the duration of work of the biocatalyst. The biotechnological processes actually introduced into practice involve a high economic cost contributed by the enzymes themselves.[175,176] Evidently the stabilisation of enzymes makes it possible to reduce this cost by increasing the period during which they can be used.

High resistance to other denaturing influences. As a rule, enzymes resistant to the action of high temperatures manifest an increased resistance also to other denaturing influences: concentrated solutions of denaturing agents, extreme pH values, and degradation by proteases. This is true, for example, of natural thermostable enzymes from thermophilic micro-organisms.[177,178] The practical value of this universal stabilisation is high, since the enzymic transformations of many natural compounds and the preparative synthesis of many substances can be effected in the required direction only in organic solvents or in aqueous organic media with a high content of the organic component.[179,180]

Increase of the efficiency of the catalytic process as a result of the increase of the solubility and volatility of the reactants and the decrease of the viscosity of the solutions at elevated temperatures. With increase of temperature, the solubility of the initial reactants increases also as a rule, which makes it possible to work with their more concentrated solutions and, in conformity with the Law of Mass Action, the absolute yield of the final product can be increased. If as a result of heating it has been possible to increase significantly the volatility of one of the final products, then the equilibrium in the synthetic reactions is strongly displaced towards the final product and their yield therefore increases. The decrease of viscosity on heating makes it possible to accelerate and hence to increase the efficiency of the processes in the kinetics of which diffusion plays a significant role.

Sterilisation of the products in the course of the reaction and decrease of the probability of the microbial infection of the reactors. The latter factor must always be reckoned with when biotechnological processes are carried out and its role can be as a rule significantly reduced at elevated temperatures.

The process can be readily arrested by simple cooling. However, experiments at elevated temperatures also suffer from certain disadvantages. One of these is the increase of the rate of certain side processes, in the first place high-temperature oxidation[13] and racemisation of aminoacids and their derivatives.[181] The economically justified selection of conditions, high-temperature or low-temperature, therefore constitutes a problem which has an independent solution for each specific case.[182]

V. METHODS OF PREPARATION OF STABLE ENZYME CATALYSTS

1. The Search for Enzymes with Increased Thermal Stability in Mesophilic Sources

This approach is the oldest, traditional, and apparently does not require special comment. Its logical development has been the search for enzymes in sources which by their very nature are adapted to existence under high-temperature conditions.

2. Isolation of Enzymes from Thermophilic Sources

A homogeneous preparation of a thermophilic enzyme was first obtained 25 years ago.[183] Since then, the advantages of the use of thermophilic enzymes in biotechnology have been frequently discussed. Apart from the advantages of the thermally stable biocatalysts which were described above and which apply equally to thermophilic enzymes, we shall mention one other. Thermophilic micro-organisms are preferable to mesophilic organisms from the microbiological standpoint. Thus widescale cultivation of thermophilic strains is frequently cheaper than the cultivation of mesophilic strains owing to the decrease of the energy expenditure (there is no need to cool the growing biomass).[172] It is also important that, although thermophilic enzymes are very stable, they have not attained the absolute limit of thermal stability: there exists a certain reserve for additional stabilisation. Thus, having immobilised a thermophilic asparaginase[172] and protease, it has been possible to increase by a factor of 10 the resistance of these enzymes to irreversible thermal inactivation, which was in any case already high without this step.

Nevertheless there is virtually no information in the literature about the use of thermophilic enzymes in biotechnological practice. In our view, this is associated with the fact that, although the maximum catalytic activity of thermophilic enzymes is attained at higher temperatures (by 20–40 K), the activities of the mesophilic and thermophilic enzymes themselves are frequently identical at the temperature optimum.[48,169,185–188] Reports stating that the catalytic activity of a thermophilic enzyme at the temperature optimum is higher than that of the corresponding mesophilic enzyme have been appearing only occasionally.[189]

Not only are the catalytic activities of the thermophilic and mesophilic enzymes equal at the temperature optima but their thermal stabilities are also similar.[169] Thus, when thermophilic and mesophilic enzymes are compared, a correlation is manifested which is the same as that observed previously[190–194] for mesophilic proteins: the higher the catalytic activity, the lower the stability of the protein. In other words, having attained a greater stability, thermophilic enzymes have to sacrifice their catalytic activity partially.[187]

On the other hand, thermophilic enzymes have a property which makes them irreplacable for the purposes of biotechnology: the ability to alter their substrate specificity when the temperature is varied. This property is manifested particularly strikingly in the enzymes (proteases, nucleases, etc.) which act on high-molecular-weight substrates. The reason for this is that the substrates themselves (i.e. proteins and nucleic acids) undergo temperature-dependent conformational changes;[195] other new peptides and nucleotides bonds of the substrate are then exposed to the solvent and become accessible to the action of the enzymes. The appearance of a new specificity[196] is apparently of interest for the vigorously developing genetic engineering, which requires a set of restrictases with different specificities.[197] One may hope that thermophilic restrictases will become new and highly effective instruments in genetic engineering.

3. Synthesis of Highly Stable Enzymes for the Introduction of a Thermophilic DNA into a Mesophilic Culture

Towards the end of the 1970's, reports appeared[198-200] that the introduction into the cell of a mesophilic organism (for example, *Bacillus subtilis*) of DNA from a related thermophilic organism (for example, *Bacillus caldolyticus*) results in the transformation of the mesophilic culture into the thermophilic culture at an elevated temperature. The transformant then loses its ability to grow at the usual temperature but acquires a new property—the ability to grow at an elevated temperature.[198] The entire biosynthetic apparatus of the transformant then acquires an increased thermal stability[198,199] and the synthesis of highly stable enzymes begins in the cell.[200]

At the beginning of the 1980's, another version of the genetic approach began to be used:[201,202] instead of a whole molecule of thermophilic DNA, only its fragment—the gene coding a specific protein—is introduced into the mesophilic culture. This approach has the undoubted advantage that the required stable enzyme can be obtained with a high yield (actually tens of times greater than in its isolation from a thermophilic culture).[202] Another advantage is that the operations involved in the isolation and purification of the protein are significantly simplified. Indeed, because at the elevated temperature almost all proteins synthesised by the mesophilic culture with the exception of the required high-stable protein are denatured, it is possible to achieve a high degree of purification of the protein at the expense of a small expenditure of time and at a small cost in equipment.

4. The Protein Engineering Method

At the beginning of the 1970's, successful experiments designed to create recombinant DNA were first carried out.[203] It became clear that a new powerful instrument for the wide-scale preparation of natural products and the synthesis of biological molecules with a broad spectrum of properties which do not exist in nature had been placed in the hands of investigators. A new scientific-engineering field was created on this basis—genetic engineering. By genetic engineering, one normally understands the construction *in vitro* of functionally active genetic structures (recombinant DNA), their introduction into cells, and the subsequent biosynthesis by the cells of biological molecules which are not characteristic of them. At the present time the advances in genetic engineering both in our country[204] and abroad[205,206] are generally recognised and the prospects are hopeful.

We shall deal with only one version of the genetic-engineering approach—site-directed mutagenesis[54-58] or "protein engineering".[20] This method makes it possible to obtain modified proteins differing from the prototype proteins by the replacement of, for example, only one aminoacid residue in a specific position in the protein structure. For biotechnology, the method is of interest primarily because it makes it possible to alter specifically the structure of enzymes, their catalytic properties, and their stability.[20] We shall now consider how this is done.

In the first place we shall deal with the primary structure of the initial enzyme[103] and then with its tertiary structure.[134] Then the following stage becomes possible—the selection of the site where the aminoacid residue is to be replaced. This stage does not involve any laborious operations, such as the growing of protein crystals, the determination of the aminoacid sequence, or the interpretation of X-ray diffraction patterns, which have to be performed in the next stage. However, this is in fact the key stage, because it determines the properties of the final product. Next, it is necessary to proceed from the language of protein structure (the aminoacid sequence) to the genetic code. For this purpose, an oligopeptide fragment (4–6 aminoacid residues) in the primary structure of the protein, at the centre of which is located the aminoacid to be replaced, is selected, and an oligodeoxyribonucleotide containing 12–18 bases coding the aminoacid sequence in the chosen oligopeptide, is synthesised.[210] The mutation is programmed in precisely this stage: instead of the nucleotide triplet coding the "native aminoacid", another triplet, coding the new (planned in the preceding stage) aminoacid residue, is introduced into the synthetic oligonucleotide by chemical synthesis. The subsequent operations reduce to genetic-engineering manipulations. Firstly, one finds (or creates artificially) a single-stranded plasmid incorporating the genes coding the given protein. Secondly, using DNA-polymerases and DNA-ligases, one creates enzymically, on the basis of the single-stranded plasmid and the nucleotide synthesised, a heteroduplex double-stranded plasmid. The oligonucleotide then initiates the synthesis of a double-stranded region, fulfilling the role of a seed. Since homoduplex plasmids together with heteroduplex plasmids are synthesised on single-stranded DNA molecules as templates, they are separated using different resistances to heating of homoduplex and heteroduplex plasmids. The heteroduplex double-stranded plasmids are then introduced into a convenient host cell in which they are transformed into two homoduplex plasmids: one contains the gene of the native protein and the other that of the mutant protein. The two genes and their subsequent cloning are carried out at the cellular level. The final result of the multistage process is transformant cells in which the mutant protein, differing from the initial protein by the replacement of one aminoacid residue at a rigorously specified site, is biosynthesised.

The method of site-specific mutagenesis appeared at the beginning of the 1980's and only the first steps have been taken.[20,207] Nevertheless, even the first achievements of the method are striking. We shall consider some of them concerning the synthesis of stabilised proteins.

In the molecule of lysozyme of the T4 phage there are no S–S bonds, but two SH groups are present. One of them, belonging to the Cys-97 residue, is located in the vicinity of the N-terminal region in the tertiary structure. The Ile-3 residue was replaced by cysteine by protein engineering. Since in the tertiary structure of the mutated lysozyme the Cys-3 and Cys-97 residues adjoined one another, the S–S bond was formed in a weakly oxidising medium. The conformations of the native and mutated enzymes were identical but their catalytic properties were different.[139] However, the lysozyme modified by mutation differs from the native protein by a significantly higher thermal stability (Fig.4). The reason for such stabilisation lies in the strengthening of the structure of the protein as a result of the introduction of the S–S bond.[139] Indeed, if the S–S bond in the modified lysozyme is cleaved, then the stability of the protein becomes virtually indistinguishable from that of the initial protein (Fig.4).

Another example of mutation designed to increase stability is provided by the α-subunit of tryptophan synthase. Several forms of the enzyme, differing from one another by the replacement of the aminoacid residue Glu-49 located in the hydrophobic nucleus of the globule by another aminoacid, were obtained.[208] Such changes do not alter either the conformation or the functional activity of the α-subunit of tryptophan synthase. However, the protein proves to be more stable the more hydrophobic aminoacid has been introduced in position 49. It follows from the correlation illustrated in Fig.5 that the method of site-specific mutagenesis provides unique possibilities for increasing the internal hydrophobic character (and hence the stability) of the protein by replacing polar aminoacids by more hydrophobic aminoacids. It is then naturally necessary to make specially sure that these replacements do not disrupt the compact packing (conformation) of the protein.

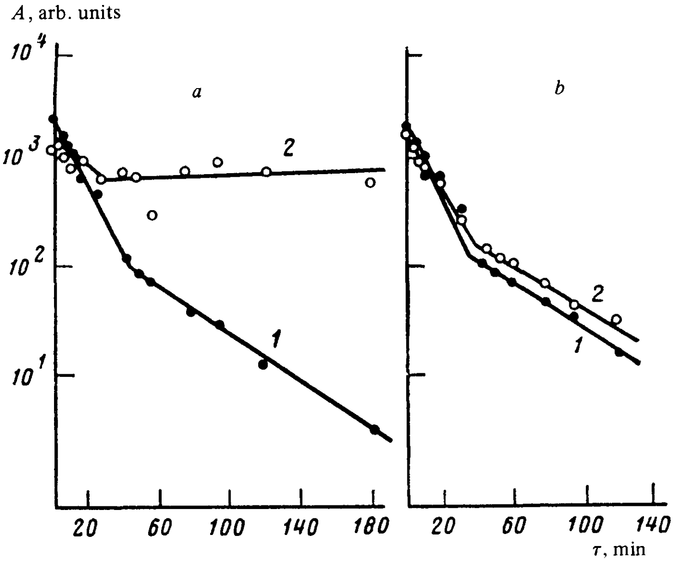

Figure 4. Kinetics of the thermal inactivation of the T4 lysozyme from a wild strain (curves *1*) and the T4 lysozyme with the substitution Ile-3 → Cys and subsequent oxidation with sodium tetrathionate (curves *2*) in the absence (*a*) and presence (*b*) of 10 × 10^{-3} M β-mercaptoethanol;[139] A = catalytic activity.

An example of the way that proteins resistant to oxidative inactivation can be obtained by the method of site-specific mutagenesis is provided by the study of Estell et al.[209] The Met-222 residue in subtilisin, which is located in the region of the active centre, readily enters into oxidative reactions, which inactivate the enzyme. It was replaced by the method of protein engineering by other residues, whereupon the activity of the enzyme did not diminish very greatly (within the limits of a factor of 10) but its resistance to inactivation by H_2O_2 increased significantly (Fig.6). The stabilisation is caused by the fact that, having removed from the active centre the readily oxidisable Met residue (having replaced it by other residues less susceptible to oxidation, namely Ser, Ala, and Leu), it proved possible to eliminate the very cause of oxidative inactivation.[209]

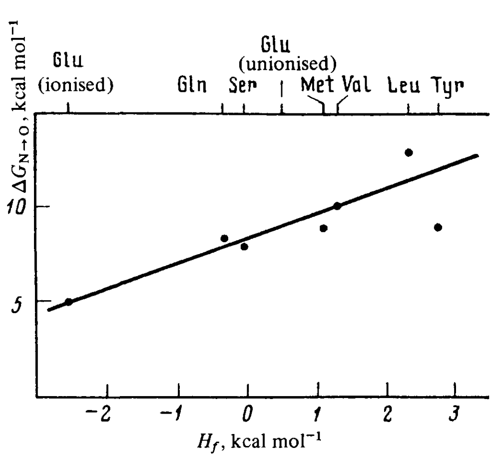

Figure 5. Dependence of the free energy of the stabilisation $(\Delta G_{N \to D})$ of the native conformation of the α-subunit of tryptophan synthase from *Escherichia coli* on the hydrophobic character (H_f) of the aminoacid residue in position 49;[208] the numerical values of the hydrophobic character of the aminoacids are based on Tanford's data.[150]

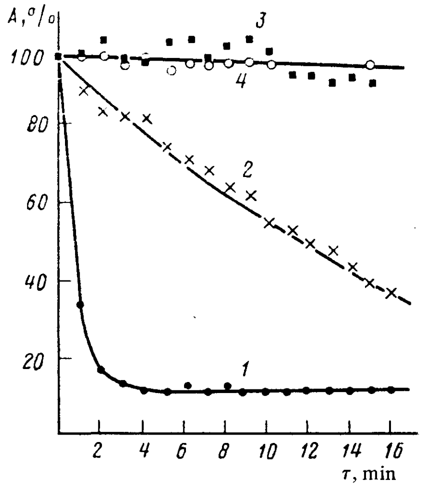

Figure 6. Kinetics of the inactivation (on treatment with 1 M H_2O_2) of subtilisin of a wild type (curve *1*) and mutant forms where position 222 contains the Cys (curve *2*), Ala (curve *3*), or Ser (curve *4*) residues;[209] A = catalytic activity.

However, the procedures of protein engineering are not simple. Successful work in this field requires the cooperation of specialists in the structure and chemistry of proteins and nucleic acids, in molecular and cell genetics, and in other branches of biochemistry and molecular biology. The work must be carried out at the highest experimental level using the latest advances in these fields and requires a large material expenditure. For this reason, traditional methods such as immobilisation and chemical modification, which have long been used to stabilise enzymes, still compete successfully with protein engineering.

5. Immobilisation of Enzymes

A series of special reviews have been devoted to the creation of stabilised enzyme preparations by the immobilisation method.[14–19] Here we shall therefore deal only with the main advances in the immobilisation approach.

As early as 1954, Lumry and Eyring formulated[211] the general ideas concerning the inactivation of enzymes, which still remain valid.[12,13] It was suggested that the inactivation be regarded as a two-stage process:

$$N \rightleftarrows D \rightarrow I$$

where N, D, and I are respectively the native, reversibly denatured, and irreversibly inactivated forms of the enzyme. Any inactivation begins as a rule with a reversible conformational change (the $N \rightleftarrows D$ stage in the scheme), which frequently embraces the entire globule. The reversible uncoiling stage is followed by irreversible processes ($D \rightarrow I$ in the Scheme), such as aggregation,[212] covalent modification of the aminoacid residues,[12,13] and irreversible conformational changes.[213–215]

The general approach to the stabilisation of enzymes based on the immobilisation method consists in a significant retardation or suppression of the primary uncoiling of the protein molecule (the $N \rightleftarrows D$ stage in the Scheme).[216] The multipoint addition of the protein molecule to the surface of a carrier proved to be the most fruitful for this purpose.[217,216] This immobilisation approach made it possible to retard by factors of hundreds and thousands both reversible[130,219] and irreversible[217,218] thermal inactivation of enzymes, their reversible uncoiling under the influence of chemical reagents,[220] and the dissociation of oligomeric fragments into subunits (see the literature references in the review of Arens et al.[216]).

The immobilisation approaches also proved to be extremely useful for the suppression of irreversible secondary processes (the $D \rightarrow I$ stage in the Scheme). Thus, if the inactivation is caused by protein–protein interactions (aggregation or autolysis), then, having immobilised the enzymes, such inactivation can be as a rule fully prevented (see the relevant reviews[14–17,62]). Immobilisation also helps to protect enzymes from inactivation by chemical modification. Such protection is achieved in two ways. Firstly, the enzyme is immobilised within a carrier, which "shields" it from contact with the inactivating molecules. An example of this approach is provided by the protection against oxidative inactivation of hydrogenases incorporated in polyelectrolyte carriers.[118] Secondly, a carrier containing functional groups competing for the inactivating substance or causing its decomposition is selected for immobilisation. For example, if the inactivation takes place under the influence of peroxy- or superoxide radicals, then, in order to achieve protection against them, the enzyme is immobilised jointly with peroxidase or catalase, which catalyse the decomposition of these radicals.[13]

6. Chemical Modification of Enzymes

The first successful studies on the stabilisation of enzymes by their chemical modification were carried out[221] in the middle 1950's. However, the view is still being encountered[65] that it is hardly possible to formulate sufficiently general rules whereby stabilised enzyme preparations can be obtained by chemical modification. Analysis of the numerous studies in this field (see the relevant reviews[18,64–66]) enabled us to reach certain conclusions about the causes of the stabilisation of proteins by their covalent modification.

As a result of the modification, the protein is sometimes converted into a more stable conformation different from the native conformation.[104,105]

Stabilisation takes place on modification of "key" functional groups[64] (they are also referred to as type II groups[66]).

New functional groups, introduced into the protein as a result of chemical modification, are capable to forming additional hydrogen bonds or salt bridges.[222]

Chemical modification by non-polar compounds intensifies the hydrophobic interactions in proteins.[223]

The hydrophilisation of the surface groups of the protein decreases the area of unfavourable contact of the outer hydrophobic residues with water.[19]

The question arises which of the mechanisms enumerated can be used as the basis of general approaches to the stabilisation of enzymes.

1. There is hardly any point in attempting to convert the protein by covalent modification into a more stable conformation different from the native conformation. The point is that the character of the conformational changes introduced by the modification is unpredictable in the vast majority of cases.

2. We shall consider the concept of "key functional groups".[64] The experiment involving chemical modification frequently looks as follows: the stability of the protein does not change with increase of the degree of modification until the attainment of a critical value, whereupon the stability increases sharply.[224] The observed variation is explained as follows:[64,66] for low degrees of modification (in the presence of a small excess of the modifying reagent), mainly the functional groups of the protein which are located on the surface and do not play an important role in the structure and stability are involved. However, in the presence of a large excess of the modifying agent, certain functional groups in deeper layers of the protein globule are modified. The modification of these groups, called "key" groups, improves the balance between the intramolecular interactions in the protein and stabilises the latter.

The application of the idea involving the modification of "key" functional groups in the protein encounters, however, a number of difficulties. The main one is how to discover which functional groups are the "key" groups. This is hardly possible to achieve *a priori*, for example, on the basis of the steric structure of the protein. The only reasonable procedure is to determine them empirically, i.e. by studying the dependence of the stability of the protein on the concentration of the modifying agent (degree of modification). Such studies must be carried out with exceptional care, because there exists a real risk of "overlooking", missing these "key" groups. Indeed, after the modification of the "key" groups, deeper aminoacid residues in the protein are usually involved, which as a rule destabilises it.[64,66] For this reason, if the "key" degree of modification of the protein has been missed in the experiment accidentally, then a stabilisation effect cannot be observed at all. Furthermore, for each specific protein and each new type of functional groups (for example, COOH, NH_2, SH, etc.), the empirical search for "key" groups must be carried out anew.

3. One may attempt to introduce into the protein molecule polar or charged groups by its modification, hoping that they will form new salt bridges with the functional groups already

present in the protein. Unfortunately, it is not easy to apply this approach in practice. For this purpose, it would be necessary to obtain maps of the steric structure of proteins and to search on the latter the uncompensated polar and charged groups which might, in principle, form new hydrogen bonds and enter into electrostatic interactions. Next, it would be necessary to find in the protein a suitable "anchor" group located in the vicinity of the uncompensated polar and charged group. Having selected or synthesised a suitable chemical agent, which would contain, on the one hand, a group reacting specifically with the anchor group and, on the other, a charged or polar fragment located at the specified distance, one could attempt to achieve the specific modification. It is not easy to perform such a delicate experiment.

4. According to some investigators,[223] the stability of proteins can be increased by rendering them hydrophobic. However, the experimental data concerning the influence of hydrophobic modification on the stability of proteins are contradictory. Together with stabilisation effects,[223] cases are known where the stability of proteins rendered hydrophobic is significantly lower than that of the native proteins.[225-227] This apparent contradiction can be explained as follows. If the hydrophobic residue (for example, the CH_3 group) is introduced on the surface of the protein, the latter should be destabilised. Indeed, as a result of the modification, the protein acquires a new thermodynamically unfavourable contact between the hydrophobic CH_3 group and water. However, there are exceptions to this general rule. As mentioned above, together with polar and charged aminoacids, there are on the surface of proteins also hydrophobic aminoacids which are frequently organised into hydrophobic surface clusters.[228,229] If the functional group located near such a cluster has been modified, then the modifying agent of suitable length cuts off the contact between the solvent and the cluster. One can imagine the situation where the interaction of the modifying agent with the cluster does not alter or even diminishes the area of the unfavourable contact between the hydrophobic surface of the protein and water. In any case, however, the modification results in the appearance of an additional contact between two hydrophobic surfaces, which should increase the stability of the protein.[223]

This view is also supported by the observed increase of the stability of certain proteins[230,231] as a result of complex formation with non-polar molecules (benzene and aliphatic acids). The interaction of proteins with these compounds can be represented in the way already described above. However, since this is a relatively weak non-covalent interaction, the protein–ligand complex dissociates readily when the excess of the non-polar substance is removed from the system. The formation of such non-covalent complexes can therefore hardly serve as the basis of a general method for the stabilisation of enzymes.

The modification permitting the introduction of a non-polar molecule into the interior of the hydrophobic core of the protein should be especially effective from the standpoint of stabilisation.[19] The essential feature of the approach permitting the attainment of this situation is that the initial state for modification is not the coiled (native) conformation of the protein but the uncoiled state (statistical coil). This state can be arrived at by treating the protein with a strong denaturant (urea) with the simultaneous cleavage of the S–S bonds[232] (in those proteins where these are present). An attempt may be made to alter the structure of the uncoiled protein in one of the three ways proposed. Firstly, it can be coiled up under "non-native" conditions, i.e. conditions which are not characteristic of the coiling process *in vivo*. There is hope that the protein will coil up into another conformation, which is also catalytically active but more stable. In particular, if the coiling is carried out under conditions favouring the enhancement of the hydrophobic contacts (concentrated solutions of salts, elevated temperature, etc.) then it is possible to obtain a protein conformation in which non-polar aminoacids are more "correctly" packed (the interior of the protein becomes more hydrophobic and the surface more polar). Secondly, it is possible to coil up the proteins in the presence of substances which enter into multipoint non-covalent interactions with them. Here non-polar and biphilic compounds are most promising in our view. The former can be captured in the interior of the hydrophobic core on coiling up the protein and the latter can be "built" into the coiled protein, being in contact via their non-polar fragment with the hydrophobic regions in the protein, while the polar or charged fragments are exposed to the solvent. Thirdly, the uncoiled protein can be modified initially by a chemical agent and then coiled up.

At the present time the approach described above is being actively developed.[233] We shall deal with only one experimental result. Immobilised trypsin was converted into the uncoiled state and then coiled up at different temperatures. The trypsin coiled up at 50 °C and above proved to be[19] more thermally stable than the initial enzyme or enzyme which had been coiled up at the usual (20–35 °C) temperatures. These results agree with data obtained *in vivo* for thermophilic microorganisms.[46,47,234-236] These organisms synthesise two sets of enzymes: stable and labile, and at high temperatures the content of the stable forms is significantly higher. The "high temperature" and "low-temperature" proteins are apparently the iso-forms of the same enzymes, having identical primary structures.[46,47] Consequently, as in model experiments, the protein *in vivo* also coils up into a more or less stable conformation depending on the temperature of the biosynthesis.

5. Finally, we shall consider the approach to the stabilisation of enzymes which we recently proposed[19] and which is being successfully developed at the present time.[237,238] It is based on the hypothesis that contact between the hydrophobic sections of the surface of the protein and water is thermodynamically unfavourable and therefore destabilises the protein. The idea of the approach is that the area of contact between the hydrophobic clusters on the protein surface and water be reduced by chemical modification.

Before applying this approach, it is essential to select a criterion of the hydrophobic character of chemical compounds. Hitherto, in discussing the influence of chemical modification on the stability of proteins, sufficient attention was not paid to this question; (see, for example, the relevant reviews[64-66]). The conclusion whether or not chemical modification of the protein rendered it hydrophobic or hydrophilic is sometimes self-evident and does not require accurate quantitative estimates. As an example of the evident acquisition of hydrophobic properties, one may quote the modification of α-chymotrypsin by aliphatic aldehydes.[224] Indeed, in this case, after the reduction of the Schiff base formed, the aminoacid groups of the enzyme are transformed into $-NH-(CH_2)_n-CH_3$. However, it is then hardly possible to estimate even qualitatively from general considerations how the hydrophilic character of the amino-group changes when it is modified by succinic anhydride [when the NH_2 group is transformed into $-NH-CO_2-(CH_2)_2-COOH$]. Nevertheless, such modification is frequently regarded as imparting hydrophilic properties.

We selected as the quantitative criterion of hydrophobic character the partition coefficient P of the compound considered between water and an immiscible organic phase proposed by Hansch and co-workers.[239,240] According to this criterion, the more positive the value of P, i.e. the greater the preference for the organic phase by the substance compared with the aqueous phase, the more hydrophobic it is. On the basis of the principle of the additivity of free energies,[241] it is possible to calculate the hydrophobic characters of various functional groups and atoms. For example, the hydrophobic increment per Cl atom (π_{Cl}) can be calculated from the experimental partition coefficient of two compounds: chlorobenzene and benzene:

$$\pi_{Cl} = \log c_{C_6H_5Cl} - \log c_{C_6H_6} = 2.84 - 2.13 = 0.71 .$$

Using this procedure, we calculated[239,240] the hydrophobic increments for the functional groups and atoms most frequently encountered in biochemistry (more than 150). Some of the values of π are listed in Table 7. The converse problem can be solved by this procedure in its turn—the hydrophobic characters of complex compounds can be estimated.

We suggest the application of the approach described above[239,240] for the estimation of the contribution by the chemical agent (modifying agent) to the change in the hydrophobic character of the protein. Quantitative analysis of this aspect permits a fresh view on certain experimental data concerning the chemical modification of proteins. Thus the oxidation of the Met-192 residue in α-chymotrypsin to the more hydrophilic form $S(O)CH_3$ increases the conformational stability of the protein by 2.1 kcal mol^{-1}. On the other hand, the difference between the free energy increments for the extraction of these groups from water into an organic solvent, namely $2.3RT(\pi_{SOCH_3} - \pi_{SCH_3})$, is very similar, i.e. 2.5 kcal mol^{-1} [240] (p.52). On this basis, one may postulate that the stabilisation of chymotrypsin observed following the oxidation of only one Met residue,[242] is caused precisely by the acquisition of hydrophilic properties by the surface of the hydrophobic cluster in the protein.

Another example of acquisition of hydrophilic properties is provided by the modification of the amino-groups of the protein (for example, by O-methylisourea) with their conversion into arginine-like structures. Table 6 shows that Arg is more hydrophilic than Lys. The numerous examples[243-248] of the stabilisation of proteins following the introduction of guanidino-groups into Lys residues can therefore be explained by the decrease of the area of contact between the hydrophobic protein and water.

A major stabilisation effect was achieved by aminating the tyrosine residues in trypsin.[237] The four tyrosine residues in the molecule of this enzyme are distributed on the surface.[249] The appearance of the amino-group in the aromatic ring of tyrosine increases its hydrophilic character by 1.24 kcal mol^{-1}. As a result of such increase in hydrophilic character, the stability in relation to irreversible denaturation of trypsin in which two and more tyrosyl residues have been modified increased by a factor greater than 100.[237]

The stabilisation method designed to render the surface of the hydrophobic clusters in the protein hydrophilic[19] has achieved the greatest successes in the acylation of α-chymotrypsin by the dianhydride of pyromellitic acid.[238] It was shown that the modification involves mainly the protein amino-groups and that three new carboxy-groups are introduced into the enzyme molecule on modification of each group. Thus, the preparation with the maximum degree of modification has been enriched by at least 50 COOH groups.[238] At weakly alkaline pH (thermal inactivation conditions), all the carboxy-groups are deprotonated and a very significant hydrophilic character of the protein surface has therefore been attained (Table 7). The modified enzyme is so much more stable than the native enzyme that it is impossible to select experimentally the temperature at which the kinetics of the inactivation of these two preparations can be compared. In order to estimate nevertheless the difference between their stabilities, it was necessary to extrapolate the experimental data (Fig.7) to an average temperature. For example, at 60 °C the stabilisation effect corresponds to a factor greater than 10^3, becoming still greater with increase of temperature, as can be seen from Fig.7.

Table 7. Parameters of the hydrophobic character of certain chemical groups.[240]

Group	π_{Ar}^{*}	π_{Alk}^{**}	Group	π_{Ar}	π_{Alk}	Group	π_{Ar}	π_{Alk}
H	0	0.23	OH	−0.67	−1.64	COOH	−0.32	−1.11
CH_3	0.56	0.77	SH	0.39	−0.23	COO^-	−4.36	−5.19
C_2H_5	1.02	1.43	OCH_3	−0.02	−1.54	$COCH_3$	−0.55	−1.13
$CH(CH_3)_2$	1.53	1.84	$NHCH_3$	−0.47	−1.38	CO_2CH_3	−0.01	−0.72
C_3H_7	1.55	1.97	CN	−0.57	−1.27	C_2H_4COOH	−0.29	—
C_6H_{11}	2.51	—	NO_2	−0.28	−1.16	$N(CH_3)_2$	0.18	−0.64
C_6H_5	1.96	1.90	NH_2	−1,23	−1.54	$\overset{+}{N}(CH_3)_3$	−5.96	—

---

*The value of π for a substituent in the aromatic ring.

**The value of π for a substituent in an aliphatic compound.

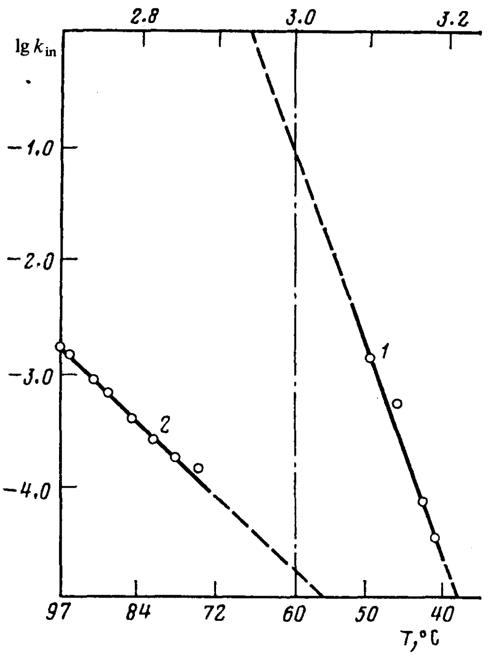

Figure 7. Temperature variation of the rate constant k_{in} for the thermal inactivation of native α-chymotrypsin (line 1) and α-chymotrypsin modified with pyromellitic dianhydride (line 2); the degree of modification of the acylated preparation is a maximum.[238]

Thus, by imparting hydrophilic properties to the surface of chymotrypsin (by introducing a large number of carboxylate anions), it is possible to attain[238] enormous stabilisation effects. Previously effects of this order were observed only on multipoint binding of the enzyme to the surface of a carrier[130,217,218] (see also the relevant reviews[11-19]). Thousandfold (and greater) stabilisation effects[238] are so far the highest achieved using low-molecular-weight modifying agents for proteins. The stability of the chymotrypsin modified by pyromellitic dianhydride is not inferior to that of proteases from extreme thermophiles[250] and is at present the most stable among all the known proteolytic enzymes.

--- o0o ---

In the present review we attempted to anser two questions. Firstly, how to discover the structural determinants of the stability of proteins (i.e. the structural features and intra- and inter-molecular interactions which ensure an increased stability of the protein) and, secondly, which approaches and methodological procedures must be used in order to obtain, knowing these structural determinants of the stability of proteins, stabilised enzyme preparations for biotechnology. We do not share the pessimism which is frequently expressed concerning the possibility of recognising the molecular causes of the stability of proteins and of applying them in practice in order to devise stabilisation approaches. On the contrary, the advances achieved hitherto are extremely hopeful. We are confident that new methods and ideas (some of these were discussed or proposed in the present review) will generate an additional stimulus to studies in this field.

Development of the Physical Chemistry of the Solvated Electron

A.M.Brodskii and A.V.Tsarevskii

The principal results of experimental and theoretical studies of excess electrons in condensed media are examined and the physical nature of localised (solvated) electrons as well as the characteristics of the chemical and electrochemical reactions in which they participate are discussed.
The bibliography includes 131 references.

I. INTRODUCTION

In 1808 Davy observed the phenomenon involving the acquisition of a bronze colour by potassium in liquid ammonia,[1] which was evidently the first description of the effects associated with the formation of the solvated electron. Approximately 50 years later, a similar observation was made by Weyl,[2] who is traditionally regarded as the first investigator of the unusual physicochemical properties of metal–ammonia solutions. After Weyl's investigations, the interest in metal–ammonia solutions continued without interruption, passing through periods of growth and decline. It was shown that the unusual metal-like properties of metal–ammonia solutions are caused[3,4] by the "abstraction" of an electron from the metal. During the last decades it has been established that the states of thermalised excess electrons, whose nature is analogous, arise in many disordered condensed media, without intrinsic conductivity, under the influence of radiation or the injection (emission) of electrons.

The phenomena occurring following the introduction of excess electrons into the media indicated have become the subject of continued attention from investigators working in a number of branches of the physics of condensed media, chemical physics, radiation chemistry, and even biology. Since 1964, international conferences, called the Weyl Colloquia, have been held regularly on this topic. The proceedings of these conferences, containing important information about the state of research into the properties of excess electrons in condensed media, have been published.[5–10] The results of such studies are also presented in books and reviews whose authors have concentrated their attention on the physicochemical,[11–16] physical,[17–21] chemicophysical, and radiation-chemical[22–28] aspects of the problem.

Initially, mainly localised electronic states in polar liquids attracted the attention of investigators. Such electrons were called solvated and were designated by the symbol e_s. The interest in solvated electrons increased especially after the discovery at the beginning of the 1960's of the short-lived solvated (hydrated) electron e_{aq} in water and aqueous electrolyte solutions.[29] The very important role of e_{aq} in radiation-chemical transformations and in the alteration of the physical properties of irradiated aqueous systems was then established.[23–26] There exist a number of hypotheses concerning the possible involvement of e_{aq} in various biochemical reactions[30–34] and in the synthesis of organic substances accompanying the binding of nitrogen and involved in the origin of life on Earth.[26]

States analogous to e_s in polar liquids and differing sharply from the excited states of electrons in crystals have been discovered and investigated also in non-polar liquids—liquid inert gases and hydrocarbons.[19,22,35–39] The electrons captured in vitreous matrices at low temperatures have properties similar to those of e_s.[40] The extensive experimental data obtained proved in many instances to be unexpected and did not fit the existing theoretical schemes. Together with e_s, the so called "dry" excess electrons, resembling the delocalised conductivity electrons in metals, were discovered and investigated.† Bielectrons $(e_s)_2$—systems with a double charge exhibiting a specific reactivity—

---

† Historically the term solvated electrons was given to localised equilibrium states of excess electrons in polar media. The term "dry" electrons is usually understood as the delocalised states of excess electrons, which have not as yet attained equilibrium with the "slow subsystem"—the polar medium. We may note that delocalised equilibrium states of excess electrons are also possible (if one leaves aside the consideration of chemical reactions involving excess electrons), which are called quasi-free electrons. Furthermore, the term "captured electron" (in the English language literature "trapped" electrons) is frequently encountered in the literature—this represents a non-equilibrium (quasi-equilibrium) localised state of the electron in frozen polar media (glasses). If one also takes into account the fact that excess electrons can exist in different excited states, the terminological difficulties of the authors become understandable. In subsequent exposition, the term "solvated electron" (e_s) should be understood in its initial (historically) sense, unless it is specially stipulated which particular quantum-mechanical state of the excess electron is being considered. We may point out that the questions of terminology have been considered in fair detail by Pikaev;[23,28] we shall be forced to return to them again in the Section devoted to the consideration of the energetic characteristics of excess electrons.

have also been discovered.[41] The synthesis of the latter aroused special interest among investigators in connection with the hypothetical possibility of constructing superconductors of a new type on the basis of their Bose condensate properties.[42,43]

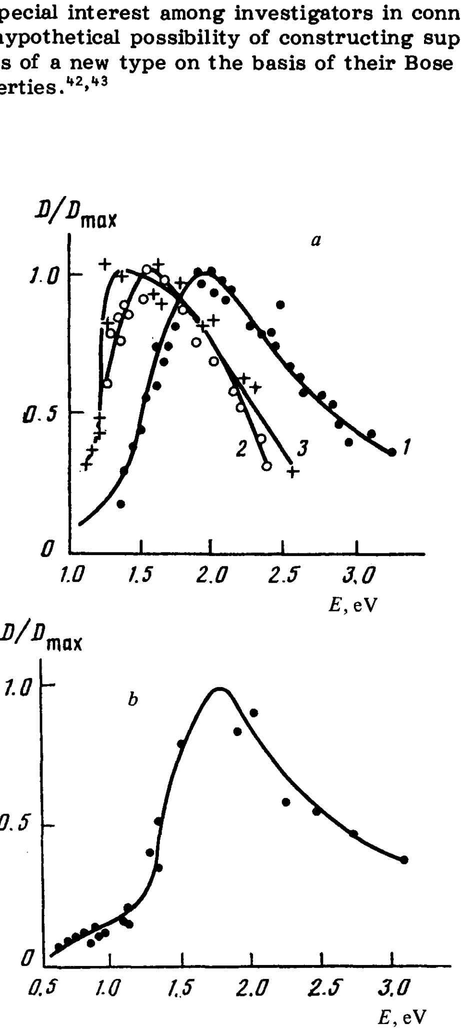

Figure 1. The absorption spectra of e_s in methanol at different temperatures (°C): *a*: *1*) 20; *2*) 148; *3*) 208; *b*: 244.[44]

The optical absorption curves for solvated electrons in different substances, their mixtures, and solutions, which have many properties in common, have been investigated in detail. In most cases these curves consist of a single broad structureless peak located in the visible or in the near ultraviolet depending on the microscopic structure of the solvent. The characteristic universal features of the shape of the absorption curves, to which we shall frequently refer below, are presented in Fig.1. Evidently the absorption peak is asymmetric: with increase of the energy, the comparatively sharp increase of the absorption is replaced by a slower descent. Such asymmetry is unusual in atomic and molecular spectroscopy (if one disregards the absorption spectra of a number of negative ions), but has analogies in nuclear physics.[21] In particular, the shape of the peak resembles very closely, after the appropriate alteration of the energy scale, the frequency dependence of the photosplitting of the deuteron. It was found that the shape of this absorption peak is extremely stable; for example, in the case of water it is almost invariant at temperatures from −4 °C up to a supercritical temperature. An important characteristic feature of the behaviour of the absorption peak from the standpoint of theory is its tendency to undergo a bathochromic shift with increase of temperature. It is seen in Fig.1 that the spectra of e_s in alcohol have the same features.

After a brief description of the various methods for the detection and investigation of e_s, we shall consider in the present review its physical nature, its chemical reactions, and its electrochemical behaviour. Special attention is devoted to the unusual nature of the chemical reactions of the solvated electron, the most active reductant, which is caused to a large extent by the possible occurrence of tunnel processes involving e_s. The characteristics of the thermodynamics of the solvated electron, including the thermodynamic relations between e_s and the quasi-stable "dry" electrons, will also be discussed.

II. EXPERIMENTAL RESEARCH METHODS

It is difficult to name an experimental physicochemical method which has not been used in the study of excess electrons in condensed media. This can be naturally accounted for by the fact that solvated electrons constitute unique experimental objects—the simplest anions which interact strongly with the medium and are characterised by both specific EPR and optical absorption spectra, readily generated by various procedures (pulsed and steady), having a wide variety of chemical properties, and, as already mentioned above, participating in many physicochemical processes. Therefore, regardless of whether the investigator is interested in quantum chemistry, magneto-resonance analytical methods, conductivity, the optics of condensed media, the chemistry of solutions, radiation chemistry, electrochemistry, cooperative phenomena, or other questions, the analysis of the nature and behaviour of excess electrons in various media enables him to test the selected method, to obtain interesting information, and to assess critically the existing theoretical schemes.

The possibility of using well tested physical methods, with a high time resolution, is an appreciable advantage in the study of solvated electrons (including the kinetics of their reactions). Here we have in mind in the first place the optical spectroscopic and EPR methods and also the method of induced pulsed electrical conductivity developed recently (and various modifications and combinations of the methods indicated). Most information about e_s has been obtained by studying the optical absorption spectra by an extremely wide variety of methods. High speed spectrometry with time resolution down to several picoseconds[45–53] with e_s generated by pulse radiolysis[48,50–53] and flash photolysis[45–47,49] has been used in the study of kinetics of the solvation and chemical reactions of e_s. Stationary and nanosecond spectra of e_s generated in different ways have been investigated as a function of temperature,[44,54] pressure,[55] the state of aggregation of the matrix (glass, liquid, and crystal), etc. Attempts (albeit with negative results) to observe the luminescence of solvated electrons have been described.[45,56]

Apart from the optical spectra, the IR and UV spectra of solvent–excess electron systems have been investigated.[57–59] Combined electro-optical,[60] magneto-optical,[61] and ellipsometric[62,63] methods are extremely promising. Excess electrons have also been investigated in experiments on photoemission and thermoemission from a metal into a solution and from a solution into a vacuum.[64–66] Many experiments concerning the influence of photoannealing on e_s spectra have been performed.[45–53] At the present time, one may claim that the optical properties of e_s have been more fully investigated than those of other colour centres in condensed media, including the usual halide ions. At the same time, to this day there is no generally accepted theoretical scheme which would explain the characteristic optical properties of e_s.

Various pulsed and stationary NMR and EPR methods have been used to investigate the immediate environment of solvated electrons.[7-12,19] Particularly valuable results have been obtained for frozen systems by the spin-echo modulation method.[67-69] The spin-echo modulation method, developed specially[67] for the investigation of solvated ions, has already yielded extensive information about the solvation shells of various metal ions in frozen electrolytes. However, in the case of e_s the results obtained must be treated with greater caution, according to Golden and Tuttle,[70] because in their interpretation one usually employs effective constants for spin interactions, which, as a consequence of the comparatively broad distribution of the e_s electron density, always have values as if the electron were localised in a cavity even when in fact there is no increase in the distances between the molecules of the medium at the site of the localisation of the excess electron.

There exist examples of the employment of fairly rare methods, such as the annihilation of positrons,[10,14] mass-spectrometric analysis of charged clusters of the type $(H_2O)_n^-$ in vapours,[71] and measurement of ultrasonic absorption.[10,14] Some of the results obtained by these procedures do not fit in any way the familiar theoretical schemes, which, incidentally, may be attributed to the inadequate accuracy and reliability of the selected experimental method.

Clearly, even a brief description of the experimental methods employed and the results obtained would occupy too much space. For this reason, we confined ourselves above to mentioning only the principal and most thoroughly developed fields of experimental research. We shall only state that, by analysing the nature of e_s, it is possible to assess fairly reliably various experimental and theoretical approaches in various fields of chemical physics.

III. THEORETICAL DESCRIPTION

The problem of the selection of an adequate model for the description of the solvated electron—an excess localised electron in a disordered, usually polar, condensed medium—is complex and interesting. Any progress towards its solution appears important not only for specialists, directly concerned with the solvated electron, but also for the general theory of condensed media.

During the period from 1940 to 1946, Ogg[72] developed the first quantitative theory of the electron solvated in ammonia. It was postulated that a spherical cavity with a radius R is formed around the electron in ammonia and that the ammonia molecules at the boundary of the cavity create for the electron an effective spherical potential well with infinitely high walls. The energy of the electron is made up of the positive kinetic energy T_e, determined with the aid of the uncertainty principle from the formula $T_e = (2\pi\hbar)^2/2mR^2$, and the energy of the interaction with the polarisation field:

$$V=-\frac{e^2}{R}\left(1-\frac{1}{\varepsilon_0}\right) \tag{1}$$

where ε_0 is the dielectric constant of the medium and m and e are the mass and charge of the electron.

The equilibrium value of the radius R_{eq} corresponds to the condition for a minimum in the total energy of the system. Ogg compared the "pushing apart" of the molecules by the electron in the cavity with the observed increase in the specific volume of ammonia following the dissolution of alkali metals in it. On excitation with light, the electron leaves the cavity. The threshold frequency Ω of the light absorbed by the solvated electron is determined from the relation

$$\hbar\Omega=T_e+V \tag{2}$$

The frequencies Ω and the high value R_{eq} = 20 Å obtained by Ogg clearly conflict with experiment. The main cause of this discrepancy is, as has now become clear, the unduly high kinetic energy of the solvated electron in the model of the potential well with infinite walls, which provides a poor description of the states of e_s, which are in reality comparatively weakly bound. However, the idea itself of the formation of a "cavity" greatly stimulated further theoretical investigation of e_s. In essence, an analogous computational scheme (with, however, the minimisation not of the energy but of the free energy of the electron—medium system) has been used as the basis of the modern description of the localised states of excess electrons in inert gases.[17,35-39]

Davydov[73] was the first to use for the description of solvated electrons in ammonia the Landau–Pekar theory of large radius polarons, developed previously[74] for the description of electronic states in ionic crystals. Subsequently this approach was used by Deigen.[75] Within the framework of the Davydov–Deigen theory, which its authors put forward in opposition to Ogg's cavity theory, it has been possible to obtain the quantitative values of a whole series of characteristics of the electron in ammonia in agreement with experiment, and in the first place the position of the maximum of the optical absorption band, which was related to the Franck–Condon 1s – 2p transition. This theory has played an important role in the prediction of the existence of and the determination of the frequency range in the optical absorption of the short-lived hydrated electron e_{aq}. On its basis, many attempts have been made to refine the calculations of the energy parameters and other characteristics of the ground and excited states of solvated electrons (see, for example, Mazurenko and Mukhomorov[76]).

The computational scheme, in which longitudinal optical phonons appear as collective excitations, has been most frequently used in the solvated electron theory. The appearance of such collective excitation is associated with the movement of a system of dipoles, whose orientation changes after the introduction of a charge into the system. The direct use of the theory of the interaction of electrons with phonons is possible only in the case of weak interactions with the aid of the procedures of the perturbation theory. Another limiting case, that of the strong interaction, is of greatest interest for the theory of solvated electrons. A special approach, whose main element is the use of an analogue of the Hartree self-consistent field method frequently used in quantum chemistry, has been developed for this purpose.

One of the most logical and clearest schemes for the representation of the above approach is as follows.[77] The complete vector of the state of the system $|\Psi\rangle$ is expressed approximately in the form of the direct product of the vector of the state $|\phi\rangle$, which depends solely on the electronic parameters, and the vector of the state $|\chi\rangle$, which depends only on the characteristics of the phonon field:

$$|\Psi\rangle=|\varphi\rangle|\chi\rangle \tag{3}$$

The exact Hamiltonian of the system H, i.e.

$$H=H_0^{el}+H_0^{ph}+\sum_{\mathbf{q}}(Q_{\mathbf{q}}a_{\mathbf{q}}e^{i\mathbf{qr}}+Q_{\mathbf{q}}^{*}a_{\mathbf{q}}^{+}e^{-i\mathbf{qr}})$$

is then replaced by the approximate Hamiltonian $\tilde{H}$, which depends explicitly on the time t:

$$\tilde{H} = H_0^{el} + H_0^{ph} + \sum_{\mathbf{q}} [Q_{\mathbf{q}} a_{\mathbf{q}} \rho_{\mathbf{q}}(t) + Q_{\mathbf{q}}^* a_{\mathbf{q}}^+ \rho_{\mathbf{q}}^*(t)] + \\ + \sum_{\mathbf{q}} [Q_{\mathbf{q}} A_{\mathbf{q}}(t) e^{i\mathbf{qr}} + Q_{\mathbf{q}}^* A_{\mathbf{q}}^*(t) e^{-i\mathbf{qr}}] + F(t) \tag{4}$$

where the summation is carried out with respect to the wave vectors of the phonons $\mathbf{q}$, H_0^{el} and H_0^{ph} are the Hamiltonians of the non-interacting electron and phonons respectively, $Q_{\mathbf{q}}$ is the shape factor of the electron–phonon interaction,# $a_{\mathbf{q}}$ ($a_{\mathbf{q}}^+$) the operator of the annihilation (generation) of the phonon, $\rho_{\mathbf{q}}(t)$, $A_{\mathbf{q}}(t)$, and $F(t)$ are certain (non-operator) time functions, and the asterisk * implies the complex conjugate. It follows from the condition for the minimum deviation of $\tilde{H}$ from H, which is formulated as the requirement for a minimum in the functional $<\Psi|(\tilde{H} - H)^2|\Psi>$ for all the vectors of the state $|\Psi>$ of type (3) that the following equations must hold:

$$\begin{gathered} \rho_{\mathbf{q}}(t) = \int \varphi^*(\mathbf{r}, t) \cdot \varphi(\mathbf{r}, t) \cdot e^{i\mathbf{qr}} d^3r \\ \varphi(\mathbf{r}, t) = \langle \mathbf{r} | \varphi(t) \rangle \\ A_{\mathbf{q}}(t) = \langle \chi | a_{\mathbf{q}} | \chi \rangle \\ F(t) = -\sum_{\mathbf{q}} [Q_{\mathbf{q}} A_{\mathbf{q}}(t) \cdot \rho_{\mathbf{q}}(t) + Q_{\mathbf{q}}^* A_{\mathbf{q}}^*(t) \cdot \rho_{\mathbf{q}}^*(t)] \end{gathered} \tag{5}$$

When the ground state is considered, the c-number term $F(t)$, which is independent of the coordinates and momenta of the electron and phonons can be rejected in the Hamiltonian (4), because its retention leads only to a change in the phase of the wave function which is insignificant when stationary states are considered. From Eqns.(4) and (5), it is possible to obtain dynamic equations which can be conveniently formulated for the wave function $\phi(r, t)$ of the electrons in the Schrödinger representation and for the phonon operators $a_{\mathbf{q}}$ in the Heisenberg representation:

$$\begin{gathered} i\hbar \frac{\partial \varphi}{\partial t} = \left\{ H_0^{el} + \sum_{\mathbf{q}} [Q_{\mathbf{q}} A_{\mathbf{q}}(t) \cdot e^{i\mathbf{qr}} + Q_{\mathbf{q}}^* A_{\mathbf{q}}^*(t) e^{-i\mathbf{qr}}] \right\} \varphi \\ i\hbar \frac{\partial a_{\mathbf{q}}\ (s)}{\partial t} = [\tilde{H}, a_{\mathbf{q}}] = \hbar\omega_{\mathbf{q}} a_{\mathbf{q}} + Q_{\mathbf{q}}^* \rho_{\mathbf{q}}^*(t) \end{gathered} \tag{6}$$

where $\omega_{\mathbf{q}} = \omega$ for the optical phonons and $\omega_q = C_s q/\hbar$ for the acoustic phonons.

In Eqns.(6), the electronic (phonon) field depends on the phonon (electronic) field solely via the average values of the corresponding operators, analogously to what happens in the Hartree method. The second Eqn.(6) represents the equation for an oscillator in the presence of an external force. The basis set of the so called coherent states, which remain coherent in the course of the evolution of the system in time, i.e. each coherent state passes to another specific coherent state corresponding to it, is convenient in this case. By selecting, in terms of the Heisenberg representation considered, a coherent state with an eigenvalue $\alpha_{\mathbf{q}}$ of the operator $a_{\mathbf{q}}$ at time $t = -\infty$, we have

$$a_{\mathbf{q}}(t) | \alpha_{\mathbf{q}} \rangle = \alpha_{\mathbf{q}}(t) | \alpha_{\mathbf{q}} \rangle, \ | \alpha_{\mathbf{q}} \rangle = \sum_{n_{\mathbf{q}}=0}^{\infty} \frac{\alpha_{\mathbf{q}}^{n_{\mathbf{q}}}}{n_{\mathbf{q}}!} | n_{\mathbf{q}}(t) \rangle \cdot e^{-|\alpha_{\mathbf{q}}|^2/2} \tag{7}$$

where $|n_{\mathbf{q}}(t)>$ is a state with a specified number of phonons and a wave vector $\mathbf{q}$. Bearing in mind that phonons with different $\mathbf{q}$ are independent in terms of the given approximation, it is sufficient to consider, instead of the second operator equation (6), the usual differential equation for the average values of $a_{\mathbf{q}}$ in terms of coherent states which enter into the first Eqn.(6):

$$A_{\mathbf{q}}(t) \equiv \langle \alpha_{\mathbf{q}} | a_{\mathbf{q}} | \alpha_{\mathbf{q}} \rangle \tag{8}$$

Thus, the second Eqn.(6) is replaced by the equation for the classical field $A_{\mathbf{q}}(t)$. Its solution is

$$A_{\mathbf{q}}(t) = A_{\mathbf{q}}^0 \cdot e^{-i\omega t} - i\hbar^{-1} Q_{\mathbf{q}}^* \int_{-\infty}^{t} e^{i\omega(t'-t)} \rho_{\mathbf{q}}^*(t')\, dt' \tag{9}$$

In the majority of the calculations carried out hitherto, the following two additional assumptions have been used (explicitly or implicitly). Firstly, the first term on the right-hand side of Eqn.(9) is rejected, which can be interpreted as abandonment of allowance for the influence on e_s of the real free phonons arising in the medium even at equilibrium due to thermal excitation. Secondly, the adiabatic approximation, consisting in the replacement of $\rho_{\mathbf{q}}^*(t')$ in the integrand in Eqn.(9) by $\rho_{\mathbf{q}}^*$—the average for the electronic ground state considered along a finite trajectory—is applied. The validity of the latter approximation is justified by the different time scales of the movements of the inertial phonon and rapid electronic subsystems.

After the replacement of the summation by integration, the problem of finding the stationary electronic function is reduced, in accordance with the usual rule, to its solution for the eigenvalues for a non-linear integro-differential operator:

$$E^e \varphi(\mathbf{r}) = [H_0^{el} - V_{sc}(\mathbf{r}, \varphi(\mathbf{r}))] \varphi(\mathbf{r}) \tag{10}$$

where

$$\begin{gathered} V_{sc}(\mathbf{r}, \varphi(\mathbf{r})) = \int d^3r' [|\varphi(\mathbf{r}')|^2 z(\mathbf{r}, \mathbf{r}')] \\ z(\mathbf{r}, \mathbf{r}') = \frac{1}{8\pi^3} \int d^3q \left\{ \frac{|Q_{\mathbf{q}}|^2}{\hbar\omega_{\mathbf{q}}} \cos[\mathbf{q}(\mathbf{r} - \mathbf{r}')] \right\} \end{gathered}$$

After solving the problem formulated above for the eigenvalues, the overall energy of the system can be represented in the form

$$E = E^e + E^m \tag{11}$$

where E^m is the energy of reorganisation:

$$E^m = \left\langle \alpha \middle| \sum_{\mathbf{q}} \hbar\omega a_{\mathbf{q}}^+ a_{\mathbf{q}} \middle| \alpha \right\rangle = \sum_{\mathbf{q}} \frac{|Q_{\mathbf{q}}|^2 \cdot |\rho_{\mathbf{q}}|^2}{\hbar\omega} = \\ = \frac{1}{2} \iint d^3r\, d^3r' [|\varphi(\mathbf{r}) \cdot \varphi(\mathbf{r}')|^2 z(\mathbf{r}, \mathbf{r}')] = \frac{1}{2} d^3r \varphi^*(\mathbf{r}) V_{sc} \varphi(\mathbf{r}) \tag{12}$$

In calculating E^m, Eqn.(9) was used for $A_{\mathbf{q}}$ without taking into account the free phonons.

The direct solution of Eqn.(10) with substitution in it of a particular specific expression for $z(\mathbf{r}, \mathbf{r}')$ represents an extremely complex problem, which is usually solved by variational methods.

#In the "classical" theory of the polaron, the shape factor $Q_{\mathbf{q}}$ assumes the form $Q_{\mathbf{q}} = -i(\pi\alpha_F/V)^{1/2} (\hbar^5\omega^3/m)^{1/4} q^{-1}$, where $\alpha_F = (\varepsilon_\infty^{-1} - \varepsilon_0^{-1}) (e^2/\hbar\omega)(m\omega/\hbar)^{1/2}$ is a dimensionless coupling constant (Fröhlich constant), ω and $\mathbf{q}$ are the frequency and the wave vector of the optical phonon, ε_∞ and ε_0 are the high-frequency and static dielectric constants of the medium, and V is the volume of the system. If interactions with acoustic phonons are considered, then $\omega = \omega(q) = C_s q/\hbar$ and $Q_{\mathbf{q}} = -i\sigma(\hbar q/2MC_sV)^{1/2}$, where C_s is the velocity of sound, M the mass of the unit cell, and σ the constant of the deformation potential.

The question of the limits of applicability of the numerous approximations introduced in the description of the strong coupling of electrons with phonons set out above is fairly complex. In the first place it is known that the Hartree type self-consistent field approximation cannot be characterised as an expansion in terms of a small dimensionless parameter and is justified in definite specific cases only as a result of certain numerical cancellations. One can only claim that such approximation is known to be applicable to a large number of phonons or, what amounts to the same thing, at high temperatures T in the system considered, because the correct classical limit for phonon equations is then obtained in terms of the basis set of coherent states. The additional adiabatic approximation used is known to be unjustified in the description of excited electronic states in the vicinity of the boundary of the continuous spectrum. The question of the methods of calculation of excited states with the aid of the variational procedure considered remains in general open. Its logical realisation requires expressions for the wave functions of higher states, which are so far unknown. Indirect estimates of the difference between the energies of the excited and ground states, which are in principle feasible, are extremely inaccurate. Referring to adiabatic conditions, the excited states in optical transitions are frequently calculated using the Hamiltonian of the ground state. This approach is quite justifiably disputed by Devreese et al.[78]

To the considerations presented in the studies quoted above, one must add that, when optical transitions are considered, one cannot simply reject, which is frequently done, the time(t)-dependent c-number terms $F(t)$ in Eqn.(4), such terms being different in different states. The fact that the theory must take into account quantitatively the effects arising owing to the disorder in the medium is significant. Logical allowance for these effects and also for microscopic interactions, symbolically introduced into Eqn.(4), within the framework of polaron models remains so far a matter for the future.

In connection with the uncertainty of the initial postulates of the theory, comparison of the conclusions which follow from it with experimental data is especially important. As already stated, many attempts have been made at a direct application of the large-radius polaron theory, in which the interaction with longitudinal optical phonons is specified by the Fröhlich Hamiltonian and there are no microscopic interactions, to the description of solvated electrons (see Refs.73–76 and the references in the last paper). However, this theory proved to be unable to explain many properties of solvated electrons. It has not been possible to interpret with its aid the shape of the optical absorption curve, the temperature dependence of the position of the maximum on this curve, and the influence of the phase state and pressure of the medium.§

The fundamental questions concerning the mechanism of the solvation of the electron have been investigated experimentally in a series of studies.[80–82] The authors investigated the optical spectra of e_s in mixtures of associated polar liquids having different or similar dielectric constants and also the changes in the spectra of e_s following the dilution of polar liquids by a non-polar solvent which is neutral as regards association. The most important result is the conclusion that the properties of e_s are correlated with the microstructure of the mixtures and that there is no dependence of the spectroscopic characteristics of e_s on the macroscopic parameters of the system (dielectric constant, density, etc.). On the basis of their experimental data, the authors[80–82] claim that the intrinsic structural elements of the medium—hydrogen bonded complexes of different molecules or self-associated species which function as electron traps—are of decisive importance for the mechanism of the solvation of the electron. The main cause of the broadening of the spectrum is the distribution of e_s among different associated species.[82]

Subsequently the approach proposed[80–82] was extended to dilute solutions of ammonia in various alkanes. The optical absorption corresponding to the photoexcitation of electrons localised in the associated polar molecules was then observed and investigated. The very fact of the solvation of the electron at very low concentrations of the polar component in the mixture (approximately 0.1 mole %) is of interest. The spectrum of e_s then remains almost the same as in pure NH_3 even when the medium is non-polar. The solvated electrons in such systems can probably be regarded as analogous to excess electrons in the vapours of polar liquids[83] and the spectrum of e_s then makes it possible to infer the energy characteristics of the electron in an "isolated" cluster of polar molecules.

The need to take into account in the solvated electron theory the influence of specific chemical interactions of e_s with the medium, which follows from the analysis of the experimental data, led to the development of semicontinuous models. Apart from the long-range interactions of e_s with long wavelength phonons, in such models account is taken, mainly phenomenologically, of the interactions with the molecules in the immediate environment—the solvation shell. Analysis of such models and of the difficulties associated with their use in the interpretation of experimental data, in the first place of the absorption spectra of e_s, has been carried out.[22]

The difficulties arising when the interactions of the electron with the solvent as a continuous system are considered stimulated the development of alternative theoretical models based on microscopic interactions of e_s with clusters—a small number of molecules surrounding the electron. These clusters are investigated by quantum-chemical methods. Such calculations for e_s are sometimes referred to as *ab initio* calculations for the electron. Using the terminology of solid state physics, the cluster models are seen to be closest to small radius polaron models. By virtue of the characteristics of a disordered medium, a tunnel electron jump is in this case difficult, because the equivalent position may prove to be fairly remote. If the characteristic time of any kind of processes involving e_s, for example optical transitions, is shorter than the characteristic time of the jumps, then the latter can be altogether neglected in the study of the given processes, i.e. the electron may be regarded as fixed at a specific molecular cluster.

In one of the first studies on these lines,[84] the states of the excess electrons in systems comprising water and ammoni dimers for a specific fixed geometry of the molecules in the dimers were calculated within the framework of a simplified version of the molecular orbital theory. For excitation energies identified with the difference between the energies of the lowest and highest orbitals, $\hbar\Omega = 2.5$ eV in the case o H_2O and 1.63 eV in the case of NH_3 were obtained.

The first quantum-chemical calculations for e_s revealed also the main difficulties encountered. It was found that (1) the state of e_s in the dimeric model is relatively unstable as regards the escape of the electron to a quasi-free state

---

§ The question of the influence of temperature and pressure on optical spectra has not been finally solved even for the classical case of large radius polarons.[79]

and (2) the electron (especially in an excited state) is not localised within the limits of the cluster. In order to eliminate these difficulties, clusters consisting of a large number of molecules were considered in subsequent studies and also attempts were made to take into account the influence of the dielectric continuum outside the solvation sphere (cluster). Such *ab initio* calculations for clusters consisting of four water or ammonia molecules have been carried out.[85,86] They yielded not only extensive numerical information, in general in agreement with experimental data (we have in mind the optical transition energies $\hbar\Omega$ and the geometrical dimensions of the clusters), but also involved a discussion of the question of the stability of the states of e_s. It was found that the overall energy E_s represents the difference between two quantities: the energy gain in the localisation (capture) of the electron in the cluster with the optimum configuration and the energy expenditure necessary for the formation of such a cluster (or defect). The overall solvation energy E_s is positive although not large.[86]

However, in our view the energy gains obtained in the solvation of the electron are comparable to the accuracy of the calculation and the question of the stability of the clusters (i.e. of their existence in the vapour phase) should still be regarded as open. The above studies[85,86] have confirmed but not eliminated the difficulties arising in quantum-chemical models in view of the large effective radius of e_s in the excited state. In view of this result, the calculations of the characteristic excited states of e_s must be treated with a great deal of scepticism, because the interactions of the electron with the molecules of the second solvation shell should be significant for such states.

An evident deficiency of the above studies is their complete neglect of the interactions of the electron with the medium surrounding the cluster. Such interactions should lead to at least two effects; firstly, owing to the influence of the medium, the discrete lines in the absorption spectra of the cluster e_s should spread (or the corresponding vibronic bands should be modified); secondly, the presence of the medium can lead to an increased stability of the localised e_s (for example, via the polaron mechanism).

A configurational model of e_{aq} has been proposed.[87] The states of the H_2O^- ion, in the field of six dipoles interacting with one another which consist of the molecules in the first solvation shell, have been calculated by the LCAO method. The local energy minima of the cluster, corresponding to the electronic ground state of e_s, have been calculated as a function of the orientation of the dipoles. The "Franck–Condon" excited states of e_s were then found for each such local minimum in the energy of the cluster. The optical absorption spectral lines for such a cluster *in vacuo* should correspond to the differences between these energies. The attempt at a quantitative calculation of not only the main characteristics of the optical absorption band of e_s but also of the dependence of the spectrum on temperature and pressure must be regarded as a fundamentally new step in the study of Byakov et al.[87]

For the description of the absorption spectrum of the solvated electron, the above workers[87] resorted, apparently for the first time in quantum-chemical calculations of this kind, to the general theory of the absorption of light by impurity species in the medium. This general theory, developed by Ovchinnikov and Ovchinnikova,[88] relates the broadening of the discrete lines to the interaction of the electron with the optical phonons of the medium. Analysis of the spectrum of e_{aq} within the framework of the configurational model showed that, depending on the disposition (orientation) of the dipoles in the first solvation shell, there are several groups of stable "ground" states of e_{aq} (i.e. local energy minima of the electronic ground state). Its own "Franck–Condon" excited state corresponds to each of these ground states. It has been observed that the energies of the Franck–Condon transitions decrease on average with increase in the energy of the "ground" state. This finding explains the effect of the bathochromic temperature-induced shift of the absorption maximum: with increase in temperature, increasingly high "ground" states, which correspond to absorption in a longer-wavelength region, are populated. The interaction of the cluster with the medium leads to the spreading of the discrete spectral lines and to the appearance of a structureless spectral band, which is displaced to the left along the frequency axis if the temperature is increased. Since the band width is mainly related to the disposition of the initially discrete lines, its temperature dependence may not follow the proportionality to $\varepsilon_\infty^{-1} - \varepsilon_0^{-1}$ predicted by the polaron theory[76] and this also applies to the asymmetry of the band.

The experimental EPR data for e_s, indicating (in terms of the usual interpretation) the symmetry of the electron density distribution among the 4–6 protons of the immediate environment, may constitute an evident objection against the above model.[87] However, the authors[87] took into account this possible objection and carried out an analysis of the EPR spectra of e_s in terms of their model. An unexpected conclusion arising from this analysis is that of the possible equivalence of protons from the standpoint of EPR spectroscopy accompanied by a clear geometrical asymmetry of the disposition of the molecules in the configurational model (we recall that initial localisation of the electron in the cluster on one central H_2O molecule is postulated). The observed uncertainty in the reproduction of the geometrical structure of e_s on the basis of EPR data must be borne in mind also in the interpretation of complex spin echo experiments (see also Golden and Tuttle[70]). Unfortunately the authors[87] did not continue an analogous analysis of e_s for other media and it therefore remains unclear whether the mechanisms of the bathochromic shift, broadening, and asymmetry of the optical absorption band of e_{aq} which they quote[87] are universal for all (or the majority) of solvents or whether they apply only to H_2O.

The attempt to take into account the dielectric continuum has also been undertaken in a study[89] whose author reformulated the usual self-consistent field problem in terms of the Hartree potential and included the corresponding polaron contribution to the minimised energy functional in the quantum-chemical calculation for a negatively charged cluster consisting of four molecules of the medium. The calculation confirmed yet again the conclusion that the state of e_s in the gas phase is unstable, that the electron cloud incorporating the molecules of the medium adjoining the cluster has a large radius, and that the electron is almost fully delocalised in the excited state. Unfortunately, in the above study[89] the question of the shape of the absorption band and of its temperature dependence was not considered. The broadening of the band was explained qualitatively by the presence of geometrically different clusters, i.e., as is usual for cluster models, a heterogeneous mechanism for the broadening of the band was postulated.

It is noteworthy that a non-empirical calculation for a negatively charged cluster incorporating 4–6 molecules is at the limit of feasibility as regards modern computers and many natural questions, for example, concerning the infrared spectra of such clusters or the constants for the interaction of an additional electron with the intramolecular vibrations therefore still remain unanswered. It must be emphasised yet again that the quantum-mechanical methods used in the study of e_s provide only more or less approximate results and it would be naive to expect to obtain with their aid answers to all the questions. Experiments still remain the principal source of information.¶

The complex problems arising in the comparison of different theoretical computational schemes for e_s, the presence of a large number of parameters, and the uncertainty of the initial data led to studies in which the structure of e_s was investigated with the aid of methods of analysis of optical spectra unrelated or weakly related to model representations.[22,90–95] Such analysis indicates primarily the short-range character of the interactions leading to the localisation of e_s and makes it possible to treat optical absorption as electron transition from a bound state to a continuum.

We believe that the most convincing confirmation of the transition from the bound state to a continuum is provided by the results of the analysis of absorption spectra with the aid of optical sum rules, the virial theorem, and threshold formulae.[22,90–95] In an early study[96] it was already noted that the region of the characteristic absorption peak of the solvated electron corresponds virtually to the maximum value of the oscillator strength. Hence it was possible to conclude that at least the given peak corresponds to the transition of e_s to a continuum. Detailed analysis of the experimental results based on a wide variety of sum rules and model-free threshold formulae[22] demonstrates quite convincingly that the optical section of the absorption spectrum of the solvated electron does indeed correspond to the "bound state–continuum" transition. The long-energy sections of the spectrum can then correspond in certain specific cases to contributions by "bound state–resonance level" transitions. The contributions of such transitions are apparently extremely significant in the case of the electron in ammonia. The conclusions reached in a review[22] and in subsequent communications[92–95] concerning the analysis of the moments (optical) of the spectral absorption curves of the solvated electron are mainly in agreement. A significant feature of the above studies[92–95] was the discussion in the latter of the influence of the temperature of the system on the sum rules.

One of the most important conclusions from the model-free analysis of the optical absorption spectra of solvation electrons with the aid of sum rules and threshold formulae is that the interactions retaining the electron in the localised state are short-range in character.[22] A direct consequence of this conclusion has been an attempt to describe the optical spectra of the solvated electron within the framework of the stationary short-range potential model. The first study based on this approach was apparently that of Kajiwara et al.[97], in which the radial dependence of the potential was represented by a rectangular well characterised by two parameters. This approach has definite features in common with the cavity model adopted as early as the 1940's in Ogg's studies.

The studies summarised by Frankevich and Yakovlev[22] dealt with the so called zero radius potential with a single parameter expressed directly in terms of a quantity having a direct physical significance, namely in terms of the energy of the bound state of the electron. The zero radius potential, actively employed in nuclear physics, has the significance of the limit of the potential of the rectangular well (in terms of the zeroth spherical harmonic) when the width of the well tends to zero and its depth tends to infinity so that the single stationary level (or the antibonding state) does not change. Systems in a short-range potential field, the energy of the systems being close to the continuous spectrum threshold, are satisfactorily described in a similar way.

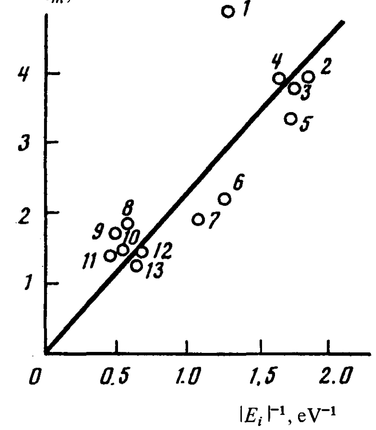

Figure 2. The extinction coefficient at the absorption maximum expressed as a function of $|E_i|^{-1}$. Straight line—theoretical relation corresponding to the zero radius potential model; circles—experimental data: *1*) ammonia; *2*) diethyl ether; *3*) methyltetrahydrofuran; *4*) tetrahydrofuran; *5*) dimethoxyethane; *6*) 1,3-propylenediamine; *7*) ethylenediamine; *8*) water; *9*) methanol; *10*) ethanol; *11*) ethylene glycol; *12*) isopropyl alcohol; *13*) 1-propanol.[44]

It is possible to extend the zero radius potential to the case of certain bound states, including states with the highest angular momenta, which is usual for specific systems with solvated electrons. The number of "adjustable" parameters can be increased by passing to potentials with a finite radius. In the case of the zero radius potential, the dependence of the cross-section σ of the photoinduced "bound state–continuum" transition on the frequency of the incident light Ω and on the energy of the initial state E_i is expressed by the simple formula

$$\sigma(\Omega, E_i) = \frac{32\pi^2 e^2}{3c\hbar} k_i \left(\frac{k_f}{k_f^2 + k_i^2}\right)^3 ,$$
$$\hbar^2 k_i^2 = 2m|E_i|; \ \hbar^2 k_f^2 = 2m(E_i + \hbar\Omega) . \qquad (13)$$

Eqn.(13) reproduces very satisfactorily in many instances the principal characteristics of the main absorption peak of the solvated electron. For example, according to Eqn.(13), there should be a linear relation, with a rigorously defined coefficient, between the extinction coefficient ε_m at the absorption maximum [which is proportion to $\sigma(\Omega_m)$] and the reciprocal of the frequency Ω_m^{-1}, corresponding to the absorption maximum. The corresponding theoretical curve together with the experimental points for a series of substances[90] is shown in Fig.2. The only deviation of the experimental points from the theoretical curve, exceeding the experimental

---

¶In this connection one cannot fail to mention again the study[62] in which an ellipsometric investigation of e_s in hexamethylphosphoramide revealed a change in the vibration frequency of the non-polar C–H bond but no influence of the excess electrons on the polar C–N and P=O bonds was observed. This information necessitates in many respects a re-examination of the initial postulates for the construction of cluster models.

error, is observed in the case of the electron in ammonia. This finding is attributed[90] to the comparatively large interaction region (the presence of a "cavity") in the case of ammonia. Agreement with experiment can be attained if it is assumed that the size of this "cavity" in ammonia is in the range 1–2 Å. The relation between Ω_m and the threshold energy, which follows from Eqn.(13), also holds very satisfactorily:[22]

$$\hbar\Omega_m \cong 2|E_i| \ . \tag{14}$$

It is useful to quote the results of the analysis of the expression for the polarisability of the solvated electron α. In the general case of the motion of the localised electron with an energy E_i in an external potential field, the polarisability is given by

$$\alpha = K\frac{e^2\hbar^2}{mE_i^2} \ , \tag{15}$$

where K is a numerical multiplier. For the zero radius potential, the multiplier K assumes the minimum value $K = 1/16$ for the ground 1s state, while for a long-range potential of the Coulombic type, this quantity is 70 times greater and amounts to 9/2. For the remaining monotonic potentials, K lies in the range between 1/16 and 9/2. The polarisabilities obtained using the sum rule[22] for electrons in different media and the theoretical relation (15) for $K = 1/16$ are compared in Fig.3. The satisfactory agreement of the results constitutes important additional evidence in support of the short-range character of the interactions promoting the localisation of the electron in the solvated state.

However well the behaviour of the solvated electron is described with the aid of the zero radius potential model, such description is known beforehand to be incomplete, since it does not take into account the influence of many-particle effects. However, precisely these effects determine interesting phenomena such as the dependence of the shape and position of the absorption peak in the optical frequency range on the structure of the medium and temperature and also the manifestation of absorption in the infrared region associated with the modification of the collective modes as a result of the introduction of an excess electron into the medium. They also influence the kinetics of processes with participation of the solvated electron.

The question of allowance for many-particle effects in the solvated electron theory has been frequently posed in the literature. The problem has been most often considered in terms of a linear treatment based on the formulation of the Hamiltonian H taking into account the interaction and dynamics of the motion of all the particles in the system considered or, at least, sufficiently large clusters. One of the examples of this approach has been given by Golden and Tuttle.[98] In an approach of this kind, the introduction of insufficiently well-founded approximations and hypotheses of a model character is inevitable even when large computers are used for the calculations. Without denying the importance of such studies, we nevertheless doubt if real advances can be achieved on these lines, especially if an explanation can be found for the observed simple and universal characteristics of the behaviour of the spectra of solvated electrons.

We believe that another approach, corresponding to a scheme actively and successfully used in modern physics of condensed media is more promising. According to this scheme, the short-range interactions to which correspond the greatest changes in the energy of the system when a solvated electron is introduced into it are assumed to be specified and parametrised with the aid of a finite number of parameters, which can be calculated, in principle, by quantum-chemical methods. In the case of the solvated electron, the parameters of the zero radius or separable potential can be used as parameters of this kind. On the other hand, the long-range interactions are regarded as interactions with long-wavelength low-energy collective excitations of disordered media. Precisely such interactions determine, for example, the temperature effects for a constant density and also the principal kinetic features of the phenomena considered. The approach described has much in common with the semicontinuous model mentioned above, the only difference being that the interactions are separated in accordance with their energy and not spatial scale. An attempt to apply the above approach to the elucidation of the temperature dependence of the optical spectra was made in our earlier study.[99]

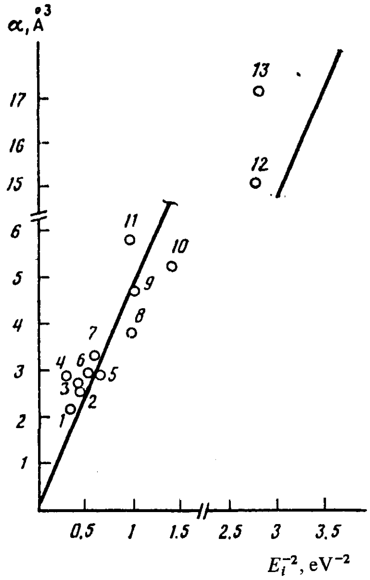

Figure 3. Dependence of the polarisability α on E_i^{-2}. IV. CHEMICAL REACTIONS

The chemical reactions of e_s in water, alcohols, ketones, and other polar liquids have been studied in especially great detail in the radiation chemistry of solvating compounds. The corresponding reactions have been described in a number of monographs[16,19–21,71] and we shall not deal with them in detail. In recent years much attention has been devoted to the detailed mechanism and other features of the reactions of e_s in mixtures of various solvents and to the reactions of stable e_s with a number of compounds dissolved in liquids such as ammonia, amines, and hexamethylphosphoramide.

We shall consider initially the bimolecular and unimolecular reactions of solvated electrons with water as the most important examples:

$$2\,e_{aq} + 2\,H_2O \rightleftarrows H_2 + 2\,OH^- , \qquad (16a)$$

$$e_{aq} + H_2O \rightleftarrows H + OH^- . \qquad (16b)$$

The analogous reactions in pure ammonia, i.e.

$$2e_s + 2NH_3 \rightleftarrows H_3 + 2NH_3^- \qquad (17a)$$

$$e_s + NH_3 \rightleftarrows H + NH_2^- , \qquad (17b)$$

hardly occur and e_s is extremely stable. The kinetic and thermodynamic characteristics of reactions (16) and (17) are presented below (at room temperature):

Reaction	k, litre mol^{-1} s^{-1}	ΔH^0, kJ mol^{-1}	ΔS^0, J mol^{-1} K^{-1}
(16a)	$5\cdot10^9$	−397	−12
(16b)	10^3	10	−48
(17a)	$\leqslant 1$	−168	−466
(17b)	$\leqslant 1$	125	−272

The kinetic data for the reactions were taken from Antropov[16] and the thermodynamic data from Schindewolf.[100]

Thus the absence of appreciable reactions of e_s in ammonia is caused by kinetic and not thermodynamic factors. The high absolute entropy of the solvated electron in ammonia $|S^0| = 169$ J mol^{-1} K^{-1} [101] (the entropy of the hydrated electron is $|S^0| = 13$ J mol^{-1} K^{-1}) leads to a high activation energy for the reactions of e_s in ammonia according to the activated complex (transition state) theory.[100–103]

The above arguments should also indicate a low probability of the reaction of the electron solvated in ammonia with admixtures of water ($\Delta H^0 = 52$ kJ mol^{-1}, $\Delta S^0 = -316$ J mol^{-1} K^{-1}):[103]

$$2e_s + 2H_2O \rightleftarrows H_2 + 2OH^- . \qquad (18)$$

The possibility of an endothermic unimolecular reaction is apparently ruled out in this instance. However, direct experiments have shown[104–106] that the electron in ammonia reacts with added water at an appreciable rate, which has not so far been unambiguously explained. It has been suggested[103] that the acceleration of this reaction is caused by the formation of an unknown intermediate X in accordance with the scheme

$$2e_s = (NH_3) + 2H_2O \rightarrow [2X] \rightarrow H_2 + 2OH^- . \qquad (19)$$

Evidence for the formation of intermediates in the reaction of e_s with water had been obtained earlier in experiments involving flash photolysis with additional lower-frequency illumination displaced in time relative to the initial pulse.[107,108] It was suggested that such intermediates may be the bielectron $(e_s)_2$, formed via the recombination of two solvated electrons, and, in a sodium–ammonia solution, the neutral complex (Na^+e_s), which is much larger than the Na atom. The question of the possible formation of $(e_s)_2$ and of complexes of the type $[Na(e_s)_2]$ has attracted much attention.[25] The detailed microscopic mechanism of even the most thoroughly investigated reactions of e_s with water cannot so far be regarded as unambiguously elucidated.

Much attention has been devoted recently to the reactions of e_s with aromatic and unsaturated hydrocarbons in various solvents and to reactions modelling processes involving charge transfer (electron capture by an acceptor). Studies of reactions with aromatic compounds[109–113] made it possible to identify the ranges of parameters within which the rates are controlled either by diffusional or kinetic limitations. In the case of diffusion-dependent control, the fact that the localised solvated electron e_s is in equilibrium with a delocalised "quasi-free" electron e_d assumes special importance. Although the fraction of delocalised electrons is small, their mobility is high and may determine the characteristic features of the migration. On the other hand, in most reactions (except perhaps the reactions of H atoms) the rate of interaction with e_s is much greater than the rate of interaction with e_d in conformity with the Franck–Condon principle. Thus, as noted for the first time by Frankevich and Yakovlev,[22] when the reactions of the solvated electron are considered account must be taken of both possible (localised and delocalised) states of the latter.

After the publication of the study of Frankevich and Yakovlev,[22] other communications appeared in which a system of two differential equations, corresponding to different states of the electron linked to one another by an equilibrium constant, is used instead of a single (diffusion) equation for the formal diffusional description of e_s capture and neutralisation processes.[18,114] The exact solution of such equations is difficult. The usual simplification is the hypothesis that the mobility (diffusion coefficient) of the electron in the localised state is much lower than the mobility (diffusion coefficient) of the quasi-free electron. On this hypothesis, it is possible to retain the form of the experimental relaxation curves and the values of the "adjustable" parameters become more reasonable.

This type of approach has been used in a study[114] whose authors began with generalised Noyes formula[115] for the effective reaction rate constant:

$$k_{\mathrm{eff}} = [pk_s + (1-p)\,k_d]\Big/\left[1 + \frac{pk_s + (1-p)\,k_d}{R_r D_{\mathrm{eff}}}\right] , \qquad (20)$$

where p is the probability of the localisation of the electron, k_s and k_d are the rate constants for the reactions with acceptors in the localised and delocalised states respectively, D_{eff} is the effective diffusion coefficient of the electron, and R_r is the reaction radius. In this way it has been possible, in particular, to explain the observed non-monotonic nature of the dependence of k_{eff} on the mobility of the solvated electron μ in the reactions of the latter in various hydrocarbons. Qualitatively, this phenomenon can be explained as follows. For low values of μ, the reaction proceeds under diffusion controlled conditions and the reaction rate constant is proportional to the mobility. The increase of the mobility promotes an increasing delocalisation of the electrons, which reduces the effective rate constant (subject to the condition that the reaction with the acceptor in the localised state is much faster than in the delocalised state). With the aid of the model considered, the authors[114] were able to explain also the dependence of the activation energy of the reaction on the effective mobility of the electron in hydrocarbons.

In the study of the kinetics proper of the reactions of solvated electrons with aromatic compounds, the validity of correlations involving a linear dependence of the rate on the free energy change in accordance with the Hammett equation was considered.[111] After the studies of Marcus[116] and Levich,[117] most attention was devoted (see Kestner[118] and the literature quoted therein) to the general theory of processes of the type

$$T^- + A \rightarrow T + A^- \qquad (21)$$

where T denotes a trap for the solvated electron ($e_s \equiv T^-$), which disappears over a finite period after it loses its charge.

One of the reasons for the interest in reaction (21) is that it is the simplest example of charge transfer. Furthermore, reactions (21) are included among the elementary steps of many electrochemical and biological processes. Processes involving e_s can be followed directly with the aid of effective optical methods with a short resolution time. Additional difficulties in the theoretical study of reactions (21) are associated with the need to allow for non-adiabatic effects. The most important qualitative result of the theoretical and experimental studies of the above reactions is the conclusion that electron transfer over a large distance is impossible and that this process is influenced by the orientation of the molecules of the medium, especially in biological systems and glasses.[119]

In conclusion of the present Section, we may point to the possibility, established recently (see the review of Glausinger et al.[42] and the literature quoted therein), of the formation (in the form of films or powders) of new compounds—electrides, obtained for the first time on evaporating solutions of solvated electrons. Electrides is the name given to salts in which the localised electrons behave as anions and the positive ions are alkali metal complexes. The salts Cs^+. .(18C6)e^-, where the symbol 18C6 denotes a complex-forming crown compound (a macrocyclic polyether), is an example of an electride.[120] As a result of the strong electron–electron interaction and the delocalisation of electrons, electrides exhibit extremely unusual properties, approaching the properties of metals, including high electrical conductivity and absorption spectra of the plasma type.[42] The hypothesis that electrides are Wigner crystals is of interest.

V. ELECTROCHEMICAL PROPERTIES

Chemically stable systems with solvated electrons include in the first place solutions of metals in ammonia (the counterions in such systems are usually alkali metal ions) and also in aprotic solvents such as hexamethylphosphoramide (HMP), dimethyl sulphoxide, diglyme, etc.

The method of electrochemical generation of solvated electrons in such systems, which makes it possible to investigate e_s under stationary conditions in controlled chemical reactions in the bulk of the solution and on the electrode, is very interesting. Although the electrochemical generation of solvated electrons in ammonia was reported as early as 1948,[121] the qualitative investigation of this process did not begin until the 1970's (see the relevant reviews[24,26]) after the investigation of the characteristics of photoemission into electrolyte solutions.[64,65] Clearly the photoemission and the electrochemical e_s generation processes are in many respects analogous and differ essentially only in the detailed mechanisms of the excitation of the electron from the Fermi level of the metal: in the first case the excitation is optical and in the second thermal.

For high negative potentials of the cathode, the cathodic generation of electrons should be observed theoretically in all electrolytes. However, in fact the actual occurrence of cathodic generation requires that (1) the solution should be stable in relation to the cathodic reduction of positive ions at fairly high negative potentials of the cathode and (2) that the reaction of the electrons in the bulk phase with positive ions should be at least hindered. Otherwise, instead of the cathodic generation of e_s, the reduction of counterions either on the electrode (deposition of the metal) or immediately in the region near the electrode is observed. We may note that a number of workers[24,122] hold the view that many of the known electrochemical reduction reactions proceed precisely via a mechanism involving the generation of e_s with subsequent interaction (in the part of the solution near the electrode) of the solvated electrons and positive ions.

This type of mechanism has been discussed in the literature even for the usual discharge of H^+ ions in the electrolysis of water. However, detailed study has shown that in water the "classical" discharge of H^+ ions nevertheless takes place on the electrode.[24] Among all the solutions, the conditions specified are satisfied best by the aprotic systems enumerated above (HMP, diglyme, etc.). It is therefore not in any way surprising that the greatest number of data on the cathodic generation of e_s have in fact been obtained using HMP, which is a liquid under normal conditions.

In the cathodic generation of e_s, two reaction pathways are possible in principle. In the realisation of the first of these, the electrons of the metal, thermally excited above the level corresponding to the electrochemical potential of the delocalised electron on the "bottom of the conductivity band of the solution",† overcome the surface barrier, move along the conductivity band, and are thermalised and solvated at a certain distance from the electrode. The possibility of the generation of solvated electrons under these conditions is determined by the activated excitation of the electron to the V_0 level. The second reaction pathway involves the tunnel transition of the electrons of the metal to the E_s level of the solvated electrons in solution. The electron must then "tunnel" over a certain distance into the solution. The activation energy for such a process, equal to $E_s - E_F$ (E_F is the Fermi level in the metal), is naturally smaller than the activation energy for the first pathway, but we have here instead kinetic limitations associated with the low probability of tunnelling over comparatively large distances. Clearly, for different potentials and states of the surface of the cathode, one or other mechanism of the cathodic generation of e_s takes place preferentially.

There is experimental evidence for the operation of both mechanisms of the generation of e_s.[24,123,124] In the above studies it was also concluded that there is a possibility of a change in the generation mechanism when the state of the electrode surface changes (the surface is passivated). Indeed, at a fixed potential of the electrode, the formation on the latter of a passivating film increases the tunnelling distance. For a sufficient thickness of the film, the process involving the excitation of the electron to the conductivity band of the solution, whereupon the electron passes over the surface barrier, is more probable.

The study of the anodic oxidation reactions of solvated electrons showed that they are controlled by diffusion and that the oxidation potential depends on the state of the electrode surface. Apart from the discharge of the solvated electrodes on the anode, the polarisation curves for HMP revealed yet another limiting current plateau, corresponding to the discharge of non-paramagnetic complexes containing two electrons and an alkali metal ion. In relation to discharge on the anode, the monoelectrons are significantly more active than the non-paramagnetic complexes;[124] their oxidation potentials differ by approximately 0.5 eV. The study of the anodic reactions of solvated electrons made it possible

---

†The very concept of the "conductivity band" in a disordered system with a strong electron–phonon (electron–exciton) interaction requires discussion. Being in a delocalised state, the electron "does not have time" to interact with the slow orientational polarisation of the medium. Here it is more appropriate to speak of the influence of the electronic and nuclear polarisation of the medium, i.e. of the interaction of the electron with high-frequency phonons and excitons, which can be regarded as weak. In this case one can actually use the ideas about the conductivity band developed for ordered media. The validity of the hypothesis of the "bottom of the conductivity band of the solution" has been demonstrated by experiments on photoemission into solutions and from solutions (see Brodskii and co-workers[64,65]).

to estimate accurately their concentrations in solution from the limiting discharge current and to establish, on the basis of the concentration of the electrons, the concentration dependence of the equilibrium "electronic" potential and to calculate the standard potential of the reversible electron electrode in HMP.[124] An analogous study has been carried out also for ammonia.[103]

Investigation of the bulk-phase reactions of cathodically generated electrons is extremely promising. Since solvated electrons are "rapidly moving" species, i.e. have high diffusion coefficients, in many cases it is more convenient to carry out the reaction in the bulk phase by supplying electrons to the latter than to ensure the transport of the reducible species to the electrode. Furthermore, the change in many solvents of the density of the medium near the sites where the electron is localised promotes the mixing of the solution by convection, which also accelerates the reaction in the bulk phase. Solvated electrons, whose standard potential is close to the standard potentials of alkali metal ions, are one of the most powerful reductants and, since they can be generated at large concentrations, it is possible to achieve many reactions with organic compounds which are difficult to reduce. At the present time there already exist many examples of such processes.[24,26,122–124]

VI. PRINCIPAL ENERGETIC CHARACTERISTICS

The following scheme of the states of solvated electrons can be put forward. The delocalised "dry" electron moves along the "conductivity band", whose bottom is at the level V_0 reckoned from the energy level of the electron *in vacuo*. After solvation, accompanied by a possible rearrangement of the medium and the localisation of the electron, the energy of the self-consistent "electron–medium" system is $E^e_s + E^m$, where E^e_s is the energy of the electron and E^m the energy of the reorganised medium. Apart from the ground and delocalised (quasi-free) states of the electron, excited localised states may arise, which can be regarded as resonances in the continuous spectrum of the electron–phonon system. In an optical transition, which proceeds in accordance with the Franck–Condon principle without change in the "slow" coordinates of the medium, the electron passes from the ground state to one of the excited states or to a "band" state. The medium then remains in the initial state and the excited levels are therefore non-equilibrium in nature and their energies, generally speaking, differ from the energies of the corresponding equilibrium levels. We shall denote the "Franck–Condon" excited levels by an asterisk: for example, $(2p)^*$ is the $2p$ state of the electron not adjusted for consistency with the state of the medium and $(2p)$ is the state adjusted for such consistency.

In order to find the difference between the chemical potentials of the delocalised (quasi-free) and localised solvated electrons ($\mu_d - \mu_s$), it is necessary to take into account the entropy factor. When the Boltzmann formula is used, we obtain

$$\mu_d-\mu_s=-E^e-E^m+V_0+kT\ln\left[\frac{(mkT/2\pi h^2)^{3/2}a^3c_s}{c_dg}\right] \cdot \qquad (22)$$

The formula for the chemical potential of an ideal gas was used here for the delocalised electron and the degeneracy factor g, effectively allowing for the change in the number of states of the phonon subsystem on localisation of the electrons, was introduced; the factor a is approximately equal to the average radius of e_s, i.e. corresponds in order of magnitude to the intermolecular distance, and $c_{s(d)}$ is the concentration of localised (delocalised) electrons. We emphasise that the concept of the "solvated electron" refers to the entire many-particle excess electron + medium system. At equilibrium ($\mu_d = \mu_s$), we have

$$c_s/c_d=c(g)\cdot\exp\left(\frac{V_0-E^e_s-E^m}{kT}\right) \qquad (23)$$

and the numerical coefficient $c(g)$ attains 10^3 at room temperature even if $g = 1$. We may note that the possible existence of systems in which the localisation of electrons is favoured by thermodynamic factors when the energy of the localised state exceeds that of the delocalised electron at the bottom of the "conductivity band" follows from the previous treatment. In the description of the interaction with electromagnetic radiation, such a system can be regarded as one with inverse population and laser action is possible in it as a result of the energy of the phonon subsystem.

Table 1. Thermodynamic and energy parameters of solvated electrons determined in different experiments.

Type of experiment	Quantity determined
Measurement of the optical absorption spectrum	Oscillator strength of optical transitions (Refs,22, 90–94]; the position of the absorption maximum (corresponds to the energy differences $E^e_{(2p)*} - E^e_s$ if a discrete level exists and to $\sim 2(V_0 - E^e_s)$ if the spectrum corresponds to the photoionisation of e_s and there are no autoionisation states)
Measurement of the photoconductivity excitation spectrum	Photoconductivity threshold, energies of autoionisation states: $V_0 - E^e_s$, $E^e_{(2p)*} - E^e_s$, etc.
Photoemission into a liquid	Position of the bottom of the conductivity band V_0 (if the emission is into the "band"), the energy E^e_s (if there is a tunnel transition to a bound level)
Cathodic generation	Thermodynamic parameters of the ground state of e_s
Photoemission from the solution to a vacuum (vapour)	The photoemission threshold E^e_s
Thermal emission from the solution to a vacuum (vapour)	Free energy of activation for thermal emission $E^e_s + E^m - T\Delta S$
Dissolution of the metal	Free energy of solvation $E^e_s + E^m - T\Delta S$

Table 1 shows a systematic arrangement of the energy and thermodynamic characteristics of solvated electrons obtained in different experiments. It also includes the differences ΔS between the specific entropies of the delocalised and localised states which can be written in the following form by analogy with Eqn.(22):

$$\Delta S=kT\left[c_s\ln\left(\frac{a^3c_s}{g}\right)+c_d\ln\left(\left(\frac{mkT}{2\pi\hbar^2}\right)^{-3/2}\right)\right] \qquad (24)$$

We may note that we never use the thermodynamic characteristics of the electrons *in vacuo*, because they cannot form a homogeneous equilibrium system *in vacuo*.

A number of comments may be made concerning the amount of information yielded by the different experiments indicated in Table 1. The greatest number of data naturally refer to the spectroscopic characteristics of the solvated electron.

However, when the nature of the transition has been established, these data by themselves say nothing about the energy parameters of the different states of e_s. Only careful analysis of the spectroscopic data using the sum rules, additional thermodynamic information, and other data would make it possible to estimate the energy parameters of e_s from the optical spectra. For example, in the measurement of the spectra of e_s in ammonia–alcohol and hydrazine–alcohol mixtures the superficially strange conclusion is reached that the electrons "solvated in ammonia and hydrazine", absorbing at lower frequencies than the "alcoholic" electrons, are favoured by energy factors.[80–82] However, if it is assumed that the spectrum of e_s in ammonia is determined by transitions between bound states and the spectrum of the electron in alcohol is determined by transitions of the "bound state–conductivity band" type then the observed facts can find a natural explanation.

The study of photoemission from a metal to a vacuum, an electrolyte, or a dense electrolyte vapour can yield much information about the position of the solvated electron at the bottom of the conductivity band as a function of the density of the electrolyte.[64,83] Joint measurements of the absorption and photoconductivity spectra and the spectra of the photoemission from the metals to the solution and from the solution to a vacuum would then make it possible to obtain all the energy characteristics of the ground and excited states of e_s. Unfortunately at the present time there are no photoconductivity data at all and the remaining data have been obtained in different systems and are non-systematic.

There exist certain data on thermal emission from solutions,[126] but these have been subjected to a justified criticism[64] in view of the lack in the relevant communication of information about the temperature dependence of the density of the vapour phase (and hence about the energy characteristics of the electron in it).

Table 2. Certain energy characteristics of e_s.

Characteristic	Medium		
	ammonia	HMP	water
Maximum of absorption spectrum, eV	0.88 [14]	0.45 [129]	1.72 [16]
Position of bottom of conductivity band, eV	—	—0.9 [128]	—1.3 [128]
Solvation energy, eV	1.7 [127]	1.0 [126]	1.5 [128]
Solvation entropy, J mol^{-1} K^{-1}	154 [103]. 47 [130]	—	49 [130]. 12 [101]
Threshold of photoemission from the solution to a vacuum, eV	1.53 [131]	0.9 [131]	—

Note. The numerals in square brackets represent references (Ed.of Translation).

Presumably experiments on the electrochemical generation of e_s [24,108,111,124] can yield the most accurate thermodynamic data. The same may be said of data on the thermodynamics of electrochemical reactions obtained from measurements of the e.m.f.'s of cells containing solvated electrons. Unfortunely, the majority of experiments on the cathodic generation of e_s have been carried out in HMP and the e.m.f. data have been obtained solely for electrons in ammonia. Altogether, there exist at the present time an enormous number of different experimental data referring to different systems but a sufficiently complete set of information has been accumulated for only one system—that in ammonia.

Table 2 summarises the known energy and thermodynamic characteristics of solvated electrons in a number of solvents. The very large positive entropies of solvation of the electron in ammonia and HMP, greatly exceeding the entropies of solvation of ions in these solvents, are noteworthy.# Furthermore, the similarity of the heats of solvation of the electron in HMP and ammonia to the thresholds of the photoemission of electrons from these solvents, i.e. the closeness of the value of E^m to zero, is striking, although the photoemission data for these solvents should be regarded as estimates only. Hitherto no experiments have been carried out on the photoconductivity of electrons solvated in liquid solvents, although there is a genuine need for them. Furthermore, from our standpoint, the lack of photoconductivity data to a large extent vitiates the existing extensive information about the spectra of e_s.

---o0o---

As shown in the introduction, different physicochemical effects associated with the solvated electron have come to the centre of attention during different periods. In particular, during the 1960's, the role of solvated electrons in the radiation chemistry of aqueous systems aroused special interest. At the present time, the study of the details of the dynamics of various reactions involving e_s, especially reactions with charge transfer in polar solutions and vitreous matrices, electrochemical reactions, and complex biochemical processes, including the role of e_s in photosynthesis, is of greatest current interest. Comparison of the data obtained with theoretical conclusions provides unique possibilities for testing various concepts in chemical kinetics.

It follows from the foregoing that numerous problems concerning the characteristics of e_s have not yet been solved. It is especially important to determine theoretically and experimentally the dependence of the transport properties of the solvated electron on temperature over the widest possible range of the latter and to study the photoconductivity. The possibilities of investigating the chemical and electrochemical reactions of solvated electrons and of the unusual compounds such as the electrides formed with their participation have not been fully utilised. There is no doubt that the interest in the role of the solvated electron in photosynthetic processes and in the transfer of excitations in biological systems will grow. Finally, in the immediate future the quantum chemistry of e_s should develop further. It is significant that the theoretical study of an exotic anion such as e_s makes it possible to compare effectively and to assess the approaches developed both in quantum chemistry and in the electronic theory of disordered media.

The Cleavage of the Carbon-Carbon Bond in Carbonyl Compounds and Alcohols under the Influence of Bases

G.A.Artamkina and I.P.Beletskaya

The characteristics of the cleavage of the carbon-carbon bond in carbonyl compounds and alcohols of different types are considered. It is shown that the ease of dissociation of this bond is determined primarily by the stability of the carbanion formed. Among other factors, the nature of the solvent, the base, and the counterion are important. The importance of the latter factor has the greatest influence on the stability of the O-M bond in alcohols and hydroxycarbonyl compounds. The bibliography includes 281 references.

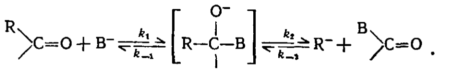
V. The retroaldol condensation 995

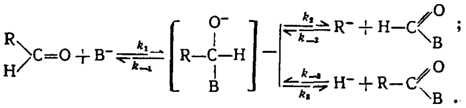
I. INTRODUCTION

The heterolytic cleavage of the carbon–carbon bond is a fairly rare although important reaction in organic chemistry. Such cleavage is usually associated with the formation of carbanions (in a free or cryptoanionic state) and proceeds reversibly, so that, if the stability of the carbanions is insufficient, the occurrence of the reaction requires the presence of special carbanion acceptors. The reactions considered here include the following:

1. The reaction of carbonyl compounds with bases:



In the general case we have here competition between the abstraction of B^- and R^- (stages with the rate constants k_{-1} and k_2). The bases employed in this reaction are usually OH^- or OR^-, but amides and other nucleophiles, including carbanions, can also be used. We may note that for aldehydes there is also the possibility of the abstraction of a hydride ion (stage with the rate constant k_3):



The reactions of the type considered include also the retro-Claisen condensation, in particular, the so called acid cleavage of the acetoacetic ester.

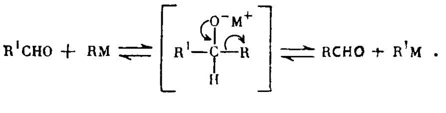
2. Decarboxylation of carboxylic acids with participation of the anion:

$$RCOO^-M^+ \rightleftharpoons R^-M^+ + CO_2\ .$$

3. Decomposition of carbinolates (alkoxides)—the reaction which is the opposite of the addition of organometallic compounds to the carbonyl group—the most important process leading to the formation of the carbon–carbon bond:

Such reactions include the retroaldol condensation (the reverse reaction, i.e. the aldol condensation, involves the addition of an alkali metal enolate to the carbonyl group).

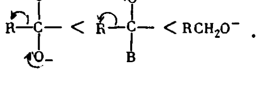
Naturally, the decisive factor in all the reactions considered is the stability of the carbanion split off, so that, in the presence of several substituents in the carbinolate RR^1R^2COM, the C–C bond ruptured is that having the substituent which corresponds to strongest CH acid RH. Thus, in principle, it is possible to formulate the equilibrium in which one carbanion induces the displacement from an aldehyde or ketone another more stable carbanion:



$$R^1CHO + RM \rightleftharpoons \left[R^1-\overset{\overset{\displaystyle O^-M^+}{|}}{\underset{\underset{\displaystyle H}{|}}{C}}-R \right] \rightleftharpoons RCHO + R^1M\ .$$

However, there exist also other factors, which likewise determine the possibility of the cleavage reactions considered. These are primarily the nature of the base and the solvent and, when a specific type of base is used, the nature of the counterion. The role of the last factor is associated with the difference between the effects of the counterion on the ease of ionisation of the O–M and B–M bonds and is determined by the exclusively strong dependence of the stability of the O–M bond (in relation to ionisation) on the nature of M (which is much more pronounced than in the case of, for example, the C–M bond).

As was to be expected, the free anion is cleaved most readily. If anions such as the carbinolate, the tetrahedral anionic intermediate formed when the base adds to the carbonyl group, as well as the dianion arising on treatment with an excess of alkali are compared, then their stabilities are seen to vary in the sequence



$$R-\overset{\overset{\displaystyle O^-}{|}}{\underset{\underset{\displaystyle O^-}{|}}{C}}- < R-\overset{\overset{\displaystyle O^-}{|}}{\underset{\underset{\displaystyle B}{|}}{C}}- < RCH_2O^-\ .$$

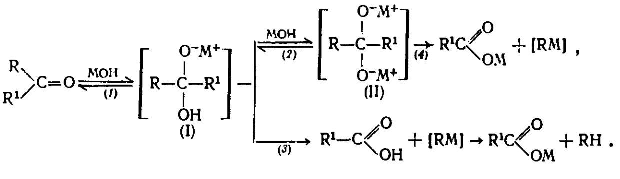
Thus it is possible to trace the general characteristics of the reactions involving the cleavage of the C–C bond occurring in compounds of different classes and having at first sight little in common. The present review is devoted to the analysis of the available data concerning the influence of the stability of the carbanion, the nature of the solvent, and the nature of the counterion on the ease of cleavage of the carbon–carbon bond.

II. THE CLEAVAGE OF KETONES AND ALDEHYDES BY BASES

1. General Considerations

Ketones are usually cleaved by bases with difficulty. An exception is ketones containing in the α-position strong electron-accepting groups, for example, NO_2 or SO_2,[1] quaternary ammonium,[2] and keto- or ester groups.[3] The last case represents the well known reaction involving the acid cleavage of β-dicarbonyl compounds.[4] Trihalogenomethyl ketone and trihalogenoacetaldehydes are readily cleaved (haloform cleavage reaction).[5] The study of the kinetics of the cleavage of such carbonyl compounds by alkalis in aqueous solution showed that all these processes can be represented by a single scheme (Scheme 1):[1-3]

Scheme 1

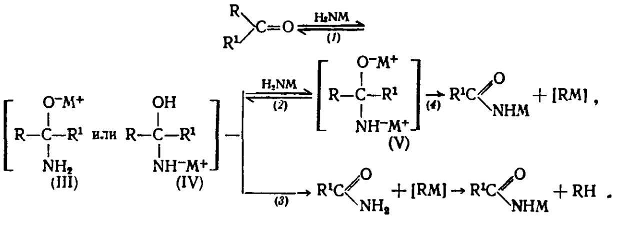


where R is a stronger electron-accepting group than R^1.

Kinetic studies have made it possible to postulate that, depending on the nature of the carbonyl compound, the rate-limiting stage can be both stage (1), involving the addition of the hydroxide anion to the carbonyl group (for example, for nitroacetone, ω-nitroacetophenone,[1] αα-dimethylacetophenone,[3] and thienyltrifluoroacetone[1,6]) and the formation of the dianion (II) (for ketoalkylpyridinium salts and sulphonylketones[1,2]) or its decomposition (for example, for acetylacetone, methylacetylacetone,[3] chloral hydrate, and 2,6-dihalogenobenzaldehydes[7,8]).

Potassium or sodium amides in liquid NH_3 or in aromatic hydrocarbons such as benzene, toluene, and xylenes (Haller–Bauer cleavage) are frequently used as bases for the cleavage of ketones.[9-11] The fundamental scheme for these processes (Scheme 2) is analogous to that presented above:[9,12,13]

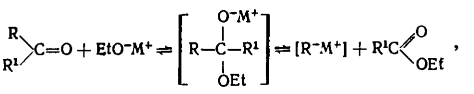
Scheme 2



It follows from Schemes 1 and 2 that the first stage in the cleavage of carbonyl compounds by bases involves the addition of bases to the carbonyl group with formation of the intermediate (I) or (III)/(IV). Adducts of type (III) have been frequently isolated in reactions with NH_3 or amides at low temperatures; on decomposition with water, they regenerated the initial ketones.[14-17] Similar adducts with alkalis, alkoxides, and other bases are probably less stable. We may note that the adducts of formaldehyde with hydroxide and methoxide ions have been recently detected in the gas phase.†[18]

The majority of cleavage reactions of carbonyl compounds apparently require the formation of the dianions (II) or (V), which follows from kinetic data (second order with respect to the alkali).[1-3,8,12,13] The heterolysis of such dianions should naturally proceed more readily than that of the monoanions. The formation of the dianions is indicated also by the fact that, in the absence of a proton donor, the hydrocarbon RH is not formed.[20] When fairly stable carbanions R^-, such as the nitromethyl or trifluoromethyl carbanions, are formed, the monoanion (I) can apparently also undergo heterolysis;[1] in this case it may be protonated by the acid formed, giving rise to the hydrocarbon RH.

When carbonyl compounds are cleaved by alkoxides in alcohols, there is a possibility of the formation of only the monoanion, but it has been demonstrated nevertheless that acetylacetone and 2-ketoalkylpyridinium salts are readily cleaved under these conditions:[21]

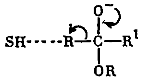


$$\begin{array}{c}R\\R^1\end{array}\!\!>C{=}O + EtO^-M^+ \rightleftharpoons \left[R{-}\overset{O^-M^+}{\underset{OEt}{C}}{-}R^1\right] \rightleftharpoons [R^-M^+] + R^1C\begin{array}{l}{\nearrow}O\\ \searrow OEt\end{array} ,$$

$$[R^-M^+] + EtOH \rightarrow RH + EtO^-M^+ .$$

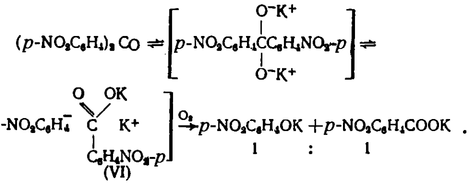
In the general case, when asymmetric ketones are cleaved by bases, there is a possibility of the formation of a mixture of two acids (or their derivatives) and two hydrocarbons:[9,22,2

The mode of reaction is determined by the relative stabilities of the carbanions R^- and $(R^1)^-$—the most stable carbanion is split off. Therefore, if the stabilities of the carbanions are approximately identical, i.e. the pK_a of the corresponding RH and R^1H are similar, then a mixture of four products is formed. The ease of cleavage of carbonyl compounds is also determined by the stabilities of the carbanions produced (see below). The question arises whether these reactions lead to the formation of the carbanion R^- as a kinetically independent species or is it possible, as has in fact been suggested,[24] that the product RH is formed as a result of the attack by the proton-donating compound (SH) directly on R in the adduct:

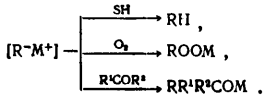


According to Artamkina et al.,[20] the ion pair VI participates in the reaction, as shown in Scheme 3 for the cleavage of $(p\text{-}NO_2C_6H_4)_2CO$, where oxygen functions as the trapping agent for R^-:

Scheme 3



Naturally, the organometallic compound RM itself can also be formed in these reactions if R^- is a sufficiently stable carbanion. On the other hand, in the majority of cases the reaction requires the presence of a suitable compound functioning as the trapping agent for the carbanion:



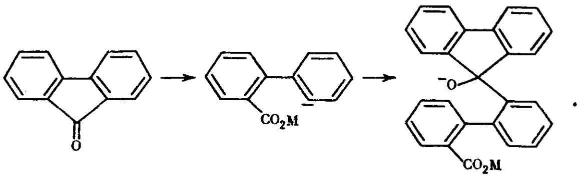
---

† The adduct of an alkoxide with *NN*-dimethyltrifluoroacetamide has been recently detected in solution.[19]

The cleavage of carbonyl compounds is usually carried out in aqueous or alcoholic solutions and the trapping is a proton-donating compound. This role can sometimes be assumed by O_2.[20] In the absence of a proton donor, the ketone itself can act as the trapping agent. For example, in the cleavage of benzophenone and its *pp*′-difluoro-derivative, triarylcarbinols have been obtained in 75–86% yield by treatment with KOH in dimethoxyethane (DME):[20]

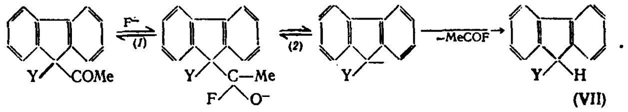
$$[XC_6H_4^-K^+] \xrightarrow{(XC_6H_4)_2CO} (XC_6H_4)_3COK,$$
$$X = H,\ p\text{-F}.$$

The formation of small amounts of triarylcarbinols (X=H or *p*-Cl) has also been noted in other studies.[23–26] A similar reaction has likewise been observed in the cleavage of fluorenone;[27–29] the yield of the carbinol reached 94% in some cases:[28]



In the absence of carbanionic trapping agents, the stages (3) and (4) (in Schemes 1 and 2) are as a rule reversible and the process as a whole therefore becomes reversible. This has been clearly demonstrated for the cleavage of 9-substituted 9-acetylfluorenes by the fluoride ion (KF-18-crown-6 ether or Bu_4NF/SiO_2) and it was shown that both stage (1) and stage (2) (Scheme 4) are reversible:[30]

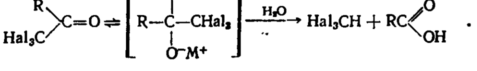
Scheme 4



When Y = CN, the equilibrium is strongly displaced towards the reaction products. Subsequent hydrolysis showed that the yield of RH (VII) diminishes in the sequence Y = CN > $PhCH_2$ > Me and on passing from a non-polar to a polar solvent.[30]

Specific examples of the cleavage of carbonyl compounds by various bases are examined below.

2. The Haloform Reaction



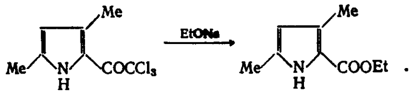
$$\begin{matrix}R\\Hal_3C\end{matrix}\!\!>C{=}O \rightleftharpoons \left[R-\overset{\displaystyle O^-M^+}{\underset{\displaystyle O^-M^+}{C}}-CHal_2\right] \xrightarrow{H_2O} Hal_3CH + RC\!\!<\!\!\begin{matrix}O\\OH\end{matrix}\ .$$

Such reactions occur frequently and usually readily,[5] because trihalogenomethyl anions are fairly stable (the pK_a of the corresponding CH acids are 13.7–15.5 [31]). The cleavage sometimes occurs simply on treatment with water, as happens, for example, for hexabromo- and hexachloro-acetones,[32,33] but usually bases have to be employed. Thus ααα-trichloroacetophenone can be heated for 7 h at 170 °C without change, but in the presence of catalytic amounts of MeCOOK it is immediately cleaved.[34] αα-Dibromoacetophenone is cleaved on boiling with a sodium carbonate solution.[35] Perfluoro-t-butylphenyl ketone is entirely stable, but decomposes rapidly in the presence of catalytic amounts of CsF in DME:[36]

$$PhCOC(CF_3)_3 \xrightarrow{F^-} PhCOF + (CF_3)_3C^- \xrightarrow[-F^-]{} (CF_3)_2C{=}CF_2\ .$$

However, KOH and NaOH are usually employed as bases in the haloform reaction, $Ca(OH)_2$ and $Ba(OH)_2$ being more rarely used.[5]

The haloform reaction is used to synthesise bromoform and iodoform, the determination of the structures of organic compounds, and sometimes for the synthesis of acids or their esters.[5] For example, ferrocenemonocarboxylic and ferrocenedicarboxylic acid are obtained by treating mono- or diacetylferrocenes with hypohalites.[37] Aliphatic acids with branched groups of the type of Me_3CCOOH and Me_3CCH_2COOH or unsaturated acids, which are sometimes difficult to obtain in other ways, can be synthesised with the aid of this reaction; in the presence or alcohols, esters are produced,[34,38] for example:



Phenylesters can also be obtained by a similar procedure:[38]

$$PhCOCCl_3 - \begin{cases} \xrightarrow{PhOH,\ KOAc} \underset{80\%}{PhCOOPh}, \\ \xrightarrow{(o,\ p)\text{-}MeC_6H_4OH} \underset{90\%}{PhCOOC_6H_4Me\text{-}(o,\ p)}. \end{cases}$$

Hexachloroacetone is used for the trichloroacetylation of alcohols and phenols:[39–41]

$$\underset{\displaystyle \overset{\|}{O}}{Cl_3CCCCl_3} + ClCH_2CH_2OH \xrightarrow[\text{pentane, 20°C, 16 h}]{K_2CO_3} \underset{\displaystyle \overset{\|}{O}}{Cl_3CCOCH_2CH_2Cl} + CHCl_3\ .$$

In aprotic dipolar solvents such as nitromethane,[40] dimethyl sulphoxide (DMSO), dimethylformamide, (DMF), pyridine, and hexamethylphosphoramide (HMP),[41] the reaction can be carried out in the absence of a catalyst. DMF proved to be especially effective.[41]

The decomposition of hexachloro- or hexabromo-acetone is also induced by ammonia[33] and amines, even aromatic amines:[42]

$$CCl_3COCCl_3 + RC_6H_4NH_2 \xrightarrow[20-80°]{H_2O} Cl_3CCONHC_6H_4R,$$
$$R = H;\ MeO,\ Me,\ OH,\ Cl\ .$$

The trichloroacetylation of peptides has been carried out in an analogous manner.[43]

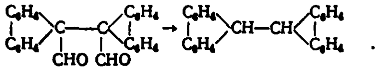
On treatment with hypohalites, carbonyl compounds of other classes are also cleaved—α-ketoesters, β-diketones, or β-ketoesters. In essence, these reactions are analogous to the haloform cleavage reactions. Some of them have been described in a review.[5]

3. The Cleavage of Aldehydes by Bases

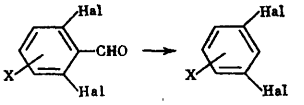
Aldehydes without α-hydrogen atoms usually enter into the Cannizzaro reaction,[44] but there are a number of exceptions whereupon treatment of aldehydes with alkali results in their cleavage:

$$RCHO + MOH - \begin{cases} \xrightarrow[(1)]{} RCH_2OH + RCOOH, \\ \xrightarrow[(2)]{} RH + HCOOH\ . \end{cases}$$

Naturally, the second mode of reaction occurs in those cases where the Group R is sufficiently electron accepting. The well-known examples of such reactions are the cleavage of chloral,[45] bromal,[46] mixed bromochloroacetaldehydes,[47] and even aldehydes containing the SO_3K or SO_3H group in the α-positions[48–51] on treatment with alkalis. On heating with 20% KOH (130 °C, 5 h)[52,53] or with alcoholic KOH (120 °C, 5 h),[54] triphenylacetaldehyde is cleaved to triphenylmethane. Aldehydes containing an acetylenic group in the α-position (propargyl, phenylpropargyl,[55] and tetrolic[56] aldehydes) are cleaved by dilute KOH solutions at 20 °C. Other examples of the ready cleavage of aldehydes, for example, bisdiphenylene succinic aldehyde[52] or trichloroacrolein,[57] can also be quoted:



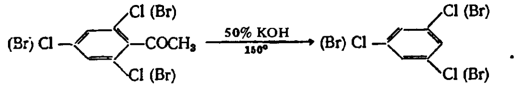
In the series of aromatic aldehydes, an essential condition for their cleavage in an alkaline medium is the presence of two electron-accepting substituents, and halogen atoms, for example, must be in the *ortho*-positions. 2,6-Dihalogenobenzaldehydes are cleaved by refluxing with 50% KOH and under these conditions the aromatic ring can contain also other substituents, including electron-donating substituents (Me, MeO):[58]



Dinitrobenzaldehydes react much more readily and in this case not only 2,6-dinitro- but also 2,4-dinitro-benzaldehydes are cleaved.[59] Trinitrobenzaldehyde is cleaved especially easily—it is sufficient to heat it with alcoholic solutions of NaOH or NH_3, Na_2CO_3 (10%), or even aniline (the yield of trinitrobenzene is up to 95%).[59] Thus the general trend is evident: the reaction is faster, the more stable the carbanion formed. A single chlorine atom in the *ortho*-position in benzaldehyde is insufficient to alter the mode of reaction—the usual Cannizzaro reaction takes place in this case.[58]

4. The Cleavage of Ketones by Alkalis and Alkoxides

As will be seen from the data presented below, the cleavage of ketones obeys the rules which have been noted above for aldehydes. Thus acetophenone and its monochloro-derivatives are cleaved by alkali with difficulty. It is of interest that the cleavage proceeds with abstraction of the methyl and not the phenyl group.[60] It may be that the ease of protonation of the more nucleophilic group plays a role in this case. The reaction is accompanied by charring and the yield of benzoic acids is insignificant.[60] Even when acetophenone is heated with KOH melt at 220–250 °C, only 20% of benzoic acid is formed.[61] The same has been observed for methylacetophenones.[60] The situation changes sharply when two chlorine or bromine atoms are introduced in the *ortho*-positions in the benzene ring; the process proceeds even more readily with 2,4,6-trichloro-, 2,4,6-tribromo-, and 2,3,4,5,6-pentachloro-acetophenones (50% KOH, 150 °C), but the products of these reactions are halogenobenzenes and not benzoic acids:[60]



Naturally 2,4,6-tribromo-ααα-trichloroacetophenone gives rise to 2,4,6-tribromobenzoic acid on cleavage.[62]

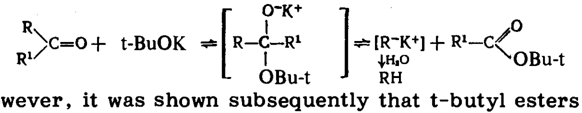
Acetophenone and other enolisable ketones undergo the condensation reaction more readily than the cleavage reaction and cleavage has therefore been investigated for non-enolisable ketones, in the first place benzophenone and its derivatives.[22,23,63–67] Benzophenone was cleaved as early as 1849 by fusing it with KOH at 260 °C:[63]

$$Ph_2CO + KOH \xrightarrow{[illegible]} PhCOOK + PhH\ .$$

Under just as severe conditions, *mono*- and di-methylbenzophenones are cleaved with formation of toluic acids.[64–67] The introduction of even one chlorine atom in the *ortho*-position in the benzene ring proved to be sufficient to increase significantly the rate of reaction, whereupon chlorobenzene and benzoic acid are formed.[23] The influence of chlorine is so great that 2,4,6-trichlorobenzophenone is cleaved even by refluxing for 2 h with a dilute (20%) alcoholic solution of KOH.[68] Benzophenone itself and many of its substituted derivatives (with methyl and halogeno-substituents) are reduced under these conditions to diphenylmethanols, while benzophenones with strong electron-donating substituents do not react or char.[24,68,69] It is noteworthy that at the present time a method is available for the cleavage of benzophenone under much milder conditions—refluxing the ground KOH in DME or tetrahydrofuran (THF).[20] Fluorenone and its substituted derivatives are cleaved in a KOH melt[27] or in diphenyl ether.[70]

In recent years, t-BuOK has been most widely used for the cleavage of ketones, usually in aprotic dipolar solvents.[25,26,71–76] This method was proposed by Swan as early as 1948.[24] Ether, dioxan, pyridine, DMSO, HMP, and DME and also benzene and hexane can be used as solvents in these reactions. A very important factor is the presence of small amounts of water in the reaction mixture. Careful experiments have shown that t-BuOK : H_2O = 3 : 1 is the optimum ratio. In the absence of a proton source, the yields of acid are insignificant (the reaction usually does not occur at all). The mechanism initially proposed by Swan[24] (Scheme 5) includes the attack by t-BuOK on the ketone; water serves as the trapping agent for the carbanion and generates under these conditions the OH^- anion, which is essential for the hydrolysis of the t-butyl ester:

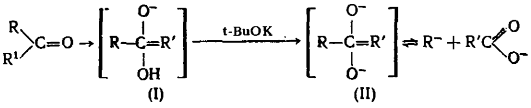
Scheme 5



$$RR^1C{=}O + t\text{-}BuOK \rightleftharpoons \left[R{-}\overset{O^-K^+}{\underset{OBu\text{-}t}{C}}{-}R^1\right] \rightleftharpoons \underset{\substack{\downarrow H_2O\\ RH}}{[R^-K^+]} + R^1{-}C(=O)OBu\text{-}t\ .$$

However, it was shown subsequently that t-butyl esters are not intermediates in these reactions[73] and an alternative mechanism (Scheme 6) was therefore proposed in which the carbonyl group is initially attacked by the OH^- anion with formation of the adduct (I), while t-BuOK abstracts a proton from it, affording the dianion (II):[25,73,74,76]

Scheme 6

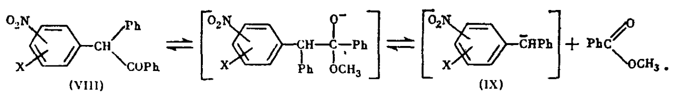


$$RR^1C{=}O \rightarrow \underset{(I)}{\left[R{-}\overset{O^-}{\underset{OH}{C}}{=}R'\right]} \xrightarrow{t\text{-}BuOK} \underset{(II)}{\left[R{-}\overset{O^-}{\underset{O^-}{C}}{=}R'\right]} \rightleftharpoons R^- + R'C(=O)O^-\ .$$

In this version, the role of water consists in generating the hydroxide from t-BuOK. There exists yet another point of view on the mechanism of this reaction—the 3 : 1 : 1 t-BuOK–t-BuOH–H_2O mixture gives rise to an aggregate, which is soluble in organic solvents and in which OH^- is only slightly solvated and is therefore extremely reactive. In this case KOH should cleave ketones in aprotic solvents also in the absence of the t-BuOK–t-BuOH mixture. Indeed, a suspension of KOH, obtained by adding water to an excess of KH in THF, cleaves nortricyclanone in 2 h at 30 °C.[73] However, as mentioned above, ground KOH in THF or DME cleaves even benzophenone under relatively mild conditions.[20] Other di- and tri-cyclic ketones are cleaved in the t-BuOK–H_2O–aprotic solvent system. The authors believe that the driving force of their cleavage is the removal of strain from the system and the formation of stable cyclopropyl and allyl carbanions.[71–73] According to this view, camphenilone and fenchone, which are less strained than, for example, nortricyclanone, dehydronorcamphor, or 7-oxonorbornene, are not cleaved or are cleaved with difficulty.[72] The possibility of the cleavage of ketones such as $PhC(Me_2)COPh$ or $MeOC.(Me_2)COPh$ is also explained by the elimination of steric strain.[77,78]

We may note that dehydronorcamphor, which is an enolisable ketone, is fairly smoothly cleaved by t-BuOK.[71,73,79] Yet another interesting example is the cleavage of α-(*p*- and o-nitrophenyl)deoxybenzoins (VIII), which leads to the formation of benzoic acid and products of the further reaction of the carbanions (IX)—substituted anthranilic acid derivatives and tetraphenylethanes (Scheme 7):[80]

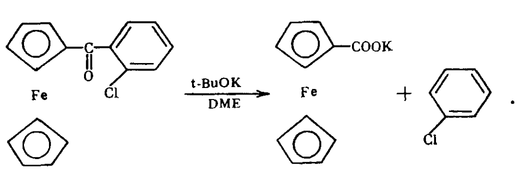
Scheme 7



Ketones of the carbaborane series are readily cleaved by treatment with EtOK in ethanol,[81] because the carbaborane formed is a fairly strong CH acid ($pK_a \cong 18$):[31]

$$\underset{B_{10}H_{10}}{\mathrm{Ph{-}C{-}C{-}COPh}} \xrightarrow[EtOH]{EtOK} \underset{B_{10}H_{10}}{\mathrm{PhC{-}CH}} + \mathrm{PhCOOEt}\ .$$

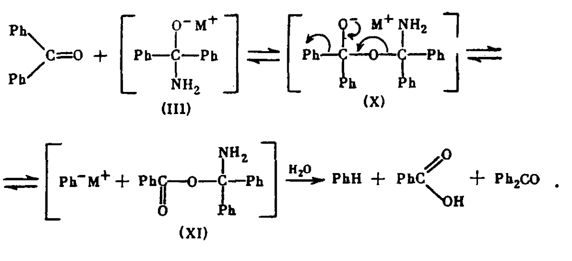
The t-BuOK–DME system has been used for the synthesis of carboxylic acids of the ferrocene and cymantrene series:[82]



5. The Cleavage of Ketones by Alkali Metal Amides

Potassium amide in liquid ammonia does not cleave benzophenone,[12,13] but it does partly cleave benzopinacol[83] and readily cleaves o-halogenobenzophenones.[12,13,17,84] Under more severe conditions, i.e. on refluxing ketones with $H_2NK.(H_2NNa)$ in toluene or xylene, both Ph_2CO and its *ortho*, *para*, and *meta*-substituted derivatives (with the Me, Cl, and Br substituents) are cleaved.[9,85] As a rule, when ketones are cleaved by alkali metal amides, not only amides but also the corresponding acids are formed.[9,12,84] Under the mild conditions used in the isolation of the reaction products, the amide cannot hydrolyse to the acid. The acid is apparently formed in the course of the reaction itself. It has been suggested that the mechanism of the formation of acids on cleavage of ketones by alkali metal amides[12] is analogous to the mechanism of the formation of benzilic acid on treatment of benzil with H_2NNa or RO^- in aprotic solvents.[86] The anion (III) acts as a base, attacking a second ketone molecule, and the heterolysis of the intermediate adduct (X) affords compound (XI), which is converted on hydrolysis into benzoic acid (Scheme 8):

Scheme 8



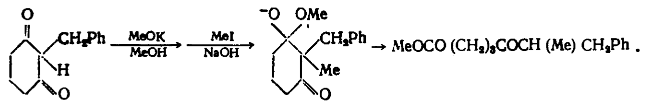
We may note that the intermediate formation of o-halogenophenyl anions has been demonstrated in the reaction with o-halogenobenzophenones.[12,13]

6. The Cleavage of β-Dicarbonyl Compounds

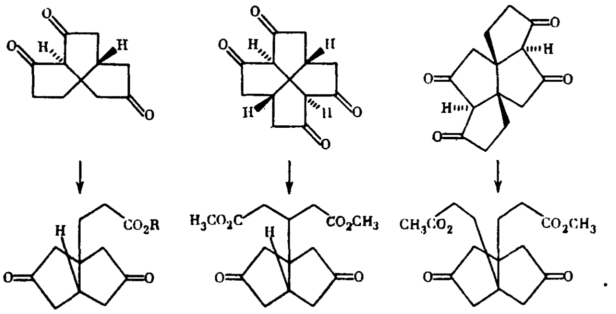
The best evidence that β-dicarbonyl compounds are cleaved by bases in the keto-form is probably provided by the finding that αα-disubstituted β-diketones or β-ketoesters, which are incapable of enolisation, are cleaved most readily.[3,87,88] It has been convincingly demonstrated for thenoyltrifluoroacetone that the enolate is stable in an alkaline medium and that the corresponding hydrate decomposes rapidly.[6] The stage involving the protonation of the enolate of the β-dicarbonyl compound can therefore become important for acid substrates which exist in the enolic forms in alkaline solutions. This situation obtain, for example, in the alkaline cleavage of aroylacetaldehydes, which are fully enolised in 0.1–1 M NaOH solutions:[89]

$$ArCOCH_2CHO + HO^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ArCOCH{=}CHO^-\ .$$

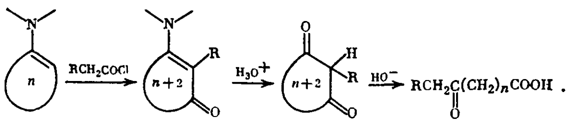
The cleavage of β-dicarbonyl compounds is used fairly often in synthesis.[4,90–92] This method is most important for the series of cyclic β-diketones, where it is used to synthesise oxocarboxylic acids:[4,90–92]



Recently this method has been used to cleave standard tri- and tetra-spiro-β-diketones:[95]



As an example, one may also quote the synthesis of 13-keto-acids, including the reaction of 1-morpholinocyclododecene with an acid chloride and the subsequent cleavage of the 1,3-diketone in an alkaline medium:[93,94]

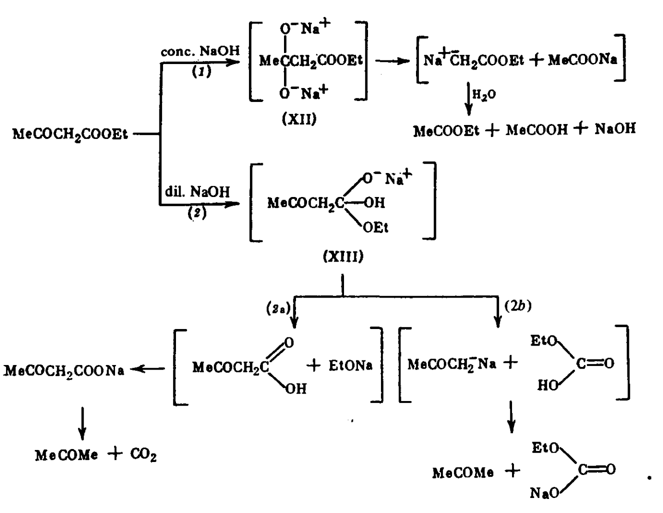


Dibasic ketoacids can be obtained by the reaction of an enamine with the chloride of a dibasic acid.[93,94]

The cleavage of β-dicarbonyl compounds in an alkaline medium is frequently an undesirable side reaction in the alkylation of β-diketones or β-ketoesters. However, the cleavage can be reduced to a minimum by carrying out the reactions at low temperatures, using sterically hindered bases, for example, t-BuOK in t-BuOH, or using NaH in aprotic dipolar solvents.[4]

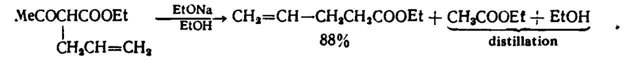
An unusual problem arises in the so called acid cleavage of acetoacetic ester and its analogues (the reaction which is the opposite of its synthesis, i.e. is the retro-Claisen condensation), which is always accompanied by the formation of ketones (ketone degradation) (Scheme 9).

Scheme 9



The first of these reactions involves the addition of the alkali to the keto-group [the adduct (XII)], which should proceed more readily than the addition to the ester group [the adduct (XIII)]. Nevertheless, both reactions [(*1*) and (*2*)] take place almost simultaneously. A possible explanation of this finding is that the dissociation of the C–C bond requires as a rule the formation of the dianion, which is indicated by the second (or higher) order of the reaction with respect to the alkali, while the cleavage of the C–O bond (hydrolysis) can occur in the monoanion. In fact, the intermediate (XIII) can decompose not only via the hydrolysis stage (*2a*) but also via the other pathway (*2b*), especially since this entails the formation of the acetonyl carbanion, which is more stable than the ethyl acetate anion [pK_a(MeCOMe) = 20 and pK_a(Me.COOEt) = 24 [31])]. The operation of this pathway [pathway (*2b*) as well as pathway (*1*) should be promoted by concentrated alkali. It may be that the high reactivity of the keto-group has an effect in the competition between pathways (*1*) and (*2b*).

In practice, the cleavage of dialkyl- or even monoalkylacetoacetic esters at the carbonyl group can be successfully achieved when the reaction is carried out in the presence of an excess of alcohol with catalytic amounts of an alkoxide and with continuous distillation of ethyl acetate from the reaction mixture,[92,96] for example:



$$\underset{\displaystyle CH_2CH{=}CH_2}{MeCOCHCOOEt} \xrightarrow[EtOH]{EtONa} \underset{88\%}{CH_2{=}CH{-}CH_2CH_2COOEt} + \underbrace{CH_3COOEt + EtOH}_{distillation}\ .$$

It is noteworthy that unsubstituted β ketoesters are not cleaved under these conditions but are converted into enolates, which are fairly resistant to the action of bases.

III. DECARBOXYLATION OF CARBOXYLIC ACIDS AND DEALKOXYCARBONYLATION OF ESTERS

The decarboxylation of carboxylic acids and their derivatives is an important process both in synthetic organic chemistry[97–99] and in biochemistry (the latter applies mainly to the decarboxylation of β-ketoacids [100,101]) and this is why much attention has been devoted to its investigation. The unimolecular thermal decarboxylation of acids, involving the formation of a carbanion, has been thoroughly studied:[97]

$$RCOOH \rightarrow R^- + CO_2 + H^+ .$$

Both the neutral acid and its anion or zwitter-ion, for example in the case of acids of the pyridine series, can be decarboxylated.[97] However, we shall not be interested in the decomposition of the carboxylate ion, which may arise both on treatment of the acid with bases and as a result of the dissociation of the acid. It is therefore natural that, when one is dealing with the decarboxylation of neutral acid, one has in mind fairly strong acid and fairly polar solvents. The decomposition of carboxylate ions leads to carbanions, whose formation has been unambiguously demonstrated with the aid of electrophilic trapping agents—bromine, aldehydes, ketones, nitro-compounds, D_2O, etc.[97]

1. Decarboxylation of Monocarboxylic Acids

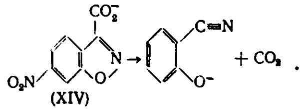
Fairly strong acids such as trihalogenoacetic, 2,4,6-trinitrobenzoic, and α-nitrocarboxylic acids are almost fully dissociated in aqueous solutions even in the absence of bases and it has been shown that they are decarboxylated in the anionic forms:[102–111]

$$RCOO^- \rightarrow R^- + CO_2\ .$$

This has been confirmed by the identity of the activation energies for the decarboxylation of the acids and their salts. In non-aqueous solvents, where the acids are insignificantly ionised, the rate of reaction after the addition of the base is proportional to the concentration of the anion formed. The unionised acids are entirely stable.[102–111] Although water promotes the dissociation of acids and salts, which should facilitate the decarboxylation, it can also stabilise the carboxylate anion as a result of solvation. Indeed, it has been shown that an increase of the fraction of ethanol or formamide in water up to a certain concentration increases the rate of decarboxylation of CCl_3CCOH or its sodium salt.[104,106] Analogous behaviour has been observed for trinitrobenzoic acid after the addition of ethanol or dioxan to the aqueous solution.[108,109] In the decarboxylation of (4-chlorophenyl)-α-cyanoacetate anion, the rate increases sharply in alcohol and increases almost by a factor of 3000 in dioxan compared with water.[112] However, a certain amount of water is apparently necessary to suppress the reversibility of the reaction even in fairly strong aprotic solvents, because water serves as a "trap" for the carbanion. Thus the rate of decarboxylation of potassium triphenylacetate in THF proved to be a maximum after the addition of 1–3 moles of H_2O per mole of the substrate. At higher concentrations of water, the rate of reaction falls, whilst at lower concentrations the decarboxylation ceases altogether (more precisely the degree of reaction is determined by the concentration of water):[113]

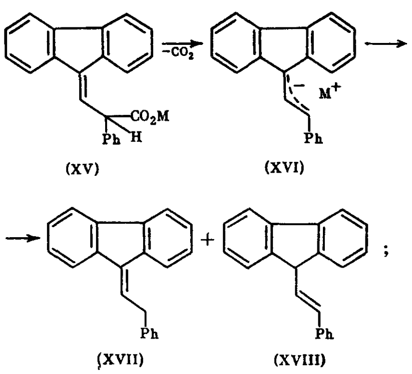
$$Ph_3CCO_2K.\text{crown ether} \rightleftarrows K^+.\text{crown ether} + Ph_3CCO_2^- \xrightarrow[-CO_2]{} Ph_3C^- \xrightarrow{H_2O} Ph_3CH.$$

An especially marked increase of the rate of decarboxylation has been observed in aprotic dipolar solvents, for example, the rate of decarboxylation of the anion of 3-carboxy-6-nitrobenzoisoxazole (XIV) increases by a factor of 10^5 in DMSO or benzonitrile and by a factor of 10^6 in HMP compared with water:[114–116]



(XIV)

An exceptionally great role of the solvent has been noted also in the decarboxylation of the 3-(fluoren-9-ylidene)-2-phenylproprionate anion (XV):[117]



(XV) (XVI)

(XVII) (XVIII)

M = H (a), Na (b).

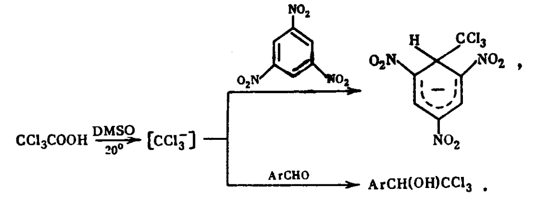
It is of interest that the dissolution of the acid (XVa) in DMSO leads to the instantaneous and quantitative formation of the products (XVII) and (XVIII). On the other hand, the addition of toluene-*p*-sulphonic acid fully suppresses the decarboxylation, which demonstrates yet again that the acid (XVa) is decarboxylated via the anion (XVI).[117]

The addition of crown ethers acts in the same direction as aprotic dipolar solvents.[113,117] It is believed that the main role of crown ethers consists in increasing the solubility of the salts in THF or dioxan, although, apart from this, the formation of complexes with the crown ether apparently increases the resistivity of RCOOM.[113,117]

The influence of the structure of the substituent (R = 9-phenylfluorenyl, fluorenyl, phenylethynyl, triphenylmethyl, and diphenylmethyl) on the rate of decarboxylation of RCOOM in THF or dioxan in the presence of 18-crown-6 ether has been investigated[113] and it has been shown that there is a correlation between the rate of reaction and the pK_a of the CH acids formed during the reaction. Sodium 9-phenylfluorene-9-carboxylate, which forms the most stable carbanion (for the substituents R investigated) (pK_a = 17.9 for 9-phenylfluorene), is decarboxylated at the highest rate, while sodium diphenylacetate, to which corresponds the diphenylmethylanion whose stability is fairly low (pK_a = 32 for Ph_2CH_2), is decarboxylated at the lowest rate.[113] In the presence of 18-crown-6 ether, the rate of decarboxylation increases by a factor of 13–500 depending on the structure.

The extremely marked dependence of the rate of decarboxylation on the nature of the solvent and the added crown ethers undoubtedly indicates the important role of the ions and ion pairs in this process. This is also indicated by data concerning the influence of the counterion. The rate of decarboxylation of triphenylacetates Ph_3CCOOM in THF diminshes in the sequence K > Na > Li. In the presence of 18-crown-6 ether, the rate of reaction increases approximately by a factor of 100.[113] In the decarboxylation of trichloroacetate salts in ethanol, the tetra-alkylammonium salts decompose fastest.[106]

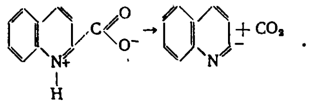
The decarboxylation of acids or their salts in aprotic solvents has long been used to obtain carbanions. Thus trichloroacetic acid in DMSO proved to be the best source of the CCl_3^- anion, because the latter is fairly stable# in this system and can be used in various syntheses:[118-120]



The decarboxylation of 4-nitro-, 2,4-dinitro-, and 2,4,6-trinitro-phenylacetates in DMSO, THF, or DME has been proposed for the generation of nitrobenzyl carbanions, which are difficult to obtain by other methods. The reactions in THF or DME are accelerated by crown ethers.[121]

2. Decarboxylation of Heterocyclic Acids

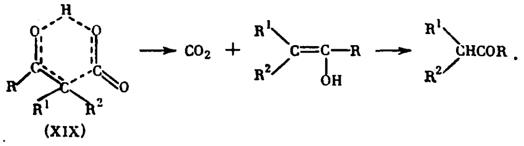
It has been suggested that heterocyclic acids—picolinic, quinaldinic, isoquinaldinic, pyridine-4-acetic, etc. acid—are decarboxylated via zwitter-ions:[97]



Indeed, these acids are stable in highly basic or acid solutions but decompose in neutral solutions.

3. Decarboxylation of β-Ketoacids or β-Dicarboxylic Acids

The decarboxylation of β-ketoacids and β-dicarboxylic acids differs from the decarboxylation of acids with other electron-accepting groups (see above) by certain features. In such cases, both the anions and the undissocated acids are decarboxylated in water and aqueous solutions, the undissociated acids being cleaved more rapidly than the ionised forms.[97,122-125] For example, acetoacetic acid is decarboxylated approximately 50 times faster and malonic acid approximately 10 times faster than the corresponding anion.[97,122-125] The dianions of malonic and phenylmalonic acids are stable in aqueous media.[125,126] It is believed that the decarboxylation of such keto-acids or dicarboxylic acids proceeds via a six-membered transition state of type (XIX) [97,111,122-124,127-129] with the intermediate formation of the enolic forms of the ketones or acids:[97,111]



(XIX)

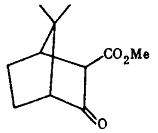
It is of interest that in the case of dibromomalonic acid the monoanion is decarboxylated incomparably faster than the undissociated acid.[126] Phenylmalonic acid occupies an intermediate position—the rate of cleavage of its monoanion is approximately 5 times higher than the rate of cleavage of the undissociated acid.[126] The monoanions of oxalylacetic acid are also decarboxylated faster, whilst the dianions are stable, as for malonic acid.[130-132]

It is noteworthy that at present there are virtually no data on the decarboxylation of β-ketoacids or β-dicarboxylic acids in anionic forms. There has been only one study in which the influence of the cation and crown ether on the decarboxylation of the acid (XX) and (XXI) was investigated and

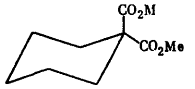
---

The CCl_3^- anion, formed, for example, on treating chloroform with a base, decompses fairly rapidly with elimination of Cl^-, affording dichlorocarbene.

it was shown that the same tendency is observed for these acids as for triphenylacetic acid.



(XX)



(XXI)

The potassium salt is decarboxylated faster in dioxan than the sodium salt and the reaction is accelerated by 18-crown-6 ether.[133] In the decarboxylation of benzoylacetate anions, a fairly marked influence of the substituents was noted, in contrast to the decarboxylation of the undissociated acids.[101,124]

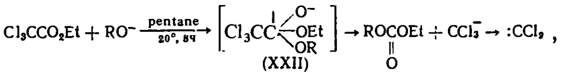
It has been suggested that the lithium enolate of acetoacetic acid be used for the synthesis of ketones:[134]

$$\mathrm{MeCOCH_2COOH} \xrightarrow[0^\circ]{\mathrm{BuLi,\ THF}} \mathrm{MeC{=}CHCO_2Li}\ (\mathrm{OLi}) \xrightarrow{1)\,\mathrm{RX}\ 2)\,\mathrm{H_2O}} \mathrm{MeCOCH_2R} + \mathrm{CO_2}\,.$$

The decarboxylation proceeds smoothly at 0 °C.

4. Dealkoxycarbonylation of Carboxylic Acid Esters

Carboxylic acid esters can be cleaved by strong bases (the dealkoxycarbonylation reaction) as happens with carbonyl compounds. Thus ethyl trichloroacetate is cleaved by sodium alkoxides:[135]

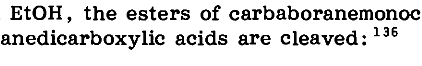


$$\mathrm{Cl_3CCO_2Et} + \mathrm{RO^-} \xrightarrow[20^\circ,\ 8\text{ч}]{\text{pentane}} \left[\mathrm{Cl_3C\overset{|}{C}(O^-)(OEt)(OR)}\right] \rightarrow \mathrm{ROC(=O)OEt} + \mathrm{CCl_3^-} \rightarrow \mathrm{:CCl_2}\,,$$

(XXII)

R = Me, t-Bu.

The intermediate formation of the adducts (XXII) has been unambiguously demonstrated by the isolation of dialkyl carbonates (73–94%). On treatment with catalytic amounts of EtONa and EtOH, the esters of carbaboranemonocarboxylic and carbaboranedicarboxylic acids are cleaved:[136]

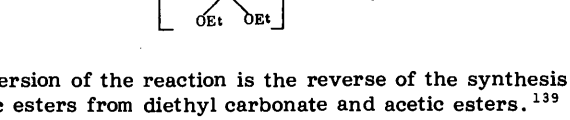


$$\mathrm{H{-}C{-}C{-}COOEt}\ (\mathrm{B_{10}H_{10}}) \xrightarrow[\mathrm{EtOH}]{\mathrm{EtONa}} \mathrm{HC{-}CH}\ (\mathrm{B_{10}H_{10}}) + \mathrm{CO(OEt)_2}\,.$$

We may note that the amides of methyl- and phenyl-barenic acids are just as readily cleaved by H_2NNa in liquid NH_3.[137]

Malonic esters can be cleaved with sodium ethoxide in certain cases, although as a rule this requires high temperatures.[4,138] The cleavage of the diphenylmalonic ester with EtONa in EtOH results in the quantitative formation of diethyl carbonate and the enolate of diphenylacetic ester§ (Scheme 10):[138]

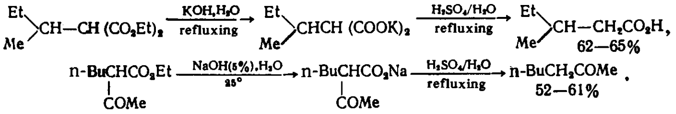
Scheme 10



This version of the reaction is the reverse of the synthesis of malonic esters from diethyl carbonate and acetic esters.[139]

The equilibrium is displaced by distilling of diethyl carbonate. However, in contrast to the cleavage of carbonyl compounds by alkali or alkoxides, this reaction involving esters is not so well known and has not found extensive applications. In many cases it appears as a side reaction, for example, in the acid cleavage of β-ketoesters (see Section II) and in all cases where malonic or cyanoacetic esters have to be heated for a long time with alcoholic alkoxides.[4]

The decarboxylation of β-ketoacid or *gem*-dicarboxylic acid esters is widely used in the synthesis of ketones and monocarboxylic acids. The hydrolysis is usually carried out with acids or dilute alkalis using so far as possible an insignificant excess of the latter in order to avoid the side reaction involving the acid cleavage in the case of ketoesters. Examples are presented below:[4]



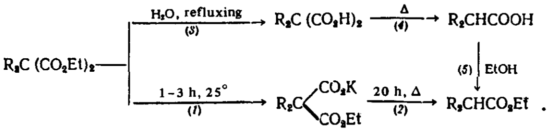
$$\mathrm{Et(Me)CH{-}CH(CO_2Et)_2} \xrightarrow[\text{refluxing}]{\mathrm{KOH,H_2O}} \mathrm{Et(Me)CHCH(COOK)_2} \xrightarrow[\text{refluxing}]{\mathrm{H_2SO_4/H_2O}} \mathrm{Et(Me)CH{-}CH_2CO_2H}\,,\ 62\text{–}65\%$$

$$\text{n-}\mathrm{BuCH(COMe)CO_2Et} \xrightarrow[25^\circ]{\mathrm{NaOH(5\%),H_2O}} \text{n-}\mathrm{BuCH(COMe)CO_2Na} \xrightarrow[\text{refluxing}]{\mathrm{H_2SO_4/H_2O}} \text{n-}\mathrm{BuCH_2COMe}\,.\ 52\text{–}61\%$$

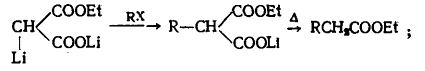
Thus the problem reduces to obtaining acids or their anions, which are then subjected to thermal decarboxylation (already described above).

A method has been proposed recently for the decarboxylation of dicarboxylic acids involving the selective hydrolysis of the diester to the monoester and its decarboxylation in the presence of 18-crown-6 ether [the KOH/crown ether/benzene/ /dioxan/ethanol system (5%)].[133] Since acid esters and not the acids themselves are used in the synthesis, this method is a convenient single-stage alternative to the traditional three-stage synthesis of esters [stages (3)–(5) in Scheme 11]:[133]

Scheme 11



Enolisation may take place as a side reaction, which has already been observed for phenylmalonic esters; nitromalonic ester enolises wholly under these conditions. In this system, it has been possible to carry out the dealkoxycarbonylation of certain ketoesters.[133] Another procedure involves the synthesis of acid esters by alkylating or acylating the dilithio-derivative of monoethyl malonate with subsequent decarboxylation:[140,141]



$$\mathrm{CH(Li)(COOEt)(COOLi)} \xrightarrow{\mathrm{RX}} \mathrm{R{-}CH(COOEt)(COOLi)} \xrightarrow{\Delta} \mathrm{RCH_2COOEt}\,;$$

R=Alk, Ac.

Yet another method has been vigorously developed recently—the decarboxylation of β-ketoesters, malonates, α-cyanoesters, etc. in aprotic dipolar solvents in the presence of small amounts of added water (1–2 moles per mole of the substrate) and salts such as NaCN, NaCl, NaBr, NaI CaI_2, and LiCl (possibly even in catalytic amounts) as 140–180 °C.[98,99,142–147] This method, which had been used earlier to convert monocarboxylic esters into acids (a reaction of the S_N2 type),[148,149] proved to be convenient in many instances for the decarboxylation of substrates sensitive to attack by alkalis or acids. In many cases the best results have been achieved by employing $Me_4NOCOMe$ in DMSO (130 °C) or in HMP (100 °C).[150–152] The *p*-aminothiophenol–Cs_2CO_3–DMF system (130 °C) is probably still more effective, making it possible to eliminate immediately two methoxycarbonyl groups from a single molecule.[153]

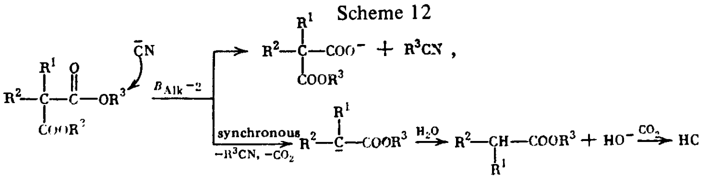
---

§ When dialkylmalonates are cleaved by EtONa, another pathway predominates: $R_2C(COOEt)_2 + EtONa \rightarrow R_2CHCOOEt + CO + CO_2 + C_2H_6$, etc.; α-vinyl, α-ethyl-, and phenylethylmalonic esters, which are cleaved simultaneously via both pathways, constitute an intermediate case.[138]

It has been suggested that moist DMSO be used in the dealkoxycarbonylation of reactive substrates such as $NCCH_2.COOEt$, $PhCH(COOEt)_2$, 2-ethoxycarbonylcyclopentanone, etc.;[145–147] the cleavage can also be carried out in dry DMSO, but the addition of water lowers the reaction temperature.[146,147] For less reactive substrates, it is essential to add water and frequently also a salt. The greatest effect is produced by NaCN.[144–146]

It is assumed that, in the absence of a salt, the ester is hydrolysed in moist DMSO by the $B_{AC}2$ route. In the KCN–DMSO mixture, the reaction pathway depends on the substrate. Thus in the case of dimethyldiethylmalonate, the formation of MeCN indicates that the $B_{Alk}2$ mechanism of the cleavage reaction predominates[98] (Scheme 12):

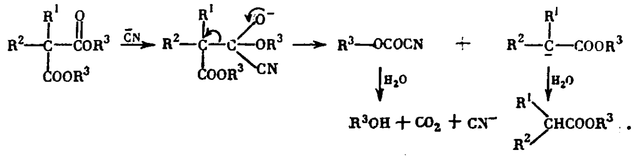
Scheme 12



This scheme is probably valid for other salts MX and for other substrates such as β-ketoesters and α-cyanoesters.[98]

The $B_{AC}2$ mechanism should be preferred for reactions of monosubstituted malonic esters when the process is catalytic (Scheme 13):

Scheme 13

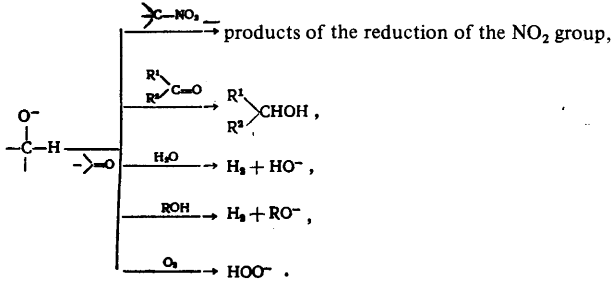


The intermediate formation of carbanions in these reactions can not only be readily demonstrated (by stereoselectivity data and by obtaining α-deuteriated esters and ketones), but can also be used in synthesis. For example, the cleavage of β-ketoesters, α-cyanoesters, or malonates in anhydrous DMSO in the presence of LiCl makes it possible to obtain α-alkylated ketones, acids, and nitriles. Dealkoxycarbonylation in the presence of PhSSPh in HMP affords α-phenylthioketones or α-phenylthioesters.[99] Numerous examples of the synthetic application of the method are quoted in Krapcho's review.[98,99] It has also been suggested that a non-ionic base—1,4-diazabicyclo[2.2.2]octane in xylene—be used for the decarboxycarbonylation of β-ketoesters; the yields of ketones are 84–90%.[154]

IV. THE CLEAVAGE OF ALKOXIDES

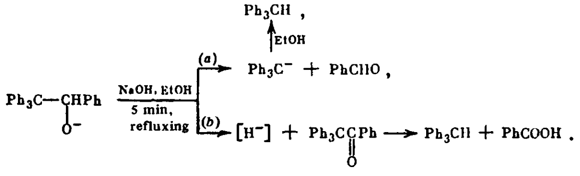
The alkoxides derived from primary and secondary alcohols are known to be potential sources of the hydride ion, which they can transfer to suitable acceptors such as carbonyl compounds, olefins, nitro-compounds, alcohols, etc.[155] (Scheme 14):

Scheme 14

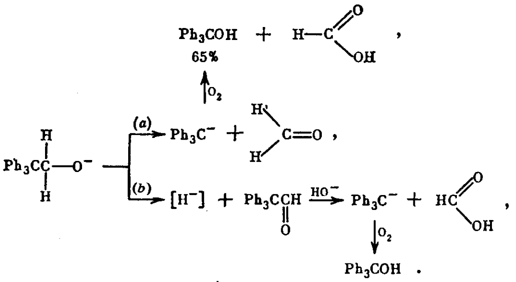


It is assumed that water behaves as the hydride ion acceptor in the dehydrogenation of primary aliphatic and aliphatic-aromatic alcohols by heating with caustic alkalis in aqueous solutions as 200—300 °C (the Dumas–Stass reaction[156]).[157] An alcohol molecule can also serve as the acceptor (200–225 °C).[158,159] In all these reactions (see Scheme 14) a C–H bond is ruptured and they are usually regarded as dehydrogenation or oxidation of alcohols. However, in this Section we shall be interested only in reactions in which C–C bonds are dissociated. This pathway occurs fairly rarely for alkoxides derived from primary or secondary alcohols and requires the presence in the latter of a group R which gives rise to a sufficiently stable carbanion. An example may be provided by the cleavage of phenyltritylcarbinol in an alcoholic solution of NaOH with formation of a mixture of triphenylmethane and benzaldehyde (65% of each) [pathway (*a*), Scheme 15].[160] In principle, the second pathway (*b*) is also possible, because the stabilities of Ph_3C^- and H^- are comparable,[161] but in this case this does not occur (Scheme 15):

Scheme 15

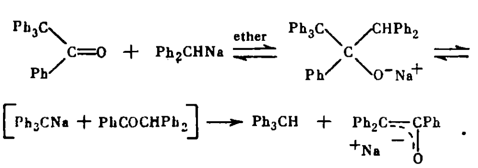


1-Aryl-2,2,2-trichloro- and 1-aryl-2,2,2-tribromo-ethanols are cleaved even more readily.[162] Alcohols of the carbaborane series likewise tend to be cleaved in an alkaline medium.[81] Even a primary alcohol containing the trityl group, namely 2,2,2-triphenylethanol (DME, KOH–O_2), is easily cleaved in an alkaline medium:[163]

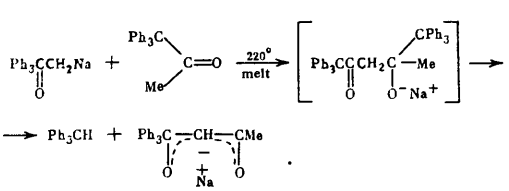


Here it is impossible to make an unambiguous choice between pathways (*a*) and (*b*), since the compositions of the products are identical.

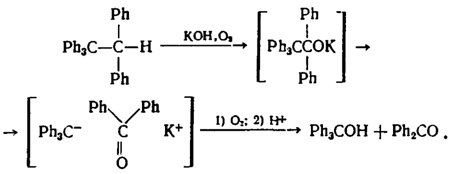
Tertiary alcohols have the greatest tendency to be cleaved, the reaction involving only the rupture of a C–C bond in such compounds. As will be seen below, the ease of cleavage of alkoxides is determined by three most important factors: (1) the presence in the alkoxide RR^1R^2COM of a group to which corresponds a stable carbanion; (2) the bulk of the groups R, R^1, and R^2, because steric compression is eliminated in the transition state of this reaction; (3) the nature of the counterion giving rise to a fairly stable carbanion, in order to achieve their cleavage the introduction into the reaction mixture of trapping agents for the carbanion has been frequently resorted to. The trapping agent is the proton and the cleavage is therefore usually carried out in the presence of water or alcohol. Sometimes the carbonyl compound formed can serve as the source of the proton in the decomposition of alkoxides if it is capable of enolisation. Thus, when an attempt was made to obtain a tertiary alcohol from benzopinacolone and the sodio-derivative of diphenylmethanol, the spontaneous decomposition of the resulting carbinolate was observed:[164]



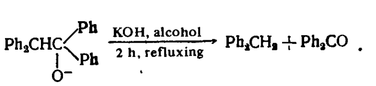
Because of the possibility of the ready elimination of the trityl anion, it has been possible to achieve an unusual Claisen-type condensation of methyl trityl ketone, where the leaving group is, however, the trityl anion:[165]



The alkoxides derived from pentaphenylethanol are apparently also unstable. At any rate, all attempts to obtain pentaphenylethanol by the reaction of Ph_2CO with Ph_3CM (M = Li, Na, or MgBr) proved unsuccessful.[166,167] The extreme instability of this alkoxide is probably to be explained by the steric strain in the molecule combined with the presence of the Ph_3C group, which gives rise to a fairly stable carbanion. This view is confirmed by the results of the oxidation of pentaphenylethane in an alkaline medium.[163] The reaction products in the THF(DME)–KOH–18-crown-6 ether system are triphenylmethanol and benzophenone. Evidently, the alkoxide formed in the reaction is unstable and decomposes to Ph_2CO and Ph_3C^-:[163]



Under mild conditions, the diphenylmethyl anion is split off:[168,169]



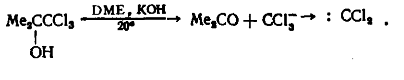
$$\text{Ph}_2\text{CHC(Ph)}_2\text{O}^- \xrightarrow[\text{2 h, refluxing}]{\text{KOH, alcohol}} \text{Ph}_2\text{CH}_2 + \text{Ph}_2\text{CO}\ .$$

In aqueous alcoholic solutions in the presence of KOH, tertiary alcohols containing the CCl_3 group are readily cleaved:[170,171]

$$(p\text{-XC}_6\text{H}_4)_2\text{C(OH)CCl}_3 \rightarrow (p\text{-XC}_6\text{H}_4)_2\text{C(O}^-\text{K}^+)\text{CCl}_3 \rightarrow (p\text{-XC}_3\text{H}_4)_2\text{CO} + \text{CCl}_3\text{H}\ ,$$
X=H, Cl.

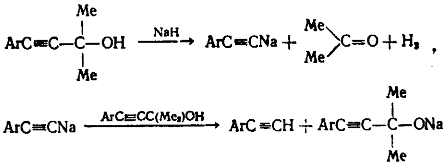
It has been shown that the rate of reaction increases linearly with increase of the concentration of the base.

When dimethyl(trichloromethyl)methanol was maintained in the DME–KOH system in the presence of cyclohexene, dichloronorcarane was obtained,[163] which is associated with the formation of $:CCl_3$ from the trichloromethyl anion:

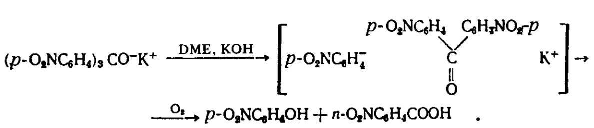


$$\text{Me}_2\text{C(OH)CCl}_3 \xrightarrow[20^\circ]{\text{DME, KOH}} \text{Me}_2\text{CO} + \text{CCl}_3^- \rightarrow :\text{CCl}_2\ .$$

Acetylenic alcohols[172–175] and β-nitroalcohols[176] are fairly readily cleaved. It has been suggested that Ag_2CO_3 on celites in toluene,[174] Ag_2CO_3 and Ag_2O in DMSO (20 °C),[175] or K_2CO_3 at 150–160 °C [173] be used for the cleavage of acetylenic alcohols. Such cleavage can sometimes be conveniently used for the synthesis of arylacetylenes:[177,178]

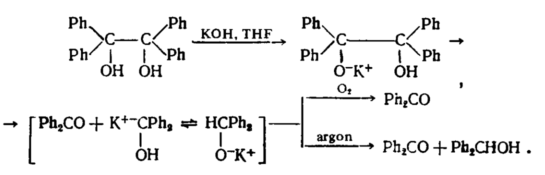


In the examples enumerated above, the proton usually serves as the "trap" for carbanions. Oxygen can sometimes be conveniently used as such a "trap".[20,163] Thus tris(p-nitrophenyl)methanol is readily cleaved in the DME–$KOH–O_2$ system, forming p-nitrophenol and p-nitrobenzoic acid.[20,163,179] We may note that, in the cleavage of alcohols as well as carbonyl compounds (see Section II), the attack by the electrophile or oxidant may be directed to a polarised C–C bond or ion pair and not to the free carbanion R^-:

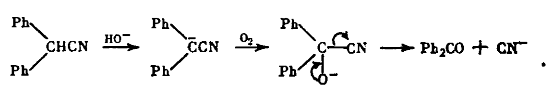


In the absence of O_2, a mixture of products which is difficult to separate, including the products of the reduction of the NO_2 group is formed. Lithium carbinolate is stable under these conditions. Triphenylmethanol is recovered unchanged even after heating for 48 h at 60–70 °C in the KOH–HMP–O_2 system, but the introduction of even one NO_2 group in the *para*-position in the benzene ring is sufficient for the rapid cleavage of the carbinolate (DME–KOH–O_2) with formation of p-nitrophenol and benzophenone. Even benzyldiphenylmethanol is cleaved in this system (60–70 °C, yield of PhCOOH 70–75%). The stability of the benzyl anion ($pK_a = 35$ for PhMe [31]) is apparently critical for the given conditions,[163] because the phenyl anion is not split off.

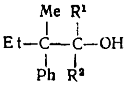
Aromatic ditertiary alcohols, for example, benzopinacol, are extremely readily cleaved:[163]



From the standpoint of the stability of alkoxides, the ready decomposition of cyanohydrins into the initial components in an alkaline medium can be readily understood, because the stable cyanide anion is split off.[180,181] This reaction apparently constitutes the basis of the oxidative decyanation of secondary nitriles in an alkaline medium:[182–184]



In the examples quoted above, the tendency of alcohols to be cleaved was determined mainly by the stability of the carbanion formed, although one cannot fully rule out also the influence of steric factors. This influence becomes of primary importance in the cleavage of tertiary alcohols of the benzyl type,[77,78] i.e.



$$\mathrm{Et{-}C(Me)(Ph){-}C(R^1)(R^2){-}OH}$$

The rate of cleavage of these alcohols varies within wide limits as a function of the experimental conditions—the nature of the solvent and the base, etc. However, in general the ease of cleavage increases gradually in the following sequence of R^1R^2 groups: Ph_2 < PhMe < EtMe < Me_2, which corresponds overall to a gradual decrease in the size of the leaving group. This fact led to the conclusion that the weakening of the steric compression is one of the driving forces in anionic cleavages of this kind.[77,78] We may note that, in the given instances, a fairly stable carbanion is nevertheless formed.

Under more severe conditions (200–300 °C), the alkoxides derived from purely aliphatic tertiary alcohols are cleaved, the rate of cleavage being higher the greater the degree of branching.[185] Triethylmethanol is not cleaved even on heating to 335 °C in the presence of $NaNH_2$, but sodium di-t-butylneopentylmethoxide is cleaved when an attempt is made to obtain it from the corresponding carbinol and NaH:[185]

$$\mathrm{(Me_3C)_2\,(Me_3CCH_2)COH \xrightarrow{NaH} (Me_3C)_2\,(Me_3CCH_3)\,CO^-Na^+ \rightarrow}$$
$$\mathrm{\rightarrow (Me_3C)_2\,CO + Me_3CCOCH_2CMe_3 + Me_2C{=}CH_2 + Me_4C\ .}$$

The carbanionic character of the cleavage of these alcohols, which do not give rise to stable carbanions, is emphasised by the just as marked influence of the counterion as that noted for alcohols capable of splitting off fairly stable carbanions R^-: Li > K > MgX [185] (see below). The successful use of organolithium compounds, in contrast to RMgX, for the synthesis of branched alcohols can apparently be accounted for precisely by the stability of the alkoxides,[186,187] Thus diisopropylneopentylmethanol is formed in 70% yield by the reaction of iso-Pr_2CO with neopentyl-lithium,[185] but the yield is only 4% in the reaction with neopentylmagnesium chloride.[188]

The influence of the solvent is usually very great in reactions with participation of carbanions. The reaction involving the cleavage of alcohols is not exceptional in this sense. Thus, on treatment with dimsylpotassium in DMSO, tri-t-butylmethanol undergoes exothermic cleavage with formation of bi-t-butyl ketone and isobutane:[189]

$$\mathrm{(Me_3C)_3\,COH \xrightarrow{MeSOCH_2^-K^+} (Me_3C)_3\,CO^-K^+ \rightarrow Me_3CCOCMe_3 + [Me_3C^-K^+]\ ,}$$
$$\mathrm{[Me_3C^-K^+] \xrightarrow{MeSOCH_3} Me_3CH + Me_3SOCH_2^-K^+\ .}$$

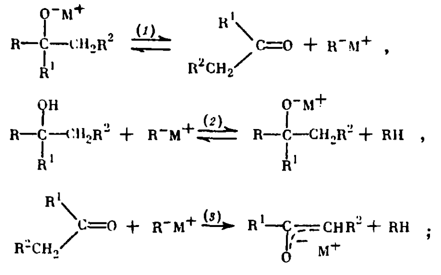
Even more stable alcohols are cleaved in HMP on treatment with BuLi:[190]

$$\mathrm{RR^1R^2COH \xrightarrow{BuLi} RR^1R^2CO^-Li^+ \rightarrow R^1R^2CO + RLi \xrightarrow{H_2O} RH\ .}$$

R, R^1, and R^2 represent different combinations of adamantyl, norbornyl, and 1-bicyclo[2.2.2]octyl and t-butyl groups. We may note that even lithium alkoxides are readily cleaved in this case.

In connection with the possibility of cleaving alkoxides, the question of the reversibility of the reaction involving the addition of organometallic compounds to aldehydes and ketones must inevitably arise. In contrast to other carbonyl compound condensation reactions (for example, the aldol and Claisen condensations), the reversibility of this reaction is not quite so widely known. Apparently, the reaction of RM with ketones as a reversible process was first† considered by Zook et al.[185] Their study of the decomposition of alkoxides derived from tertiary alcohols led them to the conclusion that the process is general for alkoxides with a branched structure and represents the reaction which is the reverse of the addition of RM to ketones (Scheme 16):

Scheme 16

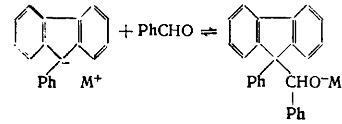


M = alkali metal .

According to the authors, the process can be reversible even when the equilibrium position in stage (*1*) is displaced far to the left, because, in the presence of an excess of the tertiary alcohol or the enolisable ketone, the equilibrium is displaced or is altogether disturbed by the conversion of RM into a hydrocarbon [stages (*2*) and (*3*) in Scheme 16].[185] It is noteworthy that the very possibility of the decomposition of the alkoxide with formation of a ketone and RM is evidence in support of the reversibility of reaction (*1*) in the general case. At the present time convincing evidence has been obtained for the existence of such equilibrium in various systems.

It is known that in aprotic media the stability of alcohols falls significantly compared with protic media.[192] Furthermore, the stability of the alkoxides ROM depends very markedly on the counterion M, diminishing in the sequence Li > Na > K.[193–195] The influence of the counterion on the association constant is manifested particularly strongly in aprotic dipolar solvents. Thus in DMSO the ionic association constants for t-BuOK are 10^8, 10^6, 270, and 200 litre mol^{-1} for M = Li, Na, K, and Cs respectively.[194] The equilibrium position (Scheme 16) can therefore vary significantly as a function of the nature of the counterion. Indeed, in the study of the reaction of benzaldehyde and cyclohexanone with fluorenyl and 9-phenylfluorenyl salts it was shown that the equilibrium in ether and DME is displaced wholly to the right for M = Li and Na and wholly to the left for M = Cs (scheme 17):[196,197]

Scheme 17



(XXIII) M=Cs

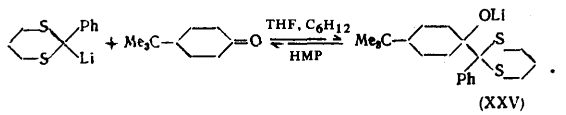
(XXIV) M=Li, Na

---

† Some indication of the reversibility of the reaction of RLi with ketones may be found in the paper of Swain and Kent,[191] although in the equation presented only the stage involving the formation of the complex between the carbonyl compound and RLi was reversible.

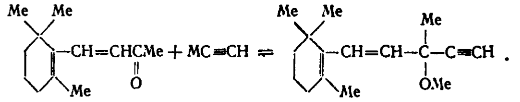
For M = K, it was possible to observe a "living" equilibrium in which both the alkoxide (XXIV) and the initial carbanion (XXIII) are involved. The equilibrium position depends significantly also on the solvent. Thus, if at the end of the reaction with the lithium salt in DME the solvent is replaced by HMP, the reaction equilibrium is fully displaced towards the initial reactants.[196,197]

A similar situation has been observed in the reaction of 2-lithio-2-phenyl-1,3-dithiane with t-butylcyclohexanone:[198]



(XXV)

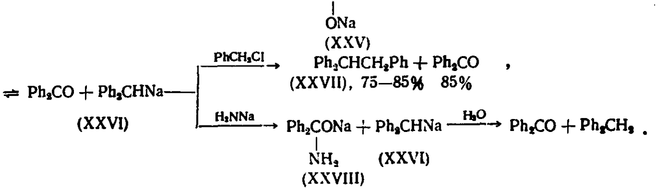
The carbinolate (XXV) is formed in 90% in C_6H_{12} and 75% yield in THF, while in HMP the reaction does not occur. The authors showed that this is associated with the reversibility of the reaction, because the carbinolate (XXV), known to be formed *a priori* in HMP, was converted into the initial compound. The changes in the degree of reaction of α- and β-ionones and benzylideneacetone with metal acetylides can probably be accounted for precisely by the different stabilities of the alkoxides (or, in other works, by the reversibility of the reaction).[199] Thus, in the reaction with β-ionone, the yield of the alcohol is low for M = K, increases to 15–27% for M = Na, and reaches 63–86% for M = Li:



An analogous picture has been observed in the reaction with benzylideneacetone (the yield of the alcohol is 40% for M = K, 71% for M = Li, and 96% for M = Ca) and with β-ionone (30% for M = Na, 67% for M = Li, and 67% for M = Ca).[199] The failure of the attempt to synthesise tertiary alcohols of the carbaborane series from ketones and lithio-derivatives of barenes has been explained[81] by the instability of such alcohols.

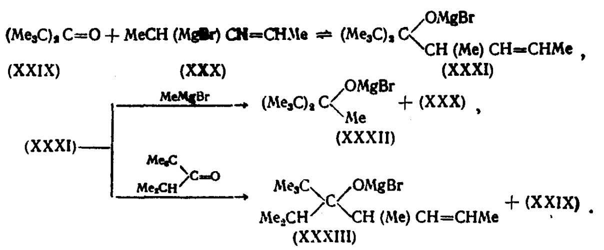
The reversible reactions quoted above involve stable carbanions of the type of fluorenyl or ethynyl carbanions. In the case of less stable carbanions, the reversibility of the reaction can be demonstrated by employing "trapping agents"—a carbonyl compound or RM. The existence of equilibrium in the reaction of benzophenone with diphenylmethylsodium was apparently first demonstrated precisely with the aid of this procedure (Scheme 18):[17,200]

Scheme 18

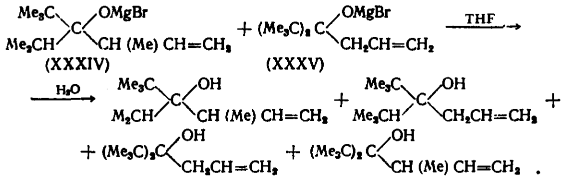


Indeed the addition of benzyl chloride to the reaction mixture leads to the formation of the alkylation product (XXVII), while the introduction of sodium amide results in the isolation of the adduct (XXVIII). The latter reaction is accompanied by the appearance of a red colour due to the carbanion (XXVI).[17]

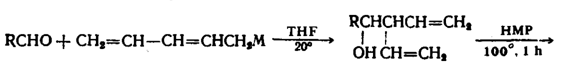
The reversibility of the reaction with ketones has been convincingly demonstrated also for organometallic compounds of the allyl type (M = Li, MgX, or ZnX).[201–214] One of the procedures used for this purpose is similar to that quoted by Hamrick and Hauser.[17] On treatment of the adducts (XXXI) with an excess of RMgX (R = Me or CH_2=CHMe), the tertiary alkoxide (XXXII) was obtained, in which the dimethylallyl group had been replaced by R, while on heating compound (XXXI) with iso-PrCOBu-t, which is more reactive than the ketone (XXIX), the adduct (XXXIII) was isolated together with t-Bu_2CO (XXIX):



In the case of CH_2=CH=CH_2MgX or α- and γ-dimethylallylmagnesium halides, where the initial and rearranged products are identical, the reversibility of the reaction was demonstrated by means of a "cross" reaction—when a mixture of the two carbinolates (XXXIV) and (XXXV) is refluxed, a mixture of four carbinolates is formed evidently as a result of the decomposition of compounds (XXXIV) and (XXXV) into the initial reactants and their subsequent interaction:[206]

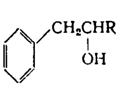


The thermal decomposition of carbinolates of the allyl type has also been carried out.[202,207,215] As was to be expected, the rate of decomposition increases with increase of the bulk of the substituents: t-Bu > iso-Pr ≅ cyclo-C_6H_{11} > Ph > Et.[207] It has been suggested that the reactions of allylic organometallic compounds, containing a strained diene system, with ketones and even with aldehydes are also reversible.[218,219] As already reported, the ratios of the products in these reactions depend significantly on their conditions. The strong influence of the nature of the cation M (Li, Na, Zn, and Al) on the mode of reaction has been noted in many communications.[204,215–218] It is therefore evident that the reversibility of such reactions can be used for synthesis purposes. Indeed, studies in which alcohols with a specified structure were synthesised by the reaction of such RM with carbonyl compounds have already been published.[215–218] For example, when the aldehydes RCHO are treated with CH_2=CHCH=$CHCH_2$M (M = ZnBr or Li) at the usual temperature, alcohols with a branched structure are formed exclusively, but, with increase of temperature and after the replacement of THF by HMP, the formation of only linear alcohols is observed:[216]

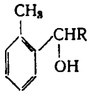


$$\mathrm{RCHO + CH_2{=}CH{-}CH{=}CHCH_2M \xrightarrow[20^\circ]{THF} \underset{OH\ CH=CH_2}{RCHCHCH=CH_2} \xrightarrow[100^\circ,\ 1\ h]{HMP} \underset{OH}{RCHCH_2CH=CHCH=CH_2}}\ .$$

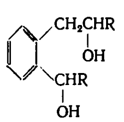
Thus the ability of allylic carbinolates to decompose into the initial ketone and allylmetal has been established. The possibility of the cleavage of magnesium carbinolates with formation of the benzyl Grignard reagent has been comparatively recently demonstrated. Throughout many years, chemists have been interested in the reaction of benzylmagnesium halides with aldehydes, in which the formation of "anomalous" products, namely o-tolylmethanol (XXXVII) [220–225] and the diol (XXXVIII) or its dehydration product,[222–231] was observed together with the formation of the so called "normal" alcohols (XXXVI):



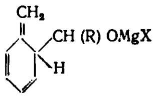
(XXXVI)



(XXXVII)



(XXXVIII)



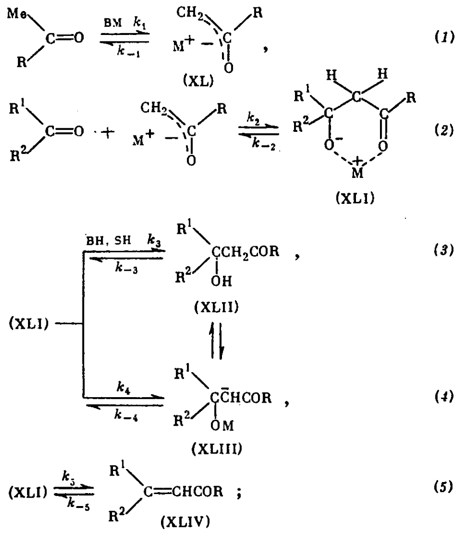
(XXXIX) .

Convincing evidence showing that the diol (XXXVIII) and possibly also the "normal" alcohol (XXXVI) are secondary products, whose formation can be explained by the reversible dissociation of the adduct (XXXIX) arising initially and subsequent reactions, has been obtained only comparatively recently.[232–234]

V. THE RETROALDOL CONDENSATION

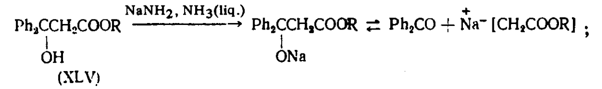
As shown in Section IV, tertiary alcohols containing a group R to which corresponds a sufficiently stable carbanion are cleaved in an alkaline medium, the ease of such cleavage depending primarily on the stability of the carbanion. It is quite evident that the alkoxides derived from β-hydroxycarbonyl compounds (the products of aldol condensation) must be unstable, because their cleavage results in the formation of the enolates of aldehydes, ketones, and esters, i.e. fairly strong CH acids (pK_a = 25–20).[31] Indeed, aldol condensation in an alkaline medium is a reversible process (Scheme 19) and all its stages are reversible:

Scheme 19



a) $R^1 = R^2$ = Alk or Ar
b) R^1 = Alk, Ar; R^2 = H
c) R^1 = Alk, Ar; R^2 = OAlk .

In order to obtain the target products, it is therefore necessary to select special conditions. However, in general, one may say that the condensation is promoted by the use of strong bases in stoichiometric or even larger amounts [in order to shift the equilibrium (*1*) to the right], by the removal of the condensation product from the reaction sphere [for example by its precipitation as the carbinolate (XLI) or the dianion (XLIII)], by a low temperature, and by a short reaction time.[4,92] On the other hand, the retroaldol cleavage will be promoted by the employment of catalytic amounts of bases, by an elevated temperature, by a long reaction time, and by the presence of trapping agents (for example, water or alcohol), which are capable of reacting with the enolates (XL), displacing thereby the equilibrium in stage (*1*) to the left. Indeed, retroaldol cleavage is as a rule carried out in aqueous or alcoholic solutions. In non-aqueous media there is also a possibility of retroaldol decomposition, because the initial reactants are more stable than the condensation products. However, since in non-aqueous media the hydroxycarbonyl compound (XLII) can itself function as a trapping agent for the enolate (XL), in the presence of stoichiometric amounts of bases, whereupon only the carbinolate (XLI) is present in solution, the retroaldol decomposition may not occur. Such a situation has been observed for the β-hydroxyester (XLV), which is cleaved by catalytic amounts of H_2NNa in liquid ammonia, but is not cleaved by the stoichiometric amount of H_2NNa:[235]



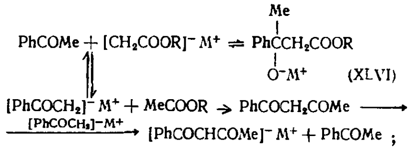
$$\underset{\underset{(XLV)}{OH}}{\mathrm{Ph_2\overset{}{C}CH_2COOR}} \xrightarrow{\mathrm{NaNH_2,\,NH_3(liq.)}} \underset{ONa}{\mathrm{Ph_2CCH_2COOR}} \rightleftarrows \mathrm{Ph_2CO} + \overset{+}{\mathrm{Na}}{}^{-}[\mathrm{CH_2COOR}]\ ;$$

R=Et, iso-Pr, t-Bu.

As an example illustrating the influence of the reaction time on the yield of products, one may quote the condensation of benzophenone with alkyl acetates MeCOOR (R = Et or iso-Pr) in the presence of equimolar (and larger) amounts of H_2NNa in liquid ammonia.[235] For a short reaction time (neutralisation 5 min after the addition of Ph_2CO to the enolate), β-hydroxyesters (XLV) are formed in yields of ~70%, but, following an increase of the reaction time to 1 h, only the initial reactants are recovered.

Yet another procedure which is resorted to in order to shift the equilibria in aldol condensations involves the selection of the corresponding cations M^+. The dependence on the nature of the cation is the most interesting feature of these reactions. Thus acetophenone readily condenses in liquid ammonia with the enolates of alkyl acetates $[CH_2COOR]M^+$, where M = Li or ZnCl, but the adducts are not formed under these conditions with the Na enolates. Comparison of the alkoxides (XLVI), know to have been obtained *a priori*, showed that the lithium alkoxides are much more stable than the sodium or potassium alkoxides. Indeed, the sodium salt (XLVI) decomposes on refluxing in ether for 2 h, while the lithium or ZnCl salts are cleaved only on refluxing in toluene or dibutyl ether[235,236] (Scheme 20):

Scheme 20

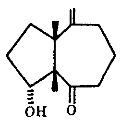


$$\mathrm{PhCOMe} + [\mathrm{CH_2COOR}]^- M^+ \rightleftharpoons \underset{O^-M^+}{\overset{Me}{\mathrm{Ph\overset{|}{C}CH_2COOR}}}\quad (XLVI)$$

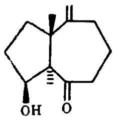
$$[\mathrm{PhCOCH_2}]^- M^+ + \mathrm{MeCOOR} \rightarrow \mathrm{PhCOCH_2COMe} \longrightarrow \xrightarrow{[\mathrm{PhCOCH_2}]^- M^+} [\mathrm{PhCOCHCOMe}]^- M^+ + \mathrm{PhCOMe}\ ;$$

M=Li, Na, K, ZnCl .

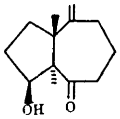
We may note that the decomposition of compound (XLVI) can lead not only to the initial reactants but also to products of other condensations, for example, to benzoylacetone and acetophenone, which are formed as a result of the transmetallation and subsequent Claisen acylation. A similar influence of the cation M^+ has been noted also for the adducts (XLV).[235] In the series of the usual alcohols ROH, the dependence of the stability of the alkoxides on the nature of the counterion is well known (see Section III). In the case of β-hydroxycarbonyl compounds, the dependence of the stability of the enolate on the nature of the metal is determined not only by the strength of the O–M bond but also by the ability of the carbonyl group to form chelates, which promotes a shift of the equilibrium in the second stage of the condensation to the right (see Scheme 19). The ability of a definite series of metals (Li, Zn, B, etc.) to form stable chelates is widely used to achieve high regio- and stereoselectivities of aldol condensations.[4,237,238] Consequently, it is best to employ potassium or sodium as the cation for the retroaldol reaction. An interesting application of the retroaldol–aldol condensation sequence has been proposed[239] for the synthesis of isomeric perhydroazulene hydroxyketones (XLVII)–(L). Depending on M^+ in the base (Li, Na, or K) and the reaction time, it is possible to obtain predominantly the isomers (XLIX) or (L) or an equilibrium mixture of all four isomers from the isomers (XLVII) and (XLVIII).[239]



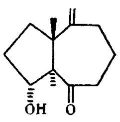
(XLVII)



(XLVIII)



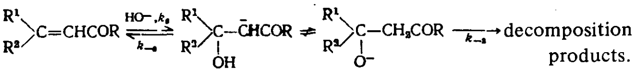
(XLIX)



(L)

Thus, when (iso-Pr)$_2$NLi was used in THF, the selective conversion of the isomer (XLVII) into (XLIX) and of (XLVIII) into (L) was observed. The stereoselective course of the reaction was promoted by the low temperature and the short reaction time. For example, when the isomer (XLVII) is treated with (iso-Pr)$_2$NLi for 5 min (THF, 20 °C), then the isomer (XLIX) is formed in 65% yield, but, when the reaction mixture is kept for 45 min, almost equal amounts of the isomers (XLIX) and (L) are isolated. When the isomer (XLVII) or (XLVIII) is treated with a methanol solution of NaOH, virtually identical mixtures of all four isomers are formed, i.e. equilibrium is established in the system.[239]

Kinetic study of the decomposition of β-hydroxyketones (ketols) in an alkaline medium showed that ketols undergo two competing reactions—decomposition into the initial carbonyl compounds and dehydration.[204–205] Dehydration (crotonic condensation, Claisen–Schmidt condensation) is the reaction by means of which it is sometimes possible to displace the equilibria in such reactions towards the formation of the products. However, enones can also be unstable in alkaline media; by combining with the hydroxide anion via the Michael reaction, they are reconverted into the ketols and further into cleavage products, the ketol being present in such cases at a stationary concentration. Under certain conditions, it is possible to observe also an equilibrium mixture of all the components:[240–245]

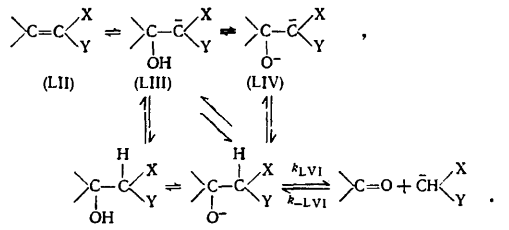


(XLIV) (LI) (XLI)

Each of the processes—dehydration and cleavage of the ketols into the initial reactants—is of second order overall and of first order with respect to each reactant (sometimes even higher with respect to the alkali) and the rate-determining stages are usually the reactions on the anions (XLI) and (LI) (k_{-2} and k_{-6}).[240–251]

Naturally in an alkaline medium not only enones but also other compounds with an activated double bond are cleaved (for example, the products of the Knoevenagel condensation). It has been established qualitatively that the ease of cleavage of compounds of the type  $R^1R^2C{=}CXY$ (LII) (X and Y are electron-accepting groups and R^1 and R^2 = alkyl or aryl) depends primarily on the number and strength of the electron-accepting groups X and Y, which determines the stability of the carbanions formed. The influence of alkyl and aryl groups is not so great, but alkyl derivatives are as a rule cleaved more readily than aryl derivatives. The presence of electron-accepting groups in the substituents R^1 and R^2 inhibits the reaction, which is in fact understandable, since the "expelling force" of the group R^1R^2CO diminishes.[252–254] However, despite the simple and understandable qualitative pictures, the mechanism of this reaction is fairly complex and depends significantly on the pH of the medium.[256–263] An overall mechanism of the hydrolytic cleavage of activated olefins (Scheme 21) has been proposed on the basis of the analysis of kinetic data for the cleavage of a series of olefins using a flow technique with spectrophotometric recording:[258–263]

Scheme 21



The most general mechanism in basic media involves the addition of the base to the olefin (LII) with formation of the anion (LIII), which is followed by its protonation to compound (LV), the formation of the anion (LVI), and its decomposition into products. In a highly alkaline medium, there is a possibility of another pathway—the formation of the dianion (LIV) and its subsequent protonation to compound (LVI) or intramolecular proton transfer in the anion (LIII) with formation of the anion (LVI). For example, it has been shown that, in the cleavage of 1,1-dinitro-2,2-diphenylethylene in 50% DMSO (H_2O) at pH 13.5, the rate-determining stage is the protonation of the dianion (LIV); at pH 12.5–13.5, the rate is determined by the protonation of compound (LIII) and at pH 11–12 it is determined by the attack by the hydroxide ion with formation of compound (LIII); at pH 10, the slow stage probably involves the attack by water on the substrate (LII).[259] The conversion of compound (LV) into the reaction products (in which the present authors are interested) using the stopped flow technique can be identified as an independent two-stage process,[258–263] the rate-determining stage of which may be also the deprotonation of the adduct (LV), while the rapid stage is the decomposition of compound (LVI) into the products.[258,259,263]

Table 1. Kinetic data for the retrodecomposition of the anion (LVI) and for its formation in water at 25 °C.[261]

Kinetic data	$PhCH{=}C(CN)_2$	$ArCH{=}C(NO_2)_2$*	k_{LVI}, s^{-1}	$4.66\cdot10^4$	$6\ 32\cdot10^2$	$5\cdot10^8$
k_{-LVI}, litre mol^{-1}	$1.70\cdot10^5$	0.2	—
K, mol $litre^{-1}$	$2.74\cdot10^{-1}$	$3\ 16\cdot10^3$	$1.09\cdot10^8$
pK_a for CH_2X_2	11.19	10.2	4.83

---

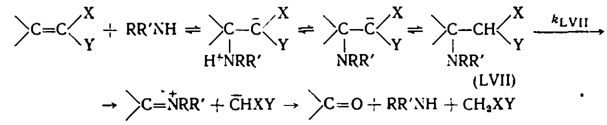
*Ar = 3,4-methylenedioxyphenyl.[257]

However, on comparing the rate constants for the decomposition of the anion (LVI) into the products, it was found that, for the olefins investigated, there is no correlation between these rates and the pK_a of the corresponding hydrocarbons (Table 1). Dicyanomethane is a weaker CH acid than dinitromethane, while the rate of abstraction of the dicyanomethyl anion from the adduct (LVI) is higher almost by two orders of magnitude than the rate of abstraction of $\bar{C}H(NO_2)_2$.[261] The causes of this are so far not understood. Table 1 also lists the rate constants k_{-LVI} for the condensation stage and the equilibrium constants.

An analogous picture has been observed in the hydrolytic cleavage of activated olefins by amines.[264] It has been shown that an adduct of type (LVII) is formed as an intermediate in this process and subsequently decomposes into the product [264–267] (Scheme 22).

Comparison of the rates of cleavage of several such adducts showed that in this case there is no correlation between the rate of cleavage and the pK_a of the hydrocarbon CH_2XY. Thus, as was to be expected, the adduct of the olefin (LVIII) is cleaved faster than the adduct of the olefin (LIX) but more slowly than the adducts of benzylidenemalonitrile, although, judging from the pK_a of the hydrocarbon CH_2XY, the opposite sequence should have been obtained (Table 2).

Scheme 22

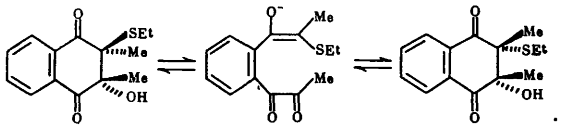


$$\rangle C{=}C\langle^{X}_{Y} + RR'NH \rightleftharpoons \rangle\underset{H^{+}NRR'}{C}{-}\bar{C}\langle^{X}_{Y} \rightleftharpoons \rangle\underset{NRR'}{C}{-}\bar{C}\langle^{X}_{Y} \rightleftharpoons \underset{(LVII)}{\rangle\underset{NRR'}{C}{-}CH\langle^{X}_{Y}} \xrightarrow{k_{LVII}} \rangle C{=}\overset{+}{N}RR' + \bar{C}HXY \rightarrow \rangle C{=}O + RR'NH + CH_2XY$$

Table 2. The rate constants for the decomposition of the adducts (LVII) with piperidine (RR'NH = piperidine).[264]

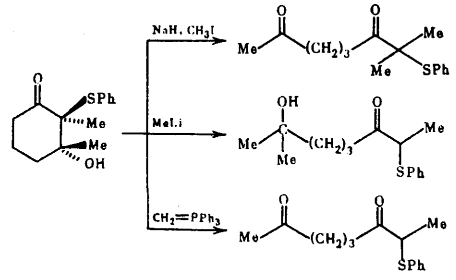
Kinetic data	 (LVIII)	 (LIX)	PhCH=C(CN)$_2$
k_{LVII}, s^{-1}	9.4	4.5·10^{-3}	33
pK_a for CH_2XY	8.06	12.62	10.21

The retroaldol decomposition is frequently an undesirable side reaction, which must be borne in mind in carrying out condensations of the aldol or crotonic type. However, this reaction has also found some applications in synthesis. As an example, one may quote its use for the *cis–trans*-isomerisation of β-hydroxycarbonyl compounds.[268,269] Thus the *trans*-dihydronaphthoquinone derivative (LX) undergoes a base (EtS$^-$ or EtO$^-$)-catalysed rearrangement to the *cis*-isomer (LXI) via a sequence of retroaldol–aldol condensations [and conversely (LXI) → (LX)]:[268,269]



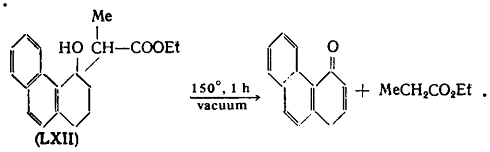
(LX) (LXI)

It has been suggested that the enolates formed in retroaldol processes be made to react with electrophilic trapping agents in order to obtain acyclic compounds with functional groups from cyclic compounds:[270]



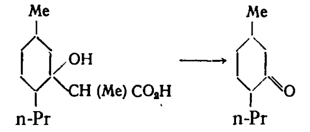
The cleavage of unsaturated acids or nitriles is used to synthesise isotope-labelled acids having two carbon atoms less than in the initial compounds.[271] The cleavage of β-hydrocarbonyl compounds and activated olefins can be usefully employed in all cases where the cleavage products are less readily available than the initial compounds.[91,272]

In conclusion, we may note that cases of ready thermal decomposition of β-hydroxycarbonyl compounds are known. Thus the hydroxyketone (LXII) is cleaved quantitatively into ethyl propionate and 4-oxo-1,2,3,4-tetrahydrophenanthrene at 150 °C:[273]

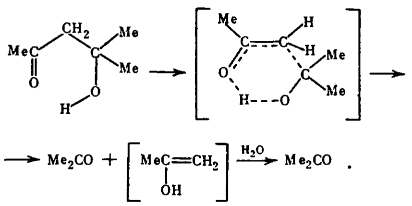


(LXII)

α-Menthylpropionic acid is cleaved on distillation:[274]



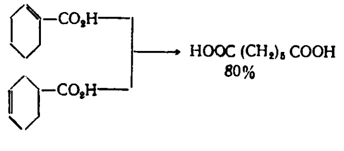
It has been suggested that a six-membered transition state is formed on thermal decomposition in the gas phase or in inert solvents:[275]



The examples listed above do not exhaust the possible types of cleavage of C–C bonds in alkaline media. Fairly numerous complex reactions involving to some extent retrodecomposition (retro-Claisen, retroaldol, etc.) stages, examined above, are known. We shall quote here several such reactions which are of practical importance. For example, the cleavage of unsaturated aliphatic acids constitutes a method of synthesis of saturated acids having two carbon atoms less than the initial acids:[276]

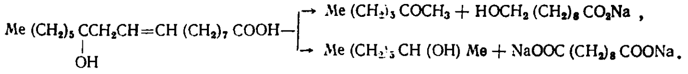
$$Me(CH_2)_7CH{=}CH(CH_2)_7CO_2H \xrightarrow{200-360°} Me(CH_2)_{14}CO_2H + CH_3CO_2H + H_2 \ .$$

By heating cyclohexene-1-carboxylic or cyclohexene-3-carboxylic acid or their nitriles with alkalis in autoclaves at high temperatures (250–350 °C), pimelic acid is obtained:[277–279]



Azelaic acid is obtained in exactly the same way from cyclooctene-1-carboxylic and cyclooctene-4-carboxylic acids.[280] In most such reactions, the mechanism cannot be always readily traced, although it is evident that the unsaturated acids isomerise to αβ-unsaturated acids, combine with water via the Michael reaction, and the resulting hydroxyacids are dehydrogenated to ketoacids, which then undergo the retro-Claisen decomposition.

The cleavage of ricinoleic acid (obtained by hydrolysing castor oil) to sebacic and ω-hydroxydecanoic acids, which has found an application in industry, is even more complex:[281]



$$\mathrm{Me(CH_2)_5\underset{\displaystyle OH}{\underset{|}{C}}H_2CH{=}CH(CH_2)_7COOH} - \begin{cases} \rightarrow \mathrm{Me(CH_2)_5COCH_3 + HOCH_2(CH_2)_8CO_2Na}, \\ \rightarrow \mathrm{Me(CH_2)_5CH(OH)Me + NaOOC(CH_2)_8COONa}. \end{cases}$$

The mechanism of this reaction is unknown.

Computer-assisted Synthesis

N.S.Zefirov and E.V.Gordeeva

The state, problems, and prospects of the new field of computer-assisted chemisty, namely the design and search for new ways of synthesising organic compounds with the aid of a computer (computer-assisted synthesis), are described. The principal developments in programming, used directly by organic chemists are examined. The existing programs for computer-assisted synthesis are subjected to a comparative analysis and the features which more than 20 computer systems have in common, including the "FLAMINGOES" system devised by the authors, as well as the differences between them are elucidated. The bibliography includes 123 references.

I. INTRODUCTION

One of the most important scientific developments involving the application of computers in chemistry is the search for ways of synthesising organic compounds with the aid of a computer, which has come to be referred to in the literature as "computer-assisted synthesis", abbreviated to CS. Since 1969, when the paper of Corey and Wipke,[1] giving a description of the first program for computer-assisted synthesis, was published, this field has developed fairly rapidly and at the present time one may speak of CS not as a set of individual developments but as a major field of science (see, for example, the relevant reviews[2-7]).

The aim of the present review is to cover the principal aspects of the problem of CS. At the same time we have not included in the review the general problems of the strategy and planning of synthesis, because they have already been adequately dealt with in the literature.[8,9] On the contrary, in the present review we shall as far as possible take into account the specific computer-dependent features of the search for methods of synthesis with the aid of a computer. We thought it more useful to differentiate the key factors in the creation of programs for the solution of problems in CS without going into the details of the formulation of algorithms and the machine execution of specific programs, because the number of CS programs is fairly large and is continuously growing. We believe that, within the framework of the selected structure of the description, it will be possible to define clearly the similarities and differences between the existing CS programs and to elucidate the fundamentally new features of a particular approach.

In the concluding part of the review, we shall examine the main principles of the "FLAMINGOES" computer system which we have developed and which can be used, in particular, also for the solution of problems in the planning of synthesis.

It is noteworthy that, like any new field of science, CS has no established universal terminology, which is a significant obstacle to reviewing the relevant data. In the present review, an attempt has been made to present the main aspects of CS in terms of a more unified terminology, which embraces the most apt and accurate, in our view, formulations.

II. FORMULATION OF THE PROBLEM. "THE SYNTHESIS TREE"

Suppose that a certain compound has been specified for which it is necessary to find the possible methods of synthesis from other, precursor compounds. In this case we solve the problem of planning the synthesis in the reverse (retrosynthetic) direction.[1] It is also possible to formulate the opposite problem of the forward (synthetic) planning of the synthesis, i.e. the problem of finding the possible ways in which the given compound or set of compounds reacts and the reaction products.[1] The compound specified (set of compounds) will henceforth be referred to as the chemical system (ChS); as a rule, in the retrosynthetic approach the chemical system includes only one compound while in the direct planning of synthesis there are one or several compounds.

The result of the execution of a CS program in both the forward and reverse directions of the search is the construction of the "synthesis tree", i.e. a graph whose vertices correspond to the initial, intermediate, and final compounds but whose edges represent the chemical reactions in the course of which these compounds are interconverted. If the computer search is carried out in the reverse (retrosynthetic) direction, then the "synthesis tree" is a schematic representation of the possible ways of synthesising the specified chemical system from initial compounds via the intermediate formation of the precursors of the specified chemical system. If the search is carried out in the forward (synthetic) direction, then the "synthesis tree" can be interpreted as the "reactions tree", i.e. as the schematic representation of the possible ways in which the specified chemical system can react.

"The synthesis tree" is constructed as follows in the course of the execution of the CS program. The structure of the compound incorporated in the specified chemical system is introduced into the program. The program generates a set of precursors of the specified chemical system on the basis of empirical or logical instructions inherent in the program. This procedure can be repeated for all or some of the structures generated in the first stage and so on until certain specified conditions governing the completion of the construction of the "synthesis tree" have been fulfilled.

The most important and fundamental factor in CS is the formal treatment and coding of human thought, i.e. without the ideas and reasoning with which the organic chemist operates in selecting or assessing chemical reactions. All the computer systems existing at present for the planning of synthesis constitute only the first and probably fairly tentative steps towards the solution of this fundamental problem. Indeed, so long as a rigorous general theory of organic chemistry has not been created not only an exact prediction of the results of a certain reaction but also the *a priori* assessment of the possibility of the occurrence of this reaction is impossible.[10] Nevertheless, the attempt to reproduce with the aid of the computer all the logical, empirical, and intuitive considerations by which the organic chemist is guided in planning a synthesis appears very useful as a basis for the creation of an artificial intelligence in organic chemistry.

Using the terminology introduced, it is possible to define the task of selecting and assessing the methods of synthesis as one involving the reduction of the "synthesis tree",[11] i.e. the elimination from the latter of chemical reactions and compounds which do not satisfy particular selection criteria. The selection criteria make it possible to diminish greatly the "synthesis tree" and also to organise the generation of the precursor of a given chemical system in such a way that the program generates in the first place the most probable or the most interesting methods of synthesis. The selection criteria are most effective if they operate at the early stages of the construction of the "synthesis tree".

The "synthesis tree" can be constructed under different conditions: (a) non-interactively when the program effects the search, after the input of the necessary initial information, without the interference of the user and without requiring additional information; (b) interactively when the program cannot adopt "independently" a solution in certain situations and turns to the human operator for assistance. Ideally, the CS program should generate the optimum "synthesis tree" without the involvement of the user, but the real situation in theoretical organic chemistry makes it possible to solve under automatic conditions only fairly narrow problems or it requires the introduction into the program of very rigorous limitations, which inevitably leads to the loss of interesting results.

At the present time CS is developing in the direction of increasing the "independence" of programs, although the commonest computer systems provide also for the possibility of an interactive search.

III. PRINCIPAL PROGRAMS FOR COMPUTER ASSISTED SYNTHESIS

As already stated, the aim of the present review is to cover the main aspects of the given scientific field as a whole. The specific features of the tasks to be performed by CS define the main problems on which attention should be concentrated: (a) the representation and analysis of the chemical structure in CS programs; (b) the representation and analysis of chemical reactions (transformations) in CS programs; (c) the selection criteria in CS programs. To facilitate the understanding of the data described below, we quote a brief compilation of the main CS programs with an indication of the leaders of the project, the Company, and the literature references (the most novel computer developments are designated by an asterisk).

"AHMOS"* (Automatisierte Heuristische Modellierung Organisch-chemischer Synthesen); Weise (GDR).[12–15]

"ASSOR" (Allgemeines Simulations-System Organischer Reaktionen); Schubert [Federal Republic of Germany (FRG)].[16,17]

"CAMEO"* (Computer-Assisted Mechanistic Evaluation of Organic Reactions); Jorgensen (USA).[18–26]

"CASP" (Computer-Assistierten Synthese Planung); developed by a Company (FRG, Switzerland).[6]

"CHIRP" (Chemical Engineering Investigation of Reaction Paths); Agnihotri and Motard (USA).[27]

"CICLOPS" (Computers in Chemistry, Logic Oriented Planning of Syntheses); Ugi and Gasteiger (FRG).[28]

"EROS"* (Erzeugung von Reaktionen fur die Organische Synthese); Gasteiger (FRG).[29,30]

"FLAMINGOES"* (Formal-Logical Approach to Molecular Interconversions. Non-empirical Generation, Orientation and Evaluation of Syntheses); Zefirov (USSR).[31–34]

"LHASA"* (Logic and Heuristic Applied to Synthetic Analysis); Corey (USA).[35–41]

"MASSO"; Moreau (France).[42]

"MATCHEM" (MAThematical model of constitutional CHEMistry); Ugi and Gasteiger (FRG).[28]

"OCSS" (Organic Chemical Simulation of Synthesis); Corey and Wipke (USA).[1]

"PASCOP" (Programme d'Assistance a la Synthese des Composes OrganoPhosphores); Kaufmann and Choplin (France).[43–48]

"REACT"; Carhart, Smith, and Djerassi (USA).[49,50]

"REACT" (REACTion path synthesis program for the petrochemical industry); Govind and Powers (USA).[51]

"SECS"* (Simulation and Evaluation of Chemical Synthesis); Wipke (USA).[11]

"SOS" (Simulation of Organic Synthesis); Barone and Chanon (France).[52–54]

"SYNCHEM"* (SYNthetic CHEMistry); Gelernter (USA).[55–58]

"SYNGEN"* (SYNthesis GENeration); Hendrickson (USA).[59–61]

"TOSCA"* (TOpological Synthesis design by Computer Application); Sander (FRG).[62]

Bersohn's program* (Canada).[63–65]

Whitlock's program (USA).[66]

"EPOS"* (Empirical Planning of Organic Synthesis); Koptyug, Smirnov, and Piottukh-Peletskii (USSR).[67]

Many of the programs listed are not fully novel developments, but constitute modifications of programs developed previously, specially designed for the solution of narrower problems than the prototype programs. Thus Whitlock's program and the "SOS" and "PASCOP" systems are based on the same principles as the "LHASA" and "SECS" programs but are designed for the investigation of narrower fields of organic chemistry, such as the synthesis of acyclic structures, the chemistry of heterocyclic compounds, and the chemistry of organophosphorus compounds. The "SECS" program is also the basis of the "CASP" computer system. We shall base the subsequent exposition mainly on novel developments (designated by an asterisk), omitting the non-fundamental modifications of programs and obsolete versions such as "OCSS" (see the newer programs "LHASA" and

"SECS"), "CICLOPS", "MATCHEM" (see the program "EROS"), and "MASSO" (see the program "SYNGEN").

The programs "REACT" and the "CHIRP", "ASSOR", "AHMOS", and "CAMEO" systems occupy a special place among the computer systems enumerated. The program "REACT" (Carhart, Smith, and Djerassi) is an auxiliary component of the "CONGEN" system designed to establish the structure of an unknown compound from spectroscopic and chemical data. The "REACT" system (Govind and Powers) is in many respects similar to the "LHASA" and "EROS" programs but is specially designed for the investigation of chemical engineering processes.

The "AHMOS", "CAMEO", and "ASSOR" programs represent the "mechanistic" tendency in CS. The "AHMOS" and "CAMEO" systems search exclusively in the forward (synthetic) direction generating not the methods of synthesis of chemical compounds but the possible ways in which the specified chemical system can react taking into account the reaction mechanisms and the laws of physical organic chemistry. The "ASSOR" program has many features in common with the "EROS" system (they sprang from a common root—the "MATCHEM"—"CICLOPS" systems), but "ASSOR" is distinguished by a more detailed stage-by-stage examination of the transformations generated in the specified chemical system. The machine search in the "ASSOR" systems can be prosecuted in both the synthetic and retrosynthetic directions, in contrast to the "AHMOS" and "CAMEO" programs. For the description of the "FLAMINGOES" and "EPOS" programs, see Sections VIII and VI respectively.

IV. REPRESENTATION AND ANALYSIS OF CHEMICAL STRUCTURES

As already stated, the functioning of any CS program begins with the input of certain initial data based on information about the structure of the specified chemical system. Virtually all CS programs have at the present time the facility for the input of the structure of a specified CS in the form of a figure with the aid of special graphical devices (graphical display, light pen, etc.).[68] The figure is input as a rule in the form to which the user is most accustomed. The graphical information obtained is transformed into an internal representation of this structure in the program. We shall consider the main principles of the coding of the molecular structure in computer programs, because even at this stage it is possible to determine which particular aspects of molecular structures are the most important for the solution of CS problems.

Any CS program takes into account in the first place the types of atoms in the specified chemical system and the bonds between them, including the multiplicity of the bonds. In other words, a common feature of all the programs is the representation of the structure by a chemical multigraph and its Adjoint matrix.[69] In a number of CS programs, the so called "connection tables", based on the Adjoint matrix of the corresponding multigraph, are used[1,70] for the description of the structure of a chemical compound. The connection tables can also contain additional information about the specified chemical system, for example, they can describe the stereochemical characteristics of the structure[11,24,40,71-75] and atomic charges.[18,39,40,53] In the "SYNGEN" program, the description of the specified chemical system includes only the atoms of the skeleton and the bond between them. Furthermore, for each atom of the skeleton provision is made in the connection table for a "functionality" column, indicating the character of the bonds between the given atom and particular functional groups (FG).[61,76]

The "EROS" program retains the description of the structure in the form of a *BE* matrix, which indicates the bond orders between the atoms of the specified chemical system (non-diagonal elements) and the number of free electrons in the outer valence shell of each atom (the matrix diagonal).[29]

The "SYNCHEM" program[55] uses both the usual representation of structures in the form of connection tables and in the form of the Wiswesser line-formula notation (WLN). The description of the specified chemical system in the form of a connection table is used in the analysis and transformations of structures, while the Wiswesser notation is convenient for the storage and compilation of structural data banks and libraries. Furthermore, the programs are associated with the library of available substances, compiled on the basis of the catalogue of the Aldrich Company in which the reagents are described precisely with the aid of the Wiswesser notation.

In the course of the analysis of the structures forming part of the composition of the specified chemical system, the CS programs extract additional information necessary for further work, namely the characteristic features of the structure of the skeleton (the number and interlinking of the rings and chains), the number and form of the FG, the symmetry of the structure, stereochemistry, etc. The structure is analysed as a rule under automatic conditions in a special recognition unit.[77-87]

V. EMPIRICAL AND NON-EMPIRICAL COMPUTER-ASSISTED SYNTHESIS

Before proceeding with the description of various ways of representing chemical reactions in CS programs, one should note that there are various types of access to these formalised descriptions. At this stage it is in fact possible to differentiate two fundamentally different approaches: the empirical CS, where the transformations of a specified chemical system are effected on the basis of coded information about known organic reactions, and the non-empirical CS, where the transformations are generated by logical-combinatorial procedures without resorting to factual information. In the former case, chemical reactions must be compiled beforehand in the form of a library, while in the latter a set of logical instructions and/or a combinatorial algorithm, which directly generates the transformations, is used to search for the transformations in the specified chemical system.

The advantage of the empirical approach is that the program predicts as a rule entirely probable methods of synthesis and the majority of the selection criteria are contained implicitly in the description of each specific reaction. On the other hand, such programs are linked to a specific library of reactions and are incapable of suggesting a fundamentally new synthetic pathway or finding a new reaction. The non-empirical CS programs are free from this disadvantage, but they require the inclusion in the program of rigorous selection criteria in order to avoid the generation of unrealistic or chemically uninteresting results. At the present time many non-empirical CS programs include also the interaction with data banks by resorting to which it is possible to assess chemically the results obtained, i.e. it is possible to realise an empirical selection criterion.[13,18,61]

VI. REPRESENTATION AND ANALYSIS OF CHEMICAL REACTIONS

The main stage in the computer-assisted planning of synthesis is the search for reactions effecting transformations in specified chemical systems. It is significant that, for the solution of the problem of retrosynthesis, it is essential to consider retroreactions ("antithetical reactions" or "transformations"[1]), i.e. reactions which are the opposite of those which result in the formation of a specified chemical system. Different terminology is used in the literature for the designation of such reactions. Strictly speaking, the term "redistribution of bonds" reflects most accurately the formalised character of the representation of chemical reactions in CS programs, but in the present review we shall employ the term "transformation" as the most widely used.

The majority of CS programs refer to the empirical approach and use in their execution libraries of transformations (LT).[1,11,40,44,50,51,53,57,64,66] It is possible to differentiate the following common features of all LT. Firstly, the description of the transformation includes the enumeration of the structural fragments which must be present in the specified chemical system in order that the given transformation can be effected. Secondly, the description contains a set of different tests, which determine the possibility, in principle, of effecting the given transformation in the specific chemical system and/or determine the priority ("rating") of the transformation described. Furthermore, the description also includes a list of the structural changes which must be carried out in order to generate the structures corresponding to the result of the application of the given transformation to the specified chemical system. Finally, an identifier must be present for each transformation.

The aspects listed above are characteristic of all LT described in the literature,[11,40,55,88] but, depending on the specific features of the concrete CS program, the description of the transformations can be supplemented by additional information. For example, in the "LHASA" and "SECS" programs, a "character" is attributed to each transformation, i.e. an abbreviated specification of the structural changes in the specified chemical system induced by the given transformation (the formation or dissociation of a bond, ring opening or closure, the introduction, removal or modification of FG, etc.).[11,40] Furthermore, the LT of the "LHASA" and "SECS" programs contain information about the reaction conditions (temperature and auxiliary reagents) and also literature references. In the "REACT" system (Govind and Powers),[51] much attention has also been devoted to the description of the technological conditions for the successful occurrence of specific processes.

The description of transformations in Bersohn's program includes the indication of the yield of the corresponding synthetic reaction and additional tests analysing the correctness of the structures obtained as a result of the given transformation.[88]

The "LHASA"[39–41] and "SECS"[11] programs have the largest and most highly organised LT. The transformations are recorded in these libraries in special languages (CHMTRN in the "LHASA" program and ALCHEM in the "SECS" program), which combine the rigorous logical constructions of the algorithmic machine language and an English vocabulary comprehensible to the chemist.

Gelernter uses a different form of description of transformations, which is closer to the machine interpretation.[55] The set of tests which must be performed on the structure of the specified chemical system is represented by Boolean functions.[89] As a result of the successive operation of these functions, special codes are produced, which enables the program to reach a conclusion about the applicability of the transformation, to attribute to it the appropriate rating, or to report that another transformation must be resorted to in a preliminary step.

the "EPOS" system, the first empirical CS program in the USSR, is being developed at the Scientific-Information Centre for Molecular Spectroscopy of the Novosibirsk Institute of Organic Chemistry of the Siberian Division of the USSR Academy of Sciences.[67] The program is designed for retrosynthetic planning of organic synthesis using a library of transformations; in terms of the form of access to the LT, the system is similar to Gelernter's program.

In contrast to the empirical CS programs, in the programs based on the non-empirical approach, the transformations of a specified chemical system are effected as a result of the application of certain logical instructions and not on the basis of a bond redistribution scheme obtained from the LT.[13,16,18,27,28–34,42,61,62]

The "EROS" and "TOSCA" programs employ sets of "reaction generators", i.e. instructions which describe in the most general form the bond redistribution in the course of chemical reactions.[29,30,62] In the latest version of the "EROS" program,[30] five reaction generators are used, which when combined describe the majority of organic reactions: (1) X: + I–J → I–X–J; (2) I–X–J → X: + I–J; (3) I–J + K–L → I–K + J–L; (4) I–J + K–L + M–N → N–I + J–K + L–M; (5) I–J + K–L + X: → J: + I–K + L–X, where I, J, K, L, M, and N are reaction centres, i.e. atoms linked by bonds which undergo a change in their order by unity. The dissociation of the "bond" between the centres I and J in the reaction generator can imply both real dissociation and a decrease of the bond order in the specified chemical system: analogously the formation of a "bond" in the reaction generator can correspond both to the real formation of a bond and to an increase of the multiplicity of the bond already present. The centre X: corresponds to an atom whose valence changes by two units in the course of the reaction, for example, the carbene centre in the carbene addition reaction. The functioning of the "TOSCA" program is based on reaction generators analogous to the generators (3) and (4). An additional transformation of the type I–J–K + L–M → I–K + L–J–M is also used.[62]

Evidently the same reaction generator can give rise to different chemical reactions for different centres and bonds in the chemical system. For example, the generator (3) can correspond both to addition to the double bond and to a substitution reaction. Thus reaction generators applied to a specific chemical system can give rise, together with well known reactions, to completely new transformations.

The description of the reaction mechanism constitutes a specific feature of the "ASSOR" program,[16,17] which operates with only four transformations (principal reactions). These transformations correspond to oxidation–reduction processes ($I^{\cdot} + J \rightleftarrows I + J^{\cdot}$ and $I^{-} + J^{+} \rightleftarrows I^{+} + J^{-}$) and to dissociation–association processes ($I{-}J \rightleftarrows + I^{+} + J^{-}$ and $I{-}J \rightleftarrows I^{-} + J^{+}$), which are represented in the most general form. Such representation of the transformations is in many respects analogous to the reaction generator in the "EROS" program, aut the "ASSOR" system pays more attention to the reaction mechanism, which entails an increase of the number of CS stages. For example, four search stages in the "ASSOR" program correspond to the result of the operation of the generator (3) (one stage of the machine search in the "EROS" program).

The "AHMOS" system[12,13] uses a formalised representation of organic reactions, which is also in many respects analogous to the representation of reactions in the "EROS" program. The principal differences consist in the fact that, firstly, the transformations in the "AHMOS" program are more specific than the reaction generator, because they contain an indication of the type of reaction centre (electrophile, nucleophile, etc). Secondly, the transformations in the "AHMOS" program correspond in fact to the elementary stages of organic reactions and not to the overall result of the process. Weise[13] considers the transformations corresponding to the following processes:

(1) addition: $E + Nu \rightarrow E^{-}{-}Nu^{+}$;

(2) substitution: $EFABG{-}NFABG + Nu \rightarrow EFABG{-}Nu^{+} + {}^{-}NFABG$;

(3) dissociation: $EFABG{-}NFABG \rightarrow {}^{+}EFABG + {}^{-}NFABG$;

(4) protonation: $X{-}H + Nu \rightarrow X^{-} + Nu^{+}{-}H$;

(5) sextet rearrangement; $Y{-}X{-}Z \rightarrow X^{+}{-}Z^{-}{-}Y$;

(6) polarisation: $X^{-}{-}Z \rightarrow X{=}Z^{-}$ or $X^{-}{-}Z{=}Y^{+} \rightarrow X{=}Z{-}Y$;

(7) electrophilic substitution: $E + H{-}C(Ar) \rightarrow E^{-}{-}C(Ar) + H^{+}$;

(8) elimination: $Nu + H{-}X{-}EFABG{-}NFABG \rightarrow X{=}EFABG + H{-}Nu^{+} + {}^{-}NFABG$.

Here E is an electrophile, Nu a nucleophile, EFABG and NFABG are respectively electrofugitive and nucleofugitive leaving groups, and X, Y, and Z are other reaction centres (Z is a sextet atom).

The non-empirical CS program "FLAMINGOES"[31-34] can operate with both multistage chemical reactions (with an arbitrary degree of complexity) and with individual stages of the mechanism. The universality of the "FLAMINGOES" computer system compared with other non-empirical CS programs is achieved by using not an individual extremely limited set of reaction generators but a general combinatorial algorithm in the course of the execution of which the most varied chemical reactions and/or reaction stages can be generated, including completely new or little investigated processes (for a more detailed description of the "FLAMINGOES" system, see Section VIII).

The program "SYNGEN"[60,61] is based on a novel classification of organic compounds by Hendrickson.[90-95] This system is also based on the claim that the majority of organic reactions can be represented as a change in the immediate environment at one or several carbon atoms on passing from the initial compounds to the products (or in retrosynthesis on passing from the specified chemical system to the precursors). It is suggested that the entire wide variety of the possible environments of a carbon atom can be expressed by four bond types:

(1) type H: σ-bond with a hydrogen atom or an atom less electronegative than hydrogen;

(2) type R: σ-bond with another carbon atom;

(3) type Π: π-bond with another carbon atom;

(4) type Z: σ- or π-bond with an atom more electronegative than hydrogen.

The number of bonds of each type is designated respectively by h, σ, π, and z; evidently, $h + \sigma + \pi + z = 4$. Hendrickson calls the sum $f = \pi + z$ the functionality of the carbon atom. In this system any reaction will be defined if the change in the environment at all the carbon atoms on passing from one chemical system to another is specified. For an individual carbon atom, this change is designated by two letters: the first characterises the type of bond formed and the second the type of bond ruptured. Thus altogether there is a possibility of $4 \times 4 = 16$ types of structural changes at the carbon atom.

Hendrickson divided the entire set of organic reactions into three classes. The first class includes constructive reactions, i.e. reactions as a result of which the carbon skeleton of the organic compound is altered. Constructive reactions involve three types of structural changes: RH, RΠ, RZ. The trans-functionalisation reactions (the introduction, elimination, or alteration of the FG), including nine types of structural changes, namely HH, HZ, ZH, ZZ, ΠH, ΠZ, HΠ, ZΠ, and ΠΠ, belong to the second class. The remaining four types of changes in the environment of the carbon atoms refer to destructive reactions, which are not used in the "SYNGEN" program.

Among all the constructive reactions, the "SYNGEN" program employs only those in the course of which a single C–C σ-bond is formed and the environment changes at not more than three carbon atoms in the chain on either side of the bond formed. For such constructive reactions and also for the trans-functionalisation reactions, lists of instructions are stored in the program in a coded form and ensure the execution of the necessary transformations in the specified chemical systems; these instructions are also referred to as half-reactions. On the one hand, the compilation of such instructions does not involve the use of factual data from organic chemistry, but, on the other, the set of possible half-reactions is stored in the computer memory like the libraries of transformations in the empirical CS programs. Consequently Hendrickson's method is to some extent intermediate between the empirical and non-empirical CS.

VII. THE SELECTION CRITERIA

In the previous Sections it was shown how the chemical information in the known computer systems is formalised and coded. However, as already stated, the most important problem in CS is the creation and formalisation of selection criteria whose operation in fact imparts to the CS programs the features of an "artificial intelligence".

In empirical CS programs, the selection criteria can be used in three main stages of the search: (1) the choice of a definite "strategy of the synthesis", which limits the number and form of the transformations available in the LT; (2) the assessment or grading of concrete transformations before their use in the specified chemical system; (3) the assessment or grading of concrete precursors of the given chemical system obtained as a result of the transformation.

"The strategies of the synthesis", which make it possible to direct the machine search in a specified direction, have been developed to the greatest extent in the "LHASA" and "SECS" programs. We shall list the main types of such strategies.[11,35,39-41]

1. "The strategy of applicability", i.e. the search in the LT for all the transformations which are applicable to a specified chemical system. The main disadvantage of this strategy consists in the fact that large classes of transformations, such as the introduction, removal, or modification of FG are almost always applicable, which leads to an appreciable growth of the "synthesis tree".[11,35]

2. Strategies designed to achieve the transformations, i.e. the search in the LT for known sufficiently reliable reactions with the aid of which it is possible to carry out an elegant synthesis of specified chemical systems.[41] Such reactions include, for example, the following processes: the Diels–Alder reaction, the Robinson annelation, the Aldol condensation, and sigmatropic rearrangements. Another variety of strategies designed for transformations consists in the construction with the aid of the simplest, "mechanistic" transformations (the addition of a proton, the removal of a proton, etc.) of the possible mechanisms of the formation of the specified chemical system.[41]

3. Structurally oriented strategies, i.e. the search for transformations leading precisely to precursors of the specified chemical system which contain definite structural fragments.[11,41]

4. Topological strategies, i.e. the search for transformations leading to the rupture of one or several "strategic" bonds as a result of which the structure of the initial chemical system may be appreciably simplified.[11,41,96]

5. Stereochemical strategies, i.e. the search for transformations with the aid of which it is possible to synthesise the specified chemical system with a definite configuration of all the stereocentres.[41]

6. Strategies oriented towards functional groups, i.e. the search for transformations which effect the introduction, removal, protection, or modification of FG. This strategy usually precedes the application of other strategies, whose direct application is frequently difficult precisely because of the presence in the specified chemical system of concrete functional groups.[11,41,97–99]

The selection of a definite strategy can be achieved automatically or with participation of the user. The application of several strategies makes it possible as a rule to find extremely effective and elegant methods of synthesis.[40,41]

In the programs of Bersohn[63,64] and Gelernter[55–57] access to the LT is achieved on the basis of data obtained in the course of the analysis of the structure of the specified chemical system or, in other words, "the strategy of applicability" is carried out. In Bersohn's program, the application of this strategy is rigorously ordered. Firstly, all the structural fragments found by the computer in the recognition unit receive different ratings. The highest rating is given to structural fragments in the formation of which the greatest number of bonds are formed simultaneously, as happens, for example, in the formation of a three-membered ring in the Simmons–Smith reaction and of a six-membered ring in the Diels–Alder reaction.

Secondly, the reactions in each section of the LT are also arranged in order of decreasing priority of the corresponding synthetic reactions. The highest rating is given to the reactions involving the introduction of FG; next follow the reactions leading to the construction of the molecular skeleton, the isomerisation reactions, and the reactions leading to the protection of the FG, the removal of the protection, the modification of the FG, and the elimination of the FG. Fragmentation reactions have the lowest rating, because the corresponding transformations complicate the structure of the specified chemical system.[64]

One of the most fundamental and hitherto unsolved problems of organic chemistry—the problem of the *a priori* estimation of the probability of the occurrence of the reaction—is solved in CS programs with the aid of formal and empirical selection criteria. The transformation is regarded as formally feasible if the given chemical system contains a structural fragment formally essential for the execution of the given transformation. Empirical selection criteria are based on a more profound analysis of the structure of the specified chemical system, the reaction conditions, the reactants, etc. The final assessment (rating) of the transformation is determined as a result of a series of tests, which are as a rule contained in the description of the transformation itself.[11,39,40,55,88] The information obtained in the recognition unit is most actively employed precisely at this stage. For a more detailed analysis of the transformations, additional information may be resorted to.

Additional selection criteria have been developed most in the "SECS" program.[11] Thus the applicability of a particular transformation from the LT is determined not only by the results of the tests contained in the description of the transformation but also in conformity with a specified "list of aims", which contains information about the required changes in the skeleton on the FG. In conformity with this list, the transformations of the LT are rejected if the character of the transformation does not correspond to any of the "aims" in the list. If the transformation satisfies the given criterion but the structural fragment indicated in the description of the transformation differs from the structural fragment of the specified chemical system only by the presence and/or type of FG, then, before the direct application of the transformation, the "SECS" program carries out the necessary modification of the structure (in the "LHASA" program the strategy oriented towards the FG operates analogously).

In the first version of the program "SECS" much attention was already devoted to allowance for the steric and electronic effects in assessing a specific transformation. The subprogram "SYMIN" constructs in the computer memory a three-dimensional model of the specified chemical system using calculations by the method of molecular mechanics. In order to estimate the probabilities of reactions with participation of coupled systems, the calculations of molecular orbitals by the Hückel method are used. Depending on the results obtained, the rating of the transformations selected from the LT may be altered.

An important criterion of the applicability of selected transformations is a test designed to show that the conditions favourable for the occurrence of the corresponding synthetic reaction would induce undesirable changes in the specified chemical system. The "SECS" program analyses the sensitivity of various FG under the conditions of the given reaction and selects the protecting reagent. If the reaction conditions and the structure of the specified chemical system preclude a satisfactory protection of the FG, the transformation is regarded as unsuitable.

In the absence of information about the symmetry of the specified chemical system, the application of the same transformation to a structure having several symmetry elements inevitably leads to the duplication of results. The "SECS" program determines the entire symmetry group of the three-dimensional model of the specified chemical system, which makes it possible to generate subsequently only non-equivalent results.

Bersohn's[63,64] and Gelernter's[55–57] programs operate non-interactively, generating the methods of synthesis of the specified chemical system without interference by the user. Consequently the selection criteria underlying these programs must be more rigorously formalised than the criteria in the "LHASA" and "SECS" programs. Thus in Bersohn's program the transformations within a single class of priority are assessed by a special rating which is higher the higher the yield of the corresponding synthetic reaction.[88]

In an earlier study, Bersohn and co-workers[63] used additional criteria for the assessment of individual stages of the synthesis. Each transformation received its rating, which was characterised in terms of arbitrary units by the "simplification"/"cost" ratio. The value of "simplification" increased if the transformation resulted in a decrease of the number of rings, the number of FG, and the number of non-hydrogen atoms. The "cost" depended on many factors, including the yield of the reaction.

In the "SYNCHEM" program[55–57] each transformation is assessed rigorously in conformity with a set of tests in the form of Boolean functions. These tests embody many of the heuristic rules by which the chemist is guided in assessing a chemical reaction. On the basis of the results of these tests, the initial rating of the transformation can be altered (for example, it can be increased if a conjugated activating group is present or it can be reduced if the transformation is interfered with by steric hindrance). The successive application of the Boolean functions can result in a partial modification of the very scheme of the transformation. For example, if a FG sensitive to the reagent used during the reaction is found, then the program can introduce another reagent or can resort to a procedure involving the protection of the FG.

Together with the assessment of the transformations, the precursors themselves are assessed in empirical CS programs. For example, in the "SECS" program[11] different variants are rejected with the aid of the following structural selection criteria: the breakdown of Bredt's rule; the presence of an antiaromatic system; the presence of a cumulated system; a triple bond in a small ring; a *trans*-olefin in a small ring; a cyclic system with a bridge in the *trans*-position; *trans*-condensed three-membered rings; an incorrect valence of an atom; two charges of identical sign on different atoms; an unstable combination of FG. Analogous selection criteria for structures are applied in the majority of both empirical and non-empirical CS programs.

Apart from the criteria testing the formal correctness and "chemical significance" of the structure generated, a very effective criterion, determining the completion of the construction of the synthetic chain in the specified chemical system, is used in a number of non-interactive CS programs designed for retrosynthesis.[55,56,60,61,63,64] In order to apply this criterion, the program must be supplemented by a special data bank—the library (catalogue) of the available substances (DBS). If the structure of the successive precursor generated in the course of the machine search is identical with one of the structures stored in the DBS, the construction of one of the possible synthetic pathways is regarded as completed. Bearing in mind that the reactions leading to the introduction, removal, or modification of FG play a secondary role compared with the reactions involving the construction or modification of the skeleton, one may assume that agreement to within the number and form of the FG is sufficient to satisfy the given criterion.[60,61]

The main problem encountered by non-empirical CS programs is that of the selection from the entire set of the possible synthetic pathways of the most probable and interesting from the chemical point of view. In the non-empirical programs, it is possible to differentiate subproblems in the solution of which selection criteria are employed: the limitation of the types of transformations generated in a concrete specified chemical system; the limitation of the applicability of the transformations in the specified chemical systems; the evaluation or rejection of the generated precursors of the specified chemical system. The selection criteria for the precursors[18,62] are in many respects similar to the analogous criteria in empirical CS programs, and we shall therefore transfer the centre of attention of our discussion to the specific features of the selection criteria of the first two types in non-empirical CS programs.

The possibility of selecting the types of transformations which can be generated in the specified chemical system in an explicit form is present in the "EROS" program,[29,30] where, firstly, provision is made for the situation where the user excludes from the list of reaction generators stored in the computer memory those which correspond to the processes which in his view cannot lead to the specified chemical system. With the user's implicit agreement, it is assumed that all five reaction generators can be applied to the search for the precursors of the specified chemical system. Secondly, there is a possibility of imposing definite limitations on the form and size of the "synthesis tree".[30] In particular, one can seek the maximum number of levels of the "synthesis tree" (the number of CS stages), the number of precursors at each stage, the maximum number of precursors generated for a single chemical system, and the maximum number of precursors which can be regarded as specified by the chemical system in the next CS stage.

The main principle in accordance with which the types of transformations are selected in the "SYNGEN" program[60,61] is that the planning of the synthesis must be based in the first place on the constructive reactions, i.e. reactions in the course of which the skeleton of the specified CS is formed. The trans-functionalisation reactions in the course of which the FG are modified but the molecular skeleton is unaffected are regarded as auxiliary.

As shown in Section VI, the description of any transformation in the non-empirical CS programs in a general form can be represented as a set of reaction centres with an indication how the bonds between them are distributed. Consequently the selection criterion which can limit the applicability of particular transformations consists in the selection of the potential reaction centres or reactive bonds from the entire set of atoms and bonds in the specified chemical system.

In the "EROS" program,[29,30] the given criterion is applied in the analysis of the structure of the specified chemical system in the course of which the bonds capable, in principle, of rupturing during subsequent transformations are determined. Such bonds can be recognised both automatically and with participation of the user. In the automatic mode, the multiple bonds, the C–X, H–X, and X–X bonds (X is a heteroatom), as well as the adjoining bonds are revealed as reactive. Aromatic bonds are not regarded as reactive. The user can arbitrarily correct the list of reactive bonds initially formulated by the computer. Furthermore, the user can specify the optimum enthalpy of the reaction and the range of the permissible enthalpies. For each transformation generated by the computer, the enthalpy is calculated in accordance with Allen's scheme.[100–103] Gasteiger[103] claims that this in general non-rigorous approach yields a satisfactory agreement with experimental data and can serve for a rough estimation of the probability of the reaction. If the calculated reaction enthalpy falls within the range of permissible values, the transformation is regarded as probable; otherwise the precursor found by the computer is rejected. The specified optimum enthalpy makes it possible to estimate in detail the probability of the process predicted by the computer. The closer the calculated reaction enthalpy to the specified value, the higher the rating of the transformation and the corresponding precursors will be investigated in the first place in the next CS stage. We may note that the "CHIRP" program, which is related to the "EROS" system, uses the calculated Gibbs free energies for the estimation of the probability of the transformations in the specified chemical system.[27]

Gasteiger and co-workers have also carried out studies designed to create non-empirical selection criteria for reactive bonds, criteria based on a quantitative determination of the partial atomic charges,[104,105] inductive[106] and resonance[107] effects, dipole moments,[107] and polarisability effects.[108] Iterative procedures, which make it possible to determine the distribution of partial charges in simple compounds with small numbers of atoms, containing heteroatoms, have been described.[104,105] On the basis of the data obtained, it is possible to calculate the C–X (X is a heteroatom) bond energies,[105] the pK_a,[105] and $J(^{13}C{-}H)$,[109] and the proton affinities.[106,108,110,111] It may be hoped that in its subsequent development the method based on the partial balancing of the orbital electronegativity[105,112] will indeed make a significant contribution to the creation of a general theory of the reactivity of organic compounds, but at the present time the selection of reactive bonds on the basis of topological and structural characteristics constitutes a more general, faster, and more reliable method.

The "TOSCA" program[62] employs an interesting and novel method for the limitation of the applicability of transformations in the specified chemical system. Like the empirical CS programs, the operation of the "TOSCA" system is based on the selected strategy of the synthesis. The program employs two strategies: consonant and dissonant. The consonant strategy consists in the search for nucleophilic and electrophilic substitution and addition reactions. The dissonant strategy involves the search for oxidation and reduction processes—reactions leading to a change in polarity. In contrast to the empirical programs, in the "TOSCA" program the strategy is chosen precisely as the stage corresponding to the selection of the potential reaction centres and reactive bonds. All the atoms incorporated in the specified chemical system, starting with the heteroatoms, are designated by the "+" or "-" sign in accordance with their electrophilic or nucleophilic properties. If all the bonds are consonant in the specified chemical system, i.e. there is not one pair of adjacent atoms with identical charges, preference is given to the consonant strategy.

For a specified chemical system containing dissonant bonds (adjacent atoms with identical signs), it is possible to select both a dissonant and a consonant strategy. In the consonant strategy, limitations are imposed on the operation of transformations: bonds may be formed only between atoms with opposite signs while dissonant bonds are revealed as unreactive. On the other hand, the dissonant strategy permits the recombination of atoms with identical signs.

The logic of the "SYNGEN" program[60,61] is based on the idea of "ideal synthesis" as a sequence of constructive reactions.[10] For this reason, bonds in the molecular skeletons incorporated in specified chemical systems are chosen exclusively as the reactive bonds. The "SYNGEN" program initially seeks all possible ways of subdividing the skeleton into constituent components—synthons. In the general case, the number of subdivisions can be very great and additional criteria for the evaluation of the effectiveness of a particular set of synthons for the synthesis of specified chemical systems are therefore necessary. On the basis of the concept of "ideal synthesis", Hendrickson introduces the criterion of convergence.[10,60,95] In convergence synthesis, the fragments of the target structure are formed independently and are combined only at the end of the synthesis. In conformity with this requirement, the subdivision of the skeleton of a specified chemical system in the first stage should lead to two synthons with approximately equal numbers of atoms, to four such synthons in the second stage, to eight synthons in the third stage, etc.

In the course of a single subdivision of the skeleton, the rupture of one to two bonds and the closure of at most one ring are permitted. Preference is given to subdivisions for which the "reassembly" of the molecule is described by effective synthetic reactions, for example the Diels–Alder reaction. It is essential to differentiate the situation where the synthons obtained as a result of the subdivision of the skeleton are found to be identical, since the synthetic scheme simplifies greatly in this instance. Apart from the identity or similarity of the synthons, a test is made to discover if each synthon found is present in the DBS. For synthons which are absent from the DBS, the subdivision operation is repeated.[60,61]

Each sequence of subdivisions of the skeleton of the specified chemical system, leading to synthons for which correspondences in the DBS have been found, generates the so called "ordered bond set".[60] This set consists of bonds which must be broken in a specific sequence in order to obtain the specified subdivision into synthons. The bonds entering into the given set are considered in succession in the same order and all the suitable (on the basis of the presence of concrete FG in the specified chemical system) constructive half-reactions or, where necessary, transfunctionalisation reactions are applied to each bond. This results in the discovery of not only the skeletons of the initial compounds but also of the FG present in these compounds.

As already stated, the "AHMOS"[12-15] and "CAMEO" systems occupy a special place among the CS programs. In terms of the character of the representation of the structure of the transformations, these programs are close to the "EROS" and "LHASA" systems respectively. The "AHMOS" program has come to be classified as a non-empirical CS, while the "CAMEO" system, based on several small data banks, occupies an intermediate position between the non-empirical and empirical systems. We placed the special discussion of the "AHMOS" and "CAMEO" programs in the Section devoted to the selection criteria, because novel criteria based on the laws of physical organic chemistry in fact constitute an inseparable feature of these programs.

Pearson's classification of acids and bases serves as the basis of the selection criteria used by the "AHMOS" program.[12,13] Weise considers six types of reaction centres: a hard electrophile, a soft electrophile, a hard nucleophile, a soft nucleophile, a nucleofuge, and an electrofuge. The program has a small data bank in which the reactivity indices of different FG, reflecting quantitatively the nucleophilic and electrophilic properties of these groups, are stored. On the basis of the scale of evaluations introduced, all the FG found by the program in the recognition unit receive their rating—the reactivity index. Subsequently the program uses these ratings to calculate another quantitative characteristic—the "tendency to react" index for different modes of interaction of electrophiles and nucleophiles provided for by the program (see Section IV). The values obtained are compared with the specified threshold values and the transformations whose occurrence is most preferred in the specified chemical system are thus determined. The program effects priority transformations, generating thereby the possible products of the reaction of the specified chemical system.

The criteria for the evaluation and selection of the possible mechanisms of an organic reaction have been specially developed in the studies of Jorgensen and co-workers.[18-26] The "CAMEO" program for the prediction of the reaction products when the starting materials and the reaction conditions are specified has been created on the basis of these criteria. It is noteworthy that the program carries out the search in the forward (synthetic) direction and is designed not so much for the generation of whole reaction sequences as for the evaluation of the possibility of the occurrence of a particular reaction in different directions. The program has several units, each of which is designed to work with a definite class of reactions. Overall, the "CAMEO" program covers the following processes: interaction of electrophiles and nucleophiles under the conditions of base catalysis[18] including certain reactions of organometallic compounds,[19] the reactions of organosilicon compounds,[19] pericyclic reactions,[21,22] and nucleophilic and electrophilic substitution in aromatic compounds.[23-25] For each of these classes of reactions, special criteria estimating the probability of the process in a particular direction have been developed.

We shall consider in greater detail the criteria for the selection of transformations interpreted in the "CAMEO" program as the reactions of electrophiles and nucleophiles under the conditions of base catalysis.[18] The potential reaction centres are selected as follows: with the aid of a small data bank and a special algorithm,[26] the program determines the most acid protons and generates transformations corresponding to the transfer of protons to the base. The atoms to which the protons are linked are regarded as potential reaction centres—nucleophiles. For organometallic compounds,[19] account is also taken of the possibility of the occurrence of competing addition and exchange reactions. The processes leading to a weaker base are regarded as dominant.

The potential electrophilic centres are determined from structural characteristics (for example, a multiple bond) and also from the pK_a of the leaving group taking into account the specified reaction conditions. With the aid of a set of heuristic rules and data on the structure of the reactants and the character of the FG obtained in the recognition unit, the possibility of the occurrence of competing addition, substitution, and elimination processes with participation of nucleophilic and electrophilic reaction centres is determined.

Subsequently this unit of the "CAMEO" program underwent significant modifications and includes at the present time also the recognition and investigation of reactions with participation of organosilicon reactants[20] and vinyl and aromatic electrophiles.[23]

The functioning of the unit for the study of electrophilic substitution reactions in aromatic systems[25] is based on the determination of the potential reaction centres participating in the process. The most important procedure in this unit is the calculation of the relative reactivities of different centres in the aromatic system. Depending on the reaction conditions and the type of aromatic system (substituted benzene, a heterocycle, a polycyclic system), an initial relative reactivity index is assigned to the system. Using the data obtained in the analysis of a specified chemical system in the recognition unit and the set of heuristic rules, the program takes into account the influence of substituents. An equation has been derived for the calculation of the correction to the initial index as a function of the number and type of electron-donating and electron-accepting substituents. After the calculation of the relative reactivity indices of the aromatic systems as a whole, the program proceeds to determination of the different reaction centres in each system, being guided by the set of heuristic rules. Account is taken also of the steric effect of the substituent.

The stereochemical selection criteria play a major role in the study of pericyclic reactions.[21] Thus dienes are assumed to be unreactive if steric hindrance prevents them from attaining the *S-cis*-configuration. Apart from the stereochemical criteria, various heuristic rules can be used for the selection of reactive dienes, dienophiles, 1,3-dipoles, and dipolarophiles. The main criterion for the selection of pericyclic reactions is applied in the comparison of the energies of frontier orbitals. It is assumed that the lower the difference between these energies, the easier the cycloaddition. Furthermore, the program predicts the relative regioselectivity and stereoselectivity of the process from the results of the calculation of the energies of the frontier orbitals. The energies are determined from the ionisation potentials taken from the special data bank of the "CAMEO" program.

The analysis of [2 + 2]cycloaddition reactions, [2,3]- and [3,3]-sigmatropic rearrangements, and $[1,j]$ shifts of σ-bonds ($j = 3,5,7$)[22] was subsequently included in the program. In order to estimate the priority of a particular reaction pathway, the activation energies calculated on the basis of the analysis of a large number of experimental kinetic data for reactions of the types enumerated were used. Contrary to the authors' expectation,[21] it was found that the enormous variety of the rates of pericyclic reactions and the influence of too many factors on the rate of reaction are all causes which preclude at the present time the development of general principles for the estimation of the probabilities of pericyclic reactions.

VIII. THE UNIVERSAL COMPUTER SYSTEM "FLAMINGOES" FOR THE SOLUTION OF PROBLEMS OF SYNTHESIS AND FOR THE DETERMINATION OF REACTION MECHANISMS IN ORGANIC CHEMISTRY

The "FLAMINGOES" computer system (Formal-Logical Approach to Molecular Interconversion. Non-Empirical Generation, Orientation, and Evaluation Synthesis) constitutes a novel development in the application of computers to organic chemistry achieved by the authors of this review.[31-34] The formal-logical approach, developed previously by Zefirov and Trach,[113-119] is used for the formal specification of the chemical information used in the given system. The general treatment of the chemical processes, based on this approach, made it possible to create the given universal computer system, which is suitable for the solution of any problems of organic chemistry formalised as a constructive list of bond redistributions in chemical structures. The principal types of problems to the solution of which the "FLAMINGOES" system can be applied are, firstly, computer-assisted synthesis, secondly, the study of rearrangements, and, thirdly, the prediction of the mechanisms of complex multistage reactions.

We shall consider briefly the representation and analysis of chemical reactions in the "FLAMINGOES" system. The most important types of organic reactions are formally described as a result of a cyclic bond redistribution (CBR) in the initial chemical system, which leads to the formation of the final chemical system.[113] Consequently, an alternative approach to the solution of the CS problem (alternative to the use of a LT or a set of reaction generators) is a systematic unrepeated generation of all possible CBR in the specified chemical system, which permits the finding of a complete set of the possible precursors of the specified structure (in retrosynthesis) or the complete set of products of the possible reactions in the initial chemical system (in forward CS). If the results obtained are promising for further study, the procedure involving the generation of transformations (in the form of CBR) can be extended to several stages.

The "FLAMINGOES" system, which is based on a systematic unrepeated generation of CBR, has no direct analogies among foreign programs. Retaining all the advantages of the non-empirical approach (the generation of transformations independently of data banks, the possibility of operating with new or little investigated reactions), the "FLAMINGOES" system approaches empirical programs as regards the breadth of coverage of chemical data, since ~90% of the known chemical reactions can be described as processes with CBR and hence such processes can be generated by the "FLAMINGOES" system in the course of the solution of problems of computer-assisted synthesis.

We shall consider the principal types of selection criteria used in the "FLAMINGOES" system. Firstly, the formal criterion designed to test that the correct valences of the atoms and bond orders are used is introduced.

Secondly, the program uses the following empirical criterion: in order to limit the number of formally correct but chemically uninteresting solutions, the "FLAMINGOES" system can be designed to generate not all the CBR possible in the specified chemical system but only those which correspond to the specified limitations to the size of the CBR and also the limitations to the number of bonds formed and the number of bonds ruptured. The "FLAMINGOES" system is interactive and the chemist can introduce all the limitations into the program in the dialogue mode. It is noteworthy that the permissible dimensions of the CBR and also the numbers of formed and ruptured bonds define the set of permissible transformations in the specified chemical system.[113]

Thirdly, the "FLAMINGOES" computer system uses the equivalence criterion. The generation of the CBR in the chemical system for which the corresponding graph has several automorphisms inevitably leads to repeated results. The operation of the equivalence criterion has been organised in the "FLAMINGOES" system in such a way that one can avoid the duplication of the results already in the CBR generation stage; in order to apply this selection criterion, use is made of the information about the group of automorphisms of the graph corresponding to the initial chemical system. It must be emphasised that all the most important selection criteria in the "FLAMINGOES" program operate at the earliest possible generation stages long before the explicit construction of the final chemical system.

The "FLAMINGOES" program is written in the BASIC language and is designed for the USSR produced personal computer "Iskra 226" (64 K). The present version of the "FLAMINGOES" system includes the main program and nine principal subprograms and occupies 60 kbyte of the computer memory. The average generation time is 3–5 s per result. We shall now consider the principal program units comprising the "FLAMINGOES" system.

1. The input of the initial chemical system. In this unit the chemist introduces the structure of the initial chemical system in the form of a figure on the graphical display. The program uses the Adjoint matrix of the multigraph corresponding to the initial chemical system in order to represent the structure. In this unit the user also specifies the number of stages of the computer-assisted synthesis.

2. Construction of the group of automorphisms. In the course of the execution of the given subprogram, all the automorphic features of the graph corresponding to the initial chemical system are automatically generated. Information about the symmetry of the graph is essential for the generation of only non-equivalent CRB, i.e. for the application of the corresponding selection criterion. The unit designed to construct the group of automorphic features is based on the "AVTOGRAF" [?AUTOGRAPH. Ed. of Translation] FORTRAN package.[120]

3. The input of information necessary for the application of the empirical selection criteria:

(a) The limitation of the applicability of transformations in the specified chemical system (see above): in the present version of the "FLAMINGOES" program, heteroatoms and atoms linked by a multiple bond are automatically revealed as potential reaction centres. The chemist is then able to correct arbitrarily, in the dialogue mode, the set of centres put forward by the computer. In addition, the chemist selects from the set of potential reaction centres those which can undergo a change in their valence. For each selected centre, it is necessary to indicate the permissible variant of the change in valence.

(b) The limitation of the types of transformations generated in the specified chemical system (see above). The chemist is able to introduce the limitations on the permissible size of the CBR and on the number of bonds formed and ruptured.

It is noteworthy that provision is made in the program for the "search without limitations" mode in the course of which all formally possible CBR are generated (with ring sizes from three-membered to eight-membered). This mode makes it possible to discover all the strategic pathways to the synthesis of the specified compound which are possible in principle, especially for structures with few atoms for which the number of solutions will not be unduly great.

4. Unrepeated generation of CBR. This subprogram is the most important combinatorial unit in the "FLAMINGOES" computer system. The rapidity of the operation of this unit determines the rapidity of the operation of the program as a whole. A lexicographic inspection of the "sorting tree", in the course of which all possible CBR are generated taking into account the formal and empirical selection criteria, is effected in module A. Module B applies the equivalence criterion on the basis of information about the group of automorphisms of the graph.

5. The output of the final chemical systems. The structures of the final chemical systems can ae output (if the user so wishes) by the printing device (in the form of digital codes for the corresponding CBR), on the graphical display, and on the printer-plotter (in the form of figures).

6. The selection of results for investigation in the next stage (multi-stage CS). The chemist can select from the set of generated results the final chemical systems which are of interest for further study. The selected chemical systems are stored in a special block within the program itself; when the possibilities for the unrepeated generation of CBR in the specified chemical system have been exhausted, the program selects in succession structures encoded in the above block and introduces them as the initial chemical system in the next stage of the computer search.

The "FLAMINGOES" system has extensive possibilities for the solution of a wide variety of problems in synthetic organic chemistry and for the determination of the mechanisms of organic reactions. The initial chemical system, specified by the chemist in the dialogue mode (see paragraph 1), can contain up to 32 centres, the centres being individual atoms or whole atomic groups, introduced as a single whole. Taking into account the possibilities of the "Iskra-226" personal computer, the number of stages in computer-assisted synthesis which can be stored simultaneously in the operating computer memory does not exceed six, but, when external memory devices are used (for example a magnetic floppy disc), the number of CS stages can be arbitrarily large. The "FLAMINGOES" system makes it possible to operate with any organic structures, including complex polyatomic compounds, heterocyclic and organometallic compounds, and ionic and radical species.

In order to demonstrate the possibilities of the "FLAMINGOES" system, a computer search was carried out and a study was made of the pathways leading to the synthesis of a series of skeletal compounds and rearrangements in families of isomers and of the possible mechanisms of organic reactions with participation of ionic and radical species.[31–34] The investigation demonstrated a satisfactory level of the predictive power of the "FLAMINGOES" system. In the course of the operation of the program, not only were virtually all the literature data on the transformations investigated reproduced but also new novel methods of synthesis, rearrangements, and mechanisms of the reactions of the organic compounds investigated were predicted.[121,122]

IX. PROSPECTS FOR THE DEVELOPMENT OF COMPUTER-ASSISTED SYNTHESIS

At the present time there is no doubt whatsoever that the application of computers is essential for the solution of problems in the planning of synthesis, in the prediction of reaction pathways, and in the study of rearrangements. Furthermore, the formalised representation of chemical information in the computer permits strategic planning of a chemical experiment using new or little investigated processes.

As stated above, computer-assisted synthesis is developing in two directions, namely as empirical and non-empirical CS. At the beginning of their development, the programs for computer-assisted synthesis must fulfill the role not only of the apparatus for the planning of the synthesis, but, to a greater extent, they must serve as an automated reference device for synthetic methods in organic chemistry. Naturally, this role can be managed only by empirical CS systems. However, highly organised data banks for chemical reactions, for example "REACCS",[123] specially designed to be used in the search for known reactions on the basis of specified structural fragments, reaction conditions, etc., appeared in the 1980's. Therefore, the problem of the search for a novel strategy for synthesis, the problem whose exhaustive solution is within the capacity of precisely the non-empirical programs—the "artificial intelligence" systems—has come to the fore at the present time in connection with the solution of problems associated with the planning of syntheses. Therefore, despite the fact that the empirical procedures have been developed to an incomparably greater extent, we believe that the future belongs to a combination of these approaches or in other words to the "semiempirical" CS programs. The enrichment of the non-empirical programs by empirical selection criteria permitting a combination of the advantages of the exhaustive unbiased combinatorial sorting with a system of expert evaluations, developed as a result of the entire experience gained in organic chemistry, appears to be especially promising from this point of view.

The High-temperature Corrosion of Constructional Ceramic Materials Based on Silicon Nitride

Yu.G.Gogotsi and V.A.Lavrenko

The kinetics and mechanism of the processes taking place during the corrosion of ceramic materials based on silicon nitride in an atmosphere of oxygen, air, or fuel combustion products and under the influence of sodium salts have been examined. The influence of the composition and structure of the materials on their stability to oxidation has been demonstrated. The influence of corrosion on the physicomechanical properties of silicon nitride materials has also been examined. Methods of protection from corrosion, and the principles of the production of materials with a high heat resistance, have been described. The bibliography contains 138 references.

I. INTRODUCTION

One of the most urgent problems in present-day technology concerns the production of ceramic materials suitable for manufacturing parts for gas turbine engines (GTE), heat exchangers, and other high-temperature equipment.[1-6]

The use of ceramic GTE makes it possible to increase the temperature of the gas at the outlet from the combustion chamber to 1400°, increase the efficiency, and decrease the fuel consumption.[4] The replacement of heat-resistant alloys by inexpensive ceramic in engine construction also leads to a sharp decrease in the consumption of scarce materials, such as tungsten, cobalt, and nickel, and to a decrease in the mass and cost of the engine.

In the solution of the problems of producing ceramic materials for engines, an important role is played not only by technologists, materials scientists, and strength specialists, but also by chemists. This is due to the fact that the constructional ceramic must have a high corrosion resistance in gaseous oxidising media. During use, the engine parts may be subjected to the action of atmospheric oxygen, fuel combustion products, and marine salts at temperatures up to 1500°.[7] The corrosion of the materials leads to a significant change in their physicomechanical properties, and may lead to breakdown of the entire ceramic construction, as took place, for example, during the testing of Ford's ceramic stator.[8]

The most promising constructional ceramic materials at present are those based on silicon nitride;[9-12] they are obtained by the following methods:

1) hot pressing in graphite or boron nitride press moulds at temperatures of 1700–1850° and pressures of 10–50 MPa;

2) isostatic hot pressing in static gas chambers under nitrogen pressures exceeding 100 MPa at temperatures up to 2000°;

3) activated sintering in furnaces at normal or slightly increased pressures; activation of the sintering usually requires the introduction of more than 10% of oxide additives into the materials;

4) reaction sintering of blanks of silicon or its mixtures with Si_3N_4, based on the reaction $Si + 2N_2 \rightarrow Si_3N_4$ at temperatures close to 1400°;

5) deposition from the gas phase, based on the reactions of silicon halides (SiF_4, $SiCl_4$, etc.) or silane SiH_4 with ammonia on heating.

Compact non-porous materials can be obtained by ordinary and isostatic hot pressing[9] and by deposition from the gas phase. The porosity of the specimens is usually 5–10% for activated sintering, and 15–30% for reaction sintering.[10]

Although thousands of papers and a number of fundamental monographs[13-17] have been devoted to the study of the high-temperature corrosion of metals, practically no attention was paid to the high-temperature corrosion of silicon nitride ceramics until 10–15 years ago. Although the first paper on the oxidation of Si_3N_4 appeared in 1959,[18] no significant progress was made in this field until the mid-seventies. Only an approach to this problem which was not directed towards the partial question of "the corrosion of Si_3N_4", but towards the complex problem of studying the corrosion of a whole class of materials, with allowance for the individual characteristic features of each material (method of preparation, concentration of impurities and additives, structure, etc.), made it possible to understand the mechanisms of the reactions taking place and to find ways of producing materials with a high corrosion resistance, capable of retaining sufficiently good mechanical properties at the temperatures at which they are used.

Extensive studies in the last ten years have examined the kinetics and mechanism of the corrosion of the ceramics at high temperatures in different media and the influence of corrosion on the crack resistance and other mechanical properties of ceramic materials, and ways of protecting them from active corrosion during use have been found. At the same time, there is little information on this topic in reference books and monographs giving data on the physicochemical properties of nitride ceramic materials.[19-27]

In the present work, an attempt has been made to summarise the progress made in the study of the corrosion of silicon nitride constructional ceramics and the production of materials with a high corrosion resistance at high temperatures.

II. THE THERMODYNAMICS, KINETICS, AND MECHANISM OF THE OXIDATION OF SILICON NITRIDE MATERIALS

Published data on the chemical reactions taking place during the oxidation of silicon nitride are contradictory. It has been suggested[18] that when it is heated in air to 1200°, silicon dioxide and nitrogen are formed by the reaction:

$$Si_3N_4+3O_2\rightarrow 3SiO_2+2N_2 \tag{1}$$

Other workers[28,29] detected silicon oxide nitride in the reaction products. This is believed to be formed by the reactions[28]

$$Si_3N_4+O_2\rightarrow Si_2N_2O+SiO(gas)+N_2$$
$$4Si_3N_4+3O_2\rightarrow 6Si_2N_2O+2N_2$$

In Ref.24, another reaction giving Si_2N_2O was proposed:

$$2Si_3N_4+3O_2\rightarrow 2SiO_2+2Si_2N_2O+2N_2$$

The oxide nitride in turn may be oxidised to SiO_2:[29]

$$2Si_2N_2O+3O_2\rightarrow 4SiO_2+2N_2 \tag{2}$$

A study of the oxidation of powdered Si_3N_4 under non-isothermal conditions[30] established that the oxide nitride is formed in the first stage of the process at temperatures up to 1100°. In the second stage (at temperatures of 1200° and above), Si_3N_4 and Si_2N_2O are oxidised to SiO_2 by reactions (1) and (2). At low partial pressures of oxygen, reactions giving gaseous silicon monoxide take place:[31,32]

$$Si_3N_4+3SiO_2\rightarrow 6SiO(gas)+2N_2 \tag{3}$$
$$2Si_3N_4+3O_2\rightarrow 6SiO(gas)+4N_2. \tag{4}$$

A thermodynamic calculation of the equilibria in the Si_3N_4–O_2 system (Fig.1) showed that, in addition to reactions (1)–(4), a whole series of other reactions giving solid (SiO_2, SiO) and gaseous (N_2, N_2O, NO, NO_2, SiO) products may take place:[24]

$$Si_3N_4+4O_2\rightarrow 3SiO_2+2N_2O \tag{5}$$
$$Si_3N_4+5O_2\rightarrow 3SiO_2+4NO \tag{6}$$
$$Si_3N_4+7O_2\rightarrow 3SiO_2+4NO_2 \tag{7}$$
$$2Si_3N_4+3O_2\rightarrow 6SiO(solid)+4N_2 \tag{8}$$
$$2Si_3N_4+7O_2\rightarrow 6SiO(solid)+8NO \tag{9}$$
$$2Si_3N_4+11O_2\rightarrow 6SiO(solid)+8NO_2 \tag{10}$$
$$2Si_3N_4+5O_2\rightarrow 6SiO(gas)+4N_2O \tag{11}$$
$$2Si_3N_4+7O_2\rightarrow 6SiO(gas)+8NO \tag{12}$$
$$2Si_3N_4+11O_2\rightarrow 6SiO(gas)+8NO_2 \tag{13}$$
$$Si_3N_4+O_2\rightarrow SiO_2+2SiN(gas)+N_2 \tag{14}$$
$$2Si_3N_4+O_2\rightarrow 2SiO(solid)+4SiN(gas)+2N_2 \tag{15}$$
$$2Si_3N_4+O_2\rightarrow 2SiO(gas)+4SiN(gas)+2N_2 \tag{16}$$
$$2Si_3N_4+O_2\rightarrow 6Si+2N_2O+2N_2 \tag{17}$$
$$Si_3N_4+2O_2\rightarrow 3Si+4NO \tag{18}$$
$$Si_3N_4+4O_2\rightarrow 3Si+4NO_2 \tag{19}$$

Fig.1 shows that the highest absolute values of the change in the Gibbs free energy correspond to the reactions giving silica. At both low and normal pressures, however, their thermodynamic probability decreases with increase in temperature.

To determine which of the possible reactions of Si_3N_4 oxidation is the main reaction, the gaseous products of the oxidation of Si_3N_4 were studied[33] by mass spectrometry. The species O_2^+, N_2^+, NO^+, N_2^{2+}, and O_2^{2+} were detected; SiO^+ ions could not be detected. It was concluded that the main reaction in the oxidation of Si_3N_4 in an atmosphere of air or oxygen (22.7 kPa) is reaction (6), and that the next stage of the process involves the high-temperature dissociation of **NO**:

$$2NO\rightarrow N_2+O_2$$

Infrared spectroscopy at an oxygen pressure of 10^5 Pa [34,35] detected nitrogen dioxide among the oxidation products.

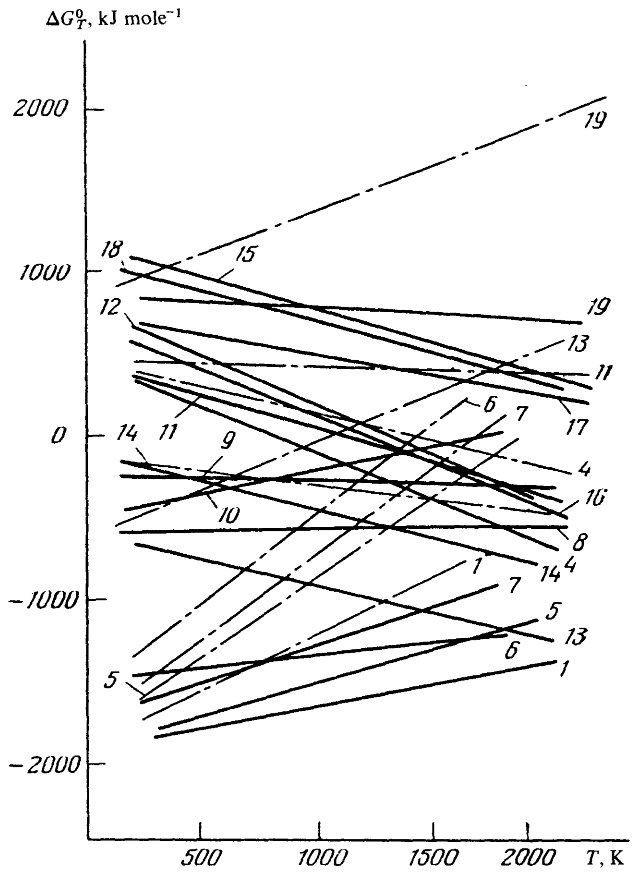

Figure 1. Dependence of the change in the Gibbs free energy ΔG^0_T on the temperature of the reaction of silicon nitride with oxygen at oxygen pressures of 10^5 Pa (continuous line) and 1.3×10^{-3} Pa (broken line) (the numbering corresponds to that of the equations for the reactions).[24]

In Ref.36 it was reported that reaction (3) can take place above 1500°. This suggestion was based on the fact that during the oxidation of the materials at high temperatures, the smooth surface of the specimens becomes blistered as a result of active gas liberation through the oxide film. It is also necessary to take account of the fact that at temperatures above 1420°, Si_3N_4 begins to dissociate to the elements, and the silicon formed reacts with SiO_2 to give gaseous silicon monoxide. It has been reported that the additives introduced into the material may have a catalytic influence on the processes taking place during the oxidation. Thus for example the addition of 5% NaF leads to the formation of silicon oxide nitride instead of SiO_2,[37] whereas the presence of magnesium facilitates the oxidation of Si_3N_4 to SiO_2.[38] The most desirable reactions are those giving silicon dioxide, since this facilitates the formation on the surface of the specimen of a protective layer which prevents further oxidation of the material.

At low partial pressures of oxygen, when only gaseous oxidation products are formed,[31,32] or under conditions in which the solid oxide layer formed on the surface does not show protective properties,[39,40] the rate of oxidation is independent of the time from the start of the process. In this case the following linear relationship is observed:

$$dx/d\tau = K_{\text{lin}} \text{ or } x = K_{\text{lin}}\tau + C_{\text{lin}}$$

where K_{lin} is the linear reaction rate constant, C_{lin} the constant of integration, τ the oxidation time, and x the relative change in mass on unit surface area of the specimen ($\Delta m/S$). The fact that the rate of oxidation remains constant with time indicates that the limiting stage of the process is the reaction at the phase interface.[13]

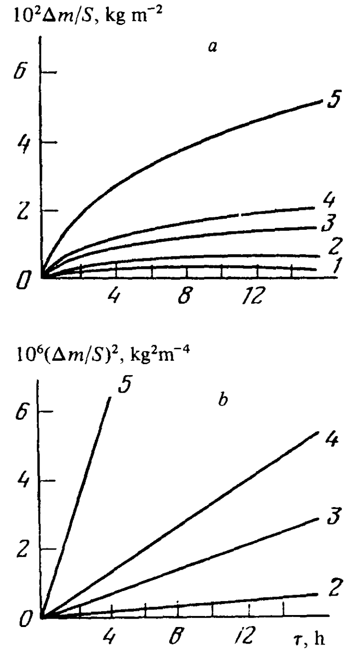

Figure 2. Kinetic curves for the oxidation of Norton's hot-pressed material HS-130 in oxygen, constructed on coordinates $\Delta m/S-\tau$ (*a*) and $(\Delta m/S)^2-\tau$ (*b*),[31] for different temperatures (°C): *1*) 1090, *2*) 1205, *3*) 1260, *4*) 1315, *5*) 1370.

In those cases where the surface of the specimen is covered by a compact oxide layer during oxidation, a parabolic time dependence is observed (Fig.2):

$$dx/d\tau = K'_{\text{par}}/x \text{ or } x^2 = K_{\text{par}}\tau + C_{\text{par}}$$

where K'_{par} and K_{par} are the parabolic reaction rate constants, and C_{par} the constant of integration. The fact that the parabolic oxidation law is observed indicates that the rate of the process is limited by diffusion through the oxide layer.[13] This process can be described by the theory of high-temperature oxidation proposed by Wagner,[41] according to which the rate of the overall reaction is determined by the bulk diffusion of the reacting ions or the corresponding point defects, or by electron transfer through the oxide layer. The driving force of the reaction is the change in the Gibbs free energy, associated with the formation of the oxide from the element and oxygen, as a result of which concentration gradients are produced in the oxidised layer. In this interpretation, the rate of growth of the oxide film is determined by the concentration gradients and the rates of diffusion of the components.

Wagner's theory is applicable to the oxidation of materials based on silicon nitride,[31] but the process is complicated by the fact that, in addition to solid products, gaseous oxidation products are formed; this makes a quantitative estimation and interpretation of the results difficult. The application of Wagner's theory with certain assumptions[42] made it possible to predict that oxidation leading to the formation of silicon monoxide by reactions (3) and (4) can take place, for example at 1300°, only if the oxygen pressure is less than 80 Pa.[31] The ranges corresponding to the "active" oxidation of Si_3N_4, when only gaseous products are formed, and to the "passive" oxidation, when solid products are formed, are shown in Fig.3 [43] (the first lies below the straight line, and the second above it). There is lack of agreement on which is the limiting stage in the oxidation when solid products are formed: diffusion of oxygen to the Si_3N_4/SiO_2 interface,[44] diffusion of nitrogen to the SiO_2/medium interface,[45] or diffusion of additives and impurities from inner layers towards the surface of the specimen.[46]

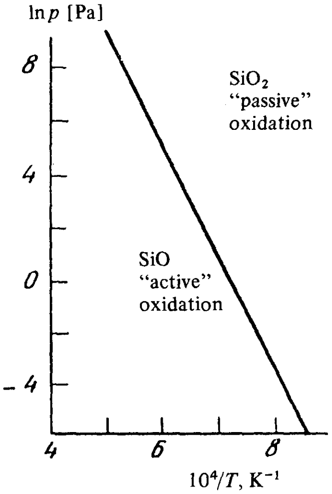

Figure 3. Dependence of the partial pressures of oxygen at which the change from "active" to "passive" oxidation takes place on the temperature of the process.[43]

Table 1 shows that the apparent activation energy of the oxidation of most forms of powdered and compact materials based on Si_3N_4 is close to 300 kJ mole^{-1}, that is it is close to the activation energy of the diffusion of oxygen in silicon dioxide. This indicates that the main contribution to the activation energy is made by the diffusion of oxygen through the oxide layer, and that this is the limiting stage of the process. The activation energy of the oxidation of silicon carbide is also close to 300 kJ mole^{-1} (see Table 1), since in this case also the rate of the process is limited by the diffusion of oxygen through the SiO_2 layer. At the same time, for some materials, the values of E show considerable deviations, towards both higher and lower values. In these cases the mechanism of the oxidation is apparently influenced considerably by other factors such as the diffusion of additives and impurities, transformations in the oxide layer, etc.

Table 1. Apparent activation energies (E) of the oxidation of various materials, and the activation energy of the diffusion of oxygen in silicon dioxide.

Material	Medium	t, °C	E, kJ mole^{-1}	Refs.
β-Si_3N_4 powder	air	1000—1100	280	[30]
β-Si_3N_4 powder	air	1200—1500	390	[30]
Si_3N_4 powder	dry air	1065—1340	285	[47]
Si_3N_4 powder	dry oxygen	1065—1340	255	[47]
α-Si_3N_4 powder	air	1150—1230	294	[48]
Reaction-sintered Si_3N_4	air	1100—1200	130	[49]
Reaction-sintered Si_3N_4	air	<1100	320	[49]

SiC powder	dry oxygen	1200—1500	277	[54]
Diffusion of oxygen in fused SiO_2	–	925—1225	298	[55]

In all cases except Ref.30, the apparent activation energy E was determined using the Arrhenius equation from the parabolic kinetic curves for the oxidation, obtained under isothermal conditions:

$$K_{\text{par}}=A\cdot e^{-E/RT}$$

where A is the pre-exponential factor, R the universal gas constant, and T the temperature. In Ref.30, E was found from the results of experiments under non-isothermal conditions at different heating rates using the equation

$$E=2{,}19R\frac{d\,(\lg\beta)}{d(1/T_p)}$$

where β is the heating rate, and T_p the temperature of the peak on the corresponding differential thermal analysis curve.

In those cases where the oxidation is accompanied by a continuous change in the area of the reaction surface as a result of the filling of the pores by the oxide phase formed, the change in the mass of the specimens with time may also be given by the logarithmic law:[56]

$$x=K_{\log}\lg\tau+C_{\log}$$

where $K_{\log}$ is the logarithmic rate constant, and $C_{\log}$ a constant. In the opinion of the authors of Ref.57, the kinetics of the oxidation of porous reactive silicon nitride can be described by Evans' equation for the case of self-blocking pores:

$$x=x_\infty(1-e^{-K\tau})$$

where x_∞ is the final increase in mass, corresponding to the horizontal section on the kinetic curve, and K a constant whose value depends on the time taken to reach this section. The use of various other familiar equations was also proposed. Analysis shows, however, that the kinetic curves for the isothermal oxidation of porous materials (Fig.4) cannot be accurately described by any of these equations throughout the range of temperatures (800–1500°) and times of treatment studied. This is due to the change in the mechanism of the process and the nature of the filling of the pores with increase in the temperature and time of oxidation.

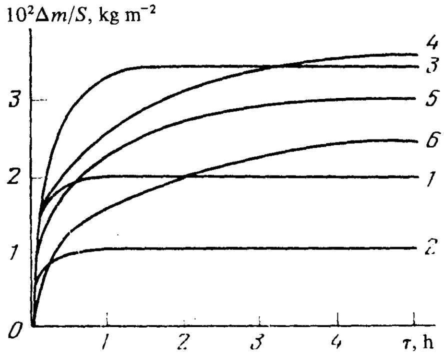

Figure 4. Kinetic curves for the oxidation of the reaction-sintered material NKKKM-80 in air[56] at different temperatures (°C): *1*) 1450, *2*) 1350, *3*) 1100, *4*) 1000, *5*) 900, *6*) 800.

Thus the mechanism of the oxidation may change with change in the conditions of the process (temperature, pressure, and other factors) and in the additives introduced into the ceramic, leading to changes in the composition of the oxidation products and the nature of the kinetic curves.

III. COMPOSITION AND STRUCTURE OF THE OXIDE LAYER

As shown in the previous section, the oxidation of silicon nitride materials in oxygen-containing media at a relatively high partial pressure of oxygen (see Fig.3) begins at temperatures above 700° and leads to the formation of a layer of silicon dioxide on the surface of the specimens.

At temperatures up to 1065°, the silicon dioxide formed is amorphous. At higher temperatures, in the opinion of many workers,[58,59] cristobalite is also formed. In Ref.56, both cristobalite and amorphous SiO_2 were detected throughout the temperature range from 800° to 1450°, but their quantitative ratio in the oxide layer was different for different oxidation temperatures. The appearance of cristobalite has also been observed in the oxidation of silicon oxide nitride.[60] In the oxidation of various materials, the formation of tridymite at temperatures above 1125° [47] and of quartz above 1385° [46] has been observed. There are no published data on the detection of other forms of SiO_2.

The phase transformations in silicon dioxide depend markedly on the temperature, rate of cooling, and presence of impurities.[61] These factors apparently determine whether the silicon dioxide formed in the oxidation is present in the amorphous state or as one of its crystalline forms. In addition to silicon dioxide, the surface layer of specimens oxidised in a charge of Si_3N_4 and other powders which actively absorb oxygen may also contain the oxide nitride.[62] The formation of Si_2N_2O was also detected in the oxidation of reaction-sintered silicon nitride at 1500° in a closed vessel made of a ceramic based on silicon nitride.[56] In a tubular furnace with free access of air, the formation of the oxide nitride could not be detected. It is therefore formed only when there is an oxygen deficit. In an excess of oxygen, the formation of SiO_2 is usually observed.

It has been reported[24] that at temperatures up to 900° in air, solid silicon monoxide may also be formed on the surface of the specimen as a brown phase with inclusions of bright-red crystals. This was not confirmed by other workers, however.[35,40,56] There are no reliable reports of the formation, between the SiO_2 and Si_3N_4 layers, of intermediate layers consisting of lower oxides or the oxide nitride, as observed in the oxidation of many metals[13] and metal-like refractory compounds.[24]

The surface oxide layer always contains impurities with a high affinity for oxygen, in quantities much greater than their average concentration in the bulk of the material. Thus according to Ref.31, after the oxidation of a specimen with the composition Si_3N_4 + 1% MgO at 1400° in dry oxygen, the protective film consists chiefly of enstatite $MgSiO_3$. The presence in the surface layer of up to 40% calcium at a calcium concentration of less than 1% in the starting material has been reported.[58] The migration of calcium, magnesium, and other impurity elements to the surface of the specimen leads to the formation of a silicate phase with a softening temperature in the range 1100–1300°.[38,63] The formation of a low-melting silicate phase, on the one hand, is beneficial, since it leads to the healing of cracks, pores, and other defects[64] and to a more uniform distribution of the oxidation products on the surface of the specimen. On the other hand, diffusion through the liquid layer takes place more readily, leading to an increase in the rate of oxidation. When a liquid phase is formed at the grain boundaries, the strength of the material decreases sharply.[65]

The dissolution of Si_3N_4 in the liquid oxide phase leads to an increase in its viscosity and to the formation of a vitreous coating on the surface of the specimens.[38] The addition of lanthanide oxides, and the presence of water vapour in the reaction atmosphere, on the other hand, favour crystallisation of the oxide layer.[50]

IV. INFLUENCE OF THE COMPOSITION AND STRUCTURE OF THE MATERIALS ON THEIR STABILITY TO OXIDATION

1. Influence of the Phase Composition

Silicon nitride exists in two polymorphic forms with similar structures, differing only in the sequence of tetrahedral elements in the direction of the c axis.[22] The nitriding of silicon usually gives both forms: α-Si_3N_4 is formed preferentially in the temperature range 1200–1400°, and β-Si_3N_4 above 1450°. On heating to 1450–1500°, slow irreversible conversion of the α-phase into the β-phase takes place.[21] Practically all industrial specimens of powdered silicon nitride consist of a mixture of the α- and β-forms.[66,67] At the same time, hot-pressed and sintered materials obtained at ~1700° and above usually do not contain α-Si_3N_4. Its presence is possible only in reaction-sintered materials.

The study of powders with different concentrations of α- and β-Si_3N_4 [24] has shown that, other conditions being equal, the tendency to undergo oxidation is greater for those consisting chiefly of α-Si_3N_4. The initial rate of the process increases with increase in the oxygen pressure, indicating the possible adsorption of molecular oxygen. At certain temperatures and partial pressures of oxygen, a solid solution of O_2 in α-Si_3N_4 is formed.[24] With increase in the oxidation temperature, the concentration of α-Si_3N_4 in specimens of reaction-sintered Si_3N_4 also decreases.[28] This apparently takes place as a result of the preferential oxidation of the α-phase. The lower stability of α-Si_3N_4 to oxidation may be due to its instability at high temperatures. The rearrangement of the crystal lattice of α-Si_3N_4 facilitates the addition of oxygen atoms and oxidation of the material.

Deposition from the gas phase may give not only crystalline but also amorphous silicon nitride,[12,53] which has a higher stability to oxidation than the crystalline forms.[53]

2. Influence of Porosity

The oxidation of specimens of hot-pressed Si_3N_4, having a density close to the theoretical, takes place chiefly on the surface. The resulting surface oxide layer, depending on the oxidation temperature, the chemical composition of the material, and the oxidising medium, may be porous or compact, crystalline or amorphous.[31,68–71] Typical kinetic curves for the oxidation of compact hot-pressed Si_3N_4,[31] obeying a parabolic time dependence, are given in Fig.2.

The oxidation of specimens of reaction-sintered silicon nitride, having the usual porosity of 15–30%,[72–75] take place throughout the entire volume (the corresponding kinetic curves are given in Fig.4). The rate of oxidation of porous specimens is much higher than that of the compact materials. The difference is particularly marked at relatively low temperatures (compare Figs.2 and 4). As a result of the oxidation of reaction-sintered Si_3N_4 with a porosity of 2270 kg m^{-3} at 1040° for 200 h, 28% SiO_2 accumulated in the specimen, whereas its concentration in the original material (as an impurity at the grain boundaries) did not exceed 4%.[72]

According to Ref.76, the dependence of the rate of oxidation on the porosity is linear and is given by the equation

$$\Delta m = kS_0 + 3kf(1-\rho)/\bar{R}$$

where Δm is the increase in mass, S_0 the geometric surface area of the specimen, f the fraction of open pores (relative to the total porosity), $\bar{R}$ the average radius of the pores, ρ the relative density of the material, and k a coefficient. This equation shows that an important role is played not only by the total fraction of open pores, but also by the radius of the pores (see also Fig.5). In Ref.77 it was suggested that the main influence on the stability to oxidation is in fact shown not by the radius of the pores but by the radius of the channels connecting them. The filling of these channels by an oxide phase having a greater volume than the original Si_3N_4 leads to a decrease in the rate of internal oxidation of the material. Thus for materials with a smaller average radius of the pores (or of the channels connecting the large pores), the formation of a protective layer on the surface of the specimens takes place more rapidly at a lower degree of oxidation (Fig.5).

Active oxidation of the specimen throughout its volume takes place under conditions in which a solid oxide layer exists on its surface. This corresponds to curves *4–6* in Fig.4. When the oxide phase melts (see section III), a viscous protective film, covering all the open pores, is formed after a certain time interval on the surface of the specimens, leading to a change in the nature of the kinetic curves with increase in the oxidation temperature (curves *1–3* in Fig.4).

In the oxidation of the porous material, its density increases,[78] and the porosity decreases, whereas in the oxidation of hot-pressed Si_3N_4 there is a slight decrease in the density. This last feature is due to the fact that the silicon dixode formed is less dense than Si_3N_4. In the oxidation of the compact material, the SiO_2 layer is formed only on the surface, whereas in the oxidation of a porous specimen, only ~25% of the silicon dioxide formed corresponds to the surface layer,[59] and the slight change in the volume of the specimen is accompanied by a fairly large change in its mass.

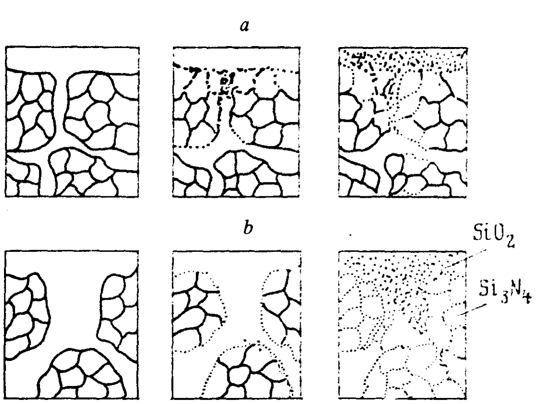

Figure 5. Model of the oxidation of reaction-sintered silicon nitride with fine (*a*) and coarse (*b*) pores under the conditions of formation of a solid oxide layer.

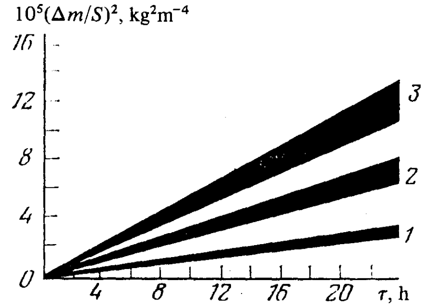

Figure 6. Kinetics of the oxidation of the material HS-130 at 1400° in different media:[81] *1)* CO/CO_2, $p_{total} = 2 \times 10^4$ Pa, $p_{O_2} = 10^{-4}$–10^{-1} Pa; *2)* O_2, $p_{total} = p_{O_2} = 8 \times 10^2$–$8 \times 10^4$ Pa; *3)* O_2/N_2, O_2/Ar, $p_{total} = 8 \times 10^4$ Pa, $p_{O_2} = 8 \times 10^2$–8×10^4 Pa.

Even at temperatures below 1000°, oxidation leads to gradual covering of the pores (Fig.6), and, after some time, to the formation of a protective film of silica on the surface of the specimen, which stops practically completely the penetration of oxygen into the inner layers of the material. Under these conditions, the diffusion of oxygen through the layer of oxide becomes the limiting stage of the process. Subsequently, the reaction takes place in the same way as in the oxidation of the non-porous hot-pressed material.

The density and behaviour during oxidation of sintered materials having a porosity of ~10%[79] are intermediate between those of the hot-pressed and reaction-sintered materials. The materials obtained by deposition from the gas phase have a high density. Their properties are closer to those of the hot-pressed materials,[53] and their mechanical properties and stability to oxidation are often even greater than those of these materials.

3. Influence of Additives and Impurities

Practically all materials based on silicon nitride contain additives to activate sintering: MgO,[80,81] Al_2O_3,[82] Y_2O_3,[83] BeO,[52] CeO_2,[51] ZrO_2,[58] etc. The most frequently used additive is magnesium oxide. The best compaction is achieved when a secondary phase with the composition $MgSiN_2$—Mg_2SiO_4 is formed between the granules.[80] After the oxidation of these materials, the surface layer contains enstatite $MgSiO_3$ and forsterite Mg_2SiO_4,[79] formed by the reactions:

$$2MgO+SiO_2 \rightarrow Mg_2SiO_4$$

$$Mg_2SiO_4+SiO_2 \rightarrow 2MgSiO_3$$

The rate of oxidation increases with increase in the quantity of MgO added. This is due to the fact that the vitreous magnesium silicate phase formed at the grain boundaries softens at temperatures above 1100°, and its viscosity and melting point decrease with increase in the concentration of magnesium in it.[84]

The stability of materials of this type towards oxidation can be increased by adding zirconium dioxide in addition to magnesium oxide.[58] The hot-pressed material containing 1% MgO and 2% ZrO_2 has a much higher stability towards high-temperature oxidation than the same material without zirconium dioxide. It is considered[58] that the addition of ZrO_2 decreases the rate of the diffusion of oxygen through the oxide film and the transfer of magnesium ions to the surface of the specimen. Materials containing added ZrO_2 or ZrC have a high stability at temperatures up to 1500°.

The addition of yttrium oxide makes it possible to obtain a crystalline phase at the grain boundaries, and not the vitreous phase obtained when MgO is used, and also increases the high-temperature strength of the materials.[83] The silicon yttrium oxide nitrides formed by the reaction of Y_2O_3 with Si_3N_4 and SiO_2, which is always present on the surface of the silicon nitride granules, have been studied in detail.[85] It is recommended that the technological conditions be selected in such a way that the secondary phase consists of $Y_4Si_2O_7N_2$. This is facilitated by adding aluminium and magnesium oxides. This material has the greatest stability to oxidation. According to other data,[39] material from the Si_3N_4—$Y_2Si_2O_7$—Si_2ON_2 system has a very high resistance to oxidation.

Cerium oxide has approximately the same influence as yttrium oxide on the properties of the materials.[51] Materials containing added CeO_2 and Y_2O_3 have a high resistance to oxidation at 1300—1400°.[86] In the temperature range 900 to 1200°, the crystalline oxide film formed on the surface of the specimens does not show protective properties, so that intensive oxidation of the materials with a deterioration in their mechanical properties takes place.[40] It has been suggested[39,40] that the temperature separating these two ranges be called the critical temperature (T_C). Above T_C, the oxide layer is compact and shows good protective properties; the kinetics of the oxidation obey a parabolic law, and the rate of oxidation decreases with decrease in the concentration of the additive. Below T_C, the surface layer contains connected pores, and therefore has poor protective properties; the kinetics of the oxidation are close to linear. For the materials of the Si_3N_4—Y_2O_3 system studied in Ref.40, T_C = 1200—1250°. At a temperature below T_C, the maximum rate of oxidation is reached at 1000°.

The formation of a non-porous oxide layer requires that the material contain compounds which lower the liquidus temperature of the phase between the granules. One such compound is Al_2O_3. The addition of 2% aluminium oxide decreases the rate of crystallisation of the phase between the granules, facilitating glass formation, and lowers T_C by 200 K.[40] This material retains an acceptable strength only up to 1200°, but unlike materials to which only Y_2O_3 has been added, it shows good resistance to oxidation at 1000°, since this temperature is only slightly below its T_C value. A hot-pressed material consisting of 93% Si_3N_4, 5% Y_2O_3, and 2% Al_2O_3 showed good resistance in tests involving prolonged oxidation (up to 30 d) at 1200°.[69] The production of a hot-pressed material containing 8% Y_2O_3, whose properties did not deteriorate at 1000—1200°, has been reported.[68] The addition of aluminium oxide to silicon nitride gives so-called sialons,[87,88] which consist of a solid solution with the β-Si_3N_4 lattice, in which some of the silicon atoms are replaced by aluminium atoms, and some of the nitrogen atoms by oxygen atoms. Similar solid solutions are formed when the oxides of beryllium and various other elements are added.

Materials containing added beryllium oxide[52,89] also have a high resistance to oxidation. It has been reported[52] that a hot-pressed material with the composition $Si_{2.9}Be_{0.1}N_{3.8}O_{0.2}$ has a much greater heat resistance than industrial materials being produced. The activation energy of the oxidation of this material is almost twice that for most other silicon nitride specimens (see Table 1).

When the original powders are ground, they usually contain iron or tungsten carbide as impurities, depending on the material used to prepare the grinding bodies and the mill lining. Iron oxides in quantities up to 2.5% are sometimes added deliberately to reaction-sintered materials to facilitate the nitriding process.[90] After pressing or reaction sintering, these impurities are present in the prepared material at the grain boundaries either in the original state or as melts of the silicides or a mixed carbide of iron and tungsten.[38,90] At a high oxygen concentration, they are oxidised and dissolve in the intergranular phase, lowering its melting point. This leads to the formation of a liquid phase in the surface phase at high temperatures and to a deterioration in the high-temperature strength.[91,92]

In addition to the above elements, the technical raw material used to prepare most materials also contains traces of calcium, magnesium, aluminium, strontium, nickel, cobalt, manganese, copper, titanium, and other elements in quantities of 1.00 to 0.01%.[65,98] The presence of these elements in the material leads to a decrease in the viscosity of the silicate glass. The decrease in the viscosity is greater, the greater the ionic radius of the element and the higher the rate of oxidation. The oxidation resistance of the material HS-130, produced by the American firm Norton (Fig.2), is 10 times that of the similar material HS-110 in which the concentration of impurities is 10 times higher.[94] After oxidation, the impurities are present in the vitreous phase or separate as different crystalline phases.[95]

Thus additives and impurities which lower the melting point of the oxide phase may play a beneficial role, facilitating the formation of a compact protective layer even at temperatures of ~1000°. At the same time, at higher temperatures, they lead to a sharp increase in the rate of oxidation of the material. To produce heat-resistant materials, it is apparently necessary to remove the original impurities from the raw material, and then to introduce a strictly limited quantity of certain additives which give the material the required properties.

V. CORROSION UNDER THE INFLUENCE OF SALTS

During use, the ceramic parts of engines may be subjected to the action of various salts,[7,96] leading to breakdown of the protective oxide layer[97] and to more active corrosion of the material.

The presence of sodium salts in the surface layer leads to a decrease in the viscosity of the oxide phase and to an increase in the rate of oxidation of the specimens.[49] The oxide layer formed on the surface of specimens impregnated before oxidation with solutions of different sodium salts contain many pores and cracks.[98] The cracking of the surface layer is due to the difference in the coefficients of thermal expansion of the material and the sodium silicate glass formed, and the large number of pores is due to the low viscosity of the latter.

It has been reported that materials based on silicon nitride have a high stability to the action of molten NaCl,[98,99] marine salt,[98,100] and LiCl–KCl and LiF–LiCl–KCl mixtures,[101] but that they have a poor corrosion resistance in melts with strong oxidising properties, such as Na_2SO_4 [98] and the eutectics Na_2SO_4–NaCl [99] and Na_2SO_4–V_2O_5.[102] The reaction of silicon nitride with sodium sulphate gives the silicates Na_2SiO_3 and $Na_2Si_2O_5$. The processes taking place during corrosion in an Na_2SO_4 melt can be described as follows. In the temperature range 800–900°, the surface layer of the material is oxidised by atmospheric oxygen according to Eqn.(1). When the salt melts (at 890°), it begins to react with the silicon dioxide formed

$$2SiO_2+2Na_2SO_4\rightarrow 2Na_2SiO_3+2SO_2+O_2$$

leading to its dissolution. After the SiO_2 layer has dissolved, the salt reacts with Si_3N_4:

$$6Na_2SO_4+2Si_3N_4+3O_2\rightarrow 6Na_2SiO_3+4N_2+6SO_2$$

Silicon nitride materials have a higher resistance to the action of molten Na_2SO_4 than silicon carbide materials.[99]

VI. CORROSION IN DIFFERENT GASEOUS MEDIA

According to Ref.18, the rate of oxidation of silicon nitride in moist air is twice that in dry air. The reaction of Si_3N_4 with water vapour gives ammonia:

$$Si_3N_4+6H_2O\rightarrow 3SiO_2+4NH_3$$

At the same time, in other studies,[50] even mass spectrometry did not detect ammonia in the products of the reaction of Si_3N_4 with moist air (the partial pressure of water vapour was 3.3×10^3 Pa). The activation energy of the oxidation of hot-pressed silicon nitride in moist oxygen is greater than that in dry oxygen (see Table 1). This is attributed to the change in the viscosity of the oxide film as a result of the dissolution and diffusion of OH^- ions in it.[50]

At high temperatures, silicon nitride materials have a greater resistance in CO–CO_2 mixtures containing oxygen at a partial pressure of 10^{-4}–10^{-1} Pa, compared with an atomosphere of oxygen or air.[81] The shaded areas in Fig.6 give the ranges corresponding to the kinetic curves for the oxidation of hot-pressed silicon nitride in oxygen, CO–CO_2, and mixtures of oxygen with argon and nitrogen. At an oxygen pressure of 1.33 Pa in the CO–CO_2 mixture, a mass loss is even observed, due to the formation of gaseous silicon monoxide. The rate of oxidation of Si_3N_4 is independent of the partial pressure of nitrogen in the gas mixture.[31] Hydrogen also has no significant influence on silicon nitride.[18] Heating powdered Si_3N_4 in a stream of chlorine for 1 h at 1200° leads to an increase in mass of 1%.[18]

Silicon nitride ceramic has a high resistance to corrosion under the influence of the products of the combustion of high-quality fuel.[102] If however these products contain sodium and vanadium, even at concentrations of 0.005%, very strong corrosion of the material is observed. After 225 h at a temperature of 900–1100°, an oxide layer with a thickness of ~1 mm, containing up to 75% SiO_2, 7% V_2O_5, and 8% Na_2O, is formed on the surface of specimens of reaction-sintered silicon nitride.[102]

In spite of the limited amount of available data, it may be concluded that silicon nitride materials can be used successfully in atmospheres of dry nitrogen, hydrogen, chlorine, oxides of carbon, and also fuel combustion products at temperatures above 1000°. The working atmosphere, however, should not contain moisture or elements such as sodium, vanadium, etc. which lead to modification of the protective oxide layer on the surface of the material and to an increase in the rate of corrosion.

VII. THE INFLUENCE OF OXIDATION ON THE PROPERTIES OF THE MATERIALS

Oxidation has a marked influence on most physicomechanical properties of a material. A particularly important role is played by the internal oxidation of porous materials, but at high degrees of oxidation there is a marked change in the properties of even compact hot-pressed materials. Thus when reaction-sintered and hot-pressed silicon nitride is used in an oxidising medium at high temperatures, the influence of oxidation cannot be neglected, and must be taken into account when predicting the properties of the materials.

The increase in the concentration of SiO_2 in the material on oxidation leads to an increase in the coefficient of thermal expansion.[57] As a result of the increase in volume when Si_3N_4 is converted into SiO_2 and the difference in the coefficients of thermal expansion of the material and the oxide phase, compression stresses are produced in the surface layers of the specimens, leading to an increase in the strength of the material. When the stresses are too high, however, cracking of the surface layer takes place, with deterioration in the properties of the material.[103] Compression stresses are produced in the surface layer during the oxidation of the hot-pressed material containing added ZrO_2 even at temperatures of 600–800°.[104] This is due to the fact that it contains a secondary phase with the composition $ZrO_{2-2x}N_{4x/3}$ ($0.25\leqslant x\leqslant 0.43$), which at temperatures above 500° is oxidised to give monoclinic ZrO_2, with an increase in volume by 45%. At the temperatures at which the process takes place, neither Si_3N_4 nor Si_2N_2O are oxidised. Since the material is compact, the oxidation of the secondary phase takes place only on the surface. The compression stresses produced increase the strength, preventing the production of cracks in the surface layer.

Published data on the influence of oxidation on the strength of the materials are contradictory. According to some authors,[72,105] oxidation leads to a decrease in the bending strength, the strength decreasing to a greater extent with increase in the time of treatment. According to other data,[106,107] oxidation leads to an increase in the strength of the specimens as a result of the healing of surface defects. It is reported[107] that although oxidation increases the strength of the material in the initial period, increase in the time of treatment at 1200° to 100 h leads to a decrease in the strength of hot-pressed Si_3N_4 as a result of etching of the grain boundaries and the formation, along the boundaries, of grooves which act as stress concentrators and which may develop into cracks when a load is applied. At the same time it has been reported[108,109] that increase in the treatment time from 5 to 100 h does not lead to a change in the strength of reaction-bonded silicon nitride, irrespective of the temperature of testing (Fig.7). Treatment of specimens of reaction-bonded Si_3N_4 in air for 24 h at 1400° leads to an increase in its high-temperature strength.[26]

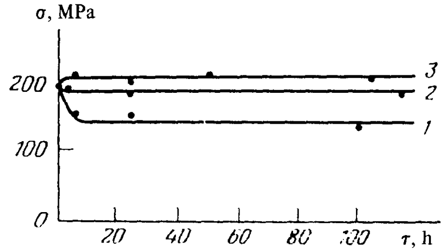

Figure 7. Dependence of the tensile strength of reaction-sintered silicon nitride at 20° on the time of treatment in air[108] at different temperatures (°C): *1*) 1400, *2*) 1200, *3*) 1000.

The bending strength of reaction-bonded and hot-pressed specimens of silicon nitride after oxidation at 1370° with and without an applied load was studied in Ref.105. During oxidation without the load, the strength of the reaction-sintered material increased, but that of the hot-pressed material decreased as a result of the growth of the nitride granules.

All the above data related to the strength determined in bending tests. In Ref.110 it was shown that the changes in the surface of the specimens produced by oxidation, as a result of the non-uniform distribution of the stresses, have a greater influence on bending than on elongation.

According to data obtained by the AiResearch Manufacturing Co., treatment for 50 h in air at 980° leads to an increase in the strength of hot-pressed silicon nitride. Turbine rotor blades produced by the firm were subjected to this treatment. The reaction-sintered materials were subjected to treatment for 2 h at 1400° or for 1 h at 1460°, followed by slow cooling in the furnace to room temperature.

Internal oxidation leads to a sharp deterioration in the creep resistance of the material.[77] Materials based on Si_3N_4 show good creep resistance at high temperatures in protective and reducing media. On heating in air or in oxygen, however, a silicate phase is formed as a result of oxidation of the material along the grain boundaries, leading to an increase in creep.

The influence of various changes taking place in the structure of materials during oxidation on their mechanical properties at room temperature and high temperatures has been analysed.[111-115] Some of the processes taking place during oxidation lead to an increase in the strength, crack resistance, and creep resistance (healing of defects, removal of impurities from the inner layers of the material, etc.), whereas others lead to a deterioration in the mechanical properties (cracking of the oxide layer, etching of the grain boundaries, etc.).[113] By selecting definite oxidation conditions depending on the structure and composition of the material, it is possible to achieve an increase in its strength and other mechanical characteristics. Extensive oxidation of a material leads to a deterioration in the mechanical characteristics; this is usually observed in the oxidation of porous specimens or during oxidation under conditions in which the oxide layer formed does not exhibit protective properties. It is therefore necessary to protect materials from active oxidation.

VIII. THE EFFECT OF SALTS ON THE STRENGTH AND CRACK RESISTANCE OF THE CERAMIC

Oxidation in the presence of sodium salts leads to a decrease in the strength and the critical stress intensity factors (Table 2), both at room temperature and at 1200°.[98] The decrease in strength at high temperatures is due to the formation of a liquid silicate phase in the surface layers of the material, and the decrease at room temperature is due to cracking of the oxide layer (see section V). The higher the oxidation temperature, the lower the strength of the specimens at room temperature.

Table 2. The influence of salts on the strength and crack resistance of the reaction-sintered material NKKKM-81.[98]

Form of treatment	T = 20°		T = 1200°	
	σ_b, MPa	K_{I_c}, MN m$^{-3/2}$	σ_b, MPa	K_{I_c}, MN m$^{-3/2}$
Without treatment	207	3,21	177	3.19
Corrosion in an NaCl melt at 950° (1 h)	195	3.14	128	2.83
Oxidation at 1200° (15 min) in the presence of NaCl	163	—	131	2,71
Oxidation at 1200° (15 min) in the presence of marine salt	157	—	110	2.57
Oxidation at 1200° (15 min) in the presence of Na_2SO_4	177	—	93	2.38

Notation: T is the temperature at which the tests were carried out, σ_b the bending strength, and K_{I_c} the critical stress intensity factor.

Table 2 shows that corrosion in melts of marine salt, sodium chloride, and the NaCl–Na_2SO_4 eutectic leads to a deterioration in all the mechanical characteristics of the materials at all temperatures of testing.[98,116,117] Increase in the time of treatment in molten NaCl from 1 h to 5 h, however, does not lead to a further decrease in strength.[98] Molten salts which have a stronger corrosive action on the material lead to a marked decrease in strength. This is due to the formation of defects in the surface layer of the specimens as a result of the corrosion breakdown of the grain boundaries and individual phase components of the material.[98,116]

In spite of the fact that corrosion under the influence of salts leads to considerable deterioration in the properties of silicon nitride materials, there is very little published information on methods of protection from "salt" corrosion.

IX. CORROSION UNDER STRESS

It is well known that the simultaneous action of a corrosive medium and mechanical loading on metals,[118] glass,[119] molecular crystals,[120] plastics,[121] and other materials leads to so-called corrosion under stress or to corrosion cracking. Since only the first steps are now being taken in the use of ceramics as constructional materials, the corrosion of silicon nitride ceramic under stress has been little studied.

The authors of Ref.122 consider that materials based on Si_3N_4 do not undergo corrosion under stress. This conclusion was based on the following factors: 1) the energy of thermal activation of the process is much higher than the typical energy for a chemical reaction; 2) attempts to stimulate the growth of a crack at the temperature of the surrounding medium in the presence of corrosive agents were unsuccessful; and 3) in the study of corrosion under stress at high temperatures, cracks produced artificially showed a tendency to close. At the same time, it has been reported[123,124] that reaction-sintered and hot-pressed silicon nitride specimens are sensitive to corrosion under the influence of stresses in moist air, water vapour, and aqueous media at temperatures up to 300°. The lower the pH of the medium, the lower the strength of the specimens. The authors of Ref.123 consider that the corrosion of silicon nitride materials under stress is due to ion exchange between the medium and a vitreous phase between the granules. Since practically all materials based on Si_3N_4 contain a secondary vitreous phase, they should be sensitive to corrosion under stress to the extent that the glasses and their breakdown can be described by the theory developed for glasses by Charles and Hillig.[125]

The influence of the external medium may also be due to the dependence of the time to breakdown on the magnitude of the applied load, observed in static fatigue tests on silicon nitride materials.[126,127] When a reaction-sintered ceramic based on silicon nitride was tested in air at temperatures close to 800°, a marked deterioration in the strength properties, which depended on the time of treatment under load, was detected. In this case, not only did the chemical reaction with the medium influence the mechanical properties, but the mechanical stresses also influenced the oxidation process. The quantity of cristobalite in the specimens after testing increased with increase in the applied load.[128] The information available at present, however, does not make it possible to determine reliably the mechanism of the breakdown of silicon nitride ceramic under the influence of mechanical stresses in a corrosive medium.

X. THE PROTECTION OF THE MATERIALS FROM OXIDATION

Various methods of protection from oxidation have been described. The chief method for protecting the ceramic is by depositing coatings of nitrides, carbides, or oxides on its surface.[129–131] Silicon nitride and carbide obtained by deposition from the gas phase have a very high resistance to oxidation. Oxide coatings can also provide reliable protection for the materials. The optimum work capacity of articles with coatings is achieved by depositing silicon nitride, since this ensures good adhesion to the support and a decrease in the possibility of separation or cracking of the coating when heated as a result of a difference in the temperature coefficients of linear expansion of the support and the coating.[25] The principal methods used to apply coatings are by deposition from the gas phase[129,130] and by plasma spraying.[131,132]

The reactions of silicon halides or silane with ammonia are widely used to obtain protective coatings of silicon nitride. The method of pyrolytic deposition with controlled nucleus formation[133] makes it possible to obtain fine-granular coatings consisting of equiaxial crystals. The deposition of a fine-granular coating with a thickness of 0.05 mm and granule dimensions of 1–10 μm on the surface of specimens of reaction-sintered silicon nitride increases the resistance of the material to oxidation during cyclic heating to 1200° by a factor of 100.[133] To give the ceramic other special properties in addition to corrosion resistance (erosion resistance, hardness, etc.), it is also possible to deposit composite coatings with a matrix of amorphous Si_3N_4 and inclusions of TiN, BN, and other compounds.[134]

Coatings of silicon carbide are obtained by the gas-phase synthesis of SiC from volatile silicon halides and hydrocarbons.[135] The deposition of a coating of pyrolytic silicon carbide on the surface of the material by the decomposition of trichloromethylsilane in a tubular furnace at 920° has been proposed.[75,136] The material with a porosity of 25%, covered with a layer of SiC, had an absolute creep resistance at 1200°, indicating the absence of internal oxidation. Coatings of titanium and zirconium diborides and aluminium nitride can also be applied.[133]

Good results were obtained when specimens with a porosity of 28% were impregnated with liquid silicon in a nitrogen atmosphere.[137] After this treatment, a compact protective layer with a thickness of 40–100 μm was formed on the surface of the specimens. An interesting feature is that this layer consisted entirely of β-Si_3N_4, which is known to be extremely stable to oxidation, whereas its concentration in the specimen did not exceed 4%. The increase in the mass of specimens with a coating thickness of 45 μm during their oxidation in the temperature range 800–1400° was one tenth of that for the non-protected specimens. For specimens with a film thickness of 100 μm, practically no increase in mass was observed up to 1400°. The specimens showed a high resistance to oxidation in moist air at 1400°, whereas under similar conditions the non-protected specimens were oxidised to the extent of 30%. In practice, however, the use of this method of protection encounters considerable difficulties, associated with the need for thorough removal of oxygen-containing silicon compounds from the surface, since Si_3N_4 containing SiO_2 or Si_2N_2O on its surface is not wetted by liquid silicon.

According to data given by Norton, reaction-sintered materials can be protected from oxidation by treating with solutions of $Al(NO_3)_3$, $ZrOCl_2$, organometallic compounds of zirconium, or a mixture of $ZrOCl_2$ and $Y(NO_3)_3$. After repeated impregnation, the specimens are heated in a nitrogen atmosphere; the decomposition products collect and fill the pores on the surface of the specimens. The strength of the materials remains unchanged after this treatment, but if materials to which zirconium compounds have been added are heated for 50 h in air at 1230°, their bending strength increases considerably.

Impregnating porous reaction-sintered materials with organosilicon compounds followed by their thermal decomposition makes it possible to increase the resistance of the materials not only to oxidation but also to corrosion under the influence of salts.[138]

The processes described above are not always easy to carry out from the technological viewpoint. A much simpler method of protection is by preliminary oxidation of the specimens under appropriate conditions. As already noted, to obtain useful materials it is necessary to create conditions favouring the formation on the surface of the articles (during use in an oxidising medium at high temperatures) of a compact protective oxide layer. In a certain temperature range (for most materials at temperatures close to 1000°), however, the rate of oxidation is already fairly high, but a protective layer has not yet been formed. This is particularly dangerous for porous materials, since it may lead to their extensive internal oxidation. To eliminate undesirable phenomena, it has been proposed that a compact oxide layer be produced artificially on the surface of reaction-sintered materials by placing them for a short time in a furnace heated to 1300 to 1350°.[56] Thermal treatment in this way is used by the AiResearch Manufacturing Co. to protect materials from further oxidation during use, with a simultaneous increase in their strength.

---o0o---

Thus oxidation during use represents a serious danger for silicon nitride materials, since it may lead to a marked deterioration in their mechanical characteristics. This applies particularly to porous reaction-sintered ceramic. At the same time, a knowledge of the regular features of the process makes it possible, by using definite oxidation conditions, to achieve an increase in the strength of the materials and to protect them from active oxidation during subsequent use. Here it is necessary to take account of the fact that the materials described in the present review differ considerably in their behaviour in oxidising media at high temperatures, depending on their composition and structure.

Although much of the published material on the oxidation of silicon nitride ceramic is contradictory, the principal regular features of this process have now been established. At the same time, however, corrosion under the influence of salts and in an atmosphere of fuel combustion products has still been insufficiently studied. In addition, the conditions under which a ceramic based on silicon nitride undergoes corrosion under the influence of stresses have not yet been established. To ensure that the materials can function at high temperatures in media containing salts of sodium and other metals, a more detailed study of the corrosion processes using modern methods of physicochemical analysis is necessary.

Although silicon nitride materials may undergo considerable corrosion in the media described above at temperatures higher than 1000°, with a deterioration in their mechanical properties, they nevertheless retain under these conditions a higher strength than other heat-resistant and corrosion-resistant metallic alloys.

Organophosphorus Compounds in Reactions with Quinones

A.A.Kutyrev and V.V.Moskva

The results of studies on the chemical behaviour of organophosphorus compounds in reactions with quinones are surveyed. Attention is concentrated on discovering the trends and general characteristics of such processes.
The bibliography includes 134 references.

I. Introduction 1028
II. Compounds of dicoordinate and tricoordinate phosphorus 1028
III. Compounds of tetracoordinate and pentacoordinate phosphorus 1036

I. INTRODUCTION

During the last quarter of a century, studies in the chemistry and technology of organophosphorus compounds have expanded greatly throughout the world, in many respects due to the growing needs for biologically active preparations, among which the aromatic esters of phosphorus acids play a leading role.

Until recently, there has been no reliable information about the reaction mechanisms and frequently also about the structure of the products of the interaction of organophosphorus compounds with quinones. Only the wide-scale application of modern physical research methods made it possible to solve some of these problems.[1-4] Nevertheless, a number of processes with participation of phosphorus(III) compounds do not fit within the framework of existing ideas[5] and the reactivities of compounds of pentacoordinate phosphorus in relation to quinones are not susceptible to prediction.

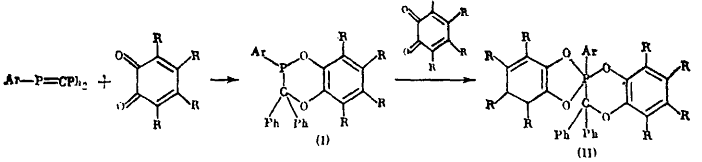
There are no publications in the literature of a review character on the interactions of phosphorus compounds with quinones. The monographs and reviews devoted to various aspects of the chemistry of organophosphorus compounds[6-10, 13,14] and quinonoid compounds[4,11,12] provide only disjointed descriptions of individual phosphorus-containing reagents in their reactions with certain quinones.

In the present review an attempt has been made to survey the experimental data on the synthesis, reactivities, and mechanisms of the reactions of organophosphorus compounds with quinones. The aim was not to discuss comprehensively all the reactions described in the literature but an attempt has been made to concentrate attention on the general characteristic features of these chemical reactions.

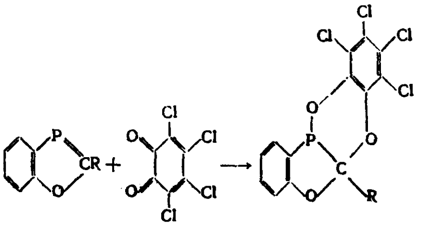
II. COMPOUNDS OF DICOORDINATE AND TRICOORDINATE PHOSPHORUS

1. Reactions of Phosphines and Related Compounds with Quinones

The study of the interaction of aryldiphenylmethylenephosphine with tetrachloro-1,2-benzoquinone, 3,5-di(t-butyl)-1,2-benzoquinone, and phenanthrenequinone showed that 1:1 cyclic [2+4] adducts (I) are formed in all cases. For a 1:2 ratio of phospha-alkenes and quinones, the main reaction products are phosphoranes (II):[15]



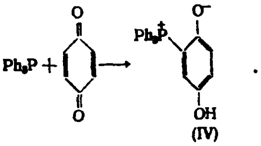
1,3-Benzoxaphosphole reacts with tetrachloro-1,2-benzoquinone to form the phosphinite (III):[16]



(III)

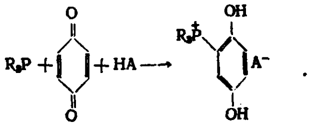
Tertiary phosphines readily react with quinones, forming products with P—O or P—C bonds,[17-20] whose structure is determined by the nature of the substituents in the quinone and the phosphine.

The addition of triphenylphosphine to *p*-benzoquinone leads to the phosphobetaine (IV):[4,17,18]

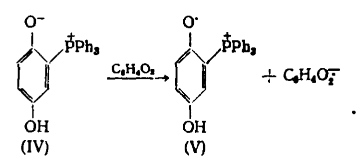


(IV)

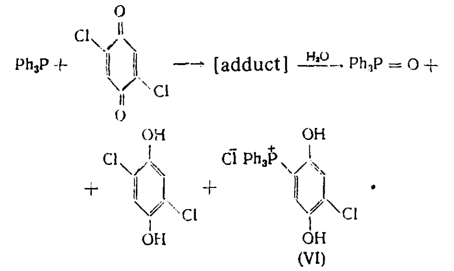
This reaction has been used to obtain a whole series of quaternary phosphonium salts, which are used to promote the interaction of vicinal epoxides with phenols and carboxylic acids or their anhydrides in order to obtain polymer films:[19]



The oxidation of the phosphobetaine (IV) can afford the paramagnetic radical-cation (V):[10,18]

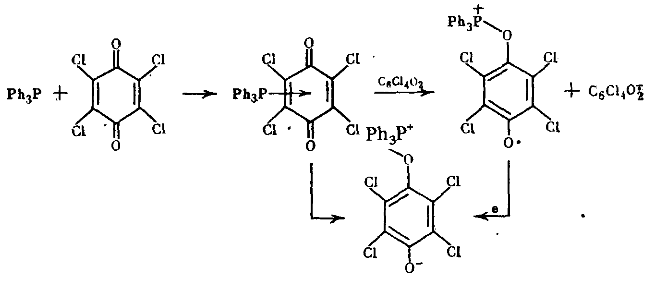


The interaction of triphenylphosphine with 2,5-dichloro-1,4-benzoquinone gives rise to an adduct, which is converted on treatment with water into diphenylphosphine oxide, 2,5-dichlorohydroquinone, and 2,5-dihydroxy-4-chlorophenyl(triphenyl)phosphonium chloride (VI):[20]

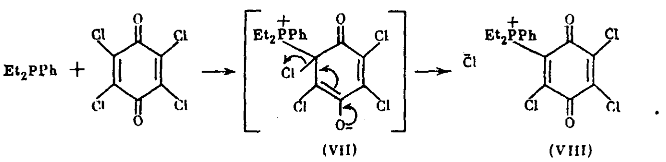


The EPR spectrum of the 2,5-dichloro-1,4-benzoquinone–triarylphosphine system, with a complex hyperfine structure of the signals, indicates the formation of phosphorus-containing paramagnetic species.[35]

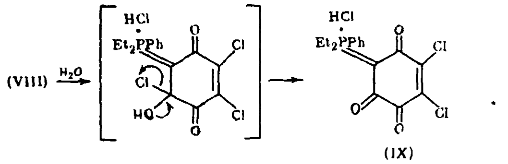
It has been demonstrated by UV and EPR spectroscopic methods that, in the reactions of triphenylphosphine with chloranil and also with bromoanil and iodanil, the paramagnetic products are formed mainly as a result of the oxidation by the quinone of phosphine–quinone charge-transfer complexes, but this is only one of the pathways leading to the final product:[17]



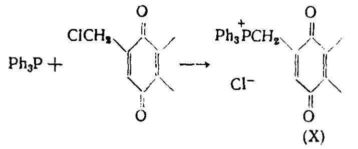
Diethylphenylphosphine reacts with chloranil to form the phosphorus-containing dipolar product (VIII), which is probably formed from the intermediate (VII):[21]



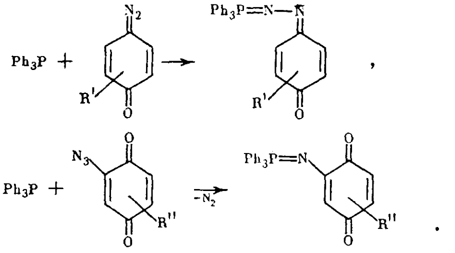
The chlorine atom in the *o*-position in the phosphabetaine (VIII) is readily substituted by a hydroxy-group from water, **which leads to a new type of stable phosphorus ylides (IX):**



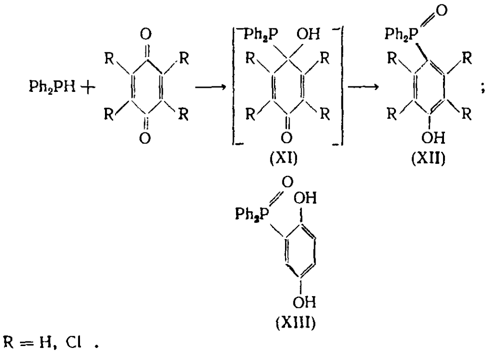
The interaction of phosphines with quinones having a chloromethyl substituent has been described. The main product is the phosphonium salt (X):[22]



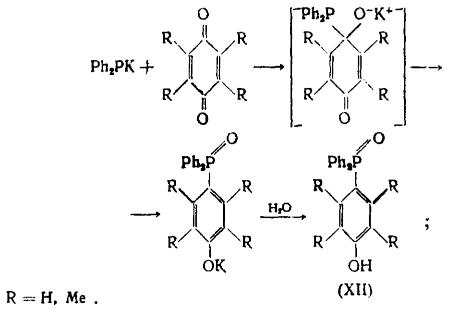
The adducts of phosphines with nitrogen-containing quinone derivatives also have a quinonoid structure:[4,23,24]



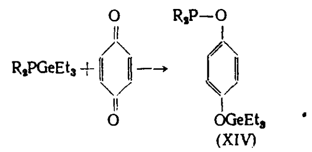
Secondary phosphines add to p-benzoquinones more vigorously than tertiary phosphines with formation of intermediates (XI) with a P–C bond, which are subsequently converted into the phosphine oxides (XII) [25] [however, according to other data,[26] the reaction product is compound (XIII)]:



The reaction apparently begins with nucleophilic attack by the phosphorus atom on the carbon of the carbonyl group.[25,27] It is accelerated with increase of the nucleophilicity of the phosphorus centre (for example, when hydrogen is replaced by an alkali metal[27]):

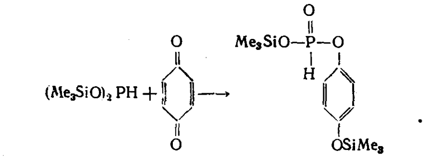


Dialkylgermylphosphine reacts with quinone via another mechanism. In this case the main product is *p*-triethylgermyloxyphenyl phosphinite (XIV)—a stable substance capable of being distilled, which was isolated from the reaction mixture in 50% yield:[28]

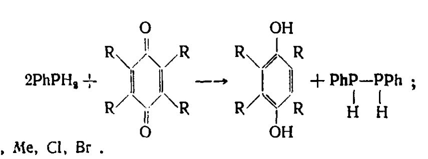


(XIV)

Silyl hypophosphites add to the 1,6-positions of p-benzoquinone without affecting the P–H bond:[29]

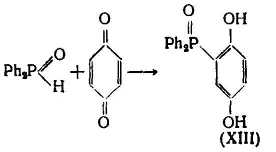


In contrast to secondary phosphines, primary phosphines do not add to quinones but reduce them to hydroquinones, being converted into diphosphines in this process:[30]



R = H, Me, Cl, Br .

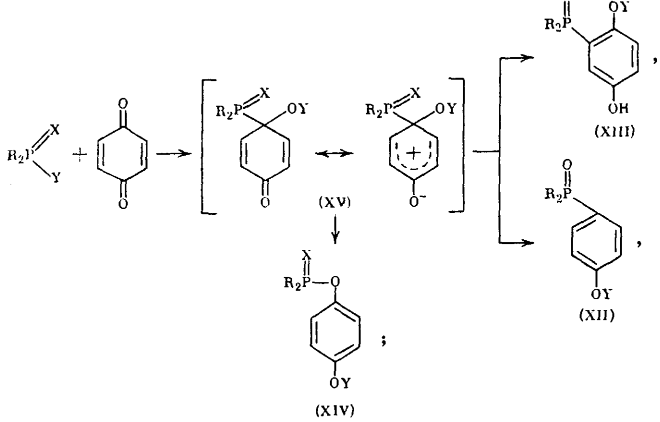
It is noteworthy that secondary phosphine oxides also react with quinones. The interaction of diphenylphosphinous acid with quinones leads to the C-phosphorylated adduct (XIII),[5,31] although, as will be shown below, almost all phosphorus-containing reagents having the general formula $R_2P{<}^{E}_{H}$ (R = AlkO, ArO, or Alk_2N: E = O, NR′, or S) react with quinones to form O-phosphorylation products:



(XIII)

It is believed[5] that this anomaly is caused by the involvement in the reaction of the tautomeric form of diphenylphosphinous acid with tricoordinate phosphorus.

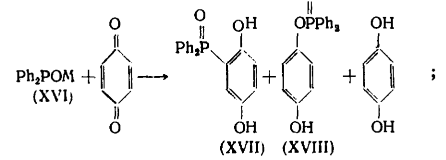
According to the views of other investigators, the intermediate (XV) is formed in this reaction and stabilised by being converted into the final C-phosphorylated hydroquinone (XIII):[7]



(XIII): R = Ar, X = O, Y = H: (XII): R = Ar, X = LEP (lone electron pair), Y = H, K; (XIV): R = Et, X = LEP, Y = GeR_3.

The characteristic features of the structure of the intermediate (XV) preclude the aromatisation process via the traditional deprotonation, since the ring carbon atom linked to the phosphorus group introduced contains no proton. Other pathways leading to the stabilisation of the cyclohexadienone, involving the migration of the phosphorus-containing group to the oxygen atom or a neighbouring carbon atom, are therefore followed.[7] Within the framework of the proposed scheme, one can also consider the mechanisms of the reactions of other organophosphorus compounds, namely diphenylphosphine, potassium diphenylphosphide,[25,27] and germylphosphine,[28] with p-quinones.

In contrast to diphenylphosphinous acid, its metal-substituted derivatives with p-benzoquinone to form both C- and O-phosphorylated products. For example, the phosphine oxide (XVII), the phosphinate (XVIII), and the hydroquinone in proportions of 1 : 1 : 1.5 and 1 : 0.5 : 1 have been isolated respectively in the reactions of lithium and magnesium salts of diphenylphosphinous acid (XVI) with p-benzoquinone:[32]

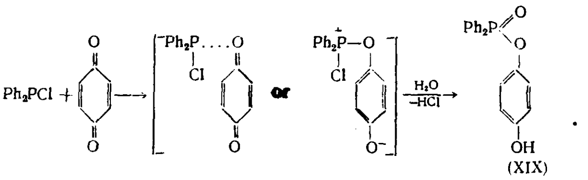


M = Li, MgCl.

The authors suggest that the phosphine oxide (XVII) is a result of the direct addition of the phosphinite (XVI) to a carbon atom of the quinonoid ring. The formation of two other products has been explained from the standpoint of the one-electron transfer mechanism.

In our view, the interaction can proceed via both the mechanism put forward by Koda et al.[32] and via the mechanism described above involving the initial addition of the phosphorus-containing reagent to a carbonyl group of the quinone and subsequent isomerisation of the intermediate (XV) to the O- and C-phosphorylation products.

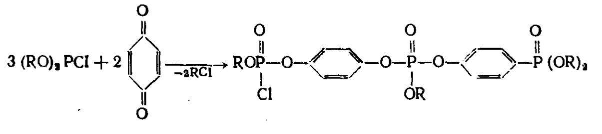
Chlorodiphenylphosphine reacts with quinone to form a 1 : 1 adduct to which the structure of a molecular or betaine-like complex has been attributed.[31] Treatment of the complex with water leads to the isolation of the O-phosphorylation product (XIX):



(XIX)

On the other hand, if the reaction is carried out in the presence of water, the C-phosphorylated hydroquinone (XIII) is formed. It is believed that chlorodiphenylphosphine hydrolyses to diphenylphosphinous acid, which is in fact the C-phosphorylating agent.[31]

Oligophosphates have been obtained in the reaction of dialkyl phosphorochloridites with 1,4-benzoquinone:[33]



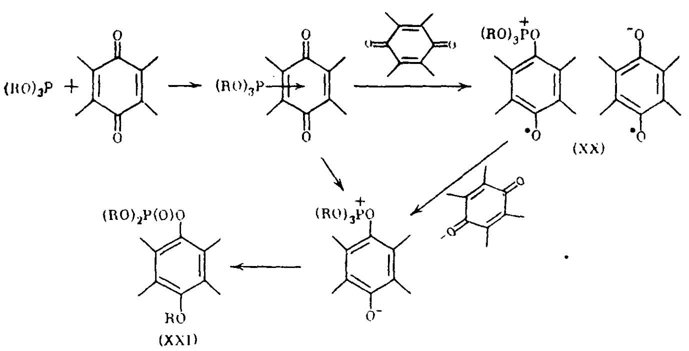
Thus the interaction of phosphines with quinones involves the intermediate formation of charge-transfer complexes and the subsequent structural reorganisation leads to the final reaction products. The pathway resulting in stabilisation depends significantly on the nature of the substituents in the reactants and in many cases can be interpreted in terms of the theory of hard and soft acids and bases.[21,34]

The formation of tertiary phosphine oxides (XII) and (XIII) is characteristic of secondary phosphines and metal phosphides.

Primary phosphines do not add to p-quinones and an oxidation-reduction process takes place instead.

2. Reactions of Phosphites with *p*-Quinones

All phosphite esters interact with p-quinone via the 1,6-addition mechanism.[2,3,21,35] This pathway predominates among other possible reaction pathways, since it leads to stable aromatic phosphates (XXI):



It has been suggested that the reaction mechanism involves the formation of the radical-ion pair (XX), but other pathways leading to the final products are also possible.[10,17]

Trimethyl phosphite adds to monosubstituted *p*-benzoquinones, affording mainly the O-phosphorylated adducts (XXII) and (XXIII) and sometimes the phosphonates (XXIV) (Table 1):[2]

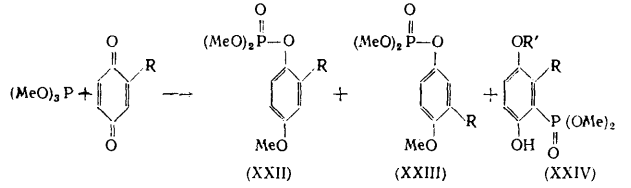


Table 1. The products of the reaction of trimethyl phosphite with *p*-benzoquinones.[2]

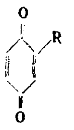
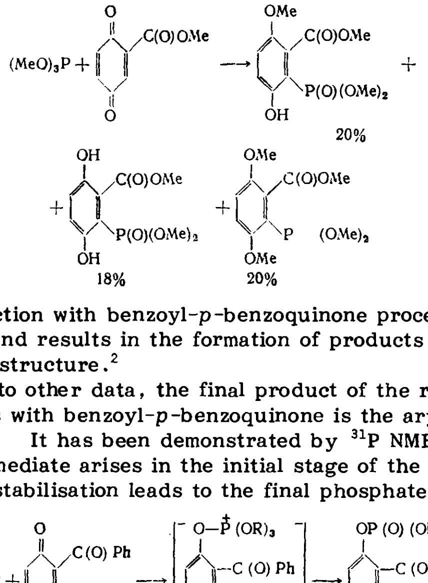


R	Yield of phosphate (XXII), %	Yield of phosphate (XXIII), %	Yield of phosphonate (XXIV), %*
OMe	79	2,5	—
Me	44	36	—
t-Bu	—	72	—
$SiMe_3$	—	67	—
CH_2OMe	17	50	—
Br	23	48	—
Cl	28	47	—
C(O)Ph	—	—	42
C(O)OMe	—	—	38

*The overall yield of the phosphonates (XXIV, R′ = H and Me).

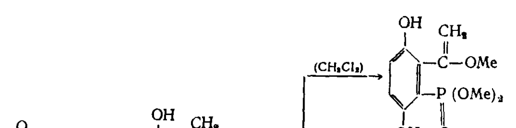
It has been established that the ratio of the phosphates (XXII) and (XXIII) is influenced by the nature of the substituent **R**. For example, the reaction with methoxy-p-benzoquinone produces mainly the 2-substituted aryl phosphate (XXII) and a small amount of the regioisomeric phosphate (XXIII). On passing to methyl-p-benzoquinone, the phosphorylation proceeds with a much lower degree of regioselectivity (Table 1). Nevertheless, t-butyl-*p*-benzoquinone and trimethylsilyl-p-benzoquinone react to form only the 3-substituted isomer (XXIII). Methoxymethyl-p-benzoquinone reacts with trimethyl phosphite to form the phosphates (XXII) and (XXIII) in proportions of 1 : 3, while in the reactions of bromo- and chloro-p-benzoquinones the products are in proportions of 1 : 2 (Table 1).

Only *C*-phosphorylated products have been detected in the reactions of trimethyl phosphite with quinones containing π-acceptor substituents. For example, phosphite reacts with methoxycarbonyl-*p*-benzoquinone to form phosphonates of type (XXIV):

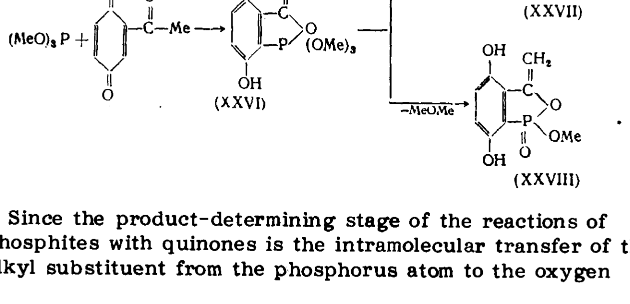


The interaction with benzoyl-*p*-benzoquinone proceeds analogously and results in the formation of products with the phosphonate structure.[2]

According to other data, the final product of the reactions of phosphites with benzoyl-*p*-benzoquinone is the aryl phosphate (XXV). It has been demonstrated by ^{31}P NMR that a dipolar intermediate arises in the initial stage of the reaction and that its stabilisation leads to the final phosphate (XXV):[36]

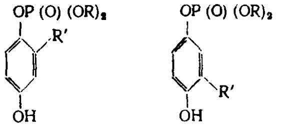


Acetylquinone reacts differently. It has been established that the phosphorane (XXVI) formed initially rearranges in CH_2Cl_2 to the methyl ester (XXVII). In other solvents, the phosphorane (XXVI) is converted into the cyclic phosphonate (XXVIII):[36]

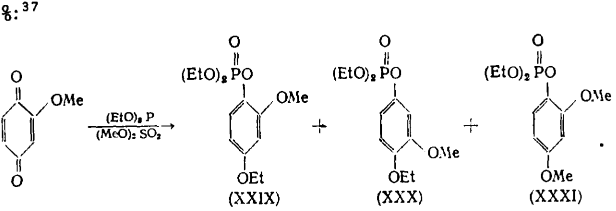


Since the product-determining stage of the reactions of phosphites with quinones is the intramolecular transfer of the alkyl substituent from the phosphorus atom to the oxygen atom in the *p*-position in the betaine intermediate, the addition of electrophiles to the reaction mixture can lead to the synthesis of non-traditional final compounds.

This type of result can be achieved when a source of protons is employed.[37] However, the method is not applicable to all quinones. Chlorotrimethylsilane is a more effective trapping agent. The reactions of quinones with the two-component phosphite/chlorotrimethylsilane system lead, after hydrolysis, to the formation of *p*-hydroxyaryl phosphates as the main product:[37]

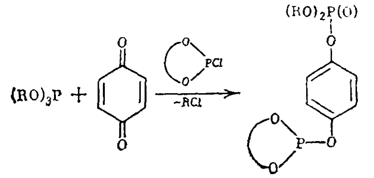


Dimethyl sulphate is yet another trapping agent. However, the reaction of triethyl phosphite with methoxy-*p*-benzoquinone in the presence of dimethyl sulphate affords the 4-ethoxyphosphates (XXIX) (49%) and (XXX) (12%). The yield of the expected 4-methoxyphosphate (XXXI) is only 5%:[37]

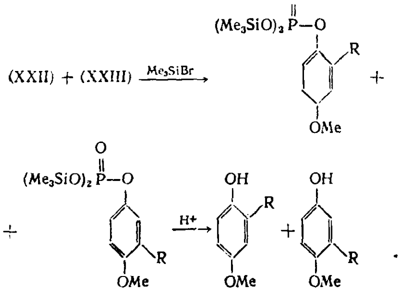


(XXIX) (XXX) (XXXI)

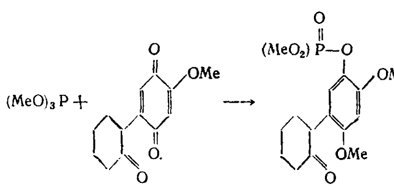
If cyclic phosphorochloridites are used as the trapping agents, then the products of the interaction of phosphites with *p*-benzoquinone are diphosphorylated hydroquinones. The compounds synthesised have many useful properties, in particular they impart fire resistance to materials:[38]



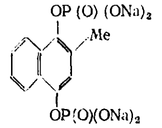
The hydrolysis of aryl dimethyl phosphates (XXII) and (XXIII) by refluxing in the NaOH/H₂O/ROH mixture or water in the presence of catalysts comprising a caesium fluoride[39] and the potassium fluoride cyclohexyl-18-crown ether system[40] gives rise to poor results, which may be a consequence of the tendency of electron-saturated dialkylphosphorylphenols to be oxidised, especially in basic media. The hydrolysis is more successful if the phosphates are subjected to preliminary dealkylation with bromotrimethylsilane and are converted into the corresponding silyl phosphates:[40]



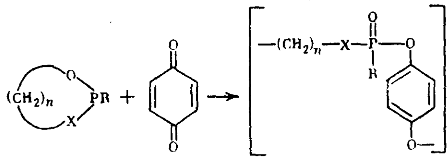
The interest in the reactions of phosphites with quinones has been aroused by the possibility of synthesising practically useful products, in particular biologically active preparations. The most convenient method of synthesis of 2-arylcyclohexanones, which are the basic compounds for the manufacture of the antibiotic "lysolipin I", is apparently based on this reaction:[2,41]



The tetrasodium salt of 2-methyl-1,4-naphthylene diphosphate, obtained from phosphite and 2-methyl-1,4-naphthoquinone, is one of the few radiosensitising agents for the radiotherapy of malignant tumours.[42] At a concentration of 4×10^{-6} M, this compound causes 50% suppression of mitosis in living tissues. It has been suggested that the action of this preparation consists in blocking the synthetic processes in cells associated with phosphorylation. It is noteworthy that the preparation itself has no therapeutic effect on malignant tumours.[42]



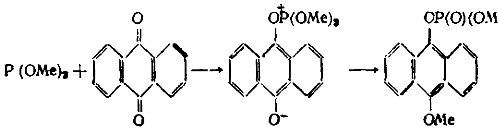
The synthesis of many industrial materials is based on the reactions of phosphites with quinones. For example, aromatic half-esters having the general formula $(OAr)_n$, used for the manufacture of moulded articles, adhesives, and fire extinguishing agents,[43] are formed by the reaction of substituted and unsubstituted quinones with compounds of tervalent phosphorus of the type $(RO)_2PR'$, while mixtures of cyclic phosphites and *p*-benzoquinone produce the polymers (XXXII), which have been used successfully as adhesives, plasticisers, and modifying agents reducing the combustibility of various chemical products:[44]



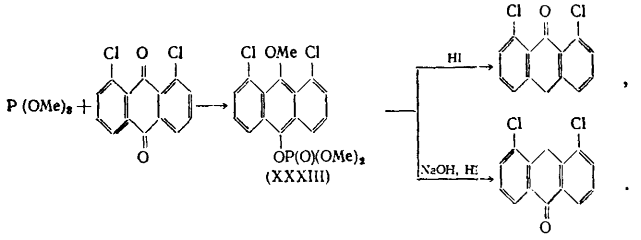
X = O, S, NR'.

(XXXII)

Under severe conditions, trimethyl phosphite is capable of adding to anthraquinone. The reaction mechanism includes two stages: the appearance of a dipolar intermediate and its isomerisation to the final 10-methoxy-9-dimethylphosphorylanthracene:[45]

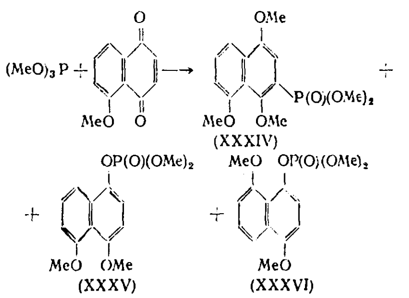


In the case of 1,8-dichloroanthraquinone, the relatively bulky phosphorus-containing residue enters the less hindered 10-position, while the methyl group enters the 9-position, forming the adduct (XXXIII):

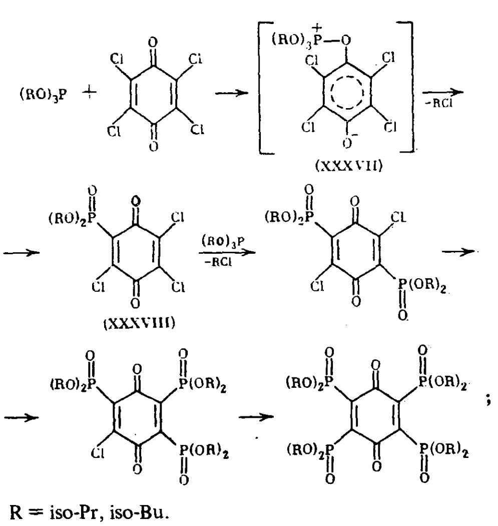


Selective hydrolysis of the methoxy- and phosphoryloxy-groups of the phosphate (XXXIII) and subsequent reduction of the hydrolysis products by hydriodic acid makes it possible to synthesise 1,8- and 4,5-dichloroanthrones which are otherwise difficult to obtain.[45]

The reactions of phosphites with naphthoquinones are less regioselective. Treatment of O-methyljuglone[5-methoxy-1,4-naphthoquinone] yielded all three possible isomeric products, the overall yield of the phosphates (XXXV) and (XXXVI) being lower than the yield of the phosphonate (XXXIV):[2]

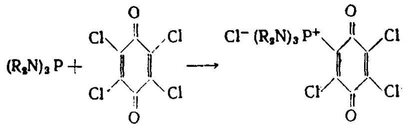


The reactions of phosphites having bulky alkyl substituents sometimes lead to unexpected results, in contrast to phosphites with unbranched substituents. Thus, instead of the usual addition to the quinone, the interactions of triisopropyl and triisobutyl phosphites with chloranil entail the substitution of the chlorine atoms in chloranil by phosphoryl groups. It has been suggested that the anomalous course of the reaction is caused by the steric hindrance of the dipolar intermediate (XXXVII), which is stabilised via the intramolecular Arbuzov reaction, affording the monophosphorylated quinone (XXXVIII). The latter reacts with the initial phosphite with successive substitution of the residual chlorine atoms in the quinone by phosphoryl groups:[46]

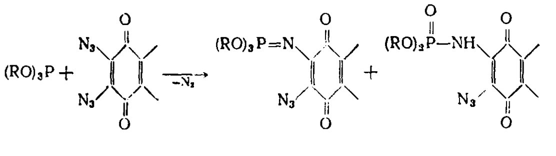


R = iso-Pr, iso-Bu.

Similar processes take place also in phosphorous triamides,[47] but in this system only one chlorine atom is substituted:

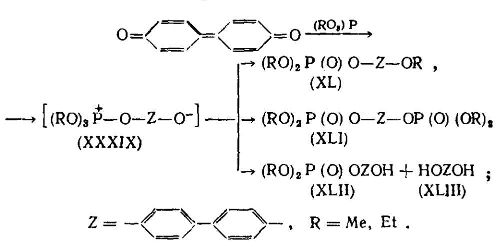


Trialkyl phosphites as well as phosphines react with azidoquinones. Although they are in the last place in the reactivity series of phosphoramidites (trialkylphosphines > triarylphosphines > trialkyl phosphites), nevertheless it is possible to isolate the products of their reactions with 2,3-diazidoquinone:[4,48]



Triaryl and trialkyl phosphorothioites do not react with azidoquinones.

The reactions of the full phosphite esters with diphenoquinone have been investigated in detail:[49]



4-Alkoxy-4′-biphenylyl dialkyl phosphate (XL), 4,4′-biphenylylene tetra-alkyl bisphosphate (XLI), dialkyl 4-hydroxy-4′-biphenylyl phosphate (XLII), 4,4′-dihydroxybiphenyl (XLIII), and the product of the self-polymerisation of diphenoquinone were isolated from the reaction mixture (Table 2).

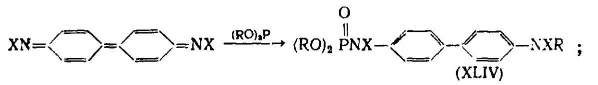
Table 2. Yields of the products of the reaction of $(RO)_3P$ with diphenoquinone[49]

R	Yields of products, %				
	(XL)	(XLI)	(XLII)	(XLIII)	Diphenoquinone polymer
Me	15	15	7	15	35
Et	17	15	5	*	50

*The yield was not accurately established.

The author suggests the following reaction mechanism. Initially there is nucleophilic addition of the phosphite to diphenoquinone with formation of the intermediate dipolar adduct (XXXIX), which subsequently rearranges to the phosphate (XL). According to the authors, the rearrangement proceeds via an intermolecular mechanism: the phenoxide oxygen of one molecule attacks the alkyl residue of another. When the object of attack by the phenoxide oxygen is the phosphorus atom, the process then terminates with formation of the bisphosphate (XLI). Owing to the inevitable presence of moisture, the adduct (XXXIX) hydrolyses and affords the phosphate (XLII) and dihydroxybiphenyl (XLIII). Together with the main reaction of the phosphite with diphenoquinone, another parallel reaction takes place—the polymerisation of diphenoquinone catalysed by the organophosphorus compound.

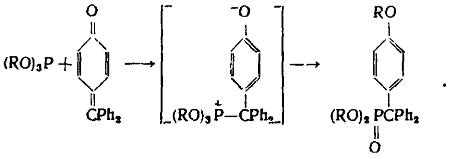
The products of the reactions of phosphites with diphenoquinoneimides are the phosphoramidates (XLIV), which have been isolated quantitatively:[49]



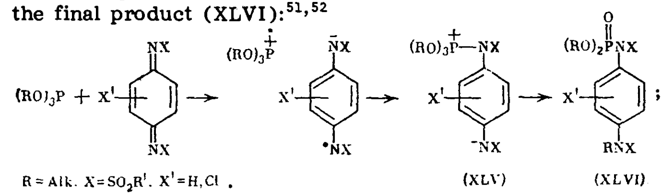
$X = SO_2Me$, SO_2Ph; $R = Me$, Et.

The reactivity of quinones in reactions with nucleophiles, including compounds of tricoordinate phosphorus, is determined both by the usual parameters (substituent, solvent, catalyst, etc.) and by specific parameters characteristic only of quinonoid systems. The latter include the oxidation-reduction properties of quinones. The redox potential of diphenoquinone (954 mV) is much higher than the potentials of "simple" quinones, for example chloranil (712 mV) or p-benzoquinone (696 mV).[4] This is in fact used to explain the significant differences between the reactions of phosphites with diphenoquinone.[49]

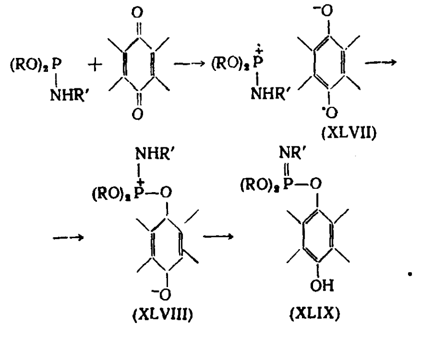
By virtue of the high electron-donating capacity of full phosphite esters, it is possible to achieve the reaction of quinonemethides with them. Fuchsone reacts with trialkyl phosphates on heating to form 1:1 adducts. As in most cases of the phosphorylation of *p*-quinones, in this instance the mechanism involves 1,6-addition to the conjugated bond system:[50]



The reaction with 1,4-benzoquinonebis-sulphonylimine begins with a one-electron transfer stage involving the formation of the phospite radical-cation and the quinonediimine radical-anion, whose interaction leads to the intermediate dipolar ion (XLV), which is transformed further into the final product (XLVI):[51,52]

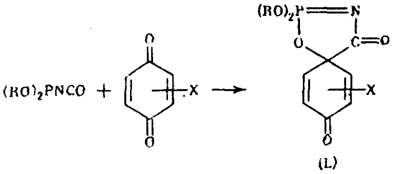


The amides of dialkylphosphorous acids readily interact with *p*-quinones, affording dialkyl *p*-hydroxyaryl *N*-organylphosphorimidates (XLIX):[53]



The signals of the chloroanil radical-anion and the phosphite radical-cation can be detected in the EPR spectra of the reaction mixture of *N*-acetylphosphoramidite and chloranil. A reaction mechanism has been proposed involving the initial formation of the radical-ion pair (XLVII), whose reaction via the stage involving the dipolar intermediate (XLVIII) leads to the final product (XLIX).[53]

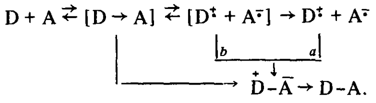
The interaction of *p*-benzoquinone with dialkyl phosphoroisocyanatidites is unusual: cycloaddition with participation of the carbonyl group in the quinone affords crystalline sparingly soluble oxazaphosphaspirocyclohexadienones (L):[54]



(L)

In the general case the interaction of compounds of tricoordinate phosphorus with *p*-quinones and their derivatives can be considered from the standpoint of one-electron transfer between the donor (D), i.e. the phosphorus(III) compound, and the acceptor (A), i.e. the *p*-quinone. This process is arbitrarily divided into three stages:[55] (1) the stage involving partial electron transfer (the formation of a charge-transfer complex); (2) the stage with total charge transfer (the formation of a radical pair in a solvent "cage"); (3) the stage involving the formation of fairly stable products (recombination or the emergence of the products from the "cage").

The following process mechanism can be put forward for the reactions of phosphorus(III) compounds with quinones:



$$D + A \rightleftarrows [D \to A] \rightleftarrows [D^{\dot{+}} + A^{\dot{-}}] \to D^{\dot{+}} + A^{\dot{-}}$$
$$\overset{+}{D}-\overset{-}{A} \to D-A.$$

Complexes $[D \to A]$ with partial electron transfer are formed initially and are followed by complexes $[D^{\dot{+}} + A^{\dot{-}}]$ with complete electron transfer. The radical-ion pair then emerges from the solvent "cage" and the free paramagnetic radical-ions $D^{\dot{+}}$ and $A^{\dot{-}}$ appear and in many cases can be detected by chemically induced dynamic nuclear polarisation (CIDNP) and electron paramagnetic resonance (EPR) methods. The recombination of the radical species via pathway *a* or *b* leads to the dipolar structures $\overset{+}{D}-\overset{-}{A}$, which in the case of phosphines are the final reaction products. The betaines $\overset{+}{D}-\overset{-}{A}$ can also be stabilised directly starting with the complex $[D \to A]$, by-passing the one-electron transfer stage.[10] The majority of the processes occurring in the phosphite (phosphine)—*p*-quinone system fit within the framework of the proposed mechanism.

3. The Reactions of Tricoordinate Phosphorus with o-Quinones

The polarographic method has been applied to the study of electron affinities of various quinones (Table 3).

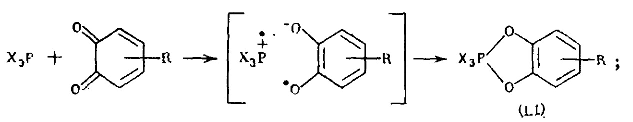
When a number of *o*- and *p*-quinones were reduced, two one-electron reduction stages with fairly different half-wave potentials were observed.

The data in Table 3 permit the following conclusions: firstly, *o*- and *p*-quinones have similar electron affinities and one-electron transfer with the intermediate formation of radical-ions is therefore also possible for the reactions of *o*-quinones; secondly, the smaller difference between the first and second half-wave potentials ΔE for o-quinones compared with p-quinones shows that the transition from the one-electron mechanism to the two-electron mechanism is easier for o-quinones than for p-quinones.[56]

Table 3. Polarographic characteristics of the reduction of quinones.[56]

Quinone	$E'_{1/2}$, V	$E''_{1/2}$, V	$\Delta E = E''_{1/2} - E'_{1/2}$
Chloranil	−0.25	−1.17	−0.92
p-Benzoquinone	−0.56	−1.53	−0.97
Naphthoquinone	−0.81	−1.70	−0.89
Tetrabromo-*o*-benzoquinone	0.15	−0.57	−0.72
Tetrachloro-*o*-benzoquinone	−0.25	−0.61	−0.36
9,10-Phenanthrenequinone	−0.60	−1.23	−0.63
4,5-Dimethoxy-1,2-benzoquinone	−0.70	−1.20	−0.50

It has been established that both phosphines and phosphites react with *o*-quinones, affording adducts with the phosphorane structure (LI):[3,13,57]



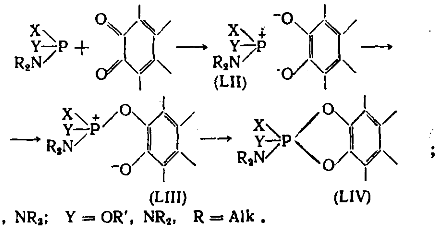
(LI)

X = Alk, Ar, AlkO, ArO, Cl .

A process mechanism incorporating a one-electron transfer stage, analogous to the mechanism of the reactions of phosphorus(III) compounds with *p*-quinones examined previously, has been proposed on the basis of kinetic and spectroscopic data.[58]

Phosphorus trichloride interacts with tetrachloro-*o*-benzoquinone, 9,10-phenanthrenequinone, 4,6-di(t-butyl)-1,2-benzoquinone, and 1,2-naphthoquinone, forming trichloro-1,2-phenylenephosphoranes (LI). A characteristic doublet signal, due to the interaction of the unpaired electron with the phosphorus nucleus, can be observed in the EPR spectra of the reaction mixtures, which indicates the possibility of the appearance of phosphorus-containing radical-ion species in the course of the reaction.[59]

EPR study of the interaction of phosphoramidites with tetrachloro-o-benzoquinone showed that the o-chloranil radical-anion and the phosphoramidite radical-cation (LII) exist for a time in the reaction mixture. The authors suggested that involvement of these species in the formation of the dipolar intermediate (LIII), which is converted into the final phosphorane (LIV):[56,57]

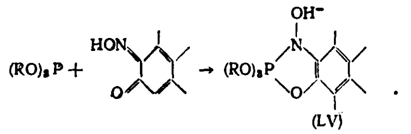


(LII) (LIII) (LIV)

X = OR', NR₂; Y = OR', NR₂, R = Alk .

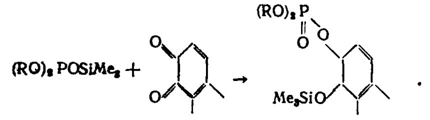
Phosphoramidites interact analogously with tetrabromo-*o*-benzoquinone. The one-electron transfer mechanism does not operate in all the reactions of 9,10-phenanthrenequinone, which has a smaller electron affinity (see Table 3), with phosphoramidites. On passing to 4,5-dimethoxy-1,2-benzoquinone, which is a still weaker acceptor, the formation of paramagnetic species is never detected. This confirms the conclusion that the replacement of the one-electron mechanism by the two-electron mechanism is more probable for *o*-quinones than for p-quinones.

The overall mode of reaction of phosphites with *o*-quinones, leading to the formation of phosphorane adducts, persists also for *o*-quinone monoximes. On reaction with phenanthrenequinone monoxime, trialkyl phosphites give rise to cyclic nitrogen-containing phosphoranes (LV), from which the initial quinone oxime can be regenerated:[60]



(LV)

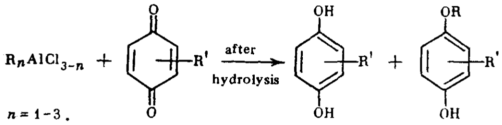
Silicon-containing phosphites react with *o*-quinones in the same way as with *p*-quinones, producing *o*-siloxyaryl phosphates:[61-63]



The absence from the given process of products with a pentacoordinate phosphorus atom is probably associated with their instability and ready isomerisation to aryl phosphates as a consequence of the high lability of the trimethylsilyl group.[14]

It is of interest to compare the reactivities of tricoordinate phosphorus compounds and other organoelemental nucleophiles in reactions with quinones. It has been established that the incompletely substituted alkyl(aryl)chloro(silanes) react on heating with *p*-benzoquinone in the presence of platinum catalysts, affording silyl ethers of hydroquinone.[64]

Hydroquinones and their monoalkyl ethers have been synthesised by the reaction of organoaluminium compounds with *p*-quinones and subsequent hydrolysis of the products:

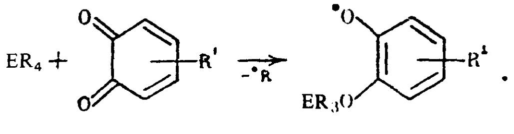


Paramagnetic intermediates—aluminium salts of semiquinone—were detected in the reaction of triethylaluminium and aluminium chloride with *p*-benzoquinone.[65]

2-Alkyl-3-chloro-1,4-naphthoquinones can be obtained from a mixture of trialkylaluminium with 2,3-dichloro-1,4-naphthoquinone. Similar naphthoquinones are formed in the reaction with participation of alkylzinc chlorides and tetra-alkylstannanes.[66] When gallium trichloride interacts with *p*-benzoquinone, 2:1 complexes are produced. The dipole moments for the formations of these compounds were determined by dielectric constant measurements.[67]

Thus organotin, organozinc, organoaluminium, and organosilicon, as well as organoantimony and organoarsenic compounds[68,69] do not add to *p*-quinones, in contrast to phosphorus(III) reagents, but convert them into alkylquinones, alkylhydroquinones, and hydroquinone ethers, the reactions requiring heating and the use of catalysts. However, despite the significant difference between the types of interaction of organophosphorus and other organoelemental compounds with *p*-quinones, the majority of the reactions proceed via a stage involving the formation of radical-ion species.[65,68,69]

The reactions of various metal halides with *o*-quinones have been studied in detail. The investigation of the EPR spectra of complexes of 1,2-naphthoquinone and 9,10-phenenthrenequinone with aluminium, gallium, and indium halides led to the conclusion that the compounds MX_3 exhibit electron-donating properties in relation to *o*-quinones. Electron transfer from the metal halides to the *o*-quinone molecule with formation of a paramagnetic chelate complex has been suggested.[70] Paramagnetic complexes were also obtained in reactions of *o*-quinones with organometallic compounds ER_4 (E = Sn, Si, or Ti; R = alkyl or halogen):

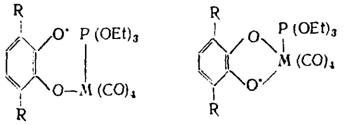


The reaction of tin tetrachloride with 3,6-di(t-butyl)-1,2-benzoquinone resulted in the formation of the *o*-benzosemiquinone complex, which a tetragonal pyramidal structure assigned on the basis of spectroscopic data.[71]

Evidently in their reactions with *o*-quinones organoelemental compounds having an unshared electron pair behave as electron-donating agents and, depending on the nature of the central atom and its environment, form cyclic or acyclic adducts.

In conclusion of this Section, devoted to a survey of studies on the reactions of phorphorus(III) compounds with quinones, the *o*-semiquinonoid complexes of metals with phosphite ligands must be considered.

The photolysis of metal decacarbonyls produces the radicals $M(CO)_5$ (M = Mn or Re),[72] whose interaction with *o*-quinones and triethyl phosphite leads to the appearance of the primary radical (LVI), which is converted further into the secondary radical (LVII):[73]



(LVI) (LVII)

M = Mn, Re; R = t-Bu.

Kinetic measurements have shown that the rate of conversion (k = 0.0013 s^{-1}) of the radical (LVI) into the radical (LVII) is appreciably lower than the rate of conversion (k = 0.017 s^{-1}) of the analogous non-phosphorus radicals.[73] The large difference between the rate constants for the destruction of the primary radicals as a function of the presence of the phosphite ligand has been attributed to the influence of the electron-accepting properties of triethyl phosphite on the rate-limiting stage of the process.[74] It also follows from the EPR spectra that the substitution of a CO group by a triethyl phosphite molecule in the radical (LVI) and (LVII) shifts the electron density from the *o*-quinonoid ligand to the phosphorus atom.

A similar conclusion follows from the analysis of the electronic absorption spectra of complexes of types (LVI) and (LVII). It has been suggested that the shift of electron density as a result of exchange interactions between the phosphorus and oxygen atoms proceeds via the *d* orbitals of the metal atom by virtue of the coplanarity of these atoms.[73,75]

III. COMPOUNDS OF TETRACOORDINATE AND PENTACOORDINATE PHOSPHORUS

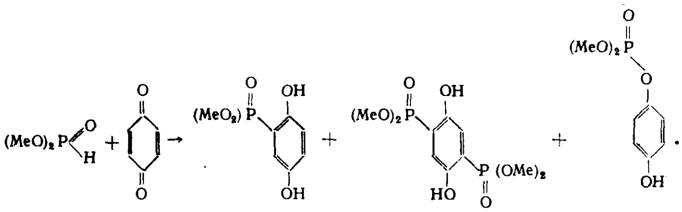
1. Reactions of Dialkyl Phosphites with Quinones

Almost all hydrophosphoryl compounds give rise to *O*-phosphorylation products in their reactions with quinones.[76-84,109] Hydrophosphites are no exception. The reaction of *p*-benzoquinone with 50% hypophosphorous acid results in the formation of reduction products—quinhydrone and hydroquinone, but, when this reaction is carried out in an anhydrous medium or in the presence of a small amount of water, an adduct, namely mono-*p*-hydroxylphenyl phosphite (yield up to 46%), is formed together with the benzoquinone reduction products:[76,77]

$$H_2P(O)OH + O{=}C_6H_4{=}O \rightarrow HP(O)(OH)O{-}C_6H_4{-}OH\ .$$

It has been established that dialkyl phosphites add to various *o*- and *p*-quinones, forming dialkyl hydroxyaryl phosphates.[78-84] The reaction is accelerated in the presence of bases, but can proceed also via a homolytic pathway.[7]

An exception to this general rule is the interaction of dimethyl phosphite with *p*-benzoquinone, which leads to the formation of the *C*-phosphorylated product (LVIII) and the *CC*-diphosphorylated product (LIX). An adduct having the phosphate structure has also been detected in the reaction mixture:[85]



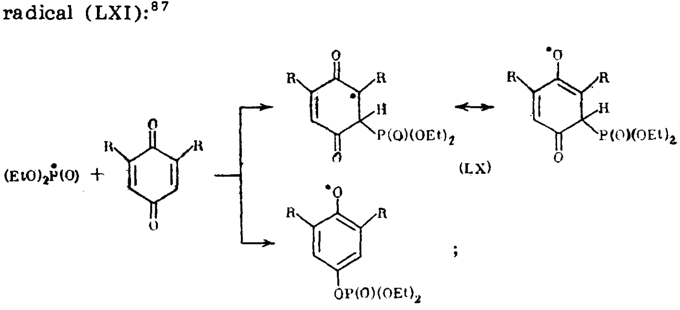
(LVIII) (LIX)

The photolysis of the corresponding hydrophosphoryl compounds in the presence of di(t-butyl) peroxide leads to the formation of phosphoryl radicals:[86]

$$Me_3COOCMe_3 \xrightarrow{h\nu} 2Me_3CO^{\cdot}\ ,$$

$$(RO)_2P(O)H + {}^{\cdot}OCMe_3 \xrightarrow[-Me_3COH]{} (RO)_2\dot{P}(O)\ .$$

These radicals add to 2,6-di(t-butyl)-1,4-benzoquinone, affording the phosphonate radical (LX) and the phosphate radical (LXI):[87]



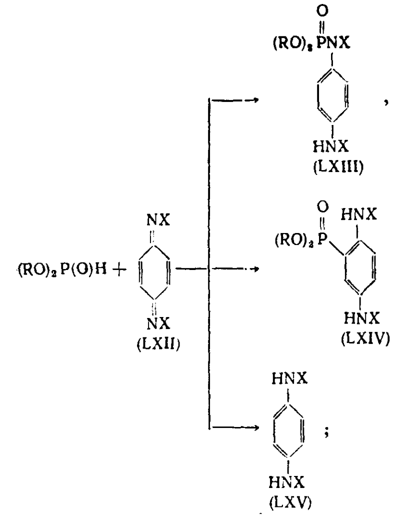
(LX)

R = t-Bu. (LXI)

Species with an analogous structure are formed in the reactions of phosphonyl radicals with quinonemethides and 3,3,5,5-tetra(t-butyl)diphenoquinone.[87]

The synthesis of phenoxy-radicals of types (LX) and (LXI) by easy methods is a problem of current importance whose solution would lead to prospects for the synthesis of a wide variety of phosphorus-containing aromatic compounds.

Dialkyl phosphites react with p-benzoquinonebisbenzenesulphonylimine (LXII), forming a mixture consisting of the phosphoramidate (LXIII), the phosphonate (LXIV), and the bisamide (LXV):



R=Alk, X=SO_2Ph .

The yield of the compounds depends on the nature of the phosphite reagent, the molar ratio of the reactants, and the reaction conditions (Table 4).[88]

Table 4. The reaction of $(RO)_2P(O)H$* with p-benzoquinonebisbenzenesulphonylimine (LXII).[88]

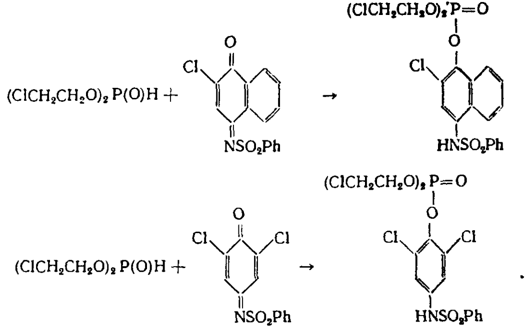
*The ratio $(RO)_2P(O)H$: (LXII) = 15 : 1.
**$(RO)_2P(O)H$ with a low purity.

All three products are obtained from dimethyl and diethyl phosphites, while diisopropyl phosphite gives rise to only the phosphonate (LXIV) (see Table 4). It has been noted that the quinoneimine (LXII) reacts with dialkyl phosphites only in the presence of a fifteenfold excess of the phosphite. If the amount of phosphite is less, then the reaction does not occur whatever the conditions. This is true only for freshly distilled dialkyl phosphites. When reagents with a low degree of purity are used, hydrolysis results in the formation of phosphorous acid, which has powerful reducing properties. Under these conditions, the main reaction product is the bisamide (LXV) (Table 4).

An increase of temperature and reaction time decreases the yields of the phosphorus compounds and increases the yield of the bisamide (LXV). The presence or absence of the solvent in the reaction mixture has almost no effect on the ratio of the reaction products.[88]

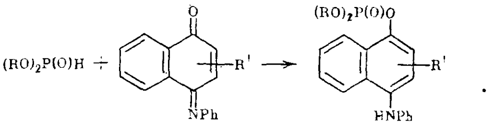
In order to obtain practically useful compounds, di(chloroalkyl) phosphites were introduced into the reaction with quinoneimines:



The resulting 2-chloro- or 2,6-dichloro-arene-4-sulphonamidoaryl di(chloroalkyl) phosphates have been recommended as additives to oils and fuels.

In contrast to the reactions of unsubstituted dialkyl phosphites, this process proceeds more vigorously, requiring a lower temperature to initiate the reaction.[89]

p-Quinone anils combine with dialkyl phosphites to form O-phosphorylated adducts:[84]

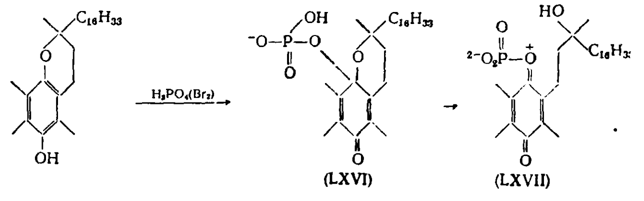


2. Reactions of Phosphates with Quinones

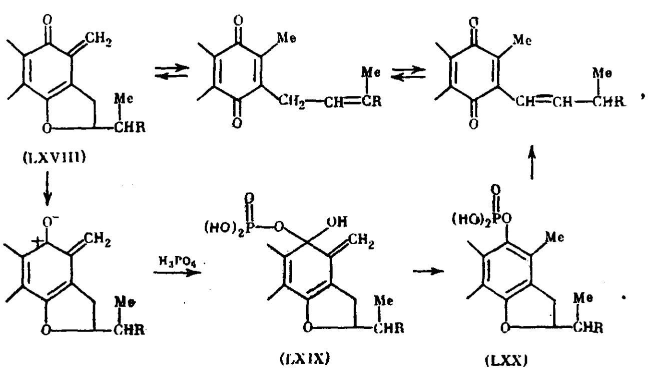
Many natural products, isolated from higher and lower plants and animals, belong to the class of quinones. They include dyes, growth regulators, antibiotics, and catalysts of respiratory processes. For example, juglone, detected in the roots and leaves of the walnut tree, exhibits a pronounced allelopathic activity, lawsone, the yellow pigment of henna leaves, is known as a fungicide, plumbagin, identified in the roots, stems, and leaves of certain tropical plants, is a mirobicide, and quinones of the vitamin K series, contained in micro-organisms and plants, are catalysts of the biosynthesis of certain proteins.[90]

The interest of chemists in the reactions of such natural products with various reagents, including organophosphorus reagents, is understandable, because such investigations are closely related to the synthesis of promising biologically active preparations.

It has been found that the product of the reaction of the natural terpene tocopherol with phosphoric acid tocopheroxide (LXVI), whose acetal phosphate group is capable of phosphorylating adenosine diphosphoric acid with formation of its triphosphoric acid analogue—the energy source in cell processes. The active principle is in this instance the quinonoid system (LXVII), which acts as a phosphorylating agent:[91]

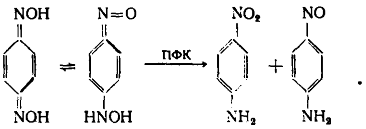


Phosphoric acid also adds to one of the active forms of vitamin K_1 (LXVIII) with formation of the phosphate (LXIX), which is subsequently reduced by flavin-nucleotide to the phosphate (LXX). On treatment with adenosine diphosphate and cytochrome, the latter gives rise to the initial quinone and adenosine triphosphoric acid:[92]

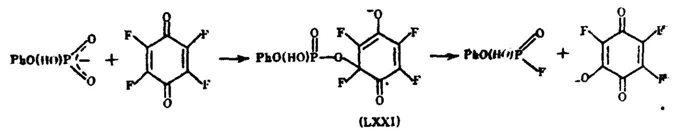


(LXVIII) (LXIX) (LXX)

It has been established that in the presence of an excess of polyphosphoric acid (PPA), quinone dioxime disproportionates with formation of p-nitroaniline and p-nitrosoaniline, which can be isolated respectively from diluted and neutralised solutions:[93]



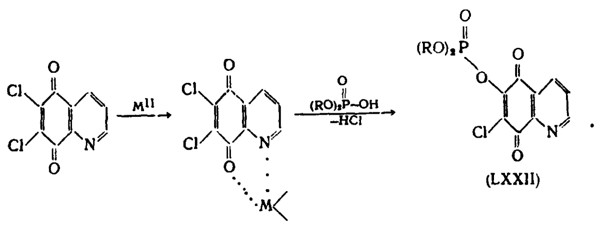
The anion of the phenyl ester of phosphoric acid, which is an active nucleophile, interacts with fluoranil. The fragmentation of the intermediate (LXXI) formed initially leads to the final reaction products:[94]



(LXXI)

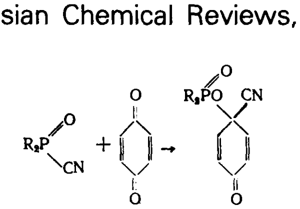
This reaction can be used as a method of synthesis of phosphorofluoridic acids.

Dialkylphosphoric acids do not interact with 6,7-dichloroquinoline-5,8-quinone, but in the presence of transition metal ions the reaction does occur. The products of the catalytic process are substituted quinolinequinones (LXXII). The activating effect of the metal ion has been explained by the increase of the deficiency of electron density at the C(6) atom, which promotes the substitution of the chloro-group in this position (as the chloride anion) by the phosphoryl group:[95]

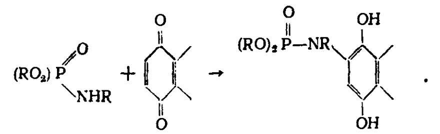


(LXXII)

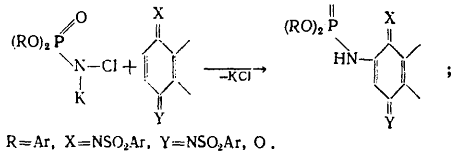
A rare variant of the nucleophilic addition to a C=O bond of the quinone occurs in the reactions of phosphinic acid cyanides with p-benzoquinone:[96]



Phosphoramidates having the N–H bond interact with quinones, forming phosphorylated 1,4-adducts:[47]



It has been established that quinoneimines can be aminated by N-chlorophosphoramidates:[97]

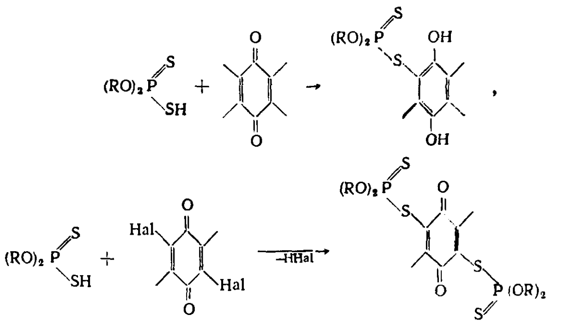


R=Ar, X=NSO_2Ar, Y=NSO_2Ar, O.

Among compounds of tetracoordinate phosphorus, sulphur-containing phosphates have been studied in greatest detail in their reactions with quinones because their preparative and kinetic investigation is easy.

The interaction of phosphorodithioates with quinones proceeds readily and fairly selectively in the absence of catalysts. The reaction products can be isolated from the reaction mixture quantitatively, do not require special purification, and their identification presents no difficulties. Phosphorodithioates and quinones are uncommonly suitable reactants for kinetic and spectroscopic studies. The advantages enumerated above as well as the ready availability and stability of the initial compounds have made the reactions of phosphorodithioic acids with quinones irreplaceable as objects of comprehensive and profound study.

Phosphorodithioic acids enter into addition[98] or substitution[99] reactions with quinones and their halogeno-derivatives:



The products have found applications in veterinary science and the pharmaceutical industry and are used as antioxidants and insecticides. As representatives of the class of phosphorodithioates, they are characterised by a broad spectrum of insectoacaricidal activity, rapidity of action, small consumption of the preparation per unit area treated, and the absence of toxic residues. They are most effective in the fight against insect species resistant to other organophosphorus insectoacaricides.[100]

It has been found that the silyl esters of phosphorodithioic acid are also capable of adding to p-quinones with formation of 1,4-addition products.[101]

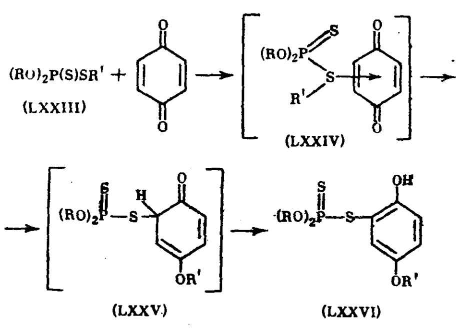
Spectrophotometric study of the reaction involving the addition of phosphorodithioic acids and silyl phosphorodithioates to *p*-benzoquinone showed that the rate of reaction is described by a second-order equation, of first order with respect to each reactant. Silyl phosphorodithioates are less reactive in heptane than the corresponding acids and the sensitivity of the reaction to the influence of substituents at the phosphorus atom is low. Whereas a tendency for the reaction to be accelerated with increase of the acidity of individual groups of dithio-derivatives of phosphorus (phosphates, phosphonates, and phosphinates) has been traced, overall there is no such trend. This may be a consequence of the important role of not only the acid but also the nucleophilic properties of phosphorodithioates in the addition reaction.[103]

An appreciable increase of the rate of reaction is observed in basic solvents. In the correlation equations taking into account the influence of the polarity, polarisability, and specific properties of the medium[102] on the rate of reaction of *OO*-diethylphosphorodithioic acid and its *S*-trimethylsilyl ester with *p*-benzoquinone, only the contribution of the nucleophilic solvation of the solvent is statistically significant.[103]

On passing to media with pronounced nucleophilic properties, the reactivity of silyl phosphorodithioates becomes comparable in terms of rate of reaction to that of phosphorodithioic acids.

In order to elucidate the cause of such relations, the deuterium kinetic isotope effects (KIE) have been investigated for phosphorodithioic acids and *p*-benzoquinone in various solvents. In all cases the "reverse" KIE is observed for the dithio-acids, which indicates an appreciable strengthening of the binding of the hydrogen atom in the transition state of the proton transfer stage from the phosphorus-containing reactant (LXXIIIa) to *p*-benzoquinone and may be a consequence of the fact that the activated complex has a structure resembling that of the intermediate (LXXV).[104]

When deuteriated *p*-benzoquinone was used, the KIE for the reaction with phosphorodithioates (LXXIIIa, b) in heptane and benzene proved to be unity, i.e. the migration of the ring proton takes place after the rate-limiting stage of the reaction. In basic media (dioxan, acetonitrile), where the KIE exceeds unity, the conversion of the intermediate (LXXV) into the product (LXXVI) becomes rate-determining. An analogous pattern of changes in the KIE for *p*-benzoquinone has been observed also in the reaction with *OO*-diethyl *S*-trimethylsilyl phosphorodithioate.

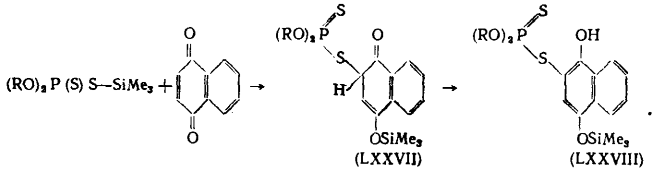


(a) R'= H (D):(b)R' = Si .

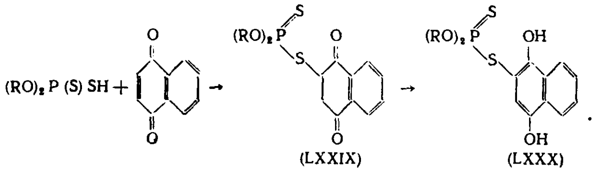
The set of data examined suggests that the addition of phosphorodithioates to *p*-benzoquinone proceeds in accordance with the scheme presented above. The fact that the same mechanism operates in the interaction of phosphorodithioic acids (LXXIIIa) and their *S*-trimethylsilyl esters (LXXIIIb) with quinone has been confirmed by the correlation between lg *k* for both processes in the media employed.[103]

In view of the high electron-accepting capacity of *p*-benzoquinone [105] and the appreciable nucleophilicity of the sulphur in phosphorodithioates,[106] the initial formation of a complex of the *n*–π type (LXXIV) may be postulated. Its concentration and stability are evidently low, since it is not detected spectroscopically. This factor does not in its turn rule out the possibility of the reversal of the initial step of the interaction under certain experimental conditions. Next, the complex is converted endothermically into the intermediate (LXXV) and in weakly basic media this process is rate-determining, so the silyl phosphorodithioates are more reactive than phosphorus acids. The presence of the complex formation stage and the appearance of a late rate-limiting transition state explain the low sensitivity of the rate of reaction to the influence of substituents at the phosphorus atom and to the dielectric properties of the medium.[107] In markedly nucleophilic solvents, the transfer of the ring proton to the carbonyl group of the intermediate, (LXXV) → (LXXVI), becomes rate-determining and the reactivity of silyl phosphorodithioates is comparable, in terms of the rate of reaction, to that of phorphorus acids.

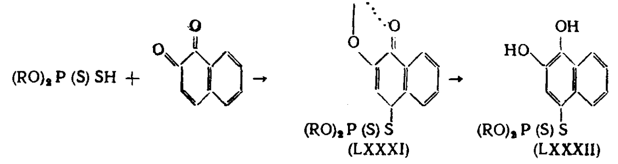
The interaction of phosphorodithioic acids and silyl phosphorodithioates with 1,4-naphthoquinone proceeds in accordance with a mechanism formally analogous to that in the reaction with *p*-benzoquinone. In the case of silyl phosphorodithioates, the 1,4-adduct (LXXVII) is formed as an intermediate, as in the reaction with *p*-benzoquinone:



However, it follows from the analysis of the time variation of the IR spectra of a mixture of solutions of 1,4-naphthoquinone and the dithio-acid that a product (LXXIX) of the addition to a C=C bond of the quinone is formed initially and is then gradually converted into dihydroxyphosphorothioylthionaphthalene (LXXX):[108]



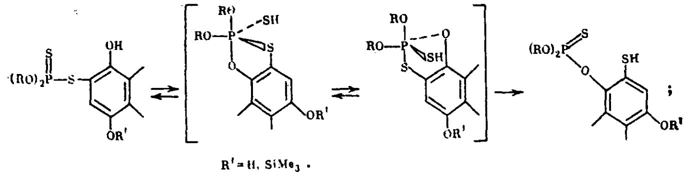
The reaction of phosphorodithioic acids with 1,2-naphthoquinone is unusual. The intermediate (LXXXI), detected by IR spectroscopy, isomerises over a period of time to the final adduct (LXXXII):



The stability of the enolic form of the intermediate (LXXXI) is apparently due to the energy gain by the system as a result of the formation of a stable intramolecular hydrogen-bonded complex.[108]

Thus the mechanism of the reactions of phosphorodithioic acids with quinones depends on the structure of the unsaturated reactant and involves the initial addition either to a C=C double bond or to the C=C – C=O conjugated system; silyl phosphorodithioates form initially 1,4-adducts in all cases.

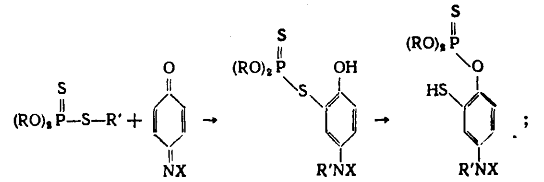
The final products of the reactions of phosphorodithioates with the *p*-quinones (LXXVI), (LXXVIII), and (LXXX) are capable of isomerising on heating to the corresponding phosphoromonothioates.[103,107] The mechanism of the rearrangement involves the intermediate formation of mercaptophosphoranes:



R' = H, SiMe$_3$.

Kinetic study of the isomerisation,[103,107] which takes place via a unimolecular mechanism, showed that the influence of the nature of the substituents at the phosphorus atom is determined by a set of electronic and steric factors and obeys the rules of the "hydroxyphosphorane concept".[110]

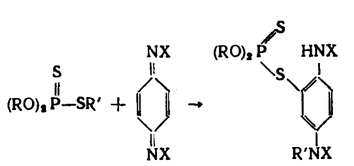
The interaction of phosphorodithioates with *N*-benzenesulphonyl-1,4-quinoneimine affords 5-(*N*-benzenesulphonamido)-2-hydroxyphenyl phosphorodithioates (LXXXIII), which isomerise to the corresponding phosphoromonothioates (LXXXIV):



(LXXXIII) (LXXXIV)

R'=H, SiMe$_3$; X=SO$_2$C$_6$H$_5$.

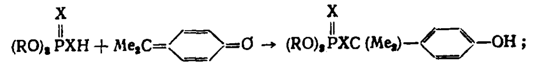
On passing to 1,4-quinonediimines, the reaction stops at the adduct (LXXXV) formation stage:[101]



(LXXXV)

R'=H, SiMe$_3$; X=SO$_2$Ph .

Phosphates and phosphorodithioates also add to quinonemethides, the reaction resulting in the formation of 1,6-adducts:[111]



$$(RO)_2\overset{X}{\overset{\|}{P}}XH + Me_2C{=}C_6H_4{=}O \rightarrow (RO)_2\overset{X}{\overset{\|}{P}}XC(Me_2){-}C_6H_4{-}OH\,;$$

X=O, S .

It is noteworthy that not only phosphorodithioic acids but also other organic compounds with a mobile hydrogen atom, for example, alcohols, amines,[4,12,112,113] mercaptans,[114,115] and carboxylic,[116] sulphinic, and sulphonic acids and their derivatives[117,118] react readily with quinones. The reductive aromatisation of the quinonoid systems is the driving force of these processes.

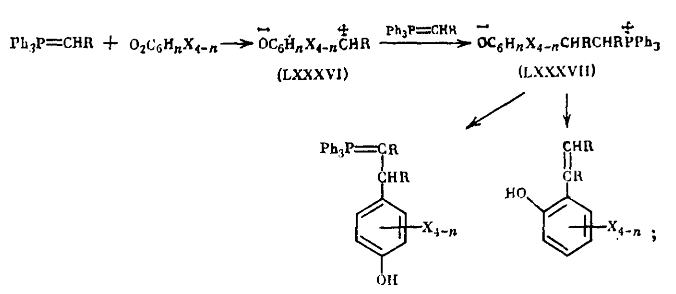
Comparison of the reactivities of phosphites and phosphates has shown that, apart from aromatisation, the formation of the extremely stable P=O bond promotes the reactions with quinones. This factor gives rise to process energetics such that in the case of phosphites addition in the 1,6-positions in the *p*-quinone takes place.

On the whole, *Ad* processes of this kind are encountered extremely rarely in the chemistry of *p*-quinones and occur only in certain cases.[78,119,120]

The structure of phosphates rules out the possibility of the formation of the phosphoryl group, so that the interaction with *p*-quinone follows the usual pathway and leads to the traditional 1,4-adducts, observed in the majority of reactions.

3. Reactions of Phosphoranes with Quinones

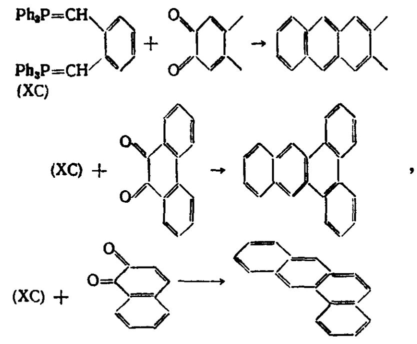
The quinonemethides (LXXXVI) are formed as intermediates in the reactions of alkylidenetriphenylphosphoranes with *o*- and *p*-quinones. They react with the initial phosphorane and give rise to the unstable betaines (LXXXVII). Depending on the substituents of the phosphorane component and in the ring, the betaines (LXXXVII) are either converted into the tautomer (LXXXVIII) or undergo the Hofmann degradation with formation of the olefin (LXXXIX):[121]



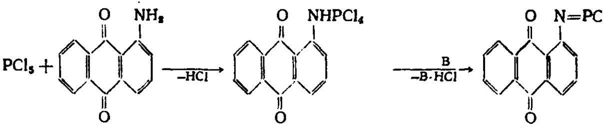
(LXXXVI) (LXXXVII)

R = COOMe, Ph; X = Cl, Ph; n = 2, 4. (LXXXVIII) (LXXXIX)

The reaction of *o*-phenylenebismethylenephosphorane (XC) with *o*-quinones can be used as a method of single-stage synthesis of complex carbocyclic aromatic compounds:[122]



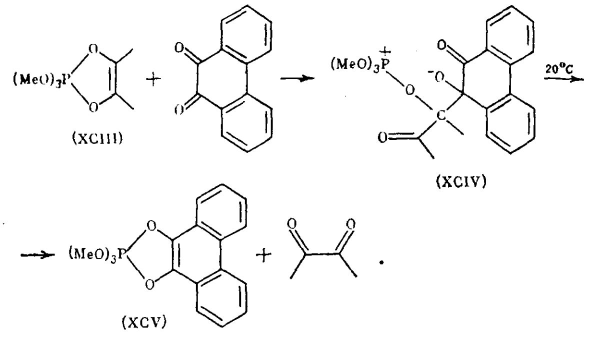
The interaction of phosphorus pentachloride with 1-aminoanthraquinone is of interest. It results in the formation of *N*-tetrachlorophosphoranyl-1-amino-anthraquinone (XCI)—a crystalline substance, which does not change after prolonged storage:



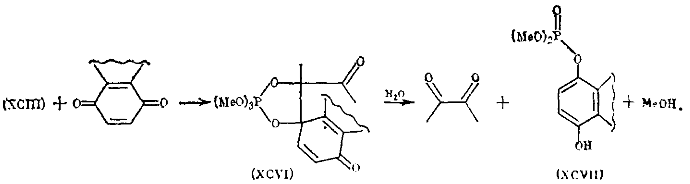
(XCI) (XCII)

Aminotetrachlorophosphoranes of the type RNHPCl$_4$ had been postulated earlier as intermediates in the reactions involving the phosphorylation of a wide variety of amines by phosphorus pentachloride. However, they were not isolated in a pure state. *N*-Tetrachlorophosphoranyl-1-aminoanthraquinone is the first representative of such compounds. Its stability may be associated with stabilisation by an intramolecular hydrogen bond. On treatment with tertiary bases, the phosphorane (XCI) is converted into trichlorophosphazoanthraquinone (XCII).[123]

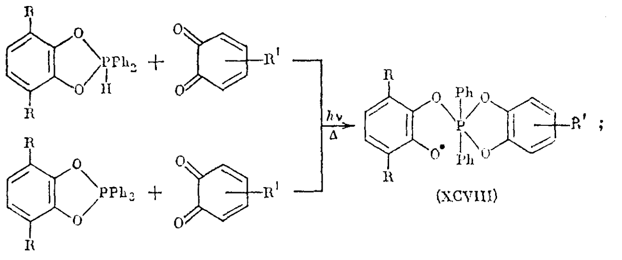
The dioxaphospholen (XCIII), obtained by the reaction of trimethyl phosphite with diacetyl, is capable of reacting with phenanthrenequinone. It has been suggested that the phospholen (XCIII), which exhibits a high phosphorylating activity, attacks the carbonyl group of phenanthrenequinone, which results in the formation of the dipolar adduct (XCIV).[124] At 20 °C, the adduct (XCIV) decomposes and the final products of reaction are diacetyl and the phosphorane (XCV):



The reaction of the phospholen (XCIII) with *p*-quinone leads to the formation of the phosphorane adducts (XCVI), which are unstable above 20 °C and whose hydrolysis affords p-hydroxyaryl dimethyl phosphates (XCVII):[124,125]



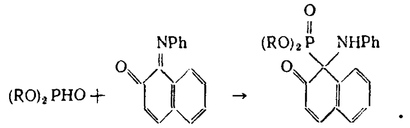
The interaction of [3,6-di(t-butyl)-1,2-phenylenedioxy]-diphenylphosphorane with *o*-quinones on exposure to UV radiation, gives rise to the radical species (XCVIII), which has also been obtained in reactions with participation of [3,6-di(t-butyl)-1,2-phenylenedioxy]triphenylphosphorane:[126]



R = t-Bu.

It follows from the data examined that the reactions of phosphorus-containing reagents with quinones and quinonoid systems frequently lead to non-trivial and sometimes unexpected results. The knowledge of such reactions undoubtedly enriches theoretical organic chemistry, opens up new ways to the synthesis of compounds with unique structures which had been hitherto inaccessible, and also provides unlimited possibilities for obtaining a wide variety of substances with properties of practical value: polymeric materials, biologically active compounds, and medicinal preparations.

During the preparation of the manuscript for printing, several interesting publications devoted to the interactions of organophosphorus compounds with quinones appeared in the literature. The results of a study of the reactions of dialkyl phosphites with sterically hindered *p*-quinones have been described.[127,128] The interaction takes place with the addition, usual in such cases, in the 1,6-positions of p-quinone with formation of adducts having the phosphate structure. An unusual reaction of dialkyl phosphites with the monoanil of *o*-naphthoquinone has been discovered.[129] Instead of the expected addition via the system of conjugated bonds of the anil X= C–C =Y, where X = C, O, or N and Y = O or N, with formation of phosphates, the reaction involving the rupture of the C=N bond and leading to the formation of adducts with the phosphonate structure takes place:



An analogous C=N bond rupture with retention of the remainder of the molecule has been found in the interaction of dialkyl phosphites with the anil of a sterically hindered quinone.[128] Radical processes with participation of quinonoid and phosphorus-containing reagents have been investigated in two studies.[130,131] Lawesson reported a new reaction of the "Lawesson reagent", which is popular in the chemistry of organophosphorus compounds at the present time. On reaction with substituted and unsubstituted p-quinones of the benzene, naphthalene, and anthracene series, it forms in certain cases phosphorus- and sulphur-containing cyclic products of a new type.[132] It has been shown[133] that the hydrazides of phosphoric acids react with p-benzoquinone in two ways: with formation of oxidation-reduction and condensation products. The operation of a particular reaction pathway depends on the expermental conditions.[133] The products of the interaction of phosphorus pentachloride with p-benzoquinone have been described.[134]

Modern Asymmetric Synthesis of α-Aminoacids

K.A.Kochetkov and V.M.Belikov

The principal aspects of the asymmetric synthesis of α-aminoacids with a large variety of structures are surveyed and the questions of the appearance of asymmetric induction as a result of the chirality of the catalyst, the initial compound, the reagent, or the leaving group are discussed. Studies carried out in recent years using chiral reagents capable of being regenerated and catalytic methods are examined in detail. The asymmetric reactions of α-aminoacids and other methods of synthesis are discussed briefly. Examples of the synthesis of aminoacids from chiral compounds without involving the chirality centres are not considered.

The bibliography includes 299 references.

I. INTRODUCTION

Aminoacids are widely distributed in nature and more than 500 have been discovered hitherto.[1] Despite the wide variety of the existing methods,[2,3] the search for new ways of synthesising α-aminoacids (AA) remains of current inerest, racemic AA being usually synthesised from readily available compounds under conditions ruling out multistage reactions,[4] for example:

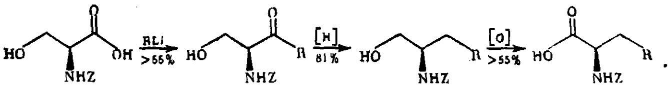
$$PhCH_2Cl + MeCONH_2 + MeCOBu \xrightarrow[Co_2(CO)_8,\,110°]{H_2,\,CO} (R,\,S)\text{-Phe}.$$

The development of the asymmetric synthesis of AA in recent years was dictated, on the one hand, by the need arising from the synthesis of natural products containing chiral carbon atoms with a AA fragment, and, on the other hand, by the necessity to develop the asymmetric synthesis of simple AA from available compounds using chiral reagents or catalysts capable of being regenerated.

Optically active AA are nowadays widely used as chiral synthons—chiral units—for the preparation of physiologically active substances,[5-7] including antiobiotics.[8] The application of AA successfully supplemented the use of carbohydrates[9,10] for the synthesis of natural products with a complex structure and, in contrast to carbohydrates, usually the entire AA molecule is employed without degradation. Furthermore, in view of their simpler structure, AA are usually available in the form of both stereoisomers. A large number of reactions involving the formation of a new chiral centre, induced with the aid of AA, are also known. Thus AA and their derivatives are used as cocatalysts of asymmetric reduction, the aldol reaction, and the Strecker synthesis.[11,12] The employment of polyaminoacids makes it possible to simulate successfully the action of enzymes. For example, the epoxidation of chalcones by hydrogen peroxide in the H_2O–CCl_4–poly-AA system has been carried out with an optical yield up to 96%.[13]

The reviews on the chemical asymmetric synthesis of AA [3,14,15] deal mainly with old studies concerned with the development of classical methods. The synthesis of AA has been partly considered in a number of reviews[15-20] and in monographs.[21,22]

We shall examine the principal aspects of the asymmetric synthesis of AA, elucidating whenever possible the causes of asymmetric induction, concentrating attention on syntheses using chiral reagents capable of being regenerated and on catalytic methods. Examples of asymmetric transformation without the involvement of the centre of chirality, as in the synthesis of (R)-AA from (S)-Ser [23] (see the scheme below) will not be discussed.



(S)-Ser (B)-AA

The questions of micellar catalysis and the use of enzymic reactions and their combinations with chemical methods for the synthesis of optically active AA have already been considered.[24-26]

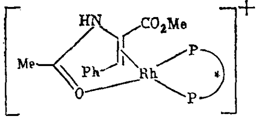
Asymmetric synthesis is the term applied to a process in which a prochiral molecule or its fragment is converted into a chiral molecule with unequal amounts of stereoisomeric products.[27] The process proceeds under the influence of a chiral reagent, the chiral component of the initial molecule, or a chiral catalyst. The interaction of the chiral and prochiral molecules inevitably results in the formation of intermediate diastereoisomeric compounds and (or) diastereoisomeric transition states, the energy difference between which actually determines the ratio of the diastereoisomers or enantiomers formed. This result is estimated in practice in terms of the diastereoisomeric (enantiomeric) excess of the reaction products or the optical yield (OY):

$$p = \mathrm{OY} = \left|\frac{[S]-[R]}{[S]+[R]}\right| \cdot 100\,\% = \frac{[\alpha]_{\mathrm{obs}}}{[\alpha]_{\mathrm{pure}}} \cdot 100\,\% \ .$$

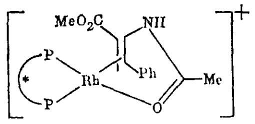
The aim of the asymmetric synthesis is to carry out the reaction with the maximum value of p for which it is sufficient to have low values of $\Delta\Delta G$, comparable to the energy of rotation about the C–C bond:

$\Delta\Delta G$, kcal mol^{-1}	0.82	1.30	1.74	2.72
p, %	60	80	90	98

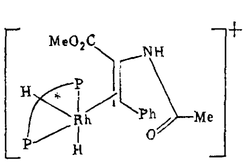
Kinetically and thermodynamically controlled asymmetric syntheses are distinguished. The most striking example of kinetic control is the asymmetric reduction of *N*-acyldehydroaminoacids or chiral phosphinerhodium catalysts, where the activity of the minor intermediate diastereoisomer (I) [its content does not exceed 5% relative to compound (II)], which is higher by a factor of 10^2–10^3, determines the stereochemical course of the process and the formation of the diastereoisomer (III) with $p \geq 95\%$ [28] (Fig. 1).



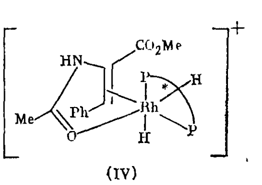
(I)



(II)

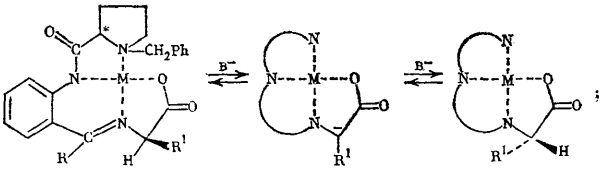


(III)



(IV)

As an example of thermodynamic control, we may quote the retroracemisation of the aminoacid fragment in transition metal complexes (V) of Schiff bases derived from chiral carbonyl compounds.[29–31] As a result of the epimerisation of the α-carbon atom of the aminoacid fragment, the mixture of the complexes (V) and (VI) formed initially is converted via compound (VII) into an equilibrium mixture with the ratio (V)/(VI) up to 10 : 1. After the decomposition of the mixture, AA with *p* up to 90% are isolated:



(V) (VII) (VI)
M = Ni, Cu; R = H, Me Ph; R^1 = Me, iso-Pr, Ph, CH$_2$Ph etc.

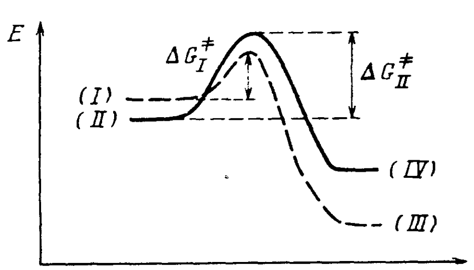


Figure 1. The energy diagram for the stage involving the formation of the rhodium hydride complex.[28]

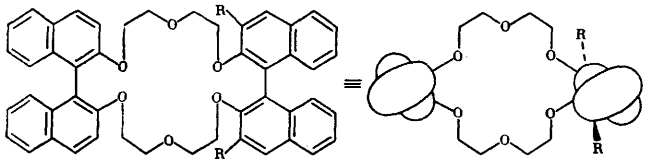
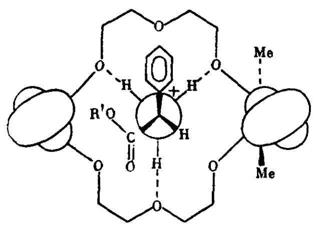
In most studies on the synthesis of AA, only the reaction result (the optical yield) is considered, without elucidating the causes of the asymmetric induction. Its manifestation is usually explained from stereochemical standpoints,[32] although the influence of electronic factors has also been demonstrated in a number of instances.

II. CHIRAL RECOGNITION AND TRANSPORT OF AMINOACIDS

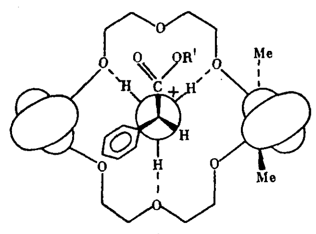
The success of asymmetric synthesis is associated with the elucidation of the nature and extent of the chiral recognition in complexes of aminoacid enantiomers with chiral compounds. Crown ethers are known to form readily 1 : 1 complexes with AA.[33] The complex-forming properties of crown ethers in relation to ammonium ions have attracted attention in view of their similarity to natural ionophores—antibiotics capable of binding metals, biologically important amines, and AA.[34] The chiral recognition of amines and AA by chiral crown ethers of type (VIII) with binaphthyl fragments,[35–38] spiro-crown ethers,[39] pyridinocrown ethers,[40] various crown and aza-crown compounds,[41,42] and other compounds[34,43] has been studied recently. Thus the diasteroisomers (*S*,*S*,*S*)-(IX) and (*S*,*S*,*R*)-(X) have been obtained from salts formed by AA esters with acids and from compound (VIII). The experimental value of ΔΔ*G* (up to 2 kcal mole^{-1}) is actually related to the difference between the interactions of the chiral binaphthyl fragments with H or the CCOR′ group:[44]



R = H, Me (VIII)

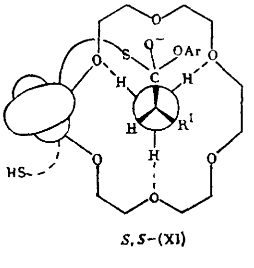


(*S*,*S*,*S*)-(IX)

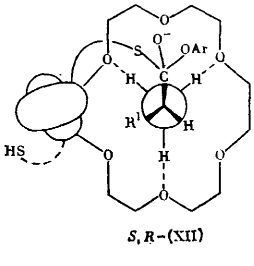


(*S*,*S*,*R*)-(X)

The enantioselective thiolysis of the *p*-nitrophenyl esters of AA (AA–OAr) on treatment with an analogue of compound (VIII) containing one binaphthyl fragment with the group R = $CH_2OC_6H_4SH$ is an example of the reaction with esters of type (VIII) whose stereoselectivity can be explained by considering molecular models of the intermediate complex.[36] Comparison of the structures of (*S*,*S*)-(XI) and (*S*,*R*)-(XII) indicates that the complex (XI) is preferable because of the interaction of the chiral barrier with the hydrogen atom and not with an alkyl group of the AA, as in the case of compound (XII). This explains satisfactorily the difference between the relative thiolysis rate constants; the ratio of the constants increases from 1 to 8.3 and 9.2 respectively with increasing bulk of the side chain on passing from Ala to Phe and Val.



S,*S*-(XI)



S,*R*-(XII)

The transport of AA through synthetic and natural membranes, which takes place stereoselectively in living organisms through lipophilic cell membranes, is associated with the phenomenon of recognition.[44] A number of biomimetic systems—crown ethers,[35,44] their spirobiindan derivatives,[45] and azacrown ethers[34]—have been developed for the selective transport of one of the enantiomers of the AA esters in the form of the hydrochloride. The transport is from one aqueous phase to another via a liquid membrane made up of a layer of organic solvent containing the chiral transferring agent. The cation associated with the given compound, for example Na$^+$, is transported in the opposite direction simultaneously with the transport of the AA salt. The driving force of the process is the entropy of solution and the change in the solvation energy when an inorganic salt is replaced by an organic salt. The use of (*S,S*)-(VII, R = Me) in the cell (Fig.2) made it possible to isolated (0 °C, 22 h) (*S*)-PGly-OMe with *p* up to 86% in the right-hand limb from the racemate in the left-hand limb, while the use of (*R,R*)-(VIII) affords (*R*)-PGly-OMe with *p* up to 90%. $\Delta\Delta G$ reaches 1.96 kcal mol^{-1} for p-HO–PGly–OMe [40] and −2.15 kcal mol^{-1} for Phe–OMe.[35] Such high results have so far been obtained only for AA esters. The study of the transport of free AA has so far yielded low values of *p*, which depend greatly on the experimental conditions.[34,46] The PGly enantiomers with *p* = 91.6% have been separated by means of a liquid membrane containing a chiral crown ether and a polymer.[47]

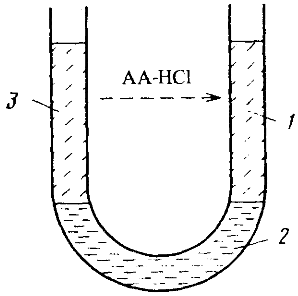


Figure 2. Cell for the phase-transfer enantioselective transport of aminoacid esters:[35] 1) 0.1 M HCl; 2) 0.027 M solution of (*S,S*-)- or (*R,R*)-(VIII) in $CHCl_3$; 3) aqueous solution of 0.08 M HCl, 0.08 M $LiPF_6$, and 0.05–0.08 M AA.HCl.

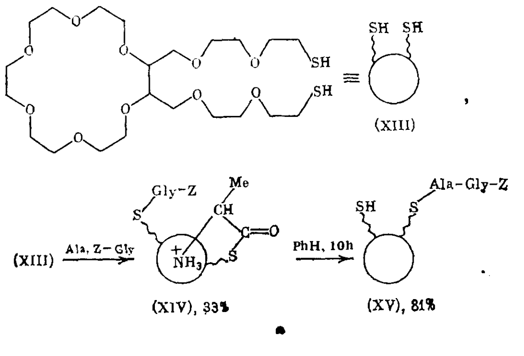
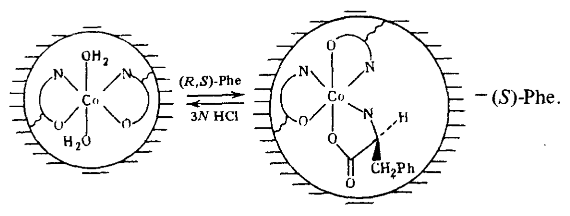
Crown ethers (XIII) with functional groups have been used as models of enzymes in the synthesis of peptides[48] (Scheme 1). The reaction involves the usual stages of peptide synthesis: the formation of a covalent intermediate, followed by the catalytic complex (XIV), and the reaction of the latter with the second substrate and the formation of the product (XV).

Scheme 1



A specific chiral environment can be created for the purpose of the recognition of AA enantiomers also by local synthesis, for example, by the copolymerisation of the cobalt(III) complex of (*R*)-Phe, containing a number of chiral groups and activated double bonds, with styrene and divinylbenzene:[50]



The polymeric gel obtained retains its initial structure of a "chiral lacuna" after hydrolysis, because, as a result of treatment with an excess of (*R,S*)-Phe, it forms preferentially a complex with (*R*)-Phe (*p* = 74%).

The diasteroisomeric interactions with AA are extremely varied. There is a possibility of the chiral recognition of N-Ac-PGly and N-Ac-Phe as a result of the formation of diastereoisomer solvates with tartaric acid derivatives via the formation of hydrogen bonds.[51] The study of chiral recognition in the formation of complexes with esters of (*R*)-, (*S*)-, and (*R,S*)-*N*-[4(1-pyrenyl)butanoyl]tryptophans in methanol and optically active octanols showed that it is associated with the differences between electrostatic, dispersion, and resonance interactions.[52]

Examples of the chiral recognition of prochiral substrates as a result of diastereoisomeric interactions, which are used for the asymmetric synthesis of AA, will be examined below.

III. ASYMMETRIC REACTIONS OF AMINOACIDS

The asymmetric transformations, sometimes referred to as *anti*- or *retro*-racemisation, include, in the stage determining the stereochemistry of the process, the inversion of the configuration of the α-carbon atom of the AA, which justifies their consideration in this review.

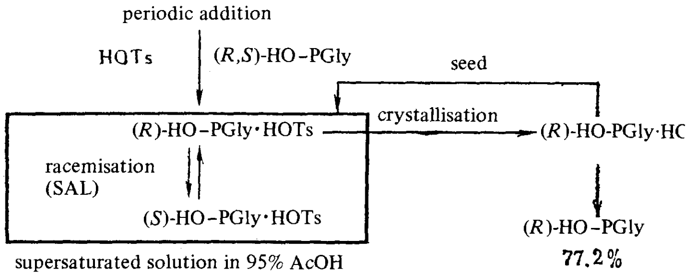


Figure 3. Schematic illustration of the asymmetric transformation of toluene-p-sulphonate of (*R,S*)-p-hydroxyphenylglycine.55

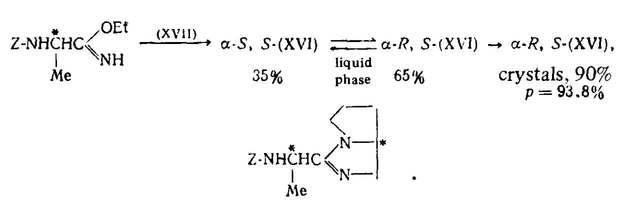
The conditions in the asymmetric transformations of *N*-Ac-Leu, *N*-butyroyl-Pro, *N*-benzoyl-PGly,[53] Ala and PGly,[54] and p-HO-Pgly [55] have now been worked out in detail. The essential feature of these transformations is a combination of the preferential crystallisation of one of the enantiomers in saturated solutions of the racemate with the racemisation of the other enantiomer. Thus a supersaturated solution of *N*-Ac(*R*,*S*)-Leu in acetic acid with catalytic amounts of acetic anhydride was cooled at a rate of 10 K h^{-1} from 100° to 40 °C after the addition of crystals of the (*S*)-isomer as a seed. This resulted in the formation of almost optically pure (*S*)-*N*-Ac-Leu in 70% yield relative to the initial racemic mixture.[53] The toluene-p-sulphonate salts of (*R*,*S*)-p-HO-PGly-[(*R*,*S*)-HO-PGly.HOTs] are racemised using 95% of acetic acid and a catalytic amount of salicylaldehyde (SAL) [55] (Fig.3).

The use of the faster racemistation of intermediate Schiff base derived from the ester (*R*,*S*)-PGly compared with the ester of one of the PGly enantiomers, which accumulates in solution, in the presence of (+)-tartaric acid affords, as a result of the asymmetric transformation of the second kind, the pure (*R*)-enantiomer in 85% yield.[56] The transition from (*R*,*S*)-Ala to (*R*)-Ala via the readily epimerising imidazolines (XVI), obtained using (*S*)-2-aminomethylpyrrolidine (XVII), has been achieved:[57]

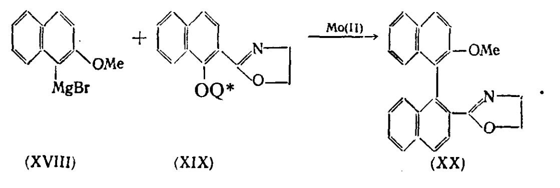


(XVI)

By combining the epimerisation and preferential crystallisation of the complex with $NiCl_2$, the asymmetric transformation of α-amino-ε-caprolactam (a precursor of lysine) has been carried out analogously in 50% yield (p = 96%).[58] The asymmetric transformations of AA via the intermediate formation of chiral complexes of Schiff bases with transition metals[29] are considered in Section VI.

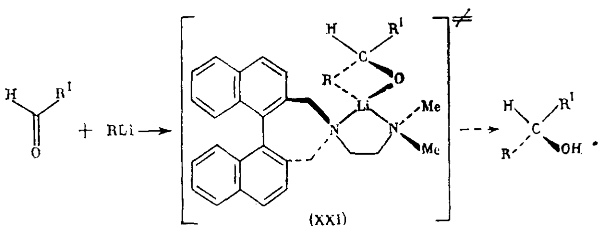
IV. ASYMMETRIC INDUCTION BY THE CHIRAL LEAVING GROUP

Asymmetric protonation or alkylation of carbanions by chiral electrophiles is also included in the electrophilic asymmetric synthesis of AA after asymmetric transformations.[59] An example of the asymmetric induction by the leaving group in the nucleophilic aromatic substitution using 2-methoxy-1-naphthylmagnesium bromide (XVIII) as the nuclophile and the quininoxy-group (OQ*) as the leaving group in the electrophile (XIX) is known.[60] The yield of the product (XX) reached 88% (p = 95%):



(XVIII) (XIX) (XX)

This result can be explained by the intermediate formation of two diastereoisomeric chelates with Mo^{2+}, ΔΔG reaching 2.4 kcal mol^{-1}. Induction by chiral lithium amides can be achieved analogously, for example, in the catalysis of the addition of alkyl-lithium to aldehydes via compound (XXI) with formation of alcohols (yield 35–75%, p = 23–95%):[61]

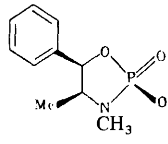


(XXI)

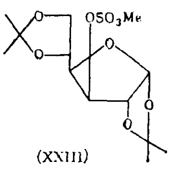
A rare instance of the use of electrophilic asymmetric amination for the synthesis of AA from the chiral reagent (XXII), prepared for (−)-ephedrine, has been described:[62]

$$Ph\bar{C}RCOOEtLi^+ \xrightarrow{(-)\text{-(XXII)}} Ph\overset{*}{C}R\,(COOEt)\,NMe_2\,;$$

R = H (yield 50%, p = 23%); R = Me (yield 56%, p = 21%);

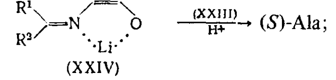


(−)-(XXII)



(XXIII) .

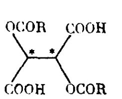
The enantioselective alkylation by compounds (XXIII) of lithium enolates obtained from a Schiff base of the glycine ester (XXIV) has been reported recently:[63]



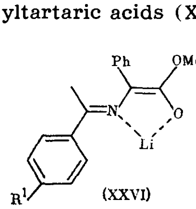
(XXIV)

R^1	H	iso-Pr	Ph	p-$NMe_2C_6H_4$	p-$NMe_2C_6H_4$
R^2	Ph	iso-Bu	t-Bu	t-Bu	adamantyl (Ad)
Yield of (*S*)-Ala, %	50	69	72	70	90
p, %	0	35	61	66	71

The result obtained is explained by the intermediate coordination of the enolate (XXIV) to the chiral alkylating agent (XXIII), which hinders the attack on the double bond from the *re*-side, the hindrance increasing with increasing bulk of the substituents in compound (XXIV). Asymmetric protonation for the synthesis of AA has been developed in detail.[59] The essential feature of the method consists in the protonation of the lithium enolates of the Schiff bases derived from AA esters by chiral acids, which are usually (2*R*, 3*R*)- or (2*S*, 3*S*)-diacyltartaric acids (XXV):



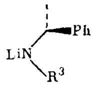
(XXV)



(XXVI)

$LiN(R^2)_2$

(XXVII)



(XXVIII)

As a consequence of the high coordinating capacity of lithium in relation to the electron-donating atoms, the product is the *syn*-enolate (XXVI), whose protonation by (*R*)- or (*S*)-(XXV) under the conditions of kinetic control affords AA enriched in one of the enantiomers. It has been established in relation to the transformations in PGly (Table 1) that the stereoselectivity increases with increasing bulk of the substituents in the amide and the acid and also with enhancement of the electron-donating character of the group in the aromatic ring of the Schiff base, which leads to the formation of a "harder" enolate. For all the AA investigated (Ala, Trp, Leu, Phe, Val, Met, PGly, NLe), the protonation of the enolate of type (XVI) by treatment with (2*R*, 3*R*)-(XXV) yielded the (*S*)-product,[59] while the chiral acids were recovered without loss of optical activity. On double asymmetric induction using (*R*)-(XXVIII), *p* increases to 70% with a chemical yield of 90%. In the case of chiral aminocarbonyl compounds, protonation by the derivatives (XXV) proceeds with p up to 92%.[66] According to Duhamel et al.,[59] it can be used for the transformation of carboxylic acids, ketones (via enamines), allyl alcohols (via α-hydroxyketones), allyl halides (via α-halogenoketones), etc. Asymmetric protonation can be achieved also without the loss of the chiral group; for example, the reaction of phthalimido-t-butylketen (XXIX) with an (*R*)-Ala ester, results in the formation of the (*R*,*R*)-dipeptide with *p* = 70%:[67]

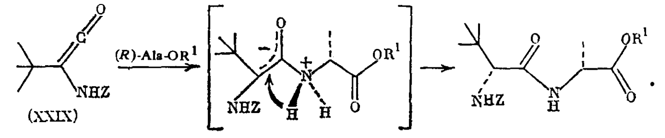


Table 1. The influence of substituents on the optical yield of (*S*)-PGly in the reaction of compound (XXV) with the enolate (XXVI).[59,63–65]

R in (XXV)	*p*, % (R¹=H)*	R¹ in (XXVI)	*p*, % (R = t-Bu)*	R² in (XXVII)	R³ in (XXVIII)	*p*, % (R¹ = H, R = t-Bu)*	(XXV)	*p*, % (R¹ = H, R = t-Bu, R² = Et)

t-Bu	50	H	50	iso-Pr	—	50	*meso*-	24
t-$BuCH_2$	16	Me	53	—	Me	60	racemate	39
	54	MeO	57	—	Et	70	—	—
Ad	—	Me_2N	61	—	—	—	—	—

*The reaction was carried out with (2*R*,3*R*)-(XXV).

The asymmetric protonation method can be developed further using chiral polyacid. The protonation of chiral anions by achiral acids has been investigated more widely and is examined below.

V. ENANTIOSELECTIVE REACTIONS OF CARBANIONS

In recent years notable advances have been made in the asymmetric synthesis involving the enantioselective formation of C–C bonds.[68] Stabilised carbanions, which exist in the form of metal complexes are frequently used for this purpose, the complexes being obtained from carbanion compounds, for example, α-alkyl-β-ketoesters,[69] α-hydroxyesters,[70] or nitrogen-containing compounds—hydrazones[71,72] or amidines.[73] The enantioselective alkylation of such carbanions proceeds with a high value of *p*.

AA are frequently obtained by alkylating the chiral Schiff bases (XXX) derived from the simplest AA, which can be readily synthesised from chiral carbonyl compounds and AA esters.[79] The use of the Schiff bases increases the CH acidity of the aminoacid fragment of the AA [80] and makes it possible to carry out reactions even with weak electrophiles (alkyl halides), ensures the ready regeneration of the chiral carbonyl compound $(R^1)^*{=}O$, and leads to comparatively high values of p (Table 2):

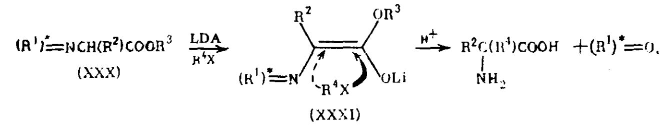

Table 2. Alkylation of chiral Schiff bases (XXX).

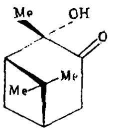
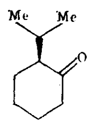
threo : *allo* = 3 : 1.
***threo* : *allo* = 12 : 1.

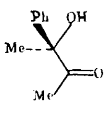
The Schiff base is deprotonated, for example, with lithium diisopropylamide (LDA) in tetrahydrofuran (THF) to give the enolate (XXXI), which is alkylated with alkyl halides, the use of the (*S*)-reagent $(R^1)^*$ giving rise to an excess of the (*R*)-product. Asymmetric induction can be achieved for achiral Schiff bases by means of chiral lithium amides obtained from (*S*)-Pro or (*S*)-Leu, but *p* does not exceed 31%.[81] The induction is also weak when the chiral centre is moved away from the α-carbon atom of the AA by employing menthyl esters, whose derivatives afford, after deprotonation and alkylation, AA in yields of 90% and *p* = 5–55%.[82] A 48% yield of (*S*)-Ala is reached when the menthyl ester of isocyanic acid is metallated.[83] The use of other AA derivatives, for example, *N*-formyl-*N*-alkylaminoacetonitrile, likewise produces low values of *p*.[84]



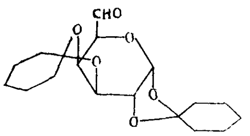
(XXXII)



(XXXIII)



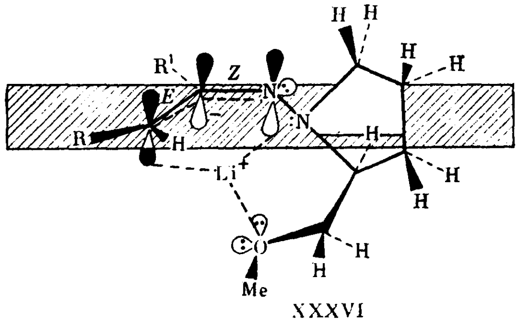
(XXXIV)



(XXXV)

In another alkylation method, proposed by Enders[85] and used to synthesise AA,[71] one begins with lithiohydrazones or lithioamidines derived from (*S*)-1-amino-2-methoxymethylpyrrolidine. The structure of the lithio-derivatives of hydrazones has not been accurately established, in contrast to that of lithium enolates. The structure (XXXVI) (Fig.4) has been proposed from spectroscopic data and confirm by an MNDO calculation. The result of the electrophilic substitution of the Li^+ ion is determined by the rotation about the N–N bonds if it is assumed that the negative end of the dipole of the electrophile forms a complex with the Li^+ ion.

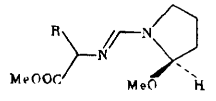
Since the electrophile attacks the anion (XXXVI) from below with formation of an (*R*)-product, then, for the more favourable *NN*-conformation in compound (XXXVI), *syn*-substitution takes place in relation to lithium. These features can be attributed also to electrophilic substitution in the amidines (XXXVII), where the preferential formation of the (*S*,*R*)-product is associated with the preferential *syn*-substitution of the lithium complex, which yields (*R*)-AA with p = 15 to 51%.[71] The result of the alkylation of enolates obtained from Schiff bases (XXXI) can be explained analogously.



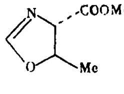
XXXVI

Figure 4. The structure of the lithio-derivative of the hydrazone (XXXVI).[85]

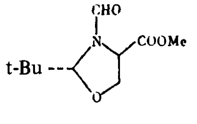
Rigid cyclic systems give rise to better results than their linear analogues. Thus the alkylation of the carbanion obtained from derivatives of the chiral 1,4-benzodiazepin-2-one yielded an AA with p up to 85%.[86] The advantages of the use of cyclic systems have been demonstrated particularly strikingly in two general methods of synthesis of a whole series of AA, developed by Seebach et al.[87] and Schöllkopf;[88,89] in both cases, the rigid chiral carbanion is attacked by the electrophile with an exceptionally high diastereoselectivity. The method of "self-reproducing chirality", proposed by Seebach, consists in effecting 1,3-asymmetric induction; it is convenient for the synthesis of α-C derivatives of the AA for which direct formation of enolates is impossible owing to β-elimination: Ser,[90] Thr,[91] Cys,[92,93] and Pro.[87] The principal feature of the method is the synthesis of chiral enolates from optically pure cyclic products: substituted oxazolines (XXXVIII) for Thr, oxazolidines (XXXIX) for Ser, and bicyclic compounds of the type (XL) for Pro and Cys:



(XXXVII)



(XXXVIII)



(XXXIX)

As shown in Scheme 2 for the adduct (XL, Y = CH_2),[87] the nucleophilic centre of the enolate is attacked by all kinds of electrophiles (D_3O^+, alkyl halides, carbonyl compounds, and alkenes) with restoration of the initial chiral centre and the formation of virtually only one of the possible diastereoisomers even in the case of three chiral centres (Table 3).

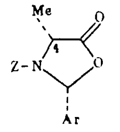
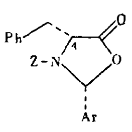
*1,2-Addition. **1,4-Addition.

The stereochemical result is because the electrophile does not distinguish kinetically the two sides of the chiral enolate (XLI) obtained from the adduct of (*S*)-proline with pivalic aldehyde (XL). The formation of compound (XL) is rigorrously distereoselective, because the existence of the (*S*,*S*)-diastereoisomer is unfavourable—in this case the pseudoaxial t-Bu group is in the eclipsed conformation relative to the 5′-CH_2 group of the pyrrolidine ring. The enolate (XLI) is formed with disappearance of the initial centre of chirality *S*-(2) and retention of the new centre *R*-(5). Presumably the Li^+ ion is coordinated to the oxygen of the enolate preferentially from the *re*-side of the plane (from below) in order to reduce the extent of the non-bonding interactions from the side of the pseudoaxial H(5) and the pyrrolidine fragment. This should lead to attack by the electrophile coordinated to the Li^+ ion from the *re*-side and the restoration of the initial centre of chirality *S*-(2), which has in fact been observed. The high stability of the carbanion (XLI) makes it possible to carry out also the Michael reaction, for example, with cyclohexenone, whereupon adducts with $p = 95\%$ are produced.[87] The method has been extended to Ala and Phe by converting them into chiral cis-2-aryl-2-benzyloxycarbonyloxazolidinones (XLII) and (XLIII); the alkylation of their potassium enolates at C(4) by treatment with MeI and $PhCH_2Br$ afforded (*R*)- or (*S*)-α-Me-Phe after alkaline hydrolysis with hydrogenolysis.[94]

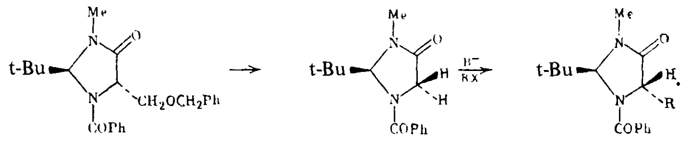


(XLII)



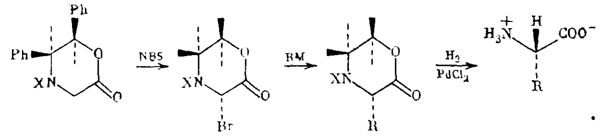
(XLIII)

The method is applicable to the synthesis of natural AA from other AA. (*S*)-β-*O*-benzyl-Ser was converted on interaction with pivalic aldehyde into the *trans*-imidazolidinone (XLIV), which gives rise, after oxidation and decarboxylation, to the imidazolidinone (XLV) containing the Gly fragment. The alkylation of its chiral enolate with MeI or $PhCH_2Br$ (produced the (2*S*, 5*S*)-imidazolidinones (XLVI) in 51 and 45% yields respectively for $p = 95\%$:[95]



(XLIV) (XLV) (XLVI)

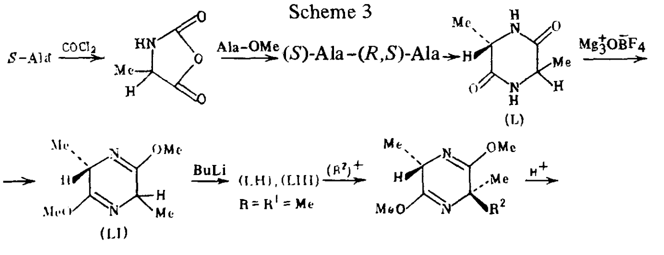
The attempts to obtain the enolate from the chiral lactone (XLVII) were unsuccessful, but the generation of an electrophilic centre by passing to compound (XLVIII) made it possible to carry out the reactions with various nucleophiles, leading to the lactone (XLIX), and to isolate the AA [(*S*)-Ala, (*S*)-NVa, (*S*)-NLe, etc.]:[96]

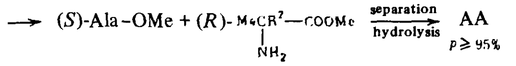


(XLVII) (XLVIII) (XLIX) $p > 96\%$

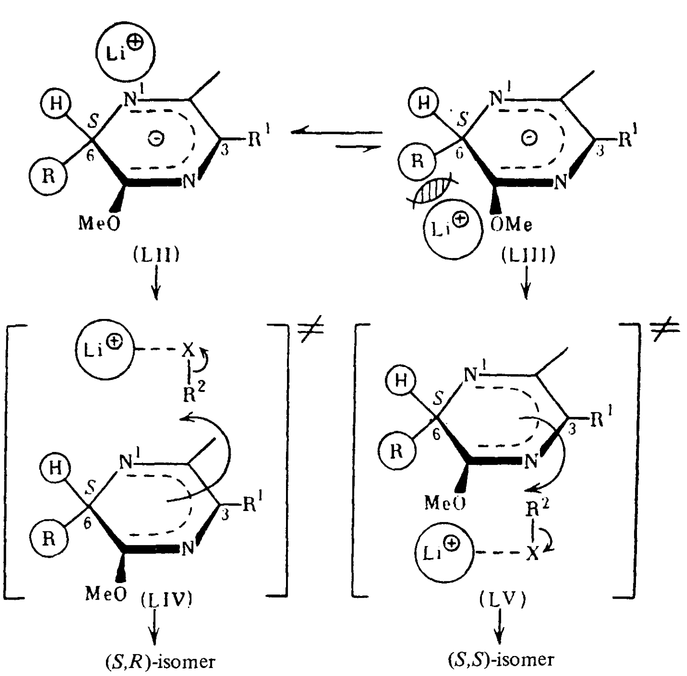
The alkylation of Asp, via acyclic enolates, gave $p = 60\%$.[97] In Schöllkopf's method,[88,89] one initially synthesises the dioxopiperazines (L) from Gly or the available racemic AA (for example, Ala) and a chiral reagent—(*S*)-Ala, (*S*)-t-Leu, (*S*)-Val, or (*S*)-α-Me-3,4-$(MeO)_2$Phe. The dioxopiperazines are alkylated to give the bislactim ethers (LI), which exhibit a high CH acidity and form the chiral carbanions (LII) and (LIII) (Fig.5); the latter react with a wide range of electrophiles diastereoselectively with a high *p* value. The heterocycle obtained is hydrolysed with liberation of the auxiliary chiral reagent and of a new optically active AA in the form of an ester, as shown in Scheme 3 for the reaction with cyclo-[(*S*)-Ala, (*R*,*S*)-Ala]:[93]

Scheme 3





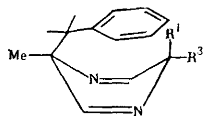
$$\longrightarrow (S)\text{-Ala-OMe} + (R)\text{-}\underset{NH_2}{\underset{|}{MeCR^2}}\text{—COOMe} \xrightarrow[\text{hydrolysis}]{\text{separation}} \underset{p \geq 95\%}{AA} .$$



R = Me, iso-Pr, t-Bu; R¹ = H, Me.

Figure 5. Schematic representation of the addition of an electrophile to the heterocyclic anion (LII)–(LIII).[88]

The authors assume that the dihydropyrazine anion is planar by virtue of the fulfillment of the Hückel condition and one of its diastereotopic sides is greatly shielded by the substituent R (Fig.5). It has been suggested that the Li^+ ion is close to the N(1) atom, which has the maximum electron density according to calculations. Thus the equilibrium is displaced towards compound (LII) virtue of the steric hindrance by the group R. The attack by the electrophile on the anion (LIII) is sterically hindered and the reaction proceeds mainly via the energetically more favourable state (LIV). The favourable combination of kinetic and thermodynamic factors is responsible for the high value of *p* (usually >95%). The role of the metal and the structure of the ion pairs were not discussed by Schöllkopf,[88,89,98] although he showed that the replacement of Li by a metal with shorter bonds [for example, $Ti(NMe_3)_3$] leads to greater asymmetric induction.[99] The structure of the alkylated products (LVI) and (LVII), obtained from compound (LII, R, $R^1 = Me$, $R^2 = CH_2Ph$) and corresponding to a folded conformation in which the benzene ring overhangs the heterocyclic ring, serves as evidence in support of the proposed mechanism.[89]



$R^1 = H$, $R^3 = Me$ (LVI)
$R^1 = Me$, $R^3 = H$ (LVII)

Such a structure, which is unfavourable as regards steric considerations, is realised also for cyclic dipeptides of the phenylalanine series.[100] Thus the stereoselectivity of the reactions of the chelate complexes of lithium considered in this Section is determined by the preferred introduction of the coordinated lithium atom on the *re*- or *si*-side relative to the nucleophilic centre of the anion and the subsequent electrophilic attack from the same side via the intermediate binding of lithium, which is the reason for the preferred *syn*-substitution mechanism. The knowledge and control of the steric and electronic factors in the stage determining the degree of asymmetric induction make it possible to regulate the stereoselectivity. Thus, the replacement of R = Me by R = t-Bu in compound (L) increases the stereoselectivity sharply, while the introduction of the phenyl group (R = Ph) gives rise to the opposite result.[89]

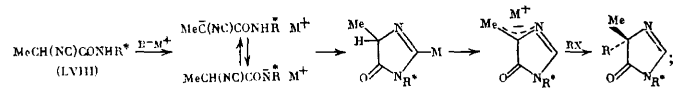
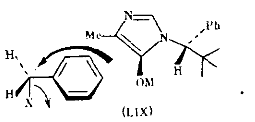
**$Ti(NMe_3)_3$ was used as the counterion.

***R^1 = Rh.

Cyclo-[(*S*)-Val-Gly] or cyclo][(*S*)-Val-Ala] is used most often in the Schöllkopf's method, which makes it possible to obtain various (*R*)-AA (Table 4). High optical yields have been achieved using (*S*)-t-Leu, which, however, is difficult to obtain.[89] Ketones also react with (LI) (p = 95%), while aldehydes react with additional induction at C′ (3), (6*S*, 3*R*, 3′*S*)-diastereoisomers being formed preferentially.[101] Dehydration leads to (*R*)-α-vinyl-Ala and (*R*)-vinyl-Gly.[102,103] Hydrolysis to the AA esters proceeds without racemisation (Table 4). The large number of stages, the long reaction time, and the difficulty of separating the AA esters lead to the formation of products in yields of only 17–24% relative to the initial AA. The alkylation of the anions of chirally 1-substituted 4-methyl-2-imdazolin-5-ones (LVII), obtained from the chiral amides of carboxylic α-isocyano-acids (LVIII), also gives rise to high values of p when the alkylating agents are benzyl halides, but the yield falls sharply (to 17–35%) when alkyl halides are employed:[116]



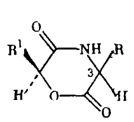
(LVII)



(LIX)

As in the alkylation of dihydropyrazine anions, the diastereoselectivity of the process is probably determined in this instance by the more favourable transition state of type (LIX).[116] The degree of asymmetric induction can be lower in this case than for the anion (LII), since the chiral centre is located further from the reaction centre and the difference between the two diastereoisomers of compound (LVII), in which the metal ion is located above and below the plane of the anion (there is a difference in the interaction of the metal with the Me and R groups), is smaller than in the case of the anion (LII) (the difference between the group R and the atom H).

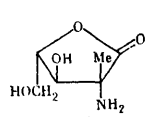
The conversion of 2-furyl- or phenyl-glycines by condensation with hydroxyacids to the corresponding 3,6-dihydro-2*H*-1,4-oxazine-2,5-diones (LX), which react diastereoselectively with R^2X via the C(3) atom, also does not differ fundamentally from the methods considered above:[117,118]



(LX)

R = Ph, 2-furyl

R¹ = $CHMe_2$, CMe_3



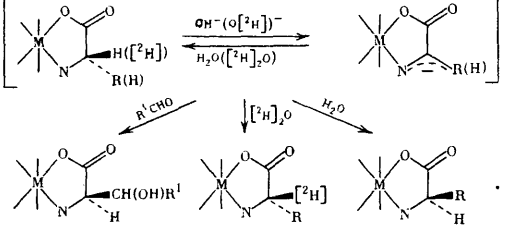
(LXI)

In view of its laborious nature, the method can be usefully employed only in the synthesis of exotic AA (see, for example, Weihrauch and Liebfritz[112]). Thus, the condensation of cyclo-[(*S*)-Ala-(*S*)-Ala] with L-glyceraldehyde yielded the biologically active lactone (LXI).[120] The use of chiral complexes of the Schiff bases derived from AA, examined in the previous Section, is more promising for the synthesis of substituted optically active AA. Interesting results may be expected also in the alkylation of the AA Schiff bases under interfacial conditions in the presence of chiral catalysts, since it is known that the alkylation of racemic phenylindanols with MeI in the presence of *N*-(*p*-trifluoromethylbenzyl)-quinine bromide gives rise to a product with p = 90%.[121]

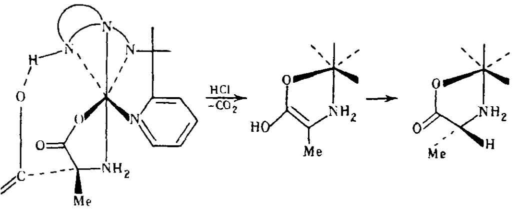
VI. SYNTHESIS AND REACTIONS OF AMINOACIDS VIA TRANSITION METAL COMPLEXES

The ligand in the chiral complexes of transition metals has a rigid orientation and X-ray diffraction analysis provides reliable information about their structure.[122] The intraligand interactions, responsible for the enantioselectivity in these systems, can therefore be assessed very accurately, which facilitates the search for useful synthetic reagents based on them. The stereochemically inert cobalt(III) complexes with amine chiral ligands and aminoacids[123,124] have been used for such purposes for years, for example the cleavage of AA.[125] The chiral recognition of the enantiomers and chiral groups in such complexes occurs mainly as a result of the sterically preferred interaction of one chiral ligand with another or with the prochiral groups of a neighbouring ligand.[126] The introduction into the complex of bonding interligand interactions, which occur for polydentate ligands, enhances the possibility of the chiral recognition of AA.[123,124] The use of chiral derivatives of amines as tetradentate ligands leads to diastereoisomeric Λ and Δ complexes of cobalt(III) with aminoacids, their ratio corresponding to the ratio of the pure AA enantiomers.[127] The epimerisation of the CH aminoacid fragment in the Λ and Δ complexes is catalysed by OH^- (Scheme 4):

Scheme 4



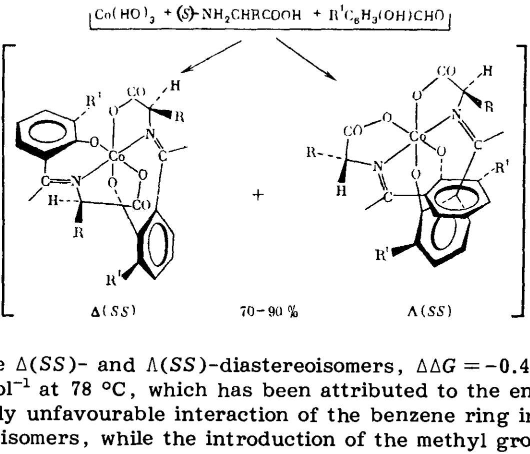
The diastereoselectivity is sometimes high and reaches $\Delta,R/\Delta,S = 91:1$ for the complexes with Asp.[128] Treatment of the racemic α-dichlorotriethylenetetraminecobalt(III) chloride with (*S*)-Pro and Et_3N in boiling alcohol results in 94.5% of the cobalt(III) complex, existing as the Δ complex.[129] Analogous complexes with α-amino-α-methylmalonic acid are used for the acid-catalysed asymmetric carboxylation to Ala.[129] The racemisation of the AA fragment in the isolation stage usually diminishes p,[130] but, for the chiral complexes with (6*R*,8*R*)-6,8-dimethyl-2,5,9,12-tetra-azatridecane[131] and *NN*-di(2-picolinyl)-(1*R*,2*R*)-diaminocyclohexanone,[132] the value of p corresponding to (*R*)-Ala is 66 and 78% respectively. According to Goodwin et al.,[132] the decarboxylation of the cobalt(III) pro-(*S*)-aminomethylmalonate complex affords the (*R*)-alanine complex, i.e. the α-carbon atom undergoes inversion. The mechanism involves the cyclic intermediate (LXIII):



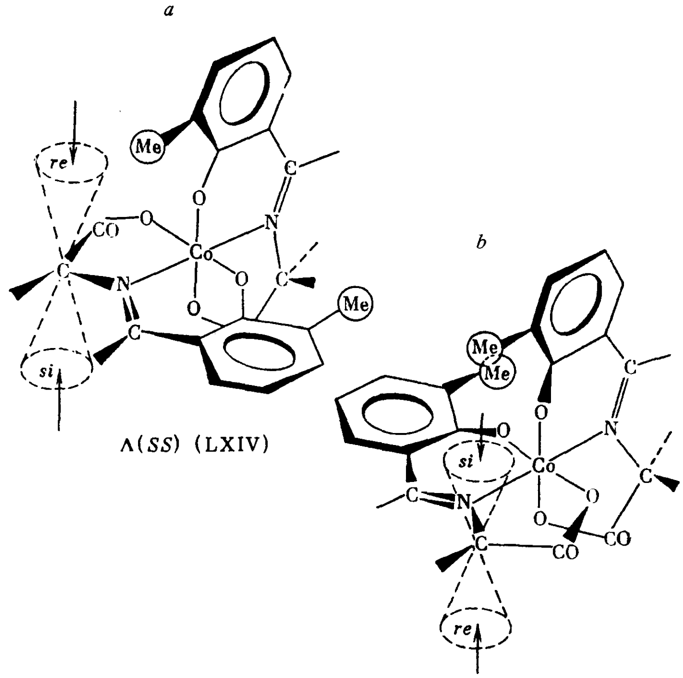
(LXII) (LXIII)

Taking into account the data in Section IV, it has been suggested that the asymmetric induction in compound (LXIII) is effected by the selective intramolecular proton transfer to the enolate fragment from the protonated pyridinium fragment in a chiral environment. The asymmetric decarboxylation of the Λ- or Δ-tetramine complex of cobalt(III) with pyrrolidine-2,2-dicarboxylic acid gives rise to (*S*)-Pro and (*R*)-Pro with p = 20 and 24% respectively.[133] Asymmetric transformations of the AA fragment are possible also in the chiral complexes of dicarbonyl(η^5-cyclopentadienyl) derivatives of molybdenum and tungsten with AA.[134] These complexes are configurationally stable in a neutral solution, while in an alkaline medium rapid interconversion of the diastereoisomers is attained. The epimerisation of the AA fragment suggested[135] and led to the development[136] of the method of synthesis of chiral [^{2}H]Gly and other [2-^{2}H]AA by the enantioselective substitution of the α-proton of the AA by deuterium. It consists in the formation of ethylenediaminecobalt(III) complexes with (*S*)-AA, the separation of the diastereoisomeric complexes by chromatography, deuterium exchange by treatment with OD^- in D_2O, repeated separation of the Δ,S and Δ,R or Λ,S and Λ,R diastereoisomers, and the isolation of AA from the complexes by reduction with $NaBH_4$.[131] The chiral complexes of transition metals have also been used for the asymmetric synthesis of Thr from Gly and MeCHO in 26–33% yield and with p = 16–35% [137] (Scheme 4). The use of simple AA complexes of transition metals suffers from a number of disadvantages, for example, the α-amino-group of the ligand is subjected to electrophilic attack, which prevents the effective synthesis of α-substituted AA by alkylation with alkyl halides.[137] There are also difficulties in selecting the chiral ligands, since the interactions within the complex are readily smoothed out;[126] finally the CH acidity of the complexes is low.[138]

The use of chiral complexes of Schiff bases derived from AA for the synthesis of biomimetic reagents for asymmetric synthesis of AA is more successful. In these complexes, where the kinetic CH acidity of the AA fragment is high,[139] the α-amino-group is reliably protected and the polydentate ligand (the Schiff base) forms a harder complex than the free AA. The relevant studies were carried out initially mainly with stereochemically inert octahedral cobalt(III) complexes, which retain their configuration in the chemical reactions of the ligands.[127,128] The AA Schiff bases with aldehydes form planar tridentate ligands, which can be arranged perpendicularly to one another in the octahedral complexes. The complexes with Gly can be resolved into the enantiomers, while those with other AA can be resolved into diastereoisomers, for example, Λ(*SS*) and Δ(*SS*).[140]



For the Δ(*SS*)- and Λ(*SS*)-diastereoisomers, $\Delta\Delta G = -0.45-1.32$ kcal mol^{-1} at 78 °C, which has been attributed to the energetically unfavourable interaction of the benzene ring in the Λ(*SS*)-isomers, while the introduction of the methyl group in the 3-position in salicylaldehyde (SAL) inverts the stereoselectivity owing to the interaction of the alkyl groups of the AA fragment and the 3-methyl group in the Δ(*SS*)-complexes, which is almost absent in the Λ(*SS*)-isomers.[140] These results make it possible to achieve the synthesis of the partly enriched (*R*)-[^{2}H]Gly and (*S*)-[^{2}H]Gly [147] by analogy with the study of Keges and Legg.[136] The steric shielding of the *re*- and *si*-sides of the intermediate planar carbanion in the complexes Λ-(LXIV) (*re*-side) and Δ-(LXV) (*si*-side) with 3-Me-SAL, which hinders the attack on the pro-(*R*)-proton in the Λ-complexes and the pro-(*S*)-proton in the Δ-complexes and leads to different rates of their exchange with the ratio of the constants up to 1 : 10 (Fig.6), has also been used. Therefore, after the exchange of 50% of the hydrogen for deuterium, (*S*)-[^{2}H]Gly was isolated from the Λ-complex and (*R*)-[^{2}H]Gly was isolated from the Δ-complex with p = 20–40% [141] without the preliminary separation of the diastereoisomers, as in the study of Keges and Legg.[136] The employment of such separation made it possible to obtain the following deuteriated AA with high values of p: (*R*)-Tyr 68%, (*S*)-Tyr (94%), (*R*)-Val (96%), (*S*)-Val)98.8%), (*R*)-NVa (93.4%), (*S*)-NVa (94%), (*R*)-Met (82%), (*S*)-Met (90%), and (*R*)-Ala (90%).[141] The stereochemistry of the formation of the C–C bond obeys the same rule as that for the formation of the C–H bond, but ultimately the thermodynamically stable complex predominates in the final mixture obtained in the condensation with aldehyde. Thus (*S*)-Thr with p = 60% and (*R*)-Thr with p = 73% have been obtained by the reaction with acetaldehyde.[139,140] The interaction with methyl acrylate in H_2O at pH 11.4 afforded a mixture of complexes, after the decomposition of which (*S*)-Gly (p = 10–46%) was isolated quantitatively.[142] Thus both the kinetic acidity of the AA fragment and the enantioselectivity of the formation of the C–C and C–H bonds can be appreciably increased with the aid of chiral cobalt(III) complexes based on the Schiff bases derived from SAL and AA. The use of menthol derivatives as the carbonyl components of the Schiff bases permitted the asymmetric transformation of the AA fragment in the complexes with racemic AA with p = 22% *S* for Ala, 12.6% *S* for Val, and 11.4% *S* for Leu.[143]

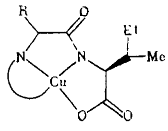


Λ(*SS*) (LXIV)

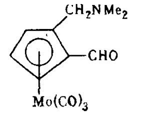
Δ(*SS*) (LXV)

Figure 6. Steric shielding of the *re*- and *si*-sides of the carbanion formed as an intermediate in the Δ(*SS*)- and Λ(*SS*)-complexes of cobalt(III).[141]

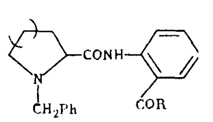
The asymmetric induction in the complexes considered was achieved as a result of the chiral disposition of the ligands within the structure of the complex, which is inert as regards substitution, but effective biomimetic reagents and catalysts[142] must be based on stereochemically labile complexes, capable of ready exchange of the ligands, which inevitably leads to the racemisation at the metal atom. In order to retain the asymmetry of such a labile system, SAL must be replaced by a chiral analogue permitting the use of Ni^{2+}, Cu^{2+}, and possibly Zn^{2+} for the asymmetric synthesis of AA. The use of optically active peptides permitted only the epimerisation of the *N*-terminal AA of the dipeptide in the copper(II) complexes (LXVI):



(LXVI)



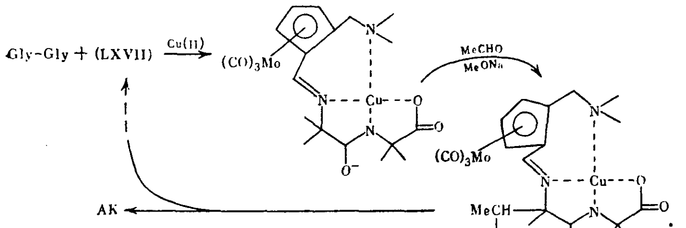
(LXVII)



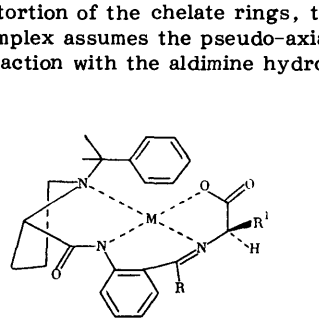
(LXVIII), n = 1, 2
R = H, Me, Ph

Dipeptides with p = 63% *S* for R = Me and 66% *S* for R = Ph have been isolated.[145] The enantiomers of 1-(*NN*-dimethylaminomethyl)-2-formylcymantrene (LXVII) [146,147] have been used as chiral reagents, capable of being regenerated, for the asymmetric synthesis and transformations of AA. Thus the interaction of (+)-(LXVII) with racemic Ala-NVa in the presence of Cu^{2+} and MeONa gives rise to a mixture of diastereoisomers whose ratio shifts towards the most favourable diastereoisomer with (*S*)-Ala (p = 55%) as a consequence of the mobility of the α-proton of the *N*-terminal AA. (*S*)-Thr (p = 92–98%) and (*S*)-allo-Thr (p = 95–100%) were isolated in proportions of 2.15–2.42 and in high yields (after the hydrolysis of the dipeptides) by condensing acetaldehyde with the complex obtained from compound (LXVII), Gly-Gly, and Cu(II):

Scheme 5



(*R*)-Thr (p = 93–96%) and (*R*)-allo-Thr (p = 100%) were obtained in proportions of 2,3 in the case of (–)-(LXVII) [146] (Scheme 5). The greater stability of the complex with (*S*)-Thr can be explained by the fact that, as a consequence of the marked distortion of the chelate rings, the alkyl substituent in the complex assumes the pseudo-axial position, in which the interaction with the aldimine hydrogen is minimal.



(*S*,*R*)-diastereoisomer (LXIX)
R = H, Me, Ph; R^1 = alkyl
M = Ni, Cu

The use of the chiral reagents (LXVIII), having a greater number of coordination sites compared with compound (LXVII), makes it possible to achieve asymmetric transformations also with AA.[29–30,148,149] In the copper(II) and nickel(II) complexes of type (LXIX), obtained in 80–90% yields from the AA and the reagent (LXVIII) in alcohol, the distortions caused by the presence of the asymmetric carbon atom are transmitted to the chelate ring, which entails different interactions of the alkyl residue of the AA and other groups in the complex.[31] These distortions, which are clearly seen in the crystalline state, are retained in solution according to spectroscopic data.[29,31]

The use of such hard systems makes it possible to alter the enantioselective effects by introducing substituents R in compound (LXIX), i.e. one can alter the ratio of the diastereoisomeric complexes under equilibrium conditions. According to Belokon et al.,[31] this ratio is determined by the difference between the energies of orientation of the alkyl group of the AA towards the benzyl group (upwards from the coordination plane) for the (*S*,*R*)-diastereoisomer (LXIX) or towards the proline fragment for the (*S*,*S*)-diastereoisomer. Non-bonding interactions of the alkyl substituent with the benzyl group, shielding the apical position, are observed in the complex (LXIX), and the increase of the bulk of the group R^1 therefore diminishes the content of the complex with (*R*)-AA. The increase of the bulk of R on passing from H to Me leads to additional distortion of the metallocycles and the assumption of the pseudoaxial position by the alkyl group of the AA. Under these conditions, there is an additional increase of the excess of the complex with (*S*)-AA. The occurrence of large diastereoselective effects in the copper(II) complexes[29] and especially in the nickel(II) complexes,[30,31] reaching p = 90% for the complex with (*S*)-Val, made it possible to achieve the retroracemisation of a series of AA [29–31,150] (Table 5).

Table 5. The enantiomeric composition of the AA after the retroracemisation of the complex (LXIX) [0.2 *N* MeONa, 40° (A); 0.1 *N* MeONa, 25° (B)].

*0.012 *N* MeONa. **0.33 *NN* MeONa. ***AdAla = adamantylalanine.

The retention of the characteristic features of the diastereoselective effects also on formation of the C–C bond made it possible to develop a general method of diastereoselective and enantioselective synthesis of β-hydroxy-α-AA by condensing aldehydes or ketones with the nickel(II) and copper(II) complexes of glycine,[151–153] leading to the complexes (LXX) and (LXXI) (Table 6). According to Belokon' et al.,[151] the condensation of compound (V, R = Ph, R^1 = H) with aldehydes under equilibrium conditions leads to the preferential formation of the product (LXX) with the AA side chain directed away from the benzyl group and with the O atom located under the metal atom, which ensures an even greater preference for the (*S*,*S*)-diastereoisomer:

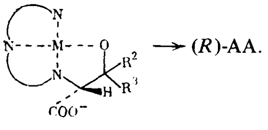
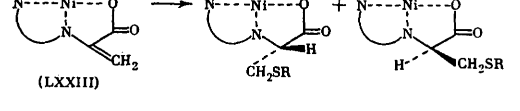
Me	Cu	PhCHO	MeONa	67	50:1	74	*R*
Me	Ni	PhCHO	MeONa	67	34:1	82	*R*
Ph	Ni	PhCHO	MeONa	67	34:1	82	*R*
Ph	Cu	PhCHO	MeONa	59	50:1	80	*R*

The observed high value p = 95% for the diastereoisomer with (*S*)-Ser (LXX, R^2 = R = H) at low pH is in full agreement with theoretical ideas. At a high pH of the solution, only the (*S*,*R*)-diastereoisomer (LXXII) is formed, which is associated with the ionisation of the hydroxy-group in compounds (LXXI) and (LXXII) and the rearrangement of the complex with coordination of the metal to the ionised hydroxy-group:



(LXXII)

It is noteworthy that, owing to steric hindrance, the second CH_2O molecule does not add to the complex with formation of α-hydroxymethylserine—the main product in the earlier attempts to synthesis Ser from Gly.[154] The preferential formation of the *threo*-products for other aldehydes is also associated with the ionisation of the hydroxy-group at a high pH and the rearrangement of the complexes.[151] The complexes (LXX) and (LXXI) have been converted by acetylation and the elimination of AcOH into the dehydroalanine complex (LXXIII),[155] which combines with thiophenol and phenylmethanethiol via the double bond with formation of the diastereoisomeric complexes of L- and D-*S*-phenyl- or L- and D-*S*-benzyl-cysteines:



(LXXIII)

Chromatographic separation on silica after decomposition yields the enantiomerically pure L- and D-*S*-phenyl- or L- and D-*S*-benzyl-cysteines in an overall yield of 80%.[156,157] The thermodynamic CH acidity of the complexes (LXIX) reaches high values [pK_a = 19.5 (R = R^1 = H), 19.2 (R = H, R = Me), 21.2 (R = H, R^1 = $CHMe_2$), and 18.8 (R = Ph, R^1 = H) in DMSO [158]] and is comparable to the acidity of malonic ester. The high CH acidity of the complexes and their stability have been used to carry out reactions with weak electrophiles—alkyl halides, which made it possible to obtain a series of optically pure α-Me-α-AA for both the (*S*)- and the (*R*)-series[159] (Table 7):

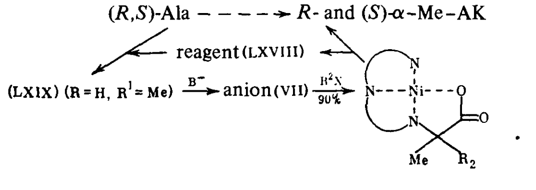


Table 7. The yields of the products of the alkylation of the complex (LXIX, R = H, R^1 = Me) by alkyl halides.[159]

R^2X	BuLi, THF	10% NaOH, CH_2Cl_2
	(*S*, *S*); (*S*, *R*)	(*S*, *S*); (*S*, *R*)
MeI	92	
$PhCH_2Br$	51; 40	63; 31
$CH_2=CHCH_2Br$	56; 33	62; 22

In contrast to the known methods for the alkylation of chiral enolates,[74-79] in this case the deprotonation can be achieved not only with BuLi in THF but also with aqueous alkali under the conditions of phase-transfer catalysis. The separation of the complexes on silica yielded, after decomposition, the optically pure α-Me-AA. Under the conditions of kinetic control, the alkylation of the complex (LXIX, R = R^1 = H) by alkyl halides proceeds with a low value of *p*, which indicates a small difference between the rates of attack by the electrophile on the anion from different sides of the coordination plane. Attack from below, the side opposite to that of the benzyl group, leading to the (*S*,*S*)-diastereoisomer, is somehwat preferable.[159] The use of complexes containing the phenyl group (R = Ph), which imparts the pseudo-axial conformation to the pro-(*S*)-proton, facilitates the attack from below with formation of the (*S*)-AA fragment and increases *p* to 90%.[160]

The general method of asymmetric synthesis of AA via transition metal complexes has many advantages over other procedures. These are the ease of formation of the chiral complexes, mild conditions of the reactions with electrophiles, the high value of *p* for AA, and the virtually complete regeneration of the chiral reagent.

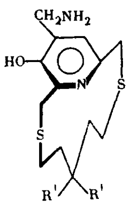
VII. CATALYTIC ASYMMETRIC TRANSAMINATION

The biomimetic approach to the synthesis of a simplified model of enzymic transamination[161] has been applied in a study[162] where the chiral pyridoxamine (LXXIV) with an *ansa*-chain in the molecule, capable of effecting the transamination of α-ketoacids to give AA with *p* up to 9.4% on catalysis by Zn^{2+}, was obtained:

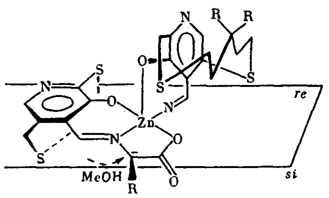
$$RCOCOOH \xrightarrow[Zn^{+2},\ pH\ 4,\ MeOH]{(LXXIV)} AA$$

R	Yield, %	*p*, %	AA	Configuration of (LXXIV)
Me	72	69	*S*-Ala	*R*
$PhCH_2$	60	61	*S*-Phe	*R*
Me_2CH	57	79	*S*-Val	*R*
Me_2CHCH_2	68	96	*S*-Leu	*R*
Me_2CHCH_2	66	94	*R*-Leu	*S*
3-Indolyl	62	60	*R*-Trp	*S*

In the case of MeO[^{2}H], α-deuteriated AA with *p* = 40–90% are isolated:[163]

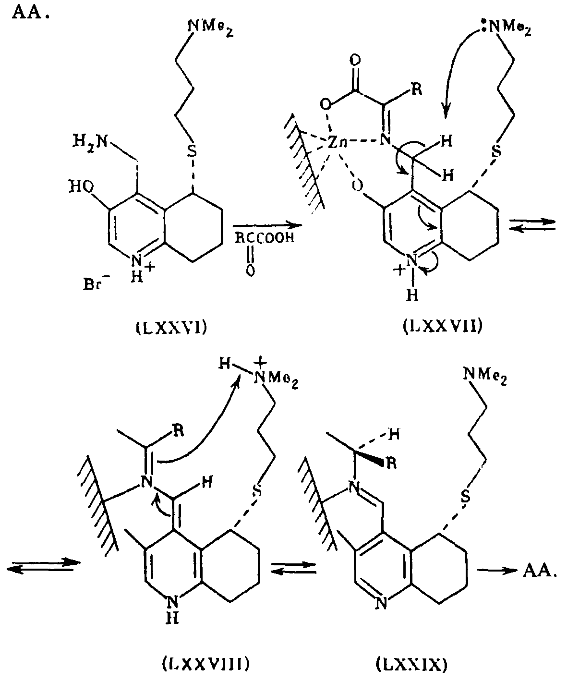


(*S*)-(LXXIV)
R' = H, Me



(LXXV)

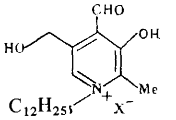
The asymmetric induction can be explained by the kinetically controlled stereoselective protonation of the carbanion formed in the intermediate Zn^{2+} Λ-complex (LXXV). Best results have been obtained with the model (LXXVI), whose activity is even closer to that of an enzyme containing the ε-amino-group in a chiral environment[164]—an analogue of the ε-amino-group of lysine in the active centre of pyridoxal.[161] The dimethylamino-group in the complex (LXXVII) acts as a base for the removal of the pro-(*S*)-hydrogen from 4'-methylketimine, after which the dimethylammonium group approaches, as a consequence of the chiral structure of the complex, the same side of the intermediate (LXXVIII) and, acting as an acid, protonates the α-position from the *si*-side, giving rise to the chiral aldimine (LXXIX) with subsequent liberation of the AA.



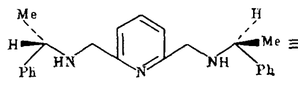
(LXXVI) (LXXVII)

(LXXVIII) (LXXIX)

The following (*R*)-AA were obtained: Ala (yield 83%, *p* =86%), NVa (68%, *p* = 92%), and Trp (89%, *p* = 88%). The use of compound (LXXVI) accelerates the reaction by an order of magnitude owing to the intermolecular general acid—base catalysis compared with the analogue without the NMe_2 group, which a 75% yield of NVa with *p* = 16%. Thus the chiral aldimine can be obtained in two ways—by introducing a steric hindrance through the attack by the carbanion from one side[163] or by the stereoselective protonation of the carbanion.[164] The feasibility of the method is associated with the availability of α-ketoacids and the necessity to employ a metal. The possibility of transamination also without a metal using the achiral *N*-laurylpyridoxal (LXXX) in a cationic micelle under conditions close to physiological conditions has been recently demonstrated.[165] The pyridoxal catalysis has been induced by means of a laser (3371 Å), which also leads to transamination in the absence of enzymes:[166]

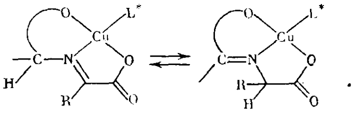


(LXXX)



(LXXXI) .

Another approach is associated with the use of metal complexes of Schiff bases obtained from pyridoxamine and the ketoacid containing compound (LXXXI) as a chiral ligand; a diastereoselective conversion of a ketimine into an aldimine then takes place in the complex.[167] When an (*S*)-ligand is used, the values of *p* for (*S*)-Ala, (*S*)-Val, and (*S*)-Leu are respectively 54, 29, and 48%:

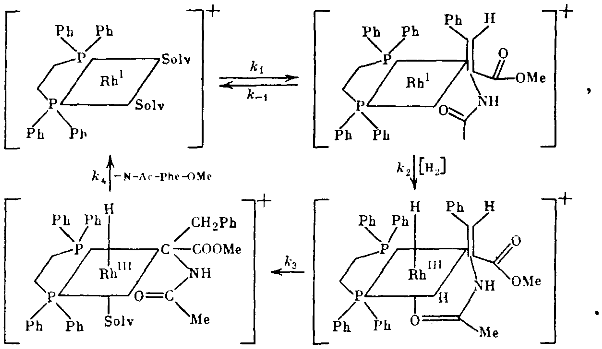


VIII. CATALYTIC ASYMMETRIC REDUCTION

The most effective way of using chiral compounds in the asymmetric synthesis of AA involves their application as catalysts.[168] Striking results have been achieved primarily in the asymmetric reduction of derivatives of prochiral αβ-dehydro-AA (Δ-AA) to the corresponding optically active AA using neutral or, more often, cationic rhodium complexes, containing chiral phosphine ligands, as catalysts.[169] In the reduction of derivatives of α-*N*-acylaminocinnamic acid (AACA), the value of p for many chiral phosphines is close to 100%.[170,171] The results have been described in a series of reviews[28,172–177] and monographs.[178,179] We shall examine data for the determination of the reaction mechanism, the present trends, and the prospects for the method.

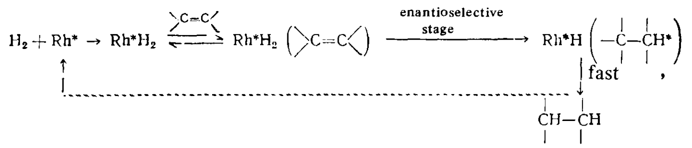
The best rhodium-based catalysts exhibit not only a high enantioselectivity but also a high activity, which approaches that of enzymes and therefore the determination of the mechanism of the reduction of AACA on the basis of the ideas of organometallic and coordination chemistry of rhodium complexes helps also in understanding the effective chiral recognition in such systems. Scheme 6 presents the mechanism of the rhodium complex-catalysed reduction of the AACA ester by Halpern's method.[28] The structure of intermediates was established by spectroscopic methods, resorting in a number of instances to X-ray diffraction;[180–183] the kinetic parameters of all the stages of the catalytic cycle have been determined.[28]

Scheme 6



In the first stage, the formation of a complex with the substrate and the ligand proceeds fairly rapidly and is almost complete even at a low substrate concentration. At 20 °C the second stage of the catalytic cycle—the oxidative addition of hydrogen to the complex—is rate determining and gives rise to a hydride complex in the form of a mixture of the two diastereoisomers (III) and (IV) (Fig.1), characterised at low temperatures as the product of the next stage—reductive elimination.[28] Examination of the structure of the principal diastereoisomer (II) [(II)/(I) > 10 : 1] in solution and in the crystalline state showed that the *re*-side of the substrate is coordinated to rhodium and that the *endo*-addition of hydrogen should give rise to the (*S*)-product, whereas the reaction leads to the isolation of the (*R*)-product with *p* > 95%.[28] It has been shown that the preferential formation of the (*R*)-product is determined by the much higher reactivity of the minor diastereoisomer (I) (Fig.1).[28,184,185]

Ojima and co-workers[186,187] do not dispute this mechanism for the normal reduction conditions but propose an alternative pathway at high hydrogen pressures:

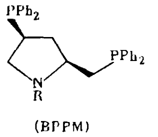


where Rh* is a rhodium complex with a chiral phosphine.

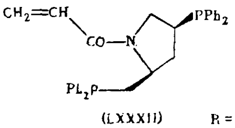
The oxidative addition of H_2 to the complex with the ligand proceeds initially and only then, in the rate-determining stage, does the substrate add on,[186,187] which also agrees with experiment.[188]

One of the important factors influencing the enantioselectivity is the hardness of the complexes (I) and (II) formed. It has been suggested that the lower yields in the reduction of the (*E*)-isomers of AACA compared with the (*Z*)-isomers are associated with the lesser degree of hardness of the complex formed.[186] Effective asymmetric reduction requires the optimum ratio of the rates of the competing reactions in the individual stages of the process, which depends very greatly on the substrate and only AACA or compounds with very similar structures satisfy these requirements.[189] Numerous findings indicating the influence of the form and conformation of the chelate phosphine rings on *p* have demonstrated that five- and seven-membered rings are preferable to six-membered rings owing to the existence of the latter in the rigid chiral C_2-twist conformation.[182,189,190] According to Butler et al.,[183] in a number of instances the size of the chelate ring is of little importance and the principal factor is the nature of the substituent in the phosphine. The main postulate important for the understanding of the stereochemical mechanism of asymmetric hydrogenation has been surveyed by Pavlov and Klabunovskii.[191] It was noted that the stereochemistry of the reaction is determined in the olefin coordination stage with formation of a chelate complex and that the main source of discrimination between the sides of the coordinated prochiral olefin and the catalyst molecule is the chiral disposition of the benzene rings around the phosphorus atom.

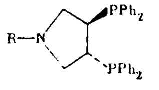
A wide scale search for new and for the modification of the existing phosphine ligands, giving rise to values of *p* close to 100% in asymmetric reduction, has been prosecuted in recent years.[183,192–196] However, the high sensitivity of rhodium catalysts to oxygen and moisture, their high cost, their non-technological nature, and the impossibility of using them at high temperatures, limit their application. There have been only a few successful attempts to reuse a homogeneous rhodium catalyst[197] and also water-soluble diphosphines.[198,199] The problem of the synthesis of chiral organometallic catalysts free from such disadvantages is solved in general by the familiar heterogenisation methods.[200] the synthesis of the rhodium catalyst is usually achieved by introducing a chiral functional group, capable of complex formation, into the achiral matrix. However, the binding of the complexes to mineral clays significantly reduces *p* as a result of the selective absorption of the reduced product by the carrier.[201] Immobilisation on cellulose derivatives gives rise to a low value of *p*,[202] as in the case where a protein is employed as both the carrier and the catalyst.[203] The rhodium complex of BPPM, deposited on charcoal and treated with chromium acetate and Et_3N, gives rise to yields comparable to those of homogeneous reduction (*p* up to 86.5%), which do not fall when the catalyst is reused:[204]



(BPPM)



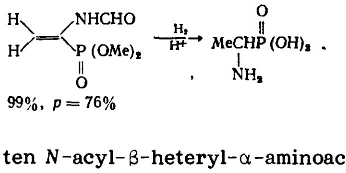
(LXXXII)



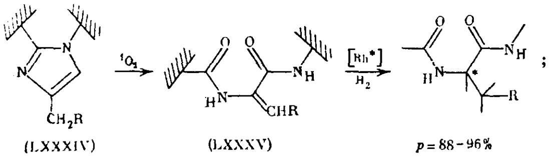
R = H, COPh (LXXXIII)

Best results have been achieved with polymers as carriers.[205,206] Thus optically active phosphine-pyrrolidine monomers (LXXXII) have been obtained, their copolymerisation with hydrophilic monomers and the divinyl monomer affording a cross-linked polymer containing 3–5% of the (LXXXII) fragments, and swelling effectively in the usual hydrogenation solvents.[205] The catalyst was obtained in the usual way by the interaction of $[RhCl(C_2H_4)_2]_2$ with an optically active polymer. Its employment yields *p* = 88–91% for both (*R*)- and (*S*)-N-acylated Phe and DOPA derivatives, the results being equivalent to those obtained under homogeneous reduction conditions. The essential feature of the method consists in a selection of the swellability characteristics of the polymer in the system of solvents employed such that the catalytic section of the polymer is open to interaction with the substrate and is not affected by the functional groups of the main polymer chain.[205] High results have been obtained with (*R*,*R*)-(LXXXIII), synthesised in 8 stages from (*R*,*R*)-tartaric acid with an overall yield of 36%.[207] The rhodium complex of this ligand on the Merrifield resin or SiO_2 permitted the reduction of AACA with *p* = 95% (catalyst/substrate = 1 : 10^4, pressure 50 bar, time h, MeOH). The hydrogenation then proceeds only slightly more slowly than under homogeneous conditions; filtration of the catalyst when the reactions have been completed makes it possible to use it more than once without loss of activity.[207] There is no doubt that the elimination of a whole series of disadvantages of homogeneous rhodium catalysts by their heterogenisation will serve in the future as a stimulus for an even wider employment of these systems. A new approach has been proposed in a study[208] in which the enantioselective hydrogenation of AACA was carried out with the aid of the achiral Wilkinson catalyst—$Rh(PPh_3)_3$—in cholesteryl tridecanoate as a chiral liquid crystal matrix. The temperature dependence of *p* has a maximum corresponding to the middle of the temperature range of the existence of the mesophase. The yield of Phe was 98–100% (*p* = 16%).

Another limitation of rhodium catalysts which prevents their wide scale use in reduction is the small number of substrates which can be used successfully. Thus, satisfactory results have been obtained for eight aminoacids: DOPA, Tyr, Phe, Trp, Ala, Lys, Leu, Val, and some of their derivatives.[171,172,209,210] Their number is now being rapidly expanded. The asymmetric synthesis of the phosphorus analogue of Ala, namely α-aminophosphonic acid, has been carried out over $[Rh\text{-}DIOP]^+$:[21]



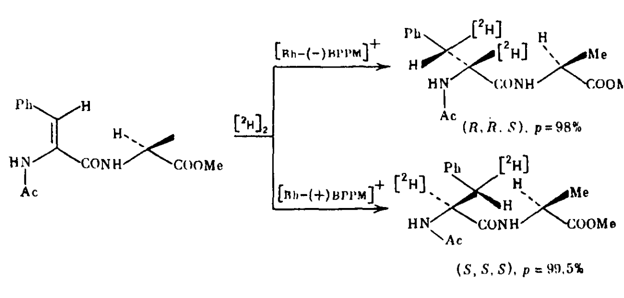
The reduction of ten *N*-acyl-β-heteryl-α-aminoacrylates on this catalyst showed that 2-thienyl, 3-thienyl, 1-methylpyrrolyl, and 3-quinolinyl derivatives are reduced comparatively rapidly with *p* = 20–70%, while the corresponding pyridyl and imidazolyl derivatives are inactive.[212] The photochemical oxidation of cleavage of trisubstituted imidazoles (LXXXIV) with subsequent reduction of the derivatives of Δ-AA amides (LXXXV) has been achieved:[213]



(LXXXIV) (LXXXV) *p* = 88–96%

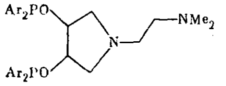
R = H, CHMe₂, Ph .

Overall, the development of the asymmetric reduction stimulated also the develoóment of new ways of synthesising Δ-AA which were previously difficult to obtain.[214] On the other hand, reduction with formation of chiral dipeptides[173,179,197,215] and complex analogues of polypeptides of the type of encephalin[187,216] as well as deuteriated and tritiated polypeptides,[199,217,218] which are difficult to obtain, has also been developing on a wide scale, for example,

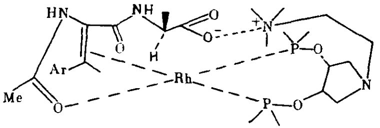


This makes it possible to modify the physiological activity of peptides by inverting the configuration of one or several chiral centres by replacing series of AA by unnatural AA, for example in enkephalin, vasopressin, etc.[187]

The effectiveness of rhodium catalysts in the synthesis of peptides differs somewhat from that for AA.[187] On the other hand, in the reduction of peptides by AACA, ligands forming seven-membered rings produce better results than those forming five-membered rings in view of their greater flexibility, which becomes an important factor when the substrate is polyfunctional.[186] The high enantioselectivity in the reduction of *N*-terminal dehydropeptides (DHP) compared with the *C*-terminal dehydropeptides[219] and also the important role of the *N*-acyl groups, associated with the possibility of their coordination to the Rh atom with formation of a five-membered chelate ring,[218] known also for Δ-AA, has been established. The chiral AA residue in DHP has less influence, since the coordination of its carboxy-group to Rh prevents the oxidative addition of H_2.[218] A detailed study has not been made, but the principal data support the general mechanism proposed for the reduction of AACA [28] (see Scheme 3).



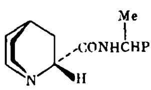
(LXXXVI)



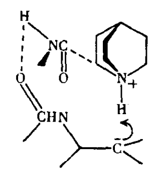
(LXXXVII)

It is of interest that, in the presence of the ω-dimethylamino-group in the ligand (LXXXVI), the diastereoselectivity is inverted also for *N*-Ac-ΔPhe-(*S*)-Phe and the (*S,S*)-dipeptide with $p = 98\%$ is produced.[220] This finding can be explained by the interaction between the NMe_2 group and the COOH group of the peptides, which fixes a definite disposition of the substrate on the catalyst (LXXXVII), while in the case of AACA, where the distance between the groups are large, such interaction does not occur and the yields of (*S*)-Phe are low. The only example of the reduction of bis-DHP over [Rh-DIOP]$^+$ immediately to a mixture of the Phe-Phe dipeptides (*S,S* + *R,R* and *R,S* + *S,R*) is quoted with $p = 9\%$ and 79% respectively.[221] Examples with double asymmetric induction frequently lead to high values of *p*. A stereochemical analysis of such induction within the framework of the interaction of two chiral reagents has been carried out.[173]

The search for effective catalysts using other metals, namely Ru,[222,223] Ir,[224] Pd,[225] and Ni and Co,[226] has been expanded recently. Systems with non-phosphine ligands are promising.[225,227] The development of effective catalysts without platinum group metals is of special interest. A reduction catalysts comprising the complex [Co(dimethylglyoxime)$_2$..base] or [Co(DMG)$_2$.B], used with a chiral catalytic system containing a tertiary amino-group in the α- or β-position relative to the amide group, has been proposed.[227] In the case of $PhCH_2NH_2$ or $P(Ph)_3$ as the base and (*S*)-*N*-[(*R*)-1-phenylethyl]quinuclidine-2-carboxamide (LXXXVII) as the chiral catalyst, the reduction of *NN*-dimethyl-5-benzylidene-hydantoin via compound (LXXXVIII) has been achieved with 93% yield and $p = 79\%$:



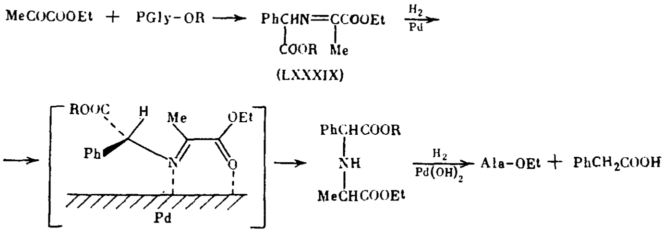
(LXXXVII)



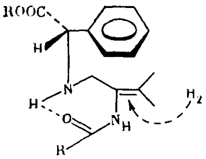
(LXXXVIII)

Thus, the asymmetric protonation of carbanions by chiral acids (Section IV) is a model reaction of the observed catalytic process. The reduction of the AACA ester [in the presence of the chiral catalytic system $CoCl_2$-(+)-neomenthyl-PPh_2-$NaBH_4$] gave $p = 37\%$ for a maximum degree of conversion of 77.5%.[228]

In hydrogenation on heterogeneous catalysts, two procedures are possible—firstly, the use of catalysts modified by treatment with optically active compounds capable of complex formation[229,230] and, secondly, the hydrogenation of the C=C and C=N bonds of the prochiral groups in compounds containing one or more chiral centres. Thus, hydrogenation of derivatives of the AA (LXXXIX) is well known:[231]

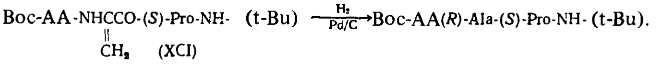


In the latest studies, the AA themselves have been used as the chiral amine,[232] but the values of *p* do not exceed 72% for a yield of 58%. The inadequate rigidity of the binding of the substrate to the catalyst, demonstrated by studying the influence of the solvent and temperature on transamination in compound (LXXXIX),[232] limits the application of the method. Indeed, for the more rigid cyclic systems, for example, in the reductive amination of 2-(*R*)-methylcyclohexanones over Raney nickel, *p* increases to 92–98%.[233] The reduction of acyclic chiral AA amides[234] or DHP [235] proceeds with low values of *p*, while their increase to 40–60% in the case of aromatic compounds can be explained by the formation of structures of type (XC),[235] in which one of the sides of the double bond is shielded and which are analogous to structures (LII)–(LIII), where one of the sides of the chiral carbanion is shielded.



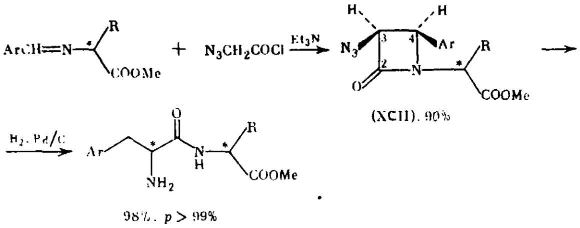
(XC)

The formation of a rigid surface chelate complex has also been proposed in a study[236] where a high value of *p* was obtained in the reduction of linear *N*-Ac-DHP on a nickel catalyst. Indeed the reduction of cyclic DHP on Pd/C usually affords dipeptides with high values of *p* (up to 96–99%).[237] Cyclo-[(*S*)-AA-(*S*)-AA] have been obtained from cyclo-[Δ-AA-(*S*)-AA]; they are hydrolysed to give (*S*)-AA. The reduction of the linear chiral tripeptides (XCI), containing the Δ-AA fragment in the middle unit, has been carried out with $p = 84–93\%$, the use of a C-terminal substituted AA giving better results than the use of N-terminal AA:[238]

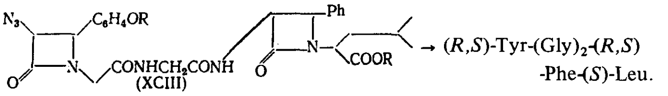


$$\text{Boc-AA-}\underset{\substack{\|\\ CH_2}}{\text{NHCCO}}\text{-(}S\text{)-Pro-NH-(t-Bu)}\ \text{(XCI)} \xrightarrow[\text{Pd/C}]{H_2} \text{Boc-AA(}R\text{)-Ala-(}S\text{)-Pro-NH-(t-Bu).}$$

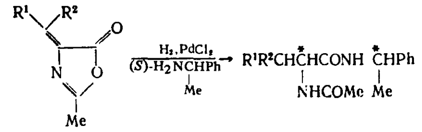
A diastereoselective synthesis of chiral peptides via β-lactams (XCII) has been developed.[239–241] β-Lactams are obtained from the Schiff bases of chiral AA and azidoacetyl chloride and are reduced after the separation of the diastereoisomers (XCII). The essential feature of the method consists in the highly selective cleavage of the N–C(4) bond in the reduction of compound (XCII) on Pd/C:



The use of Schiff bases derived from chiral amines leads to chiral AA amides.[240] The application of β-lactams as chiral synthons[9] made it possible to obtain a series of diastereoisomerically pure oligopeptides, for example a new synthesis of Leu-enkephalin from compound (XCIII) has been achieved:[240]



The reductive ammonolysis of the azlactones (XCIV), for which the rhodium-phosphine catalysts are ineffective, makes it possible to synthesise a wide variety of natural AA.[242] The reduction of compound (XCIV) on $PdCl_2$ with subsequent ammonolysis leads to the corresponding amides N-acetyl-AA:

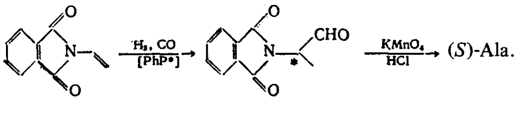


(XCIV)

R^1, R^2=H, Me, $CHMe_2$, Ar .

A yield of 98% with p = 50% (S,S) has been attained for R^1 = 3-MeO-4-$AcOC_6H_3$ and R^2 = H, which made it possible to obtain optically pure (S)-DOPA in 39.5% yield after recrystallisation and hydrolysis.[243]

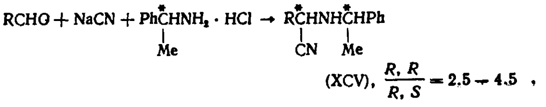
Asymmetric hydroformylation is used little in the synthesis of AA.[244] The N-vinyl derivatives of phthalimides have been converted into (S)-Ala with a yield of 33% (p = 27%)[245] and in a number of instances the yields are even lower:[246]



However, when account is taken of the latest advances in hydroformylation,[168] this application is promising.

IX. THE STRECKER SYNTHESIS

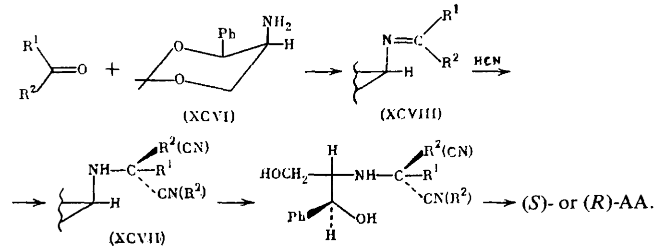
A series of reviews have been devoted to the asymmetric Strecker reaction.[2,3,15] In practice, HCN is usually allowed to react with chiral amines and carbonyl compounds[247] or with the Schiff bases obtained from them beforehand.[248] The recrystallisation of the resulting aminonitriles (XCV) using (R)-$PhCH(Me)NH_2$ makes it possible in a number of instances to raise the yield of the optically active diastereoisomers to 54%.[247] The formation of aminonitriles proceeds subject to thermodynamic control.[15]



$$RCHO + NaCN + Ph\overset{*}{C}H(Me)NH_2\cdot HCl \rightarrow R\overset{*}{C}H(CN)NH\overset{*}{C}H(Me)Ph \quad (XCV), \quad \frac{R,R}{R,S} = 2.5 \rightarrow 4.5\ ,$$

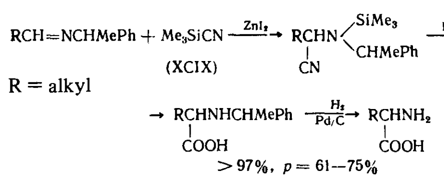
The reaction of acetophenone with HCN and (S)-PhCH(Me).NH_2 results in the preferential formation of the (S,R)-diastereoisomer analogue of compound (XCV), while the (S,S)-diastereoisomer is formed from p-methoxyacetophenone.[249] If the reaction of the readily available (4S,5S)-5-amino-2,2-dimethyl-4-phenyl-1,3-dioxolan (XCVI)[250] with thiophen-2-aldehyde or thiophen-3-aldehyde and HCN is carried out in one stage, (R,S,S)-aminonitriles (XCVII) and respectively (R)-2-thienyl- or (R)-3-thienyl-glycine are formed preferentially, while the intermediate isolation of the imine (XCVIII) results in the preferential formation of the corresponding (S)-AA[248] (Scheme 7):

Scheme 7



Optically pure α-Me-AA,[267] (S)-phenyl- and (S)-anisyl-Gly,[251] (S)-Leu, and (2S,4R)- and (2S,4S)-5,5,5-trifluoro-Leu[252] have also been obtained. The essential feature of the proposed method is the formation of diastereoisomeric readily crystallising aminonitriles (XCVII), whose ratio determines the optical yield of the AA isolated after their decomposition. In a number of instances, only the (S,S,S)-diastereoisomer (with R^1 = CH_2CMe_2OPh and R^2 = Me) or only the (R,S,S)-diastereoisomer (with R^1 = CH_2OPh and R^2 = Me) is formed.[253] In other cases the separation is carried out by recrystallisation.

The Strecker synthesis is nowadays widely used in the multistage method for the preparation of non-protein AA. Pure (S)-γ-carboxy-Glu has been obtained in a low yield from formylmethylmalonic ester in seven stages using (S)-$PhCH(Me)NH_2$.[254] The use of cyanotrimethylsilane (XCIX) is convenient in practice:[255]



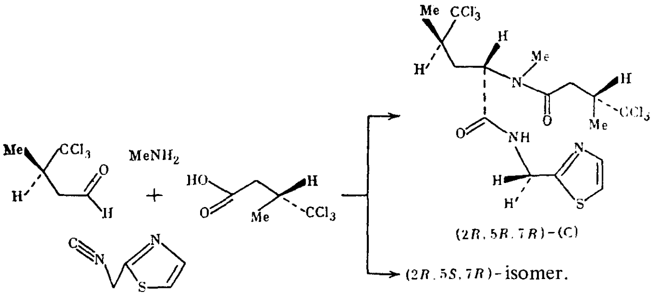
$$RCH{=}NCHMePh + Me_3SiCN \xrightarrow{ZnI_2} RCH(CN)N(SiMe_3)CHMePh \xrightarrow{H^+} (XCV) \xrightarrow{H^+}$$
(XCIX), R = alkyl
$$\rightarrow RCH(COOH)NHCHMePh \xrightarrow[Pd/C]{H_2} RCH(COOH)NH_2\ .$$
$$>97\%,\ p = 61\text{–}75\%$$

The interaction of compound (XCIX) with chiral acetals gives rise to the corresponding cyanohydrins with p = 95%.[256] Thus the Strecker synthesis continues to develop towards the use of new chiral amines in order to eliminate its principal disadvantage—the ready racemisation of diastereoisomeric α-aminonitriles. The use of chiral aminonitriles is being steadily expanded; thus they have been used to synthesise substituted α-hydroxyketones with p up to 97%.[257]

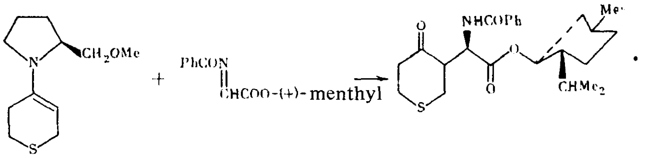
There are great possibilities in the asymmetric catalytic Strecker synthesis. The formation of benzaldehyde (R)-cyanohydrin in the presence of cyclo[(S)-Phe-(S)-His].H_2O takes place with p = 90% for a 40% degree of conversion (PhH, 35 °C, 0.5 h, substrate/catalyst = 1 : 1).[258] The value of p diminishes markedly with increase of the degree of conversion as a result of racemisation.[259] The attempts to carry out the absolute asymmetric synthesis of AA using cyanide compounds, modelling the prebiotic synthesis of AA,[22,260] gave low values of p.

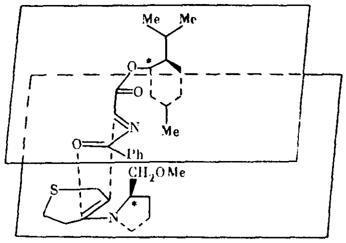
X. OTHER REACTIONS

A successful example of the use of the four-component condensation by the Ugi method is provided by the synthesis of the optically pure peptide (+)-(2*R*,5*R*,7*R*)-13-demethyldysidenin (C) and its (2*R*,5*S*,7*R*)-isomer in 17 and 13% yields respectively:[261]



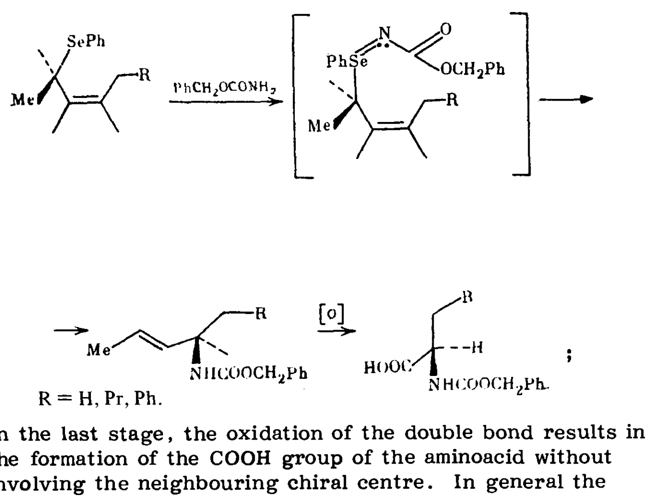
Enantiometrically and diastereoisomerically pure esters of γ-oxo-AA have been obtained[262] via a reaction of the Diels–Alder type, which can be explained by the transition state model (CI)$^{\neq}$.





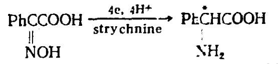
(CI)$^{\neq}$

Here the cooperative effect of the two chiral substituents ensures the stereospecific course of the process and the use of (–)-menthyl ester lowers *p*.[262] The possibility of using the [2,3]sigmatropic rearrangement of substituted optically active selenides for the synthesis of *N*-substituted (*R*)-AA in yields of 58–72% and with $p = 78–84\%$ has been demonstrated:[263]



In the last stage, the oxidation of the double bond results in the formation of the COOH group of the aminoacid without involving the neighbouring chiral centre. In general the oxidation of alcohols and olefins to obtain the carboxy-group is widely used in the synthesis of AA from other optically active compounds: of chiral Gly from D-glucose[264] and of (*R*)-AA from (*S*)-Ser.[23]

Yet another example of the strong influence of the reaction conditions on the optical yield is provided by the electrochemical synthesis of PGly from the oxime of phenylglyoxylic acid in an acetate buffer solution in the presence of strychnine:[265]



$$\underset{\text{NOH}}{\underset{\|}{\text{PhCCOOH}}} \xrightarrow[\text{strychnine}]{4e,\ 4H^+} \underset{\text{NH}_2}{\text{PhCHCOOH}}\ ;$$

cathodic potential, V	–0.95	–1.05	–1.14	–1.30	–1.35
p, %	17.1*R*	11.7*R*	0	10.1*S*	11.1*S*

When a graphite electrode coated with poly-(*S*)-Val is used in this reaction, $p < 2\%$.[266]

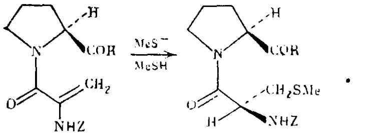
The range of photochemical asymmetric reactions investigated is limited. The first example of asymmetric photolysis, which is especially important for prebiotically valuable substrates such as AA, has been described[267] in relation to the use of (*R*,*S*)-Leu. It has been established that left-(*S*)-circularly polarised light (LCPL), obtained from a laser source with $\lambda = 212.8$ nm, effects the preferential photolysis of (*S*)-Leu, while right-(*R*)-polarised light (RCPL) effects the preferential photolysis of (*R*)-Leu. An enantiomeric excess of 1.98 has been obtained for a 52% degree of conversion with RCPL and of 2.5 for a 75% degree of conversion with LCPL. The stereocontrolled photoalkylation of the Gly residue in the peptide chain proceeds with *p* up to 40%.[268] When the reaction

$$[(S)\text{-Ala-Gly-}(S)\text{-Ala}]_n \xrightarrow[\text{toluene}]{h\nu} [(S)\text{-Ala-}(S)\text{-Phe-}(S)\text{-Ala}]_n \rightarrow (S)\text{-Phe}$$

is carried out in but-1-ene, it is possible to obtain (*R*)-NLe with *p* up to 20%:

$$[(S)\text{-Pro-Gly-}(S)\text{-Pro}]_n \xrightarrow[\text{but-1-ene}]{h\nu} (R)\text{-NLe}.$$

The biomimetic formation of Cys with high chemical) up to 95%) and optical ($p = 85\%$) yields has been achieved:[269]



---o0o---

Chemical asymmetric synthesis makes it possible to obtain any aminoacids with natural and non-natural structures and configurations in virtually quantitative optical yields. A particular advances has been attained in the use of general methods such as catalytic asymmetric hydrogenation and enantioselective alkylation of carbanions generated from aminoacid derivatives. In a number of instances, high optical yields have been attained with double asymmetric induction when the enantioselectivity of the process is determined by two asymmetry centres already present.

The theory of asymmetric induction has been developed to only a very slight extent, because the small differences between the energies of the diastereoisomeric transition or final states which are sufficient for the attainment of a high enantioselectivity of the synthesis are a consequence of slight steric or electronic requirements, which are as a rule difficult to take into account.

The majority of asymmetric syntheses have not been developed as preparative syntheses of aminoacids—their assessment is frequently based on the NMR or GLC analysis of the reaction mixtures. None of the asymmetric syntheses of aminoacids has so far found a serious industrial application, while the separation of enantiomers by crystallisation is very common. Analysis of the literature shows that this is caused by, on the one hand, the high cost and the difficulty of regenerating chiral rhodium compounds, the most effective catalyst of asymmetric synthesis, and, on the other hand, by the fact that the known chiral reagents for asymmetric synthesis, capable of being regenerated, are not as yet capable of propagating the catalytic process. These deficiencies predetermine the direction of the most promising research. Certain optically active aminoacids have become a readily available and cheap source of chirality. In many methods for asymmetric synthesis, they are used as a basis for the preparation of chiral reagents and catalysts.

---o0o---

During the preparation of the review for printing, additional data have appeared in literature. In particular, a chiral polymeric rhodium catalyst based on 3,4-(*R*,*R*)-bis-(diphenylphosphino)pyrrolidine has been obtained. When AACA and its methyl ester were reduced in its presence, products with p up to 100% were obtained.[270] The activity of the catalyst falls after repeated use. The possibility of the quantitative isolation of rhodium after the completion of the reaction has been demonstrated.[271] New data concerning the mechanism of asymmetric reduction have been published.[272] The use of a chiral polymeric platinum catalyst based on DIOP derivatives permitted the hydroformylation of *N*-vinylphthalimide with p up to 70%.[273] The asymmetric aldol reaction of aldehydes with isocyanates, catalysed by the chiral ferrocenylphosphine gold(I) complex, leads to AA with a high value of p.[274]

Poly-L-Val (2%) on CdS catalyses the synthesis of Asp from fumaric acid and NH_4Cl on UV irradiation with $p = 60\%$.[275]

A review has been devoted to the biomimetic transamination of α-ketoacids.[276]

The synthesis of AA with $p > 95\%$ from α-halogenosulphonamidoisobornyl ethers has been published.[277]

(*R*)-*N*-substituted AA have been synthesised from (*S*)-hydroxyacids.[278]

A review has been published on the regio-, diastereo, and enantiostereoselective reactions leading to the formation of a C–C bond using metallated derivatives of aminonitriles, etc.[279]

The aldol reaction of a chiral enolate containing the Gly fragment with RCHO made it possible to obtain a series of enantiomerically pure β-hydroxy-*N*-methyl-AA.[280]

The catalytic asymmetric synthesis of chiral AA amides unsubstituted in the α-amino-group from trifluoromethyl derivatives of azlactones has been achieved.[281]

The use of 2-t-butyl-1,3-oxazolin-5-ones for the synthesis of optically pure α-vinyl-,[282] α-alkyl-,[283] and β-hydroxy-AA [284] proved to be more convenient than the use of compound (XLIV), which is their analogue.

In the continuation of studies on the bislactim method of synthesis of AA, the reactions of cyclo[L-Val-Gly] with epoxides ($p > 95\%$) and Michael addition to activated olefins ($p > 95\%$), with subsequent isolation of the corresponding (*R*)-Ser [285] and (*R*)-Glu [286] have been carried out. (*R*)-Pro, [287] cyclic optically pure AA,[288,289] and various non-protein AA [290] have also been obtained. A simple synthesis of α-aminocyclopropanecarboxylic acid has been described.[291]

The use of the general asymmetric method of synthesis of AA via chiral nickel(II) complexes of type (LXIX) made it possible to synthesise enantiomerically and disastereomerically pure β- and γ-substituted Glu and (*S*)-Pro by condensing Gly with activated olefins;[292] the reaction with alkyl halides affords optically pure AA derivatives.[293]

The possibility of the electrophilic asymmetric amination of various chiral enolates, obtained from carboxylic acid derivatives, by di-t-butyl diazodiformate, has been demonstrated simultaneously in a number of studies.[294–297] The optical yield of α-hydrazinoacids and correspondingly the α-aminoacids reached 99%.

The latest reviews on asymmetric synthesis include also data on AA.[298,299]

Structural Study of Organic Polymers by the Microdiffraction Electron Microscope Method

T.M.Babchinitser and L.G.Kazaryan

The advances achieved by the method of electron microdiffraction in the study of the crystal structures of organic polymers with the aid of the transmission electron microscope are examined and the advantages and disadvantages of the method are analysed. It is shown that the diffraction studies on polymers in a transmission electron microscope not only supplement X-ray data but in many cases provide unique possibilities for structural analysis. The applied aspect of the structural studies of polymers is examined and methods are described for the preparation of the specimens and for protecting the polymeric object from the action of radiation.

The bibliography includes 122 references.

I. INTRODUCTION

Modern electron microscopy (EM) has an enormous potential, providing great possibilities for the study of the microstructures and compositions of substances and materials.[1] The structural motif of the crystal at the level of the detailed atomic structure can be visualised on high-voltage instruments. The method for the recording of electron diffraction in a selected region—electron microdiffraction (EMD), which carries information about the crystal structure, has been brought to a high degree of perfection. The EM results are supplemented by using spectroscopic-analytical devices (analysis of the energy losses by electrons, dispersion of energy, and emission—X-ray, Auger, etc.); all the elements ranging from sodium to uranium can be detected. Electron microscopy has begun to be used in crystal-chemical studies on polymers, which are difficult objects for EM because of their lack of resistance to radiation damage by the electron beam.

When transmission electron microscopy (TEM) is used for the solution of structural problems in polymer chemistry, it has now become possible to achieve in practice simultaneously the recording of the EMD pattern and of the image of the corresponding section of the object under the conditions of light and dark fields. Quantitative analysis of the data makes it possible to determine the structure of the crystalline region of the polymer, including the chain conformation with the coordinates of the atoms and the packing of the macromolecules. When the reflection intensities on the electron diffraction pattern are used, both experimental and computational—theoretical problems arise. As regards the experimental technique, there is the question of the development of standard methods for the preparation of the specimens which do not introduce artefacts into the investigation and which are suitable for obtaining an electron diffraction pattern with a high information content. This includes the problems of protecting the object against radiation damage and of increasing the quality of the EMD pattern, the accuracy of the measurements, etc. Problems of another kind include those of justifying the application of the kinematic approximation to the calculation of the structural diffraction amplitudes, the development of methods for the determination of the chain conformation, etc. These questions are considered in the present review, whose aim is to discuss the possibilities and advances achieved by the EMD method in structural research into organic polymers.

II. THE INFORMATION CONTENT AND VALIDITY OF THE RESULTS OF THE STRUCTURAL STUDY OF POLYMERS BY ELECTRON MICRODIFFRACTION

The theoretical principles of electron diffraction have been described in the monographs of Pinsker,[2] Vainshtein,[3] Cowley,[4] etc. In relation to TEM, the theory and practice of the use of the EMD method have been examined in a series of monographs and manuals by Soviet and foreign authors.[5-12] However, virtually no attention is devoted in these publications to the study of polymers and only Fischer's review,[5] published in 1964, is wholly devoted to this question. Specific data, characterising the contribution of the EMD method to structural research into polymeric compounds by the beginning of the 1980's, have been described in a report to a symposium of the American Chemical Society.[13]

It is noteworthy that, in relation to polymers, the electron diffraction method is relatively new and has developed "in the footsteps" of X-ray diffraction; therefore, in view of the aims of this review, it is useful to consider briefly the general postulates characterising the similarity and differences between electron and X-ray diffraction.

The information content in the electron diffraction pattern is determined primarily by the fact that (as in the case of X-rays) it makes it possible to recreate the molecular and atomic structure of a substance by means of calculations based on the concept of the inverse space of the crystal. In assessing the possibilities of the electron diffraction method, it must be emphasised that the electron microscope has undoubted advantages over the electron diffractometer, making it possible to combine the analysis of the diffraction pattern with the visual study of the microstructure of the corresponding section of the object. This is especially effective in the direct resolution of the crystal lattice.

In the microdiffraction mode of the operation of the transmission electron microscope, one obtains electron diffraction patterns of three main types depending on the phase state of the polymer: ring patterns (from polycrystalline specimens), point or arc patterns (from single crystal specimens), and texture patterns (from axially extended films and fibres).

An electron diffraction pattern of the first type indicates the crystallisation of the polymer and makes it possible to characterise the structure of the crystalline region by a set of interplanar spacings. The electron diffraction pattern of a single crystal consists of one of the planar sections through the inverse lattice; for the complete representation of the inverse lattice in order to determine the geometry of the unit cell, it is necessary to obtain a series of diffraction patterns for different orientations of the specimen relative to the incident beam. A texture electron diffraction pattern with arc reflections along the equator and layer lines is formed when the incident beam is directed at right angles to the extension axis of the specimen and represents either the entire or almost the entire inverse lattice making it possible to calculate the crystallographic parameters and the repeat period of the macromolecule.

The first stage of the microdiffraction study yields structural characteristics such as the space group, the unit cell parameters, the volume and density of the unit cell, the number of monomer units, and the number of chains in the cell. Furthermore, the determination of the intensities of the reflections and calculation of the experimental structural diffraction amplitudes yield information for the determination of the chain conformation and the atomic coordinates and also of the molecular packing by mathematical procedures widely developed previously in relation to X-ray diffraction. The two diffraction methods are similar both as regards the nature of the physical processes and the methodology of the treatment of the experimental data, although they have their advantages and limitations due to the characteristics of the radiation and of the experimental techniques.

X-Rays are scattered by the electron clouds of atoms, while electrons are scattered by the potential generated by the atomic nuclei and their electron clouds. The advantages of electron diffraction are associated primarily with the much shorter wavelength of the electrons, which depends on the accelerating potential:

$$\lambda = h/(2meV)^{1/2} = 12.225/V^{1/2},$$

where h is the Planck constant, m the mass of the electron, V the accelerating potential, and e the electronic charge. The non-relativistic wavelength of the electrons at an accelerating potential of, for example, 100 kV or 1 MV is 0.037 and 0.0087 Å respectively, while the wavelength of X-rays is 1.54 Å (copper anode, K_α line). High-voltage microscopes with accelerating potentials ranging from 500 to 3000 kV have now been developed, which possess a whole series of unique possibilities, in particular they make it possible to raise the resolution on the image (which depends on the wavelength) to the atomic-molecular level.

In connection with the appreciably shorter wavelength, the region of the inverse space of the crystal detected by the EMD method has expanded sharply, on the one hand, and the energy of the interaction of the radiation with the substance has increased, on the other. The characteristic features of the scattering of electrons on passage through the object result in a much greater number of reflections in the diffraction pattern and their intensity is 10^6–10^8 times greater than in the scattering of X-rays. For example, structural analysis by the electron diffraction method makes it possible to determine the positions of the hydrogen atoms, although the ratio of their structural amplitudes to the amplitudes of the carbon atom is much higher than in X-ray diffraction.

Apart from the fundamental advantages indicated above, there are also preparative advantages, namely electron microscopy makes it possible to investigate single microcrystals of the polymer, while the X-ray diffraction method operates mainly with macrospecimens in an oriented crystalline state; therefore the EMD method provides a unique possibility for the structural study of crystalline polymers which are incapable of orientational stretching. When the polymer can be obtained in the form of an oriented crystalline specimen, the possibility of obtaining the electron diffraction pattern of a single crystal together with a texture electron diffraction pattern and a texture X-ray diffraction pattern is also extremely important, since it makes it possible to overcome a series of disadvantages which lower the information content of the experimental data for the texture.[14] The disadvantages of the difraction pattern of the axial texture include the small number of Bragg maxima and the relatively low intensity, which has an especially negative effect on the reflections which require a high resolution; furthermore, a partial loss of reflections is observed owing to their overlap and disappearance against the diffuse scattering background due to the amorphous regions of the specimen.

The electron diffraction patterns of single crystals are free from the above limitations. They exhibit a greater number of reflections in the basal plane and their intensity is higher, which increases the information content of the diffraction data and in particular it makes it possible to refine the character of the systematic extinctions.[13] For example, in the study of poly(trimethylene terephthalate) it was shown[15] that the X-ray diffraction pattern of the fibre has 5–10 equatorial reflections with $hk0$ indices, while the electron diffraction pattern of a single crystal contains at least five times more reflections due to the basal plane, from which the space group and the unit cell parameters were determined acurately.

As regards the comparison of the X-ray and electron diffraction patterns of the axial texture, both methods provide analogous information, although the higher intensity of the reflections on the remote layer lines of the texture electron diffraction pattern makes it possible to determine more accurately the repeat period of the macromolecule.[16] It is noteworthy that the advantages of the texture electron diffraction patterns were elucidated already at an early stage in the development of electron diffraction and were demonstrated in a study[17] of the structure of cellulose.

The disadvantages of the EMD method are caused primarily by the fact that the electron microscope equipment is much more complex than the X-ray diffraction equipment and much more stringent requirements must be met by the technical state of the microscope, the correct focusing of the objective, the quality of the calibration of the apparatus constant, etc. Furthermore, the probability of error increases as a consequence of the effect of radiation on the microspecimen. For example, in the study of the structure of poly(trifluoroethylene) it was established[18] that the damage of the specimen on irradiation leads to unduly high unit cell parameters compared with X-ray diffraction data. The authors of special manuals on practical electron microscopy have arrived at the unambiguous conclusion that the accuracy of measurements based on electron diffraction patterns with the maximum possible prevention of errors is at least to within 0.1% of the measured interplanar spacings. One of the most important factors governing the improvement of accuracy is the calibration of each electron diffraction pattern by the vacuum sputtering of a test object (TlCl, Au, Al) on the electron microscope grid holder.

The fundamental problem of taking into account the dependence of the intensity of the reflections on structural amplitudes arises in structural analysis based on electron diffraction data.[3,4,8] The corresponding calculations in electron diffraction studies are carried out in terms of the so called kinematic theory of the scattering of waves by crystals. This presupposes that, under the influence of the primary beam, each atom becomes a source of secondary spherical waves, whose amplitude is much smaller than the amplitude of the initial wave. The scattering process is not accompanied by a change in wave length and there is no repeated scattering of the waves already scattered or such scattering may be neglected. Being propagated in all directions with phase relations determined by the geometry of the relative positions of the scattering centres, the secondary waves interfere with one another and determine the overall intensity of the reflections. However, since in the absence of X-rays the electrons strongly interact with the substance, the application of the kinematic theory is limited by the conditions stipulating a small thickness of the crystal (100–150 Å) and the absence of its bending on the support. Otherwise the intensity of the diffraction maxima may be influenced by dynamic scattering, i.e. by the repeated scattering of the already scattered electrons.

The two-wave approximation of the dynamic theory presupposes that only two waves—primary and diffracted—interact in the crystal. The multiwave theory takes into account both the multiple interaction of the diffracted waves and the finite size of the object, the different energy losses, etc. The role of dynamic scattering increases if the molecule contains heavy atoms and also with increase in the accelerating potential. Cowley,[19] Goodman and Moodie,[20] as well as Dorset and Moss[21–23] have been concerned with the influence of dynamic scattering on structural diffraction amplitudes. In relation to the analysis of diffraction by thin and deformed crystals of paraffins, the last workers demonstrated that the kinematic theory of scattering can be adopted as a suitable approximation in the calculation of the atomic structure, but in each specific case it is necessary to check the influence of the dynamic scattering in order to complete the investigation and to obtain a reasonable agreement between the experimental and calculated structural amplitudes.

III. ADVANCES AND PROSPECTS IN THE APPLICATION OF THE MICRODIFFRACTION METHOD TO THE DETERMINATION OF THE CRYSTAL STRUCTURES OF ORGANIC POLYMERS

The first studies on polymers by the electron diffraction method were carried out by Soviet workers using an electron diffractometer at the beginning of the 1950's.[24–28] Precision studies involved the determination of the structure of a synthetic polypeptide—poly(γ-methyl-L-glutamate)[29] and the refinement of the atomic coordinates (including hydrogen) in the poly(ethylene terephthalate) macromolecule.[30] There is no doubt that studies at this level prepare the ground, as it were, for the development of quantitative microdiffraction methods.

Systematic studies on organic polymeric compounds by the TEM method began at the end of the 1950's and the possibility of microdiffraction observations was already used in the first classical investigations by Till,[31] Keller,[32] and Fisher.[33] The results obtained by the EMD method played an important role in the development of ideas about the characteristic features of the crystallisation of macromolecules[34–36] and the hypothesis of the folding of polymer chains was put forward on the basis of the electron diffraction patterns of a thin film of guttapercha long before the start of systematic research into the crystallisation of polymers.[37] However, the problem of applying EMD to the structural analysis of polymers was not formulated and solved until 1974 when Claffey et al. demonstrated the possibility of using the reflection intensities in the electron diffraction pattern of a single crystal in a study of poly[3,3-di(chloromethyl)-oxacyclobutane].[38] The authors were able to confirm the X-ray diffraction data for the cell geometry, to refine the space group, and to determine the atomic coordinates and the conformation of the side chains.

The crystal structures of polymers according to electron microdiffraction data.

Notation: ρ_c is the density of the crystal, ρ_a the density of the amorphous specimen, z the number of units in the unit cell, n the number of chains in the unit cell, N the number of reflections on the electron diffraction pattern; the following notation has been adopted for the chain conformation: H = helix, P = planar, Z = zigzag, T = *trans*, and G = *gauche*.

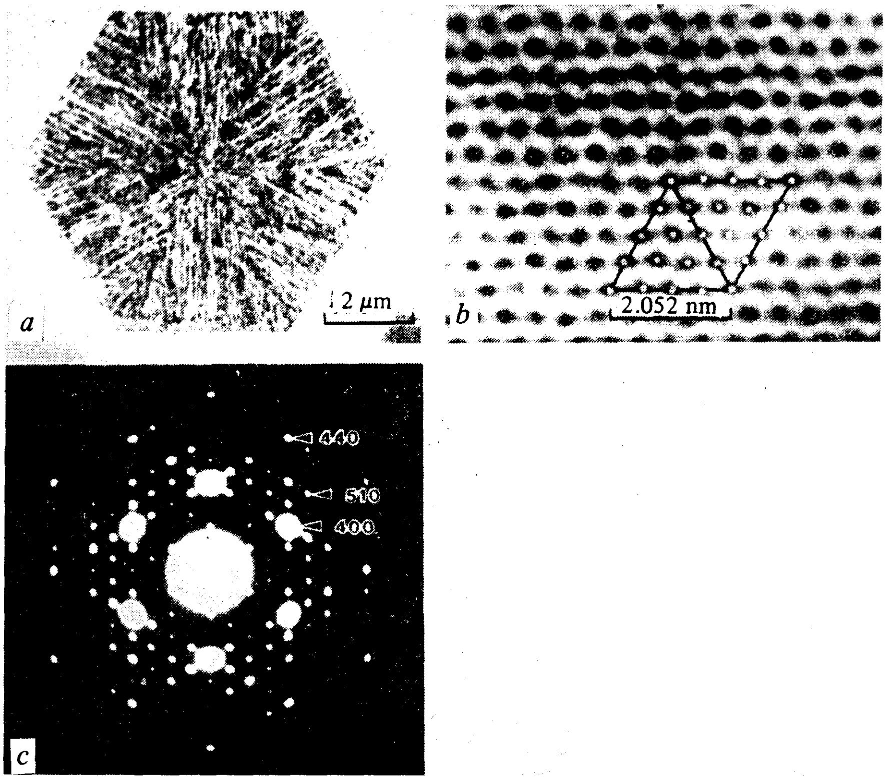

Figure 1. The electron microscope study of poly(*p*-xylene):[53] *a*) single crystal of the β-form; *b*) image of the crystal lattice obtained with the aid of a high-voltage microscope having a resolution of 0.20–0.15 nm; each dark spot corresponds to the projection of the macromolecule onto the basal plane and the white circles indicate the position of the macromolecules in the unit cell; *c*) electron diffraction pattern of a single crystal of the β-form; the numerals denote the indices of the corresponding reflections.

One of the most important results of their study[38] was the demonstration of the applicability of the kinematic approximation to the calculation of structural diffraction amplitudes. This study influenced the general level of electron microscope investigations of polymers and opened up ways to the use of TEM as a method for structural analysis. Since its publication,[38] more than 10 years have elapsed, but one must conclude that the development of research on these lines is relatively slow evidently due to the experimental difficulties in the preparation of the objects and the determination of electron diffraction patterns of a sufficiently high quality and with an adequate information content; the main bulk of the determinations of the structure of polymers are therefore carried out at the present time by the X-ray diffraction method. On the other hand, in recent years there have been undoubted advances in the use of EMD.

The advances achieved with the aid of EMD can be analysed by means of a Table which presents the most accurate studies demonstrating the level of modern research and the characteristic range of objects. The publications included in the Table can be divided into two groups—those carried out without taking into account the reflection intensities in the electron diffraction pattern for compounds (I)–(VIII) and those using them in order to carry out a complete structural analysis of compounds (IX)–(XXI).

In the studies of the first group, the determinations were made of the space group, of the unit cell parameters, and of the packing elements and, for compounds (II)–(IV), (V), and (VIII), the hypothesis concerning the chain conformation was justified. The value of studies of this kind consists primarily in the fact that the structures of the compounds investigated cannot be studied by X-ray diffraction because neither oriented specimens nor sufficiently large crystals can be obtained for such compounds. Polymers of this type include poly(*p*-oxyphenylene-*m*-carbaboranyl),[39] poly(dipropylsiloxane),[40] and also weakly orientable poly(diarylsiloxanes).[41] All the polymers enumerated were first investigated with the aid of EMD. Poly(vinylidene fluoride) had been studied earlier by X-ray diffraction but the controversy concerning the structure of its γ-form extended over a decade and it was shown that mechanical deformation leads to a polymorphic transformation (the transition from the γ-form to the β-form). The study of single crystals with the aid of the electron microscope, which rules out the necessity for the mechanical deformation of the specimen, made it possible to determine unambiguously the structure of the γ-form and also to observe the phase transition to the ε-form on thermal annealing of crystals of the γ-form.[42]

Analysis of the examples presented in the Table shows that polymers whose properties have attracted attention have been most often the objects of electron microscope studies. Such objects include, for example, the class of polyphosphazenes, forming liquid crystal systems, whose representatives are poly(bistrifluoroethoxyphosphazene) and poly(bisphenoxyphosphazene).[43] Poly(*p*-oxybenzoyl) also has interesting properties,[44,45] because its copolymers with other polyesters make it possible to obtain liquid crystal systems.[46,47] This polymer was first investigated in 1976, but the structure proposed for the double helix was not confirmed by other physical methods. A precision reinvestigation carried out in 1984 made it possible to correct the initial data and to determine unambiguously the crystal structure of the compound.[45]

In assessing the advances achieved with the aid of the EMD method in polymer chemistry on the basis of the results of compounds (IX)–(XXI) (see Table), one may conclude that this method permits crystal-chemical determinations whose aim is to establish the atomic structure and the molecular packing of high-molecular-weight compounds. A number of compounds of this group had been investigated earlier by the X-ray method. These include poly[3,3-di(chloromethyl) oxacyclobutane],[38] poly(ethylene sulphide),[14] cellulose triacetate,[48] poly(β-oxybutyroyl),[49] polyesters of terephthalic acid and aliphatic glycols,[13,15,51,52] and also *trans*-polyacetylene.[52] For these polymers, the results of EMD studies confirmed, revised, or supplemented the existing X-ray diffraction data. In other cases, the structure of the compound was determined for the first time by the EMD method, for example, those of poly(*p*-xylylene),[53,54] poly(1,4-*trans*-cyclohexanediyldimethylene succinate),[55,56] and poly(1,11-dodecadiyne).[57]

When the total structural analysis of the polymer by the EMD method is carried out, this problem is greatly facilitated in those cases where data are available for the structures of the individual fragments of the polymer unit and the way that they are linked together. The structures of low-molecular-weight compounds serving as models of the monomer units of the macromolecules have been determined for this purpose. For example, the structure of cellulose triacetate has been deduced from data on the structure of the trimer.[48] Dimethyl terephthalate and the diphenyl ethers of the corresponding glycols have been investigated as models of the units in polyesters.[15,49–51] An analogous procedure has been used in the study of poly(1,4-*trans*-cyclohexanediyldimethylene succinate).[55,56]

A number of the publications presented in the Table reveal very great advantages of diffraction electron microscopy in the study of polymorphism. Thus it has been found that the texture X-ray diffraction pattern of poly(hexamethylene terephthalate) contains reflections from several polymorphic phases which are superimposed and cannot therefore be used to establish the structure of each of these phases. On the other hand, in the study by the TEM method the crystals of each phase have their own characteristic form and give rise to an individual EMD pattern; furthermore, in the polymer

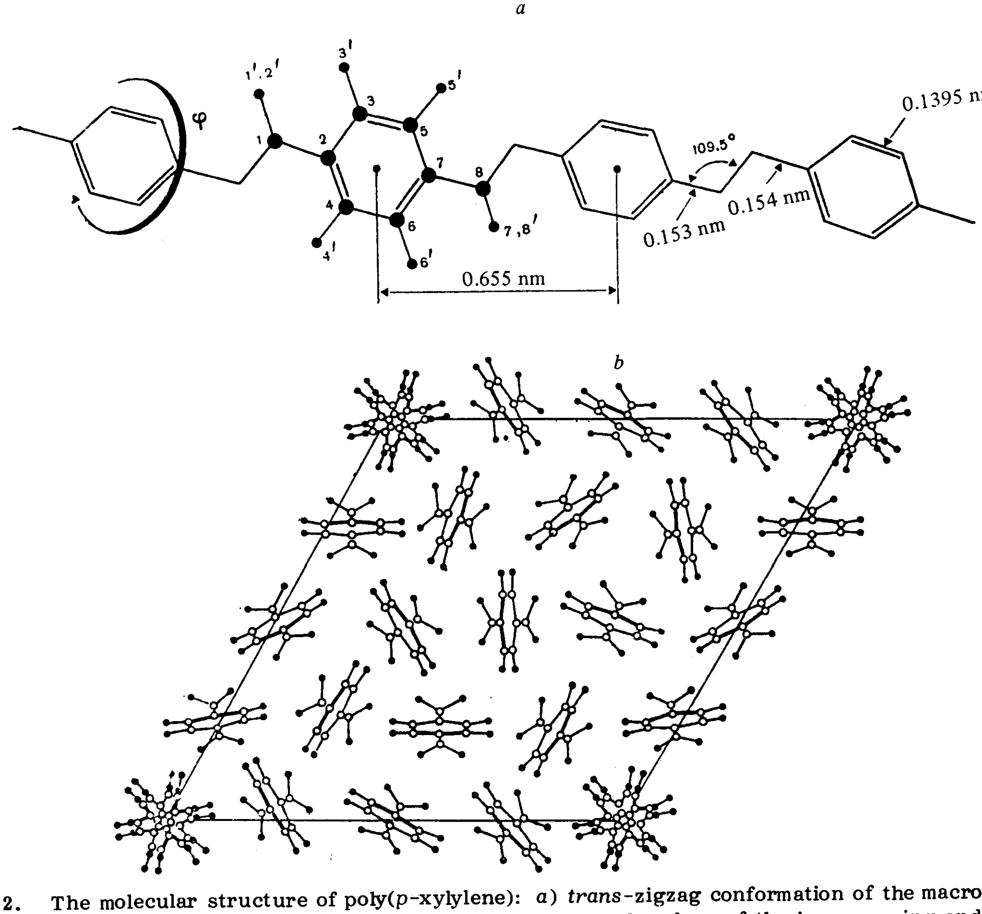

Figure 2. The molecular structure of poly(*p*-xylylene): *a*) *trans*-zigzag conformation of the macromolecule with a repeat period of 0.655 nm; $\phi = 90°$ is the angle between the plane of the benzene ring and the plane of the $-CH_2-CH_2-$linkage; *b*) three-dimensional structure of a single crystal of the β-form in projection onto the basal plane; the filled and open circles denote carbon and hydrogen atoms respectively; the unit cell contains 16 macromolecules, one of which assumes one of three equivalent positions in accordance with the *P*3 symmetry.

phase I it is possible to distinguish two similar structures. Separate analysis of electron diffraction patterns of single crystals made it possible to characterise all three polymorphic phases [(XIV)–(XVII), Table] and to index fully the reflections on the X-ray diffraction pattern. The problem of isolating one of the polymorphic phases has been solved also for poly(*p*-xylylene) [(XVIII), Table] in an investigation by Japanese workers,[53,54] which demonstrated the high level of the advances in the application of TEM to the study of polymers. Electron microscopes of two types were used—with a potential of 80 kV (JEM-7) and a high-voltage microscope (JEM-500). In both cases images of both the microstructure and of the EMD pattern were obtained (Fig.1). The structure of the β-form with an *R*-factor of 0.21 was analysed on the basis of quantitative microdiffraction data; the application of the high-voltage instrument enhanced the local nature and the resolution of the EMD patterns and also reduced the radiation damage during the recording of the pattern. A series of focal photomicrographs with a resolution of 1.5–2 Å were obtained. The photomicrographs, representing a direct resolution of the crystal lattice of the β-form, were treated by the optical filtration method. The optical diffractometer trace for the image coincided with the EMD pattern of the single crystal.

The resolution of the interplanar spacings on the photomicrograph was achieved for polydiacetylene single crystals on the basis of 1,6-di(*N*-carbazolyl)hexa-2,4-diyne[58] and also poly(*p*-phenyleneterephthalimide).[59] However, only in the case of poly(*p*-xylene) did the combination of the analysis of the high resolution image and the EMD patterns lead to the determination of the chain conformation and the atomic coordinates and to the discovery of the characteristic features of the molecular packing in the crystal (Fig.2).

The methodological procedures in the crystal-chemical determinations of the structures of polymeric compounds are extremely individual and depend to a large extent on the complexity of the structure of the object and the completeness of the available experimental data. A general approach to the solution of the problem usually involves the conformational analysis of the postulated model, which makes it possible to determine the chain parameters influencing the repeat period and also the internal energy of the system. Then the conformation in best agreement with experimental data is selected by trial and error. Apart from conformational analysis the Fourier synthesis of the electron density has been used, for example, by Claffey et al.[38] and Roche et al.[48]

The model is refined by the method of least squares, familiar from X-ray diffraction, modified for the determination of the structure of the macromolecule by introducing stereochemical limitations.[60,61] The method involving the minimisation of the packing energy[62] and the combination of the two methods mentioned[63] are also used. The *R* factor defining the agreement between the calculated theoretical and experimental structural diffraction amplitudes in accordance with the formula[8]

$$R=\sum_{hkl}\|\Phi_e|-|\Phi_t\|\Big/\sum_{hkl}|\Phi_e|,$$

where Φ_e are the observed structural amplitudes and Φ_t are the theoretical structural amplitudes for the proposed model, serves as the criterion of accuracy.

As can be seen from the corresponding columns in the Table, in modern studies the *R* factor is approximately 0.3 to 0.2, which indicates a fairly high accuracy of the results, bearing in mind the complexity of the macromolecule as an object of structural study.

Much attention has been devoted in studies of compounds (IX)–(XXI) to the validity of the application of the kinematic approximation to the calculation of structural diffraction amplitudes. Claffey et al.[38] proposed the agreement between the results of EMD and X-ray diffraction and also a weak influence of dynamic scattering on the R factor in test calculations as validity criteria. In a special appendix to a communication concerning the study of the structure of poly(1,4-*trans*-cyclohexanediyldimethylene succinate),[56] it was shown that ideal single crystals 100 Å thick are bent by not more than 2° and that dynamic scattering exerts only a weak influence on the *R* factor. In a study of poly(hexamethylene terephthalate), no bending of the crystals whatever was observed.[50] Under these conditions, the kinematic theory is fully applicable.

It must be emphasised that, in selecting the section for microdiffraction study, it is essential to employ a combination of the light field and the dark field modes of the operation of the electron microscope in order to choose suitable crystals. In the studies quoted above special attention was devoted to the reproducibility of the experimental results and to the accuracy of the measurements of the intensities. For this purpose, several tens of EMD patterns were photographed and the intensities were measured with the aid of automatic scanning microphotometers.

IV. THE PRACTICAL VALUE OF THE RESULTS OF STRUCTURAL STUDIES ON POLYMERS

Analysis of publications on the structural analysis of polymers by the EMD method has shown that in such investigations the authors endeavour to relate the characteristics of the structure of macromolecules to the physicochemical properties of the materials. Thus in a study of poly(trimethylene terephthalate), it was established[15] that the aliphatic fragment of the chain has the *trans*, *gauche*, *gauche*, *trans*-conformation and that the transition from the *gauche*-to the *trans*-conformation does not require much expenditure of energy, which accounts for the high capacity of this material for orientational stretching. As a result of a study of tolyl-substituted poly(diarylsiloxanes), it was found[41] that, with increase in the number of substituents in the benzene ring, the crystallographic cell parameters are altered, which increases the interchain distance; in its turn, this improves the solubilities and lowers the melting points of the materials.

A characteristic example of the direct relation between the structural results and the solution of problems of practical importance is provided by the study of the structure of polyacetylene. It has been shown that the conductivity of the material depends on the ratio of the *cis*- and *trans*-isomers and that only the latter isomer is thermodynamically stable.[52,64] Evidently, the knowledge of the structural characteristics of each isomer is extremely important for the solution of the problem of the specific influences on the properties of the materials in the synthesis of the polymer and its subsequent doping. However, the X-ray diffraction data obtained are controversial because of the thermodynamic instability of the *cis*-isomer and also because of the dependence of the structure of the compound on the polymerisation catalyst used. Furthermore, polyacetylene films cannot be made into highly oriented objects, which limits the scope of X-ray diffraction.

The electron microscope method provides much more information in the study of the structure of polyacetylene, since it makes it possible to carry out its formation reaction directly on the electron microscope grid, the fibrillar crystals giving rise to a high quality texture electron diffraction pattern. The first studies on these lines were performed in 1980.[65] Then Shimamura et al.[52] were able to carry out a complete structural analysis and to obtain the crystallographic characteristics of the *trans*-isomer (XVII) (see Table), which were then confirmed also in other investigations.[66,67] In

1984 Dickenson et al.[68] studied the isomerisation of polyacetylene directly on the electron microscope grid and proposed a method for the determination of the *cis–trans*-isomeric composition of the polymer with the aid of EMD patterns. Simultaneously with the study of the structure of polyacetylene, the investigation of the doped materials by the EMD method was begun. Analysis of the studies on polyacetylene shows that, although they have not yet been completed and the structural data are so far contradictory,[69] nevertheless the electron microscope method is irreplaceable in the investigation of the initial polymer and of the conducting materials based on it.

Yet another example of the large amount of information derivable by the microdiffraction method is provided by the investigation of the solid-phase polymerisation of diacetylenes. The structural analysis of poly(dodeca-1,11-diyne) and of the insoluble product obtained by its γ-irradiation has been carried out.[57] This study led to interesting conclusions about the mechanism of structure formation in the final product (XXI). Namely, it was shown that the reaction involving the cross-linking of the chains is of the solid-phase type, because a secondary product is formed following a slight rotation and migration of the molecules along the crystallographic *c* axis when the closest packing of the parallel layers of polymer chains is achieved. This was indicated by the absence of a change in the space group and by the decrease in the volume of the unit cell of the crystal.

An electron microscope study of polydiacetylene based on 1,6-di(*N*-carbazolyl)hexa-2,4-diyne has been carried out (using TEM, scanning EM, and high-resolution TEM), which made it possible to obtain crystallographic data and a direct image of the structural motif of the crystal.[58] Polydiacetylene based on 2,4-hexadiynylene bistoluene-*p*-sulphonate was investigated in solid-phase polymerisation on the electron microscope grid[70] and also directly in the chamber of the electron microscope.[71] In the latter case it was claimed that the results of the investigation are of practical interest for the preparation of photoresistors. An important structural result of the studies of the solid-phase polymerisation of diacetylenes is the demonstration of the formation of fully straightened chains distributed in the plane of lamellar and fibrillar crystals.[70]

An application of electron microscopy with practical importance involves the study of the structure of highly modular thermostable fibres of the type of poly(*p*-benzamide)[59] and poly(*p*-phenylenebenzothiazole).[72] The crystal structures of these compounds have been investigated, by X-ray diffraction, but the joint application of scanning and transmission EM (the light and dark field of modes, EMD) also helped to elucidate the structural organisation of these materials which determines their unique properties.

Thus one may conclude that the importance of the microdiffraction method consists not only in the determination of data on the structures of the crystalline regions of polymers, but also in the possibility of using the structural results for the solution of applied technological problems.

V. MODERN SOLUTIONS OF EXPERIMENTAL PROBLEMS INVOLVING THE APPLICATION OF THE ELECTRON MICRODIFFRACTION METHOD TO THE STUDY OF POLYMERIC COMPOUNDS

The success of the structural analysis of polymers depends in many respects on the solution of a series of experimental problems, such as, for example, the preparation and correct recording of data for the test objects. As shown above, electron diffraction patterns of single crystals have the highest information content (based on the resolution of the reflections and their intensities). A general method for the preparation of single crystals involves crystallisation from solutions and systematic studies of the structures of polymers were begun with its aid.[31–33] In the Soviet Union this field was pioneered by members of Kargin's School.[73–75] Various methods of crystallisation from solutions were developed by the end of the 1970's. These methods are characterised by two main procedures: the use of highly dilute solutions (0.001–0.1%) and rigorously controlled crystallisation temperatures. The long crystallisation period, necessary for the preparation of perfect crystals, is noteworthy (for example, several days in the crystallisation of polyacrylonitrile[76] or even several weeks in the case of isotactic polystyrenes[77]). Even readily crystallising polymers, such as, for example, poly(*p*-xylylene) (XVIII) (see Table), have to be maintained at the crystallisation temperature for several days.

The method and mechanism of crystallisation from solutions have been examined in greatest detail in the paper of Blundel et al.[78] and in Keller's review.[79] It was shown that, in the course of repeated dissolution and precipitation of polymers, a crystallisation "memory" is retained in the form of the spontaneous formation of nuclei on which the macromolecules are recrystallised. There exists a limiting redissolution temperature at which the crystals formed have a monolayer character with a perfect habit and a uniform thickness even at a relatively high concentration of the initial solution (0.1%), although an increase in concentration usually complicates the morphology of the supermolecular formations. For example, the temperature of the primary dissolution of polyethylene in xylene was 120 °C and was determined visually from the transparency of the solution and by dilatometric measurements. On cooling to 75 °C, exhaustive crystallisation occurred with appearance of turbidity in the solution, which again became transparent at 98 °C. Repeated isothermal crystallisation at temperatures in the range 98–105 °C led to the formation of perfect crystals giving rise to a distinct EMD pattern. This method is general for the crystallisation of polymers from solutions, naturally with an individual selection of crystallisation temperatures. It has been used in studies on the crystallisation of compounds (IV), (V), and (IX)-(XVI).

For polymers which are readily soluble in organic solvents and which are not precipitated from the solution on cooling, hot concentrated solutions are mixed with a suitable amount of precipitant. This procedure was proposed in early studies[58,59,80] and is again used nowadays, for example, in the preparation of polymers such as derivatives of polyphosphazene (VI) and (VII) (see Table). A difficult feature of the method is the need to eliminate the possibility of contact between the polymer and an excess of the precipitant, which is achieved by rigorous stirring or by breaking the tube with the solution in the flask containing the precipitant. Polymers also crystallise when solutions are cooled very slowly, for example, at a rate of 0.5 K h^{-1} and less, as was done in the crystallisation of poly(ethylene terephthalate).[81]

In carrying out crystallisation from solution, one should bear in mind that polymers can form solvates with the solvent.[82,83] A specific feature of the solvates is the breakdown of their crystal structure after the removal of the solvent or after its replacement by another liquid, as a result of which the diffraction patterns of the electron microscope preparation vanish.[64,84] In order to rule out the possibility of the formation of solvates in the preparation of perfect polymer single crystals, it is necessary to use mixtures of a poor solvent with the precipitant and a high crystallisation temperature. It is then also essential to subject the suspensions to hot filtration with subsequent drying *in vacuo*.[85]

A simpler method of preparation of single crystals has been proposed.[66,86] It actually consists in isothermal crystallisation from a dilute solution in an atmosphere of the solvent itself. The authors of these investigations obtained polyethylene, polypropylene, isotactic polybut-1-ene, polyacrylonitrile, and cellulose triacetate single crystals in the following manner: a glass plate attached to a string was lowered vertically into a thermostatted solution of the polymer and, after being kept there for a short time, was removed with the aid of a mechanical device at a rate of 1 cm h^{-1}; after it had risen fully, the plate was kept for a further 1 h in the solvent vapour, the polymer film was transferred to the surface of water by a standard method, and was fished out onto the grid holder. This method has not come to be widely used but it has been tested successfully on a series of polymers, for example, in the crystallisation of carbaborane-containing polyesters and polydiarylsiloxanes (I), (III), and (IV) (see Table).

The preparation of electron microscope objects, synthesised by solid-phase polymerisation, is also closely related to methods of crystallisation from solution. The question of preparing almost defect-free polymer single crystals by the topochemical polymerisation of diacetylene derivatives has been examined in a review,[87] which also includes electron microscope results. The usual method of preparation of the objects [for example, compound (XIX)—see Table] involves the initial growing from the solution of perfect monomer crystals in the form of lamellae[57] or needles,[59,69] which are deposited on a grid holder with a carbon support and are then subjected to various types of treatment to polymerise them, for example γ-irradiation from a ^{60}CO source. Similar methods have been used in the preparation of polyacetylene (XX) specimens (see Table): a solution of the catalyst is deposited on the grid with the support, dried, cooled to −78 °C, and maintained in a stream of acetylene at a pressure of 3–5 mmHg for 20 s; the *cis*-isomer is converted into the *trans*-isomer by heating the object on the grid at 200 °C for 2 h.[52]

In the preparation of crystals from solution, an extremely important stage involves the deposition of the object on the grid holder, because kinematic scattering conditions break down not only when the thickness of the crystals increases but also when they are bent. It has been shown that the best support for the preparation may be a thin carbon film, although it does in fact increase the diffuse background on the image and on the EMD patterns.[52,54] The orientation of the crystals on evaporation of the solution can be specified by the surface of the base, for example, the cleavage surface of NaCl or mica. A precision study by this method has been carried out[42] [compound (V)—see Table]. It was shown that, in the thermal crystallisation of poly(vinylidene fluoride), epitaxial growth in two mutually perpendicular directions is observed on the NaCl surface. Analysis of the EMD patterns of the object crystallised on mica and on the NaCl surface, with the aid of goniometric measurements, yielded information for the most accurate determination of the crystallographic parameters of the γ-phase.

As already stated in Section II, the texture electron diffraction patterns of films or fibres can be used in addition to the electron diffraction patterns of single crystals for the determination of the crystal structures of polymers. The development of methods for the orientational crystallisation of thin polymer films was dictated not only by the need to determine the molecular structure but also by the possibility of investigating the supermolecular structures of partly crystallised specimens under low-angle diffraction conditions. We shall not deal with this field of study, but procedures for the preparation of oriented crystalline specimens for electron microscopy have been described.[88–90]

The methods of preparation of thin oriented films have been described for poly(vinylidene fluoride),[91–93] poly(alkaneimides),[16] poly(diarylsiloxanes) [compounds (III) and (IV)—see Table] and poly(ethylene sulphide) (X). In the main, the preparation of the specimens reduces to casting thin films from dilute solutions (0.5–0.25%) and their monoaxial stretching with simultaneous or subsequent annealing at a temperature close to the glass point. This procedure involves considerable experimental difficulties in view of the small thickness (and hence low strength) of the films. Miniature devices in the form of frames of different design, to which the films are attached by adhesion on being withdrawn from water, are used for stretching. Devices for stretching in the microscope itself have also been proposed.[94] It is noteworthy that many investigations prefer to use the primitive method involving the stretching of the films on water with the aid of forceps[95] or on glass in a softened state with the aid of a spatula. For example, during this preparation procedure, it has been possible[14] [compounds (X)—see Table] to obtain the EMD pattern of a film of crystalline oriented poly(ethylene sulphide), which was suitable for complete structural analysis (in combination with electron diffraction patterns of single crystals). The polymer can also be subjected to deformation not only by stretching the specimen but also by shear, as has been done, for example, in the study of poly(*p*-phenyleneterephthalimide)[96] and also polyacetylene.[97]

Whereas the preparation of oriented crystalline films presents major difficulties to the investigator, the study of the structures of crystalline fibres is greatly facilitated, since in this case one can use the ultrasonic dispersion method with subsequent deposition of the object on grid holders with a support. Dispersion methods and devices have been described in practical manuals.[98] As an example of the use of dispersion in EMD studies, one may quote the investigations of highly modular thermostable fibres.[59] An unexpected result was obtained in the preparation of a poly(*p*-oxybenzoyl) (VIII) specimen, where the dispersion of the initial powder made it possible to observe in the electron microscope both polymer crystals and fibres giving rise to a texture electron diffraction pattern.

In addition to the methods described, mention should be made of the preparation of replicas and subsequent removal of the test substance, which had been proposed already at an early stage of the development of electron microscopy[99,100] and has been used successfully in modern research.[101]

Apparently the most complex method for the preparation of polymer specimens involves the use of an ultramicrotome, because it can be accompanied by the mechanical deformation of the specimens and the introduction of artefacts into the investigation. This method has been developed mainly for the study of biological objects and has been described in special manuals.[102] One of the first objects investigated by the EMD of thin sections was carbon fibres.[103] It was found that a suitable casting material for the fixation of the polymer specimens in the ultramicrotome holder is molten sulphur.[104] However, at present organic polymers are fixed with the aid of casting materials based on epoxide compositions and cryo-ultramicrotomes are used for the preparation of sections.[105,10 It is noteworthy that hitherto the method of EMD of sections has been used to investigate the local order in the specimen; there have been no publications on structural analysis using this technique.

Examination of the methods of preparation of polymer objects for microdiffraction studies shows that in many cases this procedure can introduce artefacts associated, for example, with the influence of the rate of evaporation of the solvent, random deformation, etc. These processes must be investigated in order to eliminate the artefacts and to make the results of the investigation more correct. On the other hand, phenomena of this kind are also studied specially in order to reveal a whole series of properties of polymers and in this respect electron microscopy has a considerable scope. Overall, the literature data show that there is no universal method of preparation of polymer specimens. Each object requires an individual approach and considerable preparatory work in order to select the correct conditions and success depends in many respects on the skill of the experimenter.

The problem of protecting the polymer specimen from radiation during focussing and photography merits special attention not only from the standpoint of the reliability of the diffraction data but also from the standpoint of the very possibility of such an investigation. This is especially important when the goniometric method is used, where, in the course of the short lifetime of the crystal, it is necessary to rotate the specimen in order to obtain a three-dimensional diffraction pattern, as has been done, for example, in studies of compounds (V) and (XII)–(XVI) (see Table).

One of the causes of damage to the specimen by the electron beam is ionisation and excitation of atoms and molecules, as a consequence of which the initial equilibrium state of the substance breaks down. There are special publications on this question in the literature.[107] The mechanism of the effects of irradiation on organic objects has not been finally elucidated but it has been established in relation to polymers, for the maximum irradiation dose, which is specific to each polymer, that the specimen is fully converted into an amorphous form while the morphology of the supermolecular formations is retained.[79,108] The sensitivity of the polymer specimen to irradiation is associated with its chemical structure. In particular, as aromatic fragments accumulate in the macromolecule, the resistance to irradiation increases. Thus, it has been found that crystals of poly(*p*-xylylene) are fully converted into an amorphous form in an electron microscope with an accelerating potential of 500 kV for an overall irradiation dose exceeding by a factor of 20 that for polyethylene.[54] Polymers with a higher resistance to irradiation can be successfully investigated by the EMD method, but it has been shown by a number of workers that objects sensitive to irradiation are also susceptible to electron diffraction observations and special precautions are taken against damage [compounds (XII)–(XVI)—see Table].

The method of protecting the object is to reduce to the maximum extent the intensity of the electron beam and also to shorten the residence time of the specimen under irradiation, especially the exposure time. The procedures for the protection of the object against irradiation have been examined in extremely great detail by Dobb et al.,[109] who suggested that a special disc covering the central portion of the beam during the focussing of the image be inserted in the aperture holder of the second condenser. On the other hand, the exposure of the object to the electron beam entails the appearance of carbon contaminations, which reduce the information content of both the image and of the electron diffraction pattern as a result of the enhancement of the diffuse scattering background. The question of the nature of the contaminations and of the methods of dealing with this phenomenon is considered in special manuals[98] (p.25). Devices for cooling the object to the temperature of liquid nitrogen are constantly used in studies involving the measurement of reflection intensities for protection against irradiation [compounds (IX) to (XXI)—see Table]. Such devices are present in all modern microscopes.[1] The use of highly sensitive photographic emulsions plays an important role in diminishing the exposure time during photography. The latest transmission electron microscopes are fitted with devices which make it possible to reduce the period during which the electron beam acts on the specimen with the aid of two pairs of deflecting systems.[1] The use of high-voltage microscopes makes it possible to enhance the local nature of the diffraction and also to reduce the exposure time.

However, the problem of protecting the specimen against irradiation has been solved most radically with the aid of a new technique of diffraction studies developed towards the end of the 1970's, which consists in the joint use of transmission of and scanning with an electron beam having a small diameter.[110–112] Whereas in the usual TEM the size of the irradiated part of the object is determined by the diameter of the selective diaphragm located below the object holder and amounts to ~1 μm or more, in the scanning-transmitting EM the beam diameter is itself limited and the diffraction area, determined by the diameter of the probe, can be reduced to 300–100 Å. The new method used in the scanning-transmitting electron microscope permits an enhancement of the local nature of the diffraction, an increase of its resolution, and the maximum protection against irradiation of the parts of the object adjoining the test region, as has been demonstrated in a study of polyethylene.[110] An example of the use of this method for the study of crystal structures is provided by the investigation of poly(*p*-oxybenzoyl) (VIII) (see Table).

Overall, the results of modern studies on diffraction EM have shown that, although the problem of protecting the polymer against irradiation requires constant attention, nevertheless it is not an obstacle to the use of the given method in the structural analysis of high-molecular-weight compounds.

---o0o---

The review of publications on the electron microscopy of polymers permits the conclusion that this method has advanced appreciably not only in connection with the development of high-resolution instruments but also as a consequence of the development of methods for the quantitative analysis of electron microdiffraction patterns. However, one must also conclude that the structural analysis of polymers with the aid of TEM has still not become a standard procedure. The reason for this is the inadequate availability of improved electron microscopes and also the difficulties in the preparation of the specimens and in the interpretation of electron microscope data. As regards the interpretation of visual high-resolution TEM images, it is useful to bear in mind the words of Kabayashi, the renowned specialist in this field, that to see in the electron microscope does not necessarily mean to believe.[113]

The determination of the crystal structures of polymers requires their combined study by means of several independent methods, among which electron microdiffraction plays an important role. The accumulation of experience concerning the application of EMD and the continuing improvement of the instrumental technique undoubtedly open up prospects for the development of electron microscopy up to a readily accessible standard method for the structural analysis of high-molecular-weight compounds.

During the preparation of the review for printing, a series of communications, both methodological and of a review character, concerning the use of electron microscopy for the structural investigation of polymers were published. Thus a method has been developed[114] for the epitaxial growth of polyethylene crystals in order to obtain and analyse EMD patterns. The same workers in another communication[115] analysed in detail the possibilities of the epitaxial method for the quantitative EMD analysis in comparison to crystallisation from solutions; the comparison was carried out in relation to a series of polymers, especially biological polymers.

Review data on the use of the EMD method in polymer chemistry have been included in the publication by Dorset.[116] The advances of electron microscopy in securing quantitative information about the structure and composition of polymers have been described in a review[117] which deals with problems of the use of spectroscopic-analytical information and also with the protection of the test object against damage by irradiation. A novel microdiffraction method involving the shift of the aperature diaphragm, which replaces, in the authors' view, the goniometric technique, has been proposed.[118]

Data on the structure of poly(butylene terephthalate) and of its block copolymers have been obtained by the EMD method in the scanning-transmission mode.[119] The structure of poly(3-hydroxybutyrate) has been determined.[120] Studies by Japanese workers, using the entire range of the diffraction and visual possibilities of high-voltage TEM, have been continued—in particular, the structures of a conducting polymer, namely poly(1,4-phenylene),[121] and also of isotactic polystyrene[122] have been studied.

The results of the studies quoted above demonstrate the continuously increasing contribution of the microdiffraction electron microscope method to the crystal-chemical research into high-molecular-weight compounds.

Polyorgano-polysiloxane Block Copolymers

I.M.Raigorodskii and E.Sh.Gol'dberg

The literature data on the principal methods for the synthesis of polyorgano-polysiloxane block copolymers incorporating carbochain and heterochain organic fragments are examined and surveyed. It is shown that the microphase separation, associated with the differences between the chemical natures of the blocks, exerts a decisive influence on the morphological, physicochemical, and mechanical properties of such block copolymers. The wide scope of the applications of polyorgano-polysiloxane copolymers is demonstrated.

The bibliography includes 229 references.

I. INTRODUCTION

One of the problems in polymer chemistry of current interest involves the development of methods of synthesis and the study of the properties of a relatively new class of polymeric materials—block copolymers. Linear copolymers having the structure $(AB)_n$, in which the contributions by blocks of different nature create a set of specific properties, are of considerable interest in this connection. On the other hand, the introduction as one of the blocks into such copolymers of a polyorganosiloxane, which is characterised by a low glass point, good chemical, hydrolytic, radiation, and thermal stabilities, a high permeability to gases, a weak temperature dependence of its physicochemical properties, a low surface tension, a pronounced hydrophobic character, and a high frost resistance, makes it possible to obtain materials with properties of practical value.

The thermodynamic incompatibility of the organic and organosilicon blocks leads to the appearance in such systems of microphase separation, which makes it possible to regard them as pseudo-filled systems. The physical network arising under these conditions increases the deformation-strength characteristics and influences the physicochemical properties of block copolymers. The above features of polyorgano-polysiloxanes permit the segregation of these block copolymers as a separate group of polymers.

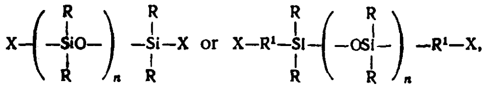
Polyorgano-polysiloxane block copolymers are of special interest for biology and medicine. The stability of these materials in biologically active media is high, they are readily sterilised, exhibit high haemo- and tissue compostibility, are resistant to ageing and the action of microorganisms, are optically transparent, and are permeable to vapours and gases. Such block copolymers can be used as implants of different rigidity, which can be achieved by regulating the composition of the copolymer.

In the reviews devoted to block copolymers published hitherto,[1-5] siloxane-containing copolymers incorporating carbochain and heterochain organic fragments have been examined. However, these publications deal with only certain individual examples of the synthesis and investigation of the properties of linear polyorgano-polysiloxane systems. We thought it timely to survey in the present review the available literature data on siloxane-containing block copolymers.

II. METHODS OF SYNTHESIS OF POLYORGANO-POLYSILOXANE BLOCK COPOLYMERS

Two main methods of synthesis of block copolymers containing siloxane fragments have now been proposed.

1. Polycondensation of organic oligomers, synthesised beforehand, with silicon-containing oligomers having the structure



$$X-\left(-\underset{R}{\overset{R}{Si}}O-\right)_n-\underset{R}{\overset{R}{Si}}-X \text{ or } X-R'-\underset{R}{\overset{R}{Si}}-\left(-O\underset{R}{\overset{R}{Si}}-\right)_n-R'-X,$$

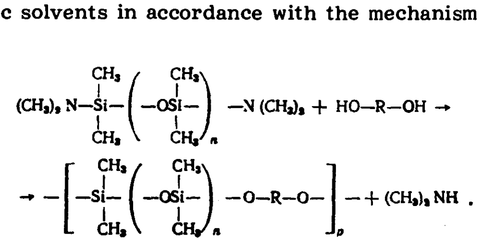
where R,R' is a carbon containing group and X is a functional group (hydroxy-, halogeno-, amino-, aminoalkyl, carboxy-, etc.).

2. Methods based on the use of cyclic organosiloxanes.

The principal methods of synthesis of linear oligomers and cyclic organosiloxanes have been examined in detail in monographs.[6-8] Depending on the nature of the initial components, block copolymers containing Si–C, Si–O–Si, Si–O–C, and Si–N interblock linkages have been described.

Polycondensation with Participation of αω-Bis(dialkylamino)-oligosiloxanes

The commonest method of synthesis of polyorgano-polysiloxane block copolymers involves the interaction of αω-bis(dimethylamino)oligodimethylsiloxanes with organic oligomers in organic solvents in accordance with the mechanism



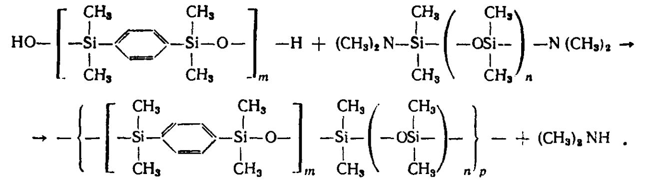
$$(CH_3)_2N-\underset{CH_3}{\overset{CH_3}{Si}}-\left(-O\underset{CH_3}{\overset{CH_3}{Si}}-\right)_n-N(CH_3)_2+HO-R-OH\rightarrow -\left[-\underset{CH_3}{\overset{CH_3}{Si}}-\left(-O\underset{CH_3}{\overset{CH_3}{Si}}-\right)_n-O-R-O-\right]_p-+(CH_3)_2NH\ .$$

The structure of the organic blocks in the copolymers obtained and the reaction conditions are indicated in Table 1.[9-26] The polycondensation results in the formation of regularly alternating block copolymers in which the molecular weight of the blocks is equivalent to the average molecular weight of the oligomers.

The dimethylamine evolved is readily removed and the reaction is therefore simple and effective and can be used to synthesise copolymer blocks of different lengths. However, the dimethylamine evolved can induce side reactions in the synthesis of copolymers containing ester linkages. It has been noted[11,25,27] that, when oligomers with a sufficiently high molecular weight are used, it is not possible to ensure reliably the equimolar reactant ratio, which leads to the formation of block copolymers with low molecular weights and a broad molecular weight distribution. In order to obtain block copolymers with a high molecular weight, it has been suggested that one of the components be gradually injected into the reaction zone; the character of the end groups and blocks of the copolymer then depends on the specific stoichiometry of the reaction. In order to avoid hydrolysis and homocondensation of alkylaminosiloxanes, the solvents must be carefully dried. The process temperature varies from 25° to 108 °C depending on the nature of the organic oligomer and the solvent employed.

When oligomers with aliphatic OH groups are used, the above reaction is much slower than with aromatic OH groups, as has been demonstrated in relation to dihydroxymethylstyrenes.[25,26]

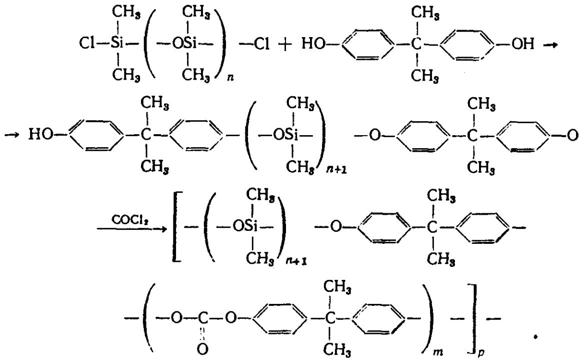
Dimethylaminosiloxanes have successfully used recently for the synthesis of polyblock polytetramethyl-*p*-silphenylene-siloxane-polysiloxane copolymers with a regular alternation of blocks:[28]



In the above example both oligomers contain silicon. However, it is useful to consider such systems in the present review because the principal features of polyorgano-polysiloxanes mentioned above can in fact be observed in them also.

Polycondensation with Participation of αω-Dichloro-oligosiloxanes

Oligodimethylsiloxanes with terminal chlorine atoms are used mainly to synthesise polycarbonate-polysiloxane block copolymers. It has been noted[29–31] that the reaction of αω-dichloro-oligosiloxane with an excess of a bisphenol in solution in chlorinated hydrocarbons in the presence of a hydrogen chloride acceptor results in the formation of a αω-dihydroxy-derivative, which is treated with phosgene in the presence of an excess of the bisphenol until the attainment of the maximum viscosity of the reaction mixture:

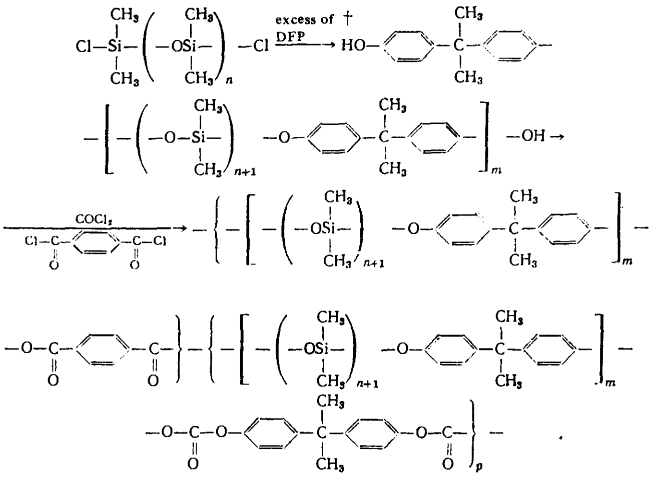


The resulting copolymer consists of statistically alternating polydisperse blocks and has a low molecular weight.

Table 1. The structure of the organic block and the conditions in the synthesis of polyorgano-polysiloxane block copolymers.

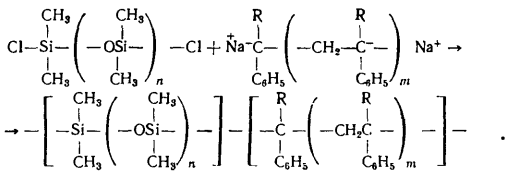
Organic block	Structure	T°, C	Solvent	Refs.
Polysulphone		25—120	Chlorobenzene, THF	[9—14]
Poly(phenylene oxide)		130	Chlorobenzene	[15—17]
Polycarbonate			Chlorobenzene	[18—20]
Polyhydroxyester		40—130	Methylene chloride, THF, chlorobenzene	[21]
Polyarylate		120—180	Trichlorobenzene	[22—24]
Poly-α-methylstyrene		120—180	Chlorobenzene, *o*-dichlorobenzene	[25—28]

The synthesis of a polyester-polysiloxane containing fragments of organic acids together with polycarbonate units has been described in a patent:[32]



In order to obtain block copolymers with a regular structure, it has been suggested that αω-dichloro-oligodimethylsiloxanes be condensed with oligomeric dihydroxycarbonates in solution in chlorobenzene in the presence of a tertiary amine (pyridine, triethylamine).[33-36] The molecular weights of the copolymer synthesised are 10^5.

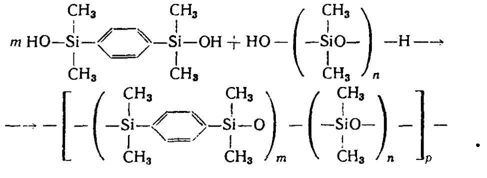
It has been shown[37,38] that the interaction of oligodimethylsiloxanes having terminal chlorine atoms with the disodioderivatives of styrene, α-alkylstyrene, or α-phenylstyrene in solution in tetrahydrofuran (THF) at room temperature can yield linear block copolymers:



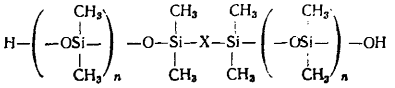
Polycondensation with Participation of αω-Dihydroxy-oligosiloxanes

The high mobility of the hydrogen atom in the hydroxy-group in dihydroxyoligosiloxanes makes it possible to use them for the synthesis of a whole series of block copolymers: polysilarylene-polysiloxanes, polyurethane-polysiloxanes, polyamidepolysiloxanes, and polyimide-polysiloxanes.

The synthesis of polysilarylene-polysiloxane block copolymers proceeds in accordance with the scheme



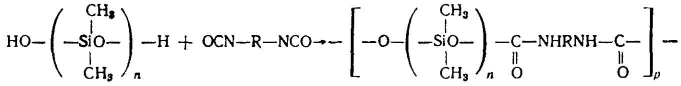
The reaction is carried out in solution in aromatic hydrocarbons at elevated temperatures in the presence of catalysts which do not cause a redistribution of units between siloxane blocks of different type, for example, tetramethylguanidine-bis-2-ethylhexanoate, N-hexylamine-2-ethylhexanoate, or a salt of formic acid and t-butylamine.[39-41] Since both initial components have the same functional groups, the condensation is statistical and the resulting high-molecular-weight copolymer contains blocks whose average length depends both on the ratio of the initial substances and on the molecular weight of the oligodimethylsiloxanes. Similar block copolymers with a more ordered structure have been obtained[42] by the reaction of diols having the formula



$$H-\left(-\underset{CH_3}{\overset{CH_3}{OSi}}-\right)_n-O-\underset{CH_3}{\overset{CH_3}{Si}}-X-\underset{CH_3}{\overset{CH_3}{Si}}-\left(-\underset{CH_3}{\overset{CH_3}{OSi}}-\right)_n-OH$$

[n = 0–1; X = 1,3 or 1,4-phenylene or the Y–Z–Y fragment, where Y = 1,3- or 1,4-phenylene and Z = O or OC(O)O] with phosgene in solution in pyridine.

Polyurethane-polysiloxanes can be obtained by polyaddition:



$$HO-\left(-\underset{CH_3}{\overset{CH_3}{SiO}}-\right)_n-H+OCN-R-NCO\rightarrow\left[-O-\left(-\underset{CH_3}{\overset{CH_3}{SiO}}-\right)_n-\underset{O}{\underset{\|}{C}}-NHRNH-\underset{O}{\underset{\|}{C}}-\right]_p-$$

The reaction is carried out in two stages: in the first stage, the hydroxylated oligodimethylsiloxane reacts with the organic diisocyanate, while in the second stage a "chain lengthening agent"—an organic diol or diamine—is introduced into the reaction mixture.[43,44]

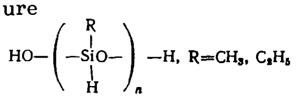
Prepolymers with terminal NCO groups, based on di- and poly-isocyanates and organic diols, can also be used as the organic component.[43,45,46]

It has been shown that the reactivity of oligosiloxane-glycols in urethane formation reactions is higher than that of aliphatic glycols,[47] which made it possible to synthesise successfully polyurethane-siloxane block copolymers containing alkylene bridges between the organic and organosilicon blocks.[48] Diamines,[49] organic oligodiols and oligodithiols,[50] as well as 1,3-bis(4-hydroxybutyl)tetramethyldisiloxane[51] have been used as the "chain lengthening agents".

Polyester-siloxane-urethanes with polyester and polydimethylsiloxane blocks alternating statistically in the chain have been obtained;[52] the synthesis was carried out in one stage by introducing the intermonomer [di(4-isocyanatophenyl)methane or 2,2′-di-(*p*-isocyanatophenyl)hexafluoropropane] into a mixture of oligodiols [poly(ethylene glycol) or poly(ethylene glycol adipate) and αω-bis(β-hydroxyethoxymethyl)oligosiloxane] at elevated temperatures in solution in chlorobenzene in the presence of tin dibutyl-laurate as the catalyst.

Polyblock polyamide-polysiloxanes have been obtained by the reaction of dihydroxyoligodimethylsiloxane with an excess of terephthalic acid chloride and subsequent condensation of the resulting polyester with hexamethylenediamine;[53] however, it was not possible to achieve a high molecular weight of the polymer, whose intrinsic viscosity did not exceed 0.3 dl g^{-1}.

A method for the modification of polycaprolactam in the synthesis of polyamide by polyorganosiloxane compounds having the structure



$$HO-\left(-\underset{H}{\overset{R}{SiO}}-\right)_n-H,\ R{=}CH_3,\ C_6H_5$$

has been described.[54] The reaction yielded block copolymers containing siloxane linkages in the carbamide groups; an increase of the content of the organosilicon component in the

---

†Excess of DFP (in Russian; Ref.32 states Me_3N in CH_2Cl_2) (Ed. of Translation).

reaction mixture above 2 wt.% inhibits the polarisation of caprolactam and impairs the physicomechanical characteristics of the block copolymer.

Treatment of a mixture of αω-bis(3-propoxy)oligodimethylsiloxane, di(hydroxyphenyl)propane, and terephthalic acid chloride in solution with phosgene afforded high yields of block copolymers with a high molecular weight.[32] The attempts to use oligosiloxanes with terminal hydroxypropyl and hydroxybutyl groups to synthesise polycarbonate-polysiloxanes by direct treatment with phosgene of a mixture of the oligosiloxane and di(hydroxyphenyl)propane under the conditions of interfacial condensation led to the formation of block copolymers with a statistical alternation of blocks and the degree of conversion of the oligodimethylsiloxane was low. Investigations[20,55] led to the discovery of the need for the preliminary treatment of the organosilicon oligomer with phosgene in order to obtain block copolymers having a high molecular weight and a high content of the organosilicon blocks. It is therefore useful to use the bischloroformates of oligomeric organosilicon diols in order to obtain polyorganopolysiloxanes by heterophase polycondensation.

Polycondensation with Participation of αω-Bis(chloroformato-organo)oligosiloxanes

The heterophase method of synthesis of block copolymers based on αω-bis(chloroformatoethoxymethyl)oligodimethylsiloxanes makes it possible to obtain high yields of regularly alternating polycarbonate-polysiloxanes[56] and polycarbonate-urethane-polysiloxanes with a unimodal molecular weight distribution (Fig.1) in accordance with the scheme[57,58]

Polycondensation with Participation of αω-Diamino-oligosiloxanes

These oligomers react readily at room temperature in solution or under the conditions of interfacial polycondensation with aliphatic and aromatic acid dichlorides[64] to produce high yields of high-molecular-weight soluble polyamide-polysiloxanes.

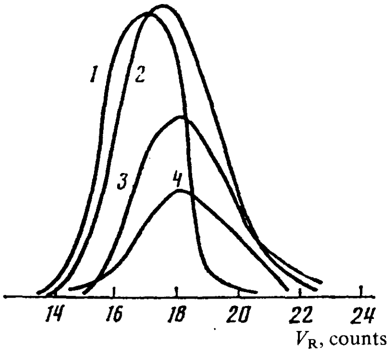


Figure 1. Chromatograms of polycarbonate-urethane-polysiloxanes with different compositions $N_{Si}:N_{CU}$: 1) 45: 6; 2) 45 : 10; 3) 45 : 3; 4) 45 : 2; N_{Si} = number of siloxane units, N_{CU} = number of carbonate-urethane units, and V_R = volume of eluent (one count = 2.5 ml).[58]

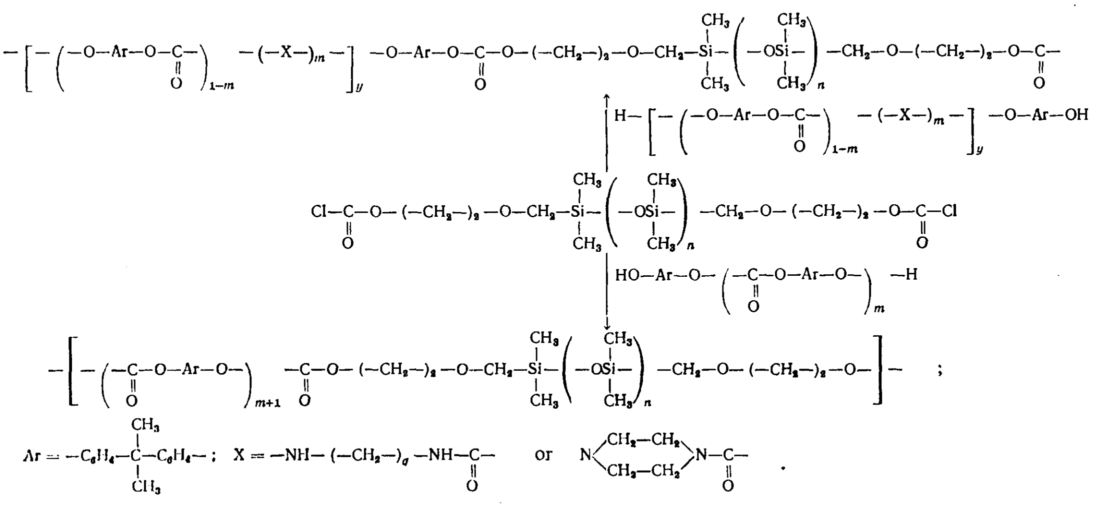
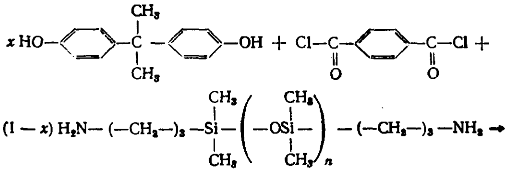
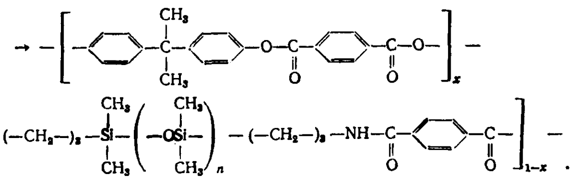


The bischloroformatosiloxanes presented in the scheme were used to obtain polyurethane-siloxanes in a heterophase system[59] and also copolymeric siloxane-carbonates[60] and siloxane-urethanes[61,62] with a statistical distribution of organic and organosilicon blocks.

Polyarylate-polysiloxanes have been synthesised by interfacial polycondensation to form αω-bis(chloroformato-organo)-oligosiloxanes and oligoarylate diols from phenolphthalein and di(hydroxyphenyl)propane.[63]

Polyamide-polysiloxanes containing polyarylate fragments have been obtained by the reaction[65]



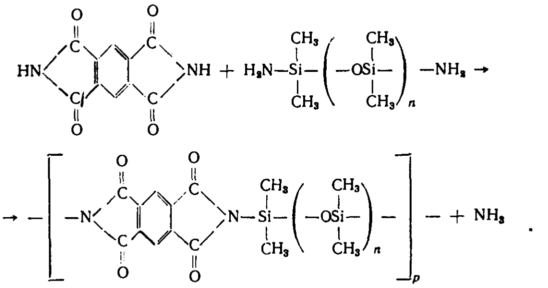


The yield of the target product is 80–90% and the intrinsic viscosity is 0.89 dl g^{-1}.

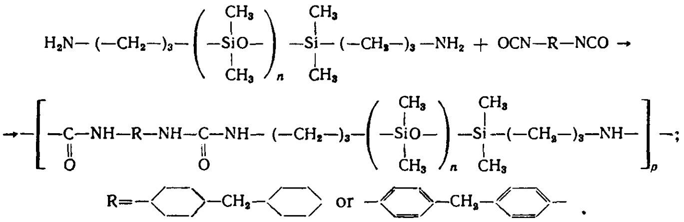
The reaction of oligodimethylsiloxane having terminal NH_2 groups with *N*-carboxyanhydrides of aminoacids of the type of DL-phenylaniline or γ-benzyl-L-glutamine in solution in chloroform at 200 °C leads to the formation of block copolymers of polysiloxane with polypeptides.[66]

Soluble polyimide-polysiloxanes have been synthesised by heating a prepolymer based on an excess of an aromatic dianhydride and an aromatic diamine[67] or the dianhydride of benzophenonetetracarboxylic acid[68] with aminoalkyl-containing oligodimethylsiloxanes.

The synthesis of polyimide-polysiloxanes whose nitrogen atoms are linked directly to silicon atoms has been described in a patent:[69]

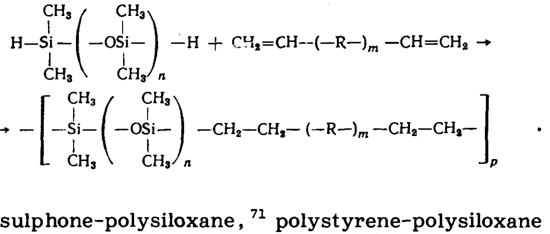


αω-Bis(aminopropyl)oligodimethylsiloxanes interact with an organic diisocyanate in 2-ethoxyethyl ether or THF with formation of polysiloxane-urea:[70]



Polycondensation with Participation of Oligosiloxanes having Terminal Silicon Hydride Groups

Copolymers with regularly alternating blocks have been obtained from oligodimethylsiloxanes having H–Si groups by the hydrosilylation reaction:



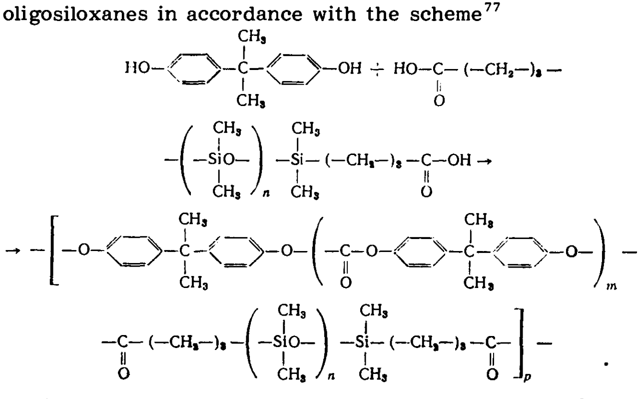
The polysulphone-polysiloxane,[71] polystyrene-polysiloxane and poly-α-methylstyrene-polysiloxane,[72,73] and polyurethane-polysiloxane[74,75] block copolymers have been synthesised by this method.

Despite the fact that the condensation conditions rule out side reactions and make it possible to obtain block copolymers with a high molecular weight, the reaction has not as yet found extensive application owing to the complexity and the multistage nature of the synthesis of the initial vinyl-containing organic oligomers and the need to employ expensive catalysts.

Polycondensation with Participation of Other Oligosiloxanes

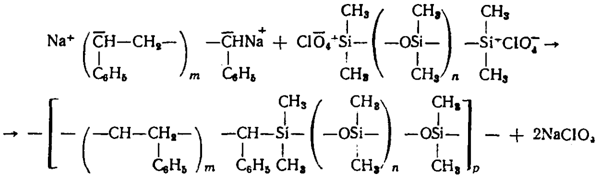
There are literature data on the synthesis of polyorganosiloxane block copolymers using oligodimethylsiloxanes having terminal acetoxy-groups. The process consists in the condensation of the terminal hydroxy-groups of polyester-urethanes obtained beforehand with the terminal acetoxy-groups of the oligosiloxane.[76]

The possibility of obtaining polyester-polysiloxanes by the heterophase condensation based on αω-bis(carboxypropyl)-oligosiloxanes in accordance with the scheme[77]



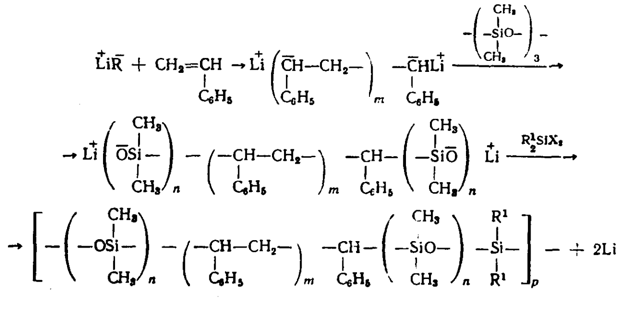
has been demonstrated. The authors note the need for the preliminary treatment of the oligosiloxane with phosgene to convert it into an acid chloride in order to increase the yield and the molecular weight of the copolymer.

Polystyrene-polysiloxane block copolymers containing regularly alternating blocks have been synthesised by the reaction of the oligostyrene anion with the oligomethylsiloxane cation in solution in THF:[78]



Reactions with Participation of Cyclic Organosiloxanes

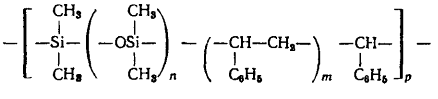
Polystyrene-polysiloxanes have been obtained by the joint anionic polymerisation of organosilicon cyclic compounds and styrenes:



The process includes the following stages: the polymerisation of styrene with a lithium initiator in the presence of a solvent (THF, benzene, or toluene) until "living chains" are formed, the introduction and polymerisation of hexamethylcyclotrisiloxane on such chains, and the joining together of the resulting blocks with bifunctional alkylsilanes.[79-83]

There is no chain termination in this process, which makes it possible to obtain a copolymer with a narrow molecular weight distribution. The block copolymer contains virtually no homopolymers nor cyclic compounds which failed to react. Dialkyldichlorosilane,[79-81] diacetoxydiphenylsilane,[82] and difluoromethyltrifluoropropylsilane[83] can be used as cross-linking agents.

In a modified synthetic scheme, the polysiloxane-polystyrene copolymer with terminal lithium atoms is treated with hydrochloric or acetic acid[81,84] to form blocks with terminal silanol groups. On further dehydropolycondensation in the presence of tin octanoate or caprylate, block copolymers having the following structure are obtained:



$$-\left[-\mathrm{Si}(CH_3)_2-\left(-\mathrm{OSi}(CH_3)_2-\right)_n-\left(-CH(C_6H_5)-CH_2-\right)_m-CH(C_6H_5)-\right]_p-$$

The copolymers of poly-α-methylstyrene with polydimethylsiloxane, containing short polystyrene[85] or α-alkylstyrene[86,87] blocks, have been obtained by analogous methods.

Polycarbonate-urethane-polysiloxane block copolymers can be obtained by the condensation in the melt of the oligocarbonate prepolymer with methylphenylcyclotrisiloxane in the presence of alkali metal hydroxides at 200–220 °C with subsequent interaction of the product with tolylene diisocyanate at 70–90 °C.[88]

Treatment of the oligocarbonate-siloxanediol synthesised in the first stage with methylphenylcyclotrisilazane in the melt at 180 °C yields polycarbonate-silazasiloxane block copolymers.[89] However, the process is complicated by the formation of isocyanate groups in side reactions, which are particularly vigorous for low molecular weights of the polysiloxane blocks. As a result of this, the block copolymers contain urethane linkages together with the polycarbonate and silazane blocks and have a branched or a cross-linked structure.

All the methods of synthesis of siloxane-containing block copolymers described above make it possible to obtain linear soluble products of different types with a predictable structure. The choice of particular conditions of synthesis permits the variation of the size of the blocks, the order in which they alternate, the molecular weight, the molecular weight distribution, and ultimately the properties of the polymers.

III. STRUCTURAL CHARACTERISTICS AND PHYSICOCHEMICAL PROPERTIES

1. The Morphology of Polyorgano-polsiloxanes

The chemical structure of the macromolecule influences the temperature dependent transitions, the chemical stability, the thermal stability, and the permeability of the block copolymers. However, the specific properties of elastoplastics, namely the elasticity, strength, and rheology of the solutions and melts, are determined by the morphology of the block copolymer and are the result of its structural heterogeneity, i.e. the incompatibility of the blocks leading to their separation into microphases.

The fundamental morphological model of silicon-containing block copolymers can be represented by a continuous matrix formed by a flexible siloxane block in which rigid blocks, associated into dispersed formations (domains) chemically linked to the continuous matrix, are distributed in a discrete fashion. The domains fulfil the function of the nodes of a chemical network or filler.[1]

The appearance of a two-phase supermolecular structure and the degree of separation into phases depend on the structure of the copolymer macromolecule and are determined by the degree of incompatibility of the components forming the blocks. A quantitative characteristic of the degree of incompatibility may be the difference between the solubility parameters of the constituent blocks of the polymer. The dependence of the degree of separation on the difference between the solubility parameters is illustrated by the quantitative correlation[90] between the solubility parameters of segments of polyorgano-polysiloxane block copolymers and their capacity for being worked in the melt (Table 2).

Table 2. The rheological characteristics of the block copolymers.[90]

Organic block	Δ*	Mouldability
Poly-α-methylstyrene	1,3	Good
Polystyrene	1,6	Good
Polycarbonate	2,2	Satisfactory
Polyarylate	2,6	Satisfactory
Polysulphone	3,3	Poor

*The difference between the solubility parameters of the blocks.

Table 2 shows that the smaller the difference between the solubility parameters of the rigid and flexible blocks of the copolymer, the more easily can it be worked in the melt. The explanation is that a large difference between the solubility parameters promotes an appreciable phase separation of the system even as far as the retention of a physical network in the melt, which significantly impairs the capacity of the copolymer for being worked. Microphase separation is also promoted by the increase in the molecular weight of the blocks and by the tendency of the rigid block to crystallise.

Despite the large number of methods at the disposal of investigators (transmission and scanning electron microscopy, large- and low-angle X-ray scattering, reversed gas chromatography), which makes it possible to determine the shape and size of the domains, the distance between them, and the nature of the interfaces, only certain classes of polyorgano-polysiloxane block copolymers have been investigated in detail owing to the difficulty of interpreting the results.

The composition and method of preparation of the specimen influences decisively the supermolecular structure of the block copolymer.

The studies of the supermolecular structures of polyorgano-polysiloxanes containing rigid amorphous blocks, comprising polycarbonate-polysiloxanes,[91-97] polyarylate-polysiloxanes,[98,102] polystyrene- and poly-α-methyl styrene-polysiloxanes[82,103,104] polyimide-polysiloxanes,[105] and polyamide-polysiloxanes[105] made it possible to put forward a morphological model of the block copolymer (Fig.2) in which certain rigid blocks are associated into domains, which act as a physical network, while the matrix consists of polysiloxane blocks, whereupon there is a possibility of partial interpenetration of the phases. When their content is low, the rigid blocks form a discrete phase, for intermediate contents both components form part of the continuous phase, and, for a high content of the rigid blocks, the polydimethylsiloxane aggregates into a discrete phase.

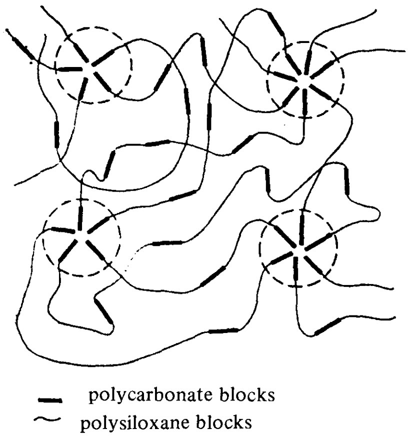


Figure 2. A morphological model of an amorphous polycarbonate–polysiloxane block copolymer.[91]

Depending on the composiiton of the block copolymer, the conditions in the preparation of the specimen, and the chemical nature of the organic blocks, the size of the domains formed by the latter varies over the range 30–350 Å.

The domains formed by the rigid blocks are separated by a distance of approximately 300 Å and the number of blocks in the domain may reach 800. With decrease in the molecular weight of the organic block, the presence of the mixed phase is manifested to a greater extent and the content of the polydimethylsiloxane component within the rigid domains increases. It has been noted that polycarbonate domains can contain up to 11 wt.% of the polydimethylsiloxane blocks.[95]

The statistically alternating block copolymers in which both blocks are polydisperse have a less ordered morphology than the block copolymers with a regular alternation of fragments. It has been suggested[94] that, in the formation of domains in such copolymers, long blocks are initially aggregated and small blocks are aggregated on the latter, which function as seeds. For this reason the short blocks "draw" the flexible polydimethylsiloxane blocks into the interior of the domain in the course of the formation of the structure.

When the content of the organic or the organosilicon blocks in the copolymer changes, the sizes of the domains can alter. Thus the surface area of the polycarbonate domains can be calculated from reverse gas chromatographic data,[96,97] and it has been shown that the area of the domains diminishes significantly with increase in the fraction of the carbonate block. The authors attribute this to the transition from the structure containing many small dispersed spherulites with a large surface area to a structure with close-packed folded domains.

A change in the method of preparation of the specimen for the same composition of the block copolymer results in a significant alteration of its structure. The supermolecular structure of film specimens then depends on the type of solvent and reflects the nature of the molecular associated species in solution. It has been shown[103,106,107] that, even in solutions of polyorganopolysiloxanes in selective and sometimes also in general solvents, the appearance of supermolecular formations and of a network between the domains has been observed, the microphase separation becoming more pronounced with increase of solvent selectivity. The most sensitive structural parameters under these conditions are the dimensions of the particles and the distance between them. For example, for polyarylate-polysiloxanes, increased selectivity of the solvent with respect to polydimethylsiloxane (enrichment of the solution in hexane) leads to a decrease in both the size of the domains themselves and in the distance between them. An analogous decrease of the distance between the domains occurs also for other methods of increasing the solvent selectivity and of altering the previous history of the specimen.

When the film is obtained from a solution in chloroform in an atmosphere of saturated xylene vapour with a gradual change in solvent composition as the xylene condenses and the chloroform evaporates, the distance between the domains decreases from 215 to 165 Å.[100]

Films based on polystyrene-polysiloxanes, obtained from toluene (common solvent), have a structure in which the polystyrene blocks produce agglomerates in the form of spaghetti-like microphases 282 ± 15 Å in diameter. The polydimethylsiloxane blocks give rise to a continuous matrix in which the polystyrene formations are separated by a distance of 170 ± 20 Å and the interpenetration of the phases is observed. With increase in the content of the polystyrene blocks, the agglomerates form cylindrical domains and there is a possibility of phase inversion.

Phase inversion has been achieved by choosing selective solvents for the same composition of the block copolymer. The toluene–cyclohexane (solvent for polydimethylsiloxane) mixture "displaces" polystyrene first on evaporation of the solvent, while films containing a discrete polydimethylsiloxane phase have been obtained from a toluene–bromobenzene (solvent for polystyrene) mixture.[103] Heat treatment of both blocks in the vicinity of the glass point promotes a better phase separation of the domain structures.[104]

Whereas the amorphous copolymers examined above exhibit some compatibility of the flexible and rigid blocks in both the continuous and discrete phases, the ability of the rigid blocks to crystallise leads to phase separation with a distinct interface.

Morphological studies of polysilphenylene-polysiloxanes revealed a two-phase structure, with a discrete phase comprising the crystallised silarylene block and an amorphous phase, consisting of non-crystallised polysilarylene and polydimethylsiloxane blocks, which is fully excluded from the crystal lattice regardless of the content of this phase in the copolymer.[108,109] The morphological model of the copolymer consists of lamellae alternating with the less ordered amorphous phase (Fig.3).

The degree of crystallinity depends on the amount of the polydimethylsiloxane component and diminishes from 53 to 15% with increase of the content of polydimethylsiloxane from 10 to 70 wt.%.[110] The temperature at which the maximum rate of growth of the crystals is observed diminishes with decrease in the content of the polysilarylene block.[111]

The morphology and cohesion between the phases in the block copolymer is influenced significantly by the solvent, temperature, conditions, and the time of formation of the structure.[112]

Thus the degree of microphase separation of polyorganopolysiloxane block copolymers is determined mainly by the composition of the copolymer, the method of preparation of the specimen, and also by the capacity of the rigid block for crystallisation.

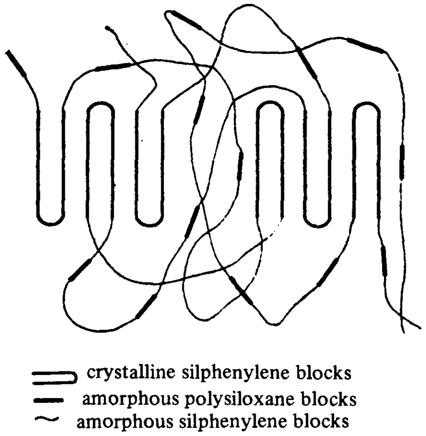

Figure 3. A morphological model of a crystalline polysilphenylene-polysiloxane block copolymer.[110]

2. The Temperature Dependent Transitions in Polyorganopolysiloxane Block Copolymers

The most characteristic feature of polyorgano-polysiloxanes, which follows from their ability to form morphological structures discussed above, is manifested by the presence of two glass points, reflecting the individual properties of each block (Table 3). Microlayer formation and the appearance of two glass points caused by it are observed for polyorganopolysiloxanes, starting with relatively low (3000–5000) molecular weights of the rigid block, which has been attributed to the large difference between the solubility parameters of the organic and polydimethylsiloxane blocks.

Table 3. Transition temperatures of polyorgano-polysiloxanes.

Organic block	T_c, °C	Transition temperatures of the block copolymer, °C			Refs.
		T_c	T_{g1}	T_{g2}	
Polysulphone	+160	−55	−110÷−120	+140÷+160	[11 113]
Polycarbonate	+149	—	−110	+37÷+104	[114]
Polycarbonate-urethane	—	−53÷−66	−105÷−110	+36÷+70	[58]
Polyarylate	+320	−50	−110÷−120	+320	[24.100]
Polystyrene	+88	−40÷−45	−108	+83	[81]
Poly-α-methylstyrene	+130	−45	−105÷−120	+80÷+130	[25]

The majority of investigators claim (Table 3) that the temperature dependent transition, which is attributed to glass formation by the polydimethylsiloxane block (T_{g1}) occurs at lower temperatures (−105 to −120 °C) and is almost independent of the molecular weights of the polydimethylsiloxane and organic blocks for all the block copolymers considered (Fig.4). Its temperature is close to the glass point of polydimethylsiloxane rubber (−120 °C).

The independence of T_{g1} of the molecular weight of polydimethylsiloxane for comparatively short lengths of the blocks (2000–3000) is probably associated with the appreciable flexibility of the polydimethylsiloxane chain and hence with the small length of the kinetic segments responsible for the glass forming processes.

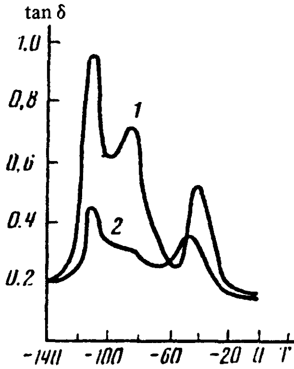

Figure 4. Temperature variation of the tangent of the mechanical loss angle (tan δ) for polyarylate-polysiloxane specimens having different compositions $N_{Si}:N_{Ar}$: 1) 420 : 20; 2) 200 : 20; N_{Si} = number of siloxane units and N_{Ar} = number of arylate units.[24]

However, a sharp increase[89,115] or decrease[116] of T_{g1} in polyorganopolysiloxanes compared with homopolyorganosiloxane has been noted in certain investigations. The authors were unable to give an unambiguous explanation, suggesting that such anomaly may be associated both with the change in the character of the packing of organosiloxane blocks and with the high degree of interpenetration of the phases during their segregation.

An increase of T_{g2} (the temperature dependent transition associated with glass formation in the rigid block) increases both with increase in the molecular weight of this block and with increase in the length of the polydimethylsiloxane block for constant lengths of the rigid block, which has been explained[25] by the increasing degree of phase separation. However, in polyarylate-polysiloxane[99] and polystyrene-polysiloxane,[82] T_{g2} hardly differs from the glass point T_g of the homopolymer over the entire range of compositions of the block copolymers investigated. The results obtained indicate, according to the authors, a more complete phase separation in these copolymers.

X-Ray diffraction studies have shown that the domains formed by silphenylene units have a high degree of crystallinity and the changes associated with glass formation by the rigid block are therefore very slight in these copolymers.[117]

Studies of polyarylene-polysiloxanes by differential scanning calorimetry also showed that there is a melting point of the silarylene blocks. With increase in the number of silarylene-siloxane units, the melting point increases and the decreased content of siloxane units also causes an increase in the melting point of the silarylene-siloxane domains.[115,118]

The decreased melting points of the silarylenesiloxane and polydimethylsiloxane blocks compared with the melting points of the corresponding homopolymers can probably be accounted for by the fact that, although the structures of the crystal lattices of the domains of the homopolymers and the block copolymers are identical (their X-ray diffraction parameters are the same), the lattices of the domains in the block copolymers are more defective,[117,119] since the development of crystallisation processes is limited by the incomplete segregation of the individual sections of the macromolecules to form domains.

It is of interest to note that amorphous polyorgano-polysiloxanes, for example, polycarbonate-polysiloxanes,[120] can be crystallised by being kept in the vapours of chlorinated hydrocarbons. The degree of crystallinity determined by the crystallisation of the polycarbonate component of the block copolymer diminishes with increase in the content of the siloxane component in the copolymer. The maximum attainable degree of crystallinity (up to 45%) for block copolymers with any silicon content is higher the greater the length of the siloxane fragment.

The crystallisation of systems containing high-molecular-weight polydimethylsiloxane blocks has been noted at a temperature T_c. The degree of crystallinity depends little on the length of the rigid block and is close to the degree of crystallinity of the pure polydimethylsiloxane rubber.[121]

The temperature dependent transitions are an important characteristic of block copolymers, since they in fact determine the temperature ranges within which these materials can be worked and used.

3. Deformation-strength Properties

The mechanical characteristics of elastoplastics are determined by the properties of the continuous phase and by the frequency of the physical cross links and they therefore depend on the same factors as the supermolecular structure: the composition of the copolymer and the method of preparation of the specimen.

Table 4. The deformation-strength properties of polyorgano-polysiloxane block copolymers.

Organic block	c, wt.%	σ, MPa	ε, %	E, MPa	Refs.
Polysulphone	55	17	350	140	[11]
Poly(phenylene oxide)	49	18	450	—	[17]
Polycarbonate	51	21	150	—	[114]
Polycarbonate-urethane	56	25	500	—	[58]
Polyarylate	60	15	180	—	[90]
Polysilarylene	50	13	750	10^3—10^4	[111,118]
Poly-α-methylstyrene	52	13	370	500	[25]

Notation: c is the content of the polydimethylsiloxane blocks, σ the breaking tensile stress, ε the relative elongation on rupture, and E the modulus of elasticity.

The main characteristic of the mechanical properties of the copolymers is the relation between the breaking tensile stress and the relative elongation on rupture. This relation determines the modulus of elasticity of the system, its strength, and its deformability.

With increased content of the polydimethylsiloxane component, the properties of all the polyorgano-polysiloxane block copolymers vary from those of rigid materials, which are difficult to deform, to flexible elastomeric compositions, which is well illustrated by Fig.5 for polycarbonate-urethane-polysiloxanes.[58]

The different conditions in the preparation of the specimens and in the tests preclude quantitative estimation of the influence of the chemical structure of the rigid block on the deformation-strength properties of the copolymer. However one may note that the presence in the block copolymer of fragments with an increased tendency towards crystallisation [poly(phenylene oxide), polysilarylene] or capable of forming interchain hydrogen bonds (polycarbonate-urethane) increases its deformability (Table 4).

It is essential to note that the molecular weight of the block copolymer has an appreciable influence on its deformation-strength properties (Fig.5).

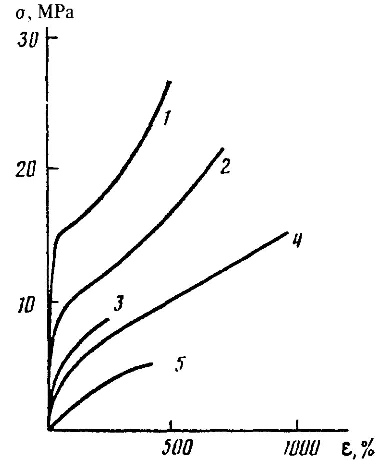

Figure 5. The influence of the composition and molecular weight of polycarbonate-urethane-polysiloxanes on the breaking tensile stress σ and the relative elongation on rupture ε; content of polydimethylsiloxane blocks (wt.%); 1) 56; 2) 62; 3) and 4) 67; 5) 77; $\bar{M}_w$: 3) 5×10^4; 4) 11×10^4.[58]

The deformation-strength properties of films based on a block copolymer of one composition can be varied within wide limits by altering the method of their preparation. On passing from a common to a selective solvent, the properties of the film approach those of the component with respect to which the solvent is selective, which is associated with the different character of structure formation in the solution from which the film is obtained.[115,122,123]

It has been shown in relation to polyarylate-polysiloxane[122] that the change in strength is manifested to a greater extent in systems enriched in the rigid block (the polyarylate) and the change in deformability is manifested more in systems enriched in polydimethylsiloxane. The influence of the solvent and of the method of formation of the film is particularly marked in systems with similar weight fractions of the components.

The expansion of the region of high elasticity occurs, as can be seen from Table 5, when the film is obtained via a gel stage, compared with the film obtained from the same solvent via the solution stage or after swelling the film in a medium in which it forms a gel and is then dried.[100]

A distinctive feature of almost all polyorgano-polysiloxane block copolymers is their ability to be worked in the melt at temperatures above the glass point of the rigid blocks. In thermal moulding, the material is usually oriented, which leads to an appreciable increase of strength.[124]

Table 5. Dependence of the deformation-strength properties of a polyarylate-polysiloxane on the nature of the solvent and the method of preparation of the film.[100]

Solvent	Solvent selectivity	σ, MPa	ε, %	E, MPa
Chloroform	common	13.0	160	66.0
Tetrachloroethane	polyarylate	19.0	95	100.0
Xylene	polydimethylsiloxane	3.0	220	7.5
Chloroform-hexane (60-40)	»	9.5	280	10.0
Chloroform-toluene (70-30)	»	9.0	420	29.0
Chloroform-hexane (60-40*)	»	10.5	375	—
Xylene (from the gel)	»	9.5	270	—

*Film obtained from solution in chloroform, swollen in a chloroform–hexane mixture, and dried.

4. Thermal and Thermo-oxidative Stability

The thermal and thermo-oxidative degradation of polyorgano-polysiloxanes has been investigated to determine the temperature and conditions for their processing and to estimate the possibility of using these materials at elevated temperatures.[11,27,63,125–127] In the first place, it is essential to note that the high energy and ionic character of the siloxane bond are responsible for the appreciable thermal stability of polysiloxane. The Si–O–C bond is more vulnerable in this respect.[128] Since the rigid blocks of the copolymers investigated also exhibit a high thermal stability, it follows that, as was to be expected, the block copolymers are stable up to high temperatures (Table 6).

Table 6. Thermal stability of polyorgano-polysiloxanes.

Organic block	Temperature of 10% weight loss, °C		Refs.
	in air	in nitrogen atmosphere	
Polysulphone	475	510	[11]
Polycarbonate	400	450	[127]
Polycarbonate-urethane	350—400	—	[58]
Polyarylene	420	480	[11]
Polysilarylene	—	427	[129]
Polyimide	—	500	[66]

As a rule, the weight content of the blocks in the copolymer changes and no appreciable alteration of the thermal stability is observed.[127,129] The reason for this is probably that the stability of the macromolecule is determined by its weakest bonds, which are located at the sites of contact between the blocks (the Si–C or Si–O–C bonds). Polyarylene-polysiloxanes, whose thermal degradation takes place preferentially with rupture of the Si–O–Si linkage whereupon the thermal stability of the copolymer diminishes with increasing content of the polysiloxane block,[130] and polysulphone-polydimethylsiloxane copolymers where the polydimethylsiloxane blocks are the first to undergo thermal degradation with formation of linear and cyclic oligodimethylsiloxanes,[131] are exceptions.

The change in the chemical structure of the rigid block (within the framework of a single class) is reflected in the thermal stability of the block copolymer.[80,129,132,133] The poly-α-methylstyrene-polysiloxane block copolymers, for example, exhibit a better thermo-oxidative stability than polystyrene-polysiloxanes having the same composition.[80] Whereas heating of polystyrene-polysiloxane in air for 80 h at 150 °C diminishes its strength by a factor of 2, this is not observed for poly-α-methylstyrene-polysiloxane.

The study of the time variation of the weight losses at 305–385 °C by polyarylate-polysiloxanes based on phenolphthalein and phenolfluorene terephthalates[133] showed that the thermal stability of the latter copolymer is higher; this has been attributed to the absence from it of the thermally unstable lactone group. As has been frequently noted,[129,134] copolymers without Si–O–C bonds in the main chain show a higher thermal stability.

5. Hydrolytic Stability

The resistance of polyorgano-polysiloxane block copolymers to hydrolysis is one of the principal indices indicating the retention of the properties of polymeric articles under the real conditions of their use. The hydrolytic stability of polyorgano-polysiloxanes is lower than that of homopolymeric polysiloxane and the degradation of the polymer takes place as a rule at the bonds between the organic and organosilicon blocks or within the organic block.

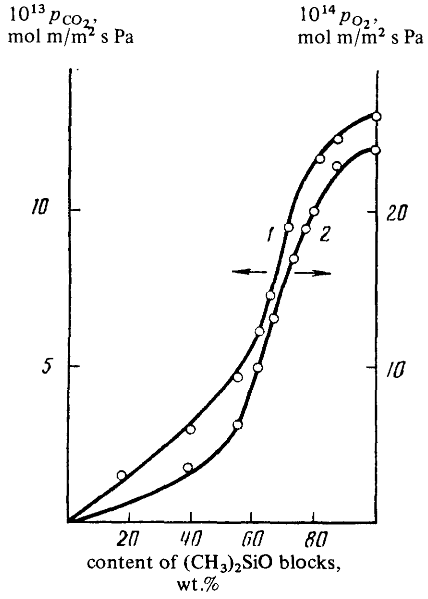

Figure 6. Dependence of the coefficient of gas permeability to CO_2 (P_{CO_2}) (curve *1*) and O_2 (P_{O_2}) (curve *2*) on the composition of polycarbonate-polysiloxane at 20 °C.[114]

It has been shown[135] that the heterogeneous hydrolytic degradation of polyarylate-polysiloxane in argon takes place to an appreciable extent at 160 °C, while the hydrolysis of polydimethylsiloxane under analogous conditions does not begin until 220 °C. It has been noted that the hydrolysis proceeds preferentially at the Si–O–C linkage and that the rate of hydrolysis increases with increase in its concentration per unit volume.

The stability of polysulphone-polysiloxanes containing the Si–O–C bond can be increased by introducing large hydrophobic silicon-containing segments into the main chain of the macromolecule.[136] As a result of this, steric hindrance arises in the hydrolysis of the Si–O–C bond and the concentration of such bonds in the copolymer falls. The hydrolytic stability of polyorganopolysiloxanes can be raised also by introducing polyester-urethane[76] fragments into the siloxane chain.

An increase in the hydrolytic stability of the block copolymers can be achieved by replacing the hydrolytically vulnerable Si–O–C bond between the blocks by the Si–C bond.[58,63,66,137]

Estimation of the hydrolytic stabilities of various polysiloxanes showed[138] that the replacement of the methyl groups in polydimethylsiloxane by sterically more bulky substituents (phenyl, ethyl, and trifluoropropyl groups) increases the hydrolytic stability of homo- and co-polysiloxanes. One can therefore assume that the synthesis of block copolymers from such polysiloxanes would make it possible to increase their hydrolytic stability.

6. The Resistance of Polyorgano-polysiloxanes to UV Radiation

In connection with the possibility of using organosiloxane block copolymers as transparent materials without a filler such as carbon black, studies have been made of the resistance of these polymers to UV radiation. The block copolymers of polyorganosiloxane and polystyrene showed satisfactory photostability.[139] However, the stability of copolymers containing aromatic rings in the main chain proved to be limited.[11,140]

The study of the photodegradation of polyarylate-polysiloxane showed that the degradation takes place mainly in the polyarylate block and that the most unstable structures in relation to UV radiation are the ester bond and the phthalide ring. The siloxane block does not absorb UV radiation but does undergo degradation with evolution of methane, which has been attributed to the occurrence of secondary radical reactions.[140] The presence of oxygen appreciably accelerates the degradative processes.

7. The Permeability of Polyorgano-polysiloxanes to Gases

Polyorganosiloxanes are known[141] to be distinguished by a high permeability to gases owing to the high flexibility and mobility of the Si–O–Si bonds and also to the weak intermolecular interaction between such macromolecules.

An advantage of the two-phase polyorgano-polysiloxane block copolymers is that strong thin film membranes can be obtained from them without chemical cross-linking or the use of a filler. The presence of the highly permeable siloxane block therefore entails prospects for an important application of the block copolymers considered as gas separating membranes.

The permeability of such membranes to gases is up to 80% of the permeability of siloxane rubber and increases with increasing content of the polydimethylsiloxane blocks in polyarylate-polysiloxanes,[63,142] polycarbonate-polysiloxanes,[114] polycarbonate-urethane-polysiloxanes,[58] and polysulphone-polysiloxanes.[143]

The study of the influence of the composition of polycarbonate-polysiloxane on the gas-permeability to CO_2 and O_2, carried out by the gas-chromatographic method on film specimens,[114] revealed the S-shaped character of the dependence of the gas-permeability coefficient on the content of the polydimethylsiloxane blocks (Fig.6). The sharp increase in this coefficient in the region where the content of the polydimethylsiloxane blocks is up to 50–60 wt.% suggests that phase inversion takes place for this composition of the copolymer.[114]

The selectivity of the gas separation (CO_2/O_2) remains approximately 6 regardless of the composition of the copolymer. This has been attributed[114] to the fact that the properties of the siloxane phase depend little on the composition of the copolymer. It has also been noted that a characteristic feature of the membranes in the region of compositions investigated is the virtual absence of a temperature dependence of the permeability to CO_2 in the range 20–90 °C as a function of the ratio of the block lengths. This has been explained by the mutual compensation of the activation energies for the diffusion of CO_2 and the heat of solution of CO_2 in the block copolymer.

Since the permeability to gases is determined by the content of the siloxane component regardless of the nature of the rigid blocks constituting the relatively impermeable phase, comparison of the block copolymers having different organic blocks[144] showed that they are to a large extent analogous in their gas separating properties. For this reason, in selecting polymeric materials for gas separating membranes, the criterion to be used as a guide should probably be their physicochemical characteristics, their resistance to degradation, and the technological feasibility of their preparation.

Analysis of the literature data permits comparative estimation of the properties of polyorgano-polysiloxane block copolymers containing different rigid elements (Table 7).

Table 7. Comparative characteristics of the properties of polyorgano-polysiloxane block copolymers*.

Rigid block	Deformability	Upper temperature limit of operating range	Thermal stability	Hydrolytic stability	UV stability	Mouldability	Thermoweldability	Atmospheric stability
Polysulphone	*	*	+	+	*	—	—	—
Poly(phenylene oxide)	+	+	—	*	*	—	—	—
Polycarbonate	*	*	*	*	*	*	+	*
Polyarylate	*	+	+	*	*	*	—	*
Polysilarylene	+	+	*	*	*	—	—	*
Polystyrene	*	—	*	*	+	+	—	+
Poly-α-methylstyrene	*	—	*	*	—	+	—	—
Polyurethane	+	*	*	+	—	*	—	*

Notation: "*"—presence of given property; "–"—absence of given property (or information about it); "+"—advantage in terms of the given property.

The Table shows that such block copolymers have a set of useful properties. The choice of the material for each specific application is determined by the property which should predominate.

It is noteworthy that, since modern economic trends are characterised by a tendency towards further growth of prices of petrochemical raw materials and energy, the manufacture of organosilicon products and materials based on them will be one of the most promising branches of chemical industry due to the relatively low consumption of raw materials and energy per unit output.[145]

IV. APPLICATIONS

Polyorgano-polysiloxane block copolymers can be used for the modification of homopolymers whose structure is analogous to that of the rigid fragment. Small amounts of added block copolymer (approximately 5%) impart new and unexpected properties to the homopolymer. The possibility of such modification follows from the two-phase morphology and the specific properties of the polyorganosiloxane block.

Thus the introduction of 5 wt.% of polysulphone-polysiloxane into the polysulphone homopolymer increases its impact strength by a factor of 20; this is also accompanied by an increase in the resistance to cracking.[9,126] Such behaviour can be explained by the solubility of the polysulphone fragment of the block copolymer in the chemically identical homopolymer matrix and by the segregation of the polysiloxane blocks into a discrete phase. This leads to the effective dispersion of the copolymer in the matrix and a high degree of interfacial adhesion.

A characteristic feature is that the modification is observed only after the introduction of a copolymer exhibiting a two-phase morphology.[14] The increased deformation following the rupture of polycarbonate-(polycarbonate-siloxane-urethane) blends compared with the deformations of the two components of the blend can be accounted for by analogous causes.[146]

Another possible type of modification involves the decrease in the wettability and of the coefficient of friction of the surface of the homopolymer by introducing into the latter a certain amount of the block copolymer.[63,147]

It has been shown by X-ray photoelectron microscopy[148,149] and electronic spectroscopy for chemical analysis[150] that the surface of the block copolymer and of the homopolymer–block copolymer blend is always enriched in the component with the lower surface energy, i.e. in the polysiloxane,[151] which ensures the modifying effect.

The principal applications of polyorgano-polysiloxane block copolymers are determined by the ability of these copolymers to effect highly productive selective separation of gases.[152]

Films based on polyarylate-polysiloxane are used as membranes for the enrichment of natural gas in helium[153] and for the isolation of helium from petroleum gas,[154] for the separation of the "carbon dioxide–hydrogen" or "oxygen–nitrogen" gas mixtures,[62,137,144,155] and for the isolation of sulphur dioxide from mixtures.[156] Polycarbonate-polysiloxane is used for the isolation of oxygen from "nitrogen–oxygen" mixtures.[157,158] Gas- and water-permeable coatings are obtained from polystyrene-polysiloxane.[159]

Ultrathin membranes,[160,161] thermostable films,[162] and films with thermal shrinking for the packing of food products[15] can be obtained by processing polysiloxane block copolymers. These materials are suitable for coatings with improved dielectric properties[66,163,164] and for non-shrinkable coatings with improved strength characteristics.[165] These coatings adhere to metallic surfaces,[166] exhibit a satisfactory resistance to the action of light and weather,[139] and, by virtue of their hydrophobic nature, prevent the icing of glass.[167]

The block copolymers of the given type are believed to be effective stabilisers of polymers[168] and are used as part of compositions with high impact strength,[169–172] thermal stability,[173] and effective adhesion properties[174] and as part of soil compositions.[175]

Polyorgano-polysiloxane block copolymers exhibit a satisfactory fire resistance,[176–179] which increases with increasing content of the siloxane blocks. This has been explained by the formation during combustion of varieties of coke-containing silicon, which increases the resistance of the material to oxidation.[180] Depending on the chemical structure of the organic fragment, the first resistance increases in the sequence polycarbonate based on di(hydroxyphenyl)propane = polycarbonate based on di(hydroxyphenyl)fluorene > polystyrene-poly(2,6-diphenyl-1,4-phenylene oxide).[181]

These materials have found applications in electrical engineering[182] as electrically insulating materials and in electronics[183,184] as coatings for transistors, resistors, and integrated circuits. They retain their useful properties at both elevated[185] and reduced[186] temperatures.

Laminated materials, in which the inner adhesive layer is a polycarbonate-polysiloxane,[29,187,188] as well as technical filaments made of polymethylstyrene-polysiloxanes[189] have been described.

A promising field in which polysiloxane block copolymers may be used currently is medicine.[190,191] Among all the synthetic polymers used in medicine in the USSR, organosilicon compounds are the commonest.[192] All the siloxane elastomers are used as vulcanised materials, reinforced by a filler, which are readily sterilised. However, their main disadvantage, which significantly restricts their applications, is their low mechanical strength and low anticlotting activity.

It is striking that the anticlotting properties of filled silicone rubber are determined not by the chemical nature of the rubber but by the presence on its surface of a filler—silicon dioxide, whose silanol groups are capable of forming hydrogen bonds with plasma proteins and inducing the coagulation of blood.[76,193] The use of polyorgano-polysiloxane block copolymers for medical purposes permits the elimination of these disadvantages. It was shown above that their strength can vary within wide limits and can surpass the strength of siloxane rubber by a factor of 2–3.

The copolymer containing 90 wt.% of polyester-urethane and 10 wt.% of polydimethylsiloxane is used nowadays as a blood-compatible material, having the necessary set of formation-strength characteristics.[76,150,194] Auxiliary devices for the maintenance of cardiac activity, intra-aortal balloons, and various types of pumps for ensuring the circulation of blood and made from this material.

Polyorgano-polysiloxane block copolymers are used as biomaterials,[73,77] medical hermetic sealing compounds,[195] and optical contact lenses correcting astigmatism.[196]

The possibility of obtaining selective gas-permeable films from copolymeric materials permitted their use as the membrane element in different types of "artificial lung" apparatus.[190]

The polyorgano-polysiloxane block copolymers examined in this review represent a new class of materials with a set of useful practical properties determined by their microheterogeneity. Detailed investigation of the factors permitting a fine regulation of the supermolecular structure of these copolymers will assist in the creation of materials with properties specified beforehand.

---oOo---

During the preparation of this review for printing, new communications concerning research into polyorgano-polysiloxanes were published.

The synthesis of linear soluble block copolymers based on αω-diepoxyoligosiloxanes and the diglycidyl ether of di(hydroxyphenyl)propane at 60 °C in dioxan in the presence of stoichiometric amounts of piperazine has been examined.[197]

The interaction of diepoxy-derivatives of oligosiloxane with $\alpha\omega$-di(hydroxyphenyl)oligosulphones in concentrated solution at elevated temperatures resulted in the formation of polysulphone-polysiloxanes,[198] but the molecular weights of the block copolymers synthesised proved to be low.

A number of publications deal with questions of the synthesis and modification of polyamide-polysiloxanes,[199,201] polyurea-polysiloxanes,[202,203] and polyimide-polysiloxanes[204–207] with participation of $\alpha\omega$-diaminosiloxanes. High-molecular-weight polyamide-polysiloxanes have also been obtained by the copolymerisation in the melt at 130 °C of oligodimethylsiloxane having terminal anhydride groups with ε-caprolactam in the presence of an anionic initiator.[208]

The methods of synthesis of polyester- and polyurethane-polysiloxanes using organic functional group-substituted $\alpha\omega$-dihydroxy(carboxy)oligosiloxanes[202,203,209,210] and $\alpha\omega$-di(chloroformyloxymethyl)oligosiloxanes[211] and the hydrosilylation reaction[212,213] in the synthesis of polysulphone-polysiloxanes are being developed.

The detailed study of the physicochemical properties of polyorganopolysiloxanes is being continued. The composition and structure of block copolymers,[214,215] their microheterogeneity characteristics,[216–222] their surfaces,[223,224] the molecular mobility at the interface,[225] processes involving the transport of gases across membranes made of such block copolymers,[226,227] their biodegradation,[228] and their operating properties[229] have been analysed by different methods in recently published studies.

Kinetic Aspects of the Irreversible Thermal Inactivation of Enzymes

D.I.Metelitsa and A.N.Eremin

The methods for the kinetic description and the mechanisms of the thermal inactivation of proteins (enzymes) in various media (aqueous solutions, inverted surfactant micelles, and microsomal membranes) are examined critically. The effective kinetic constants calculated from a first order equation and by approximate methods in conformity with an associative-dissociative mechanism are compared. The temperature dependence of the effective inactivation rate constants is analysed for enzymes and the causes of its deviation from the Arrhenius equation are discussed. The influence of polyols and detergents on the stability of enzymes and their modified forms is analysed and the thermodynamic activation parameters (ΔH^*, ΔS^*, and ΔG^*) for the thermal inactivation of different enzymes in various media are compared and discussed. Recommendations are given concerning the quantitative description of the thermal stability of proteins (enzymes) under the real conditions of their application.

The bibliography includes 138 references.

I. INTRODUCTION

Major advances have now been achieved in the study of the structure and the principles governing the structural organisation of proteins,[1] but the problem of establishing the interrelation between the structure and stability of biomacromolecules remains one of the unsolved problems in modern biophysical chemistry.[2] It is well known that the changes in the conformation of proteins affect their spectroscopic and many other physicochemical characteristics.[1-3] Sometimes these characteristics fail to "notice" small and only at first sight insignificant conformational transformations of proteins. Slight changes in the structure of the active centre of the biomacromolecule fairly frequently have a significant influence on its stability and functional activity. The study of the loss of stability and activity by proteins is of fundamental importance for modern enzymology, bioorganic chemistry, and related disciplines. On the other hand, unless the principal structural factors determining the stability of protein molecules in media of different nature are known, it is impossible to solve practical problems concerning the stabilisation of biologically important polymers. The necessity for the solution of this problem is dictated by the development of modern biotechnology and engineering enzymology, which require the carrying out of many enzymic processes under severe conditions, i.e. at elevated temperatures, under the influence of mixtures of organic solvents, in aqueous media with extreme pH values, in the presence of detergents of different nature, etc.

Modern biotechnology requires accurate quantitative characteristics of the stability of biopolymers. Numerous data obtained under different conditions frequently cannot be compared let alone used in calculations for enzyme reactors, the permitted usage times of biopreparations, etc. because of the lack of a quantitative treatment. The quantitative characteristics of the stability of biopolymers are especially important under the conditions of their practical application, i.e. in aqueous media, in the presence of organic solvents, detergents, denaturing additives, and stabilising substances, and in the immobilised state.

The interest in the inactivation and reactivation of proteins and enzymes was manifested very long ago[4,5] and this multiaspect problem still remains in the centre of attention of specialists in various disciplines.[3,6–23] Various aspects of the denaturation and inactivation of biopolymers have been examined in monographs,[3,7–11,14,16,18] review articles,[12,13,15,17,21,22] and textbooks.[1,2] The structure of proteins and the role of conformational changes in their denaturation processes have been described in detail in several books.[1–3,9–11] The thermodynamics of the reversible and irreversible denaturation processes have been considered in a number of communications.[3,7,12] The methods for the investigation of the denaturation processes involving proteins and enzymes have been described in detail in the books by Joly[3] and Kushner.[11] The biological aspects of the stability of multienzyme complexes and other biopolymers have been dealt with by Kushner and the kinetic aspects of this problem have been considered in the monograph of Berezin and Varfolomeev.[16] The principal ways of stabilising enzymes have been examined in a number of communications[13–15,19,22] and two reviews[20,21] have been devoted to problems of the reactivation of biocatalysts. The general characteristics of the changes in the thermal stability of proteins and enzymes after the chemical modification of their functional groups have been considered in a review[22] and the relative contributions of thermodynamic and kinetic factors to the stabilisation of immobilised proteins have been dealt with by Kozlov.[23]

In our view, the extensive but by no means complete literature data mentioned above reflect inadequately and sometimes do not deal with many important kinetic aspects of the irreversible inactivation of enzymes. Regarding the stability of enzymes as a function of their structure, which in many respects depends on the environment, and being guided by the fundamental and practical problems mentioned above, we had several specific aims in the present review: (1) to examine the methods for the rapid and correct characterisation of the rates of enzyme inactivation processes under the real conditions of the application of enzymes; (2) to characterise quantitatively the thermal stability of a number of enzymes (lysozyme, lactate, malate, and glucose-6-phosphate dehydrogenases, horseradish peroxidase, and catalase) and proteins (myoglobin and cytochrome b_5) by means of these procedures; (3) to compare in relation to specific examples the thermal stabilities of enzymes in aqueous solutions and inverted surfactant micelles in organic solvents (peroxidase, glucose-6-phosphate dehydrogenase, and cytochromes b_5 and P-450) and also in aqueous solutions and in native biological membranes (cytochrome P-450); (4) to analyse the characteristic features of the stabilising action on enzymes by polyols and detergents of different nature; (5) to consider critically the thermodynamic activation characteristics of the irreversible inactivation of proteins under various conditions and the possibility of their relation with the structure of the biopolymers and the environment.

II. METHODS FOR THE KINETIC CHARACTERISATION OF THE INACTIVATION OF PROTEINS

The concept of "inactivation" is frequently incorrectly replaced in the literature by the term "denaturation". Inactivation is always associated with the loss of functional activity by the protein and enzyme and can be due to a series of causes which do not induce the denaturation of the biopolymer. The term "inactivation" is much broader than "denaturation". We shall attempt to define clearly these concepts. Kushner has analysed the different definitions of the denaturation of biopolymers.[11] As a result, he justified what he believed to be the most correct definition of this process, namely that denaturation is a conformational change in the biological macromolecule leading to the irreversible or reversible loss of its ability to perform a specific biological function. Denaturation can be induced by physical and chemical factors (heating, ultrasound, irradiation, extreme pH values) and may accompany protein aggregation processes, the dissociation of the subunit biomacromolecules into monomers, the thiol–disulphide exchange, and the cleavage of S–S bonds and can also be the result of immobilisation and chemical modification of the functional groups of the biopolymer.[3,11,20–23] It is assumed that the denaturation process is not accompanied by the dissociation of covalent bonds in the polymer chains of the biomacromolecule.[1–3,11,13,14] The denaturation of the protein always leads to its inactivation. However, inactivation may be caused by factors which do not entail conformational consequences, i.e. denaturing: for example, the interaction of macromolecules with one another or the modification of functionally important groups which does not alter the conformation of the biopolymer as a whole.[20,21] Thus any change leading to the irreversible or reversible loss of a specific biological function may be regarded as the inactivation of the biomacromolecule.

The reversible "native protein (nat) $\rightleftarrows$ inactivated protein (in)" process can be characterised by the equilibrium constant K = [in]/[nat], where [in] and [nat] are the equilibrium concentrations of the inactivated and native forms respectively. In this case, if the protein is present in a highly dilute solution, the equilibrium constant K can be related to the characteristics of the equilibrium inactivation (the enthalpy ΔH and entropy ΔS) by the expression:

$$-\ln K=\Delta G/RT=\Delta H/RT-\Delta S/R$$

The enthalpy ΔH can be determined from the van't Hoff equation subject to the condition that ΔH and ΔS are independent of temperature:

$$-[\mathrm{d}\ln K/\mathrm{d}(1/T)]=\Delta H/R$$

The values of ΔH and ΔS have now been measured by various methods for the reversible inactivation processes involving a multiplicity of proteins. In order to determine these thermodynamic characteristics, measurements are made of the equilibrium constant between the native and denatured forms or the heat of denaturation is found by scanning microcalorimetry.[12] Tables giving compilations of these data may be found in monographs and reviews.[1–3,7,10–12]

An experimental criterion in testing for irreversibility is especially important in the study of irreversible protein (enzyme) inactivation processes. Those proteins whose functional activity has changed in such a way that after the removal of the given influence the initial level of functional activity is not restored for a long time should be regarded as irreversibly inactivated.[20] A certain indefiniteness in this concept is associated with the arbitrary choice of the time after which the initial functional activity of the protein is not restored.

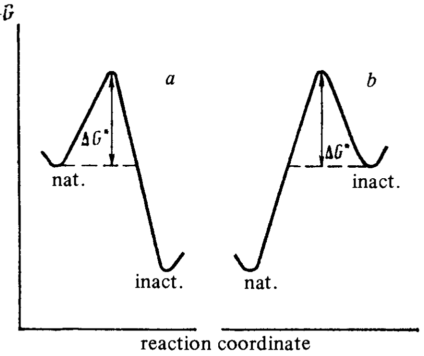

Figure 1. The energy diagram for the possible pathways in the irreversible protein inactivation process: *a*) thermodynamic; *b*) kinetic.[20,21]

The nature of irreversible inactivation can be both thermodynamic and kinetic (Fig.1).[20,21] In the former case the free energy of the stabilisation of the protein $\Delta G_{\mathrm{in}} = G_{\mathrm{in}} - G_{\mathrm{nat}}$ is greater than zero and the free energy of its destabilisation $\Delta G = -\Delta G_{\mathrm{in}} < 0$. The protein cannot be reactivated, since the free energy of the native form is characterised by a local minimum, while the free energy of the inactivated form is characterised by a global minimum (Fig.1*a*). In the case of the kinetic irreversibility, the protein passes from the native state with a global free energy minimum to the inactivated state with a local minimum in the Gibbs free energy: in this case the free energy of the stabilisation of the protein $\Delta G_{\mathrm{in}} < 0$ and the energy of its destabilisation $\Delta G = -\Delta G_{\mathrm{in}} > 0$. The two states are separated by a high activation barrier, which prevents the rapid reactivation of the protein (Fig.1*b*) The practical separation of thermodynamic and kinetic irreversibility in the inactivation of proteins is a complex problem, the ways for the solution of which are only being outlined.[23] The aim of the present review is not the analysis of the contributions to the thermodynamic parameters ΔG, ΔH, and ΔS by forces of different nature and the examination of data on the reversible inactivation of proteins, since this has already been done in a monograph[3] and other reviews.[12,17,22]

In irreversible inactivation, the kinetic stability of proteins has come to be characterised by the rate constant k_{in}, which is usually determined from the variation of the properties of proteins by fluorescence and electronic and circular dichroism (CD) spectroscopic methods or from the change in activity. In the general case, the retention of the activity of the biocatalyst does not always correspond to the retention of the integrity of the entire protein globule.[22] If one of the postulates of the theory of absolute reaction rates, stating that the rate of attainment of equilibrium between the reactants and the activated complex is much greater than the rate of the chemical reaction itself, is valid, then this theory can be applied to protein inactivation processes.[3,6] According to Eyring,[6] we have the following expression for molecular reactions:

$$k_{\text{in}}=(kT/h)\exp(-\Delta G^{*}/RT)=(kT/h)\,\mathrm{e}^{\Delta S^{*}/R}\mathrm{e}^{-\Delta H^{*}/RT}\ , \tag{1}$$

where k is the Boltzman constant, h the Planck constant, and ΔG^*, ΔH^*, and ΔS^* are the increments in the free energy, enthalpy, and entropy on formation of the activated complex. The change in the activation enthalpy is linked to the activation energy by the relation $\Delta H^* = E_{\text{act}}-RT$.

However, in the early studies, whose complete survey may be found in a monograph,[3] it was already shown that the irreversible inactivation process can be described by a kinetic first-order equation for by no means all enzymes and not under all conditions. The enzyme inactivation kinetics frequently do not obey the first order law from the beginning of the process or are not described by this law when the inactivation of proteins is continued until the attainment of high degrees of inactivation. The first order equation is usually inapplicable to the description of the inactivation of subunit enzymes in buffer solutions.[24–33] It has been shown[24–32] that, in the inactivation of alkaline phosphatase,[31] kidney acylase,[29] and glucose oxidase,[26,27] these subunit enzymes dissociate into the monomers, which are then irreversibly inactivated. The dissociation of the enzyme into subunits is observed also in the inactivation of glyceraldehyde-3-phosphate dehydrogenase,[34] catalase,[35,36] and many other proteins with a quaternary structure.[20,21,37–39] The appearance of subunits in the inactivation of enzymes has been confirmed by gel-electrophoretic[26,27,29,34] and sedimentation[36] methods. Numerous experimental data have shown that the inactivation of subunit enzymes can be described in the simplest case by the scheme:[24–33]

$$\mathrm{E}\underset{k_{-1}}{\overset{k_1}{\rightleftarrows}}\mathrm{A}\xrightarrow{k_2}\mathrm{I}\ , \tag{2}$$

where E is the native enzyme, A its reversibly denatured form which partly retains its catalytic activity or a subunit of the oligomeric enzyme, and I the irreversibly inactivated form of the protein lacking enzyme activity. For many enzymes, the inactivation scheme may be much more complex, since the process includes not one but several reversible stages, which greatly hinders its kinetic description. For example, in the presence of Mg^{2+} or Zn^{2+} ions, alkaline phosphatase forms tetramers, which are inactivated via a three-stage dissociative mechanism:[31]

$$\mathrm{E}_4 \rightleftarrows 2\mathrm{E}_2 \rightleftarrows 4\mathrm{E} \rightarrow 4\mathrm{I} \tag{3}$$

In scheme (3), the tetramers E_4 and the dimers E_2 are catalytically active, while the monomers E are inactive and the form I is irreversibly denatured. It has been stated that only the alkaline phosphatase dimers E_2 are catalytically active in the enzymic process.[40] The dissociative mechanism of the inactivation of many subunit proteins is not unexpected, since it reflects their complex structural organisation and the important role which structural levels of different orders play in the functioning of oligomeric protein.

At first sight, it is surprising that comparatively simple monomeric proteins, for example, lysozyme, exhibit a complex inactivation pattern both in solution and in the crystalline state: at pH 3–7 the thermal inactivation of lysozyme is a two-stage reversible process,[41] which corresponds to scheme (2). The stepwise character of the thermal denaturation of lysozyme has been confirmed by the change in the optical density of its solutions in the temperature range 20–90 °C. At 60–70 °C conformational changes take place in lysozyme in solution, accompanied by a decrease of the content of α-helices from 30 to ~10%. Conformational transitions in lysozyme in solution between 20° and 30 °C have been observed also by ^{13}C NMR.[43] The inactivation of lysozyme by ultrasound in the temperature range 20–80 °C showed that the enzyme undergoes several conformational transitions, including one which occurs at ~30 °C.[44] The study of the thermal denaturation of lysozyme in weakly alkaline solutions by fluorescence[45] and circular dichroism[46] methods confirmed the validity of scheme (2) for this enzyme. In the first irreversible stage of the inactivation of lysozyme, the α-helix structure of the protein changes little, but in the second, irreversible stage its complete breakdown is observed over section 5–15 of the polypeptide chain together with the ionisation of the Glu-35 residue, which greatly destabilises the adjoining α-helices. We obtained data indicating the maximum rate of inactivation of the protein in solution at pH 6.5, which confirmed the important role of Glu-35 in the irreversible inactivation of the enzyme,[47] since $\mathrm{p}K_a \cong 6.5$ which is characteristic of only the Glu-35 residue localised in the lysozyme molecule in the vicinity of the active centre.[48,49]

We have examined two causes of the deviation of the inactivation of enzymes from the kinetic first-order law—the subunit nature of many proteins and the complex multistage character of the inactivation of monomeric proteins. In a study of the inactivation of enzymes in biological membranes, the process kinetics are complicated still more by the involvement in the process of isoenzymes of the same enzyme or of different conformers of the same form of the protein. This is the situation in the inactivation of cytochrome P-450 in microsomal membranes.[50] The heterogeneity of cytochrome P-450 in liver microsomes leads to a break on the kinetic curves in the semilogarithmic form, reflecting the inactivation of different forms or different conformers of cytochrome P-450 (Fig.2). In this case the time variation of the concentration of the catalytically active cytochrome is represented by the sum of two exponential functions. The rate constant k_{in}, determined graphically for the first process stage from the semilogarithmic form of the kinetic curve, approaches its true value provided that the rate of inactivation in the second stage is much lower than in the first.

Yet another cause of complication of the kinetics of the inactivation of monomeric proteins is their association (aggregation) in buffer solutions.[3,20,21,51] As a rule, inactivation with formation of aggregates is described by the two-stage kinetic scheme[51] $\mathrm{E} \rightleftarrows \mathrm{D} \rightarrow \mathrm{I}$, in which E is the native form, E the denatured form, and I the inactivated form (aggregate). Evidently, this scheme does not differ formally from scheme (2).

Examination of extensive experimental data on the inactivation of monomeric and oligomeric (subunit) proteins led Arens et al.[33] to the conclusion that the inactivation of all proteins can be described by a general formal scheme which is identical with scheme (2). The first reversible stage reflects the dissociation of subunit proteins and the conformational changes (denaturation) in monomeric proteins. The presence of the first reversible stage leads in both cases to the appearance of breaks in the kinetic curves for the inactivation of enzymes recorded in the low-temperature region, i.e. these curves are not described by a first-order equation over the entire time interval.[24-32] The positions of the breaks depend on the initial protein concentration in solution.[24-31]

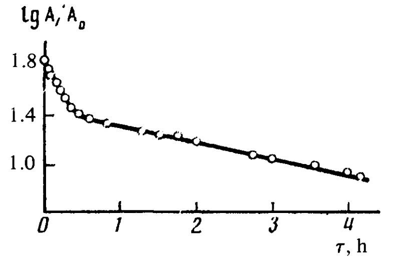

Figure 2. The semilogarithmic form of the kinetic curve for the inactivation of cytochrome P-450 in rabbit liver microsomes at 52 °C in tris-HCl buffer at pH 7.54.[50]

The complete kinetic characterisation of the protein inactivation process [scheme (2)] presupposes the determination of the rate constants for the forward (k_1 and k_2) and reverse (k_{-1}) reactions, the equilibrium constant between the native enzyme E and its denatured form A ($K = k_1/k_{-1}$), and also the expressions, in an integral form, for the concentrations of E and A at a specific instant. Analysis of scheme (2) subject to the initial conditions $t = 0$, $[E]_0 = a$, and $[A]_0 = [I]_0 = 0$ yields the following expressions for the current concentrations of E and A:[52]

$$E = a\left\{\frac{\lambda_2 - k_1^{-1}k_2}{\lambda_2(\lambda_2-\lambda_3)}e^{-\lambda_2 k_1 t} + \frac{k_1^{-1}k_2-\lambda_3}{\lambda_3(\lambda_2-\lambda_3)}e^{-\lambda_3 k_1 t}\right\}$$

$$[A] = a/\lambda_2 - \lambda_3\cdot(e^{-k_1\lambda_3 t} - e^{k_1\lambda_2 t}), \text{ where } \lambda_2 = {}^1/_2(\alpha+\beta);$$

$$\lambda_3 = {}^1/_2(\alpha-\beta);\ \alpha = 1 + k_{-1}/k_1 + k_2/k_1;\ \beta = [\alpha^2 - 4k_2/k_1]^{1/2}$$

Evidently the current concentrations of the E and A forms of the protein are described by extremely complex equations. We may note that in practice it is frequently impossible to measure the concentrations of the protein forms A and I and one usually follows only the consumption of the initial enzyme E.

The system of equations describing scheme (2) and other similar schemes is non-linear and has no analytical solution.[30,32] In a series of studies[24-32] dealing in detail with the kinetics of the inactivation of oligomeric enzymes, Poltorak, Chukhrai, and co-workers therefore proposed several procedures for the approximate solution of the equations for the determination of the kinetic constants k_1, k_{-1}, and k_2 and the dissociation constants of the subunit enzymes K. One of the versions of the approximate solution makes it possible to obtain the rate constant for the dissociation of the oligomeric protein from the equation[31,32]

$$2(v/v_0) - {}^1/_2(v/v_0)^2 = {}^3/_2 - k_1 t \ , \qquad (4)$$

where v_0 and v are the rates of inactivation of the protein in the initial instant and after time t, which must not exceed the time τ corresponding to the break in the plot of ln v against t. In the second version of the approximate description of the kinetics of the inactivation of subunit enzymes, the following equation is used:[30-32]

$$(1/t)\ln v/v_0 = -k_1 + ({}^4/_3)k_1^2k_{-1}[E]_0 t^2 \ , \qquad (5)$$

in which $[E]_0$ is the initial concentration of the enzyme and the time t must also be less than τ. The linearisation of the kinetic inactivation curves with the aid of Eqn.(5) makes it possible to calculate not only the rate constant k_1 but also the rate constant k_{-1} for the reverse reaction and then also the constant for the dissociation of the subunit proteins into monomers or dimers in the thermal transformation of the tetrameric protein. Eqns.(4) and (5) have been used successfully to characterise kinetically the inactivation processes involving kidney acylase,[29] alkaline phosphatase,[31] and certain other oligomeric proteins.

Thus a correct kinetic description of the inactivation of enzymes with an arbitrary choice of the initial concentration reduces to a complex analysis of the kinetic curves, since their semilogarithmic forms have breaks, while the effective rate constants k_{in}, calculated with the aid of such semilogarithmic forms, are as a rule functions of the initial protein concentration and therefore strictly speaking are not constants. It is therefore necessary to seek methods for the approximate solution of the system of equations describing the associative-dissociative scheme (2) in order to find simple ways of linearing the kinetic relations.

Does this imply that there can be no cases where the kinetic curves for the thermal inactivation of enzymes can be linearised in terms of plots of ln v against t? In our view this is not so, since protein inactivation conditions such that the reversible dissociation of the subunit enzyme or the first reversible stage of the conformational transformation of the monomeric protein are reduced to a minimum or are altogether absent have been realised in practice.

First case. The subunit enzyme has been treated with bifunctional reagents and its reversible dissociation into monomers is difficult.[14,15,29,34] For example, kidney acylase modified by glutaraldehyde is inactivated in accordance with a first order law, since the stage involving the reversible dissociation of the enzyme has been virtually ruled out.[29] In this case, the semilogarithmic forms of the kinetic curves show no breaks of any kind when inactivation is continued up to extremely advanced stages.

Second case. The subunit enzyme dissociates into monomers via an "all or nothing" mechanism and the process is accompanied by the complete loss of catalytic function. As an example, one may quote the dissociation of tetrameric catalase into monomers in acid and alkaline media,[35] on treatment with denaturing agents,[53,54] in the course of lyophilisation,[55] and as a result of the introduction of succinyl groups into the protein by treatment with succinic anhydride.[36] Regardless of how the dissociation of catalase is initiated, this process is accompanied by the loss of catalase activity and its kinetics obey a first-order law even for high degrees of inactivation.[35,36,56]

Third case. The dissociation of the subunit protein into monomers is the rate-limiting stage of the entire inactivation process. In the study of an NAD-dependent hydrogenase, the validity of the dissociative scheme for the thermal inactivation of this tetrameric protein was demonstrated:[38]

$$E_{4\text{-in}} \xleftarrow{k_i} E_4 \overset{k_1}{\rightleftarrows} 2E_2 \xrightarrow{k_d} E_{2\text{-in}},$$

where k_i and k_d are the inactivation and denaturation rate constants. The authors showed[38] that the rate of inactivation of the enzyme is determined by the dissociation of the tetramers into dimers. The semilogarithmic forms of the kinetic curves describing the loss of activity by hydrogenase therefore have no breaks up to considerable degrees of inactivation of the protein. In the case of monomeric proteins, there is also a possibility of inactivation pathways in which the rate of the entire process is limited by the first stage. Such examples will be presented below.

Fourth case. The protein is inactivated in highly dilute solutions where the association of the enzyme subunits or the aggregation of the monomeric protein is hindered or reduced to a minimum. In this case, subject to the condition that the rate-limiting stage of the entire process is the first reaction stage [see Scheme (2)], the inactivation kinetics obey a first order law and the semilogarithmic form of the kinetic curves should have no breaks of any kind.

We shall consider next the kinetics of the inactivation of proteins whose transformations under different conditions have been investigated in our laboratory.[35,36,47,50,56–70] They include monomeric (lysozyme,[47] myoglobin,[60] cytochrome b_5,[63,69] horseradish peroxidase,[61,62] and cytochrome P-450 LM-2[50,64,66–69]) and subunit biopolymers (lactate dehydrogenase,[58] malate dehydrogenase,[59] and catalase[35,36,56]). The thermal inactivation of all the proteins enumerated was studied

Table 1. Thermodynamic activation parameters for the irreversible inactivation of enzymes in different media.

Enzyme	Inactivation conditions	Δt[a]	E_{act}, kcal mol^{-1}	t° C	ΔH^*, kcal mol^{-1}	ΔS^*, cal mol^{-1} K^{-1}	ΔG^*, kcal mol^{-1}	Refs.
Glucose-6-phosphate dehydrogenase,	0.1 M NaOH-glycine buffer, pH 9.1	23—46	4.34; 131.40	25 45	3.75; 130.80	—70.20; 341.00	24.66; 22.40	[57]
EC 1.1.1.49	Inverted micelles; 0.1 M AOT[c] 0.1 M Triton X-45, 12% of 0.1 M NaOH-glycine buffer, pH 9.1	23—46	19.40; 61,42	25 45	18.80; 60.80	—18.15; 118.80	24,20; 23.02	[57]
Lysozyme, EC 3.2.1.17	0.067 M phosphate buffer, pH 6.2	20—80	24.20	37	23.60	—7.50	25.90	[47]
Lactate dehydrogenase, EC 1.1.1.27	0.1 M phosphate buffer, pH 8.2	20—60	6.40: 44.60	25 37	5.81 44.00	—60.06 63,50	23.70 24.40	[58]

Pairs of activation parameters are quoted in those cases where the temperature variations of the constants exhibit a break in the Arrhenius plots.

in buffer solutions and, for some of them (peroxidases,[57,62] glucose-6-phosphate dehydrogenase,[57] cytochrome b_5,[68,69] and cytochrome P-450 LM-2[66-69]), in inverted surfactant micelles in organic solvents. The thermal inactivation of the integral membrane enzyme cytochrome P-450 LM-2 was studied in biomembranes (liver microsomes).[50,64,65] Among the test objects, there are water-soluble (lysozyme, peroxidase, catalase, myoglobin, and dehydrogenases) and hydrophobic biopolymers (cytochromes b_5 and P-450), as well as modified enzymes (succinylated catalyse,[36] systems obtained by coupling strophanthin K to peroxidase,[61] and catalase[56]). The choice of these test objects was dictated not only by fundamental research but also the wide-scale employment of the majority of them in practice.[71-73] The proteins which we investigated, the conditions and temperatures ranges in which they are inactivated, and the thermodynamic activation parameters are listed in Table 1.

We confined ourselves to a quantitative examination of data obtained solely in our laboratory, although Table 1 might have been supplemented by the results of studies of other groups in our country[14,15,19,20-34,74,75] and abroad.[17,76-80] This limitation of the range of kinetic studies of the thermal inactivation of proteins (enzymes) considered is due to the following causes: firstly, the data of other workers have already been surveyed and examined critically in earlier publications[14,15,19-22] or in the course of the preparation of the present review[74,75] and in our view does not require a fresh analysis; secondly, the quantitative characteristics of thermal inactivation have been frequently obtained by different workers under different conditions, so that it is sometimes difficult to establish the initial concentrations of the proteins subjected to thermal inactivation, which leads to contradictory results when the effective kinetic constants are referred to particular stages of the protein inactivation and reactivation processes investigated, which have been analysed, for example, in a recent monograph.[81] Analysis of the kinetic constants for the thermal inactivation of proteins without referring them to the initial concentrations of the inactivated objects is incorrect, as will be shown below, and can lead to erroneous conclusions about the character and mechanism of the thermal inactivation of biopolymers. We have therefore confined ourselves to a quantitative consideration of our own data, since the results analysed here have been obtained under controlled conditions, which can be readily compared for different objects in different media.

III. KINETICS OF THE INACTIVATION OF ENZYMES IN DIFFERENT MEDIA

1. Kinetics of the Inactivation of Enzymes in Aqueous Media

Lysozyme (EC 3.2.1.17) is inactivated in accordance with scheme (2).[41,44-47] At protein concentrations in the range 0.14–5.48 M (in the temperature range 40–70 °C), the first order rate constant depends on the initial concentration (Fig.3), the dependence being described by the equation

$$k_{in} = k_0 \exp(-\alpha[E]_0) \, , \tag{6}$$

where $[E]_0$ is the initial protein concentration, k_0 the inactivation rate constant at infinite dilution of the protein which is independent of $[E]_0$, and α a coefficient which depends on temperature and has the dimensions of the reciprocal of concentration.[47] The temperature variation of α (Fig.3) is described by the equation

$$\alpha = \alpha_0(1 - \gamma/T) \tag{7}$$

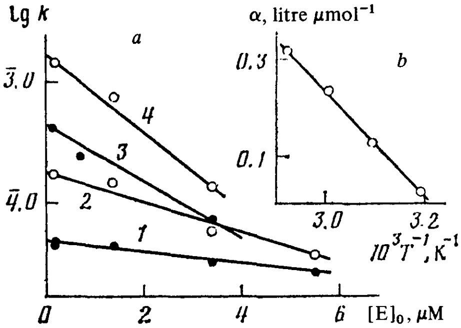

Figure 3. *a*) Dependence of the effective rate constants for the inactivation of lysozyme on its initial concentration at different temperatures (°C): *1*) 40; *2*) 50; *3*) 60; *4*) 70; *b*) temperature dependence of α.[47]

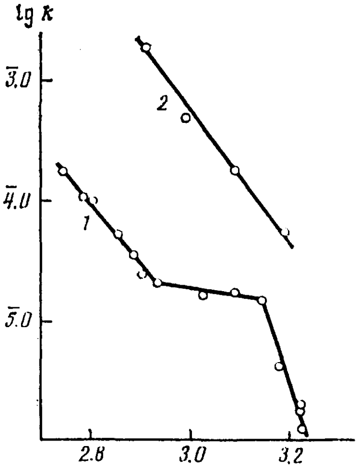

Figure 4. Temperature dependence of the rate constants for the inactivation of lysozyme at a concentration of 0.20 mg ml⁻¹ (curve *1*) and at infinite dilution of the enzyme (curve *2*).[47]

The temperature variation of the effective inactivation rate constants k_{in} at high lysozyme concentrations is characterised by breaks in the Arrhenius plot (Fig.4), while the temperature variation of the rate constants k_0, obtained by extrapolating k_{in} to zero protein concentration, does not exhibit breaks (Fig.4, line *2*). E_{act} and the expression for the rate constants in a general form can be found from Fig.4 (line *2*):[47]

$$k_0 = 4.0 \times 10^{11} \exp(-24\,200/RT) \, . \qquad (8$$

From Eqns.(6)–(8), we obtain a general expression for the effective rate constant k_{in}:[47]

$$k_{in} = 4.0 \times 10^{11}\exp\{-24\,200/RT-\alpha_0(1-\gamma/T[E]_0\} \quad (9)$$

Evidently, the temperature dependence of k_{in} is not described by the Arrhenius law, since k_{in} depends not only on temperature but also on the protein concentration $[E]_0$. The correct kinetic constant characterising the inactivation of lysozyme can only be k_0, since it does not depend on the protein concentration in solution.

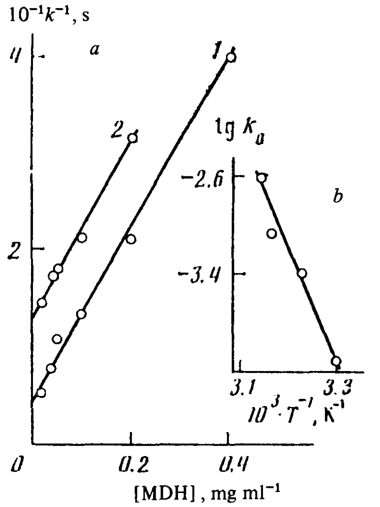

Figure 5. *a*) Dependence of the effective rate constants for the thermal inactivation of malate dehydrogenase (MDH) on the initial enzyme concentration at 45 °C (curve *1*) and 43 °C (curve *2*); *b*) temperature dependence of the rate constant k_0 for the inactivation of malate dehydrogenase corresponding to the infinite dilution of the protein.[59]

Malate dehydrogenase (EC 1.1.1.37) is inactivated in accordance with a scheme analogous to scheme (2):

$$E_2 \overset{k_1}{\rightleftarrows} 2E \xrightarrow{k_d} E_d,$$

in which E_2 is the dimer, E the enzyme subunit, k_1 the rate constant for the dissociation of the dimer, and k_d the rate constant for the denaturation of the subunit.[59] For an arbitrarily selected protein concentration, the inactivation rate constants k_{in}, evaluated from the semilogarithmic forms of the kinetic curves describing the decrease of the activity of the enzyme, depend on the initial dimer concentration (Fig.5):[59]

$$k_{in} = k_0/(1+\alpha k_0[E_2]_0) \quad (10)$$

where k_0 is the rate constant for the inactivation of the protein at infinite dilution and α is a constant which depends on temperature and has the dimensions of the reciprocal of the rate (litre mol^{-1} s). The temperature variation of the rate constant for the inactivation of malate dehydrogenase k_0 (Fig.5) is described by the equation:[59]

$$k_0 = 1.42 \times 10^{27}\exp(-43\,000/RT) \quad (11)$$

The temperature variation of the effective rate constants k_{in} is not described by the Arrhenius equation, since they depend on temperature, the enzyme concentration, and the coefficient α.

Table 2. The rate constants k_{in} for the inactivation of malate dehydrogenase (MDH), calculated from the lg ν–time relations,[59] and the rate constants k_1 calculated from Eqn.(4).[31,32]

$[MDH]_0 = 0.01$ mg ml^{-1}			$[MDH]_0 = 0.05$ mg ml^{-1}		
t° C	$10^4 k_{in}$, s^{-1}	$10^4 k_1$, s^{-1}	t° C	$10^5 k_{in}$, s^{-1}	$10^5 k_1$, s^{-1}
20	0.128	0.139	28	0,798	1.670
25	0.294	0.278	30	3.220	2.900
26.5	0.319	0.296	34	10.01	9.52
28	0.437	0,389	37	11.70	12.30
30	0,511	0.407	38	11.80	12.50
34	0.766	0.714	40	19.30	17.20
37	1,440	1.480	43.5	69.00	62.50
40	2.920	3.180	46	115,00	105.00
45	9 590	9.170	49	478.00	400.00

It is of interest to compare the effective rate constants k_{in}, calculated for different initial protein concentrations and temperatures, with the rate constants k_1 (see the inactivation scheme presented above) calculated from Eqn.(4).[31,32] Table 2 compares the values of k_{in} and k_1 under different conditions. At low enzyme concentrations, the two constants differ little, but, with increase of the concentration of malate dehydrogenase by a factor of 5, the difference between them becomes significant. We believe that the agreement between k_{in} and k_1 at low protein concentrations is not fortuitous. The stage involving the dissociation of the enzyme dimers is rate limiting in its inactivation and the reverse stage, involving the reassociation of the malate dehydrogenase subunits at low enzyme concentrations, is difficult or does not occur at all. Nor can one rule out the possibility that the inactivation is limited by the conformational changes in the dimer, occurring when it dissociates into subunits.

Lactate dehydrogenase (EC 1.1.1.27). It is a tetrameric enzyme, whose inactivation can be described by several schemes with successive dissociation into dimers and monomers.[58] In the temperature range 20–60 °C, the effective inactivation rate constant depends on the initial concentration of the tetramer E_4. This dependence is described by Eqn.(10), in which the concentration of the dimer E_2 has been replaced by the concentration of the tetramer E_4. In the range 35–60 °C, the temperature dependence of k_0 obeys the equation:[58]

$$k_0 = 1.30 \times 10^{27}\exp(-44\,600/RT) \quad (12)$$

Below 35 °C, E_{act} falls to 6.40 kcal mol^{-1}.

Catalase (EC 1.11.1.6) from ox liver. The dissociation of the enzyme obeys the "all or nothing" principle: $E_4 \overset{k_1}{\rightleftarrows} 4E$.[53,54] The enzyme subunits lack catalase activity.[35,36,53,55] The constant for the dissociation of catalase into subunits k_1 depends strongly on the pH and is described by Eqns.(13) and (14) respectively in acid and alkaline media:[35]

$$k_1 = 5.0 \times 10^7[H^+]^{2.3}, \quad (13)$$

$$k_1 = 5.0\,[H^+]^{-1.4} \quad (14)$$

In 0.1 M phosphate buffer at pH 6.6 at temperatures in the range 20–45 °C, the thermal inactivation of catalase (investigated in terms of the loss of its catalytic activity in the oxidation of ethanol by cumenyl hydroperoxide) is characterised by $E_{act} = 14.6$ kcal mol^{-1}. After its modification by 11 molecules of strophanthin K, the activation energy for the thermal degradation of the enzyme increases to 22.8 kcal mol^{-1}.[56] The temperature variation of the rate constant for the inactivation of catalase in the range 20–45 °C is described by the equation[56]

$$k_1 = 4.13 \times 10^6 \exp(-14\,600/RT)\ .$$

Horseradish peroxidase (EC 1.11.1.7). The temperature variation of k_{in} for the enzyme is described by the equation[61]

$$k_{in} = 1.7 \times 10^{10} \exp(-19\,900/RT)\ .$$

The modification of peroxidase by three strophanthin K molecules alters little the activation characteristics for the inactivation of the enzyme (Table 1). A change in the pH has a marked influence on the rate constant for the inactivation of peroxidase and the activation characteristics of the process: in 0.1 M citrate-acetate buffer at pH 6.0, the activation energy is 19.9 kcal mol^{-1},[61] while in 0.05 M phosphate-citrate buffer pH 7.0 it increases to 47.4 kcal mol^{-1}.[62]

Cytochrome P-450 LM-2 (EC 1.14.14.1). In tris-HCl buffer (pH 7.54) with 20% of glycerol, the enzyme loses its catalytic activity in the range 40–58 °C. $E_{act} = 23.5$ kcal mol^{-1} corresponds to this process.[50] It is important to note that the loss of catalytic activity is accompanied by the simultaneous decrease of the intensity of the Soret band of the carbonyl complex of cytochrome P-450 and by the appearance of a spectral band at 420 nm, corresponding to the inactive form of the haemoprotein, namely P-420.[65,82] The immobilisation of cytochrome P-450 LM-2 on polyamide does not induce an appreciable change in E_{act} for the thermal degradation of the haemoprotein (22.4 kcal mol^{-1}).[50] The kinetic curves for the decrease of the catalytic activity of cytochrome P-450 LM-2 in solution as a rule correspond to several stages which can be accounted for in two ways: firstly, the highly hydrophobic cytochrome P-450 forms aggregates in aqueous solution in which it is inactivated at different rates; secondly, in dilute solutions the inactivation of different conformers of the same form of cytochrome P-450 may be manifested, since after extraction from microsomal membranes the haemoprotein is unusually labile in aqueous media.

2. Kinetics of the Inactivation of Enzymes in Inverted Surfactant Micelles in Organic Solvents

Inverted surfactant micelles, in which enzymes and proteins are incorporated, constitute a realistic model of biological membranes, reflecting many important aspects of their structure and complex lipid–protein and protein–protein interactions.[66–69,83–85] Furthermore, microheterogeneous (protein-surfactant–water–organic solvent) systems constitute an extremely interesting medium for enzymic reactions.[83–85] It has been frequently demonstrated that enzymes of different classes, solubilised by inverted surfactant micelles, not only retain their catalytic properties but are sometimes more active than in aqueous media.[69,83–86] For the practical use of proteins in inverted surfactant micelles, it is important to know not only the catalytic activity of the biocatalysts under these conditions but also their stability at different temperatures and pH and on exposure to the influence of denaturing additives. We have shown that the stability of haemoproteins in inverted surfactant micelles depends on temperature, pH, ionic strength, and protein stabilising additives, as in aqueous media; the stability of haemoproteins is also influenced by the physicochemical properties and composition of the micelles, by the specific alteration of which it is possible to stabilise significantly the solubilised proteins.[66–69,83–85]

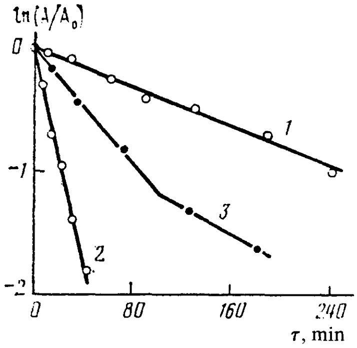

Figure 6. Semilogarithmic forms of the kinetic curves for the inactivation of glucose-6-phosphate dehydrogenase at 40 °C: *1*) buffer solution; *2*) AOT micelles in heptane; *3*) mixed AOT–Triton X-45 micelles in heptane;[57] the conditions are indicated in Table 1.

Glucose-6-phosphate dehydrogenase (EC 1.1.1.49, G6PDH) is inactivated in inverted AOT micelles (AOT = sodium salt of di-2-ethylhexyl ester of sulphosuccinic acid) in heptane in accordance with a first-order kinetic law up to high degrees of inactivation (Fig.6).[57] We may note that the enzyme is inactivated in aqueous solutions also in accordance with the same law. However, in mixed micelles made up of AOT and Triton X-45 (1:1), the inactivation of the enzyme deviates from the first-order law (Fig.6). The temperature variation of the effective rate constants for the inactivation of G6PDH in the range 23–46 °C is characterised by a break in the Arrhenius plot at 34 °C. The activation energy is $E_{act} =$ 61.4 kcal mol^{-1} above the break and 19.4 kcal mol^{-1} below it.[57] On inactivation of the enzyme in aqueous solutions, a break is also observed at 36 °C and E_{act} differs from the values calculated for micellar systems (Table 1).

Horseradish peroxidase exhibits a "periodicity" in the variation of its activity on inactivation in inverted AOT micelles and in mixed micelles comprising AOT and Triton X-45, which we attribute to complex cooperative transformations of the "water–protein–AOT–heptane" system.[57,62] This "periodicity" in the inactivation of the peroxidase is smoothed out on raising the temperature to 50–55 °C (Fig.7). We may note that in buffer solutions the inactivation of peroxidase is described by a first-order kinetic equation (Fig.7b, lines *5* and *6*),[57,61,62] i.e. the phenomenon of "periodicity" in the variation of the catalytic activity of the enzyme is associated solely with the nature of the inverted surfactant micelles. The rate constants for the inactivation of the peroxidase in micelles are also influenced by the concentration of the buffer, its pH, the percentage content of the aqueous phase, and the addition of the non-ionic detergent Triton

X-45 or glycerol to the system.[57,62] The temperature variation of the effective rate constants for the inactivation of the peroxidase in micelles is characterised by a break at 55 °C in the Arrhenius plot, and the values of E_{act} above and below this temperature differ markedly (Table 1).

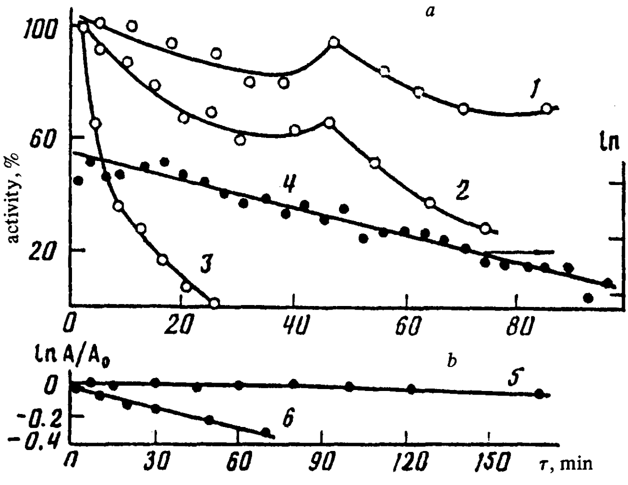

Figure 7. Kinetic curves for the variation of the catalytic activity of peroxidase in inverted micelles; 0.2 M AOT, 6% of polar phase comprising 0.05 M phosphate-citrate buffer at pH 4.6 (13.5 nM enzyme): *a*) temperature (°C) [*1*) 37; *2*) 43; *3*) 54; *4*) semilogarithmic form of the kinetic curve at 40 °C]; *b*) semilogarithmic forms of the kinetic curves for the variation of the activity of peroxidase (13.5 nM) in 0.05 M phosphate-citrate buffer at pH 7.0 at different temperatures (°C) [*5*) 45; *6*) 55].[57]

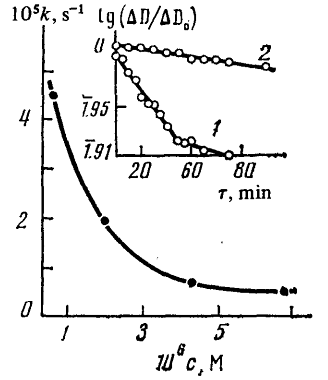

Figure 8. The influence of the concentration of cytochrome b_5 (*c*) on the rate constant for its transformation in AOT micelles in octane at 31 °C; cytochrome b_5 concentration (μM): *1*) 0.68; *2*) 6.84; (0.25 M AOT, 45% of polar phase in octane).[63]

Cytochrome b_5 is inactivated in inverted micelles at rates which depend on its initial concentration (Fig.8). At low protein concentrations, the breaks in the semilogarithmic forms of the kinetic curves describing the decrease of the intensity of the Soret band are absent but they appear on raising the concentration of the haemoprotein.[63] The character of the variation of k_{in} with the initial concentration is the same for both cytochrome b_5 in micellar systems and for malate and lactate dehydrogenases in aqueous solutions [Eqn.(10)]:[59] with increase of the concentration of the protein, the rate constant for its inactivation diminishes.

Cytochrome P-450 LM-2 is inactivated at different rates in micelles of different composition.[66-69] By increasing the complexity of the micelles, it is possible to achieve a significant stabilisation of this labile protein in micellar systems. At 40 °C, k_{in} for cytochrome P-450 in micelles containing AOT, cetyltrimethylammonium bromide, Twin 20, and Triton X-45 is 2.9×10^{-6} s^{-1}, while in liver microsomes at the same temperature it is 3.4×10^{-6} s^{-1},[66,67] i.e. the stability of the haemoprotein in a specifically selected micellar system can be actually greater than its stability in the native membrane.[66,67,69]

Thus the inverted surfactant micelles not only protect proteins against the denaturing influence of organic solvents but in certain cases are capable of ensuring their relatively high thermal stability in a hydrocarbon medium.[66-69] The optimum composition of the inverted micelles ensuring the retention of the catalytic activity of the enzyme or even its increase is specific to each protein. However, the thermal stability of enzymes in micelles is usually lower than in an aqueous medium, although enzymes in micellar systems can be stabilised by increasing the complexity of the composition of the micelles in such a way that the stability of the enzyme reaches a level characteristic of buffer solutions. For example, at 45 °C the rate constant for the inactivation of G6PDH in a buffer solution is 2.24×10^{-3} s^{-1}, while in mixed 1:1 micelles comprising AOT and Triton X-45 it is 9.12×10^{-4} s^{-1}, i.e. the enzyme is 2.4 times more stable in the micelles.[57] Yet another way of stabilising proteins in organic solvents has been proposed recently:[87] by the covalent incorporation of α-chymotrypsin in particles of cross-linked polyacrylamide gel with colloidal dimensions (100–400 Å). This catalyst is universal and can be used in both hydrocarbon and aqueous solutions.

The quantitative description of the inactivation of proteins and micelles is associated with the same difficulties as in aqueous solutions: the effective inactivation rate constants depend on the initial protein concentration;[63,70] the tempera-true variation of these constants is complicated by breaks in the Arrhenius plots, which reflect not only the effective character of the rate constants but also the characteristic features of the behaviour of the micellar systems as the temperature is raised.[57,62,70]

3. Kinetics of the Inactivation of Cytochrome P-450 in Microsomal Membranes

Cytochrome P-450 is the terminal oxidase in many hydroxylating multienzyme systems, widely distributed in nature.[82] These systems are responsible for the hydroxylation of hydrophobic compounds to form more polar hydroxy-derivatives, which are either removed from the organism or serve as key compounds in the biosynthesis of bioactive substances.[82] The majority of cytochromes P-450 are associated to different extents with membranes and are distinguished by a high lability after extraction from the native environment. The unique ability of cytochrome P-450 to catalyse the conversion of a wide variety of compounds into hydroxy-derivatives has led investigators to seek ways of the practical utilisation of this family of biocatalysts. However, the difficulty of isolating the cytochromes from the membrane, their low stability in aqueous media, the high cost of the source of the raw material, and also the multienzyme nature of the hydroxylating systems have made it necessary to seek procedures whereby stabilised organelles (microsomes, mitochondria) could be used in enzymic hydroxylation processes *in vitro*.[88,89] It is therefore a matter of great urgency to be able to characterise the inactivation of cytochromes P-450 in native membranes and to stabilise them in this medium.[50,64,65,82,88,89] We investigated the inactivation of cytochrome P-450 in rabbit liver microsomes on the basis of the loss of its catalytic activity in the oxidation of aniline and the variation of its spectroscopic properties.[50,64,65]

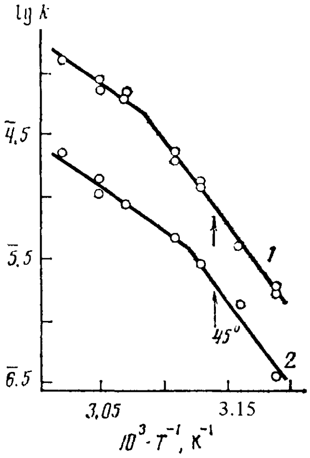

Figure 9. Temperature dependence of the rate constants for the thermal inactivation of cytochrome P-450 in rabbit liver microsomes in the absence of glycerol from the solution: *1*) first stage of the process; *2*) second stage of the process.[50]

The decrease of the catalytic activity of the haemoprotein in microsomes is accompanied by a decrease of the intensity of the Soret band of its CO complex and an increase of the concentration of the inactive form of the haemoprotein—cytochrome P-420.[65] The change in the activity of cytochrome P-450 in microsomes takes place in several stages.[64] As a rule, the effective rate constant has been determined solely for the first stage of the process. The temperature variation of k_{in} for cytochrome P-450 in microsomes is characterised by a break in the Arrhenius plots for the first and second stages of the haemoprotein inactivation process (Fig.9).[50] The causes of the appearance of the breaks will be discussed below. One of the ways of stabilising membrane proteins, and cytochrome P-450 in particular, is by incorporation in lipid dispersions and liposomes, modelling many aspects of native biological membranes. This problem is discussed in detail in a monograph.[90] The study of the thermodynamic characteristics of the thermal inactivation of cytochrome P-450 in liposomes showed that they depend on the pH and temperature and vary, compared with aqueous solutions, in the following ranges: ΔH from 78 to 80 kcal mol^{-1} and ΔS from −163 to −184 cal mol^{-1} K^{-1}. This indicates an increase of the conformational "rigidity" of the protein in liposomes compared with buffer solutions.[91]

An important task in the study of the thermal inactivation of enzymes is the correlation of the kinetic characteristics of the rate-limiting stage of this complex process and its molecular mechanism. The solution of this problem by kinetic procedures alone is impossible and requires the use of many other methods (electronic, circular dichroism, and NMR spectroscopy, sedimentation analysis, and electrophoresis). The application of a set of physicochemical methods makes it possible in many instances to relate the rate-limiting stage of the thermal inactivation to fairly definite molecular mechanisms of the transformations of the biopolymer. It has been already noted that ^{13}NMR,[43] fluorescence,[45] and circular dichroism[46] data, measurement of the optical density of lysozyme,[42] and the study of the kinetics of its inactivation[44,47] suggest that the rate-limiting stage in the thermal inactivation of this protein is associated with the ionisation of the Glu-35 residue and the decomposition of the polypeptide chain along the 5–15 section.[47–49] The rate-limiting stage in the thermal inactivation of the more complex membrane enzyme cytochrome P-450 is the cleavage of the coordinate bond between the haem iron and the cysteine residue in the polypeptide chain, which transforms the enzyme into the inactive form P-420.[50,82,90] The determination of this rate-limiting stage became possible solely from a series of studies of the kinetics of the thermal inactivation of cytochrome P-450[50,65] and of the changes in its spectroscopic characteristics.[65,82,90]

Studies of Poltorak, Chukhrai and co-workers,[24–33,74] Berezin, Martinek, and Ugarova and co-workers[14,15,19–22,75] in our country and of Pfeil[17] and Jaenicke[76–80] abroad have been devoted to the solution of the complex problem of correlating the kinetic parameters and the structural changes in enzymes during their inactivation. Examination of these problems is very important but is outside the framework of this review, which is devoted solely to the kinetic aspects of the thermal inactivation of proteins and enzymes. We can only refer the reader to a recent review,[74] which deals in detail with the processes involving the dissociative thermal inactivation of enzymes and the approximate methods of calculation of the individual kinetic parameters of these processes and indicates ways whereby subunit enzymes can be stabilised by the fixation of their quaternary structure, and also to a review[75] devoted to the principal structural and physicochemical factors governing the stabilisation of protein macromolecules in solution and methods for the stabilisation of biocatalysts by chemical modification and point mutations of proteins. A useful critical analysis of studies concerning the correlation of the kinetic data for the inactivation and reactivation of subunit enzymes and their structural changes has been carried out in a monograph.[81]

IV. THE INFLUENCE OF POLYOLS AND DETERGENTS ON THE STABILITY OF ENZYMES IN SOLUTIONS

The medium in which proteins function in the living cell differs to a large extent in composition, viscosity, polarity, and other parameters from the solutions used *in vitro*. It has long been known that various organic solvents greatly reduce the stability of proteins. The addition of many low-molecular-weight compounds (salts, sugars, polyols, detergents, etc.) to protein solutions influences the stability of the proteins (enzymes), since such substances alter the properties of the solutions and the affinity of the protein for the solvent. The influence of certain low-molecular-weight additives on the thermal stability of proteins is analysed in this Section and the mechanism of the stabilisation of the proteins is discussed.

The stabilising effect of polyols on proteins is well known.[92–102] The degree of denaturation of ovalbumin by urea decreases in the presence of sucrose,[92] polyhydric alcohols increase the temperature of the thermal transition of lysozyme and ribonuclease,[93] and sucrose has a stabilising effect on egg proteins.[93] Various methods have been used to investigate the quantitative characteristics of the stabilising action of polyols on proteins:[98,100,101] systematic studies have been made of the influence of a series of polyols on the denaturation temperatures of ovalbumin, lysozyme, conalbumin, and α-chymotrypsinogen by the calorimetric method[98] and the interaction of a number of proteins with aqueous solutions of lactose and glucose has been studied in detail by the densitometric method.[100] In our laboratory a kinetic approach has been used to characterise quantitatively the influence of polyols on the thermal stability of various proteins.[58,61,64,65] The stabilising influence of polyols has been studied in relation to horseradish peroxidase modified with three strophanthin K molecules,[61] lactate dehydrogenase in aqueous solutions,[58] and cytochrome P-450 in rabbit liver microsomes.[64,65] Regardless of the nature of the protein (dissolved in water or hydrophobic) and its structural organisation (monomeric or subunit) and also regardless of the environment of the enzyme (aqueous solution or microsomal membranes), all the low-molecular-weight polyols and dextrans decrease the rate of inactivation of proteins.[58,61,64,65]

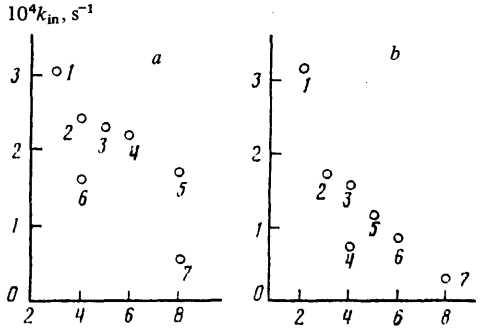

Figure 10. Variation of the rate constants for the thermal inactivation of horseradish peroxidase modified with strophanthin K (*a*) and of cytochrome P-450 in microsomes (*b*) with the number of OH groups in the polyol molecule; *a*: *1*) glycerol; *2*) rhamnose; *3*) glucose; *4*) sorbitol; *5*) maltose; *6*) xylose; *7*) sucrose; 50 °C;[61] *b*: *1*) ethylene glycol; *2*) glycerol; *3*) rhamnose; *4*) xylose; *5*) glucose; *6*) sorbitol; *7*) maltose; 50.5 °C.[64]

An increase of the concentration of glycerol and sugars in solution is accompanied by a monotonic decrease of the rate of inactivation of the peroxidase–strophanthin complex,[61] lactate dehydrogenase,[58] and cytochrome P-450 in microsomes.[64,65] Poly(ethylene glycols) 600, 1000, and 6000 and dextrans 20, 40, and 500 also stabilise the peroxidase–strophanthin complex.[61] However, dextran 20 and poly(ethylene glycols) 300 and 1000 have no stabilising effect on cytochrome P-450 in microsomes.[64] The question arises how the data concerning the stabilising action of polyols can be explained.

We showed that there is a direct relationship between the rate constants for the inactivation of the peroxidase complex and cytochrome P-450 and the number of OH groups in the molecules of stabilising additives (Fig.10): the greater the number of OH groups present in the stabiliser, the lower the value of k_{in}, i.e. the more stable the protein in solution or in microsomes.[61,64,65] In order to account for these data, we may recall the principal factors governing the stabilisation of proteins.[14,15,98] The stability of proteins is promoted by hydrogen bonds, electrostatic and hydrophobic interactions, and complex formation with certain metals. It is known that the dissolution of polyols in water has little effect on the formation of hydrogen bonds by proteins.[98] Electrostatic interactions are usually stronger in solutions of sugar than in water, but their contribution to the stabilisation of proteins is relatively small. The main factor stabilising the steric structure of proteins is hydrophobic interactions.[1–3,14,15,98] Such interactions are determined to a large extent by the nature of the solvent and hence depend greatly on the way that sugars and other polyols influence the structure of water. It has been shown that the interaction between pairs of hydrophobic groups is much stronger in solutions of glycerol and sugars than in pure water.[98] This is probably the main mechanism by means of which polyols stabilise proteins in aqueous solutions. The stabilising action of polyols is determined by the extent of their stabilising effect on aqueous solutions. The relative quantity $f = (\bar{V}_2 - V_w)/V_w$, where V_w is the van der Waals volume of the solute and $\bar{V}_2$ the partial molar volume of the same substance, including the internal volume of the molecule and the changes in the latter induced by the action of the solvent, has been suggested[98] as a structure formation characteristic of this kind. As an example we may quote of f for glycerol in water at 25 °C:[103] V_w = 51.4 ml mol^{-1}, $\bar{V}_2$ = 73.5 ml mol^{-1}, and f = 43.1%. The van der Waals volumes of sugars and other polyols have been calculated.[104] The following equation is used to determine the partial molar volumes $\bar{V}_2$:

$$\varphi_v = M_r/d_0 = 1000(d - d_0)/cd_0\ ,$$

where d and d_0 are the densities of the solution and the solvent, M_r is the molecular weight of the solute, and c the molar concentration of the solute in the solution.[98] Evidently ϕ_v varies linearly with c and extrapolation to zero concentration can yield the partial molar volume $\bar{V}_2$. The partial molar volumes of many sugars have been calculated in this way and have been published.[105] Sugars induce effective structure formation in water when their OH groups are oriented in space in such a way that the distance between them corresponds to the distance between the oxygen atoms in the molecular lattice of water.[98] More accurate quantitative characteristics of structure formation in water by polyols are not at present available.

There exist also other explanations of the stabilising effect of polyols on proteins. It has been suggested that polyol molecules can penetrate into the protein globules, which tends to intensify the hydrophobic interactions within the globule and to lower its lability.[99] In certain cases there is a possibility of specific binding of sugars and alcohols by proteins. For example, in the crystalline state lysozyme interacts with glucose, which stabilises the enzyme, since it is bound to it at at least two centres.[106] The constant for the binding of glucose to lysozyme is 2.3 M^{-1}.[106]

The stabilising influence of polyols on proteins of a wide variety of kinds indicates the principal role of the structure of the aqueous medium in which proteins are present and the secondary role of the structural organisation of the proteins themselves. It is of interest to analyse the influence of polyols on cytochrome P-450 in the microsomal membrane, i.e. in a microenvironment different to that in its aqueous solution.

Low-molecular-weight and high-molecular-weight polyols act on microsomes in different ways. The low-molecular-weight additives influence the membrane as mild surfactants: with increase of temperature, they penetrate into the lipid double layer, increase the degree of the hydration of phospholipids, lower the surface viscosity of the double layer, and increase the lateral mobility of the phospholipids.[107-110] High-molecular-weight additives poly(ethylene glycols) and dextran do not penetrate the lipid double layer, but they do reduce the surface potential of phospholipids and lead to the aggregation of vesicles;[111] by competing with phospholipids for water, they cause the contraction of the liquid crystal lattice of the double layer.[112] Thus low-molecular-weight polyols can act on the membrane as a whole, while high-molecular-weight polyols influence significantly only its surface layer. This can explain the different effect of polyols on the microsomal cytochrome P-450.[64,65] The stabilising effect of polyols must therefore be characterised taking into account their influence on the hydrophobic interactions in the protein globule and throughout the membrane as a whole. By penetrating into microsomes, glycerol promotes hydrophobic contact between pairs of non-polar groups of the cytochrome P-450 molecule, while in the regions near the membrane the polarity of the medium is reduced. Glycerol equalises the properties of the entire system and greatly increases the degree of structure formation in the medium. The considerable decrease of the entropy of activation with increasing glycerol concentration in the inactivation of microsomal cytochrome P-450 can be understood from this standpoint. On the other hand, glycerol decreases the enthalpy of activation for the thermal denaturation of cytochrome P-450 by acting on microsomes as a detergent and significantly facilitates the mobility and lability of the haemoprotein in the lipid double layer.[64,65] The influence of glycerol on the enthalpy of activation can be regarded as a destabilising factor in the thermal inactivation of cytochrome P-450, while the influence of glycerol on the entropy of activation is a stabilising factor in the thermal inactivation of the haemoprotein. It follows from our data that the ratio of these two factors favours the entropic factor, as a result of which the free energy of activation for the degradation of cytochrome P-450 in the presence of glycerol increases and the rate constant for the thermal degradation of cytochrome P-450 therefore diminishes. We may note that similar ratios of ΔH^* and ΔS^* have also been observed for other methods of stabilishing proteins, for example, when they are immobilised on carriers:[23] the binding to the matrix results in a deviation from the initial structure of the enzyme towards its denaturation, in a decrease of ΔH^*, and in a simultaneous decrease of ΔS^* as a consequence of the ordering of the structure of the immobilised protein.

Compared with polyols, detergents have a greater influence on proteins in aqueous solution. Systematic studies of the interaction of detergents with proteins in aqueous solutions are essential in view of their practical importance. Firstly, the use of detergents is inevitable in the isolation from membranes of the proteins bounds to them.[82,113-115] Secondly, the solubilisation of water-insoluble substrates of lipolytic enzyme is frequently necessary.[116] Thirdly, in order to attain high rates of enzymic reactions, non-ionic detergents are frequently added to buffer solutions.[117,118] In most cases the detergents are selected empirically. Extensive experimental data on the interaction of detergents with soluble and membrane proteins have been surveyed in a number of reviews.[115,119,120] However, the absence of systematic studies of the interaction of various detergents with proteins is still felt as an acute problem, which hinders the survey and assessment of the prospects for the development of this methodologically important field of enzymology.

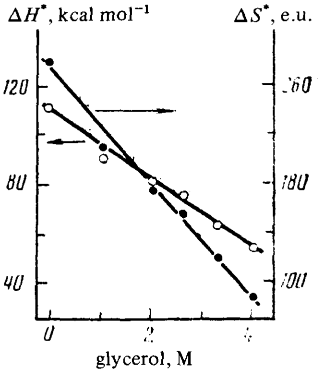

Figure 11. Dependence of ΔH^* and ΔS^* on the glycerol concentration in the inactivation of cytochrome P-450 in microsomes in a phosphate buffer at pH 7.3.[64]

Systematic studies of the interactions of various detergents in an aqueous medium with myoglobin and cytochromes c and P-450 have been carried out in our laboratory.[60] These proteins differ not only in solubility and molecular weight but also in the strength of binding of haem to the apoprotein. The detergents employed were the zwitter-ionic surfactant 1-(N-$C_{12}H_{25}$-NN-dimethylamino)propane-3-sulphonate (TM 3-12) and the non-ionic surfactants Twin 20 and Triton N-101, belonging to type A, which embraces amphiphilic compounds exhibiting lyotropic mesomorphism and forming spherical or ellipsoidal micelles in an aqueous medium.[119] We also used sodium cholate, which belongs to the group of charged detergents of type B, differing by the absence of lyotropic mesomorphism and forming aggregates in an aqueous medium containing from 2 to 8 surfactant molecules.[119] The interaction of the haemoprotein enumerated above with detergents of both types is accompanied by a decrease of the intensity of the Soret bands in the absorption spectra. The rate of this process is determined by the nature of the detergents, their concentration, and temperature and is a maximum for the zwitter-ionic surfactant TM 3-12. The rate constants for the transformation of the haemoproteins depend in a complex manner on the detergent concentrations. Their influence on the secondary structure and conformation of proteins, leading to the loss of haem, has been demonstrated by the CD method and the method involving the second derivatives of the absorption spectra of haemoproteins in the presence of detergents. In conformity with the model proposed for the interaction of detergents with haemoproteins, the process takes place at two levels—molecular and supermolecular.[60] At detergent concentrations below the critical concentration for micelle formation, a bimolecular interaction of the surfactants with the proteins is observed; above this concentration, not only surfactant molecules but also their micelles (type A) or associated species (type B) interact with the proteins. The molecular mechanism of the interaction of surfactants with proteins consist in the fact that the surfactant molecules penetrate via their hydrophobic fragments into the cavities and "cracks" in the protein molecules, making more hydrophobic the regions adjoining the aromatic aminoacids, which is confirmed by the increase of the amplitude of the second derivatives in the absorption spectra of cytochrome c and P-450 LM-2 following the addition of Twin 20 and TM 3–12.[60] Not only does the hydrophilic–hydrophobic balance change within the protein globule but also the secondary protein structures break down, which is confirmed by CD spectra, reflecting the decrease of the content of the α-helix sections in myoglobin molecules after the addition of TM 3–13.[60] The zwitter-ionic surfactant TM 3–12 interacts most strongly with proteins. The effect of surfactants on haemoprotein leads to conformational changes in the protein, facilitating the loss of haem. The transformation of myoglobin in the presence of detergents of different types takes place with $E_{act} = 17–23$ kcal mol^{-1}, which can be attributed to the dissociation of the haem iron–histidine nitrogen coordinate bond.[60] Individual detergents and their mixtures increase or decrease the values of ΔH^* for the transformation of myoglobin. A relation (compensation effect) is observed between ΔH^* and ΔS^*, which is described by the equation $\Delta H^* = A + \beta\Delta S^*$, where $A = 22\,000$ cal mol^{-1} and $\beta = 300$ K. The coefficient β should usually be close to the average experimental temperature, which has in fact been observed in the present case: $T_{av} \cong \beta = 300$ K.

Inverted surfactant micelles in organic solvents which have solubilised the proteins constitute a special case. Proteins are almost insoluble in pure organic solvents. In order to increase their solubility, certain surfactants are employed. In contrast to aqueous solutions, in the inverted micelles the detergents interact with proteins mainly via polar fragments. A mixed solvation shell consisting of surfactant molecules, the organic solvent, and water is formed around the protein globule. The composition of the solvation shell and the ratio of the components in the micellar solution influence directly the stability and activity of the proteins in the system. The reader can obtain exhaustive information about the functioning and properties of the proteins in these systems from a number of reviews.[83–85,121]

V. TEMPERATURE DEPENDENCE OF THE RATE CONSTANTS FOR THE INACTIVATION OF ENZYMES AND THE PHYSICOCHEMICAL SIGNIFICANCE OF THE THERMODYNAMIC ACTIVATION PARAMETERS FOR THIS PROCESS

The temperature variation of the rate constants for the inactivation of enzymes is described by the Arrhenius equation and is characterised by a single value of E_{act} only if the enzymes have been studied in highly dilute solutions. Only one E_{act} is characteristic of dilute solutions of monomeric lysozyme[47] and subunit lactate and malate dehydrogenases.[58,59] An increase of the protein concentration in solution leads to the appearance of breaks in the Arrhenius plots (Fig.4), since the constants k_{in} depend on the initial protein concentration and other parameters.[47,58,69] In all cases, when the initial protein concentration has been chosen arbitrarily, there are breaks in the Arrhenius plots reflecting changes in the rate constants for the inactivation of enzymes in concentrated solution. For membrane proteins, there are other causes which explain the presence of breaks in the Arrhenius plots: firstly, the conformation and stability of the proteins in the membrane depend on the effect, nature, and physical properties of the surrounding lipids, whose phase transitions induce an abrupt change in E_{act} in the thermal transformation of the protein;[82,90,113,114] secondly, at certain temperatures there is a possibility of "phase" transitions in the protein itself, leading to a sharp change of its conformation[41–44,122] and hence to a change in E_{act} for the thermal degradation process; thirdly, there is a possibility of the existence of different conformers of the same form of the biocatalyst, which are characterised by different E_{act} for the thermal denaturation process. All the possibilities listed above can be realised not only in biomembranes but also in liposomes[123,124] and possibly in inverted surfactant micelles.

Clearly the rate constants for the inactivation of proteins determined in highly dilute aqueous solutions are closest to their true values, because in this case the possibility of the association of the monomeric proteins and of the reassociation of the subunits of oligomeric enzymes is reduced to a minimum. It is therefore useful to consider E_{act} on the activation characteristics ΔH^* and ΔS^* obtained with the aid of the Arrhenius–Eyring equation (1) in the first place for those proteins whose inactivation has been characterised by the rate constants k_0 for their dilute solutions. Under such conditions, we investigated three enzymes–lysozyme,[47] malate dehydrogenase,[59] and lactate dehydrogenase.[58] It follows from the Arrhenius equations (8), (11), and (12) that only in the case of lysozyme [Eqn.(8)] is the pre-exponential factor for the rate constant close to its limiting value for unimolecular reactions.[6,52] For two subunit enzymes, the pre-exponential factor exceeds by many orders of magnitude the typical factors in the equation for unimolecular reaction rate constants (10^{10}–10^{11} s^{-1}) and corresponds to a high activation entropy (Table 1). This is not unexpected, because it has already been known for a long time that the inactivation of proteins is characterised by high values of ΔH^* and ΔS^*.[6–8,10,11,23,125]

In applying the Arrhenius–Eyring equation (1) to the transformations of enzymes and enzymic reactions, one must remember that, as a consequence of the non-elementary nature of these processes, the parameters determined from the temperature variation of k_{in} for enzymes and the rate constants for the enzymic reactions are always real quantities reflecting the entire complexity of the macrostage being characterised—the presence of microstages, which are not outwardly manifested, the influence of the solvent and the environment of the enzyme, etc.[8] (pp.175–185). For this reason, in the analysis of the thermodynamic and kinetic parameters of the inactivation of enzymes, it is essential to resort to additional considerations based on the theory of chemical kinetics and empirical data for simpler chemical and model systems and also to the results of the study of the enzyme inactivation processes by NMR and CD spectroscopic and densitometric methods, sedimentation analysis, etc.

As regards kinetic data, Likhtenshtein proposed three types of methods for their analysis in the case of enzymic processes:[8] (1) quantitative comparison of the energetic and entropic parameters for enzymic and model reactions; (2) theoretical estimation of the parameters for different versions of the mechanism of the reactions investigated; (3) correlation between the energetic and entropic parameters of enzymic processes (compensation effect). Since the present level of the theory does not allow the calculation of the absolute values of the energies and entropies of activation for reactions in a condensed phase, the third type of analysis of enzymic processes is of great interest, particularly when one is dealing with series of reactions, with the specific alteration of one of the parameters keeping the others constant, or with changes in the conditions of a process involving the same enzyme.

The correlation between the energetic and entropic parameters in an enzymic process was first noted by Doherty and Vaslow.[126] On changing the pH, the authors observed parallel compensating changes in the parameters ΔH and ΔS

in the binding of the substrate to α-chymotrypsin. Since then, numerous data concerning the compensating changes in ΔH and ΔS (ΔH^* and ΔS^*) in a wide variety of enzymic processes have been published. These data have been examined in detail and analysed in a series of investigations.[8,11,12,125–130] The survey of the available information about the inactivation of proteins shows that the principal kinetic characteristics of this process are as follows: (1) sharp changes in the rates of inactivation are observed within a fairly narrow temperature range or within narrow ranges of concentrations of hydrogen ions, organic solvents, and other additives; (2) the inactivation is characterised by anomalously large (compared with the parameters of the usual chemical reactions) values of E_{act} and ΔS^*, which reach 180 kcal mol^{-1} and 600 e.u. per mole of the protein in some cases (see Table 1 and also the compilations of data in Refs. 3, 6, 7–11, 22, 23, and 125); (3) the values of E_{act} and ΔS^* are extremely sensitive to changes in the conditions within the medium (pH, ionic strength, nature of the buffer, the presence of stabilising additives, the introduction of proteins into micelles, liposomes, and gels, etc.); (4) there is a linear relation between the experimental values of E_{act} and the activation entropy for different proteins and for the same protein under different conditions, expressed by the equation[131,132] $E_{act} = \alpha + \beta\Delta S^*$.

It follows from the numerous data discussed previously and quoted in this review that, on passing from one protein to another and also on changing the pH and the concentration of ions and denaturing additives, the activation energy and entropy almost always change in parallel (see, for example, Fig.11). The slope of the linear plots of E_{act} against ΔS^* is known to be the same as the slope of the linear plots of the reversible inactivation parameters ΔH and ΔS.[7–10,22,125] The kinetic and thermodynamic compensation effects are characterised by similar coefficients β and identical scales of the changes in the energetic and entropic parameters.[8,125]

In conformity with existing ideas, the processes involving the inactivation (denaturation) of biopolymers are cooperative conformational transitions. The thermodynamic theory of cooperative systems has been developed in a number of studies in relation to biopolymers.[133–137] Denaturation is sometimes regarded as a "fusion" process, although in the case of proteins one can speak of analogies with fusion processes and "phase" transitions only approximately, since proteins are regarded as "aperiodic" irregular crystals, characterised by differences between the energies of the cooperative linkage and by defects in various parts of large molecules. The cooperative processes in proteins are intermediate between the usual chemical reactions, in which a small number of molecules participate, and large-scale phase transitions with participation of an enormous number of identical species.[8] We shall not consider here the different kinetic models of the conformational transitions in proteins, since they have been analysed in detail in monographs and reviews.[8,10,125,133–137]

According to Privalov,[138] there is at present no doubt about the energetic discreteness of proteins, which reflects their structural discreteness, since proteins are complex systems consisting of more or less independent but fully defined cooperative subsystems. The subdivision of the macromolecule into cooperative subsystems (domains) is a general principle of the structural organisation of protein molecules, which has evolutionary, functional, and physical bases. E_{act} and the activation characteristics ΔH^*, ΔS^*, and ΔG^* for the thermal inactivation (denaturation) of proteins therefore refer to complex cooperative **rearrangements** of a part of the protein molecule and of its immediate environment. The question arises whether it is possible to refer in some cases the characteristics listed above to a rigorously defined molecular stage in the inactivation of the protein. The set of kinetic,[47] thermodynamic,[41] spectroscopic,[42,45,46] and ^{13}C NMR data[43] obtained for the inactivation of lysozyme permits the claim that this process begins with the ionisation of the Glu-35 residue, which destabilises the adjoining section of lysozymes and causes the breakdown of its α-helix structure in the region of the active centre. Thus, even in this comparatively simple object, which has been characterised in detail, the rate-limiting step in the irreversible inactivation is accompanied by complex conformational changes, which are reflected quantitatively by the values of E_{act}, ΔH^*, and ΔS^*.[47] A second example of a protein for which one can speak quite definitely about the elementary inactivation stage is cytochrome P-450. The loss of catalytic activity by this protein is associated with the increase of the length and rupture of the coordinate bond between the haem iron and the sulphur atom of the cysteine residue.[50,82,88,90] However, a change in the conformation of the apoprotein precedes this step, i.e. in this case the rate-limiting stage in the activation process is associated with marked conformational changes in the biocatalyst, which is reflected by the thermodynamic and activation characteristics of the process.[50,64,65]

The question arises in what cases is it legitimate to calculate the activation characteristics of the thermal inactivation of proteins from the temperature variation of k_{in}, the effective character of which is known beforehand. We believe that this can be usefully done only when one is dealing with a comparison of the behaviour of the same enzyme under the influence of different agents, a comparison of different enzymes acted upon by the same agent under identical conditions, or the modification of the enzyme by various agents under the same conditions. There is no point in discussing the absolute values of E_{act}, ΔS^* and ΔG^* in such cases, since only the character of the variation of these quantities when a specific parameter is varied and all the remaining parameters are kept constant, and not the values themselves, carries information. Thus analysis of the activation characteristics obtained reduces to the discussion of the compensation states between their energetic and entropic components.[7,8,11,125,127–132]

In discussing the enthalpy–entropy compensation in the inactivation (denaturation) of proteins, one should remember that there is a doubt about its existence as an independent physical phenomenon.[9] It has been claimed that, in all enzymic reactions exhibiting the enthalpy–entropy compensation, a key role is played by the solvent (liquid water), which is a constant participant in all physiological processes and constitutes a natural inexhaustible reservoir of chemical free energy in living nature.[125,129] The conformational rearrangement in proteins and the changes in their interactions with water molecules which they entail alter significantly the structure of the entire mass of liquid water. This factor and also the very narrow range of independent parameters (pH, temperature, and the salt composition of the medium), which determine the conditions of the enzymic process, lead to the appearance of trivial linear relations between the enthalpy and entropy changes.[125,129]

Blyumenfel'd[9] quite justifiably assumes that the enthalpy–entropy relations do not reflect any special essential physical features of the reactions and are a simple consequence of the general laws of equilibrium thermodynamics and may not exist at all if the equilibrium thermodynamic process ($\Delta G \cong$ const.) occurs within a very narrow range of variation of an independent variable (temperature, hydrogen ion concentration, etc.). In the study of the reactions of biopolymers, where equilibrium statistical dynamics is applicable only subject to major stipulations, any kind of serious analysis of compensation relations frequently lacks physicochemical significance.

VI. CONCLUSION

It follows from numerous experimental data that the thermal inactivation of enzymes is a complex process consisting of several consecutive-parallel stages and therefore it frequently cannot be described in terms of the first order kinetic law. As a rule, the semilogarithmic forms of kinetic curves have breaks or are altogether non-linear. Even in those cases where a first-order equation describes satisfactorily the kinetic data, the effective inactivation rate constant k_{in} depends on the initial protein concentration.

Two approaches have been proposed to achieve a rapid and correct quantitative characterisation of the process leading to the thermal inactivation of proteins. One of them has been used by Poltorak and co-workers;[24-32] the thermal inactivation scheme is described by equations which have been solved by approximate methods permitting the determination of the rate constants for the first reversible and second irreversible stages and the calculation of the equilibrium constant between the native and reversibly inactivated forms of the proteins. This method permits a quantitative description of the kinetic curves for the thermal inactivation of monomeric and subunit proteins at an arbitrarily selected initial concentration of the latter.

The second method has been used in a series of our own investigations[47,58,59,70] and consists in plotting kinetic inactivation curves for different initial protein concentrations, their linearisation in terms of a first order equation, the determination of the dependence of k_{in} on the protein concentration, and the calculation of the rate constant k_0 at infinite dilution of the protein. We believe that the rate constant k_0 is the most correct quantitative characteristic of the thermal inactivation of proteins. The disadvantages of our method are the approximate character of the equations relating k_{in} to the initial protein concentration and the difficulties in assigning a physicochemical significance to the coefficients α and γ in these equations [see Eqns.(9) and (10)]. An advantage of the method is the fact that we obtain the rate constant for infinitely dilute solutions and hence can apply the equations of classical thermodynamics in the analysis of the temperature variation of these constants. The temperature variation of k_0 is described by the Arrhenius equation, while $k_{in}-1/T$ plots are complicated by breaks and the interpretation of these relations altogether lacks physicochemical significance.

One should recall that the thermodynamic activation parameters (ΔH^*, ΔS^*, and ΔG^*), obtained from the analysis of the temperature variation of k_0, cannot be referred to a single rigorously defined molecular stage in the thermal inactivation of proteins, because they always characterise a complex cooperative process involving conformational transformations in the biopolymer. This is the main cause of the difference between these quantities and the activation parameters for the thermolysis of low-molecular-weight chemical compounds.

Methods for the Theoretical Description of the Energy of Resolvation of Ions

V.S.Markin and A.G.Volkov

Present-day theories of ion solvation have been examined. The experimental values of the standard free energies of resolvation and the standard redistribution potentials of ions between water and organic solvents have been given. The contribution of dielectric saturation to the electrostatic component of the free energy of resolvation has been analysed. The results of theoretical calculations have been compared with the experimental dependence of the standard free energy of solvation on the static and optical dielectric constants of the solvents, and also on the size of the ions. The solvophobic contribution to the energy of resolvation has been estimated.
The bibliography contains 100 references.

I. INTRODUCTION

In recent years there has been a sharp increase in interest in the experimental and theoretical determination of the values of the standard free energy of resolvation of ions. A knowledge of these quantities is required in the study of the electrochemistry of the interface between two immiscible electrolyte solutions,[1-5] the transport of ions through biological and synthetic membranes,[6] the mechanisms of interphase and surface catalysis,[7-10] the kinetics of charge transfer through an oil–water interface,[11-13] the coupling of heterogeneous reactions in bioenergetics,[5] extraction,[14] and the production of ion-selective electrodes.[15]

The term solvation refers to all the energetic and structure changes taking place in a system in the transfer of ions from the gas phase to the liquid phase of a solvent. The interaction of an ion with a solvent includes several effects: 1) electric polarisation of the medium; 2) the production in the medium of a cavity to accommodate the ion; 3) a change in the structure of the solvent, involving the breakdown of the old structure and the production of a new structure close to the ion (the formation of cavities and the change in the structure of the solvent close to the ion are sometimes combined in a single effect, called the solvophobic or hydrophobic effect); and 4) specific interaction of the ions with the solvent molecules (the formation of hydrogen bonds, donor–acceptor interaction), etc. This division is to some extent arbitrary, since different effects may overlap; for example, the electric polarisation of a solution may have a significant influence on its structure. It is possible, however, to carry out the theoretical calculation of individual effects.[16]

In the present review, present-day theories of ion solvation will be characterised briefly. To find the standard free energy of resolvation $\Delta^{\alpha}_{\beta}G^0_i$ of an ion i, the Gibbs free energies of the ion in two media, α and β, are compared. If the phase β is a vacuum, the quantity

$$\Delta^{\alpha}_{\text{vac}}G^0_i = G^{0,\alpha}_i - G^{0,\text{vac}}_i$$

is called the energy of solvation of the ion i in the phase α. The energy of resolvation can obviously be represented as the difference between two solvation energies:

$$\Delta^{\alpha}_{\beta}G^0_i = \Delta^{\alpha}_{\text{vac}}G^0_i - \Delta^{\beta}_{\text{vac}}G^0_i. \tag{1}$$

The standard free energies of resolvation of ions from water into different organic solvents are found by cyclic voltammetry, chronopotentiometry, polarography, data on the spin–lattice relaxation of the quadrupole moments of the nuclei of the ions, and also from solubility and extraction data.[1,12,14,17–30] These quantities are given in Table 1, which shows that the standard free energy of resolvation of ions depends markedly on the nature of the ion and the solvent.

Figs. 1 and 2 give the dependence of the energy of resolvation on the static and optical dielectric constants of non-aqueous solvents. Fig. 3 gives the dependence of the standard free energy of hydration on the radius of the ion. Figs. 1–3 and Table 1 show that the energy of resolvation (and hydration) decreases sharply with increase in the size of the ion and the static and optical dielectric constants of the medium.

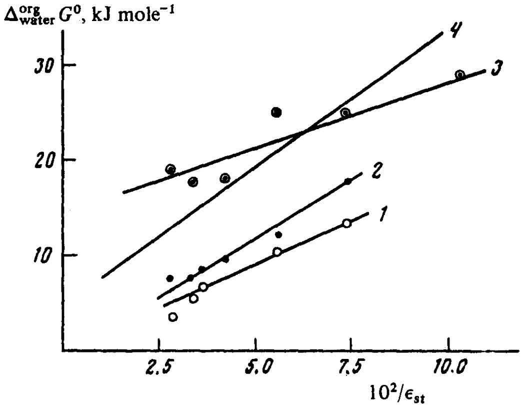

Figure 1. Dependence of the standard free energy of resolvation on the static dielectric constant of the non-aqueous phase; curves *1* (Me_4N^+), *2* (ClO_4^-), and *3* (I^-) give the experimental data from Table 1, and curve *4* gives the results of the calculation using the Born equation for Me_4N^+.

Table 1. Standard free energies of resolvation of the ions $\Delta^{\text{org}}_{\text{water}}G^0_i$ (kJ mole^{-1}) and distribution potentials $\Delta^{\text{org}}_{\text{water}}\phi^0$ (mV) of the ions between water and organic solvents at 298 K.[12,14,17–30]

* 255 mV,[20] 275 mV.[26]

The standard free energies of resolvation of ions, obtained by different methods, do not always coincide exactly with one another. These quantities can be calculated or measured by two methods. It is possible to determine the energy of solvation of the ion in the two pure solvents α and β, and then to use Eqn.(1) to find the standard free energy of the transfer of the ion i from the solvent β to the solvent α. If two immiscible liquids α and β are in contact and in equilibrium, some solvent from each of these phases dissolves in the other phase. In this case the phases α and β will be mutually saturated. The corresponding energy of resolvation of the ion on its transfer between the two equilibrated solvents is called the standard free energy of distribution.[22] For most known ions and solvents, the standard free energies of transfer and distribution coincide with one another within the limits of accuracy of the measurements. It is not excluded, however, that for some solvents and ions these quantities differ.

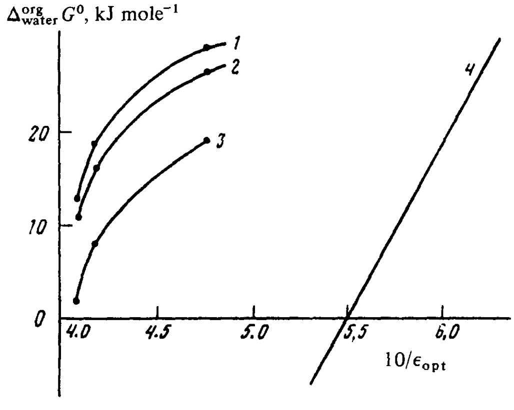

Figure 2. Dependence of the standard free energy of resolvation of the ions on the optical dielectric constant of the non-aqueous phase: curves *1* (I^-), *2* (SCN^-), and *3* (ClO_4^-) give the experimental data from Table 1, and curve *4* gives the results of the calculation using the Born equation for I^-, assuming that $\varepsilon = \varepsilon_{\rm opt}$; the values of the optical dielectric constant were taken from Table 2.

Thus in the analysis and application of the values of the standard free energy of resolvation it is necessary to consider whether ion transfer takes place between the pure solvents or between the mutually saturated solvents.

II. ELECTRIC CONTRIBUTION TO THE SOLVATION ENERGY

There are two groups of models for calculating the electric component of the solvation energy. In the first group the medium is regarded as a structureless continuum, and in the second as a set of individual particles with real or simplified properties. In early work, the structure of the solvent was taken into account by calculating directly the energies of specific configurations of the solvent molecules close to the ion; the actual configuration and the number of molecules included in it were selected somewhat arbitrarily from various physical considerations, to give agreement between the calculated and experimental data. In these models, the statistical properties of the solution, which are undoubtedly important for a correct description of the phenomenon of solvation, were ignored completely. The modern approach involves the development of a statistical theory of the ion–dipole plasma, reflecting both the energetic and statistical aspects of the phenomenon.

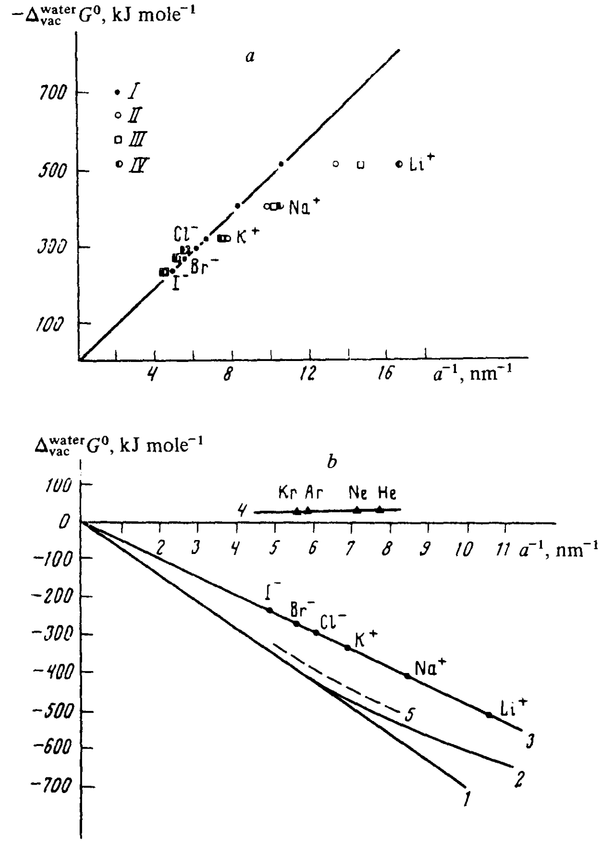

Figure 3. Dependence of the standard free energy of hydration of inorganic ions on their radius; the ionic radii were those of Gourary and Adrian (I),[31] Waddington (II),[37] Goldschmidt (III),[36] and Pauling (IV);[35] *a*: experimental data from Refs.29 and 30; *b*: *1*) calculated using the Born equation, *2*) calculated with allowance for dielectric saturation,[2] *3*) experimental data from Refs.29 and 30, *4*) standard free energies of solution of the inert gases (1 atm in the gas phase and a mole fraction of 1 in the aqueous solution at 298 K), *5*) sum of curves *2* and *4*.[2]

There is also an intermediate approach, in which, while remaining within the framework of continuum theories, attempts are made to take account of the influence of the discrete nature of the solvent on the effective parameters of the model. For this purpose, account is taken of non-linear dielectric effects, and the mutual correlation of the polarisation vectors of the solvent molecules, situated at short distances from one another, is analysed using the theory of non-local electrostatics. Each of these approaches, reflecting the role of different effects, has its own advantages.

1. The Born Model

In the first continuum model, developed by Born,[32] the ion was regarded as a solid sphere with a given radius a, immersed in a continuous medium with a constant dielectric constant ε (Fig.4a). This was a macroscopic theory, which described the properties of the solvent at short distances from the ion by macroscopic laws. The energy of solvation (more accurately, its electric part), calculated for one particle, is given according to the Born theory by the familiar equation

$$\Delta_{\text{vac}}^{\alpha} G^0(\text{el}) = -\frac{z^2 e_0^2}{8\pi\varepsilon_0 a}\left(1-\frac{1}{\varepsilon^{\alpha}}\right) \tag{2}$$

where ε_0 is the electric constant, ε^{α} the dielectric constant of the medium, z the charge number of the ion, and e_0 the charge of the electron. From this equation, the energy of resolvation when an ion is transferred from the medium α to the medium β (that is the difference between the energies in the media β and α) is given by:

$$\Delta_{\alpha}^{\beta} G^0(\text{el}) = -\frac{z^2 e_0^2}{8\pi\varepsilon_0 a}\left(\frac{1}{\varepsilon^{\alpha}}-\frac{1}{\varepsilon^{\beta}}\right) \tag{3}$$

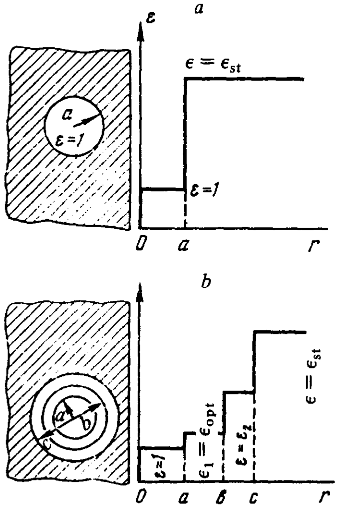

Figure 4. Models of Born (a) and Abraham and Liszi (b).[49,50]

Calculations using the Born equation give values of the solvation energy differing considerably from the experimental values.[2,33,34] Since the energy of resolvation is often the small difference between two comparatively large solvation energies, a relatively small uncertainty in the determination of each of these quantities may lead to a considerable overall uncertainty, even an incorrect sign. For example, it follows from Eqn.(3) that for $\varepsilon^{\alpha} > \varepsilon^{\beta}$, it is more favourable for the ion to be in the solvent α, irrespective of its actual size. This is not always observed experimentally, however. Small ions with a radius $a < 0.2$ nm are in fact found chiefly in a polar solvent with a high dielectric constant, but at the same time, large organic ions often enter the hydrophobic phase preferentially.

Distribution coefficients[1,14,17] and extraction, solubility[14,17] and voltammetric data[12,22,26] indicate that the standard free energy of the transfer of an ion from water to a less polar solvent is positive for ions with a small radius, and negative for ions with a large radius, whereas according to Eqn.(3) it is a constant-sign function of the radius.

Born's equation gives values of the solvation energy which are too high (too negative) (Figs.1 and 3). When comparing specific values with experimental data, it is necessary to assign a radius to each ion. This procedure is to some extent arbitrary, since the ionic radius is only an effective parameter, the use of which makes possible the most successful description of various properties of ionic systems. It is often found that different properties of a system require the choice of different ionic radii for their description. It is pointless to raise the question of which value of the ionic radius is correct, and which is not, although naturally there are reasonable physical restrictions on the range within which the value of the effective radius of an ion may lie.

This is reflected in the fact that there are at least four scales of ionic radii, namely those of Pauling,[35] Goldschmidt,[36] Waddington,[37] and Gourary and Adrian,[31] calculated on the basis of different assumptions. The first three scales differ little from one another, but the fourth differs from the others. Blandamer and Symons[38] tried to select the most successful scale of ionic radii by comparing thermodynamic data on the Gibbs free energy and entropy of hydration of the ions. They showed that if any of these quantities is plotted as a function of $1/a^2$, all the points corresponding to the alkali metal cations and the halide anions lie on the same smooth curve if the Gourary–Adrian radii are used. The other sets of radii give two different curves, one for the cations and another for the anions. It is difficult to say what importance should be given to the observed regularity, since as yet it has no theoretical foundation.

Since Born's equation (2) gives the dependence of the solvation energy on $1/a$, the same coordinates are used in Fig.3. Fig.3a gives the experimental data for six cations and anions on all four ionic radius scales. The data on the Gourary–Adrian scale lie ideally on one straight line, confirming the observation made in Ref.38. This fact undoubtedly deserves attention. The data using the other scales deviate from this straight line, although a significant deviation is observed only for the small ions Li^+, Na^+, and K^+, and the points for Cl^-, Br^-, and I^- deviate little. The experimental points are compared with the theoretical predictions in Fig.3b. To avoid overloading the Figure, the experimental points are given only on the Gourary–Adrian scale (curve *3*). The non-electrostatic part of the free energy of hydration is given by curve *4*.

Different independent methods can be used to determine the hydration energy of the inert gases. If the radii of the ions and atoms of the inert gases coincide, the free energy of solution of the gas is simply the non-electrostatic component of the free energy of hydration.

The electrostatic part of the hydration energy, calculated from the Born equation, is given by curve *1* in Fig.3b. It in fact is greater (by ~50%) than the experimental values. It may be noted that it is necessary to compare with experiment the sum of curves *1* and *4*; this improves the situation, but only very slightly. The sum of the electrostatic and non-electrostatic parts of the free energy of hydration corresponds to curve *5*; the values of the sum are in fact close to the experimental points. The discrepancy between theory and experiment is smallest when the Gourary–Adrian scale of ionic radii is used.

Thus the Born theory requires improvement. Eqn.(2) contains only two experimental parameters, the ionic radius a and the dielectric constant ε. In principle, it is possible to achieve satisfactory agreement between theory and experiment by changing either of these quantities in appropriate fashion. This formal fitting of the parameters, however, leads to physically unreasonable values of a and ε, which do not lie on any one acceptable scale. Thus although this fitting gives an empirical equation showing good agreement with experiment, it cannot give a physical explanation of the phenomenon of solvation.

The use of ideas on the dielectric saturation of the medium in the field of the ion are more attractive from this viewpoint.[2,39–52] Allowance for this effect decreases the absolute magnitude of the electric component of the solvation energy. Again, formally, it is possible to achieve very good agreement between theory and experiment by selecting suitable saturation range dimensions and dielectric constant values. Ideal agreement was obtained in this way by Abraham and Liszi's group.[47–52] There still remains the question, however, of whether these results give a physical explanation of the phenomenon of solvation, or only a successful empirical equation, convenient for practical applications. Since published views on the role of saturation effects in the solvation of ions are contradictory, this question will be examined specially.

2. Non-linear Dielectric Effects

The simplest approach to the calculation of the electrostatic part of the solvation energy, based on the continuum description, and methods for its improvement by taking account of the dielectric saturation of the medium in the field of the ion, can be considered. Some time ago, it appeared that this problem had been sufficiently elucidated; allowance for dielectric saturation gave too small a correction to the Born theory.[17,18] In recent years, however, interest has again been shown in this problem.[2,47–52] Allowance for dielectric saturation gave new results, which unlike the previous results show ideal agreement with experimental data.[47–52] An attempt has been made to analyse the situation that has arisen and to propose simple equations for estimating the effect of dielectric saturation and its role in the phenomenon of ion resolvation.

One method of improving the Born theory is by taking account of non-linear dielectric effects. The dielectric constant of a medium containing polar molecules should change with change in the intensity of the external electric field. This is due both to breakdown of the actual structure of the associated dipoles and to dielectric saturation.[39–41]

A theoretical analysis of the properties of water[42] within the framework of the model used by the author showed that when an electric field is applied, the dielectric constant of water may decrease from the static value $\varepsilon_{st} \cong 80$ to the optical value, equal to the square of the refractive index, that is $\varepsilon_{opt} = 1.8$. Saturation is reached in fields whose intensity exceeds 10^9 V m^{-1}. Because of technical difficulties, it has been possible to verify the theory only in fields with an intensity not exceeding 2×10^7 V m^{-1}, where the decrease in the dielectric constant did not exceed 1% (Fig.5). A detailed discussion of this question can be found in Refs. 43–45.

The first attempt to take account of the dielectric saturation of the medium close to the ion in the calculation of the solvation energy was made in 1926.[46] Introduction of the corresponding correction makes it possible to move the calculated values obtained using the Born theory in the required direction. Subsequently, attempts to attribute the difference between the experimental values of $\Delta^{\alpha}_{\text{vac}}G^0$ and the values calculated using the Born theory entirely to dielectric saturation raised serious objections.[33,34]

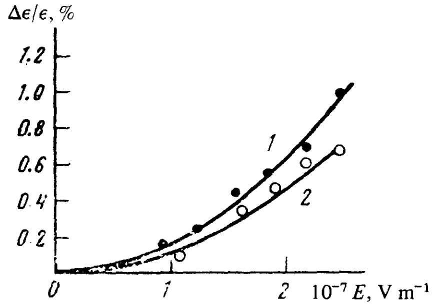

Figure 5. Influence of the intensity of the electric field E on the dielectric constant of nitrobenzene (1) and water (2);[40,41] $\Delta\varepsilon = \varepsilon_{st} - \varepsilon(E)$.

The density of the free energy of the electric field in a dielectric in the general case is described by the integral

$$g(\mathrm{r}) = \int_0^{\mathrm{D}} \mathrm{E}\,d\mathrm{D} \tag{4}$$

where $\mathbf{E}$ is the intensity of the electric field, and $\mathbf{D}$ the electric induction. In weak fields with a linear relationship $\mathbf{D} = \varepsilon_0\varepsilon\mathbf{E}$, integration of the density of the free energy (4) over the whole of space outside the ion leads to the Born equation (2).

In the general case, the electric induction can be represented as follows:[42]

$$D = \epsilon_0\epsilon_{opt}E + N\mu L(E) \tag{5}$$

where

$$\mu = \frac{\epsilon_{opt} + 2}{3}\mu_0\tilde{g}^{1/2} \tag{6}$$

N is the number of molecules of the dielectric in unit volume, μ_0 their dipole moment in a vacuum, and $\tilde{g}^{1/2}$ the Kirkwood factor, which depends on the field and takes account of the associated character of the dipolar molecules (in a non-associated liquid and in high fields, $\tilde{g} = 1$). For the function $L(E)$ it is usual to employ the Langevin model function, but to estimate the effect it is sufficient to know the dependence of D on E in the most general form. From general physical considerations it is clear that with increase in E the function $L(E)$ should increase and tend to a limiting value of 1. As a result, the dependence of D on E moves from one limiting law to another. At low intensities

$$D \cong [\epsilon_0\epsilon_{opt} + N\mu(L'|_{E=0})]E = \epsilon_0\epsilon_{opt}E \tag{7}$$

and at high intensities

$$D \cong \epsilon_0\epsilon_{opt}E + N\mu. \tag{8}$$

On the graph giving the dependence of E on D (Fig.6), the straight line ac corresponds to the linear function. As saturation takes place, the curve begins to rise steeply, reaching another asymptote be. The density of the free energy in the linear approximation is equal to the area of the triangle *acd*, and the value of the total integral (4) is equal to the much larger area of the curvilinear triangle *abd*. The difference between these values arises when the electric induction D is greater than the characteristic value D_{sat}, which can readily be shown to be equal to

$$D_{\text{sat}} = N\mu. \tag{9}$$

Since the electric induction in a spherically symmetrical field is independent of the dielectric constant

$$D = \frac{ze_0}{4\pi r^2} \tag{10}$$

it is possible to indicate the characteristic distance from the centre of the ion, within which the saturation effect has an influence:

$$r_{\text{sat}} = \left(\frac{|z|e_0}{4\pi N\mu}\right)^{1/2} \tag{11}$$

Thus the characteristic saturation radius r_{sat} is independent of the size of the ion and is determined only by its charge and the properties of the dielectric.[2] †

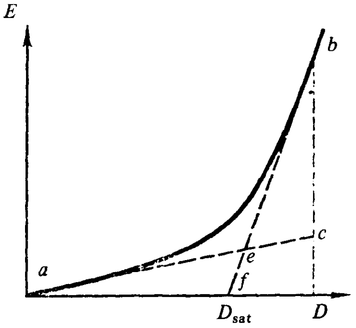

Figure 6. Dependence of the intensity of the electric field *E* on the electric induction *D*.

Comparison of the value of r_{sat} with the ionic radius a makes it possible to estimate how large a contribution the phenomenon of saturation may make to the energy of the electric field of the actual ion. For univalent ions in nitrobenzene with $N = 6 \times 10^{27}\ \text{m}^{-3}$ and $\mu_0 = 3.9$ D, it is found that $r_{\text{sat}} = 0.31$ nm, and in acetonitrile with $N = 1.1 \times 10^{28}\ \text{m}^{-3}$ and $\mu_0 = 3.97$ D, $r_{\text{sat}} = 0.29$ nm. For water ($N = 3.34 \times 10^{28}\ \text{m}^{-3}$, $\mu_0 = 1.84$ D), the characteristic saturation radius is 0.22 nm.

The values obtained are greater than the radii of monatomic inorganic ions, and for these the contribution of dielectric saturation to the energy of polarisation of the medium should be considerable. To find this contribution, it is necessary to calculate the density of the free energy of the electric field g, that is the integral (4). Approximating the latter by the area of the triangles *acd* and *fbd* in Fig.6 gives:

$$g = \frac{D^2}{2\varepsilon_0\varepsilon} \quad \text{for } D < D_{\text{sat}}$$

$$g = D^2/2\epsilon_0\epsilon + (D - D_{\text{sat}})^2/2\epsilon_0\epsilon_{\text{opt}} \text{ for } D > D_{\text{sat}}. \tag{12}$$

Integrating the density of the energy over the whole of space outside the ion gives the electric component of the solvation energy:

$$\Delta^{\alpha}_{\text{vac}}G^0(\text{el}) = -\frac{z^2e_0^2}{8\pi\varepsilon_0 a}\left[1 - \frac{1}{\varepsilon^{\alpha}} - \frac{1}{\epsilon^{\alpha}_{\text{opt}}}\left(1 - \frac{8}{3}x + 2x^2 - \frac{1}{3}x^4\right)\right] \tag{13}$$

where $x = a/r_{\text{sat}}$.

In addition to the Born term $1 - 1/\varepsilon^{\alpha}$, Eqn.(13) contains a correction to it which depends on the ratio of the radius of the ion a to the saturation radius. When $a = r_{\text{sat}}$, the correction becomes zero; it increases with decrease in a. This is understandable, since it is at short distances that dielectric saturation has an influence. For clarity, the equation obtained can be illustrated by numerical examples. Curve *2* in Fig.3 was constructed using Eqn.(13). It can be seen that allowance for saturation moves the Born straight line in the required direction, bringing it closer to the experimental points. The magnitude of the correction is different for different a. It is 16% for lithium ions. It was previously pointed out that for cations with a small radius, the deviation of the experimental points from the Born straight line reaches 30%. Thus in the case of lithium, allowance for saturation can eliminate more than half of the discrepancy. For potassium, the correction amounts to 4%, which covers 1/7 of the discrepancy between the theoretical and experimental values. Subsequently, the contribution from saturation decreases. It is 2.9% for rubidium, and 1.3% for caesium, corresponding to 0.1 and 0.04 times the required correction respectively.

Thus saturation of the dielectric constant has a significant influence on the electric component of the solvation energy only for the smallest ions, but in this case its influence may be extremely marked. Thus any continuum theory must take account of the saturation of the dielectric constant, at least in the calculation of the hydration energy of ions with a radius smaller than 0.15 nm.

The above estimate of the solvation energy with allowance for dielectric saturation was carried out within the framework of a rigorous continuum model. All the quantities were calculated from first principles. It was assumed that the dielectric constant changes regularly in space, without undergoing any sharp changes. For this reason, Eqn.(13) does not contain fitting parameters. In its derivation, no attempt was made to obtain a detailed description of the dependence of the electric induction on the intensity of the external electric field, and it was merely assumed that the true curve is fairly close to the two asymptotes (see Fig.6). For the complete curve, as already noted, there is a model description in the form of the Langevin function. It can be shown that in this approximation, the function *E(D)* rapidly reaches the second asymptote.

It should also be noted that the piecewise-linear approximation examined above leads to a slightly low value of E (for a given D), so that the values obtained for the solvation energy represent an upper estimate (absolute magnitude), although they are apparently close to the true value. The accuracy of the approximation increases with decrease in the radius of the ion. Detailed calculations based on the use of the Langevin function were carried out in Ref.53.

A simpler description of the phenomenon of saturation is given in Refs.47–52. To obtain simple analytical expressions, it is assumed that the dielectric constant changes in

---

† See V.S.Markin and A.G.Volkov, J.Electroanal.Chem.(1987) (in the press).

stepwise fashion in space (see Fig. 4b). In this model it is assumed that the ion of radius a is surrounded by two solvate layers with radii b and c respectively. Within the first layer, complete dielectric saturation is assumed, and the dielectric constant is taken as equal to its optical value ($\varepsilon_1 = \varepsilon_{opt}$). At the boundary between the two layers, the dielectric constant undergoes an abrupt change, and in the second layer it has a new constant value ε_2, estimated from the Onsager–Booth equations.[42] Thus the electrostatic component of the solvation energy is given by the equation

$$\Delta^{\alpha}_{\rm vac}G^0({\rm el}) = -\frac{z^2e_0^2}{8\pi\varepsilon_0}\left[\left(1-\frac{1}{\varepsilon_1}\right)\left(\frac{1}{a}-\frac{1}{b}\right)+\right.$$
$$\left.+\left(1-\frac{1}{\varepsilon_2}\right)\left(\frac{1}{b}-\frac{1}{c}\right)+\left(1-\frac{1}{\varepsilon_2}\right)\frac{1}{c}\right] \qquad (14)$$

The use of the fitting parameters a, b, c, ε_1, and ε_2 gave almost complete agreement between the calculated and experimental data.[48] The value of $\Delta^{\alpha}_{\rm vac}G^0$(el) is practically insensitive to the parameter c; the use of the fitting parameter b gives the main contribution only if its value is so large as to be unreasonable. According to Ref. 48, to obtain the closest agreement between the theoretical and experimental results it must be assumed that for singly-charged inorganic ions within a radius of 0.4 nm round the ion there is complete dielectric saturation of the solvent, and $\varepsilon_1 = \varepsilon_{opt}$. From what has been said above, however, it is clear that this approach is unsound.

3. The Method of Non-local Electrostatics

To calculate the electrostatic contribution to the solvation energy, use is made of another semi-macroscopic approach, namely the method of non-local electrostatics, which has been developed extremely intensively in recent years. The method of non-local electrostatics takes account of the fact that the fluctuations of the polarisation of the solvent correlate with one another in space as a result of the presence in the liquid of a structure determined by the quantum-mechanical interaction between its molecules. Thus the average polarisation at each point depends on the induction at all other points in space, correlating with the given one.[54]

The relationship between the intensity of the electric field **E** and the electric induction **D** in the method of non-local electrostatics is expressed by means of the tensor $\varepsilon_{mn}(r)$:

$$D^m(\mathbf{r}) = \sum_n \int d\mathbf{r}\,\varepsilon_0\varepsilon_{mn}(\mathbf{r}-\mathbf{r}')E^n(\mathbf{r}') \qquad (15)$$

where $m, n = x, y, z$. A noteworthy feature is that this relationship, which has complex spatial character, remains linear. The subsequent calculations are carried out by the Fourier transformation of the tensor $\varepsilon_{mn}(\mathbf{r})$, which is called the static dielectric function $\varepsilon(\mathbf{k})$:

$$\varepsilon(k) = \sum_{m,n}\frac{k_mk_n}{k^2}\int {\rm d}(\mathbf{r}-\mathbf{r}')\,{\rm e}^{-ik(\mathbf{r}-\mathbf{r}')}\varepsilon_{mn}(\mathbf{r}-\mathbf{r}') \qquad (16)$$

The electric potential created in the medium by a charged sphere with a radius a at a distance r from its centre is

$$\varphi(\mathbf{r}) = \frac{ze_0}{2\pi^2\varepsilon_0}\int_0^{\infty}\frac{{\rm d}k}{\varepsilon(k)}\frac{\sin kr}{kr}\frac{\sin ka}{ka} \qquad (17)$$

This gives the electric contribution to the solvation energy:

$$\Delta^{\alpha}_{\rm vac}G^0({\rm el}) = -\frac{z^2e_0^2}{4\pi^2\varepsilon_0}\int_0^{\infty}{\rm d}k\,\frac{\sin^2 ka}{k^2a^2}\left[1-\frac{1}{\varepsilon(k)}\right] \qquad (18)$$

To calculate the integral in Eqn. (18), it is necessary to specify in some way the functional dependence $\varepsilon(k)$. It is possible, as was done in Refs. 33 and 34, to break down the fluctuations of the polarisation of the medium into three modes related to different degrees of freedom: electronic or optical (index 1), vibrational or infrared (index 2), and orientational or Debye (index 3). If the radius of the correlation of the i^{th} mode of a fluctuation is λ_i, then

$$1-\frac{1}{\varepsilon(k)} = 1-\frac{1}{\varepsilon_1}+\left(\frac{1}{\varepsilon_1}-\frac{1}{\varepsilon_2}\right)\frac{1}{1+k^2\lambda_2^2}+\left(\frac{1}{\varepsilon_2}-\frac{1}{\varepsilon_3}\right)\frac{1}{1+k^2\lambda_3^2} \qquad (19)$$

The correlation radius of the electronic mode λ_1 is here taken as zero. It is impossible to indicate beforehand the exact values of the correlation radii λ_2 and λ_3, but an approximate estimate can be carried out from physical considerations. For the infrared vibrations, the magnitude of λ_3 depends on the type of liquid. For non-associated liquids, the correlation radius of the orientational vibrations is approximately equal to the intermolecular distance, but for associated liquids, for example water, the scale of λ_3 is indicated by the characteristic length of the chain of hydrogen bonds, which amounts to ~0.5–0.7 nm.[33, 34]

Integration in Eqn. (18) using the function (19) gives the expression

$$\Delta^{\alpha}_{\rm vac}G^0({\rm el}) = -\frac{z^2e_0^2}{8\pi\varepsilon_0a}\left[1-\frac{1}{\varepsilon_1}+\left(\frac{1}{\varepsilon_1}-\frac{1}{\varepsilon_2}\right)\psi\left(\frac{2a}{\lambda^2}\right)+\left(\frac{1}{\varepsilon_2}-\frac{1}{\varepsilon_3}\right)\psi\left(\frac{2a}{\lambda_3}\right)\right] \qquad (20)$$

where

$$\psi(x) = 1-(1-e^{-x})/x \qquad (21)$$

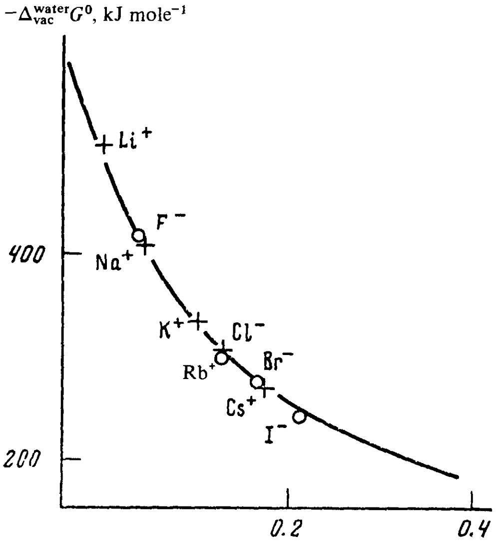

Figure 7. Dependence of the hydration energies of ions on their radius; the points give the experimental data,[29,30] and the continuous line the calculated data;[34] the values of a were taken from Ref. 31.

The electric contribution to the hydration energy, calculated[34] using these equations, is given in Fig. 7, together with the experimental data for a number of small univalent ions. The dielectric constant values used are given in Table 2. The correlation radii were chosen to be close to the characteristic values indicated from the condition for best agreement between the theoretical and experimental data: $\lambda_2 = 0.1$ nm and $\lambda_3 = 0.7$ nm. Fig.7 shows that good agreement was obtained between theory and experiment.[34] As far as the sensitivity of the results to the fitting parameters λ_i is concerned, λ_2 has the greatest weight, and a less significant role is played by λ_3, as shown in Fig.8. A detailed analysis was carried out in Ref.33. The method of non-local electrostatics essentially uses continuum models, but the effective parameters required for the calculation are derived from an analysis of the structure of the solvent. This method makes it possible to obtain extremely accurate values of the solvation energy for small ions, and then, using Eqn.(1), the values of the energy of resolvation. At the same time, for large ions, appreciable discrepancies are observed between theory and experiment. This indicates the need to take account of additional effects, in this case the work of formation of a cavity in the solvent, or the solvophobic effect.

Table 2. Values of the dielectric constants ε_i [28] used in the model of three polarisation modes (T = 293 K).

Solvent	$\epsilon_1 = \epsilon_{opt}$	ε_2	$\epsilon_3 = \epsilon_{st}$
Water	1.8	4.9	78.8
Nitrobenzene	2,4	3.7	35,0
1,2-Dichloroethane	2.0	—	10.4
Acetophenone	2,45	—	17.4
Dichloromethane	2,04	—	9.1
Methyl butyl ketone	1.9	—	14,9

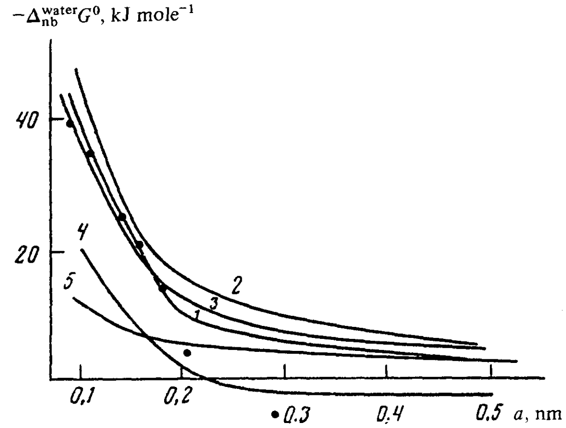

Figure 8. Influence of the spatial dispersion of the dielectric constants of the aqueous and nitrobenzene phases on the electrostatic contribution to the free energy of resolvation; the calculation was carried out by the published method[33] with $\lambda_2^{water} = 0.1$ nm and $\lambda_3^{water} = 0.7$ nm and the dielectric constants from Table 2; correlation radii, nm: *1)* $\lambda_2^{nb} = 0.1$, $\lambda_3^{nb} = 0.5$; *2)* $\lambda_2^{nb} = 0.1$, $\lambda_3^{nb} = 0.3$; *3)* $\lambda_2^{nb} = 0.13$, $\lambda_3^{nb} = 0.3$; *4)* $\lambda_2^{nb} = 0.1$, $\lambda_3^{nb} = 0.7$; *5)* calculated using the Born equation; the experimental data were taken from Table 1.

The chief disadvantage of the continuum and semi-continuum approaches to the problem of solvation lies in the actual model of the solvent. Allowance for saturation of the dielectric constant or correlation of the dipoles represents an attempt to reflect the discrete properties of the solvent while essentially remaining within the framework of the continuum model. Other similar approaches are known, in which, in the calculation of the thermodynamic properties of the system, attempts are made to take account of the unknown influence of the molecular structure of the solvent.[55] A true solution to the problem can be achieved, however, only by taking account of the discrete structure in the statistical theory of the solvent.

4. Statistical Models of the Solvent

A complete solution of the problem of solvation involves the development of a statistical theory which would regard the ions and solvent molecules "as equals", that is which would take account of their discrete molecular nature, even at the price of the introduction of model potentials.

In contrast to "primitive" models of an electrolyte, in which a continuum description of the solvent is used, in the "non-primitive" model used in present-day statistical analysis, or the ion–dipole plasma model, a solution of an electrolyte is regarded as a system of solid spheres with radii a and a_d, carrying at their centres a point electric charge or a constant point dipole respectively. It is assumed that there are the usual electrostatic interactions between the charges and the dipoles. The system is described in terms of many-particle correlation functions, for which corresponding chains of equations are written.[56–58] For their solution it is necessary to resort to various simplifications, among which the most popular is the mean-spherical approximation.[59] This model should make it possible to calculate the solvation energy of ions, and also the dielectric properties of a pure dipolar liquid.#

The dielectric constant of a dipolar liquid in the mean-spherical approximation was calculated in Ref.58, where the following equation was obtained:

$$\varepsilon = q(2\xi)/q(-\xi) \tag{22}$$

in which

$$q(x) = (1+2x)^2/(1-x)^4 \tag{23}$$

and the parameter ξ is obtained by solving the equation:

$$q(2\xi) - q(\xi) = n_d\mu^2/3\varepsilon_0 kT \tag{24}$$

Here, n_d is the number of particles of the solvent in unit volume, and μ the dipole moment of the solvent molecule. This approach made it possible to refine considerably the familiar Onsager equation.

For strongly associated liquids, the theoretical results do not show very good agreement with the experimental data. There is nothing surprising in this, since the model does not include a whole range of complex forces acting between real solvent molecules. For example, for a dipolar liquid having the same dipole moment of the molecules (1.8 D) as water, the dielectric constant obtained from Eqn.(22) at room temperature is 48. To obtain the correct value of $\varepsilon_{st} = 80$, it is necessary to take the value 2.62 D for the dipole moment of the molecules of the liquid.

A dipolar liquid is a model system consisting of solid spheres with dipoles situated at their centres. It is used in theoretical calculations of the properties of a liquid.

A model in the form of a set of solid spheres with constant dipole moments naturally cannot describe all the properties of water, but this system may serve as a reasonable model for organic solvents, and in any case this is the first necessary step in obtaining a model of water. In particular, the study of this model made it possible to detect a number of fundamentally important effects related to the solvation and interaction of ions and associated with the discrete nature of the solvent.

In Ref.59, the solvation energy of an ion (the "Born" energy) was calculated in the mean-spherical approximation:

$$\Delta^{\alpha}_{\mathrm{vac}} G^0 = -\frac{(ze_0)^2}{8\pi\varepsilon_0 (a + a_d/\lambda)}\left(1 - \frac{1}{\varepsilon}\right) \qquad (25)$$

where a_d is the diameter of the solvent molecule. The value of λ is determined by solving the equation

$$\lambda^2(1-\lambda)^4 = 16\,\varepsilon \qquad (26)$$

For all values of ε, the parameter λ lies in the range 1–3; for $\varepsilon = 80$ it is equal to 2.6. This parameter, together with the radius of the dipolar solvent molecule, defines in accordance with Eqn.(25) a new characteristic length a_d/λ, which arises naturally from the solution of the equations. This characteristic length is determined exclusively by the properties of the dipolar liquid, and depends on two of its parameters, the radius of the molecules and the dielectric constant.

Formally, Eqn.(25) looks like the equation for determining the Born energy, with a renormalised ionic radius, which has been increased by the section a_d/λ. An interesting feature is that there exists an empirical equation for describing the experimental solvation energies and free energies of resolvation, whose form is identical to that of Eqn.(25).[60] In aqueous electrolyte solutions, this correction lies in the range 0.64–0.84 Å for cations and 0.10–0.42 Å for anions. According to Eqn.(25), if the radius of the solvent molecule is taken as 1.5 Å, then $a_d/\lambda = 0.58$ Å.

The apparent increase in the radius of the ion in Eqn.(25) is related to the discrete nature of the solvent. It is obvious that the bulk value of the dielectric constant cannot be established directly at the actual "surface" of the ion. Eqn.(25) makes it possible to calculate that this value is effectively reached at a distance of $a + a_d/\lambda$ from the centre of the ion. It should be remembered, however, that this picture of a stepwise change in the dielectric constant represents only an effective approximation which can be used to describe a fairly accurate physical result obtained using the discrete model. Moreover, an analysis of this model shows that it is in general impossible to use the concept of local dielectric constant at such short distances, and it is necessary to return to the more accurate concept of the polarisation of the medium. In the macroscopic description of a dielectric, its polarisation at a distance r from the ion is given by the familiar equation $P_{\mathrm{macr}}(r) = (\varepsilon-1)ze_0/4\pi\varepsilon r^2$.

Fig.9a gives the calculated[59] dependence of the polarisation of the medium, normalised to its macroscopic value P_{macr}, on the distance r. The most important feature of this dependence is its oscillatory character. This means that, as a result of the strong ordering of the dipoles nearest to the ion, the subsequent dipoles may adopt the opposite orientation. For this reason, the description of a medium in terms of the local dielectric constant (for example, the use of the stepwise function), even if it gives good agreement with experiment, leads to erroneous ideas about the true physical picture at short distances, and this description must be approached with care.

An important consequence should be noted. The interaction of ions in a discrete medium differs fundamentally from that predicted by the macroscopic theory. This interaction is described by a potential of mean force W_{ij}, which, in addition to the Coulomb potential, includes the averaged interaction with all the solvent molecules. As shown by the same authors,[59] the potential of mean force also oscillates at short distances (Fig.9b). For example, the curve for ions of different kinds has a deep potential minimum W_{+-}, when the centres of the ions are at a distance of $4a$. This is a relatively stable configuration, in which the ions are separated by one dipolar molecule; it can be regarded as the result of the formation of ion pairs in the solution. The potential for ions of the same kind W_{++} also has a deep minimum, at $r = 3a$. This configuration gives as it were a "double" ion, for which the increase in the Coulombic energy is more than compensated by the negative displacement of the Born energy of solvation of the highly charged structure.

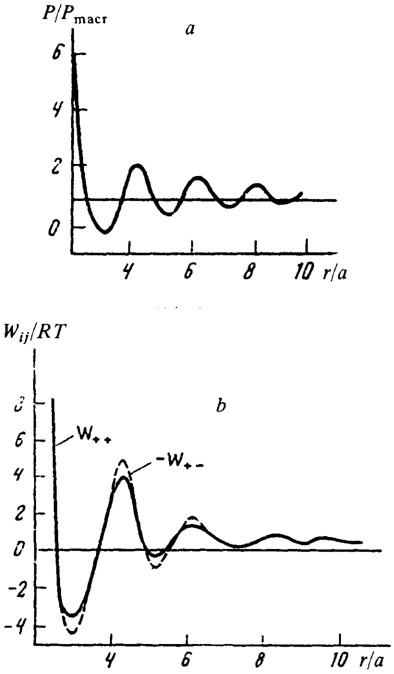

Figure 9. The normalised density of the polarisation P/P_{macr} (*a*) and the potential of the average force W_{ij} between two univalent ions i and j (*b*) as a function of the distance r from the centre of the ion.[59]

The results obtained in the mean-spherical approximation are mainly qualitative in character, but they make it possible to obtain a more correct representation of the true physical picture of solvation and to re-evaluate other theories on the basis of an understanding of how they achieve agreement with experiment.

III. THE SOLVOPHOBIC EFFECT

Present-day approaches to the calculation of the energy of the solvophobic interaction of an ion with a solvent are based on phenomenological[61,62] or statistical-mechanical molecular models,[63] which contain parameters, not always unknown, characterising the ion and the solvent. To avoid unnecessary indeterminacy, the estimation of the solvophobic contribution to the free energy of resolvation is sometimes carried out using Uhlig's semi-empirical equation,[64] the essential features of which reduce to the following.

If the concept of the surface tension at the boundary of the ion and the solvent $\gamma_{0,\alpha}$ is used, the surface energy is $4\pi a_2\gamma_{0,\alpha}$. The difference in the surface energies in the media α and β is $4\pi a^2(\gamma_{0,\alpha}-\gamma_{0,\beta})$. According to Antonov's rule

$$\gamma_{0,\alpha}-\gamma_{0,\beta}\approx\gamma_{\alpha\beta}\,\mathrm{sgn}\,(\gamma_\alpha-\gamma_\beta) \qquad (27)$$

where sgn $x = +1$ if $x \geq 0$, and sgn $x = -1$ if $x < 0$, $\gamma_{\alpha\beta}$ is the interfacial tension at the planar boundary between the media α and β, and γ_α and γ_β the surface tensions at the boundaries between air and the solvents α and β respectively at the same pressure and temperature. In this case, Uhlig's equation for the solvophobic contribution to the energy of resolvation has the form:

$$\Delta_\beta^\alpha G^0(\mathrm{svph}) = 4\pi a^2\gamma_{\alpha\beta}\,\mathrm{sgn}\,(\gamma_\alpha-\gamma_\beta) \qquad (28)$$

The contribution is obviously greater, the larger the radius of the ion *a*.

From the theoretical viewpoint, the range of applicability of Uhlig's equation is not quite clear. At the same time, it has proved surprisingly useful in calculations of distribution coefficients in systems consisting of two immiscible liquids.[33,34] Slight deviations from Uhlig's equation are observed when the interfacial tension between the two pure immiscible solvents is less than 10 mN m^{-1} and the dissolved species have dimensions of less than 0.2 nm.[35] This can readily be explained, since Uhlig's equation neglects the dependence of the surface tension on the curvature of the surface. At low values of $\gamma_{\alpha\beta}$ and for small particles, the contribution of the solvophobic effect is slight.

An important advantage of Uhlig's equation is that it does not contain fitting parameters, since $\gamma_{\alpha\beta}$ is taken from experiment. Fig.10 gives as an example the dependence of the solvophobic contribution to the energy of resolvation on the radius of the particle, calculated from Eqn.(28), for the water-nitrobenzene and water–1,2-dichloroethane systems.

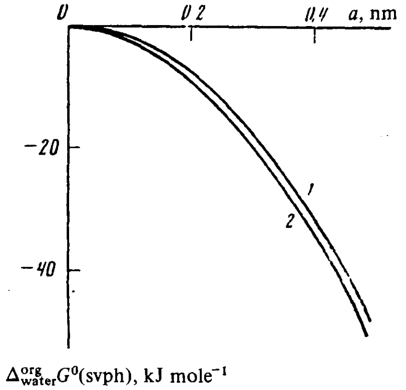

Figure 10. Solvophobic contribution to the energy of resolvation of a particle of radius *a* from water into nitrobenzene (*1*) and 1,2-dichloroethane (*2*), calculated using Uhlig's equation.[34]

IV. THE TOTAL ENERGY OF RESOLVATION

Various effects making a contribution to the energy of resolvation of ions were listed above. For most solvents of interest, the most significant role is played by electrostatic and solvophobic effects.[33] This has made it possible to represent the energy of resolvation as the sum of the contributions of two effects:[33]

$$\Delta_\beta^\alpha G^0 = \Delta_\beta^\alpha G^0(\mathrm{el}) + \Delta_\beta^\alpha G^0(\mathrm{svph}). \qquad (29)$$

The non-electrostatic part of the energy is usually taken as equal to the energy of solvation of the hypothetical discharged ion, all of whose other characteristics remain unchanged. It is usually estimated by comparing with a suitable neutral analogue, for example a noble gas. It is assumed that the energies of the formation of the cavity and the change in the structure of the solvent are the same for particles with the same shape and size, irrespective of the charge. This approach has an important advantage, emphasized in Ref.48. If identical standard states in the gas phase and the solution are taken for the ion and the neutral species imitating it, this procedure removes completely the problem of the recalculation and loss of the translational entropy of the solute in the solution in the comparison of the theoretical results with the experimental data.

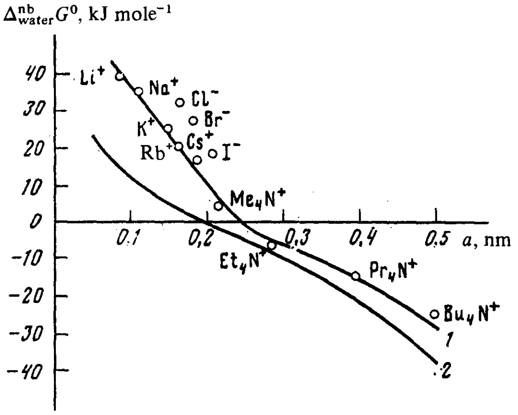

Figure 11. Dependence of the energy of resolvation on the radius of the ion in the water–nitrobenzene system, calculated from Eqn.(29): *1*) using the method of non-local electrostatics;[33,34] *2*) using the Born equation; the points give the experimental data (see Table 1).

In Ref.33, the electrostatic contribution was calculated by the method of non-local electrostatics, and the solvophobic contribution using Uhlig's equation. The results of the calculation for the most extensively studied experimental water–nitrobenzene system are given in Fig.11 (curve *1*). Comparison with curve *2*, obtained by calculation using

Born's equation, shows that allowance for the solvophobic effect alone does not make it possible to compensate the inadequacies of this simple equation.

Fig.11 shows that as a result of the solvophobic effect, the energy of resolvation may change sign with change in the radius of the ions. The results of the calculation show very good agreement with the experimental data. The deviations observed for anions in the range of small radii may be due to the formation of hydrogen bonds between the anions and the solvent molecules, or to the phenomenon of defect annihilation. The magnitude of these deviations corresponds approximately to the energy gain resulting from the formation of a weak hydrogen bond between the anion and the solvent.

The values of the energy of resolvation of small anions obtained by different authors differ considerably from one another.

V. STANDARD DISTRIBUTION POTENTIALS

When the energy of resolvation of an ion is known, it is possible to calculate the standard distribution potential $\Delta_\beta^\alpha\phi_i^0$ from the equation

$$\Delta_\beta^\alpha\varphi_i^0=-\frac{\Delta_\beta^\alpha G_i^0}{z_i F} \qquad (30)$$

where F is the Faraday constant.

Table 1 gives the distribution potentials for different ions between water and organic solvents. In the separation of the standard free energy of resolvation into ionic components and the determination of the distribution potentials, the tetraphenylborate hypothesis was used.[65–69]

It is known from thermodynamics that the absolute value of a difference in electric potentials can be measured only in conductors with the same composition. For the same reason, the difference in the galvanic potentials between a point in an aqueous phase and a point in the depth of an organic solvent cannot be measured experimentally.

If identical reversible electrodes are introduced into each of the phases of two immiscible electrolyte solutions in thermodynamic equilibrium, the inter-phase potential difference between them will be zero, since the system, being in equilibrium, cannot perform work.[70] If the reversible electrodes are different, the measured potential difference will be equal to that which would have been observed if these electrodes had been placed in the same solution.[70]

The following experimental methods are now used to measure distribution potentials and also to determine $\Delta_\beta^\alpha G^0$: polarography at a dropping electrolyte electrode;[1,12,15,27,71,72] polarography with scanning of the current at a dropping electrolyte electrode;[73–75] polarography at a rising aqueous electrode;[76] alternating-current polarography;[77–80] chronopotentiometry;[80–82] chronoammetry;[80,83] cyclic voltammetry;[12,18,22,71,84–88] measurement of the EMF of liquid circuits;[25,89,90] calculation using data on solubility,[14] distribution coefficients,[24,91–95] extraction,[91,96,97] the spin-lattice relaxation of the quadrupolar nuclei of the ions,[23,98,99] and calorimetry.[100] The accuracy of the measurement of $\Delta_\beta^\alpha\phi^0$ and $\Delta_\beta^\alpha G^0$ reaches 1 mV and 0.1 kJ mole^{-1} respectively.

---o0o---

The present review has described the most effective present-day methods for calculating the free energy of resolvation of ions. The most successful approach involves the use of the electrostatics of the media with spatial dispersion with allowance for solvophobic effects.

Methods of Synthesis of Compounds with Halogenoimidoyl Groups

T.D.Petrova and V.E.Platonov

The available information about the methods of synthesis of compounds of different classes containing the halogeno-imidoyl group $-\mathrm{N}=\overset{|}{\mathrm{C}}-\mathrm{Hal}$ are surveyed and the application of the known methods of synthesis of such compounds to new objects is examined. Data are presented on new methods of synthesis of compounds containing the $-\mathrm{N}=\overset{|}{\mathrm{C}}-\mathrm{Hal}$ group which have been developed in recent years.

The bibliography includes 239 references.

I. INTRODUCTION

Compounds containing the halogenoimidoyl group $-\mathrm{N}=\mathrm{C}-\mathrm{Hal}$ are extremely varied and have continually attracted the interest of investigators as a consequence of the high reactivity of the group, which makes it possible to involve them in a large number of reactions with formation of various acyclic and heterocyclic substances.[1-3] Furthermore, the interest in such compounds is due to the broad spectrum of the physiological activity of either the compounds themselves or the products of their reactions.[4-7]

Monographs and reviews devoted to the methods of synthesis and reactions of compounds of this large class are now available but they were published more than 15 years ago.[1,2] Thorough reviews covering the work of recent years are concerned mainly with imidoyl fluoride and fluorinated imidoyl halides,[8-11] hydrazonohalides [halogenocarbonyl hydrazones (Ed.of Translation)], and halogenoazines.[12-14] Fragmentary data on compounds with halogenoimidoyl groups have been included in several monographs.[15-22]

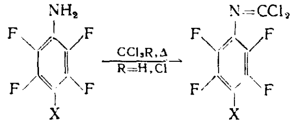
The aim of the present review is to survey data on the methods of synthesis of compounds containing the $-\mathrm{N}=\overset{|}{\mathrm{C}}-\mathrm{Hal}$ group published between 1970 and 1986. It includes as a rule recent studies which have not been covered by the existing reviews. For this reason, few data are presented on imidoyl fluoride and difluorides and also on *N*-halogeno-compounds. In the case of hydrazonohalides and halogenoazines, attention has been concentrated on studies published after 1974 and 1977 respectively. With the exception of a few examples, the review does not deal with heterocyclic compounds in which the halogenoimidoyl group forms part of the heterocycle or is attached to it.

Analysis of the literature data on the synthesis of various compounds with halogenoimidoyl groups up to 1970 permits the conclusion that, together with the development of the traditional methods of synthesis of such compounds, fundamentally new methods of their synthesis have been developed in the last 15 years and have expanded the range of these compounds and their possible applications.

II. SYNTHESES FROM AMINES, *N*-HALOGENOAMINES, AND HYDRAZINES

1. Thermolytic and Photochemical Reactions of Amines and *N*-Halogenoamines

A novel thermolytic method of synthesis of polyfluorinated *N*-(aryl)-carboimidoyl dichlorides not described previously, has been proposed comparatively recently. It consists in the copyrolysis of polyfluorinated primary aromatic amines with $CHCl_3$ or CCl_4 in a flow system at 600–670 °C:[23,24]



X = H, Cl, Br, F, CF_3, CN

The reaction is fairly general for polyfluorinated benzene derivatives and has been extended also to 2-aminoheptafluoronaphthalene and 4-amino-2,3,5,6-tetrafluoropyridine. The yield of carboimidoyl dichloride is 14–34%. The copyrolysis with CCl_4 takes place at a lower temperature, with a smaller excess of the halogenomethane and with a higher yield than the reaction with $CHCl_3$. The polyfluorinated *N*-(aryl)carboimidoyl dichlorides are also formed on copyrolysis of *N*-chloroamines with $CHCl_3$.

The disadvantages of the method include the low yield of the carboimidoyl dichloride, the high content of the polychlorinated products of the thermolysis of $CHCl_3$ and CCl_4 in the reaction mixture, and in certain cases side reactions of the substituents in the initial amine.

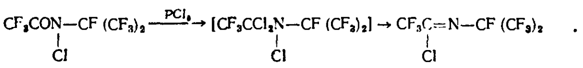
The formation of carboimidoyl dichlorides from amines and $CHCl_3$ apparently includes the preliminary generation of dichlorocarbene. However, the available data do not formally conflict with the participation in the reactions with $CHCl_3$ also of the trichloromethyl radical. The latter process is apparently the main one in the copyrolysis of amines with CCl_4.

The method of synthesis of carboimidoyl dichlorides indicated above has no analogies in the series of non-fluorinated compounds. The attempts to extend it to non-fluorinated amines, for example, aniline, was unsuccessful. The reason may be the thermal instability of the initial amines at high temperatures.

The copyrolysis of aromatic polyfluoroamines with pentafluorotrichloromethylbenzene at 500–520 °C leads to *N*-(polyfluoroaryl)pentafluorobenzimidoyl chlorides.[25] The yield is 50–77% in most cases. It has been suggested that the reaction proceeds via a radical pathway, although the possibility of the nucleophilic substitution of chlorine in pentachlorotrichloromethylbenzene under severe copyrolysis conditions is not ruled out.

The formation via a radical pathway of *N*-(pentafluorophenyl)carboimidoyl fluoride chloride as one of the products has been noted[26] in the pyrolysis of *N*-4-dichloroperfluorocyclohexa-2,5-dienylideneamine (550 °C, 1 mmHg) in a flow system.

Unstable *N*-chloroamines also having a chlorine atom at the α-carbon atom are very readily dechlorinated and are converted into the corresponding imidoyl chlorides even at room temperature:[27]



$$CF_3CON(Cl)\text{—}CF(CF_3)_2 \xrightarrow{PCl_5} [CF_3CCl_2N(Cl)\text{—}CF(CF_3)_2] \rightarrow CF_3C(Cl){=}N\text{—}CF(CF_3)_2 \quad .$$

In the photolysis of a mixture of t-butylamine with trifluoromethylbenzenes, *N*-(t-butyl)benzimidoyl fluorides are formed as the main products, but their yields are low and the process cannot be regarded as preparative.[28]

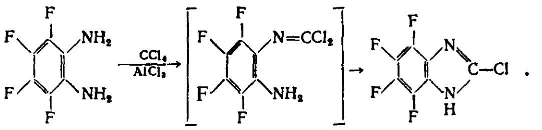
2. Reactions of Amines, *N*-Chloroamines, and Hydrazines in the Presence of Lewis Acids

A new method of synthesis of carboimidoyl dichlorides and chlorides involves the reaction of weakly basic amines with compounds of the type CCl_3R in the presence of $AlCl_3$. Thus heating of aromatic polyfluoroamines with CCl_4 and $AlCl_3$ at 40–80 °C leads to *N*-(polyfluoroaryl)carboimidoyl dichlorides in yields of 40–90%:[29,30]

$$Ar_FNH_2 \xrightarrow[AlCl_3]{CCl_4} Ar_FN{=}CCl_2$$

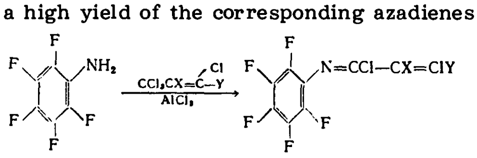
The reaction is fairly general for polyfluorinated benzene, biphenyl, naphthalene, and heterocyclic amine derivatives. The corresponding carboimidoyl dichlorides have been obtained in this way from pentafluoroaniline and *p*-substituted tetrafluoroanilines (the *p*-Br, *p*-Cl, *p*-NO_2, *p*-CN, and *p*-CH_3 derivatives and also the compound with H in the *p*-position), as well as pentachloroaniline. Compared with the pyrolytic method,[23,24] this procedure gives an increased yield and a greater range of products.

Tetrafluoro-*m*-phenylenediamines and tetrafluoro-*p*-phenylenediamines also enter into this reaction, which takes place in steps and leads to a mixture of mono- and di-carboimidoyl dichlorides with the latter predominating. On the other hand, the interaction of tetrafluoro-*o*-phenylenediamine with CCl_4 and $AlCl_3$ takes place in a more complex manner and leads to 2-chloro-4,5,6,7-tetrafluorobenzimidazole. It may be that the reaction proceeds via the intermediate *N*-(2-amino-3,4,5,6-tetrafluorophenyl)carboimidoyl dichloride, like the formation of benzimidoyl derivatives from the intermediate *o*-aminoarylamidoyl fluorides:[31]



The reaction with 4-amino-2,3,5,6-tetrachloropyridine takes place fairly smoothly.[32] In contrast to this, 4-amino-2,3,5,6-tetrafluoropyridine does not react.[30] Non-fluorinated amines react with CCl_4 and $AlCl_3$ to form carboimidoyl dichloride only if their basicity is sufficiently low. Thus *p*-nitroaniline is converted into *N*-(*p*-nitrophenyl)carboimidoyl dichloride, while aniline forms a high-melting salt-like product.[30]

Aluminium chloride is a specific catalyst in the process. Other Lewis acids proved to be virtually ineffective.[30] The replacement of CCl_4 by trichloromethylbenzene and its derivatives leads to the formation of the corresponding imidoyl chlorides even at room temperature.[30,33] Polyhalogenopropenes containing the CCl_3 group at the C=C aliphatic bond also react very readily with pentafluoroaniline, affording a high yield of the corresponding azadienes:[34]



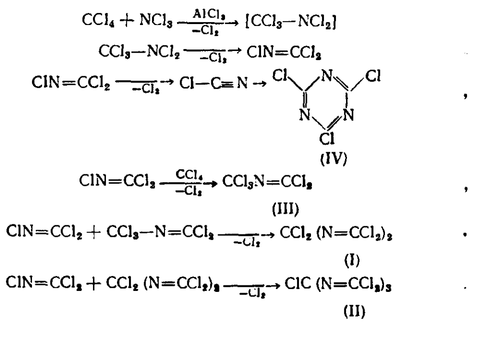
X = F, Y = Cl; X = Y = Cl; X = F, Y = C_6F_5

Hexafluorobenzene, $CHCl_3$, and CH_2Cl_2 are inert solvents for these reactions. In the synthesis of carboimidoyl dichloride and chloride by the above method, account must be taken of the side processes due to the effect of $AlCl_3$, for example, the exchange of fluorine for chlorine in the fluoroalkyl groups.[30]

One of the possible mechanisms of the formation of imidoyl chlorides and dichlorides from aromatic amines and compounds with the trichloromethyl group in the presence of $AlCl_3$ involves the formation of complexes by $AlCl_3$ with the trichloromethyl derivatives and the amine and subsequent conversion of the amine into the chloroalkyl derivative and further into the final product:[30]

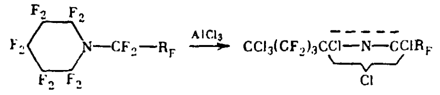
$$ArNH_2 + [R\overset{\delta+}{C}Cl_2 \ldots Cl \ldots \overset{\delta-}{Al}Cl_3] \rightarrow [Ar\overset{+}{N}H_2\text{—}CCl_2R] \xrightarrow[-H^+]{} [ArNHCCl_2R] \rightarrow$$
$$\xrightarrow[-HCl]{} ArN{=}CClR$$

The reaction of nitrogen trichloride with CCl_4 in the presence of $AlCl_3$ also leads to carboimidoyl chlorides,[35,36] but in this case a mixture of compounds is formed, whose proportions can be changed by varying the reaction conditions. It is of interest that bis- and tris-(carboimidoyl dichlorides) (I) and (II) have been obtained in this way. Small amounts of compound (III) and cyanuric chloride (IV) were isolated from the reaction mixture together with the above compound. The following mechanism of the reactions has been proposed:



$$CCl_4 + NCl_3 \xrightarrow[-Cl_2]{AlCl_3} [CCl_3\text{—}NCl_2]$$
$$CCl_3\text{—}NCl_2 \xrightarrow[-Cl_2]{} ClN{=}CCl_2$$
$$ClN{=}CCl_2 \xrightarrow[-Cl_2]{} Cl\text{—}C{\equiv}N \rightarrow \text{(IV)} \quad ,$$
$$ClN{=}CCl_2 \xrightarrow[-Cl_2]{CCl_4} \underset{\text{(III)}}{CCl_3N{=}CCl_2} \quad ,$$
$$ClN{=}CCl_2 + CCl_3\text{—}N{=}CCl_2 \xrightarrow[-Cl_2]{} \underset{\text{(I)}}{CCl_2(N{=}CCl_2)_2} \quad .$$
$$ClN{=}CCl_2 + CCl_2(N{=}CCl_2)_2 \xrightarrow[-Cl_2]{} \underset{\text{(II)}}{ClC(N{=}CCl_2)_3} \quad .$$

On treatment of perfluorinated cyclic tertiary amines with CCl_4 and $AlCl_3$, imidoyl chlorides with a linear structure are formed.[37,38] In this case, the mobile fluorine atoms in the α-position with respect to the nitrogen atom in the complex of the amine and $AlCl_3$ are exchanged for chlorine under the influence of the excess $AlCl_3$ with subsequent rearrangement of the αα'α''-polychloroamines, which are unstable under these conditions, to the sterically less hindered imidoyl chlorides. The rearrangement is accompanied by the dissociation of the C–N bond in the ring:



$R_F = (CF_3)_2CF—, CF_3CF_2CF_2—$.

The weakly basic hydrazines (V) also react with compounds having trichloromethyl groups and $AlCl_3$.[39] Pentafluorophenylhydrazine and *p*-nitrophenylhydrazine react with CCl_4 or trichloromethylbenzene and $AlCl_3$ and are converted into the corresponding *N*-(aryl)hydrazonodichloromethanes or *N*-(aryl)phenylhydrazonochlorides:

$$\underset{(V)}{ArNHNH_2} + R^1CCl_3 \xrightarrow{AlCl_3} ArNR^2N{=}C\begin{matrix}\diagup Cl\\ \diagdown R^1\end{matrix}$$

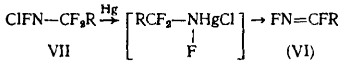
$Ar = C_6F_5$	$R^1 = Cl$	$R^2 = CCl_3$
C_6F_5	C_6F_5	H
C_6F_5	C_6H_5	H
$4NO_2-C_6H_4$	Cl	H

The direct conversion of arylhydrazine into arylhydrazonochlorides had not been noted earlier in the literature.

N-(Trifluoromethyl)carboimidoyl dibromide was obtained in 93% yield by the reaction of bis(trifluoromethyl)amine with CF_2Cl_2 and BBr_3.[40]

3. Other Reactions of Amines with *N*-Halogenoamines

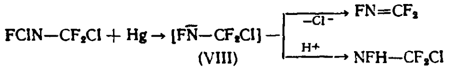
A method has been proposed for the synthesis of *N*-fluoroimidoyl fluorides (VI) in a satisfactory yield by dehalogenating amines of the type $NFClCF_2R$ (VII) by heating with mercury in the absence of a solvent.[41,42] The reaction mechanism has not been established accurately, but it has been suggested that it involves the insertion of mercury in the N–Cl bond and subsequent formation of the intermediate mercury compound:



$$\underset{VII}{ClFN—CF_2R} \xrightarrow{Hg} \left[\begin{matrix}RCF_2—NHgCl\\ |\\ F\end{matrix}\right] \rightarrow \underset{(VI)}{FN{=}CFR} \quad ;$$

$R = CF_3, C_2F_5, CF_2NClF$.

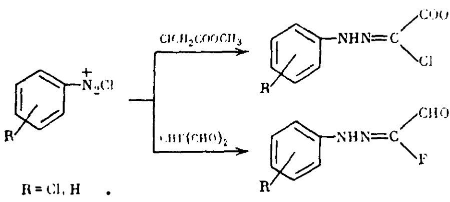
N-Fluorocarboimidoyl difluoride (VI, R = F) is formed in this way from the amine (VII, R = F) in yields up to 60%, but it cannot be separated from the impurities produced. A product which was readily purified was obtained in 90% yield by carrying out the reaction in trifluoroacetic anhydride. The use of trifluoroacetic acid as the solvent at 0 °C led to a mixture of the difluoride (VI, R = F) and *N*-(chlorodifluoromethyl)-*N*-fluoramine. Apparently the intermediate anion (VIII) is formed in the reaction in solvents and readily loses Cl^-, affording imidoyl difluoride, or abstracts a proton from the solvent and is converted into an amine:



$$FClN—CF_2Cl + Hg \rightarrow \underset{(VIII)}{[F\bar{N}—CF_2Cl]} — \begin{cases} \xrightarrow{-Cl^-} FN{=}CF_2 \\ \xrightarrow{H^+} NFH—CF_2Cl \end{cases} ,$$

Other amines of the type R_FNClF are converted only into *N*-(fluoroalkyl)-*N*-fluoramines under these conditions. *N*-(Chloro)trifluoroacetimidoyl fluoride has been obtained in a moderate yield from *NN*-dichloro-*N*-(perfluoroethyl)-amine on interaction with mercury in trifluoroacetic acid.

The coupling of diazotised anilines with methyl α-chloroacetate or fluoromalonaldehyde leads respectively to *N*-(aryl)-hydrazonochlorides or fluorides:[43-45]



III. SYNTHESES FROM COMPOUNDS WITH THE –NHCO OR –NHCS GROUP

The conversion of the –NHCO or –NHCS group into $-N{=}\overset{|}{C}-Hal$ on treatment with various halogen-containing reagents is the basis of well known and widely used methods of synthesis of halogenoimidoyl derivatives. Most of the studies in recent years on these lines have been associated with the involvement of new compounds in the reaction already described previously.

1. Reactions with Halogeno-derivatives of Phosphorus and Sulphur and with Halogens

One of the simplest and most convenient methods of synthesis of imidoyl halides is the halogenation of amides by phosphorus halides or $SOCl_2$. The following reactions have been carried out using PCl_5 and $SOCl_2$:

$$RNHCOR^1 \rightarrow RN{=}C\begin{matrix}\diagup Cl\\ \diagdown R^1\end{matrix} \quad \cdot$$

$R = CH_3$	$R^1 = C_6H_5, 4\text{-}XC_6H_4, COOC_2H_5$ (Refs.46-48)
$OCOCF_3$	CF_3 (Ref.49)
$CCl_3CHOH, CHClBrCHCl$	$C_6H_5, 4\text{-}XC_6H_4, CH_3$ (Refs.50-52)
$CCl_3CHCl, CCl_2 = CH$	$CHCl_2, CCl_3, C(CH_3)_3$
SF_5	CF_3, CH_3 (Ref.53)
$OCH_3, OC_2H_5, OC_3H_7\text{-m}$	$C_6H_5, 4\text{-}XC_6H_4$ (Refs.54-57)
$OC_3H_7\text{-iso}, OC_4H_9\text{-n}$	$2,4\text{-}XYC_6H_3$
$4\text{-}XC_6H_4CH_2, C_6H_5CH_2$	$C_6H_5, 4\text{-}NO_2C_6H_4$ (Ref.58)
$C_6H_5, 4\text{-}XC_6H_4$	$2CF_3SO_2C_6H_4, C_6H_5, 4\text{-}XC_6H_4$ (Refs.59-60).

The corresponding imidoyl bromide has been obtained from compound (IX, $R = OCH_3$, $R^1 = C_6H_5$) by reaction with PBr_3, but its yield was low;[56] an alternative method of synthesis with a yield of 51% involves the nitrosative deamination of *o*-methylbenzamide oxime in HBr.[57] *N*-Phenylbenzimidoyl bromide can be obtained from benzanilide and PBr_5 only in a mixture with the product of the bromination in the *p*-position of the aromatic ring attached to the nitrogen atom.[61]

It is of interest to note that the trichloroacetyl derivative of pentachloroaniline is converted into *N*-(pentachlorophenyl)trichloroacetimidoyl chloride on reaction with PCl_5,[62] while *N*-(pentafluorophenyl)trichloro- or -trifluoro-acetimidoyl chloride cannot be obtained from the corresponding anilides and PCl_5. Under the reaction conditions, they are converted into trichlorophosphazopentafluorophenyl.[63] The formation of organophosphorus compounds instead of the expected hydrazonochlorides has been observed also in the interaction of *N*-phenyl- and *N*-methyl-*N*-trifluoroacetohydrazides with PCl_5.[64]

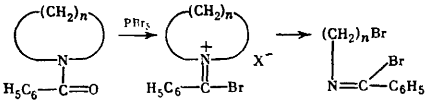
In the case of the *o*-azidobenzanilides or *N*-(*o*-azidobenzoyl)anilides, the imidoyl chlorides formed rapidly cyclise to derivatives of 2*H*-indazole or benzimidazole, so that they cannot be isolated, although there is no doubt about their intermediate formation.[65,66]

An *o*-allyl-substituted imidoyl chloride has been obtained from the *o*-allylbenzoyl derivative of *p*-nitrobenzylamine.[67] Various 2-phenylethylamides react with reagents of the type of PCl_5, $POCl_3$, and $SOCl_2$ under mild conditions to form imidoyl halides in high yields.[68,69] This finding proved to be extremely important for the understanding of the mechanism of the formation of derivatives of dihydroisoquinoline from amides and $POCl_3$ in the classical Bischler–Napieralski reaction. It permitted the conclusion that imidoyl chlorides are formed as intermediates in this reaction and made it possible to modify the conditions for its occurrence in order to attain the highest yield of the cyclisation product.

The chlorination of *NN'*-dichlorodimethylmalonamide with chlorine under UV irradiation proceeds differently to the reactions of amides described above, although it also leads to a compound with imidoyl dichloride groups:[70]

$$CH_3NHCOCCl_2CONHCH_3 \xrightarrow[h\nu]{Cl_2} CCl_2{=}N{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}CCl_2{-}\overset{\overset{\displaystyle O}{\|}}{C}{-}N{=}CCl_2 \quad .$$

Amide groups forming part of the heterocyclic ring are converted into imidoyl chlorides on treatment with PCl_5 or $POCl_3$. Chlorine-containing quinazolines,[71] phthalazines,[72] 1,2,4-triazines,[73] pyrazines,[74] pyridazines,[75,76] isoindolenines,[77] and phenanthridines[78,79] have been synthesised in this way. Cyclic benzamides of type (X) react with PBr_5 with ring opening and the formation of *N*-(ω-bromoalkyl)imidoyl bromides (XI). The reaction proceeds via the intermediate iminium bromide (XII):[80]



(X) (XII) $X = Br_3^-; Br^-$. (XI) .

A mixture of $SOCl_2$ and SO_2Cl_2 is as a rule used for the synthesis of carboimidoyl dichloride from amides. The corresponding *N*-arylcarboimidoyl dichlorides have been obtained in this way from formanilide and its 2,6-dichloro- and 2,4,5-trichloro-derivatives.[81] However, the attempt to use this method to synthesise *N*-pentafluorophenylcarboimidoyl dichloride was not very successful.[82]

The synthesis of *N*-pentafluorophenyl)perfluoropropylimidoyl fluoride by treating a tertiary amide with SF_4 in HF has been described:[83]

$$C_6F_5N(COC_3F_7)_2 + SF_4 \xrightarrow{HF} C_6F_5N{=}C\begin{matrix}\diagup F \\ \diagdown C_3F_7\end{matrix} \quad .$$

The yield of the product is 73%. The proposed reaction pathway involves the rupture of the *N*-acyl bond by HF and the formation of a secondary amide which is then converted into the imidoyl fluoride. Thiobenzanilide reacts with SF_4 and is converted into *N*-phenylbenzimidoyl fluoride in 52% yield.[84]

Like amides, hydrazides are readily chlorinated by $SOCl_2$ or PCl_5, being converted into the corresponding hydrazonochlorides:

$$R^1CONHNR^2R^3 \rightarrow R^1{-}\underset{\underset{\displaystyle Cl}{|}}{C}{=}N{-}NR^2R^3$$

$R^1 = 2\text{-}BrC_6H_4, 2\text{-}FC_6H_4$; $R^2 = H$; $R^3 = C_6H_5$ (Ref.85); $R^1 = C_6H_5$, $R^2 = H$, $R^3 = C_6F_5$ (Ref.86); $R^1 = R^3 = C_6F_5$; $R^2 = H$; $R^1 = t\text{-}C_4H_9, C_6H_5$; $R^2 = CH_3$; $R^3 = 2,4\text{-}(NO_2)_2C_6H_3, 4\text{-}NO_2C_6H_4, C_6H_5$ (Ref.87); $R^1 = C_6H_5$; $R^2 = H$; $R^3 = Ts$ (Ref.13);

$$R{-}CO{-}NH{-}NH{-}COR \xrightarrow{PCl_5, POCl_3} R{-}\overset{\overset{\displaystyle Cl}{|}}{C}{=}N{-}N{=}\overset{\overset{\displaystyle Cl}{|}}{C}{-}R \text{ [88]}, R = {-}N[CH_2CF(NO_2)_2]_2 .$$

A convenient modification of the method involves treating the hydrazides with the $POCl_3$.pyridine complex in an excess of $POCl_3$.[12,89–91] On treatment with PCl_5, certain hydrazides undergo a rearrangement in the course of which the intermediate formation of compounds with the imidoyl chloride functional groups is postulated.[92]

On treatment with PCl_5, arylureas are converted in high yields into *N*-arylbenzimidoyl chlorides,[93] while *N*-alkylideneureas are converted into chloro-1,3-diaza-1,3-dienes.[94] Compounds of a similar type with two conjugated imidoyl chloride groups are obtained by chlorinating *N*-thioaroyl-*N'*-arylthioureas.[95]

Chlorination of perfluoroalkylthioanilides leads to *N*-phenylimidoyl chlorides in high yields:[84]

$$C_6H_5NHCSCF_3 \xrightarrow{Cl_2} C_6H_5N{=}C\begin{matrix}\diagup Cl \\ \diagdown CF_3\end{matrix}$$

The formation of a small amount (up to 10%) of relatively unstable *N*-pentafluorothioimidoyl chlorides, characterised spectroscopically, has been noted in the reactions of *N*-pentafluorothiourethanes or thiourethanes with PCl_5:[96]

$$SF_5NHCOR \rightarrow SF_5N{=}C\begin{matrix}\diagup Cl \\ \diagdown R\end{matrix} \quad ,$$

$R = OC_6H_5, SCH_3, SC_6H_5$.

2. Reactions with the Vilsmeier Reagent and Its Analogues

The reactions of amides with the Vilsmeier reagent proceed in a more complex manner. Thus, when acetanilides interact with this reagent, imidoyl chlorides are formed only as intermediates, which are subsequently converted into formamidines, 2-chloroquinolines, or other heterocyclic derivatives depending on the substituent in the acetanilide and the reaction conditions.[97–101] The interaction of the Vilsmeier reagent with 2- and 3-acetamidothiophens proceeds analogously.[98,102] The reaction of the Vilsmeier reagent with *NN*-dimethylurea has been described by Boyd et al.[103]

The intermediate formation of imidoyl chlorides has been postulated in the reactions of anilides of the type $ArNHCOCH_2R$ with the aza-analogues of the Vilsmeier reagent obtained from $POCl_3$ and *N*-nitrosodimethylamine or its homologues.[100] However, *N*-(*m*-tolyl)carboimidoyl dichloride is one of the side products in the case of 3-methylpropioanilide.

3. Reactions with Triphenylphosphine and Dihalogenophosphoranes

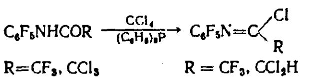
A new convenient method of synthesis of imidoyl chlorides and bromides in high yields has been proposed by Appel and co-workers[104,105] using secondary amides, the corresponding tetrahalogenomethane, and triphenylphosphine as the starting materials:

$$R^1CONHR^2 + (C_6H_5)_3P + CX_4 \rightarrow R^1CX{=}NR^2 + (C_6H_5)_3PO + CHX_3 \quad ;$$
$$R^1 = CH_3, C_6H_5;\ R^2 = C_6H_5,\ cyclo\text{-}C_6H_{11};\ X = Cl, Br \quad .$$

The study of the reaction mechanism suggested that the reaction proceeds via the intermediate *O*-phosphorylated compound formed from the amide on treatment with the complex of the tetrahalogenomethane and triphenylphosphine or the product of their reaction—a dihalogenophosphorane. Taking this into account, a method of synthesis of imidoyl chlorides and bromides from the corresponding dihalogenophosphoranes in the presence of bases (to bind the HHal formed) was developed. The yields of imidoyl halides obtained by this method are also fairly high. The reaction with the less reactive dichlorophosphorane takes place at a higher temperature than the reaction with dibromophosphorane.

The mild conditions in the synthesis of imidoyl chlorides and bromides by this method make it possible to obtain even relatively unstable compounds, which can be used for further reactions without isolation. A convenient version of the reaction has been proposed[106] using triphenylphosphine on a support, which facilitates the separation of phosphorus compounds from imidoyl halides.

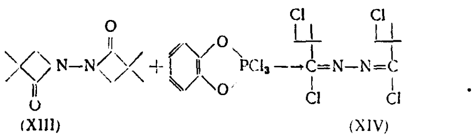
The reaction with triphenylphosphine and CCl_4 has been successfully carried out for trihalogenoacetylpentafluoroanilines in order to synthesise *N*-(pentafluorophenyl)halogenoacetimidoyl chlorides:[107]



$$C_6F_5NHCOR \xrightarrow[(C_6H_5)_3P]{CCl_4} C_6F_5N{=}C\begin{smallmatrix}Cl\\R\end{smallmatrix} \qquad .$$

$$R{=}CF_3, CCl_3 \qquad R = CF_3, CCl_2H$$

NNN'-Substituted ureas[105,108,109] and the *S*-esters of thiocarbamic acid[105] react with CCl_4 and $(C_6H_5)_3P$ like the amides. The dione (XIII) reacts with trichloro-1,2-phenylenedioxyphosphorane and is converted into the azine (XIV) in 70% yield:[110]



(XIII) (XIV)

IV. REACTIONS OF COMPOUNDS WITH A NITROGEN–CARBON MULTIPLE BOND

1. Reactions of Ketoximes and Aldoximes

Aromatic and aryl-substituted aliphatic ketoximes undergo the Beckmann rearrangement on treatment with CCl_4 and $(C_6H_5)_3P$, affording imidoyl chlorides. The unsubstituted aryl group then migrates in the diaromatic ketoximes, while in aryl-substituted aliphatic ketoximes the aryl group migrates. The yields are in the range 70–90%:[111]

$$(C_6H_5)_3P + CCl_4 + \begin{smallmatrix}R^1\\R^2\end{smallmatrix}{>}C{=}N{-}OH \rightarrow R^1{-}\underset{Cl}{\underset{|}{C}}{=}N{-}R^2 \quad ;$$

$$R^1 = C_2H_5, C_6H_5, 4\text{-}ClC_6H_4;\ R^2 = C_6H_5.$$

Under these conditions, the dialiphatic ketoximes are apparently also converted into imidoyl chlorides, but the latter cannot be isolated.[112] Imidoyl chlorides are likewise obtained in the reactions of ketoximes with dichlorophosphorane in the presence of triethylamine.[111] The intermediate *N*-chloroketimines or their precursors, namely *O*-phosphorylated ketoximes, undergo the Beckmann rearrangement in these reactions.[111]

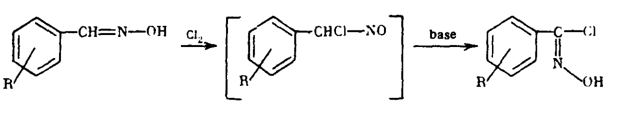
The Beckman rearrangement of *O*-substituted oxime derivatives on treatment with trimethylsilyl iodide or diethylaluminium iodide in an aprotic medium under mild conditions makes it possible to obtain high yields of imidoyl iodides, which can be used for further reactions with isolation in a pure form:[113]

$$\begin{smallmatrix}R^1\\R^2\end{smallmatrix}{>}C{=}N{-}OX \xrightarrow[\text{or } (C_2H_5)_2AlI]{(CH_3)_3SiI} R^1{-}N{=}C\begin{smallmatrix}R^2\\I\end{smallmatrix} \quad ;$$

$$X = COCH_3, COC_6H_5, COOC_2H_5 \quad .$$

Derivatives of acetone, diethyl ketone, acetophenone, cyclohexanone, and cyclododecanone oximes have been investigated in these reactions.

Aldoximes are converted into compounds with the imidoyl chloride group on treatment with various chlorinating agents. The chlorination of benzaldoximes with chlorine in chloroform or methylene chloride, containing an admixture of ethanol or in the presence of triethylamine as the catalyst, makes it possible to obtain benzohydroximoyl chlorides in satisfactory yields.[114–122] The reaction intermediates are chloronitroso-compounds, which isomerise to hydroximoyl chlorides:



$R = 4\text{-}C_6H_5;\ 4\text{-}NH_2;\ 2,6\text{-}Cl_2;\ H, 3\text{-}NO_2$ and $4\text{-}NO_2;\ 2\text{-}, 3\text{-},$ and $4\text{-}Cl;\ 2,6\text{-}Cl_2.$

The chlorination of pentachlorobenzaldoxime can be achieved without a catalyst. In order to obtain pentafluorobenzohydroximoyl chloride, nitrosyl chloride is used as the chlorinating agent since the reaction hardly occurs with chlorine.

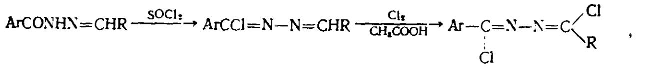
A convenient and selective method of synthesis of benzohydroximoyl chlorides from the corresponding aldoximes on treatment with *N*-chlorosuccinimide has been described.[123,124] Chloral oxime is converted into trichloroacetohydroximoyl chloride on treatment with chlorine.[125]

2. Reactions of Aldimines and Aldazines

The formation of imidoyl chlorides has been postulated in the reaction of *N*-benzylideneanilines with PCl_5. Imidoyl chlorides were converted into the corresponding amides without isolation.[126] Satisfactory results have been obtained with *N*-benzylideneaniline, *N*-benzylidene-*p*-toluidine, and *N*-benzylidene-*p*-chloroaniline, but *N*-benzylidene-*p*-nitroaniline could not be made to undergo this reaction:

$$C_6H_5CH{=}N{-}R \xrightarrow{PCl_5} \begin{smallmatrix}Cl\\C_6H_5\end{smallmatrix}{>}C{=}N{-}R \xrightarrow{H_2O} C_6H_5CONHR \quad .$$

Aldazines of the type of 2,3-diazabuta-1,3-diene are converted into monochloro- or dichloro-azines on treatment with chlorine in inert solvents or in anhydrous acetic acid, while their bromination and iodination proceed in a more complex manner. These reactions have been described in detail by Buzykin and co-workers.[12,13] A convenient version of the synthesis of such chlorides involves the interaction of aroylhydrazones with thionyl chloride and subsequent chlorination of the 1-chloro-derivatives formed to 1,4-dichloro-2,3-diazabuta-1,3-dienes [127] [Pilgram and Skiles [128] described the more complex reaction of aroylhydrazones of aliphatic perfluoroaldehydes with $SOCl_2$ in the presence of dimethylformamide (DMF)]:



$$ArCONHN{=}CHR \xrightarrow{SOCl_2} ArCCl{=}N{-}N{=}CHR \xrightarrow[CH_3COOH]{Cl_2} Ar{-}\underset{Cl}{\underset{|}{C}}{=}N{-}N{=}C\begin{smallmatrix}Cl\\R\end{smallmatrix} \quad ,$$

$Ar = C_6H_5, 4\text{-}ClC_6H_4, 4\text{-}CH_3C_6H_4;\ R = C_6H_5, 4\text{-}NO_2C_6H_4, CF_3, C_2F_5, C_3F_7.$

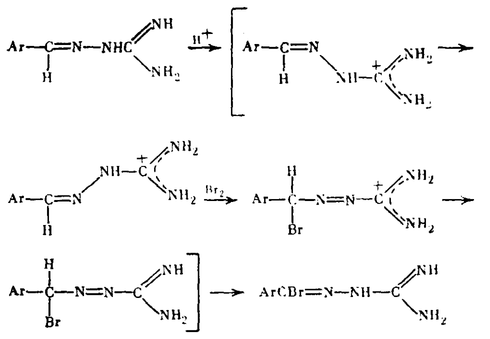
The method makes it possible to obtain the compounds in satisfactory yields and free of isomers, which is especially important for asymmetric derivatives. However, when it is used, one must take into account the symmetrisation side reactions on treatment with $SOCl_2$.[13]

3. Reactions of Hydrazones

New *N*-arylhydrazonobromides have been obtained by the usual methods for the synthesis of compounds of this kind involving treatment with the arylhydrazones of aromatic and aliphatic aldehydes with bromine in acetic acid. The reaction kinetics has been investigated and the role of the electronic steric factors in the formation of the product has been discovered.[12,89,129–131]

N-(Phenyl)trifluoroacetohydrazonobromide and the corresponding chloride can be synthesised in yields up to 70% on halogenation of the phenylhydrazone of trifluoroacetaldehyde with *N*-bromo- and *N*-chloro-succinimide in DMF.[132]

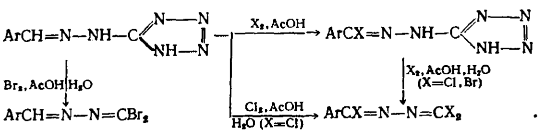
A new group of reactive *N*-amidinohydrazonobromides have been synthesised by brominating amidinohydrazones with bromine in aqueous acetic acid.[133] The compounds were isolated in the form of stable hydrobromides. The kinetic data obtained agree with the reaction mechanism in which the slow rate-determining step is the geometrical isomerisation of the protonated form of the initial thermodynamically stable (*E*)-isomer of the amidinohydrazone to the protonated form of the (*Z*)-isomer followed by the rapid stage involving the bromination of this form:



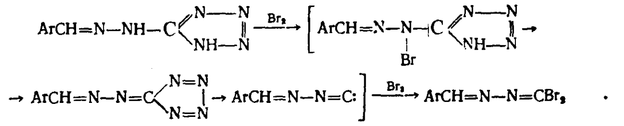
Ar = 4-XC$_6$H$_4$; X = OCH$_3$, CH$_3$, (CH$_3$)$_2$CH, H, Cl, Br.

The formation of hydrazonobromides is also postulated in the bromination of arylidenesemicarbazones with bromine in anhydrous acetic acid, but the final products are triazolones.[134]

The pathway followed in the reactions of the tetrazolylhydrazones of aromatic aldehydes with chlorine or bromine in acetic acid depends on the conditions.[13] On treatment with halogens in glacial acetic acid, the methylidyne proton of the hydrazone is slowly substituted by the halogen and tetrazolylbenzohydrazonochlorides or the corresponding bromides are obtained respectively. On treatment with halogens in aqueous acetic acid, these compounds undergo oxidative cleavage on the tetrazole ring and are converted into 1,1,4-trihalogeno-2,3-diazabutadienes. Treatment of the initial tetrazolylhydrazones with halogens in aqueous acetic acid also leads to the cleavage of the tetrazole ring. The 1,1-dibromo- and 1,1,4-trichloro-derivatives are then formed in the reactions with bromine and chlorine respectively. The bromination of the 1,1-dibromo-derivative to the 1,1,4-tribromo-derivative does not take place. Thus, in order to obtain the 1,1,4-trihalogeno-derivatives of 2,3-diazadienes, it is necessary that the methylidyne position be halogenated before the cleavage of the tetrazole ring:



The study of the bromination kinetics suggested the following mechanism of the formation of 1,1-dibromo-derivatives:



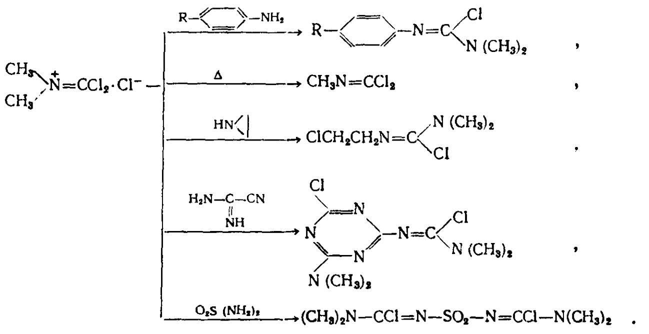
The bromination of the 5-phenyltetrazolylhydrazones of aromatic aldehydes has been described by Hegarty et al.[135] The attempts to involve ketone tetrazolylhydrazones in the bromination reaction were unsuccessful with the exception of benzophenone tetrazolylhydrazone.[136] On the other hand, *C*-alkoxycarbonyl derivatives of *N*-arylhydrazonobromides have been obtained[137] by brominating hydrazones (XV) in a mixture of glacial acetic acid and acetic anhydride in the presence of sodium acetate:

(XV)

R = Br, CH$_3$; R^1 = OC$_2$H$_5$, OCH$_3$.

4. Reactions of Dichloromethyleneammonium Salts

The highly reactive dichloromethyleneammonium salts having the general formula $R_2\overset{+}{N}{=}CCl_2.X^-$, which have been vigorously investigated in recent years, can serve as starting materials in the synthesis of carboimidoyl dichlorides and chlorides. Thus thermolysis of dichloromethylenedimethylammonium chloride above 100 °C leads to *N*-methylcarboimidoyl dichloride and its reaction with compounds containing the amino-group makes it possible to obtain smoothly chloroformamidines:



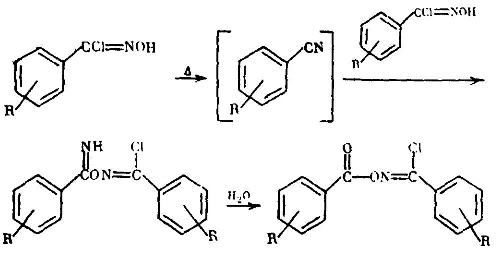
The reactions of dichloromethyleneammonium salts are described in greater detail in Refs.138–141.

5. Reactions of Imidoyl Halides

For the synthesis of new imidoyl halides, it is possible to use the reactions of the compounds themselves involving the substitution of the halogen atom at the N=C bond, the reactions of other substituents, and also isomerisation not involving the $N{=}\overset{|}{C}{-}Hal$ group. The methods associated with the reactions of the first type have been examined in a review.[142] The reactions of the second type are extremely varied. Thus difluoroacetohydroximoyl chloride can be obtained from *O*-(trifluoroacetyl)trifluoroacetohydroximoyl chloride with methanol.[46–49,143] The reverse reaction makes it possible to synthesise *O*-acylhydroximoyl chlorides from hydroximoyl chlorides:[122,144,145]

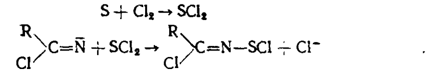
$$\underset{\displaystyle Cl}{CF_3-\overset{|}{C}}=N-OCOCF_3 \xrightarrow{CH_3OH} \underset{\displaystyle Cl}{CF_3\overset{|}{C}}=N-OH$$

Pyrolysis of benzohydroximoyl chlorides containing electron-accepting substituents in the ring leads to O-benzoylbenzohydroximoyl chlorides, but the yields of the products are low.[146] The reaction mechanism involves the reactions of intermediate benzonitriles:



R = 3-NO$_2$, 4-NO$_2$, 4-Cl.

On interaction with sulphur in the presence of a chloride ion donor (tetrabutyl or tetraethyl-ammonium chloride), *N*-chloroformimidoyl chlorides are converted into *N*-chlorothioformimidoyl chlorides.[147] The proposed reaction mechanism is presented below:

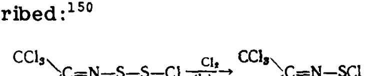


When R = Cl or CCl$_3$, the products can be isolated, but, when R = CN or –CCl$_2$–CN, further reactions take place. *N*-Alkylthio- or *N*-phenylthio-formimidoyl chlorides are formed in the reactions with disulphides.[148] Bis-*N*-chloroformimidoyl chlorides react with disulphides analogously.

The chlorination of *N*-(trifluoromethylthio)trifluoromethyldithioimidoyl fluoride or chloride takes place with cleavage of the S–S bonds:[149]

Hal = F, Cl

Another example of reactions with cleavage of the S–S bond has been described:[150]



N-Chlorocarboimidoyl difluoride reacts via a radical mechanism with fluoro-olefins at a high temperature affording *N*-halogenoalkylcarboimidoyl difluorides.[151,152] The degree of conversion of the initial imidoyl difluoride reaches 75–95%:

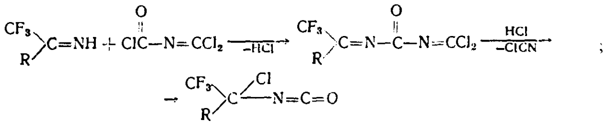
$$ClN{=}CF_2 + CF_2{=}CXF \rightarrow CF_2{=}N{-}CF_2{-}CXFCl \quad ;$$

$$X = F, Cl, Br \quad .$$

The reaction does not take place with hydrogen-containing olefins.

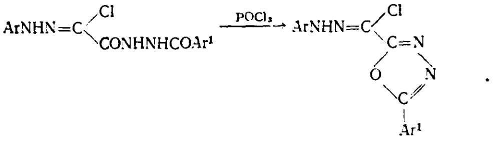
The conversion of *N*-trichloromethylcarboimidoyl dichloride into *N*-chloroformylcarboimidoyl dichloride in a high yield in reactions with aliphatic aldehydes and acid anhydrides has been described.[153]

NN'-Bisalkylideneureas have been isolated in the reactions of ketimines with trichloromethyl isocyanate, which exists preferentially in the form of *N*-chloroformylcarboimidoyl dichloride, under mild conditions in the absence of HCl.[154] In the presence of HCl and on heating, the reaction proceeds further and α-chloroalkyl isocyanates are formed in 75–80% yields:



R = C$_6$H$_5$, 4-ClC$_6$H$_4$, 4-CF$_3$C$_6$H$_4$.

The reaction of a substituent, accompanied by intramolecular cyclisation, has been observed on treating *N*-arylhydrazonochloroacetyl-*N*-benzoylhydrazines with POCl$_3$:[155]



The isomerisation of (*Z*)-isomers of O-alkylbenzohydroximoyl chlorides to the (*E*)-isomers takes place on irradiation with UV light or under the conditions of acid catalysis.[55,56,156]

The reactions of substituents in imidoyl chlorides involving chlorination have been described.[51,52,157] Some examples are presented below:

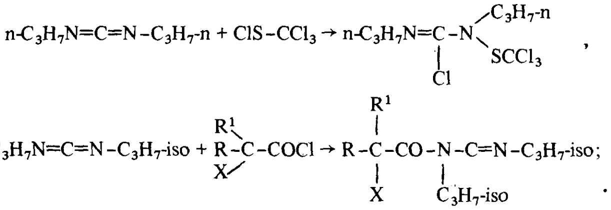
$$CCl_3CCl{=}NCH_2C_6H_5 \xrightarrow{Cl_2} CCl_3CCl{=}NCHClC_6H_5 \quad ,$$

$$RR'C{=}CClN{=}CClC_6H_5 \xrightarrow{Cl_2} RR'CCl{-}CCl_2{-}N{=}CClC_6H_5 \quad ,$$

$$R = H, Br, CH_3CHCCl; \ R'{=}Cl, Br \quad .$$

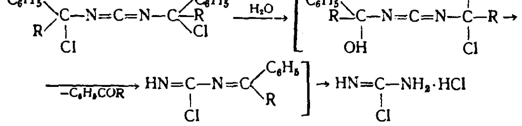
6. Reactions of Carbodiimides

Trichloromethanesulphenyl chloride or α-halogenoacid chlorides add under mild conditions to the C=N bond in carbodiimides affording the corresponding chloroformamidines:[20,158]



X = Cl, Br; R, R^1 = H, CH$_3$

On treatment with water, chloroalkylcarbodiimides are converted into the hydrochloride of chloroformamidine:[159]



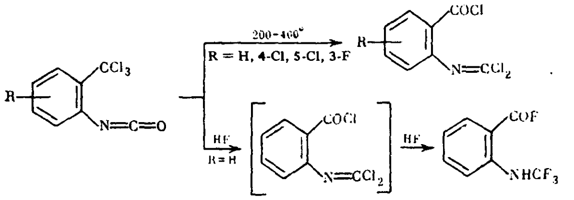
R = CF$_3$, t-C$_4$H$_9$.

Diisopropyl- or dicyclohexyl-carbodiimide reacts with bromodichloromethylphenylmercury, as a source of dichlorocarbene, giving rise to the corresponding carboimidoyl dichloride:[160]

$$R{-}N{=}C{=}N{-}R + C_6H_5HgCCl_2Br \rightarrow RN{=}CCl_2 \quad .$$

7. The Synthesis from Isocyanates and Isothiocyanates

An unusual intramolecular rearrangement with oxygen transfer in a series of o-trichloromethylphenyl isocyanates leads to *N*-phenylcarboimidoyl dichlorides.[161,162] It has been detected in the high temperature thermolysis of these compounds and, in addition, apparently also when the latter were treated with HF:



Chloro-1,3-diaza-1,3-dienes can be obtained from perchloroethyl isocyanate and triphenylphosphazo-compounds as a result of the 1,3-chlorotropic shift in the –C–N=C– triad in the carbodiimides formed initially:[94]

$$CCl_3CCl_2N{=}C{=}O + (C_6H_5)_3P{=}NR \rightarrow [CCl_3CCl_2N{=}C{=}N{-}R] \rightarrow CCl_3CCl{=}N{-}CCl{=}NR\ ;\quad R = \text{iso-}C_3H_7,\ C_6H_5.$$

Carboimidoyl dichlorides can be obtained by chlorinating isocyanates or isothiocyanates:

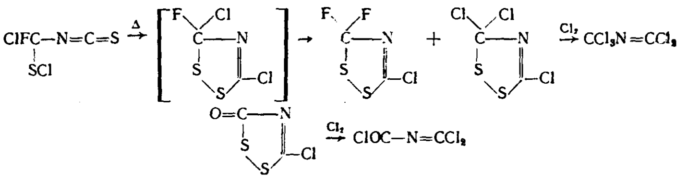
$$SF_5{-}N{=}C{=}O \xrightarrow{PCl_5} SF_5{-}N{=}CCl_2\ \text{(Ref.163)},$$

$$R{-}N{=}C{=}S \xrightarrow{Cl_2} \left[RN{=}C\begin{matrix}\diagup Cl\\ \diagdown SCl\end{matrix}\right] \rightarrow R{-}N{=}CCl_2\ \text{(Refs.164, 165)};$$

$$R{=}CH_3,\ CH_2C_6H_5,\ C_6H_5,\ CF_2Cl,\ CF_3\ ,$$

$$F\,(S)\,C{-}N{=}C{=}S \xrightarrow{Cl_2} CFCl_2{-}N{=}CCl_2\ \text{(Ref.165)}.$$

An unusual pathway leading to carboimidoyl dichloride has been discovered in the case of the chloride of chlorofluoroisothiocyanatomethanesulphenic acid.[165] On heating, this compound undergoes intramolecular cyclisation to a 1,2,4-dithiazole derivative. Such dithiazoles or their hydrolysis products afford carboimidoyl dichlorides on treatment with chlorine:

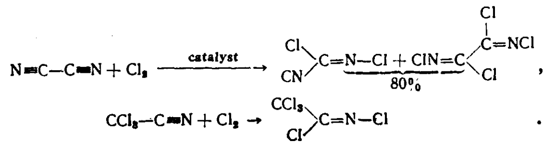


8. Addition to Nitriles, Cyanates, and Isonitriles

A large number of various imidoyl chlorides and dichlorides have been obtained by adding chlorine, sulphenyl chlorides, disulphides, sulphur dichloride, thionyl chloride, and sulphuryl chloride to the C ≡ N bonds of various nitriles. The chlorination of nitriles with electron-accepting substituents leads to substituted *N*-chloroformimidoyl chlorides.[166,167] The addition of chlorine to the activated C ≡ N bond in sulphonyl cyanides takes place readily and with a quantitative yield:

$$RSO_2C{\equiv}N + Cl_2 \rightarrow RSO_2C(Cl){=}N{-}Cl\ .$$

In the case of less activated nitriles, such as, for example, cyanogen or trichloroacetonitrile, the reaction is performed in the presence of catalysts—tetramethylammonium chloride or charcoal:

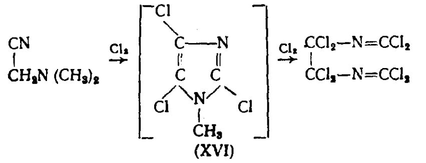


$$N{\equiv}C{-}C{\equiv}N + Cl_2 \xrightarrow{\text{catalyst}} \underbrace{\begin{matrix}Cl\diagdown\\ CN\diagup\end{matrix}C{=}N{-}Cl + ClN{=}C\begin{matrix}\diagup C(Cl){=}NCl\\ \diagdown Cl\end{matrix}}_{80\%}\ ,$$

$$CCl_3{-}C{\equiv}N + Cl_2 \rightarrow \begin{matrix}CCl_3\diagdown\\ Cl\diagup\end{matrix}C{=}N{-}Cl\ .$$

The first stage of the chlorination reaction is nucleophilic attack by the chloride ion on the electron-deficient carbon atom of the cyano-group.

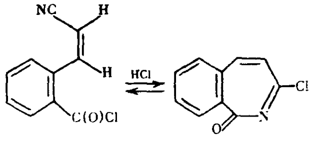
The high-temperature chlorination of dimethylaminoacetonitrile to biscarboimidoyl dichloride (XVI) proceeds via the intermediate formation of an *N*-methylimidazole derivative and subsequent ring opening:



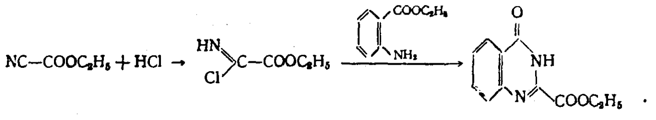
(XVI)

The reactions of nitriles with chloro-derivatives of sulphur proceed in the presence of catalysts (sources of chloride ions) and make it possible to obtain sulphur-containing imidoyl chlorides and dichlorides.[148,149,168–171]

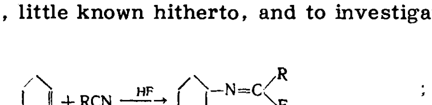
Cyclic imidoyl chlorides are formed in satisfactory yields in the reactions involving the addition of HCl to nitriles, accompanied by intramolecular cyclisation,[172] for example:



The interaction of ethyl cyanoformate and HCl in acetic acid leads to the unstable ethoxycarbonylformimidoyl chloride, which has been detected from the presence of products of its reactions with nucleophiles added to the system. Ethyl 4-quinazolone-2-carboxylate has been obtained in this way in 50% yield in the presence of *o*-ethoxycarbonylaniline:[173]



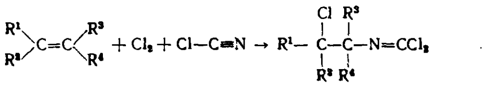
The Ritter condensation of nitriles with olefins in the presence of HF led to imidoyl fluorides, which were isolated in a pure form.[174,175] This reaction made it possible to obtain imidoyl fluorides, little known hitherto, and to investigate their properties:



R=CH₃ (33%), C₆H₅ (59%)

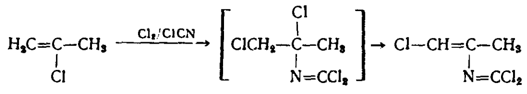
The use in these reactions of not only cyclic but also linear olefins with branched and unbranched chains at the C=C bond showed that alkenes with branched alkyl groups do not form imidoyl fluorides, while those with unbranched groups react normally. For example, pent-1-ene reacts with benzonitrile to form a mixture of *N*-(2-pentyl)benzimidoyl fluoride and the corresponding 3-pentyl derivative in 62% yield. The different behaviour in these processes of the two types of olefins is determined by the possibility of further reactions of the ions formed as intermediates in the addition of HF to olefins.

A preparative method of synthesis of aliphatic *N*-(β-chloroalkyl)carboimidoyl dichlorides consists in the electrophilic addition of chlorine to olefins in the presence of chlorocyanogen:[176]



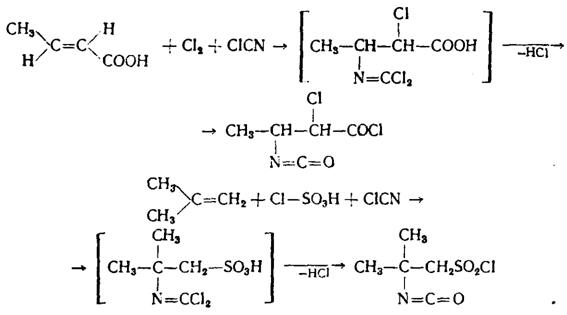
$$\begin{matrix}R^1\diagdown\\ R^2\diagup\end{matrix}C{=}C\begin{matrix}\diagup R^3\\ \diagdown R^4\end{matrix} + Cl_2 + Cl{-}C{\equiv}N \rightarrow R^1{-}\overset{Cl}{\underset{R^2}{C}}{-}\overset{R^3}{\underset{R^4}{C}}{-}N{=}CCl_2$$

Especially satisfactory yields have been obtained with vinyl chloride or butadiene. When α-halogenocarboimidoyl chlorides are formed, dehydrohalogenation, which takes place readily, makes it possible to obtain at once αβ-unsaturated carboimidoyl dichlorides:



$$H_2C{=}C(Cl){-}CH_3 \xrightarrow{Cl_2/ClCN} \left[ClCH_2{-}C(Cl)(N{=}CCl_2){-}CH_3\right] \rightarrow Cl{-}CH{=}C(N{=}CCl_2){-}CH_3$$

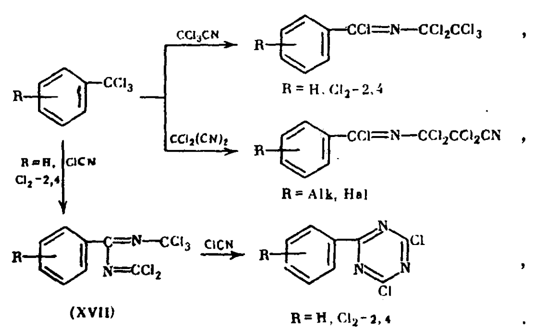
However, in those cases where the olefin contains an acid group or an electrophile capable of introducing such groups is used, the reaction does not stop with formation of carboimidoyl dichloride:



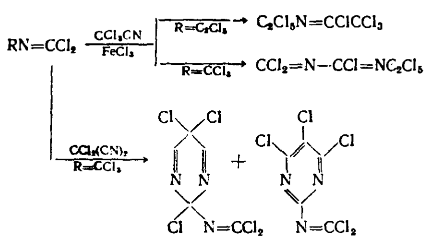
$$CH_3CH{=}CHCOOH + Cl_2 + ClCN \rightarrow \left[CH_3{-}CH(N{=}CCl_2){-}CH(Cl){-}COOH\right] \xrightarrow{-HCl} CH_3{-}CH(N{=}C{=}O){-}CH(Cl){-}COCl$$

$$(CH_3)_2C{=}CH_2 + Cl{-}SO_3H + ClCN \rightarrow \left[CH_3{-}C(CH_3)(N{=}CCl_2){-}CH_2{-}SO_3H\right] \xrightarrow{-HCl} CH_3{-}C(CH_3)(N{=}C{=}O){-}CH_2SO_2Cl$$

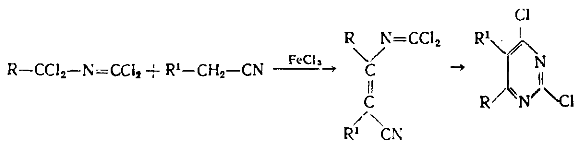
N-Polychloroalkylimidoyl chlorides or dichlorides are formed on interaction of activated nitriles, such as chlorocyanogen, trichloroacetonitrile, 2,2,3-trichloropropionitrile, and dichloromalonidinitrile with compounds having the CCl_3 or CCl_2H groups.[177,178] The reactions are catalysed by $FeCl_3$ or $AlCl_3$. The addition of chlorine-containing compounds to the activated nitrile group takes place in the first stage and is followed by the migration of chlorine (chlorotropism), which results in the formation of imidoyl chlorides or dichlorides. In a number of instances at low temperatures, the processes can be arrested at this stage. In other cases the formation of heterocyclic compounds is observed. Thus imidoyl chlorides are the main products of the reaction of dichloroacetonitrile with trichloromethylbenzenes,[177] but in the reaction with chlorocyanogen cyclisation to substituted triazines takes place readily and the intermediate carboimidoyl dichloride (XVII) could be isolated in small amounts only in the case of 2,4-dichloro-1-trichloromethylbenzene:[178]



Imidoyl chlorides have also been isolated in the reactions of trichloromethylbenzenes with dichloromalonodinitrile,[177] while the reaction with benzylidenechloro-derivatives gave rise to pyrimidine derivatives.[178] Trichloromethoxybenzenes and carboimidoyl dichlorides with perchloroalkyl groups have also been used as the polychloroalkyl component:[177–179]

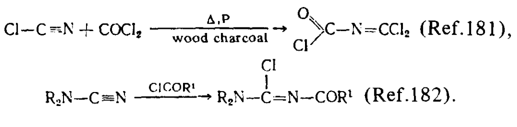


It has also been found that, in the presence of Lewis acids and at elevated temperatures, carboimidoyl dichlorides of the type $RCCl_2N{=}CCl_2$ react with nitriles having two hydrogen atoms in the α-position, affording chloropyrimidines.[180] The elimination of HCl is rate determining in this two-stage reaction. In most cases the reaction can be stopped at the first stage involving the formation of carboimidoyl dichloride:



R=Cl, CCl_3, C_6H_5; R^1=H, Cl, CH_3, C_6H_5 etc.

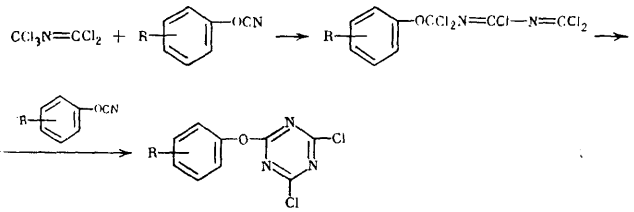
The reaction proceeds analogously also when the α-chlorine atoms in carboimidoyl dichloride have been substituted by hydrogen and the α-hydrogen atoms of the nitrile have been substituted by chlorine. *N*-Acylimidoyl chlorides and dichlorides can be obtained from nitriles and acyl chlorides:



$$Cl{-}C{\equiv}N + COCl_2 \xrightarrow[\text{wood charcoal}]{\Delta,P} \overset{O}{\underset{Cl}{>}}C{-}N{=}CCl_2 \quad \text{(Ref.181)},$$

$$R_2N{-}C{\equiv}N \xrightarrow{ClCOR^1} R_2N{-}C(Cl){=}N{-}COR^1 \quad \text{(Ref.182)}.$$

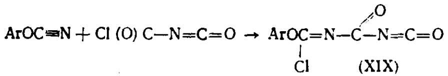
Like nitriles, phenyl isocyanates react with *N*-trichloromethylcarboimidoyl dichloride, giving rise to heterocyclic derivatives.[178] In some cases it is possible to isolate small amounts of the primary products of the chlorotropic rearrangement:



R = H, Cl-4, Cl_2-2,4, $(CH_3)_2$-2,4

Cyanates react with acyl chlorides similarly to nitriles.[182] The reaction is carried out by heating in inert solvents, the yield of products being 45–90%. Phosgene reacts at 0–20 °C.

The electrophilic addition of chloroformyl isocyanate to aromatic cyanates leads to compounds of type (XIX):[181,183]

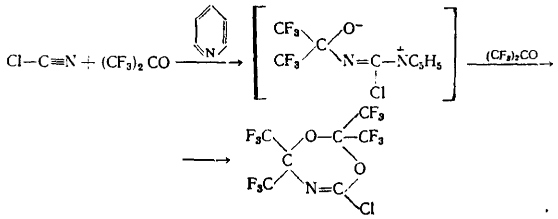


$$ArOC{\equiv}N + Cl(O)C{-}N{=}C{=}O \rightarrow ArOC(Cl){=}N{-}C({=}O){-}N{=}C{=}O$$

(XIX)

Ar = C_6H_5, 4-$CH_3C_6H_4$, 4-ClC_6H_4.

The interaction of chlorocyanogen with hexafluoroacetone in the presence of pyridine results in the formation of chlorodioxazine:[184]



N-Bromocarboimidoyl difluoride has been obtained by brominating fluorocyanogen in the presence of alkali metal fluorides:[185]

$$FC{\equiv}N + Br_2 \xrightarrow{MF} [CF_2{=}\overset{-}{N}\,\overset{+}{M}] \xrightarrow{Br_2} CF_2{=}N{-}Br$$
$$M{=}K,\ Cs,\ Rb$$

It has been suggested that *N*-pentafluorotelluroimidoyl chloride and dichloride be obtained by the photolysis of chlorocyanogen or trifluoromethylcyanogen with TeF_5Cl. Up to 10% of tetrachloro-2,3-diazabuta-1,4-diene is then obtained as a side product.[186]

The radical addition of perfluoroalkyl iodides to isonitriles with primary or secondary alkyl groups is a method of synthesis of imidoyl iodides with perfluoroalkyl groups:[187,188]

$$RNC + R_FI \rightarrow RN{=}C(I)R_F$$
$$R = n\text{-}C_4H_9,\ cyclo\text{-}C_6H_{11};\ R_FCF_3(CF_2)_n\ (n = 3, 5, 7).$$

However, there is no condensation with t-alkyl or aromatic isonitriles under these conditions. By carrying out the reactions in the presence of copper, it has been possible to involve in them also the nitriles indicated above. The yields of imidoyl iodides are mainly 70–90%. The mechanism of the copper-catalysed reaction involves the oxidative addition of R_FI to the copper complex of the isonitrile and the subsequent migration of the perfluoroalkyl group and iodine to the isonitrile ligand.

Direct fluorination of isonitriles by a stream of elemental fluorine diluted with argon or nitrogen makes it possible to obtain carboimidoyl difluoride:[189]

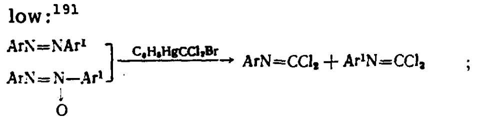
$$RNC + F_2 \rightarrow RN{=}CF_2\quad,$$
$$R = t\text{-}C_4H_9,\ C_6H_5,\ 2\text{-}FC_6H_4,\ 4\text{-}ClC_6H_4.$$

N-Trifluoromethylimidoyl halides are formed in the reactions of *N*-trifluoromethylisonitrile with HHal or SF_5Br.[190]

V. REACTIONS OF COMPOUNDS WITH A NITROGEN–NITROGEN MULTIPLE BOND

Azides, azo-compounds, and azoxy-compounds react with dichlorocarbene, generated in the course of the reaction from phenyltrihalogenomethylmercury, giving rise to carboimidoyl dichlorides.[191,192] Thus the decomposition of phenyl azide in the presence of phenyltrichloromethylmercury leads to *N*-phenylcarboimidoyl dichloride in 70% yield. Sodium trichloroacetate or ethyl trichloroacetate can also serve as a source of dichlorocarbene. The reaction kinetics has been investigated for phenyl, p-methoxyphenyl, and p-chlorophenyl azides.[192]

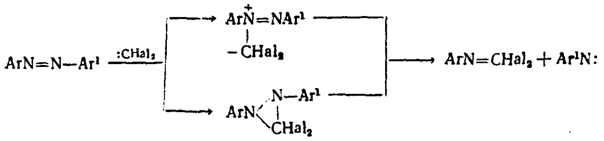
The reaction of an excess of azo- and azoxy-benzenes with bromodichloromethylphenylmercury results in the formation of a mixture of the same carboimidoyl chlorides. The azoxy-compounds are apparently initially deoxygenated by the organomercury derivative and the resulting azobenzenes react with dichlorocarbene. The overall yield of the products is low:[191]



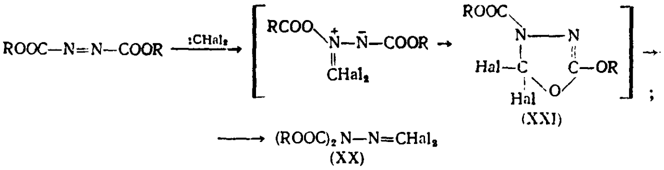
$$\left.\begin{array}{l} ArN{=}NAr^1 \\ ArN{=}N(\rightarrow O){-}Ar^1 \end{array}\right] \xrightarrow{C_6H_5HgCCl_2Br} ArN{=}CCl_2 + Ar^1N{=}CCl_2\quad;$$

$$Ar = C_6H_5,\ 4\text{-}ClC_6H_4,\ 4\text{-}CH_3C_6H_4;\ Ar^1 = C_6H_5,\ 4\text{-}ClC_6H_4.$$

The mechanism of the formation of carboimidoyl dichloride can include the participation of open-chain or cyclic intermediates, for example:



The reaction of trihalogenomethylmercury derivatives with aliphatic azo-compounds proceeds differently.[193] Depending on the mercury compound, azodicarboxylate esters afford dichloro-, dibromo-, or bromochloro-derivatives of compound (XX):

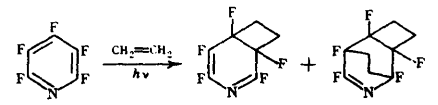


R=CH₃, C₂H₅; Hal=Cl, Br .

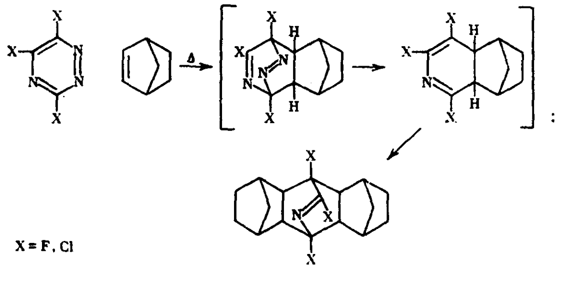
The reaction begins with the electrophilic attack by the nitrogen atom on the dihalogenocarbene with subsequent formation of intermediate 1,3,4-oxadiazolines (XXI), which have been detected spectroscopically.

VI. REACTIONS OF COMPOUNDS WITH A CARBON–CARBON MULTIPLE BOND

Compounds with the imidoyl chloride or imidoyl fluoride groups incorporated in a ring are formed in the photochemical Diels–Alder addition of unsaturated hydrocarbons to nitrogen-containing heterocycles. Thus the reactions of pentafluoropyridine with linear and cyclic olefins and also with acetylenic derivatives give rise to 1:1 and 2:1 adducts containing the imidoyl fluoride group:[194–196]



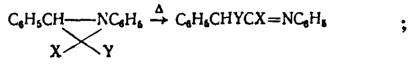
The thermal reactions of 3,5,6-trifluoro- or 3,5,6-trichloro-1,2,4-triazines with olefins proceed in a more complex manner, but in this case too the products are compounds with a halogenoimidoyl group,[197] for example:



X = F, Cl

VII. THERMOLYSIS OF 3,3-DIHALOGENOAZIRIDINES

3,3-Dihalogeno-1,2-diphenylaziridines are converted into *N*-phenylimidoyl halides in various solvents at 80–100 °C:[198]



$X=Y=Cl, Br; X=Cl, Y=Br; X=F, Y=Br; X=F, Y=Cl$.

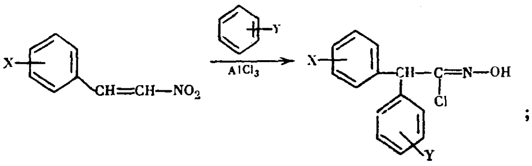
This thermal isomerisation involves the 1,2-migration of the halogen and the dissociation of the adjoining C–N bond with the opening of the aziridine ring. The study of the reaction kinetics and analysis of the calculated data made it possible to establish the reaction mechanism. The series based on the capacity of the halogens for migration, namely Br > Cl > F, found is consistent with the C–Hal bond energies. The rate of isomerisation depends not only on the nature of the migrating halogen but also on the halogen which remains. Fluorine significantly facilitates migration compared with chlorine and bromine.

The yields of the imidoyl halides are fairly high. 3,3-Dibromo-1,2-diphenylaziridine is thermally less stable than the corresponding dichloro-derivative. Tetrachloroaziridines are thermally more stable than dichloroaziridines, but at 180 °C the two isomerise to imidoyl chlorides:[191]

The rearrangement of tetrachloro-*N*-isopropylaziridine does not take place even on prolonged heating.

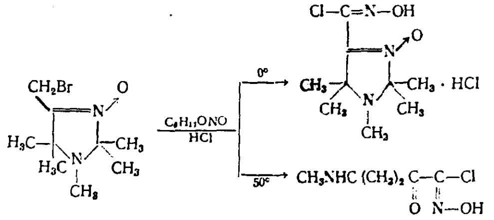
VIII. OTHER METHODS

New diarylacetohydroximoyl chlorides have been obtained by the reaction, already known previously, of β-nitrostyrenes with aromatic hydrocarbons in the presence of Lewis acids, which proceeds via 1,4-addition to the conjugated nitro-olefin chain:[199,200]

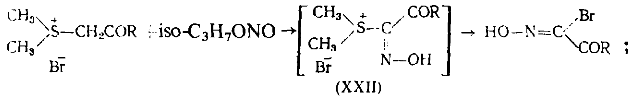


$X = 2\text{-Br};\ 2,4\text{-Cl}_2;\ 2,6\text{-Cl}_2; 2\text{-Cl}, 6\text{-F};$
$Y = H, 4\text{-CH}_3, 4\text{-C}_2H_5, 4\text{-iso-C}_3H_7, 4\text{-Br}, 4\text{-F}, 4\text{-Cl}.$

The reactions of β-nitrostyrenes with acetyl chloride form under these conditions, together with other products, *N*-acetoxyphenylchloroacetotrihydroximoyl chlorides, whose yield depends significantly on the Lewis acid employed (it is a maximum for $TiCl_4$) and the substituents in the nitrostyrene molecule.[201,202] In the reaction with benzoyl chloride in the presence of triethylamine, trifluoronitroethane is converted into trifluoroacetohydroximoyl chloride (yield 30%).[203] Certain heterocyclic hydroximoyl chlorides have been obtained by the conversion of the corresponding halogenomethyl derivatives into oximes by treatment with isopentyl nitrite in hydrochloric acid.[204,205] In a series of 3-imidazoline 3-oxides, the formation of the hydroximoyl chloride at an elevated temperature is accompanied by the opening of the heterocyclic ring:



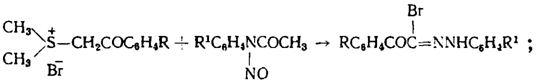
Hydroximoyl bromides have been obtained in satisfactory yields by the reactions of isopropyl nitrite with sulphonium bromides.[206] Under these conditions, the salt (XXII) is apparently formed initially and then undergoes intramolecular nucleophilic substitution by the bromide ion with formation of a sulphide:



$R=C_6H_5, CH_3, OC_2H_5$.

The nitrosation of dimethylphenylacylsulphonium bromide with sodium nitrite and HCl in aqueous dioxan leads to benzoylhydroximoyl chloride, also in a high yield.[207] Similar chlorides are formed effectively also in the nitrosation of β-ketosulphoxides with sodium nitrite in HCl, which is a fairly convenient and general method of synthesis of hydroximoyl chlorides of this kind.[208]

The azo-coupling reaction between sulphonium bromides and *N*-nitrosoacetanilides, which is similar to their nitrosation reaction, in non-aqueous solvents leads to hydrazonobromides:[209]

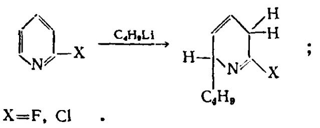


$$(CH_3)_2\overset{+}{S}\text{–}CH_2COC_6H_4R\ \bar{Br} + R^1C_6H_4N(NO)COCH_3 \rightarrow RC_6H_4COC(Br){=}NNHC_6H_4R^1\ ;$$

$R = H, 4\text{-CH}_3, 4\text{-Br}, 4\text{-NO}_2;\ R^1 = H, 4\text{-CH}_3, 4\text{-OCH}_3, 4\text{-Cl}.$

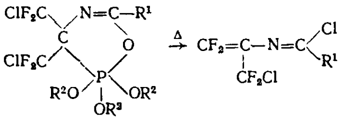
Imidoyl fluorides and difluorides are also formed in the photolysis of various polyfluoro-compounds. Thus perfluoroimidoyl fluorides and difluorides with a linear structure have been obtained in this way from perfluoroaza- and perfluorodiaza-cyclohexadienes;[210] *N*-(1-Chloro-octafluorobutyl)carboimidoyl difluoride has been obtained in 22% yield from *N*-chloroperfluoropiperidine.[211] The low-temperature photolysis of 1-adamantyl nitrite in the presence of trichloronitrosomethane results in the formation of up to 5% of *N*-[*O*-(1-adamantyl)]carboimidoyl chloride, which was isolated and characterised.[212]

Relatively unstable cyclic imidoyl fluorides and chlorides are formed from 2-fluoro and 2-chloro-pyridines by their reaction with butyl-lithium:[213]



X=F, Cl .

The thermolysis of 2,3-dihydro-1,4,2,λ^5-oxazaphosphole derivatives leads to reactive *N*-vinylimidoyl chlorides:[214]



$R^1 = t\text{-}C_4H_9, C_6H_5, 4\text{-}CH_3C_6H_4, 4\text{-}ClC_6H_4, CH{=}CH\text{-}C_6H_5$; $R^2 = CH_3, C_6H_5$.

---o0o---

During the preparation of the manuscript for printing, new data were published on the synthesis of various compounds with halogenoimidoyl groups or on their formation as intermediates. Most of these communications are concerned with the reactions of nitriles and isonitriles with acyl halides,[215-219] sulphenyl chlorides or sulphur dichloride,[220-222] and the halogens (chlorine and bromine) in the presence of mercury difluoride,[223] and also with the reactions of amide groups on treatment with PCl_5.[224-227] Halogenoimidoyl derivatives have also been obtained or have been postulated in the chlorination of aldoximes,[228] in the interaction of perhalogenoalkylamines with SbF_5 [229] or in their thermolysis,[223] in the reactions of substituents in compounds already containing the halogenoimidoyl group,[222,230] and in certain other reactions.[231-237]

The main trend in these investigations has been the study of the configurations of different halogenoimidoyl groups by spectroscopic methods and the synthesis of the individual isomers and their interconversions.[228,237-239]

Pyrido[2,3-*d*] pyrimidines

A.Sh.Oganisyan, A.S.Noravyan, and S.A.Vartanyan

The methods of synthesis and the chemical and biological properties of pyrido[2,3-*d*] pyrimidines are described. The bibliography includes 270 references.

CONTENTS

I. Introduction 1140
II. Methods of synthesis 1140
III. Chemical reactions 1145
IV. Biological properties 1148

I. INTRODUCTION

In recent years investigators have shown much interest in pyrido[2,3-*d*]pyrimidines—heterocyclic systems with a broad spectrum of biological properties[1–4] some of which have found applications in medicine as medicinal preparations.[5,6] Only one review has been published on the synthesis of pyrido[2,3,d]pyrimidines, covering the literature data up to 1968[7] including also recent information about their chemical reactions and biological properties.

As a result of the theoretical and practical interest in pyrido[2,3-*d*]pyrimidines, many publications devoted to new methods of synthesis, chemical reactions, and biological properties of compounds of this class have appeared during the last 15 years, so that it is of interest to survey and treat systematically the available literature data.

II. METHODS OF SYNTHESIS

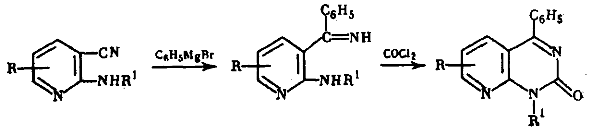
Condensed pyridopyrimidines can be synthesised from both pyridine and pyridimine derivatives.

1. Synthesis from Pyridines

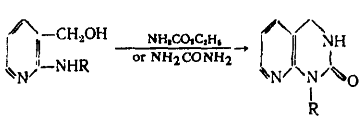
This section deals with the synthesis of pyrido[2,3-*d*]-pyrimidines with various functions group substituents in the pyrimidine ring from pyridines containing active groups in the 2- and 3-positions, which interact with the corresponding reactants, the reaction leading to closure of the pyrimidine ring.

(a) *2-Oxo-derivatives*

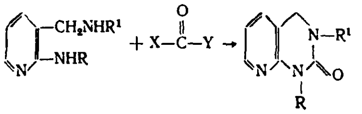
2-Oxo-4-phenyl-1,2-dihydropyrido[2,3-*d*]pyrimidines have been synthesised from 2-amino-2-cyanopyridines by reaction with a Grignard reagent and then with phosgene:[8–10]



Another method consists of the condensation of 2-amino-3-benzoylpyridines with urethane[9] or urea.[11] Under analogous conditions, 2-amino-3-hydroxymethyloyridines cyclise to the corresponding oxotetrahydropyrido[2,3-*d*]-pyrimidines:[12]

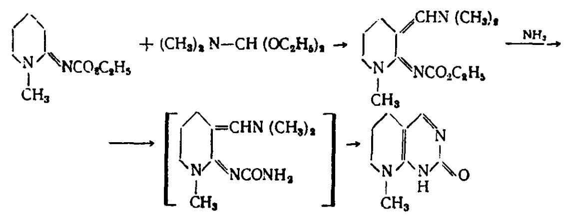


Analogues of these compounds containing substituents in the 3-position in the pyridine ring have been obtained by condensing 2-amino-3-aminomethylpyridines with various carbonic acid derivatives:[13]



X = halogen, alkoxy-group, amino-group; Y = halogen, alkoxy-group, trihalogenoalkyl.

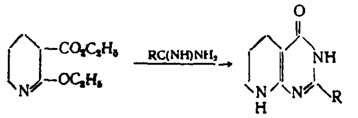
2,2-Dialkoxy-2-methylpiperidine has been used to synthesise *N*-methyl-2-oxohexahydropyridopyrimidines by its condensation with urethane to form an amidine. The reaction of the latter with dimethylformamide acetal yielded aminomethylene-ethoxycarbonyliminopiperidine whose treatment with aqueous ammonia led to the closure of the pyrimidine ring with the simultaneous elimination of dimethylamine:[14]



2-Oxodihydropyrido[2,3-*d*]pyrimidines have also been obtained by condensing 3-acetyl-2-pyridones with urea.[15]

(b) *4-Oxo-derivatives*

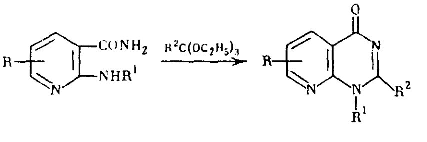
Methods of synthesis of 2-substituted 4-oxo-3,4,5,6,7,8-hexahydropyrido[2,3-d]pyrimidines from 3-ethoxycarbonyl-2-ethoxy-3,4,5,6-tetrahydropyridine have been developed:[16]



R=NH₂, CH₃

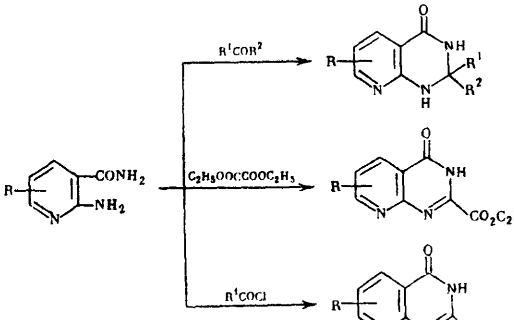
The methods of synthesis of analogous pyridopyrimidines containing alkyl groups at the nitrogen atom of the piperidine ring[17,18] and an angular substituent in the 10-position[16] have also been investigated.

2-Amino-3-carbamoylpyridines, whose condensation with orthoesters leads to the closure of the pyrimidine ring, are convenient starting materials for the synthesis of 1-substituted 4-oxo-1,4-dihydropyrido[2,3-d]pyrimidines:[19-25]

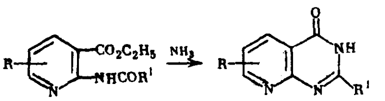


R²=H, alkyl, phenyl

The reactions of 2-amino-3-carbamoylpyridines with aldehydes or ketones,[26] diethyl oxalate,[29] and acid chlorides[30] result in the formation of the corresponding 4-oxopyridopyrimidines:

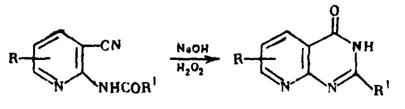


On treatment with alcoholic ammonia, 2-acylamino-3-ethoxycarbonylpyridines cyclise to form 2-substituted 4-oxodihydropyrido[2,3-*d*]pyrimidines:[30-32]

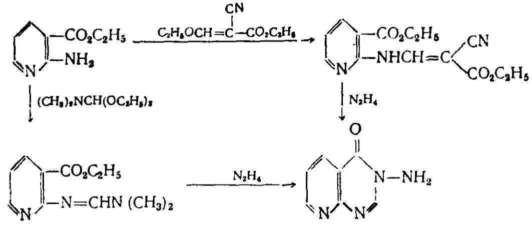


The hydrochlorides of various amines are used instead of ammonia as the cyclising agents for the synthesis of 2,3-substituted 4-oxodihydropyridopyrimidines from acylaminopyridines and the reaction is carried out in the presence of phosphorus pentoxide.[33]

2-Acylamino-3-cyanopyridines undergo an interesting reaction with sodium hydroxide and hydrogen peroxide, which yields 4-oxodihydropyridopyrimidines:[34,35]

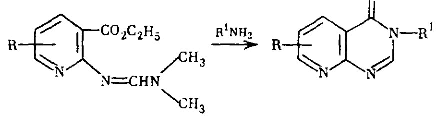


3-Amino-4-oxodihydropyrido[2,3-*d*]pyrimidine has been synthesised by condensing 2-amino-3-ethoxycarbonylpyridine with ethyl ethoxymethylenecyanoacetate or dimethylformamide acetal, this being followed by treating the intermediates with hydrazine hydrate:[36]

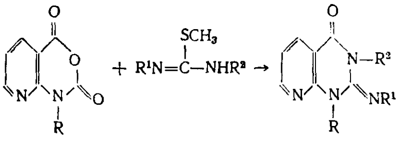


The reaction of 2-amino-3-hydrazinocarbonylpyridine with dimethylformamide diacetal gives an analogous result.[37]

On treatment of *N*-(2-pyridyl)amidines with various amines, intramolecular cyclisation takes place with formation of 3-substituted 4-oxodihydropyrido[2,3-*d*]pyrimidines:[38]

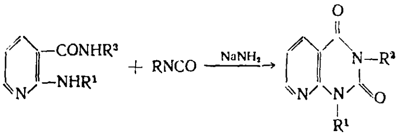


The reaction of thiourea derivatives with 1-substituted 2,4-dioxo-1,2-dihydro-4*H*-pyrido[2,3-d]1,3-oxazines, obtained by condensing aminopyridines with phosgene, has been used to synthesise various derivatives of 4-oxopyridopyrimidines:[39,40]



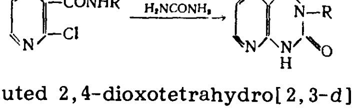
(*c*) 2,4-Dioxo-derivatives

One of the commonest methods of synthesis of 1,3-disubstituted 2,4-dioxotetrahydropyrido[2,3-*d*]pyrimidines is the condensation of derivatives of 2-amino-3-carbamoylpyridines with isocyanates in the presence of sodium amide:[41-45]

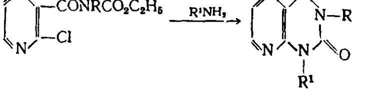


Analogous compounds have been obtained by cyclising aminocarbamoylpyridines with phosgene, chlorocarbonic acid ester or amide, and urea.[46-51]

The interaction of 2-chloro-3-carbamoylpyridines with urea afforded high yields of 3-substituted 2,4-dioxotetrahydropyridopyrimidines:[52,53]

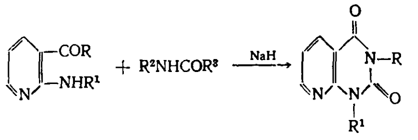


1,3-Disubstituted 2,4-dioxotetrahydro[2,3-*d*]pyrimidines can be synthesised from derivatives of 2-chloro-3-carbamoylpyridines containing the ethoxycarbonyl group at the nitrogen atom in the amide group condensing with amines:[54]



The synthesis of 1,3-disubstituted pyridopyrimidines from 2-chloro-3-carbamoylpyridines and isocyanates has been described.[55]

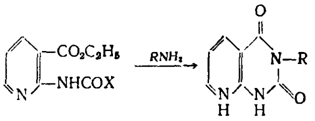
The corresponding 1,3-disubstituted dioxopyrimidines have been synthesised by condensing 3-substituted 2-halogeno-carbamoylpyridines with carbamates in the presence of sodium hydride in dimethylformamide (DMF).[56] The interaction of the same carbamates with 2-amino-3-ethoxycarbonyl- or 2-amino-3-carbamoyl-pyridines results in the formation of analogous pyridopyrimidines with a different disposition of the substituents in the pyrimidine ring—in the 1- and 3-positions:[57]



$R=OC_2H_5$, NH_2; R^3=halogen, heterocycle.

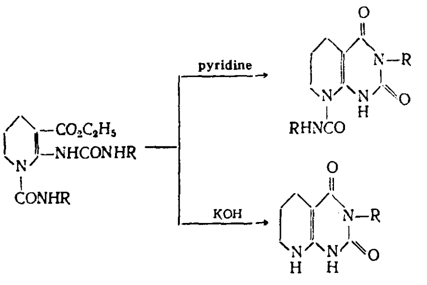
One of the ways of synthesising 2,4-dioxopyrido[2,3-*d*]-pyrimidines is condensation of 2-amino-3-carboxy- or 2-amino-3-ethoxycarbonyl-pyridines with urea, urethanes, or isocyanates.[58–65]

It has been shown that refluxing of 2-amino-3-ethoxycarbonylpyridine with chlorocarbonic esters or amide leads to the formation of 2-alkoxycarbonylamino- or ureido-derivatives of pyridine, which cyclise on treatment with amines to the corresponding dioxopyridopyrimidines:[66]

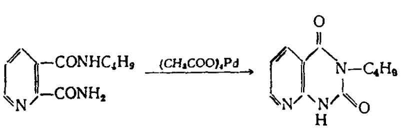


X = alkoxy-group, NH_2.

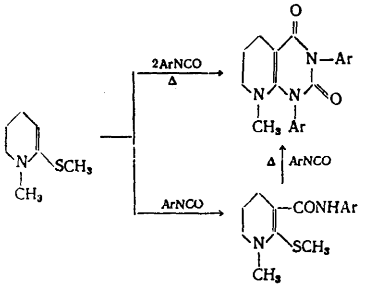
The interaction of 2-amino-3-ethoxycarbonyl-1,4,5,6-tetrahydropyridine with isocyanate yielded diureido-derivatives which cyclise in the presence of pyridine or potassium hydroxide to the corresponding 2,4-dioxo-octahydropyridopyrimidines:[67]



A novel method of synthesis of 3-butyl-2,4-dioxotetrahydropyrido[2,3-d]pyrimidine involves the refluxing of 2,3-dicarbamoylpyridine in DMF in the presence of palladium tetra-acetate:[68]



Single-stage and two-stage syntheses of 1,3-diaryl-2,4-dioxo-octahydropyridopyrimidines from 1-methyl-2-methylthiotetrahydropyridine and aryl isocyanates in accordance with the scheme

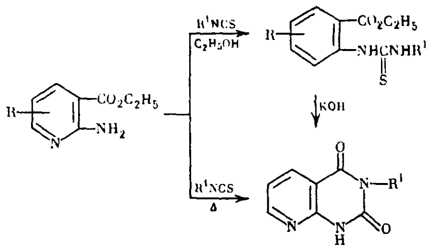


have been proposed.[69,70] The use of aryl isothiocyanates makes it possible to obtain the corresponding 2,4-dithiono-derivatives.[71]

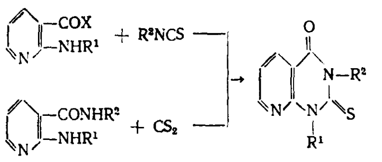
2,4-Dioxopyridopyrimidines can also be synthesised from dioxopyrido[2,3-d]-1,3-oxazine by treatment with amines and phosgene.[72,73]

(*d*) *4-Oxo-2-thionopyrido[2, 3-d]pyrimidines*

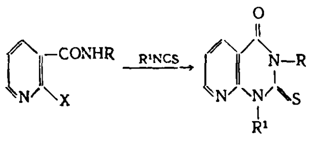
One of the convenient methods of synthesis of 4-oxo-2-thionotetrahydropyrido[2,3-*d*]pyrimidines involves the thermal cyclisation of 3-alkoxycarbonyl-2-aminopyridines by reaction with isothiocyanates with or without the isolation of the intermediate thioureidopyridines:[74–78]



1,3-Disubstituted compounds have been obtained from the esters or amides of 2-aminopyridine-3-carboxylic acids and various isothiocyanates[79] or carbon disulphide:[80,81]

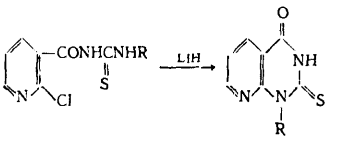


Analogous pyridopyrimides have been obtained by the reaction of 3-carbamoylpyridines, containing halogeno-, alkoxy-, alkylthio-, and sulphoxy-groups in the 2-position in the pyridine ring, with isothiocyanates:[82–84]



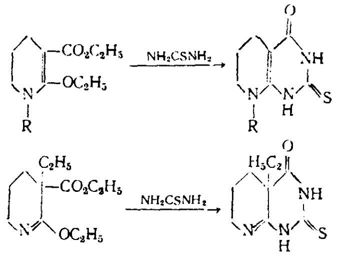
When 2-chloro-3-ethoxycarbonylpyridines are refluxed with thiourea derivatives in ethanol saturated with hydrogen chloride, the corresponding pyridopyrimidines are formed in low yields.[85–87]

1,3-Disubstituted 4-oxo-2-thionotetrahydropyridopyrimidines have been synthesised by cyclising 2-chloroicotinoylthioureas in the presence of lithium hydride:[88]



1,3-Diaryl-8-methyl-4-oxo-2-thiono-1,2,3,4,5,6,7,8-octahydropyrido[2,3-d]pyrimidines have been obtained by the reaction of 3-arylcarbamoyl-1-methyl-2-methylthiotetrahydropyridine with aryl isothiocyanate.[69]

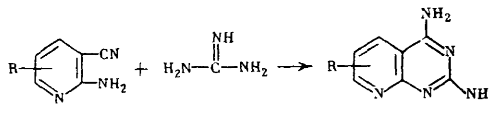
The esters of the lactim form of 3-ethoxycarbonylpiperidin-2-ones are convenient starting compounds for the synthesis of various pyrido[2,3-*d*]pyrimidines which cannot be synthesised in other ways:[16–18]



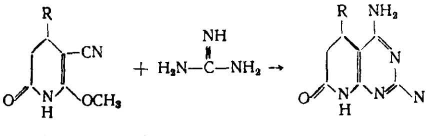
The synthesis of 4-imino-1,3-dimethyl-2-thionotetrahydropyrido[2,3-d]pyrimidine by condensing 2-chloro-3-cyanopyridine with *NN*′-dimethylthiourea has been reported.[89]

(e) *2,4-Diaminopyrido[2,3-d]pyrimidines and Other Derivatives*

2-Amino-3-cyanopyridines readily react with guanidine to form derivatives of 2,4-diaminopyrido[2,3-*d*]pyrimidines:[90,91]

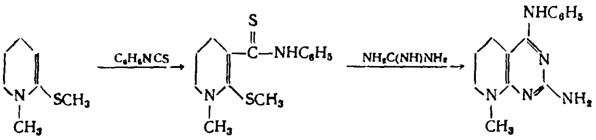


Another method of synthesis of 2,4-diaminopyridopyrimidines involves the reaction of 3-cyano-2-methoxypyridines with guanidine:[92]

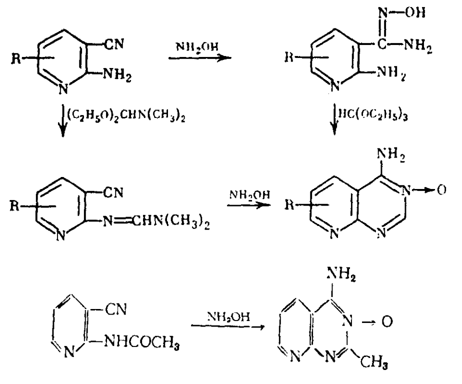


A pyridopyrimidine with an analogous structure has also been synthesised by condensing ethyl 4,4-dicyanobutyrate with guanidine.[93]

The reaction of 1-methyl-2-methylthiotetrahydropyridine with phenyl isothiocyanate afforded the corresponding thioamide, which cyclises on treatment with guanidine:[93]



The methods of synthesis of certain pyrido[2,3-d]pyrimidines, in particular the 3-*N*-oxides of 4-aminopyridopyrimidines, from 2-amino-3-cyanopyridines in accordance with the scheme[95,96]



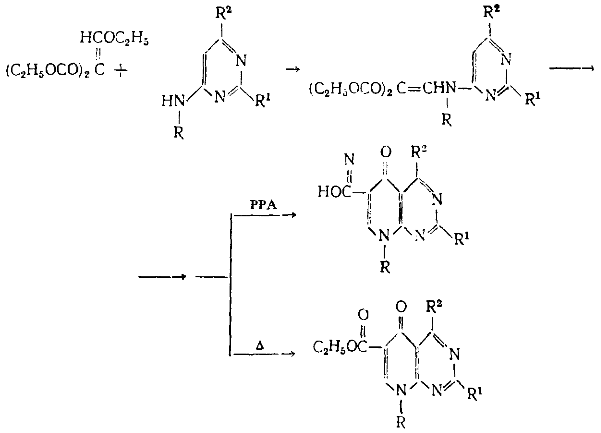
which have been described in the literature, are of interest.

The unsubstituted 5,6,7,8-tetrahydropyrido[2,3-d]pyrimidine has been obtained by condensing 2-piperidinone with formamide in the presence of phosphoryl chloride.[97,98]

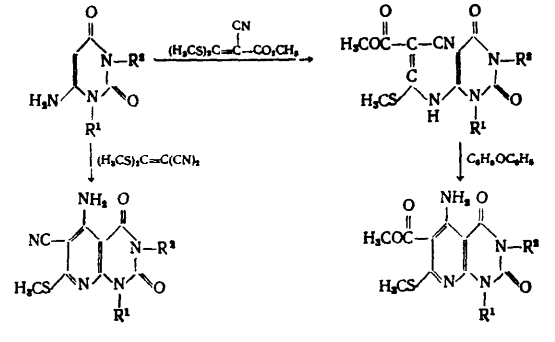
2. Synthesis from Pyrimidines

The methods described in this Section make it possible to obtain pyridopyrimidines with various substituents in the pyridine ring by forming the pyridine ring from pyrimidines with functional group substituents.

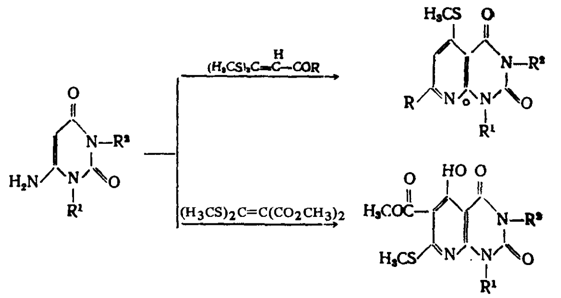
One of the commonest methods of synthesis of pyrido[2,3-*d*]pyrimidines involves the condensation of 4-aminopyrimidines with ethoxymethylenemalonic ester with subsequent cyclisation of the resulting compounds by treatment with phosphoryl chloride[99,100] or by refluxing in diphenyl ether.[101–105] Cyclisation in polyphosphoric acid (PPA) results in the formation of pyridopyrimidines with a carboxy-group in the pyridine ring:[106]



The reaction of 4-aminopyrimidines with cyanoethoxymethyleneacetic acid esters afforded the corresponding methyleneaminopyrimidines whose cyclisation is achieved in ethyl phosphate with subsequent hydrolysis by sodium hydroxide.[107] The condensation of 1,3-disubstituted 6-aminouracils with 2-cyano-3,3-bis(methylthio)acrylonitrile results in the formation in a single stage of 1,3-disubstituted 5-amino-6-cyano-7-methylthio-2,4-dioxo-1,2,3,4-tetrahydropyrido[2,3-d]pyrimidines. However, the reaction of the same 6-aminouracils with 2-cyano-3,3-bis(methylthio)acrylate under analogous conditions is accompanied by the formation of intermediates the heating of which in diphenyl ether also leads to the formation of pyridopyrimidines:[108]



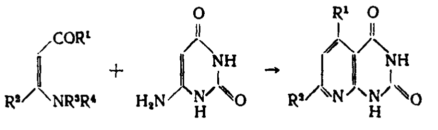
Other pyrido[2,3-d]pyrimidines containing various substituents in the pyridine ring were synthesised in the same study from 6-aminouracils in accordance with the scheme



New derivatives of pyridopyrimidines have been obtained by refluxing aminouracils with dimethyl acetylenedicarboxylate in protic solvents.[109,110]

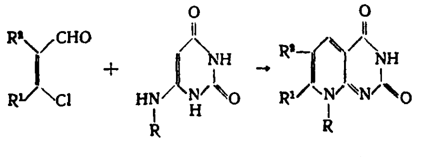
The reaction of 6-amino-1,3-dimethyluracil with unsaturated diketones also proceeds with formation of the pyridine ring.[111]

It has been shown that tetrahydropyrido[2,3-d]pyrimidines can be obtained in high yields by the reaction of 6-aminouracils with β-aminovinyl ketones:[112,113]

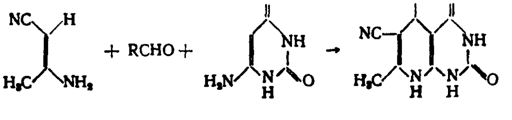


The cyclisation of 6-amino-1,3-dimethyluracil by reaction with unsaturated carbonyl compounds is carried out in the presence of basic or acid catalysts.[114]

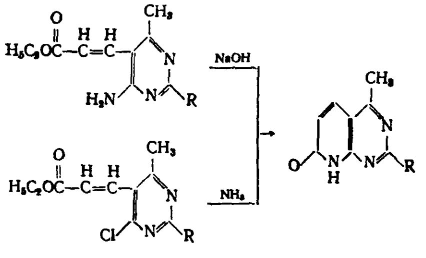
Heating of 6-aminouracils with β-chloro-substituted αβ-unsaturated carbonyl compounds in DMF leads to the formation of 6,7,8-trisubstituted pyridopyrimidines:[115]



A novel method of synthesis of certain pyridopyrimidine derivatives involves the interaction of 6-aminouracils with bisacetonitrile and aldehydes:[116]

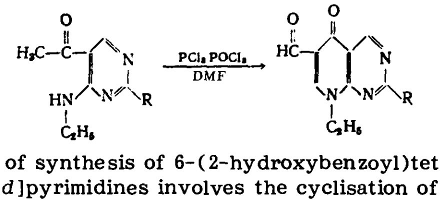


Methods of synthesis of 2-substituted 4-methyl-7-oxopyridopyrimidines based on the reaction of 2-substituted 4-amino-5-iodo-6-methyl- and 5-iodo-6-methyl-4-oxo-pyrimidines with ethyl acrylate in accordance with the scheme

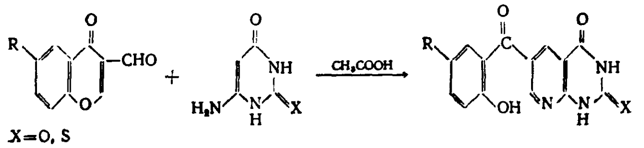


have been described.[117] Derivatives of 7-oxopyridopyrimidines can also be obtained by condensing 6-aminouracils with ethyl acrylate.[118]

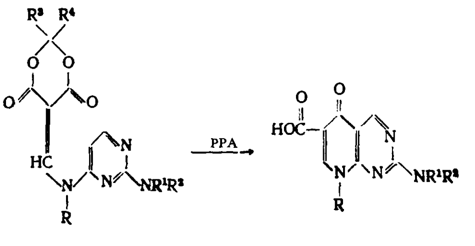
6-Formylpyridopyrimidines have been synthesised by the reaction of 2,4-diaminopyridines with DMF in the presence of phosphorus trichloride or phosphoryl chloride.[119] Other derivatives of 6-formylpyrido[2,3-*d*]pyrimidines have been synthesised under analogous conditions from 5-acetyl-4-ethylaminopyrimidines:[120,121]



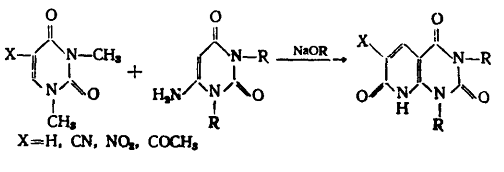
A method of synthesis of 6-(2-hydroxybenzoyl)tetrahydropyrido[2,3-*d*]pyrimidines involves the cyclisation of 4-aminouracils by reaction with chromene derivatives in acetic acid:[122]



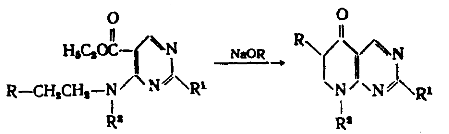
A new method of synthesising derivatives of 6-carboxypyridopyrimidines via the scheme[123–125]



has been developed. A single-stage synthesis of pyridopyrimidines from two molecules of substituted uracils has been proposed:[126,127]

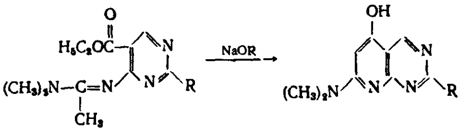


4-(2-Cyanoethyl)- or 4-(2-ethoxycarbonylethyl)-amino-5-ethoxycarbonyl pyrimidines, obtained by the reaction of 4-chloro-5-ethoxycarbonylpyrimidines with the nitriles or esters of 3-aminopropionic acids, cyclise on treatment with sodium alkoxides or hydride with formation of the corresponding 5-oxo-5,6,7,8-tetrahydropyrido[2,3-*d*]pyrimidines:[128–141]



When 4-amino-5-ethoxycarbonylpyrimidines are acylated with the chloride of the monoethyl ester of malonic acid in the presence of alkoxide, intramolecular cyclisation takes place with formation of 5,7-dioxo-5,6,7,8-tetrahydropyridopyrimidines.[142–144]

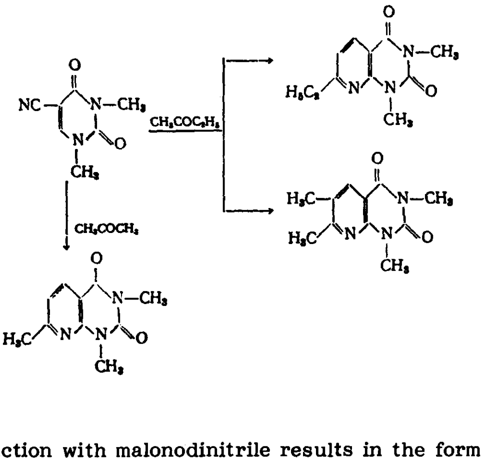
The amines formed as a result of the condensation of 4-amino-5-ethoxycarbonylpyrimidines with the diethyl acetal of dimethylacetamide in the presence of sodium alkoxide cyclise to 5-hydroxypyridopyrimidines:[145,146]



The condensation of 4-amino-5-methoxycarbonylpyrimidines with butenal, which led to the synthesis of *N*-substituted 5-oxo-6-vinyl-5,6-dihydropyridopyrimidine, has also been investigated.[147]

The reaction of 4-aminopyrimidines containing the formyl group in the 5-position with aryl acetonitriles, ketones, and cyanoacetamides yields the corresponding pyrido[2,3-*d*]-pyrimidines.[148–153]

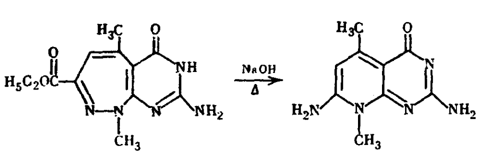
The condensation of 5-cyano-1,3-dimethyluracil with acetone involves the closure of the pyridine ring with formation of the trimethyl derivative, while treatement with butanone under the same conditions yields a mixture of the two isomeric dioxotetrahydropyrido[2,3-d]pyramidines:[154]



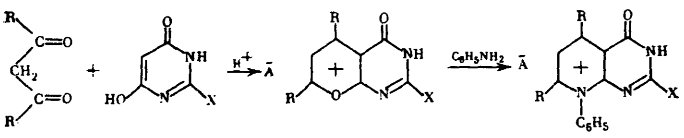
The reaction with malonodinitrile results in the formation of 7-amino-6-cyanodioxotetrahydropyrido[2,3-*d*]pyrimidine.[154]

Various derivatives of 2-thionopyridopyrimidines have been obtained by condensing arylidenethiobarbituric acid with malonodinitrile, ethyl cyanoacetate, and ethyl acetoacetate in the presence of ammonium acetate.[155]

An interesting condensation of 2-amino-4-(1-*N*-methylhydrazino)pyrimidine with ethyl 3-acetylpyruvate takes place with formation of 8-amino-3-ethoxycarbonyl-1,5-dimethyl-6-oxo-6,7-dihydropyrimido[4,5-*c*]-1,2-diazepine, whose treatment with potassium hydroxide leads to 2,7-diamino-5,8-dimethyl-4-oxo-4,8-dihydropyrido[2,3-d]pyrimidine:[156]



The synthesis of 8-phenylpyrido[2,3-*d*]pyrimidinium salts from 4,6-dihydroxypyrimidines and diketones via salts of pyrylio[2,3-*d*]pyrimidines in accordance with the following scheme has been reported:[158]



X = OH. SH. NH_2. SCH_3: A = ClO_4. H_2PO_4. CF_3COO

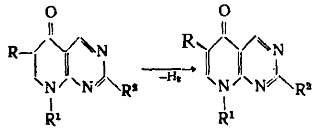
Treatment of pyrano[2,3-d]pyrimidine with aqueous ammonia solution leads to the replacement of the pyran ring by the pyridine ring, which results in the formation of 2,4-dioxopyridopyrimidine.[158]

III. CHEMICAL REACTIONS

The chemical reactions of condensed pyridopyrimidines can be carried out selectively, via the pyridine or pyrimidine ring, which makes it possible to obtain a large number of new derivatives of this series. The chemical reactions of pyridopyrimidines involving the opening of the pyrimidine ring have also been studied.

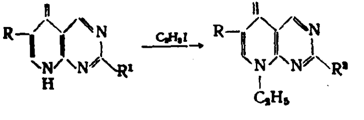
1. Reactions Via the Pyridine Component of the Molecule

It has been shown that 2,8-disubstituted 6-alkoxycarbonyl-5-oxo- or 6-cyano-5-oxo-tetrahydropyrido[2,3-*d*]pyrimidines are dehydrogenated on treatment with various dehydrogenating agents:[132,159–163]



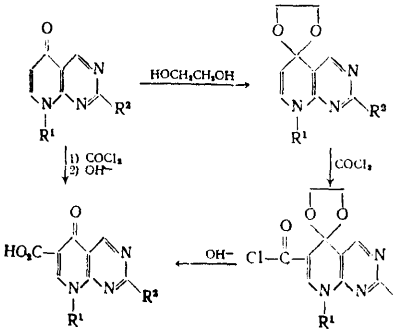
An analogous result has been obtained on brominating 2,8-disubstituted 5-oxotetrahydropyridopyrimidines with subsequent dehydrobromination of the products.[131,133,137]

5-Oxopyridopyrimidines are readily alkylated with ethyl iodide to form the corresponding 8-ethyl derivatives:[102–104,164,165]



Various methods of synthesis of derivatives of condensed pyridopyrimidines containing the carboxy-group in the 6-position have been developed.[102–104,132,133,166–174] Thus it has been shown that the hydrolysis of 6-ethoxycarbonylpyridopyrimidines leads to 6-carboxypyridopyrimidines in high yields.[102–104,132,133,166] 6-Formyl and 6-acyl derivatives of pyridopyrimidines are oxidised on treatment with various oxidants to the corresponding carboxypyridopyrimidines.[167,169] Heating of 6-oxazolidinylpyridopyrimidines in hydrochloric acid leads to the same result.[170]

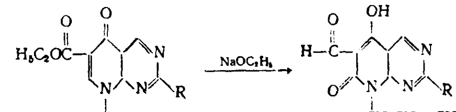
6-Carboxy-derivatives have been obtained in one or three stages from 8-alkyl-5-oxo-5,8-dihydropyridopyrimidines and phosgene:[171–173]



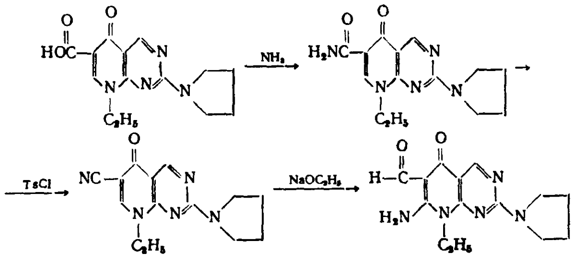
5-Alkylamino-6-carboxypyrido[2,3-d]pyrimidines can be obtained by hydrolysing 6-alkoxycarbonyl-5-alkylaminopyridopyrimidines.[174] Other workers established[147] that the oxidation of 6-vinylpyridopyrimidine with potassium permanganate leads to its 6-carboxy-derivative.

The alkylation of 8-alkyl-6-cyano- or 6-alkoxycarbonyl-8-alkyl-5-oxopyridopyrimidines has been investigated and it has been shown that the alkyl group enters the 6-position in the presence of sodium alkoxide.[132,136]

In the presence of sodium alkoxide, derivatives of 6-ethoxycarbonyl-5-oxo-5,8-dihydropyridopyrimidines are converted into the corresponding 6-formyl-5-hydroxy-7-oxopyrido[2,3-d]pyrimidines:[175]



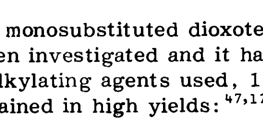
In the sams study the authors proposed the synthesis of 7-amino-8-ethyl-6-formyl-5-oxo-2-(1-pyrrolidino)-5,8-dihydropyrido[2,3-d]pyrimidine from 6-carboxypyridopyrimidine:



The oxo-group is substituted by chlorine atome when 5-oxopyridopyrimidines are treated with phosphoryl chloride. The subsequent interaction of 5-chloropyridopyrimidines with alcohols and amines leads to 5-alkoxy- and 5-amino-derivatives.[146]

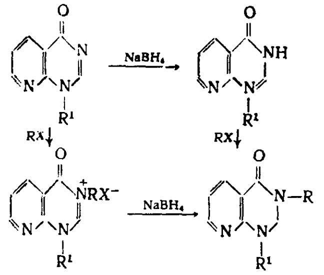
2. Reactions Via the Pyrimidine Component of the Molecule

The alkylation of monosubstituted dioxotetrahydropyridopyrimidines has been investigated and it has been shown that, regardless of the alkylating agents used, 1,3-disubstituted derivatives are obtained in high yields:[47,176–181]



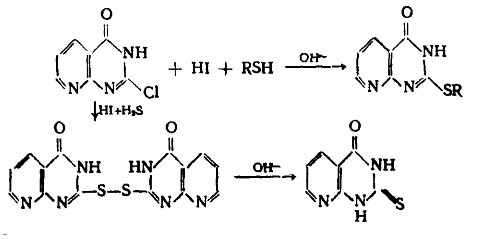
The alkylation of 1-substituted 2-oxo-1,2,3,4-tetrahydropyrido[2,3-d]pyrimidines also takes place readily.[182–184]

The interaction of 1-substituted 4-oxo-1,4-dihydropyridopyrimidines with alkyl halides and dialkyl sulphates results in the formation of the corresponding salts of the 3-*N*-alkyl derivatives, whose treatment with sodium tetrahydroborate is accompanied by the reduction of the C=N double bond in the pyrimidine ring.[185] The same workers[186] proposed another method for the 3-*N*-alkylation of pyridopyrimidines, which involves essentially the initial reduction of the C=N double bond in the initial pyridopyrimidines with subsequent alkylation of the products:

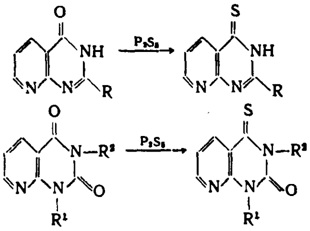


One of the important reactions of 2-oxo-, 4-oxo-, and 2,4-dioxo-pyrido pyrimidines is their conversion by treatment with phosphoryl chloride into the 2-chloro-, 4-chloro-, and 2,4-dichloro-derivatives—the starting materials for the synthesis of many pyridopyrimidine derivatives by the nucleophilic substitution of the chlorine atom. Thus the interaction of chloropyridopyrimidines with alcohols, amines, and ketones yielded the corresponding alkoxy-, amino-, and oxomethyl derivatives.[32,187–192]

The interaction of 2-chloro-4-oxodihydropyridopyrimidine with alkanethiols in the presence of hydrogen iodide afforded the corresponding 2-alkylthio-derivatives, while the reaction with hydrogen sulphide under the same conditions leads to the formation of the disulphide, which is converted into the 2-thiono-derivative as a result of hydrolysis:[193]

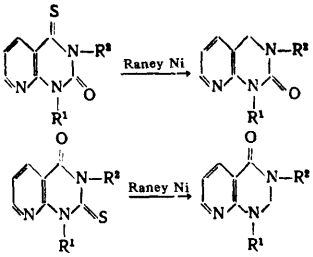


4-Oxodihydro- and 2,4-dioxotetrahydro-pyridopyrimidines are converted into the corresponding 4-thionopyridopyrimidines in high yields on treatment with phosphorus pentasulphide:[187,194]



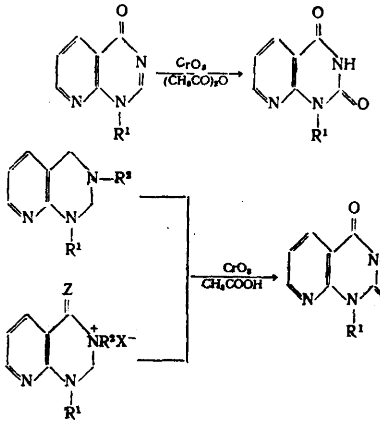
The conversion of thionopyridopyrimidines into oxopyridopyrimidines by oxidising the thiono-group with hydrogen peroxide is also possible.[195–197]

Thionopyridopyrimidines are desulphurised in the presence of Raney nickel as catalyst:[198,199]

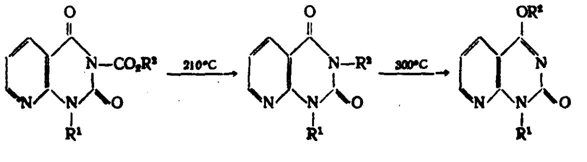


It has been shown that, on treatment with a 5% solution of sodium hydroxide, 2,4-diaminopyrido[2,3-d]pyrimidine is converted into 4-amino-2-oxo-1,2-dihydropyridopyrimidine.[91]

2,4-Dioxopyridopyrimidines are obtained by oxidising various pyridopyrimidine derivatives with chromium trioxide:[200–202]

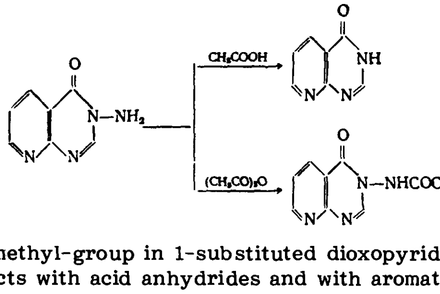


A study of the decarboxylation of 3-alkoxycarbonyl-2,4-dioxotetrahydropyridopyrimidines showed that different products are obtained depending on the temperature. Thus the corresponding 3-alkyl derivatives are formed at 210 °C, while on raising the temperature to 300 °C the alkyl group migrates from the nitrogen atom in the 3-position in the pyrimidine ring to the oxygen atom in the 4-position:[203,204]



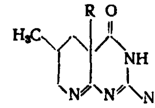
6-Substituted 8-ethyl-5-oxo-5,8-dihydropyrido[2,3-d]pyrimidines, containing the 2-methylthio-, 2-methylsulphoxy-, and 2-chloro-substituents, undergo substitution reactions with amines, forming the corresponding amino-derivatives.[101,121,205–210]

It has been shown that the interaction of 3-amino-4-oxo-3,4-dihydropyridopyrimidine with pentyl nitrite in the presence of acetic acid entails its deamination, while in the reaction with acetic anhydride the amino-group is acylated:[36]



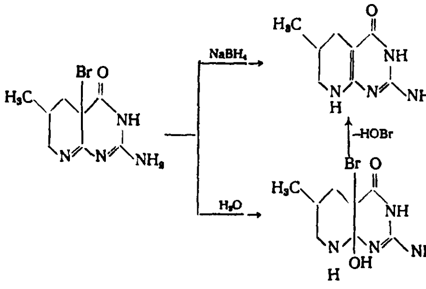
The 2-methyl-group in 1-substituted dioxopyridopyrimidines reacts with acid anhydrides and with aromatic aldehydes to form the corresponding 2-acylmethyl and 2-styryl derivatives.[211–213]

Various chemical reactions of 2-amino-6-methyl-4-oxohexahydropyridopyrimidine, in particular those making it possible to obtain new derivatives with angular substituents, have been investigated:[214,215]

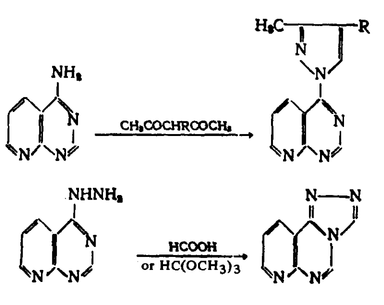


R=HOO, OH, Br

Hexhydropyridopyrimidine containing an angular bromine atom is converted by treatment with sodium tetrahydroborate into the initial pyridopyrimidine, while treatment with water entails an addition reaction which results in the formation of octahydropyridopyrimidine with two angular substituents (OH and Br), which readily splits off hypobromous acid:[215]



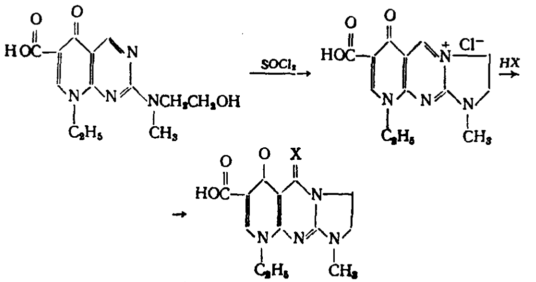
The reactions of substituted pyridopyrimidines via the substituents in the pyrimidine ring, which lead to the formation of tricyclic systems, are of great interest. Thus the condensation of 4-aminopyridopyrimidine with β-diketones and of 4-hydrazinopyridopyrimidine with formic acid or its orthoester afforded the corresponding 1-(4-pyrazolyl)pyridopyrimidine and triazolo[3,4-*f*]pyridopyrimidine:[216]



1-Subsituted 5-oxo[*H*]triazole[3,4-*f*]pyridopyrimidines have been obtained by an analogous procedure.[217]

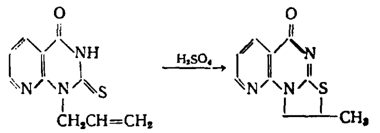
The interaction of 2-amino-3-(5-tetrazolyl)pyridine with orthoesters leads to a condensed tricyclic system—pyrido[2,3-d]tetrazolo[5,1-*f*]pyrimidine.[218,219]

Imidazopyridopyrimidine has been synthesised by the reaction of 2-(β-hydroxyethylamino)pyridopyrimidine with thionyl chloride:[220]

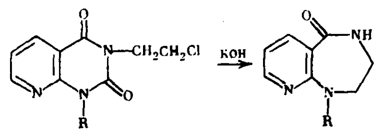


$X=OH, OCH_3, OC_2H_5, CH_2COCH_3$

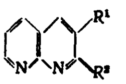
1-Allyl-4-oxo-2-thiono-1,2,3,4-tetrahydropyrido[2,3-*d*]pyrimidine undergoes intramolecular cyclisation in the presence of concentrated sulphuric acid with formation of the condensed thiazolidinopyridopyrimidine:[85]



One of the interesting reactions of 1-substituted 3-(β-chloroethyl)-2,4-dioxotetrahydropyridopyrimidines is their conversion into derivatives of pyrido-1,4-diazepines by treatment with an alcoholic solution of potassium hydroxide:[221]



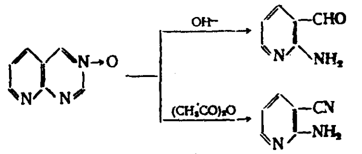
A number of reactions of pyridopyrimidine 3-oxide derivatives with ethyl cyanoacetate, ethyl acetoacetate, and malonodinitrile, leading to the corresponding 1,8-naphthyridines, have been carried out:[222]



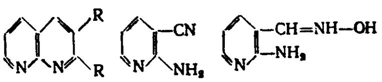
$R^1=CO_2C_2H_5, R^2=NH_2; R^1=CN, R^2=NH_2; R^1=CO_2C_2H_5, R^2=CH_3$

3. Reactions Involving the Opening of the Pyridine Ring

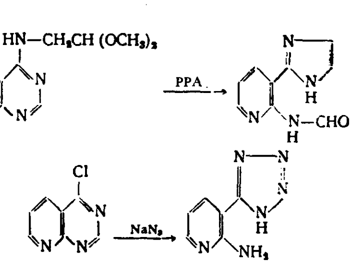
The pyramidine ring in pyrido[2,3-d]pyrimidines is known to be opened in the presence of both bases and acids. 2-Amino-3-carboxypyridines are obtained in the former case[87,223] and the 2-amino-3-formyl derivatives are formed in the latter case.[151] Treatment of 3-hydroxypyridopyrimidine with sodium or potassium hydroxide also leads to an aminoformylpyridine.[222] The opening of the pyrimidine ring by treatment with acetic anhydride has been described in the same study:



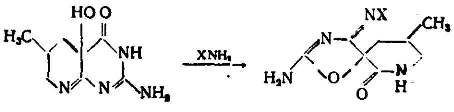
The condensation of 3-hydroxypyridopyrimidine with ketones has also been investigated and it has been established that a mixture of three compounds with the following structures is formed:[224]



The opening of the pyrimidine ring has been studied in the dimethyl acetal of 4-pyridopyrimidinylaminoacetaldehyde and 4-chloropyridopyrimidine when the latter are treated with polyphosphoric acid (PPA) and sodium azide respectively:[218,219]

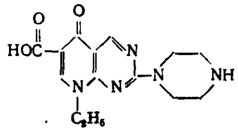


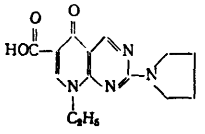
The condensation of the 2-amino-10-hydroxy-4-oxo-derivatives with methoxyamine and semicarbazide, which results in the formation of spiro-oxazolopiperidine derivatives, is also of interest:[215]



IV. BIOLOGICAL PROPERTIES

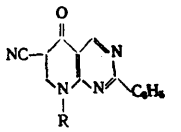
As mentioned above, derivatives belonging to the class of pyrido[2,3-d]pyrimidines exhibit a broad spectrum of biological activity, two representatives being used as effective antibacterial agents in medical practice under the names "pipemidic acid"[5,225–244] and "piromidic acid".[6,245–254]



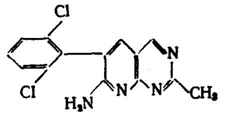


The study of the antibacterial activity of analogous derivatives containing various substituents in the 2-, 6-, and 8-positions showed that, for identical substituents in the 2- and 8-positions, the highest activity is shown by compounds with a carboxy-group in the 6-position. The most effective compounds are pyridopyrimidines with ethyl and amino-groups in the 2- and 8-positions respectively.[100,103,104,133–138,160,164,166,174,203,255–260] Furthermore, certain derivatives of this series exhibit anti-inflammatory analgesic,[206,261] and hypotensive[149,205] activities.

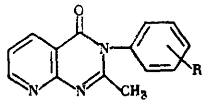
8-Substituted 6-cyano-5-oxo-2-phenyl-5,6,7,8-tetrahydropyridopyrimidines[128–130] exert a depressing activity on the central nervous system.



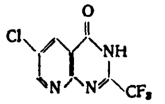
An effective hypotensive agent has been found among 2-substituted 7-amino-6-aryl derivatives:[3,149,150]



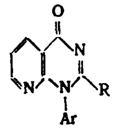
2-Substituted 4-oxodihydropyrido[2,3-d]pyrimidines exhibit antiallergic[25,29,262] and diuretic[26–28,30,263–265] activities. 3-Aryl-2-methyl-4-oxodihydropyridopyrimidines containing different substituents in the benzene ring are effective inhibitors of xanthine oxidase:[4]



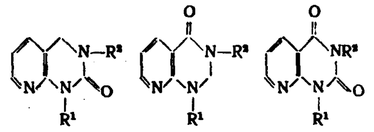
Among derivatives of 2-alkyl(or halogenoalkyl)-4-oxo-3,4-dihydropyridopyrimidines, containing various substituents in the pyridine ring, the 6-chloro-2-trifluoromethyl derivative with a strong herbicidal activity has been discovered:[2]



1-Aryl-4-oxotetrahydropyridopyrimidines exhibit diuretic, hypotensive anti-inflammatory, and tranquillising activities.[19–21] 2-Substituted derivatives of this series are also analgesics and depressants:[23,24,211,212]

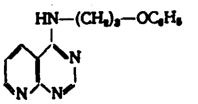


Almost all 2-oxo-derivatives,[12,13,182–184,209] 4-oxo-derivatives,[185,186,195,210,266] and 2,4-dioxo-derivatives[41,51,54–58,60–66,176–181,196–201] of 1,3-disubstituted tetrahydropyrido[2,3-d]pyrimidines show analgesic and anti-inflammatory activities and are depressants:



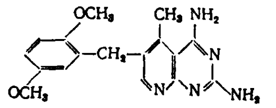
4-Oxo-2-thiono- and 2-oxo-4-thiono-tetrahydropyridopyrimidines possess the same properties[79–82,194] and some of them exhibit antihistamine[76] and diuretic[192] activities.

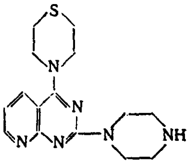
Whereas 4-chloropyridopyrimidines are neuroleptic substances,[187] the 4-alkoxy(or 4-amino)-derivatives are spasmolytic substances.[32,188] This series also includes a powerful antifungal agent—4-(3-phenoxypropylamino)pyrido[2,3-d]pyrimidine:[267]



The series of 1-substituted 4,7-diaminopyridopyrimidines includes effective depressants of the central nervous system.[152,153]

Among derivatives of 2,4-diaminopyridopyrimidines, it is possible to distinguish two compounds: the first is an effective inhibitor of several enzymes[1] and the second inhibits the aggregation of thrombocytes:[268]





Antibacterial properties have been found in certain derivatives of pyridopyrimidines containing the penicillanic acid residue.[269,270]

In conclusion it should be stated that a more far-reaching study of the methods of synthesis and new derivatives of pyrido[2,3-d]pyrimidines, directed towards the development of other methods or the simplification of individual stages of existing methods of synthesis, is of great theoretical and practical interest for the preparation of new, hitherto unknown, biologically active compounds and medicinal preparations.

Radical Polymerisation in the Associated Species of Ionogenic Surface-active Monomers in Water

V.V.Egorov and V.P.Zubov

The radical polymerisation in water of ionogenic monomers of the cationic and anionic type exhibiting surface-active properties is discussed. Together with kinetic phenomena, which can be accounted for within the framework of the hypothesis of a homophase course of the process, effects which require the assumption of the possibility of the association of the monomeric molecules are observed in the polymerisation of monomers with a low surface activity in aqueous solutions. The polymerisation of monomers with a high surface activity in micellar dispersions differs from the processes in solutions by a number of features associated with the influence of structure formation in the monomer on the kinetics of polymerisation and the macrostructure of the polymer formed. The kinetic effects induced by the increasing concentration and microviscosity of the monomer solutions and also by the change in the relative positions of its molecules in the associated species compared with the solution are discussed. Examples of the influence of processes involving the rearrangement of the associated speices on the process kinetics are presented. The possibility, in principle, of the fixation of the structure of the associated species (micelles) as a consequence of polymerisation is noted.

The kinetics of the polymerisation process in micellar and vesicular dispersions of two-chain surface-active monomers and also in monolayers at the water-gas interface are discussed.

The bibliography includes 118 references.

I. INTRODUCTION

The branch of polymer chemistry associated with the synthesis of surface-active monomers and the study of the characteristic features of their polymerisation in various media has developed widely during the last decade. The application of these compounds makes it possible to investigate the influence of processes involving the association of monomeric molecules on the kinetics of radical polymerisation in solution. Here one may expect, on the one hand, the appearance of kinetic effects associated with the formation of micelles in aqueous dispersions of surface-active monomers (SAM) (concentration effect associated with the appearance of an interface and others), which are known for a number of organic reactions in such systems.[1-4] On the other hand, there appears a possibility of studying the role of the mutual orientation of the molecules or their fragments in chemical reactions and hence of modelling certain enzymic processes.[5-7]

It is known from the literature that the kinetics of polymerisation in solution is influenced by processes involving the association of monomeric molecules induced by hydrophobic,[8] electrostatic,[9] and $\pi-\pi$ interactions[10] as well as association processes via the formation of hydrogen bonds between molecules.[11] The manifestation of effects of this kind is to be expected also in micellar SAM solutions. Organic solutions of ionogenic monomers, in which association phenomena have also been observed,[12-14] are not considered in this review. Attention will be concentrated on micellar and vesicular SAM dispersions in water and also on monolayers of monomers at the water–gas interface.

The practical importance of surface-active monomers is associated with the synthesis of the corresponding polyelectrolytes (via homo- and co-polymerisation) which have found applications in various branches of science and engineering as sorbents, flocculants, emulsion stabilisers etc.[15] One of the newest and most promising developments is the creation on their bases of carriers for the immobilisation of biological and medical preparations.[16,17] Emulsion polymerisation using SAM as copolymerising emulsifying agents is of independent importance.[18,19]

II. CLASSIFICATION OF SURFACE–ACTIVE MONOMERS

Table 1 presents the principal classes of SAM and indicates their typical representatives. It follows from the table that the number of SAM known at the present time is fairly large. Individual SAM differ by the nature of the hydrophilic component, the so called "head" (anionic, cationic, non-ionic, mixed, and complex), the activity of the polymerising group (vinyl, allyl, acrylic, styrene, maleic, etc.), and also the length of the aliphatic chain—the "tail".

In water, the above compounds, which are typical organic surfactants, are capable of forming both true and micellar solutions.[70] Furthermore, monomers which are structural analogues of phospholipids, containing in the molecule two extended aliphatic chains, are able to form structures resembling biological membranes in solution (vesicles, liposomes)[16] and at the interface (monolayers and polylayers[16]).

Yet another type of structural organisation of SAM is associated with the preparation in their presence of stable direct and inverted emulsions of compounds which are sparingly soluble respectively in water or oil, in particular vinyl monomers.[19] However, in such systems the SAM association effects have not been observed in an explicit form. Therefore, despite the enormous industrial importance of the emulsion polymerisation process in the presence of copolymerising emulsifying agents,[19] it is not considered in this review.

Table 1. Surface-active monomers ($X = Cl^-$, Br^-, I^-, or $CH_3SO_4^-$ anion; $M = Na^+$, K^+, or NH_4^+ cation).

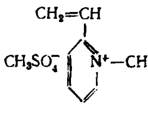
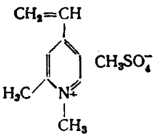
III. POLYMERISATION IN SOLUTIONS OF MONOMERS HAVING A LOW SURFACE ACTIVITY

The phenomenon of the organisation of monomeric molecules in solution has been observed for ionogenic monomers without pronounced surface-active properties. The spontaneous (in the absence of material initiators and other sources of free radicals, ions, etc.) polymerisation of vinylpyridine salts in solutions has been investigated.[20,21,70–74] Fig.1*a* presents the dependence of the initial rate of the spontaneous polymerisation of compounds based on 2-vinylpyridine or 2-methyl-5-vinylpyridine and dimethyl sulphate on the concentration of the monomers in water:[71]

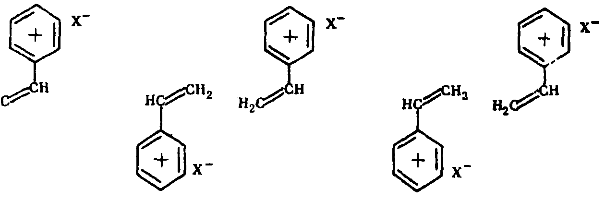


(I)

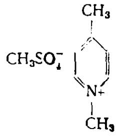


(II)

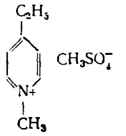
Contrary to expectation, the rate of the process in the given system increases non-linearly with the monomer concentration, which is a consequence, according to the authors, of the formation from the monomer molecules of associated species with the following structure



This hypothesis makes it possible to explain the extremum in the temperature dependence of the rate of polymerisation of the above monomers (Fig.1*b*): the usual increase of the rate of the process with increasing temperature should be accompanied in this case by an increase in the contribution by the competing process involving the decomposition of the associated species and the consequent decrease in the rate of polymerisation. The hypothesis of the association of the monomeric molecules has been confirmed[78] by the character of the dependence of the viscosity of the solutions of pyridinium salts on their concentration in water (Fig.2):



(III)



(IV)

Above a certain concentration, the slope of the straight line increases and it is known[22] that this may be associated with the appearance of associated surfactants species in solution.

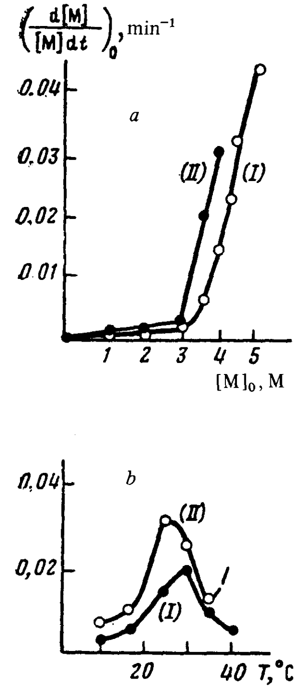


Figure 1. Dependence of the reduced initial rate of polymerisation of the vinylpyridinium monomers (I) and (II) in water on their initial concentration at 50 °C (*a*) and on temperature at [M] = 4 M (*b*).[71]

The influence of the association of the monomers on the kinetics and mechanism of the spontaneous polymerisation has been demonstrated in relation to acid vinylpyridinium salts, which are capable of forming micelles in water above a certain concentration (CCM).[72-74] Fig.3 illustrates the dependence of the critical concentration for the formation of micelles from a monomer based on 4-vinylpyridine and perchloric acid on the concentration of inert electrolyte in solution.[74] In the course of the spontaneous polymerisation over the entire range of monomer concentrations (at a fixed electrolyte concentration) below the CCM, the formation of ionene via a polyaddition mechanism is observed,[73] while above the CCM the 1,2-polymer is formed. A more detailed study of the formation reactions of these products showed[27] that both reactions take place over the entire range of monomer concentrations and that a plot, in terms of double logarithmic coordinates, of the rate of the process against the monomer concentration for each reaction considered separately does not exhibit a break. According to the authors,[27] this indicates the absence of the influence of monomer association on the polymerisation kinetics in the given system. However, the entire set of data, including the data of the above authors,[27] shows that the associated form of the monomer undergoes preferential polymerisation of the kind known for concentrated solutions of vinylpyridinium salts,[75] whereas in dilute solutions polyaddition takes place.[28,29] It is also essential to take into account the authors' view[27,28] that, in the analysis of the reactions of the monomers indicated in concentrated solutions, it is necessary to include not only the effect of association but also the influence of the ionic strength of the solution on the degree of dissociation of the monomeric salt and hence on its behaviour in the homopolymerisation reaction.

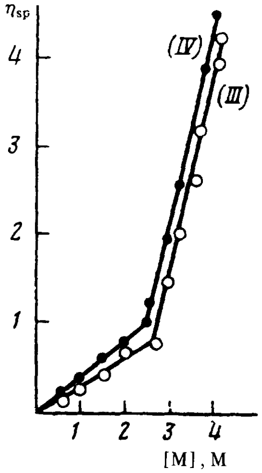

Figure 2. Concentration dependence of the specific viscosity of aqueous solutions of the pyridinium salts (III) and (IV) at 25 °C.[78]

Another type of cationic monomer—allylammonium salts—has been investigated.[22,23,76,77] The study of the kinetics of the radical polymerisation of dimethylallylammonium chloride in water yielded high reactions orders with respect to the monomer (2.9) and the initiator (0.8).[23] The rate of the process and the viscosity of the solution increased non-linearly with increase in the monomer concentration. The addition of an inert electrolyte increased the rate of the reaction and reduced its order with respect to the monomer. The observed effects are a consequence, according to the authors,[23] of the electrostatic interactions of the reaction components in solution and they are associated primarily with the influence on the overall process rate of the changes in the constants for chain initiation and propagation as a function of the monomer concentration. However, the data of Topchiev and Nazhmetdinova[76] show that the change in the termination rate constant k_t also plays a significant role. The fact that the dependence of the rate of polymerisation V_p on the monomer concentration [M] can be expressed by a linear plot of lg V_p against lg $[M]\eta_{rel}^{0.5}$, where η_{rel} is the relative viscosity of the solution, indicates unambiguously, according to the above investigators,[76] the decisive influence of viscosity on the chain termination rate constant and hence on the overall rate of the process. At the same time, the non-linearity of the dependence of the viscosity of aqueous solutions of the monomers on the concentration of the monomer salt[23] is striking, which may be a consequence of the association of the monomeric molecules.[22] However, this finding is not discussed by Wandrey et al.[23]

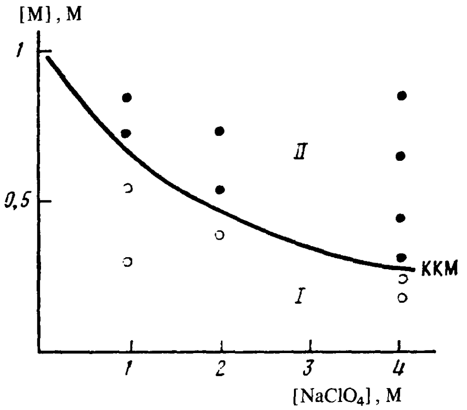

Figure 3. Dependence of the critical concentration for micelle formation of the salt of 4-vinylpyridine and perchloric acid on the sodium perchlorate concentration in water at 20 °C:[74] I) region corresponding to the formation of polyionene; II) region corresponding to the formation of the 1,2-polymer in the polymerisation of 4-vinylpyridinium perchlorate at a fixed electrolyte concentration; the circles correspond to the monomer and electrolyte concentrations used.

A high order of the reaction has been observed also in the study of the spontaneous (radical) polymerisation of the hydrochloride of *NN*-diethylaminoethyl methacrylate in water.[78] It was found that at 60 °C, below a certain critical concentration of the monomer (2–2.5 M), the rate of reaction increases in proportion to the monomer concentration raised to the power of 1.2 and that above this concentration it increases in proportion to the concentration raised to the power of 4.7. Under these conditions, the increase in the concentration of the monomer salt is accompanied by a decrease in the viscosity of the polymer formed, which is associated, according to the authors,[78] with the occurrence of chain transfer to the monomer. When the process temperature is reduced to 20 °C, the dependence of the initial rate of polymerisation on the monomer concentration passes through a maximum. The increase in the rate of the process with increasing concentration along the initial section of the relation has been explained[78] by the appearance of aggregates of the monomeric molecules in the system.

An extremum in the dependence of the rate of radical polymerisation on the monomer concentration in water has also been observed for an anionic monomer–sodium ethylenesulphonate.[36] The increase in the rate of the process may be caused by the partial neutralisation of the charges of the monomer and of the growing radical in the range of high concentrations of the monomer salt. An analogous effect has been observed after the addition of a neutral salt. On the other hand, in a dilute solution the ionisation of the reaction components, leading to their mutual repulsion, lowers the rate of chain propagation. At the same time, one must not fail to take into account the influence of the ionisation of radicals also on the rate of the bimolecular chain termination. This effect has been observed in the radical polymerisation in water of another anionic monomer—sodium 2-sulphoethyl methacrylate.[34] The increase in the ratio $k_p(fk_{dec})^{0.5}/k_t^{0.5}$ (Fig.4) of the rate constants for the decomposition of the initiator (k_{dec}), chain propagation (k_p), and chain termination (k_t) (where f is the initiation factor), which has been observed experimentally following a decrease of the monomer concentration and is usually for radical polymerisation, has been explained[34] by the effect of the ionic strength of the solution on the degree of dissociation of the monomer and the growing radical. The decrease in ionic strength owing to the dilution of the solution, leading to an increased degree of dissociation of the ionogenic groups of the monomer and the radical, induces an increase in their effective charge, which should lower both the rate of propagation and the rate of bimolecular chain termination as a result of the mutual repulsion of the reaction components. However, this effect is much more marked for the reaction between two radicals (the calculated effective charge on the macroradical is three), which decreases the rate of chain termination to a greater extent than the rate of chain propagation, as a result of which the overall rate of the process increases. At high monomer concentrations, the lack of dependence of the rate of the process on the concentration of the monomer salt (Fig.4) is associated, according to the authors,[34] with the fact that the polymerisation of the fully undissociated salt is observed. The addition of a neutral electrolyte influences the rate of polymerisation in the same direction as the increase in the monomer concentration (Table 2).

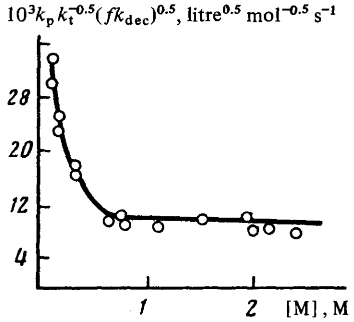

Figure 4. Dependence of the ratio of the rate constants for chain propagation (k_p), chain termination (k_t), and decomposition of the initiator (k_{dec}) on the monomer concentration in water in the radical polymerisation of sodium 2-sulphoethyl methacrylate at 60 °C; f = initiation factor.[34]

The data concerning the influence of a neutral salt on the kinetics of the polymerisation of an anionic monomer obtained in two investigations[34,36] are contradictory. The cause of this should apparently be sought in the different effects of the ionic strength of the solution on the chain propagation and termination rate constants for specific monomers.

The absence of the influence of a neutral salt on the kinetics of the radical polymerisation of derivatives of *NN*-dialkylaminoethyl methacrylate in water at a fixed pH has been observed.[14] For the complete ionisation of the monomer, this phenomenon may be attributed to the increased ability of comparatively hydrophobic polycations to bind low-molecular-weight ions even at a low ionic strength of the solution and thereby abolish the effective positive charge on the end of the chain. Not wishing to dwell especially on the question of the influence of the pH of the solution on the kinetics of the radical polymerisation of ionogenic monomers in water, we refer the reader to Kabanov and Topchiev,[9] who deal with this process in detail.

Table 2. The influence of the concentrations of the monomer and a neutral salt on the ratio of the kinetic constants for the polymerisation of sodium 2-sulphoethylmethacrylate in water at 60 °C.[34]

Monomer, M	$NaNO_3$, M	Ionic strength	$10^3 k_p(fk_{dec})^{0.5}/k_t^{0.5}$, $litre^{0.5}\ mol^{-0.5}\ s^{-1}$
0.12	—	0,12	23.4
0.107	1	1,107	11.9
1.195	—	1.195	10.4

In a number of studies, an increase in the rate of the radical polymerisation of ionising monomers with increased solvent polarity has been noted (including the situation where there is a change from organic to aqueous organic solutions[30, 79–81]). This effect is explained, on the one hand, within the framework of the electrostatic interactions between the reaction components in solution and, on the other, by the association of the monomeric molecules.[81] The influence of the nature of the counterion on the association process and hence on the kinetics of the polymerisation of ionogenic monomers in water has also been noted.[82]

The polymerisation of a series of ionic monomers, namely metal *p*-styrene-, ethylene-, and 2-propene-sulphonates, has been described.[36,83]

In considering the polymerisation in aqueous solutions of ionogenic monomers with a low surface activity, account must be taken of the fact that these systems occupy an intermediate position between true isotropic solutions and colloidal dispersions. The kinetic effects observed in polymerisation in such systems are therefore complex and their interpretation is largely contradictory. On the one hand, a number of features can be accounted for within the framework of the kinetics of homophase reactions when account is taken of the state of the ionogenic groups of the reactants (monomers, radicals). On the other hand, facts appear which do not fit within this framework and require the assumption of the possibility of the association of the monomeric molecules. One may expect that, on passing to typical surface-active monomers, the association effects will predominate and will determine the characteristics of the kinetic behaviour of such systems.

IV. POLYMERISATION IN MICELLAR DISPERSIONS OF SURFACE-ACTIVE MONOMERS

According to the general colloidal-chemical ideas concerning the behaviour of surfactants in water, one may assume that in the case of SAM, whose molecular structure is similar to that of typical organic micelle-forming surfactants, the formation of monomeric molecule–micelle associated species will be observed at SAM concentrations in water above the CCM. On the one hand, the appearance of micelles is reflected in a series of physicochemical characteristics of the system (viscosity, light scattering, surface tension, etc.[70,84,85]) and, on the other, it can alter significantly the rates of many organic reactions in solution.[1,2] This served as a basis for the hypothesis that many characteristics of the SAM polymerisation process in water are also associated with the formation of monomer micelles.[27]

One of the first examples of the polymerisation of monomers of this kind has been the polymerisation of the sodium salts of the allyl esters of α-sulphopalmitic and α-sulphostearic acids.[37] Preliminary experiments showed that the above compounds are able to reduce considerably the interfacial tension, i.e. are typical surfactants. Their radical polymerisation yielded water-soluble polymers with an average degree of polymerisation of 10.

The micelle-forming properties of vinylimidazolium salts and polymers based on them have been investigated.[86,87] With increase in the length of the aliphatic chain in the monomer and the polymer, a transition is observed from the water-soluble to micelle-forming surfactants. The appearance of micelle-forming properties in polymers has been observed for a shorter alkyl substituent than in monomers, which indicates that the polymers are more hydrophobic than the corresponding monomers.

A study of the radical copolymerisation of the above monomers with vinylpyrrolidinone in water and ethanol revealed[88,89] that, for vinyl imidazolium salts, the tendency to add to "its own" radical is significantly greater for the monomer whose molecule contains a longer aliphatic substituent and hence exhibits a greater surface activity. It has been suggested that this is a consequence of the formation of associated species (micelles) in the SAM solution. The enrichment of the micelles in the vinylimidazolium SAM compared with vinylpyrrolidinone should promote the preferential incorporation of the former in the copolymer. On the other hand, the relatively low solubility of vinylpyrrolidinone in the hydrophobic part of the micelles reduces its contribution to the final product. The copolymerisation of vinylimidazolium salts with other monomers (styrene, acrylates) has also been described.[89]

A study of the radical polymerisation of methacryloyloxyalkylammonium salts with an alkyl fragment of equal length showed that in certain cases the effects associated with the ionic character of the SAM may have a greater influence on the polymerisation kinetics in solution than the association phenomenon.[90,91] The rate constant ratio $k_p(fk_{dec})^{0.5}/k_t^{0.5}$ increased with decrease in the monomer concentration in solution to a greater extent the shorter was the length of the alkyl chain in the monomer (Fig.5). Measurements of the electrical conductivities of solutions of monomeric salts at different concentrations characterise the SAM indicated as electrolytes rather than detergents. At the same time, the "open chain" association of the monomeric molecules is not ruled out.[91] The increased rate constant ratio quoted above with decreased concentration of the monomeric salt having the hexyl substituent (Fig.5) as well as the analogous phenomenon for the sodium salt of 2-sulphoethyl methacrylate (Fig.4) have been attributed to a more significant decrease in k_t compared with k_p as a result of the dissociation of the ionogenic groups of the monomer and of the growing radical on dilution.[90] The absence of this effect in the polymerisation of the monomer having the ethyl fragment has been explained by the decrease in the effective charge on the ammonium group as a result of its interaction with the unshared electron pair of the oxygen atom.

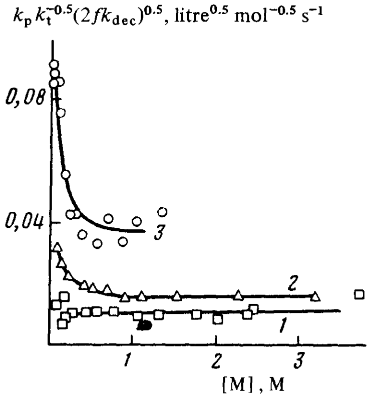

Figure 5. Dependence of the rate constant ratio for the radical polymerisation of compounds of the series $[CH_2{=}C(CH_3){-}COO(CH_2)_n{-}\overset{+}{N}(CH_3)_3]Cl^-$ at 60 °C on the monomer concentration in water:[90] 1) $n = 2$; 2) $n = 3$; 3) $n = 6$.

At the same time, Ringsdorf and Thunig[90] virtually rule out the possible influence of the aggregation of the monomeric molecules on the polymerisation process and fail to explain the increase in the rate constant ratio in the series of monomers with increase of n from 2 to 6 (Fig.5). One of the most probable causes of this effect may be association of the SAM solution at $n = 6$. Plots of $V_p/[In]^{0.5}$ against [M], where [In] is the initiator concentration, obtained in the study of the influence of the monomer concentration $[M]_0$ over a wide range of the latter on the rate of the process V_p, have breaks (Fig.6) whose nature has not been discussed.[91] Other workers[94,95] observed a similar effect and have attributed it to association phenomena (the arrangement of associated species) involving the monomeric molecules in solution (see below).

In contrast to the substance-initiated polymerisation considered above, the spontaneous polymerisation of methacryloyloxyalkylammonium salts in water, which has been shown to have a radical mechanism, has been described.[91] It was found that the order of the polymerisation reaction with respect to the monomer increases with increasing length of the aliphatic chain in its molecule.

The kinetics of the radical polymerisation of vinylpyridinium salts in water has been investigated in a number of studies.[92-95] Fig.7a presents the dependence of the initial rate of polymerisation on the concentration in water of SAM with short and long aliphatic chains in the molecule. Whereas a linear increase in the rate of the process with increasing monomer concentration in the experimental range is observed for the former, for the latter a sharp increase in the slope of the straight line is noted at a certain concentration. It has been shown[94] that the increased rate of the process is accompanied by the increase in the ratio of the propagation rate constant to the square root of the chain termination rate constant, i.e. $k_p/k_t^{0.5}$, and also in the rate of initiation. The correlation of the observed relations with the results of rheological studies on the same SAM solution (Fig.7b) enabled the authors[94] to postulate a relation between the observed kinetic effect and the structural changes in solution.

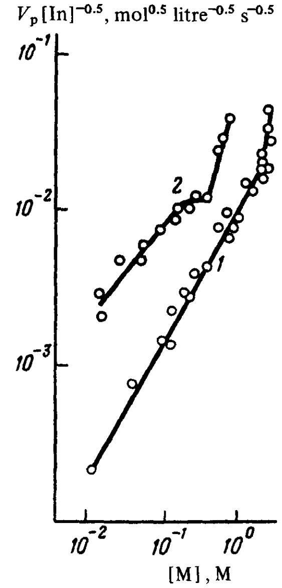

Figure 6. Variation of the ratio of the rate of polymerisation of the monomer $[CH_2{=}C(CH_3)COO(CH_2)_n\overset{+}{N}(CH_3)_3]Cl^-$ to the concentration of the initiator $K_2S_2O_8$ at 60 °C as a function of the initial monomer concentration in water:[90] 1) $n = 2$; 2) $n = 6$.

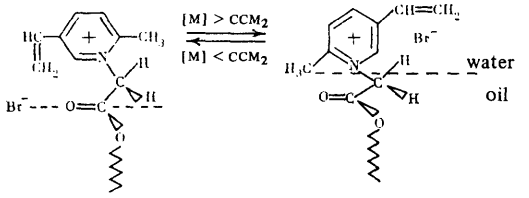
^{1}H NMR study of the above systems confirmed the hypothesis put forward. Analysis of the chemical shifts showed[93] that, whereas for the monomer with a short chain the presence of only the lowest order associated species may be postulated in the experimental concentration range, for the long-chain monomer multilayer micellar aggregates (lamellae) appear at high SAM concentrations in addition to the spherical micelles. The higher degree of organisation of SAM with an extended aliphatic chain and also the characteristic features of the disposition of the double bonds of the monomer in the micelles, promoting the occurrence of polymerisation, may in fact be the causes of the observed kinetic effect. The application of the ^{1}H NMR method made it possible to determine the conformation of the SAM molecules at the interface in the micelles.[93] The scheme below illustrates the change in the conformation of the molecule as a function of the structure of the associated species:



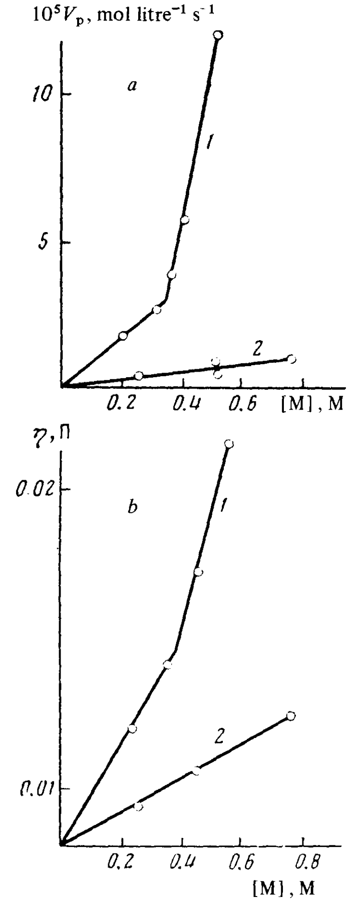


Figure 7. Dependence of the initial rate of polymerisation (*a*) and of the absolute viscosity of solutions of the salts (*b*).[95]

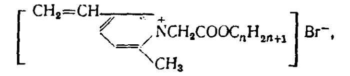

where *n* = 10 (line *1*) and *n* = 4 (line *2*), on the monomer concentration in water.[95]

Subsequently finer kinetic effects, occurring in the radical polymerisation of cationic SAM in water, were observed. Thus in a study of aqueous dispersion of SAM based on methacryloylethylammonium and allylammonium salts, it was found[96,97] that, in the region corresponding to the existence of micellar solutions, the plot of the dependence of the initial rate of polymerisation on the monomer concentration has three sections: a initial linear growth section, a middle section with a constant rate, and then a new section corresponding to growth (Fig. 8*a*). Three linear sections with different slopes are also observed on the plot of the viscosity of aqueous monomer solutions against concentration (Fig. 8*b*). The satisfactory agreement between the concentrations at the points of inflection on the rheological curves and on the "rate–monomer concentration" plots is striking. These data were interpreted as follows.[97] The initial section corresponding to an increasing rate of the process appears as a result of the increase in the total amount of the monomer in the system, in the first place within the spherical micelles, which are responsible for the process kinetics in the experimental SAM concentration range (two orders of magnitude larger than the CCM). The section with a constant rate corresponds to the appearance in the system of anisotropic SAM micelles (confirmed by the ^1H NMR method[96]), in which there is virtually no polymerisation (it is observed only in the spherical micelle phase). According to the authors,[97] this is associated with the disposition of the double bonds of the monomer in the associated species indicated which is unfavourable for polymerisation. The subsequent increase in the rate of the process with increasing concentration is a consequence of the appearance in the dispersion of SAM asssociated species with a high level of organisation, namely aggregates of micelles—multilayer lamellae. The mutual approach of the surfaces of neighbouring micelles in such lamellae induces an increase in the effective concentration of the double bonds of the monomer in the reaction zone and a change in their relative positions.

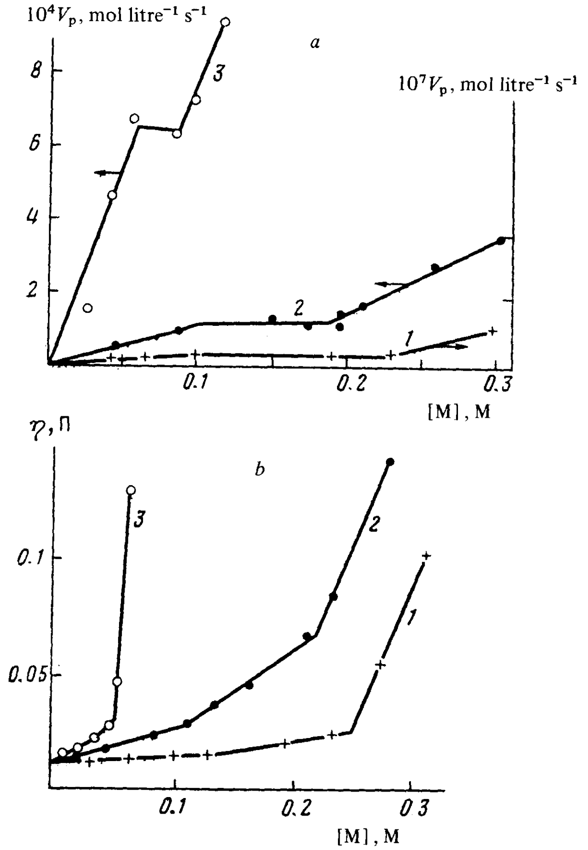

Figure 8. Dependence of the monomer concentration in water in the initial rate of polymerisation at 70 °C (*a*) and of the absolute viscosity at 40 °C of solutions of different salts[19] (*b*) 1) $[(CH_2{=}CH{-}CH_2)_2\overset{+}{N}(CH_3)CH_2COOC_{12}H_{25}]Br^-$; 2) $[CH_2{=}C(CH_3)COOC_2H_4\overset{+}{N}(CH_3)_2CH_2COOC_{12}H_{25}]Br^-$; 3) $[CH_2{=}C(CH_3)COOC_2H_4\overset{+}{N}(CH_3)_2CH_2COOC_{16}H_{25}]Br^-$.

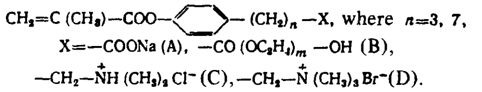
The intrinsic viscosities of polymers in all three SAM concentration ranges have been published.[97] The agreement between these values for the products corresponding to the first and second sections supports the view that at these monomer concentrations the process takes place in the same phase, namely in the spherical micelles. The increase in the viscosity of the polymer on passing to the third section is an argument in support of the appearance in the system of SAM aggregates more complex than the micelles and with a higher degree of association (lamellae). Electron microscopy data for the specimens after polymerisation confirm these hypotheses.[97] Comparison of data for the polymerisation of cationic SAM of two types—with acrylic and allyl polymerisable groups—shows that, as in the isotropic solution, in the micellar dispersion the first type exhibits a higher activity in the polymerisation process than the second, as a result of which the overall rate of the process is much higher in the former case.[97]

Structural transitions in a micellar SAM dispersion have also been observed for *N*-dodecyl-*N'*-vinylimidazolium iodide.[98] However, the radiation-initiated polymerisation of this monomer at concentrations corresponding to both true and micellar solutions afforded identical yields of polymers having similar solubilities in organic solvents and molecular weights proportional to the initial concentration of the monomer in water. This permitted the conclusion that the association of the SAM has no influence on the morphology and degree of polymerisation of the polymer formed. According to the authors,[98] the polymerisation in the micellar dispersions of the SAM indicated proceeds analogously to the reaction in the isotropic medium (monomer solution). However, this conclusion appears insufficiently convincing owing to the lack of data on the rate of polymerisation. This precludes the estimation of the influence of the association of the monomer on the process kinetics.

The polymerisation in water of monomers with hydrophilic "heads" of different nature has been investigated:[30]



Preliminary experiments showed that all the compounds indicated are surface-active. Their CCM were determined. When the polymerisation of the SAM (C) with $n = 3$ and with $n = 7$ was initiated with potassium persulphate, reaction orders of 0.33 and 0.27 respectively with respect to the initiator were obtained. The low reaction order may be associated with the positive absorption of the persulphate anion on the surfaces of the positively charged SAM micelles. When dimethyl azoisobutyrate (DAI) was used as initiator, the rate of polymerisation of the cationic monomers increased significantly on passing from the true solution in aqueous ethanol to the micellar solution in water.[30] It is suggested that this is associated with the enrichment of the SAM micelles in the oil-soluble initiator.

An increase in the rate of the process has also been observed following an increase in the length of the alkyl chain in the monomer and a decrease in the latter in solution (the range of dilute SAM solutions), which is correlated with the data presented in Fig.5. In concentrated surfactant solutions, the rate of polymerisation depended less on the length of the aliphatic fragment in the monomer than in a dilute solution and hardly changed on formation of monomer micelles in the system. The latter effect has been explained[30] by the fact that the polymeric radical is more hydrophobic than the corresponding ionogenic monomer[86,87] and can therefore form its micelle regardless of the state of the monomer solution (true or micellar) (Fig.9). If it were supposed that the rate of polymerisation is determined solely by the behaviour of the polymeric radicals, then the rate of the process would be independent of the degree of organisation of the monomer over a certain range of the concentrations of the latter. However, this hypothesis is fairly controversial because the influence of the association of the monomeric molecules on the kinetics of polymerisation in micellar SAM dispersions where, as in the case under discussion, the polymeric radicals are present as micelles, has been demonstrated for a large number of examples.[92-97] In reality, it follows from the data of the above study[30] that there is a significant dependence of the rate of polymerisation in the given system on the monomer concentration (Fig.10). The analogy between the relation described and the data of Egorov et al.[97] (Fig.8*a*) suggests a relation between the observed phenomena and the structure formation in the SAM dispersion.

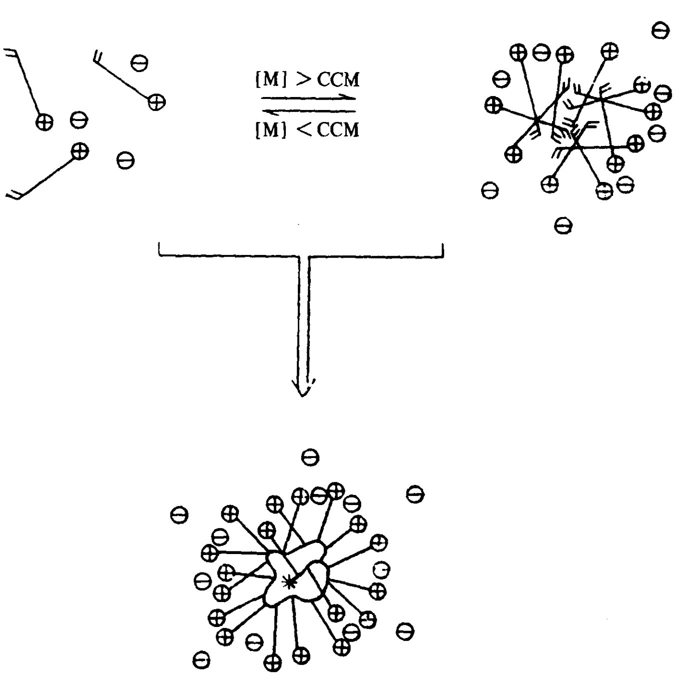


Figure 9. The formation of growth radicals in the polymerisation of methacryloylphenylalkylammonium salts in water.[30]

The radiation-initiated polymerisation of sodium undec-10-enoate in water has been investigated.[41] The polymerisation takes place only at monomer concentrations exceeding the CCM. This is probably associated with the fact that the monomer double bonds are located in the hydrophobic nuclei of the micelles in such a way that this facilitates the polymerisation.

The colloidal properties of monomers, especially micelle formation in the solutions of any cationic, anionic and nonionic polymers which are surfactants, have been investigated in a series of studies.[93,96,99] Structure formation and polymerisation in solutions of monomers which are structural analogues of glycolipids[56,57] and phospholipids[100] have also been described.

Together with single-stranded SAM, cationic monomers based on diallylammonium salts containing two extended aliphatic chains have been investigated:[97]

Since the structure of the above compounds resembles the structure of natural phospholipids, they will henceforth be referred to as lipid-like. The dependences of the initial rate of polymerisation and of the viscosity of the aqueous solutions of the SAM quoted, obtained by simple dissolution, on the monomer concentration in water are analogous to the dependences obtained for the typical SAM with a single aliphatic chain (Fig. 8*a*), which indicates an analogy in the behaviour of the lipid-like and single-stranded SAM in the polymerisation process and hence in the association process and in the rearrangement of the associated monomers in water. As for the usual SAM, the transition from the spherical to the anisotropic monomer micelles with increase in its concentration is accompanied under these conditions by a change in the order of the polymerisation reaction with respect to the monomer from 1 to 0. Further increase in the concentration leads to the appearance of lamellar SAM formations, which induces an additional increase in the rate of the process proportional to the monomer concentration. The explanation of the phenomena indicated, proposed by the authors,[97] is analogous to that quoted above for single-stranded SAM.

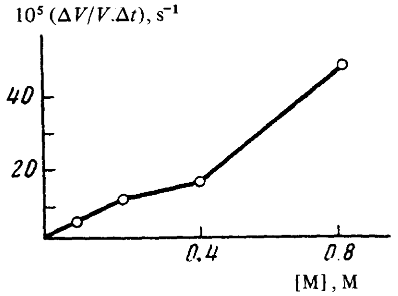

Figure 10. Dependence of the rate of polymerisation of trimethyl[3-(4-methacryloyloxyphenyl)propyl]ammonium bromide in the presence of DAI at 50 °C on the monomer concentration in water according to Siol's data.[30]

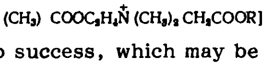
On passing from a symmetrical lipid-like monomer (aliphatic chains of similar length) to a monomer with an asymmetric hydrophobic component (with aliphatic substituents appreciably differing in length), the critical concentrations for the rearrangement of the associated species diminish, i.e. the SAM becomes more hydrophobic.[97] This entails an increase in the overall rate of the polymerisation process, which is analogous to the behaviour of the single-stranded SAM with increase in the length of the aliphatic chain in the molecule.

Attempts have been made in a number of studies to fix the structure of the micelles by polymerisation. The use of the monomers



I^- (V) (Ref.98);

$CH_2{=}C(CH_3)CON(R)-(CH_2)_{10}-COONa$ (VI) (Refs.27, 38);

$CH_2{=}C(CH_3)CON(R)-(CH_2)_{10}-CO(OC_2H_4)_5-OCH_3$ (VII) (Refs.27, 38);

$[CH_2{=}C(CH_3)COOC_2H_4\overset{+}{N}(CH_3)_2CH_2COOR]Br^-$ (VIII) (Ref.19).

did not lead to success, which may be associated, for example, with the need to employ large amounts of the initiator, as in the case of the monomers (VI) and (VII), which polymerise at a slow rate.[27]

It has been noted[27] that one of the first positive results was obtained in the polymerisation of the compound

The polymer obtained had a micellar structure, which was achieved by introducing a cross-linking agent.

Another example of the preparation of polymeric micelles has been described in studies[41,102] of the polymerisation of sodium undec-10-enoate: $CH_2{=}CH(CH_2)_8COONa$. Below the CCM, this monomer is incapable of homopolymerisation, but above this concentration the process proceeds with formation of macromolecules, whose degree of polymerisation is equal to the number of SAM molecules aggregated in the micelles. NMR data confirm the fixation of the micellar structure on polymerisation.

In the study quoted above,[97] it was possible to achieve the fixation of not only spherical micelles but also of lamellar formations, by polymerising the monomer $(CH_2{=}CH-CH_2)_2.\overset{+}{N}(CH_3)CH_2COORBr^-$, which was confirmed by electron microscopy.

Analysis of data on the fixation of SAM micelles by polymerisation shows that a positive result has been achieved either by using monomers with a double bond whose reactivity is low in the polymerisation process or by the introduction of an additional cross-linking agent.

Thus the polymerisation of SAM in aqueous micellar dispersions differs from solution (homogeneous) polymerisation by a number of features associated in the first place with the influence of structure formation in the monomeric molecules on the process kinetics and on the macrostructure of the polymer formed. We may note that there are systems where this influence cannot be traced in an explicit form. The appearance of SAM micelles in the solution induces as a rule an increase in the overall rate of polymerisation. This is associated, on the one hand, with the increase in the local monomer concentration in the associated species compared with the isotropic solution. On the other hand, a change in the elementary reaction constants and also in the reaction order with respect to the initator (for example, as a result of the concentration of the latter on the oppositely charged interface) or with respect to the monomer (for example, as a result of a change in the relative positions of the SAM molecules on passing from the true solution to the associated species) has been observed. Presumably the role of the latter factor increases significantly on passing to structural SAM formations with a higher level of organisation than in micelles, such as vesicles (as a rule made up of monomers whose molecular structure is similar to that of natural phospholipids) or highly organised monolayers of monomers at the water–air interface. Yet another factor influencing the polymerisation kinetics in such systems is the formation of polymeric radicals in the form of individual micelles separated by an electrostatic barrier. This should increase the overall rate of the process compared with the system where the polymer exists in the form of a true solution, as a result of the decreased contribution by the bimolecular chain termination. This has been demonstated, for example, in a study[100] where the radicals were induced directly in the surfactant micelles.

Together with the micelle formation proper, the SAM polymerisation reaction in water can depend significantly on the growth and rearrangement of the monomer micelles and on the appearance of associated species with a higher level of organisation (lamellae). In a number of instances it has been possible to fix this structure of the SAM associated species by polymerisation, but so far this is an exception rather than the rule.

V. POLYMERISATION IN LIPOSOMES AND MONOLAYERS OF SURFACE-ACTIVE MONOMERS

This field has been developing vigorously in recent years, as shown by the progressive increase in the number of communications devoted to monomeric and polymeric monolayers and liposomes. A number of reviews describe fairly completely the state of affairs in this field.[16,27,103] We shall deal with the factors which are important in the context of the present article. This concerns the kinetic effects in the polymerisation process in monolayers and vesicular SAM dispersions.

The study of the polymerisation conditions in a monolayer[55] showed the advantage of UV initiation over chemical initiation, the need to eliminate atmospheric oxygen, etc. It has been established in relation to the $CH_2{=}C(CH_3)COOC_{18}H_{37}$ monomer that an increase in the lateral pressure, leading to a change (ordering) of the monomer monolayer structure at the water–gas interface, may promote or hinder the polymerisation process (Fig.11*a*). It is seen from Fig.11*a* that, with increase in the external pressure, the rate of polymerisation initially increases and above a certain critical pressure it begins to decrease. The observed phenomena have been explained in the following manner.[55] At a low lateral pressure, the monomer in the disordered state (A) (see scheme in Fig.11*b*) forms the polymer (D) at a low rate. With increase in the pressure, the monomer passes to the ordered state (B), the rate of polymerisation increases, and the polymer with the structure (E) is the result. Further increase of the pressure leads to the state (C) in which the monomer is incapable of polymerisation owing to steric hindrance.

An analogy can be seen between the effects observed in the transition from the monomer state (B) to (C) and the data obtained in a study[97] where a change in the order of the polymerisation reaction with respect to the monomer from first to second was observed on passing from spherical to anisotropic monomer micelles (as the aqueous SAM solution was concentrated) during the ordering of the SAM associated species (Fig.8*a*). The observed effect has also been discussed from the standpoint of the dispositions of the monomer molecules at the interface in the associated species which are favourable and unfavourable for polymerisation.

It has also been noted[104] that, with increase in the lateral pressure in the octadecyl methacrylate monolayers, an increase in the rate of polymerisation is observed. Cases are known where the increase in the lateral pressure induces a decrease in the rate of polymerisation.[105] These phenomena can be explained within the framework of the scheme presented above.

It has been observed[39,106,107] that polymerisation in monolayers of monomers of a series of diacetylenic carboxylic acids of the type $CH_3{-}(CH_2)_n{-}C{\equiv}C{-}C{\equiv}C{-}C_8H_{16}COOH$ occurs at 20 °C if n is 11–15 and at 2 °C if $n = 9$ and does not occur at all if $n = 4$–7. The salts of the above acids with the Na^+ and K^+ counterions polymerise at high pH and those with Li^+ and bivalent cations are incapable of polymerisation under these conditions, which is associated, according to the authors,[106,107] with the differences in the packing densities of the monomers in the monolayer. It is of interest to note that the salts containing Li^+ are able to polymerise at pH < 6. It is believed that this induced by a rearrangement of the associated monomer species and that in this instance a polymer having a regular structure is formed. The retention of order in the monolayers in the polymerisation process has also been noted in a number of other studies.[40,108–109]

Two studies have been devoted to aqueous dispersions of liposomes obtained from cationic monomers based on diallylammonium salts.[96,97] The rate of radical polymerisation of monomers with two extended aliphatic chains in the molecule (lipid-like monomers), initiated by the thermal decomposition of DAI, increases overall on passing from dispersions obtained by simple dissolution of the monomer in water, to systems

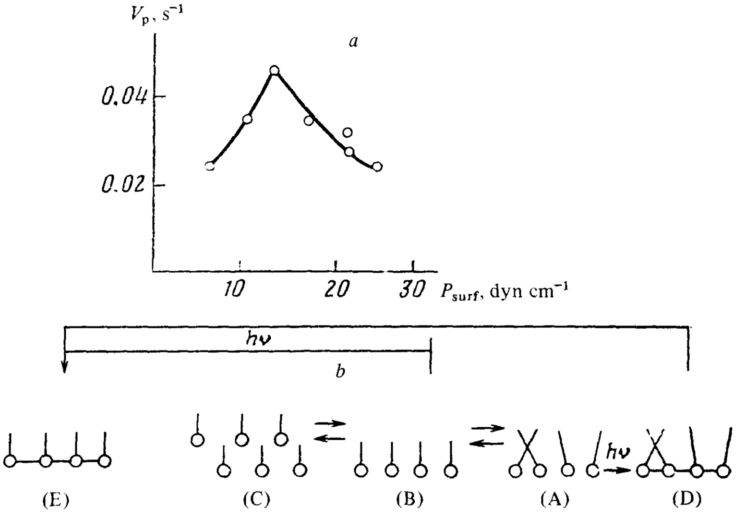


Figure 11. The behaviour of octadecyl methacrylate in the polymerisation process in a monolayer at the water–nitrogen interface at 23 °C and at different surface pressures:[55] *a*) pressure dependence of the rate of polymerisation: *b*) schematic illustration of behaviour: the arrows directed to the right correspond to a decrease of surface pressure and those directed to the left correspond to its increase; the symbol $\xrightarrow{h\nu}$ denotes polymerisation under the influence of radiation.

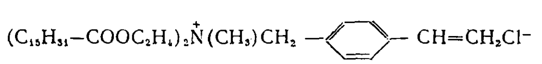
formed by dispersing the monomer with the aid of ultrasound. The inflections in the plots of the viscosity of the solution against the monomer concentration, which correspond, as mentioned above, to a rearrangement in the colloidal SAM dispersions, then vanish. At the same time it is known[110] that, when aqueous dispersions of lipids and their synthetic analogues are dispersed with ultrasound, the formation of liposomes is observed. All this enabled the above investigators[96, 97] to interpret the results as follows. Ultrasonic treatment of aqueous dispersions of diallylammonium lipid-like SAM leads to the formation of monomer liposomes, in which the level of organisation of the molecules is significantly higher than in the micelles. In the first place, in the liposomes the effective monomer concentration is higher and the disposition of the double bonds is more favourable, which increases the overall rate of the process. At the same time, one cannot fail to take into account the possible decrease in the chain termination rate constant as a result of the formation of highly organised layers, where the mobility, in the first place lateral mobility, of the molecules themselves and even more so of the polymeric radicals is significantly lower than in the micelles. The virtual identity of the initial sections of the plots of the rate of polymerisation against the monomer concentration for a micellar solution and a dispersion of liposomes suggested the possibility of the spontaneous formation of liposomes-like structures at comparatively high monomer concentrations in water, which had been established earlier for dispersions of the given SAM at a low concentration.[111] The existence of lamellar and liposome structures of these SAM in the monomer dispersion and their fixation on polymerisation have been confirmed by electronic spectroscopy.[112]

In respect of the lipid-like ammonium monomer

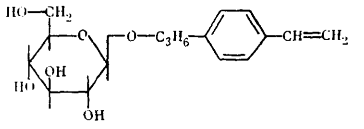


it has been shown[113] that the rate of radical polymerisation increases significantly on passing from the isotropic solution in ethanol to a vesicular dispersion (in water) as a consequence of the orientation of the monomer in the structure of the vesicle.

Thus, in the case of double-stranded lipid-like SAM, the kinetics of the polymerisation process in micellar dispersions, known for single-stranded SAM, is reproduced, on the one hand, and the appearance of higher-order structures, structurally similar to the liposomes of natural lipids, becomes possible on the other hand. The kinetics of polymerisation in such structures are determined primarily by the very high degree of order in their monomer units, which entails as a rule a high rate of the process. Another characteristic feature of these systems, compared with micellar systems, is the possibility of their fixation by polymerisation, which is almost independent of the monomer structure (only the negative influence of the size of the counterion has been noted), of the activity of its polymerising group, and also of the method of initiation. The extremely high stability (with respect to time and mechanical and other influences) of the newly formed polymeric liposomes compared with the initial monomeric liposomes, which has been noted in a number of publications,[75,103,114–116] leads to extensive possibilities for their application.

VI. PROSPECTS FOR THE ULTILISATION OF SURFACE-ACTIVE MONOMERS

The first studies on the synthesis of monomers of this new class and their polymerisation in an aqueous medium had a purely applied aim—the preparation of colloidal (micellar) surfactant structures fixed by means of polymerisation. This provided a reliable method for the investigation of the shape and structure of the micellar formations. Furthermore, the new surfactant structures proved to be effective in the investigation of the microstructure of associated species. For example, the use of a monomer containing simultaneously glycoside and styrene groups,[56] i.e.



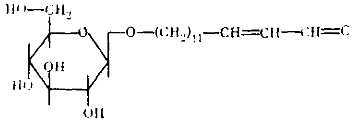
gave definite advantages in the study of the influence of the concentration of aqueous SAM solutions on association processes (rearrangement of the associated species) involving monomers, especially in the testing of changes in the microstructure of micelles.

The fixation of micellar structures by means of the polymerisation of SAM undoubtedly has a practical value, apart from its purely theoretical importance, especially for the synthesis of ion-exchange resins, carriers for medicinal and biological preparations, etc.

One of the most vigorously developing fields has been recently the synthesis of lipid-like SAM and their use for the preparation of polymeric analogues of biomembranes in the form of monolayer films, liposomes, and vesicles,[16,37,40] for the modelling with their aid of membrane processes,[16] and for the incorporation (inclusion, grafting) in the polymer of biological and medicinal preparations,[17,27] used in biology, biotechnology and medicine.

The synthesis of SAM by the modification of natural lipids[117] and other natural products[118] is of special interest. It is apparently possible to obtain in this way SAM capable of imparting a whole spectrum of unique properties of natural objects to polymers as a result of homopolymerisation and copolymerisation.

Thus it has been shown[57] that the inclusion in phospholipid liposomes of a monomer containing a carbohydrate fragment, i.e.



and its subsequent polymerisation make it possible to obtain stable models of biological membranes capable of surface "recognition" by the corresponding proteins.

Overall, the chemistry of SAM is still in the initial stage of its development. However, the likely usefulness of these objects for the solution of a whole series of problems in theoretical and practical chemistry, biology, and medicine has already been demonstrated. Presumably the development of this field will extend the existing applications of SAM and will create new ones.

The Influence of Ligands on the Catalytic Properties of Nickel-containing Systems in Oligomerisation and Polymerisation Reactions

A.G.Azizov

The results of studies on the activating influence of ligands on the catalytic properties of nickel-containing systems in oligomerisation, co-oligomerisation, and polymerisation reactions are surveyed and the electronic and steric aspects of this phenomenon are analysed from the standpoint of an S_ECi mechanism. The possibility of a homolytic and heterolytic activation of the Ni-C bond in catalytic centres by electron-accepting and electron-donating ligands respectively is examined. It is shown that the molecular weight of the oligomerisation and polymerisation products is determined by the steric effect of the ligands and that the stability of the catalytic centres depend primarily on the frequency of the active centre ⇌ potential centre transitions.

The bibliography includes 79 references.

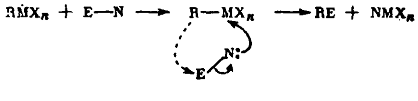
I. INTRODUCTION

In the presence of nickel-containing catalysts it is possible to obtain a broad spectrum of oligomers and polymers of unsaturated hydrocarbons. The composition, structure, and molecular weight of these products depends on the nature of the monomers, the ligand environment of the nickel in catalytic centres, the composition of the catalyst, and the reaction conditions.[1-6] It is now generally recognised that the active centres in nickel-containing catalysts for linear dimerisation, oligomerisation, and polymerisation are in most cases organometallic and hydride derivatives of nickel.[1-7] However, these compounds by themselves exhibit only an insignificant activity. Their catalytic action is greatly enhanced in the presence of electron-accepting additives capable of increasing the effective positive charge on the nickel atom as a result of the formation of charge-transfer complexes on an anion.[1] The influence of electron-donating additives in different reactions is manifested in different ways: they reduce the activity and stereoselectivity of the action of the catalyst in diene polymerisation processes, while in olefin dimerisation and codimerisation reactions they increase its activity and stability.[4-8]

There is as yet no unique approach in the literature to the explanation of the mechanisms of the activating influence of ligands on the catalytic properties of nickel-containing systems in various reactions. This is apparently associated with the fact that, although the studies by individual groups of investigators do cover a broad range of catalytic properties, each separate study was devoted to the investigation of the behaviour of nickel-containing systems only in specific reactions. The mechanisms of the formation and destruction of the active centres, and the role of the electronic and steric factors in the activation of nickel-containing systems and in the formation of the structures and the establishment of the molecular weight of the oligomerisation and polymerisation products have not been ultimately elucidated. The elucidation of these fundamental questions requires a comparative analysis of the activating influence of ligands on the catalytic properties of the same systems in different reactions and, conversely, on different systems in a single standard reaction.

Valuable information about the role of electronic and steric effects of ligands can be obtained by the systematic study of their influence on the kinetic parameters of the elementary stages of the reactions in the transition from dimerisation and codimerisation to oligomerisation and polymerisation of unsaturated hydrocarbons. Evidently, the model reactions should then be selective to the maximum possible extent and readily controllable. The highly selective oligomerisation and co-oligomerisation reactions with α-olefins of styrene and its derivatives, which occupy an intermediate position between olefins and dienes[1,5] as regards their polymer-forming capacities, are convenient objects of study.

In the present review, the experimental data are analysed on the basis of ideas about the electrophilic mechanisms of the reactions of organometallic compounds proceeding via the nucleophilic coordination of the substrate to the metal atom with subsequent electrophilic attack on the negatively charged α-carbon atom in a many-centre cyclic transition state. A similar mechanism, called the S_ECi mechanism was proposed previously,[9] for substitution and addition reactions between organometallic compounds of non-transition metals and E—N electrophiles, which consist of electrophilic (E) and nucleophilic (N) components:



$$RMX_n + E{-}N \longrightarrow R{-}MX_n \longrightarrow RE + NMX_n$$

An analogous mechanism can be used also in discussing the reactions involving the addition of unsaturated hydrocarbons to organometallic and hydride derivatives of nickel. These reactions are the key stages in the oligomerisation and polymerisation processes. Indeed, it has now come to be assumed that the addition of unsaturated hydrocarbons to hydride and organometallic centres takes place in two stages: (1) the formation of an intermediate π-complex with the transition metal and (2) the subsequent insertion of the coordinated olefin molecule via a polar cyclic transition state.

According to the Dewar–Chatt–Duncanson model, the binding of olefins to the metal in the π-complexes is achieved as a result of the direct donor–acceptor and the reverse dative interactions.[10,11] The contribution of the dative interaction diminishes with increase of the degree of oxidation of the complex-forming metal and is minimal for high degrees of oxidation of the metal.[12] This means that the π-complex formation processes at the nickel(II)-containing active centres is a nucleophilic reaction in the sense in which it has been considered by Moiseev.[13,14] On the other hand, in the coordinated state, the olefin molecule acquires the capacity for electrophilic attack,[15] because the partial charge appearing on it as a result of the donor–acceptor interaction is not fully compensated by the dative interaction. Under these conditions, in the many-centre transition state the *d* orbitals of the metal and the sp^3 orbitals of the α-carbon atom (or the *s* orbitals of hydrogen) interact with the bonding orbitals of the olefin.[16–18] As a result, the thermal addition reaction is symmetry-allowed or, according to Pearson's terminology, is partly prohibited.[19]

The formal analogy with the S_ECi mechanism is manifested by the fact that the nucleophilic attack on the transition metal atom by the substrate molecule takes place before its electrophilic insertion in the polarised $R^{\delta-}$–$M^{\delta+}$ bond via an intermediate cyclic transition state. Consequently, one can assume that the characteristics of the reactions involving the addition of an olefin (diene) to organometallic and hydride derivatives of nickel should not differ significantly in their character from the characteristics of the reactions involving the S_ECi mechanism. In this case, the opposite effects of the ligands on the catalytic properties of nickel-containing systems in dimerisation reactions, on the one hand, and in oligomerisation (polymerisation) reactions, on the other, can be accounted for by the different nature of the rate-limiting stages in these processes. Analysis of the experimental results confirms this hypothesis.

II. THE INFLUENCE OF LIGANDS ON THE MOLECULAR WEIGHT OF OLIGOSTYRENE AND THE CHARACTER OF THE CHAIN TERMINATION IN THE OLIGOMERISATION OF STYRENE

It has been shown[20–23] that the degree of polymerisation of styrene in the presence of π-alkenylnickel halides depends on the nature of the halide ion. Thus π-crotylnickel iodide induces the formation of the styrene dimer (1,3-diphenylbut-1-ene), while the bromide and chloride complexes lead to the formation of oligostyrenes with average degrees of polymerisation of 5–6 and 8–12 respectively. An even greater increase in the length of the chain (up to 200–500 units) is attained when electron acceptors such as $MnCl_2$ and $Ni(OCOCCl_3)_2$ are introduced into the system.[22]

The molecular weight of the styrene oligomerisation products in the presence of systems of the Ziegler–Natta type also depends on the catalyst.[24] The two-component system containing *NN*-diethyldithiocarbamate or nickel *OO*-dialkyl (or *OO*-diaryl) phosphorodithioate and diethylaluminium chloride directs the process towards the formation of a dimer, while the additional introduction of a phosphorus-containing ligand (phosphine, phosphite) results in the formation of oligomers with an average degree of polymerisation of 4–9. This difference between the two- and three-component systems is due to the change in the character of chain termination in the presence of a phosphorus-containing ligand in the coordination sphere of nickel: instead of spontaneous chain transfer (β-elimination), the chain is transferred to the monomer, which increases the average degree of polymerisation. Comparison of the results of Azizov et al.[25] with the data of Makovetskii and co-workers[20–22] shows that the introduction of both electron-accepting and electron-donating ligands can increase the molecular weight of the styrene oligomerisation products.

III. THE SELECTIVITY OF THE CO-OLIGOMERISATION REACTIONS OF STYRENE WITH ETHYLENE AND PROPENE

In the co-oligomerisation of styrene with α-olefins, the latter add "head to tail" and "tail to tail". The structure of the products of the reaction with participation of ethylene corresponds to formulae (I) and (II) and that of the products of the reaction involving propene corresponds to formulae (III) and (IV):

$$CH_3-\underset{C_6H_5}{CH}-\left[-CH_2-\underset{C_6H_5}{CH}-\right]_n-CH=CH_2$$

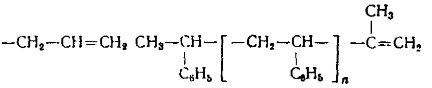
(I)

$$CH_3-\underset{C_6H_5}{CH}-\left[-CH_2-\underset{C_6H_5}{CH}-\right]_n-\underset{C_6H_5}{C}=CH-CH_3$$

(II)

$$CH_3-\underset{C_6H_5}{CH}-\left[-CH_2-\underset{C_6H_5}{CH}-\right]_n-CH_2-CH=CH_2$$

(III)



$$CH_3-\underset{C_6H_5}{CH}-\left[-CH_2-\underset{C_6H_5}{CH}-\right]_n-\overset{CH_3}{C}=CH_2$$

(IV)

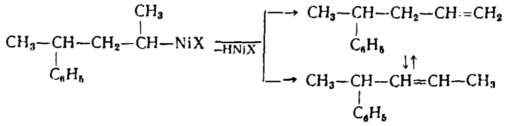
The products (I)–(III) are formed as a result of the "head to tail" addition, while the product (IV) results from the "tail to tail" addition. In the limiting case, where $n = 0$, the product of the co-oligomerisation of styrene with ethylene is 3-phenylbut-1-ene and those of the co-oligomerisation with propene are 4-phenylpent-2-ene, 4-phenylpent-1-ene, and 2-methyl-3-phenylbut-1-ene (2-M-3-PB-1).[25,26]

In contrast to the codimerisation of other pairs of the lowest olefins (for example, ethylene and propene[4,5,7]), in the codimerisation of styrene with ethylene[19] only a single product, namely 3-phenylbut-1-ene, is formed up to appreciable degrees of conversion. For very high conversions, 2-phenylbut-1-ene isomerises to 2-phenylbut-1-ene. The curve for the accumulation of 3-phenylbut-1-ene as a function of time therefore passes through a maximum, which corresponds to 80–100% conversion of styrene.[8,19] The nature of the components of the catalytic system has a considerable influence on the process selectivity. The highest yield of 3-phenylbut-1-ene (100%) is observed in the presence of catalytic systems based on organic dithio-derivatives of nickel (dithiocarbamate, phosphorodithioate).[24,27] The dimerisation of ethylene in the presence of a tertiary phosphine or a phosphite in the catalyst is appreciable only for a high degree of conversion of styrene (>90%). When a two-component system is used, the yield of 3-phenylbut-1-ene falls sharply with respect to both monomers which have reacted (it is particularly marked with respect to the ethylene which has reacted) compared with the three-components systems.[8,25,28] 3-Phenylbut-1-ene isomerises after the complete conversion of styrene.

The yields of the reaction products pass through a maximum also in the codimerisation of *p*-chlorostyrene and vinyltoluene with ethylene. On the other hand, in the codimerisation of α-methylstyrene with ethylene isomerisation is not observed and the yield of 3-methyl-3-phenylbut-1-ene corresponds fully to the consumption of α-methylstyrene.[25]

The codimerisation of styrene with propenes takes place both "head to tail" and "tail to tail". The former type leads to the formation of a mixture of 4-phenylpentenes and the latter to the formation of 2-methyl-3-phenylbut-1-ene. In certain cases propene dimers, phenyloctenes, and styrene oligomers are also formed.[27-30] In the given case the selectivity of the codimerisation also depends, other conditions being equal, on the nature of the components and on the composition of the catalyst: in the presence of two-component systems, an appreciable amount of styrene (up to 42%) is converted into oligomers and co-oligomers. Dithio-systems ensure the exclusive formation of codimers—phenylpentenes (PP). Up to the complete conversion of styrene, they catalyse the addition of the monomers of the "head to tail" type only and, in contrast to acetylacetonate systems, the increase of the Al:Ni ratio to 200:1 does not lower the selectivity of their action.[29,30]

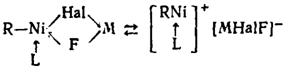
Regardless of the nature of the catalyst components, the 4-PP-1 and 4-PP-2 codimers are formed from the very beginning of the process, which is consistent with the hypothesis of their formation from the same intermediate as a result of β-elimination reactions via different pathways:



$$CH_3-\underset{C_6H_5}{\underset{|}{CH}}-CH_2-\overset{CH_3}{\overset{|}{CH}}-NiX \xrightarrow[-HNiX]{} \begin{cases} CH_3-\underset{C_6H_5}{\underset{|}{CH}}-CH_2-CH{=}CH_2 \\ \quad\downarrow\uparrow \\ CH_3-\underset{C_6H_5}{\underset{|}{CH}}-CH{=}CH-CH_3 \end{cases}$$

However, the isomerisation of 4-PP-1 to 4-PP-2 also takes place during the process. The isomerisation continues further after the formation of 2-PP-2. In contrast to 4-PP-1, 4-PP-2 isomerises to 2-PP-2 only after the complete conversion of styrene. This fact, together with the low rate of isomerisation of 3-phenylbut-1-ene, indicates a decrease of the rate of isomerisation as the double bond is located closer to the benzene ring. Comparison of the results of a thermodynamic calculation of the equilibrium composition of phenylpentenes with experimental data leads to the same conclusion.[29,30] Regardless of the nature of the catalyst components, the yield of 4-PP isomers for any degree of conversion of styrene greatly exceeds their maximum equilibrium concentrations, which are 0.1% for 4-PP-1, 72% for *trans*-4-PP-2, and 15% for *cis*-4-PP-2 at 10–50 °C. With increase of the degree of conversion, the content of 4-PP-1 in the codimerisation products diminishes, approaching the equilibrium value, while that of 4-PP-2 increases to 50–95 wt.%. The yield of 2-PP-2 (1–9%) is much smaller than the theoretical value (28–94%), which is due to the slow isomerisation of 4-PP-2.

The nature of the organoaluminium compound has a significant influence on the yield of the codimerisation products.[27] Catalytic systems based on triethylaluminium and not containing activating additives have a very low efficiency. When CH_2Cl_2, $AlCl_3$, $TiCl_4$, $BF_3.(C_2H_5)_2O$, and $C_2H_5AlCl_2$ are introduced into such systems, the rate of the process and the overall yield of the codimerisation products increase sharply, indicating that the most active codimerisation centres contain electron-accepting ligands or the products of their interaction with the organoaluminium compounds. This postulate is confirmed by the results of studies[31,32] of the interaction of the components of the $Ni(acac)_2 + P(OC_6H_5)_3 + Al(C_2H_5)_3$ and $Ni(acac)_2 + P(OC_6H_5)_3 + Al(C_2H_5)_3^{+} + BF_3(C_2H_5)_2O$ catalytic systems in solution in halogenohydrocarbons. The oxidative addition of the halogenohydrocarbon to the intermediate complexes results in the formation in the system of organometallic nickel complexes of the type



$$\underset{\underset{L}{\uparrow}}{R-Ni}\begin{matrix}\nearrow Hal \searrow \\ \nwarrow F \nearrow\end{matrix}M \rightleftarrows \left[\begin{matrix}RNi\\ \uparrow\\ L\end{matrix}\right]^+ [MHalF]^-$$

where M = B or Al, L = phosphorus-containing ligand, and X = halide ion.

The nature of the activating ligand influences also the composition of the codimerisation products. Chlorine-containing compounds direct the process towards the preferential formation of 4-PP-2.[27] In the presence of boron trifluoride etherate, the reaction products contain a large amount of 4-PP-1. Catalytic systems containing $Al(C_2H_5)_2Cl$ exhibit a high activity without electron-accepting additives and the isomeric composition of the phenylpentenes depends in this case on the nature of the electron-donating ligand and the P:Ni ratio. For the ratio P:Ni = 1, 2-methyl-3-phenylbut-1-ene, the product of the "tail to tail" addition (yield up to 15%), is present among the reaction products together with 4-phenylpentenes. The increase of the P:Ni ratio to 4:1 or the replacement of the phosphorus-containing ligand by bipyridyl fully suppresses the "tail to tail" addition. The main reaction product is then 4-PP-2 (95–96%). In the absence of electron-donating ligands, a large amount of styrene oligomerises, which reduces the yield of phenylpentenes.[27,29,30]

Thus the introduction of phosphorus-containing ligands into the coordination sphere of nickel increases the selectivity of the codimerisation of styrene with ethylene and propene. The most active catalytic centres contain electron-accepting acido-ligands and neutral ligands. The nature of the acido-ligand in the initial nickel compound has a significant influence on the activity and selectivity of the action of nickel-containing systems of the type of Ziegler–Natta catalysts, which indicates the retention of the bond between this ligand and nickel in the catalytic centres. This is also indicated by the results of kinetic studies.[8,24,27,29,30-33]

IV. GENERAL KINETIC FEATURES OF THE STYRENE OLIGOMERISATION AND CO-OLIGOMERISATION REACTIONS

The orders of the oligomerisation and co-oligomerisation with respect to the monomers depend on the nature of the components, the composition of the catalytic systems, and the reaction temperature. In the dimerisation of styrene in the presence of the nickel *NN*-diethyldithiocarbamate + diethylaluminium chloride two-component system, the reaction order depends on temperature and varies from 0.43 to 0.95 in the range 10–33 °C. When triphenyl phosphite is introduced into the catalyst, the reaction order with respect to styrene becomes unity and is independent of temperature but the molecular weight of the oligostyrene is then found to increase.[24]

A change in reaction order is observed also in the codimerisation reactions of styrene or α-methylstyrene with ethylene and propene.[8,28-30,33] In this case, the rates of formation of the codimers obey the complex relation $v = K[\text{catalyst}][\text{styrene}]^n[\text{olefin}]^m$, where K is the codimerisation rate constant and n and m depend on the nature and concentration of the olefin, the nature of the catalyst components, and temperature, varying in the range from 0 to 1 (Table 1). Thus, in the codimerisation of styrene with ethylene in the presence of the $Ni(acac)_2 + P(OC_6H_5)_3 + Al(C_2H_5)_3 + BF_3(C_2H_5)_2O$ catalytic system, which exhibits a moderate activity, at −30 °C the rate of formation of 3-phenylbut-1-ene is almost independent of both the initial styrene concentration and time, i.e. $n = m = 0$.[32]

---

* DEDTC = diethyldithiocarbamate, DEPDT = diethyl phosphorodithioate, DPPDT = diphenylphosphorodithioate, and bipy = bipyridyl.

** The reaction order with respect to nickel is 1.

An analogous behaviour has been observed also in the codimerisation of α-methylstyrene with ethylene at 15 °C.[33] With increase of temperature to 25 °C, there is a transition from the zero reaction order with respect to α-methylstyrene to the first order process. When phosphite in the catalyst is replaced by αα′-bipyridyl, the zero order with respect to styrene is retained also at 25 °C. The same reaction order is observed also in the presence of highly active catalytic systems containing organic dithio-derivatives of nickel (dithio-systems).[8,29,30] The reaction order with respect to ethylene likewise depends on temperature and, when the reaction order with respect to styrene (or α-methylstyrene) is zero, it is less than unity, while under the conditions where the rate of codimerisation is directly proportional to the styrene concentration the order with respect to ethylene is also unity. At a methylene pressure above 0.3 MPa, the rate of codimerisation in the presence of the dithio-systems is independent of the styrene and ethylene concentrations.[8]

In the codimerisation of styrene with propene, the reaction order with respect to propene in the range of concentrations of the latter 1–7 M is independent of the nature of the catalyst and is close to unity, while the order with respect to styrene varies from 0 to 1 (Table 2). Depending on the nature of the catalyst components, the kinetic curves can be S-shaped or can be straight lines, the latter being observed in the presence of three-component dithio-systems.[27,29,30] Linear kinetic plots imply that in the presence of these systems the rate of codimerisation does not change when the concentrations of the monomers are varied with time, i.e. in this case a zero reaction order with respect to both monomers is attained.

V. DEPENDENCE OF THE FORM OF THE KINETIC EQUATIONS FOR THE OLIGOMERISATION AND CO-OLIGOMERISATION OF STYRENE ON THE NATURE OF THE LIGANDS

A common stage in the processes involving the oligomerisation of styrene and its codimerisation with olefins is the addition of the first styrene molecule to nickel hydride. The second monomer added in oligomerisation is again styrene, while in co-dimerisation it is ethylene or propene. The dependence of the reaction order with respect to the reacting monomers on the nature of the catalyst components and the experimental conditions indicates in general the equilibrium character of the stages in which the monomers are added to the active centres and confirms the two-stage nature of

Table 2. The orders of the codimerisation reaction of styrene with propene with respect to the monomers.[29,30]

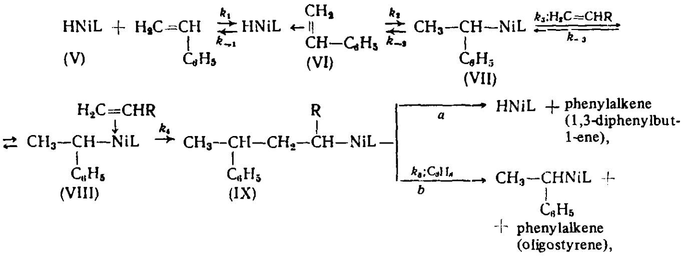
*Catalyst prepared in the presence of styrene.

this reaction (the presence of coordination and insertion stages):



where R = C_6H_5 in oligomerisation and R = H or CH_3 in codimerisation.

It has been shown[29,30,33] that the rate of codimerisation is satisfactorily described by the general kinetic equation

$$v_1 = \frac{\alpha\beta k_4 K'K''K''' [\mathrm{Ni}]_0 [\mathrm{St}]_0 p}{1 + (K' + K'K'' + \beta K'K''K''' p) [\mathrm{St}]_0} \tag{1}$$

and when the reaction order with respect to styrene is zero by the equations

$$v_1 = \frac{\alpha\beta k_4 K'K''K''' [\mathrm{Ni}]_0 p}{K' + K'K'' + \beta K'K''K''' p} \tag{2}$$

$$v_2 = \frac{\alpha\beta k_3 k_4 k_5 [\mathrm{Ni}]_0 p}{(k_{-3} + k_4) k_5 + (k_4 + k_5) \beta k_3 p} \tag{3}$$

where ν_1 and ν_2 are the rates of formation of the codimers via pathways *a* and *b* respectively, α is the fraction of active codimerisation centres relative to the initial concentration of the nickel compound, β the solubility coefficient of the olefin, k_3, k_{-3}, k_4, k_{-4}, and k_5 are the rate constants for the corresponding elementary stages, K', K'', and K''' the stability constants of the complexes (VI), (VII), and (VIII) respectively, p is the olefin pressure, and $[\mathrm{Ni}]_0$ and $[\mathrm{St}]_0$ are the initial concentrations of the nickel compound and styrene respectively.

For zero order with respect to both reacting monomers, the rate of codimerisation via pathway *b* obeys the equation[8]

$$v_2 = \frac{\alpha k_4 k_5 [\mathrm{Ni}]_0}{k_4 + k_5} \tag{4}$$

or, when $k_5 \geq k_4$, the equation

$$v_2 = \alpha k_4 [\mathrm{Ni}]_0 \tag{5}$$

When the reaction order with respect to styrene is zero and that with respect to olefins is unity, we have

$$v_1 = \frac{\alpha\beta k_4 K'K''K''' [\mathrm{Ni}]_0 p}{K' + K'K''} \tag{6}$$

$$v_2 = \frac{\alpha\beta k_3 k_4}{k_{-3} + k_4} [\mathrm{Ni}]_0 p \tag{7}$$

If $k_{-3} \gg k_4$, then according to Eqn.(7) the effective codimerisation rate constant $k_{\mathrm{eff}} = \alpha\beta k_4 K'''$, i.e. it depends both on the stability constant K''' and on the rate constant k_4 for the insertion stage. If the temperature coefficient of the constant K''' is then low, the activation energy for the overall codimerisation process is determined mainly by the activation energy for the insertion stage. On the other hand, if $k_{-3} \ll k_4$, then $k_{\mathrm{eff}} = \alpha\beta k_3$ and the activation energy is determined by the temperature dependence of the rate constant for the complex formation stage. Usually $k_{-3} \gg k_4$ in the codimerisation of styrene with ethylene and propene,[8,29,30,33] while in the oligomerisation of styrene we have the opposite situation with $k_{-3} \ll k_4$.[27-29] Consequently the first order of the oligomerisation reaction is a consequence of an appreciable contribution by the complex formation step in the propagation stage to the overall process kinetics. The effective rate constant for chain propagation in then identical with the complex formation rate constant.[8] The experimental results are described satisfactorily by the equation[24]

$$v_{\mathrm{d}} = \frac{\alpha k_1^* k_2^* k_3^* [\mathrm{Ni}]_0 [\mathrm{St}]_0}{k_3^* (k_1^* + k_2^*) + k_1^* k_2^* [\mathrm{St}]_0} \tag{8}$$

$$v_{\mathrm{ol}} = \alpha(k_p^* + k_t^*)[\mathrm{Ni}]_0[\mathrm{St}]_0, \tag{9}$$

$$\overline{P}_{\mathrm{p}} = \frac{k_p^*}{k_t^*} + 1, \tag{10}$$

where ν_{d} and ν_{ol} are the rates of dimerisation and oligomerisation of styrene respectively, $\overline{P}_{\mathrm{p}}$ is the average degree of polymerisation of styrene, k_1^* and k_2^* are the effective rate constants for the stages involving the addition of the first and second molecules of styrene in dimerisation, k_3^* is the effective rate constant for the elimination of the dimerisation product (1,3-diphenylbut-1-ene) from the complex (IX), and k_p^* and k_t^* are the effective rate constant for chain propagation and chain transfer to the monomer in the oligomerisation of styrene. The remaining notation was explained above.

VI. KINETIC PARAMETERS OF THE ELEMENTARY STAGES IN THE STYRENE OLIGOMERISATION AND CO-OLIGOMERISATION PROCESSES

Eqns.(1)–(10) and their forms in terms of the variables $1/\nu_i$ and $1/[\mathrm{M}]$, where ν_i is the rate of formation of the *i*th produce and [M] the concentration of one of the reacting monomers, make it possible to determine the rate constants for the elementary stages or their combinations and to estimate how they vary as a function of the nature of the components and the composition and conditions governing the preparation of the catalyst.

The kinetic parameters of the dimerisation and oligomerisation of styrene calculated with the aid of Eqns.(1)–(3) have been published.[24] The introduction of a phosphorus-containing ligand into the catalyst increases the activation energy for chain propagation (39 kJ mol^{-1} in the two-component system and 58–63 kJ mol^{-1} in the three-component system). At the same time, as shown above, the character of the chain termination changes on passing from dimerisation to oligomerisation: instead of the β-elimination of nickel hydride, chain transfer to the monomer takes place. The activation energy for chain termination then changes little but the ratio of the chain propagation and chain termination rate constants increases, which ultimately promotes the formation of an oligomer with a high molecular weight.[24]

Phosphorus-containing ligands exert the opposite influence on the activation energy for the codimerisation of styrene with ethylene.[8,28] On passing from the two-component to the three-component system, the activation energy for codimerisation falls sharply (almost by a factor of two), while the rate constant increases by a factor greater than 10.

The kinetic parameters change also in the codimerisation of styrene with propene:[29,30] depending on the nature of the catalyst components, the activation energy E_a ranges from 29–33 to 63–64 kJ mol^{-1}. It decreases on passing from the two-component to the three-component system and from the acetylacetonate system to the dithio-system. The activation energy for the formation of 4-PP-2 is in all cases greater than that for the formation of 4-PP-1 (by 8–16 kJ mol^{-1}). However, the rate of formation of 4-PP-2 is higher than the rate of formation of 4-PP-1 even along the initial sections of the kinetic curves, where the degree of isomerisation of 4-PP-1 to 4-PP-2 is very low.[27,29,30,34] Hence it follows that at least in the initial instant 4-PP-1 and 4-PP-2 are formed on different centres, the centres for the formation of the second isomer predominating.

The opposite influence of phosphorus-containing ligands on the activation energies for styrene oligomerisation and codimerisation processes is a direct consequence of the different nature of the rate-limiting stages in these processes. The presence of a phosphorus-containing ligand in the coordination sphere of nickel diminishes the activation energy for the insertion stage and increases that for the olefin coordination stage.

Table 3. Kinetic parameters of the polymerisation of butadiene.[1,35,37,38]

Catalytic system	T, °C	N_p, %	k_p, litre mol^{-1} min^{-1}	k_d, litre mol^{-1} min^{-1}	Activation energy***, kJ mol^{-1}

* The rate constants for the chain transfer to the monomer (k_t^M/k_p) and to the catalyst (k_{cat}/k_p) at 25 °C are $k_t^M/k_p = 2 \times 10^{-4}$ and $k_{cat}/k_p = 5 \times 10^{-3}$.

** $k_t^M/k_p = 1.3 \times 10^{-2}$ and $k_{cat}/k_p = 1.1 \times 10^{-2}$.

*** The activation energy for the polymerisation of butadiene in the presence of pure π-alkenylnickel is 60–70 kJ mol^{-1},[1] while in the presence of the $[(C_2H_5O)_2PS_2]_2Ni$ + bipyridyl + $(C_2H_5)_2AlCl$ catalytic system it amounts to 56.2 kJ mol^{-1}.[37]

VII. KINETIC PARAMETERS OF THE ELEMENTARY STAGES OF THE POLYMERISATION OF BUTADIENE

The dependence of the kinetic parameters of the elementary stages of the process on the nature of the ligands can be traced in relation to the polymerisation of butadiene in the presence of catalytic systems of three different types: π-alkenylnickel chloride + quinones,[35,36] nickel *NN*-diethyldithiocarbamate + diethylaluminium chloride, and nickel *NN*-diethyldithiocarbamate + diethylaluminium chloride + bipyridyl.[37,38] The kinetic constants were calculated from the rates and degrees of polymerisation with the aid of the corresponding kinetic equations. The initial concentrations of the chain propagation centres in the π-alkenyl systems were estimated from the initial concentration of the growing chains.[36] The standard deviation of the calculated values of the parameters listed in Table 3 from the experimental values was less than 3%.

Table 3 shows that the concentration of the propagation centres N_p is in all systems less than the initial concentration of the nickel compound, amounting to not more than 44% of $[Ni]_0$ depending on the nature of the catalyst components and the experimental conditions. In the case of the dithio-system, the calculated maximum concentration of the propagation centres diminishes with increase of temperature, which is due to their bimolecular deactivation.[37,38] The activation energy for the destruction of the centres E_d in this system exceeds that for the chain propagation E_p by ~18 kJ mol^{-1}. In the presence of an electron-donating ligand (bipyridyl), a sharp increase of the process activation energy is observed.[37]

The introduction of electron-accepting ligands (quinones) into π-alkenyl systems tends to decrease the activation energy for polymerisation.[1] Both the propagation rate constants k_p and the bimolecular deactivation rate constants k_d increase on passing from a weaker π-electron acceptor (dichloroquinone) to a stronger acceptor (chloranil, fluoranil), while the corresponding activation energy diminishes under these conditions.

The stronger activating effect of fluoranil (compared with chloranil) is a consequence of the increased concentration of the propagation centres and the high activation energy for chain propagation (25–30 kJ mol^{-1}), while the difference between the electron affinities of these quinones is small (the half-wave potentials for chloranil and fluoranil are respectively +0.01 and −0.04 V).[35,36]

The presence in the catalyst of a strongly nephelauxetic dithio-ligand[39] increases appreciably (by two orders of magnitude and above) the rate constants for the elementary stages compared with powerful π-electron acceptors such as halogenoquinones. However, this increase is achieved by virtue of the more favourable steric conditions and not as a result of the decrease of the activation energy, because the E_a in the highly active dithio-system either differs little from the E_a in the π-alkenylnickel chloride + quinone systems or exceeds it (cf. E_p and E_d in Table 3).

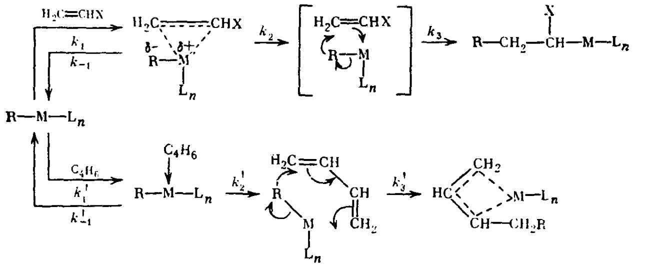
As for the π-alkenyl systems, one of the principal chain termination reactions in the presence of dithio-systems is chain transfer to the monomer. However, the rate constant for this last stage in the presence of dithio-systems is higher by two orders of magnitude, which causes the formation of low-molecular-weight polybutadiene,[37] while the less active π-alkenyl systems lead to the formation of high-molecular-weight polybutadiene.[1]

Thus, in the polymerisation of butadiene electron-accepting ligands diminish the activation energy for the chain propagation stage, while electron-donating ligands increase it. The molecular weight is determined not so much by the steric characteristics of the ligands as by their energetic (electronic) characteristics.

VIII. THE S_ECi MECHANISMS OF THE CATALYTIC ACTION OF NICKEL-CONTAINING SYSTEMS. THE ROLE OF ELECTRONIC AND STERIC PROPERTIES OF THE LIGANDS

The study of the influence of various electron-donating and electron-accepting ligands on the activity and selectivity of nickel-containing systems in dimerisation, codimerisation, oligodimerisation, and polymerisation processes and also on the kinetic parameters of these reactions has shown that electron-accepting ligands as a rule tend to decrease the activation energy and to increase the rate of the process. The influence of electron-donating ligands in various reactions is manifested in different ways: they increase the activation energies for the oligomerisation of styrene and the polymerisation of butadiene, while they decrease the activation energy for the codimerisation of styrene with ethylene and propene.

The results obtained make it possible to regard the elementary stage involving the addition of the monomer to the catalytic hydride or organometallic centre as an electrophilic reaction proceeding via a stage in which the monomer undergoes nucleophilic coordination to the metal (Abraham's S_ECi mechanism):[9]



where R = H, alkyl, benzyl, or alkenyl and L_n = set of remaining ligands.

This approach makes it possible to classify the catalytic mechanisms of nickel-containing systems in linear oligomerisation and polymerisation processes in terms of the kinetic features of the reactions and the electronic effects of the ligands from a single standpoint and to explain the causes of the opposite influence of the introduction of phosphorus-containing ligands on the activation energies for various processes.

According to these ideas, in those cases where the rate-limiting stage is the nucleophilic coordination of the monomer to the metal, the introduction of an electron-donating ligand into the coordination sphere of nickel increases the activation energy for the process. On the other hand, if the electrophilic insertion of a coordinated monomer molecule becomes the rate-limiting stage, then electron-donating ligands tend to decrease the activation energy, apparently as a consequence of the increase under their influence of the electron density at the α-carbon atom in the Ni–C bond. The activation of the system reacting via the first mechanism takes place under the influence of electron-accepting ligands, while the prescence of electron-donating ligands is essential for the activation of systems reacting via the second mechanism. The first type of activation is manifested in styrene oligomerisation reactions[31,32] and also in the polymerisation of butadiene.[1,40–42] The codimerisation reactions of styrene with ethylene and propene are examples of activation of the second type.[8,29,30]

The styrene oligomerisation and co-oligomerisation reactions then proceed via different versions of the S_ECi mechanism, which differ by the nature of the rate-limiting stages and correspondingly by the overall orders with respect to the reactants.

Investigations have shown that the overall kinetic features of the dimerisation, oligomerisation, and polymerisation reactions in the presence of nickel-containing systems vary within wide limits, so that the rates of the overall processes can be described by first-, second-, third-, and fractional-order kinetic equations.[8,24,29,30,33,35,36] In terms of the S_ECi mechanism, the corresponding versions can be classified as the S_E1Ci, S_E2Ci, S_E3Ci, and S_EnCi mechanisms.

Such mechanisms obtain when the nucleophilic coordination of the monomer is a rapid non-equilibrium process and the kinetics of the overall reaction is determined by the electrophilic insertion stage. The effective rate constant is then identical with the overall rate constant for the insertion process. A characteristic feature of the S_E1Ci mechanism is the independence of the rate of the process of the concentrations of the reacting monomers. The activation of systems acting via the S_E1Ci mechanism is possible when electron-donating ligands, increasing the heteropolar character of the $R^{\delta -}–M^{\delta +}$ bond, are introduced into the coordination sphere of the metal. This is achieved by reducing the activation energy for the insertion stage. Examples of the S_E1Ci mechanism are provided by the codimerisation reactions of styrene with ethylene and propene in the presence of dithiosystems.

The S_E2Ci mechanism is determined by the contribution of the nucleophilic coordination of the monomer to the overall process kinetics, whereupon the effective rate constant is either equal to the complex formation rate constant ($k_{eff} = k_1$) or represents a combination of the rate constants for elementary stages (for example, $k_{eff} = k_1k_2/k_{-1}$, where k_2 is the overall rate constant for the insertion stage). When the equality $k_{eff} = k_1$ holds, the process activation energy increases in the presence of electron-donating ligands, which diminish the effective positive charge on the metal and thereby retard the nucleophilic monomer coordination stage, which determines the overall rate of reaction. In order to increase the efficiency of the catalytic action of the system, it is essential to introduce electron-accepting, neutral and nephelauxetic acido-ligands into the coordination sphere of the metal. The introduction of these ligands increases the effective positive charge on the metal as a result of the formation of inner-sphere π-bonds or bridging σ-bonds (M...X...L) and also anisotropic or outer-sphere complexes with transfer of charge (and the anion), which ultimately diminishes the process activation energy. Such influence of the ligand is characteristic of styrene oligomerisation and butadiene polymerisation processes. If $k_{eff} = k_1k_2/k_{-1}$, then the introduction of electron-donating ligands into the coordination sphere of the metal decreases the process activation energy, because the stage involving the electrophilic insertion of the coordinated monomer molecule becomes rate-determining. This version of the S_E2Ci mechanism operates in the codimerisation of styrene with ethylene and propene in the presence of acetylacetonate systems. Apart from the first order with respect to the monomer, its characteristic feature is the decrease of the process activation energy after the introduction of electron-donating ligands into the catalyst.[29,30,33]

The S_E3Ci mechanism is manifested when the effective rate constant for the process includes the rate constants (or equilibrium constants) for the nucleophilic stages in which two molecules of the same monomer or the molecule of different monomers are coordinated (for example, $k_{eff} = K'K''k_2$, where K' and K'' are the stability constants of the π-complexes incorporating one and two molecules of identical or different monomers respectively and k_2 is the insertion rate constant). The addition of two molecules can take place either consecutively or simultaneously, while the insertion of one molecule is accompanied by the reversible coordination of another. The principal distinctive feature of this mechanism is the overall second order with respect to the reacting monomers (monomer) and the first order with respect to the catalyst. The influence of electron-donating and electron-accepting molecules on the process activation energy is the same as in the S_E2Ci mechanism. This case obtains in the codimerisation of styrene with ethylene and propene in the presence of acetylacetonate systems at elevated temperatures (>15 °C). It apparently occurs also in many other instances of the homo- and co-oligomerisation of olefins and also in polymerisation under the influence of metal complex systems when the overall order with respect to the monomer is two.[1,4]

The S_EnCi mechanism occupies an intermediate position between the S_E1Ci and S_E2Ci mechanisms or between the S_E2Ci and S_E3Ci mechanisms. It obtains when the contributions of the nucleophilic and electrophilic components in the S_ECi addition are comparable. The effective process rate constant is a complex combination of rate constants and at least one of the terms in the denominator of the rate equation includes the monomer concentration [for example, Eqns. (1), (2), and (8)]. A characteristic feature of this mechanism is the fractional overall order with respect to the monomers ($1 < n < 2$ or $2 < n < 3$). The temperature dependence of the reaction orders with respect to the monomers must be regarded as a second characteristic feature. The activating influence of the ligands on the properties of catalytic systems is in this case indefinite. It depends on the ratio of the rate constants for the nucleophilic and electrophilic stages in the S_ECi addition. In particular, electron-donating ligands can both decrease and increase the process activation energy or they may not influence it at all. The S_EnCi mechanism is apparently encountered more often than the other mechanisms. It can be clearly traced in the styrene dimerisation reactions and in the codimerisation of styrene with ethylene and propene and is apparently also observed in diene polymerisation reactions.[1,8,24,29,30]

The proposed classification of the mechanisms of catalytic action make it possible to make sense of the wide variety of kinetic features observed in the linear oligomerisation and polymerisation processes catalysed by nickel-containing and other systems. It helps in many respects to predict the mechanisms of the activating action of ligands and to understand the causes of opposing influences on the catalytic efficiency of systems in various ologomerisation and polymerisation reactions. The influence of polar solvents on the rate of catalytic processes can be satisfactorily explained from the standpoint of the S_ECi mechanisms: highly basic solvents (ethers, sulphides, amines) hinder the nucleophilic coordination of the monomer, competing with the latter for the inner coordination sphere of the metal, while halogenohydrocarbons, capable of forming anisotropic or outer-sphere charge-transfer complexes, accelerate it. This leads ultimately to an increase in the rate of the process, which has been demonstrated for the codimerisation of styrene with ethylene.[8]

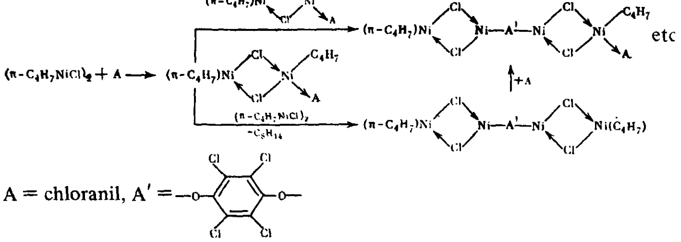
The changes, not only in the rate of polymerisation of butadiene, but also in the stereospecificity of the catalytic action of the systems under the influence of electron-donating and electron-accepting additives can be explained in terms of the S_ECi mechanisms. In the presence of electron-donating ligands in the coordination sphere of the metal, the rate of the nucleophilic coordination of the monomer is diminished, on the one hand, and the probability of such coordination of the penultimate unit, which fixes the terminal unit in the *anti*-configuration, decreases, on the other hand. The $\pi-\sigma$ and *anti–syn* isomerisation processes in the terminal unit are then facilitated, which is also promoted by the increase of the heteropolar character of the $M^{\delta+}-C^{\delta-}$ bond. As a result, the polymer microstructure shifts towards the 1,4-*trans*-configuration of the units. On the other hand, in the presence of electron-accepting ligands, both the rate of the nucleophilic coordination of the monomer and the probability of the fixation of the terminal unit in the *anti*-configuration as a result of the nucleophilic coordination of the penultimate unit increase, which leads to the 1,4-*cis*-structure of the polymer. The fact that in certain cases the influence of electron-donating ligands on the microstructure of polybutadiene, obtained in the presence of nickel-containing systems, resembles their influence in anionic systems is also striking in this respect: in both cases the content of 1,2-units increases. Thus it has been established[43–55] that the addition of triphenylphosphine to the nickel acetylacetonate + diethylaluminium chloride system with the ratios Ni : Al : P = 1 : 10 : 4 ensures the formation of polybutadiene containing 49% of the *cis*-units, 11% of the *trans*-units, and 40% of the 1,2-units.

However, one should note that this approach cannot explain all the features of the influence of ligands on the catalytic properties of the systems. In the S_ECi mechanisms, account is taken only of the influence of electronic factors from the standpoint of nucleophilic coordination and electrophilic insertion. Evidently, many oligomerisation reactions, proceeding via oxidation-reduction stages, cannot be treated, in principle, in terms of the S_ECi mechanisms. They include the majority of cyclic oligomerisation and co-oligomerisation reactions and certain linear oligomerisation reactions,[5] the key stages of which are oxidative addition (including those which lead to the formation of metallocycles) and reductive elimination. The catalysis mechanisms of these reactions constitute a special class and they are probably best referred to as redox mechanisms.

The steric effects of the ligands, which frequently play a decisive role in the overall catalytic action of the system, remain outside the range of phenomena which can be explained by the S_ECi mechanisms. These effects influence the mode of addition of the monomers, the process selectivity, the absolute rate constants for the elementary stages, and their ratios.

Ligands also have different effects on the number of catalytic centres. It has been established for the π-alkenylnickel chloride + quinone systems[41] that electron-accepting ligands diminish appreciably the concentration of such centres (4–10% of the concentration of the initial nickel compound). This conclusion was subsequently confirmed by a number of studies on the polymerisation of butadiene in the presence of catalytic systems based on π-alkenylnickel derivatives.[1]

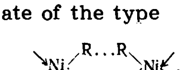
It has been shown[42] that the interaction of π-alkenylnickel halides with electron acceptors (quinones) involves an oxidation-reduction polycomplex formation reaction leading to the formation of oligomeric and polymeric complexes with terminal alkenylmetal and metal hydride fragments containing electron-acceptor molecules bound in complexes. The formation of catalytic centres is accompanied by the formation of the products of the dimerisation of the alkenyl groups, which indicates the homolytic destabilisation of the Ni–C bond under the influence of electron-accepting ligands. The overall polycomplex formation scheme for the interaction of bis-π-crotylnickel chloride with chloranil is as follows:†



---

† Other possible reactions occurring in the polycomplex formation process have been considered by Azizov.[42]

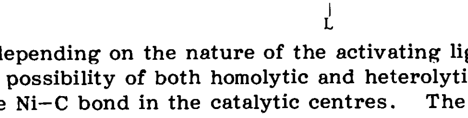
It has been suggested that the polycomplex grows via an intermediate cyclic state of the type



whose cleavage leads to the formation of the dimerisation products C_8H_{14} and the addition of a new unit to the growing end of the polycomplex. Mainly the terminal nickel atoms, constituting only a small fraction of the total number of nickel atoms, participate in the initiation of polymerisation. A low concentration of propagation centres obtains also in two-component systems of the Ziegler–Natta type, which has been established for the system based on organic dithio-derivatives of nickel and diethylaluminium chloride—10–40% of $[Na]_0$ depending on the reaction temperature.[37,40]

Electron-donating ligands exert opposite influences on the number of catalytic centres and the activation of the Ni–C bond. The increase of the effective propagation rate constant (αk_p) and the overall oligomerisation rate constant in the presence of a phosphorus-containing ligand, which is inconsistent with the increase of the activation energy for chain propagation, is striking.[24] This finding has been explained by the increase of the number of catalytic centres (or α) owing to their stabilisation as a result of complex formation with phosphorus-containing ligands. Such increase predominates over the decrease of k_p, which ultimately entails the growth of αk_p and of the overall rate of oligomerisation.

The conditions in the formation of the catalyst and the nature of the acido-ligand in the initial nickel compound also exert an appreciable influence on the number of catalytic centres in the system and hence on the effective codimerisation rate constant.[8] The preliminary formation of a three-component dithio-system in the presence of styrene entails a significant increase of the effective codimerisation rate constant.[8,28] On the other hand, the conditions governing the formation of the three-component acetylacetonate system do not exert an appreciable influence on this quantity. The activation energy depends little on the nature of the acido-ligand and on the catalyst formation conditions, but these factors do influence the pre-exponential factor, which reflects indirectly the changes in the concentration of the active centres in the system. Analysis of the changes in the pre-exponential factor in three-component systems, characterised by identical general kinetic features of the codimerisation reaction, permit the conclusion that the concentration of the active centres increases on passing from diethylphosphorodithioate to diethyl dithiocarbamate and when the catalyst is formed beforehand. The results of spectroscopic, cryoscopic, and kinetic measurements[8] have shown that this difference between the dithio-system and the acetylacetonate system is due to the slowness of the complex formation reaction between the dithio-derivative of nickel and the phosphorus-containing ligand, which takes place only after the interaction of the nickel compound with alkylaluminium halide:

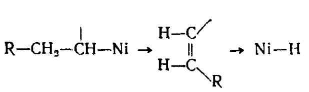


Thus, depending on the nature of the activating ligands, there is a possibility of both homolytic and heterolytic activation of the Ni–C bond in the catalytic centres. The former takes place under the influence of electron-accepting ligands, which is indicated, in particular, by the isolation of the products of the "quasi-radical" dimerisation of the alkenyl group in the reactions of π-alkenylnickel halides with electron-accepting compounds. The heterolytic activation of the Ni–C bond occurs under the influence of electron-donating ligands, which tends to decrease the activation energy for the insertion stage in the codimerisation of styrene with ethylene[8,28] and propene[29] and to increase the fraction of 1,2-units in the polymerisation of butadiene.[43–55]

The heterolytic activation of the metal–carbon bond is in certain cases apparently so great that the organometallic derivative of the transition metal becomes a catalyst of the anionic polymerisation of polar monomers, as happens, for example, in the polymerisation of methyl methacrylate in the presence of tris-π-allylchromium or the $Cr(acac)_3$–Al(isobutyl) system in combination with electron donors and also in the presence of complex catalytic systems based on vanadium and chromium compounds.[56] An analogous behaviour has been observed in the polymerisation of polar vinyl monomers under the influence of bipyridyl complexes of iron(II) and cobalt(I), having the d^6 and d^8 electronic configurations respectively.[57,58]

Homolytic activation is the main cause of the bimolecular destruction of active centres, occurring in the polymerisation of butadiene in the presence of the π-alkenyl halide + quinones[41] and nickel *NN*-diethyldithiocarbamate + diethylaluminium chloride[40] catalytic system. However, overall, the stability of the catalytic action of the system depends not only on the nature of the activating ligand but also on the type of reaction catalysed. Thus the nickel *NN*-diethyldithiocarbamate + diethylaluminium chloride system, which propagates the polymerisation of butadiene in an unstable manner (the active centres are destroyed as a function of time[40]), proved to be entirely stable in styrene oligomerisation and codimerisation processes.[8,24,34] In our view, the stability of the action of the system is determined not so much by the thermodynamic stability as by the kinetic stability of the Ni–C bond in the intermediate organometallic centres, which is reflected in the frequency of the transitions: potential centre → actual centre and actual centre → potential centre. The hydride or organometallic derivatives of nickel are then regarded as the potential centres, while the actual centres are only its organometallic derivatives.

The intensity of these transitions depend on the ease of σ,π-isomerisation[59] in the intermediate organometallic derivatives of nickel. In principle, the isomerisation can proceed without a thermal effect or with only a small positive thermal effect. This is indicated by the comparison of the energies[2,60–62] and the bonds ruptured and newly formed in the reaction:



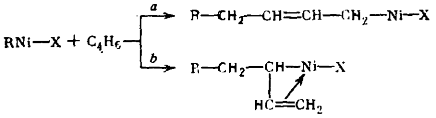
Bond	Ni—C	Ni—H	C—C	C=C	C—H	$\begin{matrix}HC\\ \Vert\\ HC\end{matrix}\to M$
Energy, kJ mol^{-1}	251	293	251	427	365	63—101

The intensity of the above transitions is therefore fairly high in the dimerisation, codimerisation, and oligomerisation processes in which intermediate alkylnickel derivatives are formed. There is insufficient time for the destruction of the catalytic centres via a bimolecular mechanism in any of the intermediate forms and the system proves to be stable. The transition: actual centre (growing chain) → potential centre (hydride or alkenyl derivative of nickel) in the polymerisation of butadiene is a slow reaction, which entails the possibility of a bimolecular destruction of the growing chains.

The intensity of the above transitions, which are in essence chain termination processes, determines also the molecular weight of the oligomerisation and polymerisation products. Among these transitions, hydrogen transfer, which proceeds with or without the elimination of a hydride complex from the intermediate organometallic derivatives of nickel has special importance. The transfer with elimination occurs, as stated above, in dimerisation and codimerisation reactions and that without elimination takes place in oligomerisation and polymerisation processes. The ease of hydrogen transfer depends on the degree of σ,π hyperconjugation between the *d* orbitals of the metal atom and the σ bonding orbitals of the β-C–H bond.[2,63] Therefore all the factors leading to a decrease of the degree of σ,π conjugation (increase of the multiplicity of the bonding of the organic group to nickel in the sequence σ-alkyl < π-benzyl < π-alkenyl, the presence of bulky ligands in the coordination sphere of the metal, decrease of temperature, stereochemical factors) in the intermediate complexes can promote an increase of the molecular weight of the reaction products. The fact that the introduction of both electron-donating (tertiary phosphines, phosphites[24]) and electron-accepting (metal trichloroacetates[20-22]) ligands into the catalyst increases the molecular weight of oligostyrene, although it has different effects on the activation energy for the overall process, is important in this respect. Consequently, the molecular weight of the oligomerisation products depends primarily on the steric effects of the ligands and not on their electronic effects.

An analogous picture has been observed also in the polymerisation of butadiene; the less active π-alkenylnickel chloride + halogenoquinones systems ensure the formation of high-molecular-weight polybutadiene,[35,40,64] while the highly active catalysts based on organic dithio-derivatives of nickel lead to the formation of only low-molecular-weight products.[37,40] Analysis of the results of kinetic measurements[35,38] has shown that the former systems are sterically less favourable at the chain termination stage involving transfer to the monomer or the transfer of a β-hydrogen atom. In the latter systems, the transfer to the monomer is a hundred times and more faster (Table 3).

It is noteworthy that in the absence from the monomer of a β-hydrogen atom which can be readily split off, the polymerisation process in the presence of nickel systems can proceed via the mechanism of "living" chains. Thus the polymerisation of 1,1-dimethylallene in the presence of bis-π-allylnickel bromide takes place via this mechanism.[65] The "living" chains mechanism is observed also in the early stages of the 1,4-polymerisation of butadiene in the presence of π-alkenyl systems,[1,36,41,66] which has also been explained by the absence of a β-hydrogen atom capable of being readily split off from the growing alkenylnickel derivative formed on 1,4-dissociation of the double bonds of butadiene (pathway *a*):



It is therefore entirely possible that chain termination in the polymerisation of butadiene in the presence of nickel-containing systems via hydrogen transfer mechanisms takes place mainly as a result of 1,2-dissociation of the double bond (pathway *b*). The relation between the molecular weight and the microstructure of polybutadiene synthesised in the presence of *cis*-directing systems may serve, in our view, as important evidence in support of this hypothesis.[67] The relation is explained by the fact that the processes concerned with the regulation of both the molecular weight and the microstructure involve the formation of the same intermediate σ-complex (via pathway *b*), in which there is a possibility of interaction between the β-C–H bond and nickel.

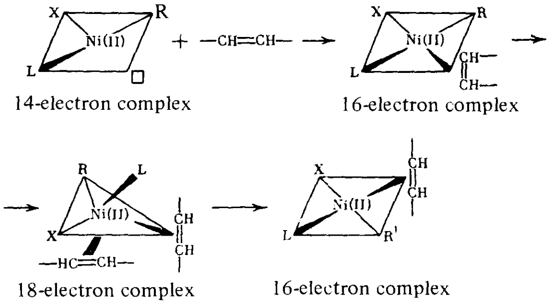
The results of a study,[68] in which the possibility of the polymerisation of butadiene via the "living" chain mechanism up to high degrees of conversion of the monomer in the presence of the bis-π-allylnickel trifluoroacetate + triphenylphosphine or chloranil catalytic system has been established, constitute convincing confirmation of the above considerations. In the polymerisation in heptane at 55 °C (with the ratio P/Ni = 0.18), a linear relation is observed between the number-average molecular weight and the degree of conversion and a satisfactory correlation between the experimental and calculated degree of polymerisation. After the exhaustion of the first and the addition of new portions of the monomer, polymerisation continues and there is a further increase of $\bar{M}_n$. It must be specially emphasised that the content of 1,4-units in the polymer investigated reaches 99% and above and also the fact that the increase of the molecular weight is promoted by both electron-donating (triphenyl phosphite) and electron-accepting (chloranil) ligands.

The conclusion that steric factors play a decisive role provides a key to the understanding of the principles governing the regulation of the structures and molecular weights of the products of the oligomerisation and polymerisation of unsaturated hydrocarbons in the presence of obtaining higher olefins and polyethylene from ethylene in the presence of these systems,[69-73] which had been previously thought to be unsuitable for these processes.

Steric effects influence also the selectivity of the codimerisation reactions of styrene with ethylene and propene. As shown above, on passing from a three-component to a two-component system, the selectivity of the codimerisation with respect to be ethylene (propene) which has reacted falls. Consequently, in the addition of the second monomer molecule to the active centres, steric hindrance in the coordination and insertion stages plays the main role and not the stabilisation energy of the newly formed Ni–C bond (which decreases in the sequence π-benzyl > σ-alkyl). In the presence of bulky phosphorus-containing ligands, the coordination of styrene is greatly hindered, as a result of which the ethylene (propene) molecule adds exclusively (or preferentially) to the intermediate benzyl derivative. In the absence of such ligands, the probability of the addition of the second styrene molecule increases and this lowers the selectivity of the codimerisation with respect to the styrene which has reacted.[8,24,27,29,30]

The opposite picture is observed in the addition of the first monomer molecule to hydride centres. As shown above, in the absence of phosphorus-containing ligands, the selectivity of the codimerisation with respect to the ethylene which has reacted, amounts to only 18%.[8,24] The remaining ethylene is converted into butenes, which means that ethylene and not styrene adds to a considerable proportion of the hydride centres. On the other hand, in the presence of phosphorus-containing ligands, styrene adds to them preferentially. The selectivity of the codimerisation with respect to the ethylene which has reacted then reaches 90–95%.[8,24] These results are also explained by the decrease of the probability of β-elimination from the benzyl derivative of nickel in the presence of phosphorus-containing ligands, hindering the σ,π-interaction, in the coordination sphere. Thus the steric effect of the ligands regulates not only the molecular weights but also the structures of the oligomerisation and polymerisation products.

However, one should note that, whereas the influence of electronic factors can be readily explained qualitatively from the standpoint of the S_ECi mechanism, this cannot be said of the steric factors. The latter apparently influence the geometry of the catalytic complexes, which in fact determines the very possibility of the catalytic process. In the dimerisation and oligomerisation reactions catalysed by transition metal complexes, there may be transitions between 14-, 16-, and 18-electron complexes.[74,75] For nickel, the 18-electron complexes are less stable than the 16-electron complexes. Therefore, if the initial centre is a 16-electron organometallic or hydride complex, the coordination of the first monomer molecule can be completed by its insertion in the Ni–C or Ni–H bond. If, on the other hand, the coordination of one monomer molecule results merely in building up the coordination sphere of the metal with formation of a stable 16-electron square-planar complex, then insertion requires the coordination of a second monomer molecule. This results in the formation of a less stable pentacoordinate 18-electron nickel complex, which readily isomerises to the tetracoordinate 16-electron complex in the insertion process:

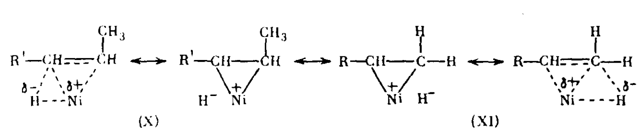


There is at present no information about the geometry of the active centres and it is therefore difficult to judge which of the geometrical dispositions is energetically most favourable. However, presumably the very possibility of the control of the sequence of the addition of monomers is determined primarily by the geometry of the intermediate states. The question of the monomer coordination and insertion sites is important in this respect. The few available experimental data show that, of the two mechanisms of the addition of olefins at the C–metal bond (*cis*-migration or insertion), *cis*-migration is preferred.[76] Evidently, in this case, for a specific disposition of the initial ligands, after each insertion stage three coordination sites appear alternately in the *cis*- and *trans*-positions relative to the ligand L. In relation to the organic group (or the α-carbon atom), the vacancy is always found to be in the *cis*-position.

The influence of the ligands on the selectivity of the codimerisation is probably determined by the different accessibilities of the *cis*- and *trans*-positions with respect to the ligand L in the coordination of monomers. In the codimerisation of styrene with ethylene (propene), ethylene (propene) is more readily coordinated in the *cis*-position in the intermediate benzyl derivative, while in the sterically less hindered *trans*-position in the initial hydride complex, the coordination of styrene is more favourable. The d_π, π_π interaction between the non-bonding *d* orbitals of the metal and the π orbitals of the benzene ring is then facilitated, which yields an additional energy gain. In the case of the sterically less favourable derivative of L having *cis*-vacancies, the d_π, π_π interaction is insignificant owing to the shielding of the non-bonding *d* orbitals of nickel by the bulky groups of the ligand L. Such alternation of the order in which the monomers are coordinated in combination with the *cis*-migration mechanism of insertion in the Ni–R bond ensures the exceptional selectivity of the codimerisation reaction.

Another version of the alternation mechanism has been proposed.[1,77,78] It has been suggested that the order in which the monomers are coordinated is determined by the number of vacancies in the coordination sphere of the metal. In the presence of a single free site, the olefin is more readily coordinated because it is more basic than the diene. In the presence of two vacancies, the coordination of the bidentate diene is more favourable. This mechanism explains satisfactorily the possibility of the formation of alternating copolymers of butadiene with α-olefins, but it can hardly operate in the codimerisation of olefins, each of which is capable of occupying only one coordination site. Apparently, depending on the nature of the metal, its ligand environment, and valence state as well as the geometry of the active complex, both versions of the alternation mechanism are possible.

Finally, one should point out that the mode of codimerisation is affected very strongly by the possibility of additional conjugation of any type. In the case of propene the greater probability of σ, π conjugation in the complex (X) compared with (XI) is apparently the main cause of the addition of nickel to the second carbon atom (contrary to the Markovnikov rule), which leads to the preferential formation of 4-phenylpent-2-ene:



In the presence of bulky ligands, the probability of σ,π conjugation diminishes, as a result of which there is in some cases an increase of the contribution by the addition of nickel to the first carbon atom and hence an increase of the content of the "tail-to-tail" adduct—2-methyl-3-phenylbut-1-ene.[27,29,30] The same effect probably occurs also in the dimerisation of propene, where the bulky phosphorus-containing ligands direct the process towards the formation of 2,3-dimethylbut-1-ene.[4–7]

Systematic studies[5,6] have shown that the influence of phosphines on the mode of addition of propene to the Ni–C and Ni–H bonds is determined to a large extent by steric factors, because among the *ortho*-, *meta*-, and *para*-substituted triphenylphosphines, an increase of the yield of 2,3-dimethylbut-1-ene and a decrease of the yield of hexenes are promoted solely by the *ortho*-substituted compounds. In the presence of aliphatic phosphines with similar electron-donating properties containing large organic groups, nickel forms a bond preferentially with the first carbon atom of propene in the first stage of the addition of propene to Ni–C, while in the absence of ligands it forms a bond preferentially with the second carbon atom [C(2)].

This has been explained by Henrici-Olivé and Olivé.[79] The authors suggest that, in the absence of steric hindrance by the ligand, the polarity of the double bond of propene is reversed in the coordination of the latter, as a result of which a negative charge appears on C(2). However, there are data according to which the addition of propene to the nickel hydride centres proceeds preferentially in the direction of Ni–C(2) even in the presence of phosphorus-containing ligands.[5,6] Consequently, the formation of the Ni–C(2) bond is presumably caused by the energy gain owing to the additional conjugation of the σ,π or $d_\pi p_\pi$ type and not by the reversal of the polarity of the double bond. On the other hand, if such interaction is blocked by the bulky groups of the ligand, then the addition takes place in accordance with the Markovnikov rule, i.e. in the direction Ni–C(1). Overall, the addition takes place via the S_ECi mechanism when both carbon atoms in the coordinated olefin molecule carry a partial positive charge.
