Benzaldehyde (together with other compounds) is formed in the photochemical oxidation of dibenzyl telluride or dibenzyl ditelluride.[69] Bis(*p*-methoxyphenyl)tellurone ($(p\text{-}RC_6H_4)_2.$ $.TeO_n$ (XLVIII, R = OMe, *n* = 2)—the first reliably characterised representative of tellurone obtained by the oxidation of bis(*p*-methoxyphenyl) telluroxide (XLVIII, *n* = 1) with sodium periodate, is an effective oxidant oxidising various substituted benzyl alcohols to the corresponding benzaldehydes.[68] Thus the oxidation of piperonyl and veratryl alcohols by compound (XLVIII, *n* = 2) gave 70–80% yields of piperonyl and veratryl aldehydes.[68] Aldehydes have also been obtained in 70–93% yield by treating bis(phenyldiiodotelluro)alkanes (XLIX) [60] with NaI in DMF under mild conditions (60 min, 20 °C):

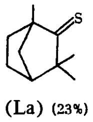
$$\underset{\text{(XLIX)}}{RCH\,(TeI_2Ph)_2} \xrightarrow{NaI} RCHO\,;$$
$$R{=}C_{11}H_{23},\ C_{12}H_{25},\ C_{14}H_{29},\ C_{16}H_{33},\ Ph\,(CH_2)_3\,.$$

2. Ketones

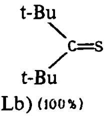
Ketones are formed when thioketones (L) are oxidised[15,16,70] by diaryl telluroxides (XLVIII, *n* = 1) and on reduction of α-halogenoketones with *OO*-diethyl phosphorotellurolates (VII) [71] or alkali metal tellurophenoxides (IV).[72]

(a) Oxidation of Thiocarbonyl Compounds by Diaryl Telluroxides

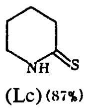
Thioketones with a wide variety of structures (L a–d) can be selectively oxidised to ketones with the aid of diaryl telluroxides[15,16,70] (under the formula of each thiocarbonyl compound given below, the yield of its oxo-analogue is indicated). Together with oxo-compounds, sulphur and diaryl tellurides are formed in these reactions in almost quantitative yields:



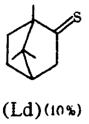
(La) (23%)



(Lb) (100%)

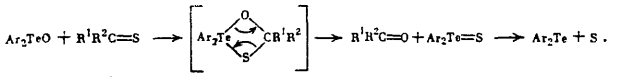


(Lc) (87%)

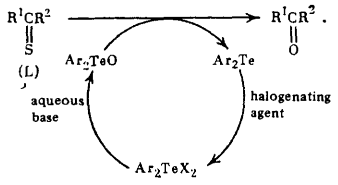


(Ld) (10%)

According to Ley et al.,[16] the mechanism of this reaction can be represented schematically as follows:



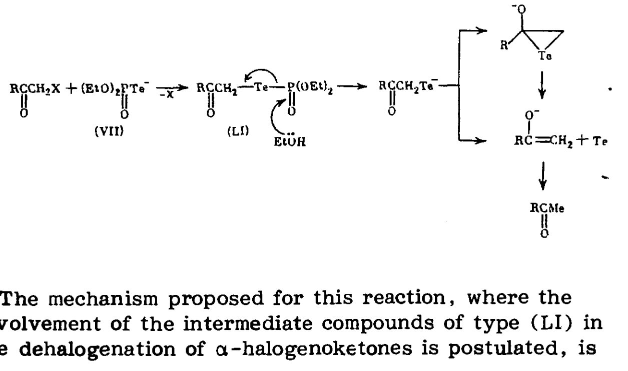
The oxidation of thioketones and thioacid esters (see below) to the corresponding oxo-derivatives has also been achieved with the aid of the catalytic oxidation-reduction cycle,[16,70] which requires the presence of a mild and effective halogenating agent into convert diaryl tellurides (I) into diaryltellurium dihalides (IX) and an aqueous solution of a base capable of converting the latter into diaryl telluroxides (XLVIII, $n = 1$). The most suitable brominating agent for tellurides is 1,2-dibromotetrachloroethane, which converts them into tellurium dibromides (IX, X = Br) in high yields at room temperature. Other reagents, namely hexachloroacetone, tetrabromoethane, and the dibromide of Meldrum's acid were much less effective in the above catalytic cycle. Among bases, an aqueous solution of potassium carbonate proved the most effective.[16,70] The optimum conditions in this reaction are stirring at room temperature in chloroform of a mixture of the carbonyl compound, 1.5% of the telluride (tellurium dihalides) or telluroxide, an excess of 1,2-dibromotetrachloroethane, and an aqueous solution of K_2CO_3:



The study of the influence of the nature of organic groups in the molecules of diaryltellurium dichloride $R^1C_6H_4TeCl_2.C_6H_4R^2$ used in this catalytic cycle showed that, as the electron-donating properties of the ring substituents R^1 and R^2 in the *p*-positions with respect to the tellurium atom are enhanced, the rate of the oxidation reaction increases in the following sequence: H,H < 4-MeO,4′-MeO < 4-MeO,4′-NMe_2 < 4NMe_2,4′-NMe_2.

(b) *Reduction of Ketones with Functional-group Substituents in the α-Position*

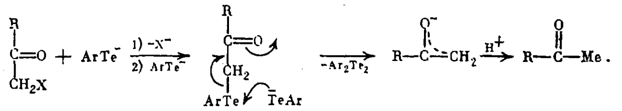
Sodium *OO*-diethyl phosphorotellurolate (VII) is a mild dehalogenating reagent for various α-halogenoketones.[71] Best results have been achieved in this reaction using stoichiometric amounts of the reactants in ethanol or THF (20° to 80 °C):



The mechanism proposed for this reaction, where the involvement of the intermediate compounds of type (LI) in the dehalogenation of α-halogenoketones is postulated, is based on the fact that the analogous reaction of 2,4′-dibromoacetophenone with sodium *OO*-diethyl phosphoroselenolate entails the formation of the selenium analogue of compound (LI), which does not, however, undergo further reactions.[71]

The readily available lithium and sodium thiophen-2-tellurolates, obtained by the reaction of 2-lithiothiophen with tellurium in THF or by the reduction of di(2-thienyl) ditelluride in an alkaline solution of $NaBH_4$ in alcohol, are extremely convenient, in the preparative sense, dehalogenating agents for various α-halogenoketones.[72]

The interaction of tellurophenoxides (2 mols) with α-halogenoketones (1 mol) results in reduction and the formation in high yields of the corresponding ketones and di(α-thienyl) ditelluride. In contrast to the reactions of α-halogenoketones with thiolate and selenolate anions, which usually give rise to a mixture of reduction and substitution products,[79,80] the use of the thiophen-2-tellurolate anion results in the formation of only the reduction products. However, it is possible that nucleophilic substitution with formation of intermediates of type (LII) is an intermediate stage in the reduction of α-halogenoketones by tellurolate anions. An indirect confirmation of this is provided by the interaction of α-bromoacetanilide (in excess) with sodium thiophen-2-tellurolate in alcohol, which results in the isolation of α-(2-thienyltelluro)acetanilide in 64% yield. This confirms the possibility, in principle, of the formation of the intermediate substitution product (LII) also in the reaction of $ArTe^-$ with α-halogenoketones and suggests the following two-stage reduction mechanism:[72]



A number of other electronegative substituents, for example, the MeCOO, $MeSO_2O$, and PhS groups, can also be readily removed from the α-position in acetophenones on treatment with alkali metal thiophen-2-tellurolates.[71]

In many cases α-halogenoketones may be reduced by employing sodium tetrahydroborate as the reducing agent in the presence of catalytic amounts of di(2-thienyl) ditelluride,[72] similarly to the formation of olefins by the reduction of vicinal dibromides examined above.[18]

3. Quinones

The formation of quinones with the aid of organotellurium compounds is based on the oxidation of dihydric phenols by diaryl telluroxides (XLVIII, $n = 1$)[15,16] or diaryl tellurones (XLVIII, $n = 2$).[68] Thus the oxidation of hydroquinone,[16] 1,4-dihydronaphthalene,[16] and 3,5-di-t-butyl-1,2-dihydroxybenzene[15,16] by di(*p*-anisyl) telluroxide leads to *p*-benzoquinone, 1,4-naphthoquinone, and 3,5-di-t-butyl-*o*-benzoquinone in 65, 97, and 80% yields respectively. In the case of di(*p*-anisyl)tellurone, the yield of *p*-benzoquinone is smaller, amounting to only 39%.[68]

4. Carboxylic Acids

(a) *Carbonylation of σ-Telluranes*

One of the possible ways of obtaining carboxylic acids from organotellurium compounds is based on the interaction of diaryltellurium dichlorides or aryltellurium trichlorides with nickel carbonyl in DMF at 70 °C and subsequent treatment with water:[73]

$$Ar_2TeCl_2 + Ni(CO)_4 + 2H_2O \rightarrow 2ArCOOH + NiTe + 2HCl + 2CO;$$
$$ArTeCl_3 + 2Ni(CO)_4 + H_2O \rightarrow ArCOOH + NiCl_2 + NiTe + HCl + 7CO.$$

Together with carboxylic acids, diarylketones and diaryl tellurides are formed in this instance as side products.

By analogy with familiar reactions of this type involving other metallic compounds, their possible mechanisms can be described by the following schemes:[73]

(1) Aryltellurium trichlorides:

$$ArTeCl_3 + Ni(CO)_4 \rightarrow NiCl_2 + ArTeNi(CO)_2Cl \xrightarrow[ArTeCl_3]{\text{arylation}} Ar_2Te, \qquad (1)$$

$$ArTeNi(CO)_2Cl + Ni(CO)_4 \rightarrow NiTe + ArNi(CO)_2Cl, \qquad (2)$$

$$ArNi(CO)_2Cl + Ni(CO)_4 \xrightarrow{\text{insertion}} \underset{\overset{\|}{O}}{ArC}Ni(CO)_2Cl - \left[\begin{array}{l} \xrightarrow{\text{arylation}} Ar_2CO, \\ \xrightarrow[H_2O]{} ArCOOH. \end{array}\right. \qquad (3)$$

(2) Diaryltellurium dichlorides

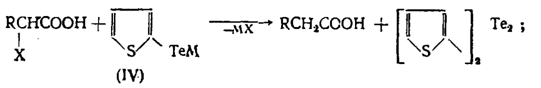
$$Ar_2TeCl_2 + Ni(CO)_4 \rightarrow ArNi(CO)_2Cl + ArTeNi(CO)_2Cl,$$

followed by reactions (1), (2), and (3).

Aliphatic tellurium dichlorides, in particular di(2-chloropropyl)tellurium dichloride, decompose under analogous conditions with formation of alkenes (in the given instance, propene), $NiCl_2$, and NiTe.[73] When $Ni(CO)_4$ is replaced by $Fe_2(CO)_9$, carbonylation does not take place. Thus the reaction of p-anisyltellurium trichloride with $Fe_2(CO)_9$ results in the formation of only di(p-anisyl) ditelluride, apparently as a consequence of the reduction of the trichloride by iron carbonyl.[73]

(b) Reduction of Carboxylic α-Halogenoacids

Like α-halogenoketones (see above), carboxylic α-halogenoacids are reduced in high yields by lithium and sodium thiophen-2-tellurolates (IV) to the corresponding carboxylic acids:[72]



(IV)

M=Li, Na; R=Ph (99%), 1-$C_{10}H_7$ (97%), $(Ph)_2$ (98%).

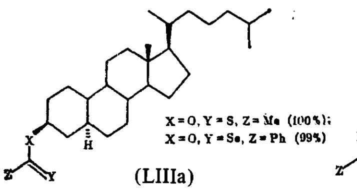
5. Derivatives of Carboxylic Acids

Organotellurium compounds have been used to obtain derivatives of carboxylic acids such as esters[15,16,70,74–76] and anhydrides.[77,78]

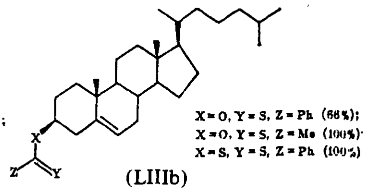
(a) Esters

Esters have been synthesised from derivatives of tricoordinate tellurium (diaryl telluroxides[15,16,70] and telluronium ylides[76]) and derivatives of tetracoordinate tellurium—diaryltellurium diacylates.[74,75]

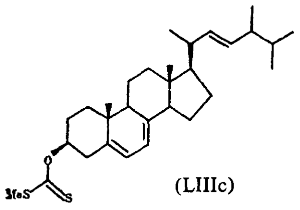
Diaryl telluroxides. Like ketones (see above), many esters were obtained in high yield by the oxidation of the corresponding thio- and selenocarbonyl compounds (LIIIa–e) with diaryl telluroxides:[15,16,70]



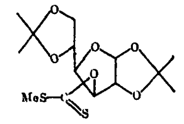
(LIIIa)



(LIIIb)



(LIIIc)



(LIIId)

$$Me(CH_2)_{17}O\overset{\overset{S}{\|}}{C}Ph$$

(LIIIe) 91%

Telluronium ylides. An effective method of synthesis of αβ-unsaturated acid esters is the interaction of carbonyl compounds with dialkyltelluronium ethoxycarbonylmethylylides (LV) obtained *in situ* by treating dibutylethoxycarbonylmethyltelluronium bromides (LVI) with potassium t-butoxide in THF. This reaction proceeds with high stereoselectivity, especially with aldehydes, and leads mainly to *E*-isomers:[76]

$$\underset{Br^-}{(C_4H_9)_2Te^+CH_2COOEt} \xrightarrow[THF]{Me_3COK} \underset{(LV)}{(C_4H_9)_2Te^+-\bar{C}HCOOEt} \xrightarrow[-(C_4H_9)_2TeO]{R^1R^2C=O}$$
$$\longrightarrow \underset{(LIV)}{R^1R^2C=CHCOOEt}.$$

The reaction is also applicable to cyclic and αβ-unsaturated ketones and aldehydes. The sharp difference between the reactivities of the telluronium ylides (LV) and the corresponding sulphonium ylides is noteworthy. Thus dimethylsulphonium ethoxycarbonylmethylide does not react with simple ketones and aldehydes, while its reaction with αβ-unsaturated carbonyl compounds yields cyclopropanes.[81]

Diaryltellurium diacylates. The methyl esters of carboxylic acids are formed in 85–90% yields on hearing diaryltellurium diacylates (IX) with methyl iodide in sealed tubes at 100 °C:[75]

$$\underset{(IX)}{(p\text{-}RC_6H_4)_2Te(OCOMe)_2} + MeI \rightarrow (p\text{-}RC_6H_4)_2TeI_2 + MeCOOMe;$$

R=H, Me, OMe.

When diphenyltellurium diacetate reacts with chlorotrimethylsilane, diphenyltellurium dichloride is formed in a high yield (it is probably accompanied by trimethylsilyl acetate):[74]

$$Ph_2Te(OCOMe)_2 + 2Me_3SiCl \rightarrow Ph_2TeCl_2 + 2MeCOOSiMe_3.$$

(b) Acid Anhydrides

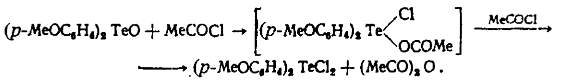
Carboxylic acid anhydrides have been obtained in 80–95% yields by the reaction of diaryltellurium diacylates (IX) with acyl chlorides:[59,77]

$$\underset{(IX)}{(p\text{-}R^1C_6H_4)_2Te(OCOR^2)_2} + 2R^2COCl \rightarrow (p\text{-}R^1C_6H_4)_2TeCl_2 + (R^2CO)_2O;$$

R^1=H, R^2=Me; R^1=Me, R^2=Ph; R^1=OMe, R^2=Et; R^1=OMe, R^2=CH_2Cl.

The high yields make it possible to regard this reaction as a preparative method of synthesis of the anhydrides of both aliphatic and aromatic carboxylic acids. The attempts to use it for the synthesis of mixed anhydrides were, however, unsuccessful. Thus, although treatment of di(p-anisyl)-tellurium bis(trifluoroacetate) with acetyl chloride afforded di(p-anisyl)tellurium dichloride in a yield exceeding 90%,[59,77] the asymmetric anhydride, namely acetyl trifluoroacetate, was not isolated, which can probably be accounted for by its disproportionation under the reaction conditions.

Anhydrides are also formed in the reaction of diaryl telluroxides with carboxylic acid chlorides, apparently via the intermediate formation of diaryltellurium chloroacylates:[78]



$$(p\text{-}MeOC_6H_4)_2TeO + MeCOCl \rightarrow \left[(p\text{-}MeOC_6H_4)_2Te\begin{matrix}Cl\\OCOMe\end{matrix}\right] \xrightarrow{MeCOCl} (p\text{-}MeOC_6H_4)_2TeCl_2 + (MeCO)_2O.$$

V. CONCLUSION

The data presented in the review demonstrate the likely usefulness of the application of organotellurium compounds in the synthesis of various classes of organic compounds and in the first place unsaturated and cyclic hydrocarbons, halogeno-derivatives of various types, and carbonyl compounds. Among these reactions, special interest attaches to catalytic reactions with participation of organotellurium compounds: tellurolate and phosphorotellurolate anions and diaryl telluroxides. In many instances the reactions which proceed readily when organotellurium reagents are used do not occur with selenium compounds having analogous structures (the synthesis of 1,5-dienes).

Further prospects for the application of organotellurium compounds in organic synthesis is as follows: (1) in the search for new possibilities of using organic derivatives of tellurium in order to obtain organic compounds, (2) in the study of conditions permitting an increase in the stereospecificity of the reactions, (3) in the development of new catalytic processes, and (4) in the elucidation of the specific features of organotellurium compounds compared with the analogous sulphur and selenium derivatives and in using these features in organic synthesis. The solution of the above problems is indissolubly linked to the expansion of studies connected with the development of methods of synthesis of organotellurium compounds using readily available starting materials and to the study of the reactivity of these compounds.

---o0o---

During the preparation of this review for publication, a series of new reports on the application of organotellurium compounds in organic synthesis appeared. Uemura and Fukuzawa[82] gave a systematic account of and discussed the results of studies on the reaction involving α-elimination of organic halides from σ-telluranes of various types, published previously in a number of communications.[62,63,65] Olefins of different structure have been obtained in the decomposition of alkyl phenyl telluroxides synthesised either by the hydrolysis of the corresponding tellurium dibromides[83] or by the oxidation of alkylphenyl tellurides by hydrogen peroxide,[83] sodium periodate,[83] and m-chloroperbenzoic acid[83,84] and also by the catalytic debromination of vicinal dibromides by diaryl tellurides under the conditions of interfacial catalysis.[85] Catalytic debromination of 1,4-dibromoalk-2-enes by sodium thiophen-2-tellurolate has been used to obtain 1,3-dienes.[86] Oxidation of allyl phenyl tellurides by the oxidants enumerated above and also by t-butyl hydroperoxides leads to allyl alochols in high yields,[87] probably via the [2,3]-sigmatropic rearrangement of the alkyl phenyl telluroxides formed as intermediates.

New methods have been proposed for the synthesis of carboxylic acids on the basis of the decomposition of tellurones formed in the oxidation of ethylene ketals of aryl α-tellurophenylethyl ketones[88] and of the insertion (in the presence of $PdCl_2$) of the CO group in the Te–C bond in diorganyl tellurides and σ-telluranes.[89] New examples of the application of organotellurium reagents in the organic synthesis have been presented: the synthesis of αβ-unsaturated epoxides by the reaction of dialkyltelluronium allylides with aldehydes,[90] the synthesis of chlorohydrin ethers by the elimination of tellurium from the products of the addition of $TeCl_4$ to allyl ethers by treatment with Raney nickel,[91] and the formation of alkyl method ethers by the oxidation of alkyl phenyl tellurides with m-chloroperbenzoic acid in methanol.[92] Diaryl telluroxides proved to be effective catalysts of aldol condensation reactions[93] and diorganyl tellurides were found to catalyse the reactions of tosyl azide with aldehydes, which is due to the intermediate formation of tellurimides (from tosyl azide and diorganyl tellurides).[94]

New Silylating Agents. Methods of Synthesis and Properties

M.D.Mizhiritskii and Yu.A.Yuzhelevskii

The methods of synthesis and properties of new silylating agents are examined and the results of studies on thier application in organic synthesis and in analytical chemistry are surveyed.
The bibliography includes 223 references.

I. Introduction 355
II. Synthesis and properties of silylating agents 355
III. Comparative characteristics of silylating agents 361

I. INTRODUCTION

Organosilicon compounds have found extensive applications in organic[1–13] and analytical[14–16] chemistry. One of the most important fields in which silicon-containing reagents are applied involves their use for silylation. The term "silylation" has come to be understood as the introduction of a triorganylsilyl, usually trimethylsilyl group, into the molecules of organic compounds instead of a mobile ("active") hydrogen atom or the metal atom replacing the latter.[14,17] The triorganylsilyl group is introduced into the organic molecule with the aid of the so called silylating agents, i.e. agents containing an Si–X bond, where X = O, N, S, C, or Hal, which is reactive with respect to a proton donor.

Silylation makes it possible to modify widely the physical and chemical properties of organic and organoelemental compounds: to protect or block certain reaction centres, to increase reactivity, to improve the solubility of substances in non-polar and weakly polar solvents, to reduce or to eliminate the possibility of the formation of hydrogen bonds, and to increase the volatility and stability of compounds.[14,18,19] Silylation is used for the purification of organic and organoelemental substances and also for their identification by physicochemical methods.[14,18,19]

Pierce's monograph[14] contains information about silylating agents and surveys data on the silylation of various classes of organic compounds published up to 1967. Later reviews,[17,18,20–25], devoted to a different aspect of silylation, also present the characteristics of silylating compounds.

In connection with the synthesis of a series of new effective silylating agents (silyl donors) and also the expansion of their applications, it became necessary to give a systematic account of and to survey data published mainly during the last 10 years. The present review is devoted to this topic.

II. SYNTHESIS AND PROPERTIES OF SILYLATING AGENTS

In recent years silylation has become an increasingly important method in synthetic organic chemistry, simplifying and improving the procedures for the preparation of many complex substances; many silylating agents, such as chlorosilanes and silazanes, are used in the large-scale industrial manufacture of antibiotics,[26,27] organosilicon monomers and polymers,[28] etc. Other silylating agents—silylated amines, amides, urea, sulphonic acids, and certain others—are widely employed in preparative synthesis.

Bearing in mind that silylation takes place with cleavage of the Si–X bond by the proton donor (HY), it is natural to arrange the silylating agents in groups in terms of the character of this bond.

1. Halogenosilanes (R_3Si–Hal)

In this group of silyl donors, chlorotrimethylsilane, which is widely used in industry, is most important.[28] The methods of its synthesis and also its silylating properties have been examined in books[14,28] and reviews.[17,20,21]

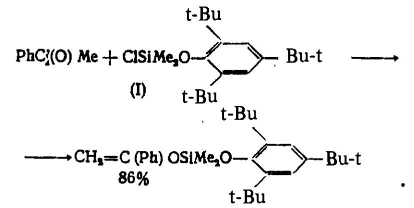
At the same time, the high sensitivity of the Me_3Si–O bond to hydrolysis, to attack by many nucleophiles, and also to hydrogenolysis[29] limits its employment in organic synthesis as a protecting group.[30,31] For this reason, silylating agents with bulkier groups at the silicon atom, for example t-butylchlorodiphenylsilane,[32] chlorotriisopropylsilane,[33,34] and especially t-butylchlorodimethylsilane, first used by Stork and Hudrlik,[35] have come to be employed more frequently in recent times. t-$BuMe_2SiCl$ is synthesised in accordance with the following scheme:[36,37]

$$Me_2SiCl_2 + t\text{-}BuLi \rightarrow t\text{-}BuMe_2SiCl + LiCl .$$

The t-$BuMe_2Si$–O bond is more resistant to hydrolysis than the Me_3Si–O bond (by a factor of 10^4) [38–40] and "withstands" reactions such as hydrogenolysis,[36] mesitylation,[41] phosphorylation,[42] reduction by diisobutylaluminium hydride,[46] oxidation by chromic acid in pyridine[43,44] or by ruthenium tetroxide,[44] and treatment by potassium t-butoxide in dimethylformamide (DMF),[45] Grignard[44] and Wittig[36] reagents, organocopper reagents,[46] and lithium in liquid ammonia.[44] The above group can be readily introduced into the organic molecule in the presence of imidazole,[47,48] *N*-dimethylaminopyridine,[49] or 1,8-diazabicyclo[5.4.0]undec-7-ene [50] as catalysts, after which it can be readily removed with the aid of sources of fluoride ions,[28] for example $Et_3N.HF$,[47] Bu_4NF,[51] KF/18-crown-6 ether,[31] and CsF/diglyme.[47] Bu_4NHSO_4/NaOH is sometimes used instead of tetrabutylammonium fluoride:[52]

$$ROH \xrightarrow[\text{imidazole/DMF}]{t\text{-}Bu_2Me_2SiCl} ROSiMe_2Bu\text{-}t \xrightarrow[\text{THF}]{Bu_4NF} ROH .$$

The 2,4,6-tri(t-butyl)phenoxydimethylsiloxy-group is even more resistant to the action of acids and bases. It is introduced into the organic molecule by treatment with the corresponding chlorosilane in the presence of sodium iodide and triethylamine in acetonitrile and is removed with the aid of potassium fluoride on celite:[53]



The chlorosilane (I) is a stable crystalline substance. It is obtained in 93% yield by the reaction of dichlorodimethylsilane with 2,4,6-tri(t-butyl)phenol and triethylamine on refluxing in acetonitrile.[53]

Silylation takes place extremely effectively in the presence of lithium sulphide in a polar medium:[54]

$$\mathrm{ROH + ClSiMe_2R' \xrightarrow[25^\circ]{Li_2S/MeCN} \underset{70-95\%}{ROSiMe_2R'}} \ ;$$

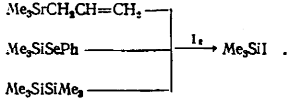
$\mathrm{R' = Me,\ t\text{-}Bu.}$

Bromotrimethyl- and especially iodotrimethyl-silanes are very active silylating agents;[55–58] they are obtained by cleaving the Si–O, Si–C, and other bonds with halogen, hydrogen halides, or the corresponding salts:[59–63]

$$\mathrm{Me_3SiOPh + Br_2 \xrightarrow{cat.} Me_3SiBr} \ ;$$

$$\mathrm{cat. = Zn, Al, Cu, Mg, Sn, Fe} \ ;$$

$$\mathrm{(Me_3Si)_2O \xrightarrow{AlI_3\ or\ Al/I_2} Me_3SiI + AlOI} \ ;$$



$$\mathrm{Me_3SrCH_2CH{=}CH_2,\ Me_3SiSePh,\ Me_3SiSiMe_3 \xrightarrow{I_2} Me_3SiI} \ .$$

However, Me₃SiBr and Me₃SiI are not often used for silylation because many functional groups are decomposed by them, for example, iodotrimethylsilane cleaves oxirans,[64,65] hydroxycyclanes,[66–68] ethers,[69,70] esters,[71–73] acetals, ketals,[73] etc.[74–78]

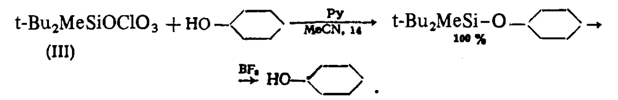
2. Reagents Containing the R_3SiO Group

Among silylating agents containing the Si–O bond, the most readily available compound is hexamethyldisiloxane. It is obtained by the hydrolysis of chlorotrimethylsilane.[28] As early as 1960,[79] it was shown that, in the presence of alkaline or acid catalysts, hexamethyldisiloxane is cleaved by alcohols and phenols, but, until recently it was believed that $(Me_3Si)_2O$ has no significant value as a silylating agent. The results of the study by Pinnick et al.[80] disproved this established view. It was found that the use of the pyridinium salt of toluenesulphonic acid Py.TosOH (II) greatly increases the effectiveness of hexamethylsiloxane as the silyl donor and makes it possible to obtain silyl ethers in yields up to 90%:

$$\mathrm{(Me_3Si)_2O + ROH \xrightarrow[\Delta,\ C_6H_6]{(II)} \underset{70-90\%}{ROSiMe_3}} \ .$$

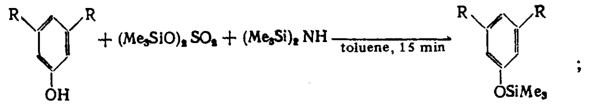
The silyl esters of inorganic acids are sometimes used as silylating agents: silyl perchlorates[13] and bis(trimethylsilyl) sulphate.[19]

Silyl perchlorates, for example compound (III), are obtained from chlorosilane and silver perchlorate[19] and are used to introduce bulky protecting groups [di(t-butyl)methylsilyl groups]:[81]



They are also used as highly selective reagents for the removal of t-butoxycarbonyl groups from peptides.[82]

Bis(trimethylsilyl) sulphate, which is used to silylate OH- and/or NH-containing biologically active compounds, is usually employed in combination with hexamethyldisilazane or *N*-dialkylaminotrimethylsilane:[83]



$\mathrm{R = t\text{-}Bu}$.

The interaction of bis(trimethylsilyl) sulphate with urea leads to trimethylsilyl isocyanate as a result of the decomposition of the thermally unstable trimethylsilylurea:[84]

$$\mathrm{(Me_3SiO)_2SO_2 + (NH_2)_2CO \xrightarrow[150^\circ]{} Me_3SiNCO + (NH_4)_2SO_4} \ .$$

Silylation of alkali metal nitrates affords trimethylsilyl nitrates:[85]

$$\mathrm{(Me_3SiO)_2SO_2 + KNO_3 \rightarrow \underset{85\%}{Me_3SiONO_2} + K_2SO_4} \ .$$

It is noteworthy that bis(trimethylsilyl) sulphate is also used as a sulphonating agent. Its interaction with aromatic compounds, pyridine, and thiophen leads to the corresponding sulpho-derivatives,[86,87] for example:

The silyl ethers of enols $\mathrm{R_3SiOC{=}C\!<}$ are effective reagents for the silylation of alcohols, carboxylic acids, and certain mercaptans, such as thiophenol:[88–90]

$$\mathrm{\underset{(IV)}{Me_3SiOCR{=}CR'R''} + RXH \rightarrow Me_3SiXR + \underset{86-99\%}{R'R''CHC(O)R}} \ .$$

However, with the aid of silylenols (IV) it is impossible to silylate amides and amines (Schiff bases are formed), ephedrine (oxazolidine is formed), and alkane-thiols (the yield of the trimethylsilyl derivative of 2-mercaptoethanol did not exceed 5%). In addition it has been shown[91] that, in the case of unsaturated alcohols and phenols, another reaction pathway can operate, i.e. the proton donor can add to the double bond of the silylenol:

$$\mathrm{CH_2{=}CHOSiMe_3 + ROH \rightarrow MeCH(OR)OSiMe_3} \ .$$

An analogous result has been obtained also for acids.[92] Despite the limiting applicability of silylenols in the silylation of NH- and SH-containing compounds, they are widely used in organic synthesis.[1,2,19,93,94] The electrophilic reactions of these compounds make it possible to obtain the vast majority of α-functional derivatives of carbonyl compounds. The oxidation and ozonolysis of silylenols lead to α-hydroxy-derivatives.

The reactions of organosilicon ethers of enols (IV) with carbenes lead to the corresponding derivatives of siloxycyclopropane, from which it is possible to obtain in their turn various substituted cyclopropanes and products resulting from the opening or rearrangement of the cyclopropane ring. The $C{=}C{-}OSiR_3$ system participates in the [2 + 2]-, [3 + 2]-, and [4 + 2]-cycloaddition reactions with formation of various cyclic adducts, which are important for the synthesis of biologically active substances.[1] The methods of synthesis of silylenols have been surveyed in a number of reviews.[1,2,19,93,94]

The side reactions accompanying silylation with the aid of silylenols can be avoided by employing the *O*-trimethylsilyl *O*-methyl acetal of methylketen, obtained by the successive interaction of ethyl acetate with lithium diisopropylamide and chlorotrimethylsilane:[95,96]

$$\mathrm{MeCOOEt} \xrightarrow[2)\ \mathrm{Me_3SiCl}]{1)\ \text{iso-}\mathrm{Pr_2NLi}} \mathrm{MeCN{=}C(OMe)OSiMe_3} \xrightarrow[\mathrm{MeCN\ or\ CH_2Cl_2},\ 15\to 40^\circ\mathrm{C}]{\mathrm{RXH}} \underset{95\text{—}99\%}{\mathrm{RXSiMe_3}};$$

$$\mathrm{RXH = PhOH,\ PhCH_2OH,\ 3,4,5\text{-}(MeO)_3C_6H_2COOH,\ PhSH,\ PhCH_2SH,\ \underbrace{C(O)C_6H_4C(O)NH}}\ .$$

The introduction at the oxygen atom of substituents capable of weakening the $(p-d)_\pi$ bonding between the silicon and oxygen atoms and of delocalising the negative charge in the transition state made it possible to obtain a series of new effective silyl donors, among which *N*-alkyl-substituted trimethylsilyl carbamates and trimethylsilyl trifluoromethanesulphonate (trimethylsilyl triflate) are most widely used.

The readily available trimethylsilyl *NN*-dialkylcarbamates exhibit effective silylating properties especially in relation to alcohols, phenols, and acids,[97] the reactions being autocatalytic:[98]

$$\mathrm{R_2NC(O)OSiMe_3 + R'OH \rightarrow \underset{75\text{—}95\%}{R'OSiMe_3} + R_2NH + CO_2};$$

$\mathrm{R = Me;\ R'OH = EtOH,\ t\text{-}C_5H_{11}OH,\ n\text{-}C_7H_{15}OH,}$
$\mathrm{n\text{-}C_{10}H_{21}OH,\ cyclo\text{-}C_6H_{11}OH,\ HO(CH_2)_2OH,}$
$\mathrm{PhOH,\ }m\mathrm{\text{-}MeC_6H_4OH,\ }m\mathrm{\text{-}HOC_6H_4OH,\ }p\mathrm{\text{-}HOC_6H_4OH,}$
$\mathrm{MeCO_2H,\ PhCO_2H.}$

Silyl *NN*-dialkylcarbamates are obtained by passing carbon dioxide through *NN*-dialkylaminotrimethylsilane[99-106] or through a mixture of dialkylamine and hexamethyldisilazane:[107, 108-110]

$$\left.\begin{array}{l}\mathrm{CO_2 + RR'NSiMe_3} \\ \mathrm{CO_2 + RR'NH/(Me_3Si)_2NH}\end{array}\right] \rightarrow \mathrm{RR'NC(O)OSiMe_3}\ .$$

The interaction of silver carbamates with chlorotrimethylsilane also leads to silylated products:[101,111]

$$\mathrm{RR'NC(O)OAg + Me_3SiCl \xrightarrow[-AgCl]{} RR'NC(O)OSiMe_3};$$
$$\mathrm{R = R' = H}\ .$$

According to the authors,[97] the most convenient method of synthesis of *N*-alkyl-substituted trimethylsilyl carbamates consists in the interaction of the adduct of an amine and carbon dioxide with chlorotrimethylsilane:

$$\mathrm{2RR'NH + CO_2 \xrightarrow[CH_2Cl_2]{-10\text{—}0^\circ} [RR'NC(O)O]^- RR'NHH_2^+ \xrightarrow[CH_2Cl_2;-RR'NH\cdot HCl]{Me_3SiCl;0\text{—}20^\circ} \underset{85\text{—}90\%}{RR'NC(O)OSiMe_3}};$$

$$\mathrm{RNH_2 + Et_3N + CO_2 \xrightarrow[CH_2Cl_2]{-10\text{—}0^\circ} [RNHC(O)O]^- Et_3NH^+ \rightarrow}$$
$$\mathrm{\rightarrow \xrightarrow[CH_2Cl_2;\ -2Et_3N\cdot HCl]{2Me_3SiCl/Et_3N;\ 0\text{—}20^\circ} \underset{>70\%}{R(Me_3Si)NC(O)OSiMe_3}}\ .$$

The trimethylsilyl carbamates obtained can be used not only as silylating agents[97,98] but also for the introduction of the amino-group into the molecules of organic compounds, for example:[97]

$$\mathrm{RR'NC(O)OSiMe_3} - \left|\begin{array}{l} \xrightarrow[20^\circ,\ 15\ \mathrm{min}]{\mathrm{R''C(O)Cl}} \underset{85\text{—}95\%}{\mathrm{R''C(O)NRR'}} \mathrm{+ CO_2 + Me_3SiCl}\ ; \\ \xrightarrow[80^\circ,\ 2\ \mathrm{h}]{\mathrm{PhSO_2Cl}} \mathrm{RhSO_2NRR' + CO_2 + Me_3SiCl}\ ; \\ \xrightarrow[\mathrm{CH_2Cl_2}]{\mathrm{(R''CO)_2O}} \underset{90\%}{\mathrm{R''C(O)NRR'}} \mathrm{+ R''C(O)OSiMe_3 + CO_2}\ ; \end{array}\right.$$

$$\mathrm{R'' = Me,\ Ph,\ ClCH_2;\ R,\ R' = Alk}\ .$$

One of the most active silylating agents is trifluoromethylsilyl trifluoromethanesulphonate (TMS triflate).[1,112-114] It is obtained by heating trifluoromethanesulphonic acid with chlorotrimethylsilane with or without a base[115-118] and also by cleaving aryltrimethylsilanes with this acid:[119]

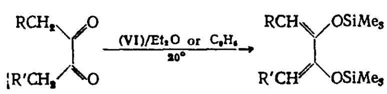
$$\mathrm{CF_3SO_2OH} - \left|\begin{array}{c} \overset{\mathrm{Me_3SiCl}}{\overline{-\mathrm{HCl}}} \\ \underset{-\mathrm{ArH}}{\underline{\mathrm{ArSiMe_3}}} \end{array}\right| \rightarrow \underset{\mathrm{(V)}}{\mathrm{CF_3SO_2OSiMe_3}}\ .$$

Silylation with TMS triflate is usually carried out in the presence of a tertiary amine, triethylamine being the most suitable base, since the salt $\mathrm{CF_3SO_2OH.NEt_3}$ is a liquid; it is insoluble in non-polar solvents and can be readily separated from the easily soluble silylated products. The end of reaction is inferred from the formation of the second phase. Triethylamine is also convenient because it is an effective solvent for weak CH acids. The reaction is usually performed in dichloroethane, since in this solvent the reactions are 10^2–10^3 faster than in $\mathrm{CCl_4}$ or $\mathrm{Et_2O}$.

TMS triflate (V) is most important for the silylation of CH acids.[114]

(1) Ketones and aldehydes[120-124] [by treatment with $\mathrm{CF_3.}$ $\mathrm{.SO_2OSiMe_3/Et_3N}$ (VI)]:

$$\mathrm{RC(O)CHR'R'' \xrightarrow{(VI)} RC(OSiMe_3){=}CR'R''};$$



;

$$\mathrm{RR'CHCHO \xrightarrow[0\text{—}5^\circ]{(VI)/Et_2O} RR'C{=}CH(OSiMe_3)}\ .$$

It has been shown that TMS triflate induces the isomerisation of the *C*-silylation product to the *O*-silylated compound:[124]

$$\mathrm{Me_3SiCH_2C(O)R \xrightarrow[20^\circ,\ min]{(V)/CCl_4} H_2C{=}C(OSiMe_3)R}$$

(2) 1,3-Dicarbonyl compounds:[125]

$$\mathrm{RCH_2C(O)CHR'C(O)R'' \xrightarrow[0^\circ,\ 30\ min]{(VI)} \underset{50\text{—}90\%}{RCH{=}C(OSiMe_3)CR'{=}C(OSiMe_3)R''}}$$

(3) Carboxylic acid esters:[126-128]

$$\mathrm{RCH_2COOR'} \xrightarrow[0\div10^\circ]{\mathrm{(VI)/Et_2O}} \left|\begin{array}{l} \xrightarrow{a} \mathrm{Me_3SiCHRCOOR'}\ ; \\ \xrightarrow{b} \mathrm{RCH{=}C(OR')OSiMe_3}\ ; \\ \xrightarrow{c} \mathrm{RCH_2C(O)OSiMe_3}\ ; \end{array}\right.$$

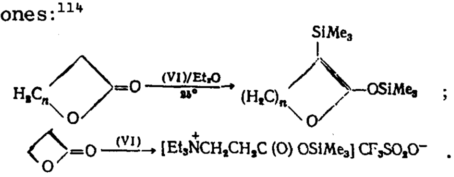
a) R = H, Me, R' = SiMe₃, CH₂Ph, Me, Et, iso-Pr; R=R'=Et; R=SiMe₃, R'=Et, iso-Pr;

b) R=Me, R'=Ph, SiMe₃; R=R'=Et; R=CN, R'=Me, Et; R=SiMe₃, R'=Me, Et, iso-Pr, SiMe₃, Ph; R=CH₂COOEt, Ph, R'=Et ;

c) R' = t-Bu.

The scheme indicates the dominant reaction pathways for various substituents. Thus the product ratio *a*/*b* is 9 : 1 for $\mathrm{CH_3COOPh}$ and 19 : 81 for $\mathrm{CH_3CH_2COOPh}$.[127]

(4) Lactones:[114]

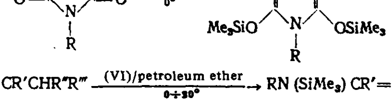


(5) Thiocarboxylic acid esters:[129]

$$\mathrm{RR'CHC(O)SR'' \xrightarrow[0\text{—}20^\circ]{(VI)/CH_2Cl_2} \underset{75\text{—}81\%}{RR'C{=}C(OSiMe_3)SR''}}\ .$$

(6) Amides,[114] imides,[114], imines,[130] and iminoesters:[114]

$$\mathrm{RR'CHC(O)NR''_2 \xrightarrow[0^\circ]{(VI)/CH_2Cl_2} RR'C{=}C(OSiMe_3)NR''_2}\ ;$$



;

$$\mathrm{RN{=}CR'CHR''R''' \xrightarrow[0\div30^\circ]{(VI)/petroleum\ ether} RN(SiMe_3)CR'{=}CR''R'''}\ ;$$

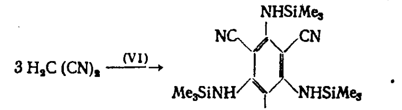
$$\mathrm{MeC(OMe){=}NR \xrightarrow{(VI)} MeC(O)N(SiMe_3)R}\ .$$

(7) Nitriles:[114,131]

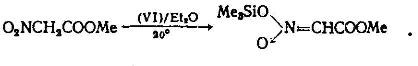
$$\mathrm{RR'CHCN} \xrightarrow{(VI)} \underset{55\%}{\mathrm{RR'C(SiMe_3)CN}} \xrightarrow[R'=H]{(VI)} \underset{33\%}{\mathrm{RC(SiMe_3)_2CN}} \ ;$$

$$\mathrm{RCH_2CN} \xrightarrow[R=Ph]{(VI)} \underset{71\%}{\mathrm{RC(SiMe_3){=}C{=}NSiMe_3}} \ ;$$

$$\mathrm{MeCN} \xrightarrow{(VI)} \mathrm{(Me_3Si)_3CCN + (Me_3Si)_2C{=}C{=}NSiMe_3} \ ;$$



(8) Nitroalkanes:[132]



$$\mathrm{O_2NCH_2COOMe} \xrightarrow[20^\circ]{(VI)/Et_2O} \mathrm{(Me_3SiO)(O^-)N{=}CHCOOMe} \ .$$

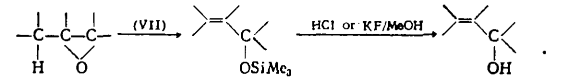
(9) Diazo-compounds:[133]

$$\mathrm{RCHN_2} \xrightarrow[-78^\circ]{(V)/Et_2O} \mathrm{RC(SiMe_3)N_2} \ ;$$

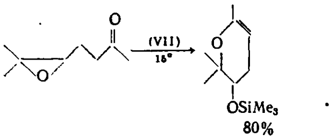
70—82%

$\mathrm{R = P(O)(OR')_2,\ COOR'}$.

Oxirans are silylated by TMS triflate with ring opening,[112,114] which is used widely in preparative chemistry. The reaction proceeds under the influence of CF_3SO_2OSiMe/1,8-diazabicyclo[5.4.0]undec-7-ene (VII):



For example, according to this scheme the following reactions take place:[112,134]

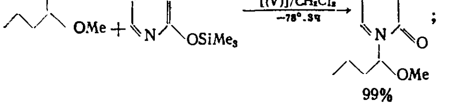


80%

It has been found that tetrahydrofuran (THF) is also cleaved in accordance with this scheme, while ethers do not react with silylated sulphonic acids.

In addition TMS triflate can be used to obtain carbenes.[135]

New methods of organic synthesis involving the employment of TMS triflate as the catalyst of exchange and addition reactions have come to be widely used recently:[112,128,136–140]



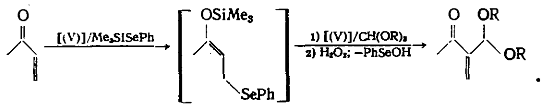
99%

$$\mathrm{Me_3SiOR + R'_3COSiMe_3} \xrightarrow[-(Me_3Si)_2O]{[(V)]} \mathrm{ROCR'_3} \ ;$$

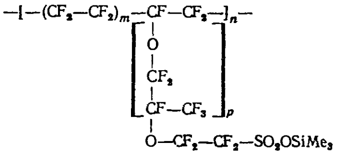
$$\mathrm{R_2C(OR')_2 + Me_3SiR''} \xrightarrow[-MeSiOR']{[(V)]} \mathrm{R_2C(OR')R''} \ ;$$

75—100%

$\mathrm{R'' = H,\ CH_2CH{=}CH_2,\ OCR'''{=}CR'''_2}$;

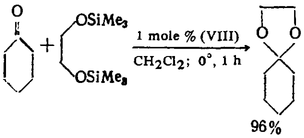


Bearing in mind that in the course of these reactions TMS triflate is lost irreversibly and also taking into account its high relative cost compared with other silylating agents, it has been suggested that TMS triflate be immobilised on a polymer base, which yielded in this way the immobilised catalyst (VIII):[141]



(VIII)

Compound (VIII) can be used both as a catalyst and as a silylating agent,[141] for example:



;

96%

$$\mathrm{EtXH} \xrightarrow[27-29^\circ,\ 2-12\ h]{(VIII)\ or\ (VIII)/Et_3N} \mathrm{EtXSiMe_3} \ ;$$

94—100%

$\mathrm{X = O, S, EtN}$.

Trimethylsilyl trichloroacetate has been recently proposed[142] as a reagent for the silylation of alcohols, phenols, carboxylic acids, amides, acetylenes, and β-ketoesters. The interaction takes place in the presence of potassium carbonate and 18-crown-6 ether on heating for 1–2 h. The chloroform obtained in the reaction promotes the latter:

$$\mathrm{CCl_3COOSiMe_3 + XH \rightarrow XSiMe_3 + CO_2 + CHCl_3} \ ;$$

$\mathrm{X = PhO\,(88\%);\ 3\text{-}MeC_6H_4O\,(90\%);\ PhCO_2\,(88\%);}$

$\mathrm{4\text{-}BrC_6H_4S\,(91\%);\ PhC{\equiv}C\,(88\%)}$ etc.

Trimethylsilyl trichloracetate reacts with aldehydes and ketones to form the silyl ether of trichloromethylmethanol, whose acid hydrolysis affords the free alcohol:

$$\mathrm{RC(O)R' + CCl_3COOSiMe_3} \xrightarrow[100^\circ]{X_2CO_3/18\text{-}crown\text{-}6\text{-}ether} \mathrm{Me_3SiOCR'RCCl_3} \rightarrow$$

$$\xrightarrow{H_3O^+} \mathrm{CCl_3CRR'OH} \ .$$

3. Compounds Containing the Si–N Bond

Compounds containing the Si–N bond are very powerful silylating agents especially for the silylation of OH groups, since in this instance the stronger Si–O bond is formed instead of the comparatively weak Si–N bond. The reaction is also promoted by the protonation of the nitrogen atom of the silyl donor, which decreases or eliminates the $(p-d)_\pi$ interaction between the silicon and nitrogen atoms and facilitates the removal of the leaving group in the form of a neutral molecule.

The most widely used Si–N containing silyl donor is hexamethyldisilazane, which is obtained by the reaction of Me_3SiCl with ammonia[19] (p.128). This reagent is widely employed in the pharmaceutical and chemical industries for the introduction of a temporary protecting group in various organic syntheses and also in chromatography for the modification of the surfaces of solid carriers.

At the same time, hexamethyldisilazane belongs to the group of "mild" silylating agents, i.e. it can be used even with very acid proton donors such as alcohols and phenols. Heating or the presence of a catalyst are necessary for the completion of the reaction. Inorganic acids, ammonium salts, sodium bisulphate, and chlorotrimethylsilane are used as catalysts.[14] The silylation method, the essential feature of which is the employment of an equimolar $(Me_3Si)_2NH/Me_3SiCl$ mixture, proved to be extremely fruitful.[143] This procedure made it possible to intensity appreciably the silylation reaction with the aid of hexamethyldisilazane, to increase the yield, and to reduce the reaction time. The role of $(Me_3Si)_2NH$

then consists in accepting the hydrogen chloride and in generating chlorotrimethylsilane:[144–147]

$$ROH + Me_3SiCl \rightarrow ROSiMe_3 + HCl\ ;$$
$$HCl + (Me_3Si)_2NH \rightarrow Me_3SiCl + NH_4Cl\ \cdot$$

Apart from the intensification process, it has been possible to expand greatly the synthetic possibilities of this reaction, extending it to classes of compounds (such as, for example, mercaptans and siloxanols) whose silylation by both Me_3SiCl and $(Me_3Si)_2NH$ (each separately) is relatively ineffective.[143–147]

Compounds containing the $\equiv Si-\underset{|}{N}-C\ (O)$ group (silylureas and silylamides) are more active silylating agents than silazanes and silylamines.[14,17] Although the majority of trimethylsilylureas can function as effective silyl donors, two representatives of this class have come to be most widely used recently: *NN'*-bis(trimethylsilyl)urea and *NN'*-diphenyl-*N*-trimethylsilylureas. The main advantage of the disilylated urea consists in the ease of its synthesis from widely distributed cheap starting materials: urea and hexamethyldisilazane.[148] The interaction of *N*- and *NN'*-substituted ureas with hexamethyldisilazane leads to isocyanates as a result of the thermal decomposition of unstable reaction intermediates. For this reason, silylureas are synthesised by the reaction of metallated ureas with chlorotrimethylsilane, of *N*-alkyl(aryl)ureas with *NO*-bis(trimethylsilyl)-acetamide, and of organoaminosilanes and organosilazanes with organic isocyanates,[149] which reduces their availability and increases their cost compared with *NN'*-bis(trimethylsilyl)ureas.

NN'-Bis(trimethylsilyl)urea is a convenient reagent for the silylation of alcohols and carboxylic acids.[150] The interaction is usually carried out in methylene chloride for 2–3 h, which ensures a high yield of the silylated derivatives (84 to 96%):

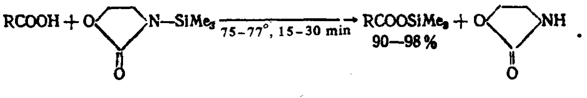
$$ROH + (Me_3SiNH)_2C{=}O \xrightarrow[20-40^\circ]{CH_2Cl_2} ROSiMe_3 + (H_2N)_2C{=}O\ ;$$
$$R = C_9H_{19},\ cyclo\text{-}C_6H_{11},\ p\text{-}MeC_6H_4,\ p\text{-}ClC_6H_4;$$
$$R'COOH + (Me_3SiNH)_2C{=}O \xrightarrow[40^\circ]{CH_2Cl_2} R'COOSiMe_3 + (H_2N)_2C{=}O\ ;$$
$$R' = Ph,\ C_5H_{11},\ ClCH_2,\ H_2C{=}C\ (Me),\ MeCH\ (OH),\ HOOCCH{=}CH{-}\ .$$

NN'-Diphenyl-*N*-trimethylsilylureas, which silylates not only alcohols and acids but also nitromethane, malononitrile, thiourea, guanidine, β-diketones, oxindole, *NN'*-dialkylurea, and other compounds, is a more effective silyl donor.[151] *NN'*-Diphenyl-*N*-trimethylsilylurea is more reactive not only compared with other silylureas but also compared with silyl donors such as *N*-silylamines and hexamethyldisilazane. For example,[151] its interaction with *NN'*-dimethylurea leads to a 100% yield of the silylated product only 2 min after mixing the initial compounds, in silylation with the aid of *N*-trimethylsilylaniline the product is formed in only 3% yield after 3 h, while in the reaction involving *N*-trimethylsilylpiperidine the yield is 10% after 3 days. The reaction with hexamethyldisilazane does not take place at all.

Trimethylsilyl derivatives of diphenylurea are obtained by the reaction of *N*-trimethylsilylaniline with phenyl isocyanate.[151] This compound is a convenient silylating agent, because diphenylurea formed in the reaction is insoluble in most organic solvents and can be readily removed from the reaction mixture by filtration. The insolubility of diphenylurea is apparently the reason why the silyl–proton exchange equilibrium is in this case almost wholly displaced to the right:

$$\underset{}{Me_3SiN\ (Ph)\ C\ (O)\ NHPh + (H_2N)_2C{=}S \xrightarrow[30-35^\circ,\ 2\ h]{MeCN} \underset{82\%}{(Me_3SiNH)_2C{=}S} + (PhNH)_2CO\ .}$$

In many instances *N*-trimethylsilyl-2-oxazolidinone[152] or silylated hydantoins [153,154] are conveniently used for the silylation of carboxylic acids and certain biologically active compounds (penicillins, steroids, etc.):



However, the commonest silylating agents containing the $N-C(O)$ group are silylamides: *NO*-bis(trimethylsilyl)-acetamide,[155] *NO*-bis(trimethylsilyl)trifluoroacetamide,[156] *N*-methyl-*N*-trimethylsilyltrifluoroacetamide,[157] and *N*-(t-butyldimethylsilyl)-*N*-methyltrifluoroacetamide.[158] The reaction of the corresponding amide with chlorotrimethylsilane in triethylamines constitutes a preparative method for the synthesis of the above silylamides, for example:[159,160]

$$RC\ (O)\ NH_2 + 2Me_3SiCl + 2Et_3N \xrightarrow[-2Et_3N.HCl]{t_b,\ 8-15\ h} \underset{\sim 80\%}{RC\ (OSiMe_3){=}NSiMe_3}\ .$$

Another method of synthesis of *NO*-bis(trimethylsilyl)amide is provided by the reaction of carboxylic acid halides with sodium bis(trimethylsilyl)amide:[161]

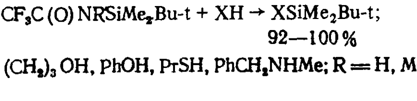
$$RC\ (O)\ Cl + NaN\ (SiMe_3)_2 \xrightarrow[-NaCl]{} RC\ (OSiMe_3){=}NSiMe_3\ ;$$
$$R = Ph,\ C_5H_4N,\ t\text{-}Bu\ .$$

NO-Bis(trimethylsilyl)amides belong to the class of the strongest silyl donors. Alcohols, acids, phenols, amines, mercaptans, amides, ureas, enols, CH acids etc. are silylated with their acid. The silylation is usually carried out in a solvent (benzene, ether, CCl_4, $CHCl_3$, acetonitrile, pyridine, and DMF), which is taken in threefold excess relative to the mass of the initial reactants.[162] Comparison of the silylating properties of *N*-(t-butyldimethylsilyl)-*N*-methyltrifluoroacetamides with those of the t-$BuMe_2SiCl$/imidazole/DMF system showed that the given silylamide is more effective as the silyl donor[163] and the reaction proceeds in acetonitrile at 20 °C:

$$CF_3C\ (O)\ NRSiMe_2Bu\text{-}t + XH \rightarrow \underset{92-100\%}{XSiMe_2Bu\text{-}t};$$
$$XH = HO\ (CH_2)_3\ OH,\ PhOH,\ PrSH,\ PhCH_2NHMe;\ R = H,\ Me\ .$$

For the analysis of organic derivatives by gas–liquid chromatography (GLC), it is more convenient to silylate them by fluorinated silylamides, since fluorinated derivatives are more volatile compared with their non-fluorinated analogues.[14,157]

It has been shown[164] that in the presence of carbon dioxide the silylation of thiazoles by hexamethyldisilazane is accelerated by a factor of 2–3, probably owing to the formation of *NO*-bis(trimethylsilyl) carbamate. It has been suggested that this compound be used as a silylating agent.[101] It can also be synthesised by silylating carbamic acid or its silver salt with chlorotrimethylsilane:



The interaction of the resulting silyl donor with alcohols and acids takes place on heating for 1–2 h and the yield of silylated derivatives reaches 96%:

$$Me_3SiNHCOOSiMe_3 + HX \rightarrow Me_3SiX + CO_2 + NH_3\ ;$$
$$HX = MeOH\ (95\%);\ MeCOOH\ (91\%)\ .$$

NO-Bis(trimethylsilyl) sulphamate has a structure similar to that of the bis(silyl) carbamate and is obtained by means of analogous reactions:[165–170]

$$\left.\begin{array}{l} NH_2SO_3NH_4 + (Me_3Si)_2NH \xrightarrow[-NH_3]{} \\ NH_2SO_3Ag + Me_3SiCl \xrightarrow[-AgCl]{} \end{array}\right] \to Me_3SiNHSO_2OSiMe_3\ .$$

However, *NO*-bis(trimethylsilyl) sulphamate is a much more powerful silyl donor than the bis(silyl) carbamate and many common silylating agents such as hexamethyldisilazane, *N*-trimethylsilyldiethylamine, *N*-trimethylsilylimidazole, and *NO*-bis(trimethylsilyl)acetamide.[167] Alcohols, phenols, acids, organosilicon compounds, and biologically active substances have been silylated with the aid of *NO*-bis(trimethylsilyl) sulphamate.[168–170] Excellent yields (in excess of 90%) of the trimethylsilyl derivatives were obtained in all cases after 30 min at 30 °C. The sulphamic acid liberated as a result of the reaction is insoluble in most organic solvents and can be readily removed by filtration:

$$\underset{93\%}{BuOH + Me_3SiNHSO_2OSiMe_3 \to BuOSiMe_3} + H_2NSO_3H\ .$$

4. Compounds Containing the Si–S Bond

Since the Si–S bond is weaker (63 kcal mol^{-1}) than the Si–O (108 kcal mol^{-1}) and Si–N (77 kcal mol^{-1}) bonds and is more readily polarisable, it is evident that thiosilanes should be more reactive in relation to proton donors than the corresponding oxygen- and nitrogen-containing organosilicon reagents.

Alkylthiosilanes are readily obtained by the reaction of chlorotrimethylsilane with alkylthiomagnesium iodide[19] or with dialkyl disulphide and sodium in ether.[171] However, their reaction with proton donors leads to the evolution of toxic merceptans with an unpleasant smell, which are in addition not always indifferent to the reaction products. These factors limit the application of alkylthiosilanes as silyl donors.

Among the compounds containing the Si–S bond, hexamethyldisilthiane meets the requirements imposed on silylating agents to the greatest extent. It can be obtained from chlorotrimethylsilane and sodium sulphide at 250 °C or by passing chlorotrimethylsilane vapour through a melt of the eutectic mixture of lithium and potassium chlorides containing 25% of potassium sulphide at 400 °C.[19] Hexamethyldisilthiane is also formed when hydrogen sulphide is silylated by chlorotrimethylsilane in the presence of tertiary amines,[19,172] organosilylamines,[19] including *N*-trimethylsilylimidazole,[19] hexamethyldisilazane,[173–175] *N*-phenyl-*N*-silylacetamide,[176] and cyanotrimethylsilane[177] and by the interaction of iodotrimethylsilane with silver[172] and mercury[172,178,179] sulphides.

The reaction of chlorotrimethylsilane with ammonium hydrogen sulphide is an extremely effective method of synthesis of hexamethyldisilthiane:[180]

$$Me_3SiCl + NH_4SH \to (Me_3Si)_2S + NH_4Cl + H_2S\ .$$

However, the easiest and most promising method of synthesis of hexamethyldisilthiane involves the cothiolysis of *N*-trimethylsilyldiethylamine or hexamethyldisilazane with chlorotrimethylsilane:[181,182]

$$Me_3SiNEt_2 + Me_3SiCl + H_2S \to (Me_3Si)_2S + Et_2NH{\cdot}HCl\ ;$$
$$(Me_3Si)_2NH + Me_3SiCl + H_2S \to (Me_3Si)_2S + NH_4Cl\ .$$

The reaction takes place with a small exothermic effect at 20–50 °C in a neutral solvent or without a solvent. The hexamethyldisilthiane formed in this process is 99.95% pure according to GLC data.

Hexamethyldisilthiane is a highly effective reagent for the silylation of alcohols,[19,183–191] aminoalcohols,[187] phosphorylated alcohols,[192] phenols,[194–195] inorganic and carboxylic acids,[194,195,197,198] enols,[199,200] arylmercaptans,[199,200] oximes,[199,200] and also certain organoelemental compounds,[199,201] including organosilicon[202] and organophosphorus compounds:[199,201]

$$(Me_3Si)_2S + 2RXH \to 2Me_3SiXR + H_2S\ ;$$
$$RXH = AlkOH,\ ArOH,\ HO(CH_2)_nOH,\ H_3BO_3,\ H_2SO_4,$$
$$HHal,\ H_2N(CH_2)_nOH,\ ArSH,\ R'C(O)CH_2C(O)R'',\ R'R''{=}NOH,$$
$$Ph_2Si(OH)_2,\ (RO)_2POOH\ \text{etc.}$$

One of the main advantages of hexamethyldisilthiane compared with other silyl donors is the simplicity of the silylation reaction, which is achieved by mixing and heating the initial reactants (at 30–120 °C) for a short time (0.5–3 h), ensuring a high yield (70–98%) of the silyl derivatives. The course of the reaction can be conveniently followed volumetrically from the amount of hydrogen sulphide formed. The reaction does not require the use of catalysts and solvents. Furthermore, hexamethyldisilthiane ensures the selective silylation of proton donors containing two and more active groups in the molecule.[199]

5. Compounds Containing Si–C Bonds

Reagents with the Si–C bond are much more resistant to the action of proton donors than the silyl donors with the Si–Hal, Si–O, Si–N, and Si–S bonds examined above. However, in the presence of catalysts certain compounds containing electron-accepting groups such as C_6F_5, CN, etc. can act as effective silyl donors. Thus, in the presence of strong acids (toluene-*p*-sulphonic[203] or trifluoromethanesulphonic[204] acids), allylsilane silylates alcohols and acids in accordance with the following scheme:

$$CH_2{=}CHCH_2SiMe_3 + ROH \xrightarrow[MeCN]{TosOH} \underset{87\text{—}99\%}{ROSiMe_3} + CH_2{=}CHMe\ .$$

The catalytic action of the above acids consist in the ready cleavage by the latter of the silicon–allyl bond with the intermediate formation of powerful silyl donors—the trimethylsilyl esters of sulphonic acids.[205] Further interaction of these intermediates with proton donors leads to silylated products with regeneration of the acid:[204]

$$CH_2{=}CHCH_2SiMe_3 + CF_3SO_2OH \xrightarrow[20-25^\circ]{CH_2Cl_2} CF_3SO_2OSiMe_3 + CH_2{=}CHMe\ ;$$
$$CF_3SO_2OSiMe_3 + RCO_2H \to RCO_2SiMe_3 + CF_3SO_2OH\ .$$

In the presence of $Bu_4N.3H_2O$ as the catalyst, alkyl trimethylsilylacetates can be used to silylate compounds containing a comparatively acid hydrogen atom, for example:[206]

$$Me_3SiCH_2COOR + XH \to \underset{88\text{—}92\%}{Me_3SiX} + MeCOOR\ ;$$
$$R = Me, Et;\ X = Ph(CH_2)_3O,\ Ph(\text{isoferrocene})_2CO,\ 4\text{-}MeC_6H_4O,\ Me(CH_2)_5S,$$
$$PhCH_2S,\ 1\text{-menthyloxy},\ Me_3CS,\ PhC{\equiv}C,\ EtCOO\ ;$$
$$Me_3SiCH_2COOMe + HO(CH_2)_2SH \to \underset{83\%}{Me_3SiO(CH_2)_2SSiMe_3} + MeCOOMe\ .$$

When the silicon atom is linked to the trichloromethyl group, the cleavage of this bond can take place also in the absence of the catalyst, for example:[207–209]

$$Me_3SiCCl_3 + Bu_2NH \xrightarrow[3-4\ h]{120-140^\circ} \underset{85\%}{Me_3SiNBu_2} + CHCl_3\ .$$

The use of (trichloromethyl)trimethylsilane is convenient also because chloroform formed as a side product can serve simultaneously as the solvent for the reaction product.

(Trichloromethyl)trimethylsilane can be obtained by the reaction of phosphorus acid amides with chlorotrimethylsilane in the presence of CCl_4 [210] and by the decarboxylation of the trimethylsilyl ester of trichloroacetic acid in the presence of triethylamine:[211]

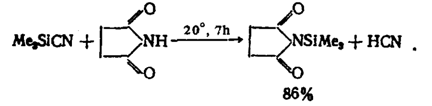
$$(R_2N)_3P + CCl_4 + Me_3SiCl \xrightarrow[Et_2O]{} (R_2N)_3PCl_2 + Me_3SiCCl_3 \ ;$$

$$CCl_3COOSiMe_3 \xrightarrow[66°,\ 4h]{Et_3N,\ THF} \underset{79\%}{Me_3SiCCl_3} + CO_2 \ .$$

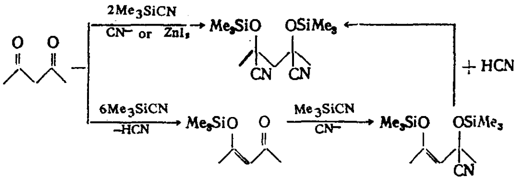
In recent years there has been a growth of interest in cyanotrimethylsilane not only as a reagent which makes it possible to introduce the cyano-group readily into the molecules of organic and organoelemental compounds[1,2] but also as a silyl donor. It has been found[177] that Me_3SiCN readily reacts with compounds containing SH and NH bonds:

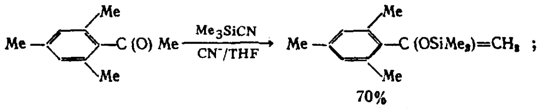
$$Me_3SiCN + H_2S \xrightarrow[80°;\ 3{,}5h]{} \underset{86\%}{(Me_3Si)_2S} + HCN \ ;$$

$$Me_3SiCN + 2Et_2NH \xrightarrow[20°,\ 2h]{} Me_3SiNEt_2 + Et_2NH{\cdot}HCN \ ;$$



The interaction of Me_3SiCN with carbonyl compounds is unusual; depending on the conditions and the catalyst, both silylation and addition to the carbonyl group can take place:[212–215]

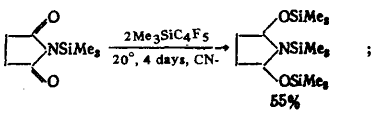


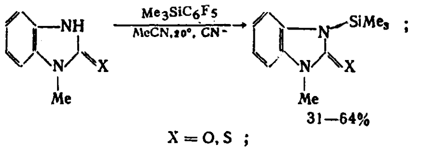


CN⁻ = KCN/18-crown-6-ether.

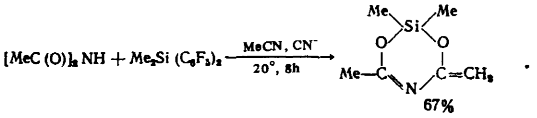
Thus cyanotrimethylsilane can be used to convert a ketone into a cyanohydrin with the simultaneous protection of the hydroxy-group, which has been used in the synthesis of prostaglandin.[2,216]

The successful selection of the catalyst for the silylation of carbonyl compounds (KCN/18-crown-6 ether) made it possible to employ also (pentafluorophenyl)trimethylsilane as the silyl donor. This resulted in the formation of silyl derivatives which are either difficult or impossible to obtain by another method, for example:[212,215,217–222]





X = O, S ;



III. COMPARATIVE CHARACTERISTICS OF SILYLATING AGENTS

Evidently factors weakening the Si–X bond in the silyl donor R_3SiX increase the rate of silylation. The effect of various factors, including the nature of the leaving group X, the substituents R, the acidity of the proton donor, and the influence of the medium and the catalyst on the efficiency of the silylation, have been described in reviews,[14–24] silyl donors of one class being usually compared. Studies in which a quantitative comparison has been made of the silylating agents with Si–X bonds of different character are more important.

The activity of silyl donors is determined either by measuring the rate of reaction of various silyl donors with the relatively inactive proton donor or the yield of the product of the silylation of this proton donor after a specific time interval is determined. For example, the activities of silyl donors of the type Me_3SiX, where X = Cl, $MeSO_3$, $4\text{-}MeC_6.H_4SO_3$, $PbSO_3$, Me_3SiOSO_3, $4\text{-}BrC_6H_4SO_3$, $CF_3CH_2SO_3$, Br, CF_3SO_3, or I, in relation to cyclopentanone and diisopropyl ketone, have been investigatea.[223] The reactions proceed in the presence of triethylamine in accordance with the following mechanism:

The rate of reaction was determined by ^1H NMR. The extremum values of the standardised rate constants (at 23 °C) and the relative rate constants for the given silylation reactions were calculated. The silylating activity scale was obtained in this way (the reactivity of Me_3SiCl was adopted as unity); the highest reactivity is shown by Me_3SiI:[223]

X	Cl	$MeSO_3$	$PhSO_3$	Me_3SiOSO_3	Br	CF_3SO_3	I
k_{rel}	1	40	160	270	$7{,}9\cdot10^4$	$6{,}7\cdot10^8$	$7\cdot10^9$

In another study[167] the authors claim that *NO*-bis(trimethylsilyl) sulphamate is more effective as a silylating agent than the majority of silyl donors. To confirm this, they compared the efficiency of the most frequently used silylating agents in relation to the silylation with sterically hindered 2,6-di-s-butylphenol; the yield of the silylated product was determined by GLC.

In another investigation[199] the interaction of dodecyl alcohol with a series of silyl donors [chlorotrimethylsilane, hexamethyldisilazane, the equimolar mixture of chlorotrimethylsilane and hexamethyldisilazane, *N*-trimethylsilyldiethylamine, *NO*-bis(trimethylsilyl)acetamide, and hexamethyldisilthiane] was chosen as the model reaction. It was shown by GLC that the reactivities of *NO*-bis(trimethylsilyl)acetamide and hexamethyldisilthiane in relation to the above alcohol are approximately the same and exceed appreciably the reactivities of the remaining silyl donors.

The available data permit the conclusion that the most active silyl donors are trimethylsilyl trifluoromethanesulphonate, iodotrimethylsilane, *NO*-bis(trimethylsilyl) sulphamate, *NO*-bis(trimethylsilyl)acetamide, and *NO*-bis(trimethylsilyl)trifluoroacetamide. Hexamethyldisilthiane and *N*-trimethylsilylimidazole are extremely active in relation to compounds containing OH groups; on the other hand, they are less suitable for silylation of NH and SH bonds.

In recent years there has been a growth of interest in catalytic silylation of proton donors by compounds containing the Si–C bond, although this method has not so far come to be sufficiently widely used.

---o0o---

Thus, efforts to create new silylating agents or to apply known reagents to silylation have been made in five directions: (1) the synthesis of silyl donors containing groups which would promote easier elimination of the silyl group (trimethylsilyl triflate and trifluoromethyl-containing amides); (2) the synthesis of silyl donors which do not form deposits, during the silylation process, hindering the isolation and purification of silylated products (hexamethyldisilthiane and silyl carbamates); (3) the synthesis of reagents forming in the course of the reaction substances which are indifferent to the reaction products and which liquefy the reaction mass, promoting a higher degree of completion of the process [trimethylsilyl trichloroacetate, alkyl trimethylsilylacetate, (trichloromethyl)trimethylsilane]; (4) the use of catalytic systems which convert known reagents into effective silyl donors (allyltrimethylsilane, hexamethyldisiloxane in the presence of the KCN/18-crown-6 ether complex); (5) the use of reagents which serve simultaneously for the introduction of protecting (silyl) groups as well as other reactive groups (cyanotrimethylsilane). We suggest that the synthetic possibilities of the first two procedures have been virtually exhausted and the main effort will therefore probably be concentrated on the last three procedures, especially that involving the creation of catalytic silylation systems.

In conclusion one should note that the usefulness of a particular silyl donor is determined both by the nature of the compound silylated and by the aim of the investigator. For example, analytical chemistry (GLC, mass spectroscopy) requires highly effective reagents such as trimethylsilyl trifluoromethanesulphonate, which silylate rapidly and quantitatively, although they are usually expensive and scarce. Since the analytical chemist deals with small amounts of substances to be analysed the cost of the silyl donor does not play a significant role for his purposes. On the other hand, in the development of the technology for the large-scale synthesis of organic substances, it is more useful to select a cheaper, albeit a less active silyl donor, such as organochlorosilane or hexamethyldisilazane. In selecting a suitable silylating agent, the synthetic chemist must take into account primarily the structure of the proton donor and the synthetic possibilities of the different silyl donors, information about which is available in monographs,[1,14] original articles,[15–24] and in the present review.

Polymeric Reagents in the Synthesis of Peptides

S.M.Andreev, N.A.Samoilova, Yu.A.Davidovich, and S.V.Rogozhin

The essential features of the method of polymeric reagents in relation to peptide synthesis are described. The polymer-activators have been classified in terms of the type of activating groups. The procedures used in the synthesis of polymer-activators and polymeric reagents are given and the principal aspects of the employment of the method of polymeric reagents in the synthesis of peptides of various structure as well as the trends and prospects for the development of the method are discussed.

The bibliography includes 201 references.

I. INTRODUCTION

The application of polymers in organic syntheses, and biotechnology has vigorously increased in recent times. For example, recently published monographs[1–7] have been devoted to these questions. Thus the employment of polymers as various supports, in particular for the immobilisation of enzymes[1,3,7,8] and the cells of micro-organisms[1,9–11] and for the affinity chromatography of proteins[5,12,13] is well known. Studies are being prosecuted in order to synthesise polymeric therapeutic agents,[1,14–16] in particular, artificial antigens[17] and synthetic models of enzymes.[3,18,19] Polymeric catalysts[2,20,21] and high-molecular-weight protecting groups are widely used.[2,22] However, the most vigorously developing field is that involving the application of polymers as chemical reagents.[2,4,24,25] The main advantage of this approach is associated primarily with an increase of the yields and the facilitation of the purification of the desired product; in many cases the specificity of the reactions carried out is greatly increased. The application of polymers in multistage monotonic operations, for example, in the synthesis of polypeptides,[26,27] polynucleotides,[28] polysaccharides,[29] and polycondensation polymers with exactly specified numbers of units[30] proved to be especially valuable. Polymers can serve under these conditions as separators of the reacting groups, imitating the conditions of high dilution. The reduction to a minimum of competing intermolecular† interactions makes it possible to employ this principle effectively for the synthesis of cyclic peptides,[7,31] macrocyclic compounds,[32] asymmetric ketones and α-substituted carboxylic acids,[33–35] the Dieckmann cyclisation,[36] the conversion of bifunctional compounds into the monoblocked form,[37,38] etc. The direction of the reaction and the selectivity can change significantly on passing from the usual low-molecular-weight reagents to polymeric reagents.[39,40]

Polymeric reagents are finding useful applications in virtually all fields of organic synthesis. In peptide synthesis the tendency has arisen to refer to polymers which fulfil acylating functions as polymeric reagents.[27,42–46]

The methods of synthesis of polymeric reagents, the use of the latter in peptide synthesis, and the trends and prospects in the development of this approach are discussed in the present review.

II. THE ESSENTIAL FEATURES OF THE METHOD OF POLYMERIC REAGENTS IN RELATION TO PEPTIDE SYNTHESIS

The search for new approaches to the synthesis of biologically active compounds which are protein in nature occupies a special place among the problems of peptide chemistry. "Classical" peptide chemistry, which deals with reactions in solution, has encountered many problems difficult to solve, which include the reduction of the yields with increase in the size of the peptide synthesised, the difficulty of isolating the desired product in a homogeneous state as a consequence of the occurrence of side reactions, and the reduction of the solubility of peptides with increase in the length of their chain.

In the attempts to overcome these difficulties, new ideas have appeared, which are associated mainly with the employment of synthetic polymers. At the beginning of the 1960's Merrifield[26,50] suggested that insoluble polymers be used as carriers of the peptide chain, serving at the same time as the C-terminal protecting group. It then became possible to use a large excess of the activated low-molecular-weight component, whose separation together with soluble side products can be readily achieved by the filtration of the peptide—polymer complex. This "solid phase" method of synthesis gained wide popularity, which was promoted to an appreciable extent by studies on its mechanisation and automation.[51,52] However, in the course of the development of this method, some disadvantages also appeared,[53,54] being associated mainly with the difficulty of eliminating the insoluble side products, accumulated in the course of the synthesis, from the final products.

If a soluble polymer is used as the C-terminal protecting group of the growing peptide, it is possible to diminish the influence of diffusion factors on the course of the reaction. This is the so called "liquid phase" method[55] of peptide synthesis. An obstacle to the wide-scale employment of the liquid phase method, especially in the synthesis of higher

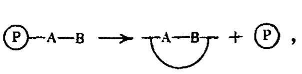
---

† The term "intrapolymer" reactions is also used for such systems.[41]

peptides, is apparently the difficulty of purifying the reaction product owing to the similarity of the solubilities and molecular weights of the polymer and the peptide synthesised.

In the middle 1960's a methodologically new trend arose, also associated with the employment of polymers but this time as activators of the carboxy-groups of aminoacids or peptides.[27,56] In the general case the covalent polymer–low-molecular-weight reagent complex, which has the free energy necessary for the occurrence of the reaction, effects the transfer of activated groups to the molecules of the other reactant present in solution (reaction (1)]. Here one can also include the reactions between groups present in the polymer phase, i.e. intramolecular (or intrapolymer) interactions [reaction (2)]. Polymeric reagents of the types indicated are also referred to as polymeric transferring agents.[42]

$$\textcircled{\text{P}}\text{—A} + \text{B} \longrightarrow \text{A—B} + \textcircled{\text{P}}\ , \qquad (1)$$



$\textcircled{\text{P}}$ - polymer-activator. (2)

Polymeric condensing agents[43] fit the above definition because the reaction takes place via an intermediate stage—the activation of component A:

$$\textcircled{\text{P}} + \text{A} + \text{B} \longrightarrow \textcircled{\text{P}}\text{—A} + \text{B} \longrightarrow \text{A—B} + \textcircled{\text{P}}\ .$$

In peptide synthesis component A is usually an *N*-substituted aminoacid, whose carboxy-group must be activated before the formation of the peptide bond. Component B is an aminoacid or a peptide with a free N-terminal amino-group. The polymer-activator carries electron-accepting groups for the generation of the positive charge on the carbonyl carbon atom of the aminoacid sufficient for effective attack by the nucleophile. In classical peptide chemistry, activated esters, anhydrides, imides, etc. are usually employed for this purpose.[47–49] In order to accelerate the aminolysis and to ensure that it goes to completion, an excess of the polymeric reagent, which is separated in the last stage of the synthesis, is used as a rule.

The physicochemical properties of the polymer play a very important role both in the synthesis and in the isolation of the product. It is possible to formulate certain general requirements which must be met by polymeric reagents: (1) the polymeric skeleton must be readily permeable to the peptide molecules over a wide range of molecular weights. In the case of polymers of the gel type, the latter must exhibit a satisfactory swellability in the solvents employed; (2) the physical properties of the polymeric species must ensure their ready separation by filtration from the soluble products and their mechanical and osmotic stabilities must be satisfactory; (3) polymeric derivatives of aminoacids must be highly reactive and resistant to racemisation; (4) polymeric reagents must be stable on storage also to the solvolytic action of solvents; (5) polymers must not absorb the soluble components; (6) it is desirable that the polymeric components should be capable of being used many times, i.e. that there should be a possibility of their regeneration without reducing their initial capacity and reactivity and without changing the physicochemical parameters of the polymer.

Among the polymeric reagents used at the present time, polymeric activated esters are most often employed for peptide synthesis:

$$\text{Z—NH—CHR}'\text{COOH} + \text{HX}\textcircled{\text{P}} \longrightarrow \text{Z—NHCHR}'\text{—CO}\sim\text{X}\textcircled{\text{P}} \xrightarrow{\text{H(NHCHRCO)}_n\text{NHCHRCOO—Y}}$$

$$\longrightarrow \text{Z—NH—CHR}'\text{CO(NHCHR)}_n\text{NHCHRCOOY} + \text{HX}\textcircled{\text{P}}\ ;$$

$\textcircled{\text{P}}$ = polymeric skeleton; X = activating group;
Y, Z = *N*- and *C*-protecting groups; $n = 0, 1, 2...$

The condensation of *N*-protecting aminoacids with a polymer-activator leads to the activation of the carboxy-group. The polymeric reagent obtained is introduced into the aminolysis reaction with the corresponding derivative of the aminoacid or peptide containing a free amino-group. The reaction product passes to the solution. After the removal of the *N*-protecting group, the resulting peptide can be made to react again with a second activated aminoacid, effecting thereby the growth of the peptide chain. An important factor in the synthesis of a polymeric aminoacid derivative is the absence of insoluble side products which might contaminate the required product in subsequent aminolysis.

III. SYNTHESIS OF POLYMER-ACTIVATORS

There exist various ways of introducing activating groups into the polymeric skeleton. In some cases the initial polymer is subjected to a series of chemical transformations, while in others a molecule with the functional group already present is attached to a suitable polymeric carrier. The functional group can also be introduced by copolymerising the corresponding monomers or by the ionic binding of the "functional" compound to a strong ion-exchange resin.

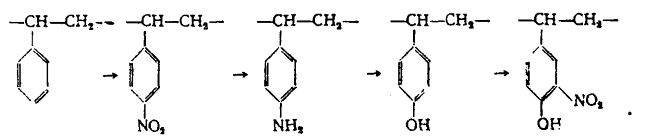
In the vast majority of studies, high-molecular-weight nitrophenols and polymers with the *N*-hydroxy-group are most successfully used for the activation of *N*-protected aminoacids.

There exists at the present time a fairly extensive literature on high-molecular-weight phenols[57,58] of different structure, whose nitration is potentially capable of ensuring the formation of the required nitrophenol polymer-activator. However, in peptide synthesis the higher requirements which must be met by the physicochemical properties of the polymer significantly restrict the choice of such polymers. For example, the widely familiar phenol-formaldehyde resins of the "resite" and "novolak" types[59] are apparently relatively unsuitable for such purposes owing to the difficulties arising in the regulation of the steric structure, the content of functional groups, and the physical shape of the polymer particles. There exist brief reports about the use of such polymers,[56,60] but experimental data on their application are virtually lacking. Amorphous powdered polymers of this type have been obtained by the polycondensation of di(4-hydroxyphenyl) sulphone with formaldehyde[61] or of salicylic acid with anisole and formaldehyde.[62] Many phenol-formaldehyde polymers have also been used in the solid phase synthesis.[31,63–65] The yields of peptides when such a resin was employed were appreciably lower compared with a hydroxylated polymer having a polystyrene skeleton. This effect has been attributed by the authors to steric hindrance—the methylene bridges were located next to the functional groups.

In one of the first studies on the use of polymeric reagents in peptide synthesis,[27] it was suggested that one should use poly-4-hydroxy-3-nitrostyrene, obtained by the hydrolysis of the copolymer of p-acetoxystyrene with 4% of divinylbenzene and subsequent nitration with concentrated acid at 0 °C.[66] This polymer was used successfully in the synthesis of low-molecular-weight model peptides bradykinin and luliberin,[67] but in the course of its application disadvantages were revealed—the decomposition of the polymeric species during the aminolysis reaction and mechanical manipulations which might have led to the contamination of the desired products.[68,69]

Williams[70] suggested that poly-*o*-nitrophenol be synthesised by the block copolymerisation of *p*-methoxystyrene with divinylbenzene, subsequent elimination of the methyl group using boron tribromide and then nitration. The effectiveness of the acylation by *N*-protected aminoacids of both the given polymer and the preceding one[27] was approximately the same (1–1.5 mmol per gramme of polymer).

A similar polymer-activator was obtained in accordance with the following scheme using polymer-analogue reactions:[56]

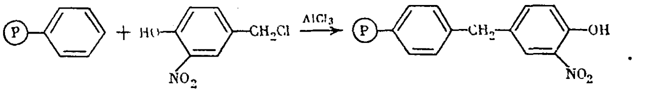


The content of reactive hydroxy-groups was 0.05–0.5 mmol per gramme of polymer, while their theoretical content was 5–7 mmol g^{-1}. Evidently the above scheme is relatively unsuitable for the synthesis of the activator owing to the occurrence of side processes leading to a sharp reduction of the reactivity of the polymer.

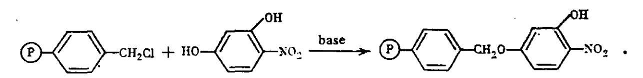
An insoluble phenolic polymer in the form of spherical grains has been obtained.[71] The authors used the copolymerisation in suspension of *p*-acetoxystyrene with styrene and divinylbenzene and the acetate group was split off by hydrazinolysis under mild conditions.

With one exception,[71] in the cases examined the polymers consisted of particles of irregular shape, which was bound to hinder their use owing to cracking and mechanical wear. The occurrence of side reactions in the synthesis of certain polymer entails, together with a decrease of the content of functional groups, also significant changes in the steric structure, for example, owing to additional cross-linking. In order to eliminate the above negative phenomena, it was suggested[72] that the complete functional group be introduced into the polymer-carrier with the required set of physical properties. The authors synthesised a polymeric *o*-nitrophenol using as the carrier spherical grains of a copolymer of styrene with 2% of divinylbenzene, which has found extensive application in the solid phase synthesis of peptides in view of satisfactory physicochemical parameters.

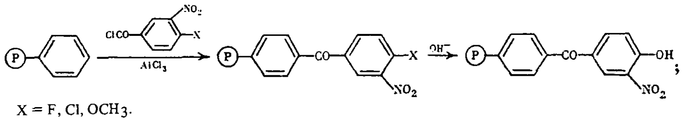
An analogous approach has been used by other workers,[69] who modified the styrene grains with 4-hydroxy-3-nitrobenzyl chloride by means of the Friedel–Crafts reaction:



A polymer-activator of similar structure has been obtained by means of the following scheme:[68]

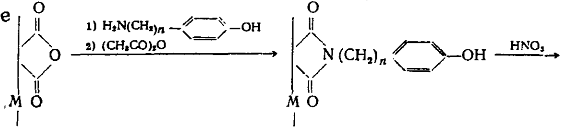


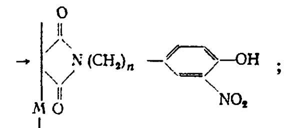
Finally, a polymeric 4-hydroxy-3-nitrobenzophenone has been proposed quite recently for acyl-activation in peptide synthesis:[73]



X = F, Cl, OCH_3.

Low-molecular-weight activated ethers of 4-hydroxy-3-nitrobenzophenone proved to be 40 times more reactive than the corresponding *o*-nitrophenyl ethers. A polymeric *o*-nitrophenol has been synthesised in the laboratory of the authors of the review on the basis of a cross-linked copolymer of styrene with maleic anhydride[74] and of ethylene with maleic anhydride





$n = 0, 1, 2$

$M = CH_2CH_2$ or $CH_2CH(C_6H_5)$.

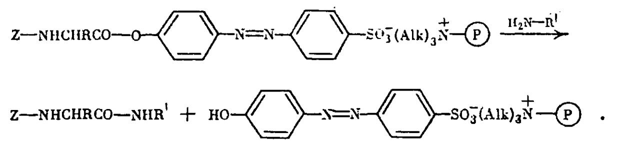
The polymer-carrier consists of spherical grains obtained by cross-linking the initial linear copolymers by aromatic diamines (3–5 mole %) in an emulsion system.[75] Their modification by aminophenols with subsequent nitration led to poly-4-hydroxy-3-nitrophenylmaleimides with a degree of conversion close to 100%.

Practically the same polymer-activator has been obtained by Japanese investigators,[76] who also synthesised a soluble polymeric nitrophenol. However, the method of synthesis of cross-linked polymers differed from that given above;[74] the authors[76] copolymerised *p*-acetoxyphenylmaleimide with styrene in the presence of divinylbenzene with subsequent elimination of the acetyl group and nitration. Both the polymeric mononitro-derivative and the dinitro-derivative—poly-4-hydroxy-3,5-dinitrophenylmaleimide—were obtained.

The polymer-activators obtained by a procedure involving the attachment of a complete activating group to the polymer-carrier were distinguished by a high mechanical strength and swellability in organic solvents of different polarity: in dimethylformamide (DMF), dioxan, methylene chloride, etc. One cannot rule out the possibility that such polymers exhibit a smaller steric effect on the aminolysis reaction, because the reaction centre in the polymeric activated ester is remote from the polymer chain.

A soluble polymer-activator with a nitrophenol group has been obtained[27] from a copolymer of DL-lysine and L-tyrosine[77] and, whilst being insoluble in solvents of low polarity, it dissolves satisfactorily in DMF, ethanol, and water at basic pH. However, this polymer has been used only for the cyclisation of linear peptides.[27] A soluble polynitrophenol obtained from poly(ethylene glycol) is also known;[78] it has been used in the synthesis of model dipeptides.[79]

Mention should be made of a study[80] where the reagent was used in the form of an electrostatic complex:

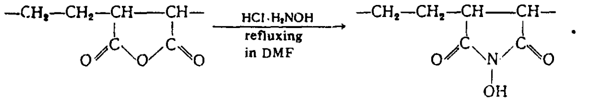


The activated ester of an *N*-protected aminoacid and 4-hydroxyazobenzene-4-sulphonic acid was attached to an ion-exchange resin (Dowex 1X2) by salt formation.[81,82] The aminolysis of the insoluble ester obtained in this way was carried out in formamide. The relatively high swellability of this polymer in highly polar media should favour the use of free aminoacids and peptides as the amino-components. The advantage of this approach consists in the fact that the activated ester was synthesised in solution and it could therefore be purified before being attached to the polymer. A disadvantage of the reagent is the risk of ion exchange and the consequent contamination of the aminolysis products. An acetylated insoluble polystyrene ion exchanger has been proposed[83] for the synthesis of the amide bond in an aqueous medium. However, under the conditions indicated, the acylation of aniline was insufficiently effective—the yield of acetanilide did not exceed 26%.

Attempts have been made to use polymeric thiophenols in peptide synthesis.[56,84,85] Among these, only poly-*o*-nitrothiophenol[85] and poly-2-mercaptopyridine[85] have been used in the synthesis of two peptides, the reagents based on the mercaptopyridine being more reactive (the yield in the condensation reaction was 90–98%). Poly-2-mercaptopyridine also proved an effective thiolytic agent—it has been used for this purpose in order to eliminate the Nps# protecting group at intermediate stages in the synthesis of leucine-enkephalin.[85]

The *O*-acylation of *N*-substituted hydroxylamines attracted much attention by investigators, because the activated esters of this type are highly reactive and are resistant to racemisation.[48] *N*-Hydroxysuccinimide esters[86] derived from *N*-hydroxybenzotriazole[87] have gained much popularity in the classical peptide synthesis and benzotriazole has been frequently used as the catalyst in peptide formation reactions.[88] These particular derivatives have served as prototypes of polymeric reagents with an *N*-hydroxy-group.

A linear copolymer of ethylene with *N*-hydroxymaleimide has been synthesised as follows:[89]

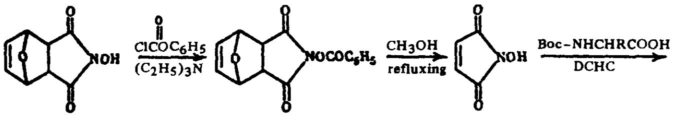


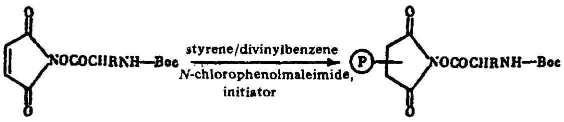
This polymer and its *O*-acyl derivatives dissolved only in polar solvents—DMF and dimethyl sulphoxide (DMSO). For this reason aminoacids were activated by this polymer in the above solvents and the resulting esters were subjected to aminolysis in dimethoxyethane or ethyl acetate in which the polymer does not dissolve. Despite the satisfactory results obtained in the synthesis of low-molecular-weight peptides, its application is limited because many peptides dissolve only in the same solvents as the given polymer. For this reason, the authors apparently used subsequently in the synthesis of higher peptides (from hexa- to octa-peptides) a highly cross-linked polymer, which was obtained by irradiating the above poly-*N*-hydroxysuccinimide with high-energy electrons.[89] The content of active hydroxy-groups then fell to 2%, i.e. the polymer virtually "worked" only in the surface layer.

In contrast to the previous workers,[89] Japanese investigators proposed different methods for the introduction of *N*-hydroxy-groups into the polymer, involving the treatment of the styrene–maleic anhydride copolymer in pyridine under milder conditions—at room temperature.[90–94] The polymer was obtained in the form of a colourless powder with an *N*-hydroxy-group content close to theoretical.[90] It was used for the acetylation and benzoylation of certain amines in a homogeneous system; it was not employed for peptide synthesis.

It has been suggested that *O*-substituted maleimides can be used for the synthesis of cross-linked spherically granulated poly-*N*-hydroxysuccinimides, provided that they are subjected to emulsion copolymerisation with styrene and divinylbenzene.[91] However, spherical grains could not be obtained under the conditions indicated. It is of interest that the maleamic acid (an aminoacid) units present in the polymer chain were readily converted into a five-membered imide ring by dehydrocondensation on treatment with aqueous hydrochloric acid,[90,91] while dehydrating agents or heat were required for the low-molecular-weight analogues.

A novel method of synthesis of the polymeric reagent has been proposed by Akiyama et al.[94]:





Boc = t-butoxycarbonyl
DCHC = dicyclohexylcarbodiimide .

According to the authors' idea, this procedure guaranteed a higher purity of the polymeric activated esters. On the other hand, the introduction of chlorophenylmaleimide into the polymer chain entailed smaller changes in the swellability of the polymer and the solvent was altered during aminolysis.

The copolymerisation of benzyloxymaleimide (or acetoxymaleimide) with styrene and 0.6% of divinylbenzene followed by acid elimination of the *O*-protecting group led to a polymer containing 3–3.5 mmol g^{-1} of *N*-hydroxy-groups.[93]

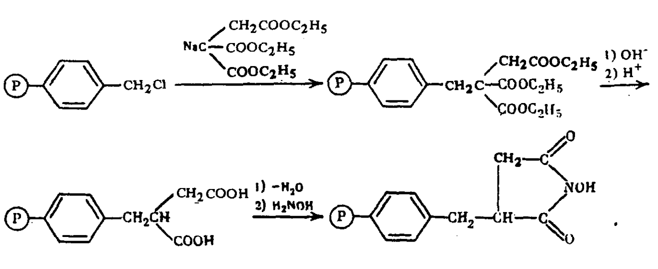
However, it is evident that the schemes for the synthesis of polymeric *N*-hydroxysuccinimides providing for the use of *O*-substituted maleimides are fairly cumbersome and require the expenditure of much time; the synthesis of the initial monomer does not take place with a high yield in all the stages. Furthermore, in the polymerisation of optically active monomers, one cannot rule out the possibility of racemisation, because the process is carried out at an elevated temperature (Akiyama et al.[94] used only simple aliphatic aminoacids).

A simpler and rapid method of synthesis of poly-*N*-hydroxysuccinimide involves the copolymerisation of maleic anhydride with a vinyl monomer (usually styrene) in the presence of divinylbenzene and subsequent modification of the anhydride groups. The introduction of *N*-hydroxy-groups by treating the anhydride polymer with hydroxylamine hydrochloride in boiling DMF has been described,[95] the degree of conversion reaching 88%. Such polymers swell satisfactorily in solvents with a high dielectric constant.

A polymer with an analogous functional group has been obtained by treating the soluble copolymer of ethylene and maleic anhydride with a mixture of hydroxylamine and a polyamine as the cross-linking agent (hydrazine, spermine, and spermidine) in an aqueous pyridine medium. The polymer was distinguished by a high permeability to large molecules, which is indicated by the high yield in the peptide formation reactions and by the quantitative acylation of the terminal amino-groups of insulin.[96]

All the polymer-activators of the *N*-hydroxysuccinimide type examined consisted outwardly of amorphous powders. Repeated use of these polymers is difficult, since the polymer particles of irregular shape are rapidly comminuted, which impairs their capacity for filtration in the swollen state.[96] It is therefore not surprising that only one publication has been devoted to each polymer.

A scheme for the synthesis of the polymer-activator, in which a cross-linked chloromethylated polystyrene in the form of spherical grains is subjected to a series of chemical transformations, has been presented in a review article:[43]

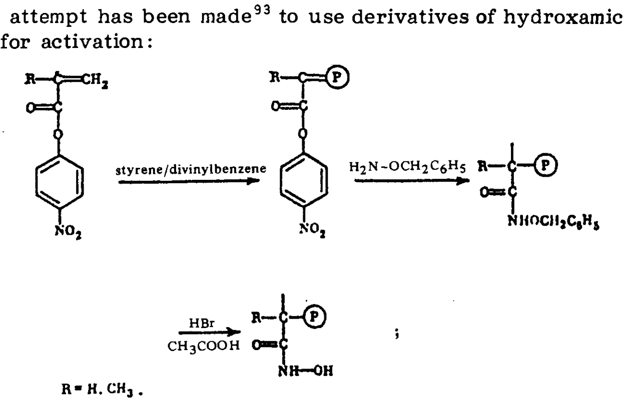


#o-Nitrophenylsulphenyl (Ed.of Translation).

Cross-linked copolymers of maleic anhydride in the form of grains having a regular spherical shape have been obtained by Soviet workers[75,97–100] by cross-linking the initial copolymers by aromatic diamines with a rigid extended molecular structure [benzidine, di(aminophenyl), ether, etc.] in DMF dispersed in a liquid polysiloxane. *N*-Hydroxy-groups were introduced by treating the anhydride polymer with hydroxylamine hydrochloride in pyridine; their content in the final polymers reached about 4 mmol per gramme of the polymer. The grains of all the poly-*N*-hydroxysuccinimides obtained swelled satisfactorily in polar organic solvents, while the polymers into the composition of which *N*-vinylpyrrolidone has been introduced[97–100] also swelled satisfactorily in an aqueous medium. The particles of the polymeric *N*-hydroxysuccinimide had a satisfactory mechanical strength and osmotic stability and were easily filtered in the swollen state. The acylation of the hydroxy-groups in the polymer was almost quantitative.[97–102] These polymers have a macronetwork isoporous skeleton[103] and it has been shown[104] that polymers with this structure are satisfactorily permeable to large molecules.

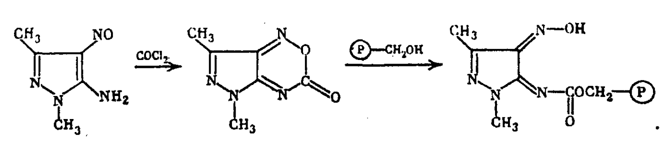
As can be seen, there exists a fairly large selection of methods for the synthesis of polymeric *N*-hydroxysuccinimides. Evidently, the simplest and cheapest versions are those which begin with copolymers of maleic anhydride. One should bear in mind that such copolymers contain rigorously alternating units[105,106] and that by selecting the appropriate comonomers it is possible to alter significantly some of their properties, for example their hydrophilic/hydrophobic properties,[98,100] and the microenvironment of the reaction centre.[94]

An attempt has been made[93] to use derivatives of hydroxamic acid for activation:



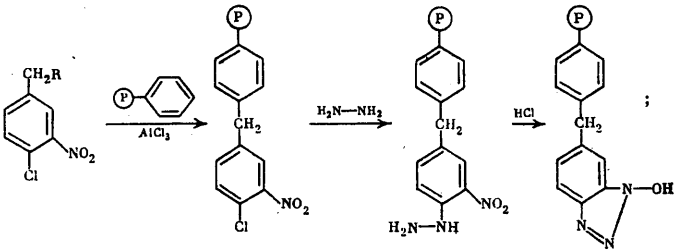
In the case of a polymer containing acrylic acid residues, the above reactions occurred with a higher yield than for a copolymer of methacrylic acid. The attempt to copolymerise methacryloylhydroxylamine acid with styrene was unsuccessful.[93] The aminolysis of O-acyl derivatives of the resulting polymer (R = H) by certain aliphatic aminoacids and amines led to fairly low yields of amides, which can be attributed to the low reactivity of this polymeric reagent[107] and steric hindrance.

Guarneri et al.[108] suggested that a polymeric derivative of 5-amino-4-nitrosopyrazole be used as the activator:



It had been shown earlier that low-molecular-weight activated esters based on 5-aminopyrazolone oxime exhibit a very high acylating capacity in the virtual absence of racemisation.[109] An interesting feature of this oxime is that, by virtue of the presence of conjugated double bonds, it is coloured green, while its *O*-acyl form is red, as a result of which it is possible to follow visually the occurrence of aminolysis. The amount of the *N*-protected aminoacids applied to the polymer (condensation with the aid of DCCD) was 0.25–1 mmol g^{-1}. The introduction of aminoacids with a bulky side group into the polymer involves certain difficulties.

Among the activated esters known at the present time, the acyl derivatives of *N*-hydroxybenzotriazole are some of the most powerful acylating agents[88] and the *N*-hydroxy-derivative itself effectively accelerates the aminolysis reactions of other activated esters[88] and is frequently used in combination with dicyclohexyl carbodiimide (DCCD) for the condensation of peptide fragments in order to reduce the extent of racemisation. An insoluble polyhydroxybenzotriazole has been obtained in accordance with the following scheme:[110]

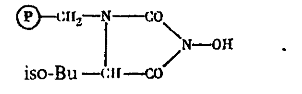


A macroporous spherically granulated copolymer of styrene with 2% of divinylbenzene (XE-305), alkylated with a chloronitrobenzyl derivative by the Friedel–Crafts reaction, was used as the carrier. Best results were obtained when a substituted benzyl alcohol (R = OH) was employed. Further treatment of the resulting derivative with hydrazine in boiling methylcellosolve with subsequent dehydration by boiling concentrated HCl afforded a polymer-substituted *N*-hydroxybenzotriazole (up to 1.4 mmol g^{-1} [111]). The polymer swelled satisfactorily in DMF and methylene chloride and reactions involving it occurred extremely rapidly. The authors[111] regard this support as almost ideal for the method of polymeric reagents in peptide synthesis.

It has been shown[73] that the reactivity of polymeric derivatives of *N*-hydroxybenzotriazole is higher than that of the corresponding derivative of o-nitrophenol by a factor of 100, while that of the low-molecular-weight analogue is higher by a factor of 8000. This difference has been attributed to the low rate of mass transfer within the polymer pores.[73]

When a soluble polymeric form of *N*-hydroxybenzotriazole was used,[78,79] no effect of the polymeric activating group on the rate of aminolysis was noted. However, it has been concluded[79] that such soluble polyoxyethylene-bound reagents are useful only in the synthesis of peptides which are satisfactorily soluble (only in this case is the separation of the polymer from the peptide at the end of the reaction sufficiently complete—by precipitation, recrystallisation, or ultrafiltration).

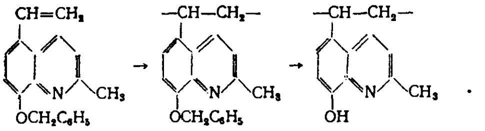
There are apparently definite prospects for the development of new polymer-activators based on substituted hydroxylamines. For example, it has been shown[112,113] that the esters of certain *NN*-diacylhydroxylamines and a series of oximes with electron-accepting substituents are highly reactive in aminolysis reactions. There exists also a brief communication[114] about the use of a polymer containing 3-hydroxyhydantoin groups in peptide synthesis:



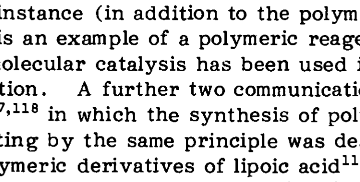
Ⓟ = polystyrene cross-linked with 2% of divinylbenzene

This polymer has been used either to activate Z-Gly in the synthesis of the peptide ZpGly-Ala-OC$_2$H$_5$ or as an additive in the synthesis of the same peptide by the DCHC method. In the second case the yield and optical purity of the products were higher.

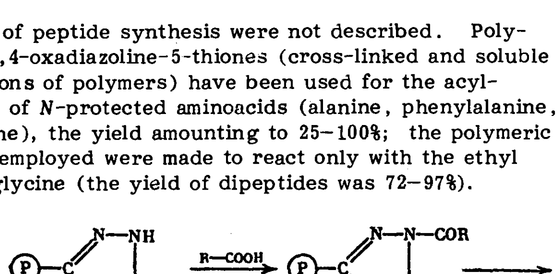
Other types of polymer-activators have been described in the literature. For example, the polymeric analogue of 8-hydroxyquinaldine has been described.[115] It had been used earlier for peptide synthesis in solution.[116] It was obtained by the copolymerisation of 8-benzyloxy-5-vinylquinaldine with 20 mol % of divinylbenzene and subsequent debenzylation with concentrated HCl:



The polymer was tested in the synthesis of a simple dipeptide. The limited amount of data available makes it impossible to assess its advantages, but it apparently possesses no advantages compared with the compounds discussed above. However, this instance (in addition to the polymeric hydroxybenzotriazole) is an example of a polymeric reagent where the effect of intramolecular catalysis has been used in the aminolysis reaction. A further two communications appeared subsequently[117,118] in which the synthesis of polymeric reagents operating by the same principle was described. These were polymeric derivatives of lipoic acid[117] (the coenzyme of acyltransferases) and 1,3,4-oxadiazoline-5-thione.[118] The first derivative[117] was used to activate only *p*-nitrobenzoic acid and the diacyl and not the monoacyl form obtained:



Examples of peptide synthesis were not described. Polymeric 1,3,4-oxadiazoline-5-thiones (cross-linked and soluble modifications of polymers) have been used for the acylactivation of *N*-protected aminoacids (alanine, phenylalanine, and leucine), the yield amounting to 25–100%; the polymeric reagents employed were made to react only with the ethyl ester of glycine (the yield of dipeptides was 72–97%).



It has been suggested that the polymeric reagent based on polyacrylamide with thiol functional groups be used in an aqueous medium for the synthesis of the amide bond.[119] The acylation of this polymer was sufficiently effective, the content of acetyl groups reaching 2.2 mmol per gramme of the polymer. The data on the application of the resulting polythioester in an aqueous medium are discussed in Section V.

An attempt has also been made to use polymeric mixed anhydrides as acylating agents.[68,83] The anhydride of an *N*-protected aminoacid and a sulphonated polystyrene was employed for the acylation of certain simple aminoacids and peptides.[68,83] An analogous reagent has been proposed[120] for the esterification of alcohols; the anhydride of benzoic acid and a carboxylated polymer has been used for the acylation of aromatic amines.[121,122] The employment of such reagents is problematic, because the nucleophilic attack is not always selective—is not directed to the required carbonyl, its direction depending to a large extent on the steric hindrance. The degree of racemisation occurring when this method is employed is greatly influenced by different factors.[123]

IV. POLYMERIC ACTIVATED ESTERS

In the general case the rate of aminolysis depends on the concentration of the reactants. Since the reaction proceeds within the polymer grain, the effective concentration of the carboxy-component (*N*-protected aminoacid) in the polymeric ester should be determined by the content of the component in the dry polymer, the swellability of the polymeric ester, and the accessibility of the reaction centres to the amino-component. The amount of solvent should be sufficient for the complete swelling of the polymer particles and for their suspension in the solution of the amino-component. Since swellability is a constant parameter of the given polymer and solvent, in order to increase the rate of the reaction it is essential to endeavour to achieve the maximum possible content of the activated aminoacids in the polymer. It is noteworthy that in the case of soluble polymers the creation of a high concentration of the carboxy-component is prevented by the increasing viscosity of the polymer solution.

The effect of the application of polymeric reagents in peptide synthesis depends to a large extent on the yields of the aminoacid derivatives and the ease with which they can be introduced into the polymer. For example, in certain studies a large excess (up to a ninefold excess[72]) of expensive amino-derivatives has been used for condensation with the polymer and, if one takes into account the fact that an excess of the carboxy-component is also used in aminolysis, then the useful employment of the aminoacid derivative then amounts to only several per cent.

The degree of acylation of the polymer-activator by *N*-protected aminoacids is determined by many factors—the method of esterification, the nature of the activating groups and their steric environment, the homogeneity of the polymer network, and the structure of the aminoacid. In order to assess the effectiveness of the methods of synthesis of the polymeric esters, one should evidently employ not the content of the aminoacid residues in the polymer but the yields of the carboxy-component introduced into the polymer and the degree of its utilisation. Here one should bear in mind that in most cases the polymer can be regenerated while the isolation of the aminoacid derivatives which have not reacted with the polymer is extremely difficult. For such assessment, it is essential to know the content of the functional groups in the polymer-activator. In certain cases the investigators restrict themselves to elemental analysis, which does not allow inferences about the content of the reactive groups or groups accessible to acylation. The occurrence of side reactions during the synthesis of the polymer-activator and also the slight changes in the architecture of the polymer skeleton can nevertheless influence significantly the effectiveness of the esterification.

An important condition for the synthesis of polymeric esters of any type is a high initial concentration of the reactants in solvents inducing an effective swelling of the polymer. In this sense, DMF, methylene chloride, and their mixtures can be well recommended.[69,101,124]

DCCD has been used as the condensing agent in the activation reaction by most investigators. For polymeric phenols, the method proved to be the most successful.

Condensation via the *p*-nitrophenyl ether or azide[60] methods yielded worse results and has been hardly used. Acylation of the polymers by the Schotten–Baumann method is also relatively unpromising from the standpoint of racemisation.[62,73]

There exist data concerning the use of symmetric anhydrides of *N*-acylaminoacids,[73,78] but best results (81–100%) have been obtained in this instance by employing a soluble polymer-activator[78] and a comparatively large excess (by a factor of 2–4) of symmetrical anhydrides.

It must be emphasised that in the case of polymeric phenols, obtained by the addition of the activating group to the polymer-carrier, a higher degree of acylation has been achieved in contrast to the polymers where the phenol ring enters into the composition of the polymer chain; it approached 100%.[69,72] When the functional group is remote from the polymer chain, more complete condensation is evidently favoured.

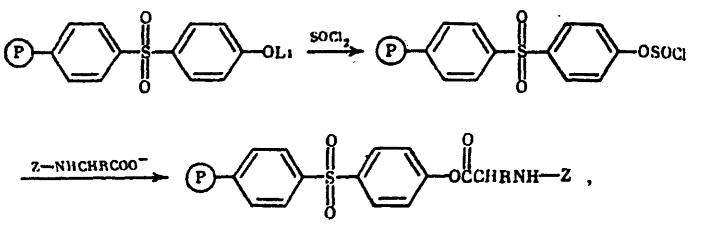
Data have been published[69] on the kinetics of the condensation of benzyloxycarbonyl- and t-butoxycarbonyl-phenylalanine with 4-hydroxy-4-nitrobenzylpolystyrene (cross-linked) in DMF and methylene chloride. It was shown that in the case of the second derivative the rate of reaction was somewhat higher. The solvent did not exert a major influence, some difference being observed only in the initial rates; after 5 h have elapsed, the degree of acylation of both aminoacid derivatives became identical and reached a maximum. In the same study it was noted[69] that the esterification of *N*-protected proline used DCCD was unsatisfactory, the method of mixed anhydride yielding much better results.

DCCD has also been used preferentially for the acylation of polymers with an *N*-hydroxy group; the condensation usually occurred with a satisfactory yield. The difficulties associated with the removal by washing from the polymeric ester of the dicyclohexylurea produced in the course of the reaction must be included among the disadvantages of the DCCD method. A case has been described[43] where, even after repeated washing of the polymer by various solvents, the urea derivative could not be fully eliminated from the polymer. It is apparently undesirable to use DCCD for the introduction of *N*-protected asparagine and glutamine into the polymer in view of the possible formation of nitrile derivatives,[125,126] which may be incorporated into the polymer. A side reaction of DCCD with *N*-hydroxysuccinimide, which can occur also in the polymer, has been described.[127]

The synthesis of polymeric aminoacid esters via mixed anhydrides has certain advantages, because the side products formed are readily soluble in organic solvents. This method has been used to acylate polyphenols,[60,61] poly(5-vinyl-8-quinaldine),[115] and also *N*-hydroxysuccinimide polymers.[89,102,126]

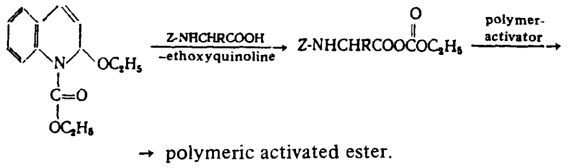
It has been shown[128,129] that high yields of low-molecular-weight *N*-hydroxysuccinimide esters of acyl aminoacids can be obtained in the virtual absence of racemisation if *N*-methylmorpholine is used as the base in the formation reaction of the mixed anhydride. This method has been employed successfully[126] also for the synthesis of polymeric *N*-hydroxysuccinimide esters using DMF and tetrahydrofuran (THF) as the solvents, the polymer being acylated by the mixed anhydride at 40–50 °C. The entire synthesis occupied about 1 h and the yields were 70–90%.

For the condensation of an *N*-protected aminoacid with a polymer having a phenol-formaldehyde structure, the latter was subjected to preliminary activation with $SOCl_2$ or $COCl_2$:[61]



where Z is an *N*-protecting group and R a side group of the aminoacid. For this polymer, the yield in the acylation reaction by the above method was virtually the same as in the carbodiimide and mixed anhydride methods (the aminoacid content in the polymer was 0.9–1.1 mmol g^{-1}).

The method based on the application of *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline can also be included among the mixed anhydride methods:[130]



Although this reagent has been used exclusively for the formation of the amide bond, especially in solid phase synthesis,[131] the authors tested it in the synthesis of polymeric *N*-hydroxysuccinimide esters.[126] It was found that the reaction proceeds fairly slowly (in DMF or THF) and the yields do not exceed 40–50%.

The use of transesterifying agents is one of the most effective methods of synthesis of activated esters.[132] The method involves the acylation of the corresponding hydroxy-component (*N*-hydroxysuccinimide, phenol derivatives) by the anhydride of a strong organic acid (trifluoroacetic, trichloroacetic) with subsequent transesterification of the resulting ester with an *N*-protected aminoacid in the presence of a base in an aprotic solvent. Despite the possibility of the occurrence of side reactions[133] in the transacylation of *N*-trifluoroacetoxysuccinimide with an *N*-acylaminoacid in the presence of a tertiary amine, this method has been used fairly successfully also for the synthesis of polymeric *N*-hydroxysuccinimide esters.[126] It is noteworthy that extremely high yields have been noted in the condensation of acylpeptides by this method, although in the presence of an optically labile *C*-terminal aminoacid there is a possibility of racemisation.[126]

Different types of polymeric activated esters of virtually all natural aminoacids have now been obtained. The benzyloxycarbonyl and t-butoxy carbonyl,[60,89,101] nitrobenzenesulphenyl,[102,124] and trifluoroacetyl[126] groups have been used as N^{α}-protecting groups.

The simplest method for the determination of the content of the activated aminoacid in the polymeric ester is the gravimetric method, which is fairly accurate if the amount of aminoacid applied to the polymer is large (in excess of 0.5 mmol per gramme). In a number of studies[90,91,93,101] the capacity was determined from the yields of the cyclohexylamide derivatives obtained as a result of the interaction of the isolated polymer with an excess of cyclohexylamine. In an alternative version,[69,73] the polymeric ester was treated with a solution of benzylamine in toluene and the excess benzylamine which failed to react was titrated with 0.1 *N* $HClO_4$ in acetic acid using Methyl Violet as the indicator. Aminoacid analysis after the exhaustive hydrolysis of the sample of the polymeric ester with a 1 : 1 mixture of 12 *N* HCl and CH_3COOH has been used in two investigations.[69,124] In one of them,[124] the benzyloxycarbonyl group was determined spectrophotometrically (at 257 nm) after the alkaline hydrolysis of the polymeric nitrophenyl ester of the *N*-protected aminoacid. In certain cases it is possible to use elemental analysis, for example, when the acyl derivative contains sulphur (the Nps group, methionine, or cysteine).[102,124] All the methods indicated yield approximately identical results and one must also bear in mind that in practice a high accuracy in the determination of the capacity of the polymeric reagent is not required because it is as a rule used in excess in the aminolysis reaction. In addition, one may mention that methods for the non-aqueous titration of activated esters have been examined in two communications,[134,135] but these apparently can also be applied to the corresponding polymeric derivatives.

V. SYNTHESIS OF PEPTIDES WITH THE AID OF POLYMERIC REAGENTS

The aminolysis of a polymeric ester, leading to the formation of a peptide bond, proceeds in the solvated polymer—solvent heterogeneous system. The rate of the process should depend on many factors: the nature of the activated ester, the rate of diffusion of the amino-component in the polymer, the accessibility of the reacting group of the polymer, the capacity of the polymeric reagent, and the partition coefficient of the amino-component between the solvent and the swollen polymer, as well as the changes in the swellability of the polymer during the reaction. The reaction kinetics can change significantly as a function of the size of the amino-component, because the rate-limiting stage of the process can change. In one case this is the chemical stage and in another the diffusion stage. In order to reduce the contribution of diffusion factors, the reaction is usually performed in solvents causing a satisfactory swelling of the polymer (extending its polymer network), or when used as carriers which are weakly swelling and have a large surface area and a large pore diameter.[110] In all cases the necessary condition for the successful aminolysis is the solvation of the reaction centres of the polymer. As the reaction proceeds and the polymeric reagent is gradually deacylated, the character of the interaction of the solvent with the polymer can change. This is expressed as a rule by the polymer becoming less hydrophobic and by a change of swellability. For example, in the case of *N*-hydroxysuccinimide hydrophobic polymers, some decrease of swellability was observed during aminolysis[75,101] (in DMF and methylene chloride) or its increase (in water)[97,98]—for hydrophilic poly-*N*-hydroxysuccinimide reagents. The magnitude of this change should depend on the reactant ratio and the capacity of the polymeric reagent. This effect should in its turn influence the permeability and the partition coefficient.

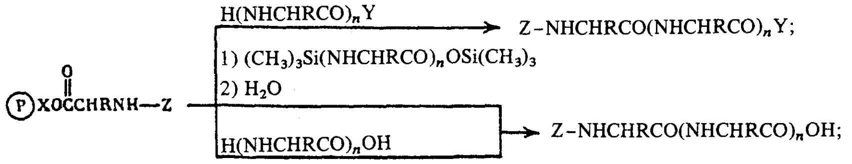
The study of the kinetics of the solid-phase synthesis[136,137] and the aminolysis of polymeric esters[138] showed that the course of such reactions differs significantly from that of reactions in solution. With increase of the degree of reaction, a sharp fall of its rate is usually observed. For example, a study of the rate of aminolysis of polymeric *N*-hydroxysuccinimide esters of Nps-aminoacids[138] showed that the rate constants calculated assuming the first order of the reaction differed at the beginning and at the end of the reaction by 1—3 orders of magnitude. The cause of this difference is apparently the fact that the reacting groups fixed in different compartments of the polymeric species exist under non-equivalent conditions owing to the different microenvironments ("clones" of the reaction centres). This leads to different rates of diffusion of the amino-component to the reaction centres ("microheterotropism"). The swellability of the polymeric reagent, varying in the course of the reaction, may exert an additional influence on the diffusion.

The dependence of the change in the rate of reaction on solvent polarity need not necessarily be correlated with the analogous dependence for reactions in solution, because the change in swellability may have a greater influence on the rate than chemical causes. Thus Kemp[139] found that the reactivity of *N*-hydroxysuccinimide esters in solution decreases in the sequence toluene—methylene chloride—DMF. In the solid phase synthesis the sequence was the same for the *N*-hydroxysuccinimide ester—aminoacyl-polymer (cross-linked polystyrene) system.[137] However, in the aminolysis of polymeric *N*-hydroxysuccinimide esters,[138] the opposite dependence was observed: in DMF the rate of reaction was a maximum and the degree of swelling of the polymer-activator was also greatest in the same solvent.[75,137]

Evidently, as regards the preparative aspect, the application of an excess of the polymeric ester should lead not only to a greater degree of completion of the reaction but should also appreciably improve its kinetic indices, because in this case the most accessible clones of the activated groups of the polymeric esters enter into the reaction while changes in the volume of the polymer are small. A graphical representation of the time variation of the degree of acylation of the methyl ester of leucine by the soluble *p*-nitrophenyl and the polymeric nitrophenyl ester of carbobenzoxyphenylalanine in chloroform in the presence of a twofold excess of the carboxy-component has been published.[69] When the initial concentrations were identical, the curves virtually coincided and the degree of conversion reached 100%.

Comparative estimation of the reactivities of the polymeric reagents is not simple in view of the absence of clear-cut criteria. The yield is in many cases almost quantitative. A "direct" kinetic comparison of two polymeric reagents has been achieved in a study[110] where the degrees of acylation of an alanine ester by t-butoxycarbonylalanine esters were compared as a function of time; the insoluble 4-hydroxy-3-nitrobenzylpolystyrene[69] and *N*-hydroxybenzotriazolylpolystyrene[110] were used as the polymer-activators. The rate of reaction for the first polymer was appreciably lower. The ratio of the reaction half-lives for these polymers was 20 : 1 and the 100% conversion times were 10 and 0.2 h respectively.

With increase of the length of the peptide synthesised, the role of the diffusion factor increases as a result of which the rate of acylation and the yields can decrease significantly. The size of the peptides synthesised hitherto with the aid of polymeric reagents has not exceeded 10 aminoacid residues in the chain. Within these limits, no clear retardation of the reaction or decrease of the yields as the peptide grows have been observed. The nature of the *N*-terminal aminoacid[110] and the character of the activating group[96] played a much more important role than the size of the amino-component. Thus it has been shown[140] that the method of polymeric reagents can be combined fairly successfully with the liquid phase method for the synthesis of peptides. In particular, the reaction involving the condensation of the polyhydroxybenzotriazole ester of t-butoxycarbonylalanine (taken in threefold excess) with the high-molecular-weight component H-Val-O-POE (POE = polyoxyethylene M-6000) during a period of 2 h occurred almost quantitatively; the yield in the analogous reaction with the ester based on polynitrophenol was 30% after 24 h.



X = activating group of the polymer Ⓟ
Z = *N*-protecting group
R, R^1 = side group of aminoacid
Y = OAlk, NH$_2$
n = 1, 2, 3, ...

High-molecular-weight amino-components, namely insulin and poly-ε-benzyloxycarbonyl-L-lysine (M = 10000), have also been acylated with the aid of the poly-*N*-hydroxysuccinimide reagent.[96] Analysis of the reaction products showed that the free amino-groups were almost wholly blocked. Admittedly, a considerable molar excess (50 to 100-fold) of the polymeric t-butoxycarbonylalanine ester was used in the reaction and for this reason one cannot rule out the possibility that the reaction proceeded mainly in the surface layer of the polymer particles.

The majority of the known polymeric reagents swell satisfactorily only in organic solvents and for this reason esters or amides of aminoacids and peptides, which are soluble in these media, were used as the amino-components. The solubility of the intermediate peptide fragments depends not only on their molecular weight but also on the character of the functional side groups and their blocking.[54] When polymeric reagents are used, the set of compatible protecting groups and the strategy used in constructing the peptide chain are essentially the same as in the classical peptide synthesis. However, the problem of the solubility of the growing amino-component is particularly acute in this method owing to the heterogeneity of the reaction system. An increase of its solubility can be achieved only by reducing to a minimum the protecting side groups, which should enhance its hydrophilic properties,[54,140,141] or special protecting groups increasing the affinity of the peptide for organic solvents, both low-molecular-weight[142] and high-molecular-weight,[140] should be used.

The application of free aminoacids and peptides as nucleophiles in combination with organic solvents is limited owing to their low solubility. However, it has been shown[143,144] that, when certain peptides are suspended in a solution of an activated ester in DMSO, the reaction can proceed at an appreciable rate and with a high yield (the equilibrium shifts towards the soluble reaction product in the course of the reaction). The above method has been used to synthesise peptides with the aid of polymeric macronetwork *N*-hydroxysuccinimide esters[101] and model tetra- and penta-peptides as well as a whole series of diastereoisomeric dipeptides have been obtained.[145] The presence of quaternary ammonium bases increases significantly the rate of reaction.[143,145] It is noteworthy that activated esters are not altogether stable in polar organic solvents[144,146] and, since in this case the rate of aminolysis is nevertheless comparatively low and depends on the solubility of the peptide, the method can prove to be unsuitable for the synthesis of complex peptides.

There have been a number of studies[101,147–149] where trimethylsilyl (TMS) derivatives of aminoacids and peptides were used in the reaction with polymeric *N*-hydroxysuccinimide esters. Such derivatives exhibit an increased solubility in aprotic solvents, but they are hydrolytically unstable. The deblocking of the TMS-derivatives is almost instantaneous on treatment with water or alcohol[150] and the TMS group is for this reason suitable as a temporary protecting group for OH, COOH, and in certain cases SH functional groups.[148,151] There exists a fairly large selection of silylating agents at the present time[152,153] and mild methods have been devised for the introduction of the TMS group into aminoacids and peptides.[148] We may note that the amino-group is usually also silylated (although not always[153]), whereupon its nucleophilic properties can be appreciably weakened but the deacylated hydroxy-component evolved in the reaction desilylates it. For this reason, in the case of trifunctional aminoacids entering into the composition of the peptide chain, a stable protecting group is required for the NH$_2$ and SH side groups. For reaction to occur, total silylation of all the functional groups, sufficient to ensure the dissolution of the amino-components, is necessary. If a non-nucleophilic silylating agent is added to the suspension of an insoluble peptide or aminoacid and the activated ester, the equilibrium shifts in the required direction—the aminocomponent is converted into the soluble reactive form. TMS-amides are usually employed as silylating agents.[153,155] However, one should bear in mind that such TMS-amides can themselves interact with the activated esters,[156] i.e. they can initiate competing reactions in the system. This can be avoided if the amino-component is silylated separately and is then introduced into the aminolysis reaction after the removal of the excess of the TMS-agent.

Aminolysis in aqueous and aqueous organic media has definite advantages. Firstly, there is no need for the blocking of the weakly nucleophilic functional groups of the amino-component, secondly, the problem of the solubility of the peptides is in many cases solved, since they usually lose their ability to dissolve in organic solvents as the chain grows, and, thirdly, an aqueous medium at the physiological pH has the least denaturing effect on biologically active compounds. Intense research has been conducted recently on these lines. This concerns the use of enzymes for the formation of the peptide bond, for the introduction and removal of the protecting groups, and in chemical methods of synthesis of the peptide bond. A recently published review has been devoted to the problems enumerated above.[157]

Three types of hydrophilic polymeric reagents, to some extent suitable for the formation of the peptide bond in aqueous media, are known: acylated polymeric sulphonic acid[83] and polymeric thiol[119,158] as well as poly-*N*-hydroxysuccinimide reagents.[97–100]

A mixed anhydride of a polymeric sulphonic acid cation exchange resin and acetic acid[83] has been used in the reaction with aniline in an aqueous medium at pH 3.5–5.5; the low yield of acetanilide (it did not exceed 26%) was explained by the hydrolytic loss of the acylating agent and the low concentration of aniline in the polymer phase (3% relative to the concentration in the external solution).

When an acetylated polymeric thiol[119,158] was used in the aminolysis of amines and aminoacids, best results (yield up to 95%) were achieved at pH 10–12 and the lowest yield of amines was obtained at pH 7.5. This type of dependence is a consequence of the catalysis of the aminolysis by OH^- ions and the positive influence of imidazole $H_2BO_2^-$ and Ag^+ ions was also noted. Best results were also obtained using sterically unhindered amines taken in excess (two equivalents).

In contrast to the polymeric reagents examined above,[83,119,158] which were in fact used only as acetylating agents (for the introduction of the *N*-acetyl group), hydrophilic poly-*N*-hydroxysuccinimide reagents have found practical applications in the synthesis of taftsin,[98,99] 26–33 fragment of cholecystokinin,[98,99] and diastereoisomeric dipeptides.[97] Poly-*N*-hydroxysuccinimide esters of *N*-acylaminoacids exhibited a high reaction capacity (up to 1.8 mmol g^{-1}) and swelled satisfactorily in aqueous media.[99] The rate constants for the competing aminolysis and hydrolysis reactions in heterogeneous system poly-*N*-hydroxysuccinimide reagent–amino-component–aqueous medium have been calculated at different pH for two peptide formation reactions.[159,160] The time variation of the calculated rate constants confirmed the idea of the clonal distribution of the reaction centres.[138] The optimum conditions for the aminolysis were discovered from the kinetic data obtained, in particular the optimum pH was in the region of the p*K* of the amino-group of the amino-component other conditions being equal.

When hydrophilic poly-*N*-hydroxysuccinimide reagents were used to analyse the optical purity of the aminoacids,[97] a polymeric ester of an *N*-protected L-aminoacid was introduced into the reaction with the aminoacid to be analysed, taken in a free form; the aminolysis was carried out at pH 8.5–9.0 (yield 55–98%). The removal of the *N*-protecting (t-butoxycarbonyl) group from the dipeptide obtained was also achieved in an aqueous medium *in situ*. Racemisation and stereoselectivity were not observed when this method was used.

Biologically active peptides—taftsin and the 26–33 fragment of cholecystokinin[98,99]—were synthesised in an aqueous medium at pH 8–9 as a rule under pH-static conditions (arginine was employed in a free state and the hydroxy-groups of tyrosine and threonine were not protected); the 26–33 fragment of cholecystokinin was obtained in an organic solvent (DMF) as a control for the method. The yields in the condensation reaction amounted to 60–86% in both aqueous and organic media.

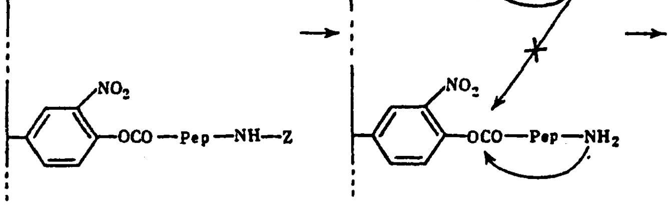
It was noted[98,99] that, when polymeric reagents are used for peptide synthesis in an aqueous medium, there is a possibility of difficulties in the elimination of the hydrolysed carboxy-components from the aminolysis products.

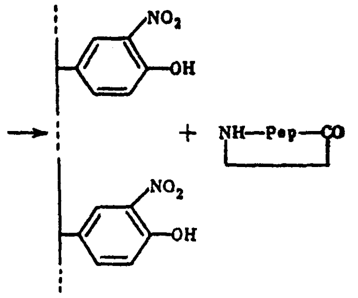
None of the versions of the aminolysis examined above eliminate the necessity for protection also of the functional side group as well as the α-aminogroup in the trifunctional aminoacid in the synthesis of the polymeric activated ester. However, in this case the group may be blocked by protecting groups which are removed simultaneously with the N^{α}-protecting group, for example the *O*-t-Bu group combined with the N^{α}-Boc group. Such a strategy has been used in the synthesis of pentagastrin.[149]

Both in the classical peptide synthesis and in the method of polymeric reagents, the aminolysis can be usually followed qualitatively with the aid of thin-layer chromatography by tracing the disappearance of the amino-component. When polymeric esters containing a chromophoric group in the acyl component are used, there is a possibility of the direct quantitative estimation of the degree of reaction by spectrophotometric measurements on the solution. The kinetics of the aminolysis of polymeric insoluble esters of Nps-aminoacids (λ = 380 nm) [138] and the interaction of the polymeric esters Boc-Ala with the *p*-nitrobenzyl ester of alanine (λ = 280 nm) were investigated in this way.[110] In a study[159] of the kinetics of the aminolysis reaction, the increase of the concentration of the peptide synthesis was followed by studying samples of the supernatant solution with the aid of liquid chromatography after the removal of the *N*-protecting group. Titrimetric determination of the amine which failed to react with the aid of $HClO_4$ in dioxan was used.[69]

In its practical aspect, the method of polymeric reagents has not so far found extensive application in the solution of specific synthetic problems. Peptides synthesised in this way served, with some exceptions, only to test the usefulness of a particular polymer-activator and to develop a methodology. As a rule, all the peptide derivatives were obtained by the stepwise growth of the peptide chain from the C-end. Apart from numerous model peptides, certain natural biologically active compounds and their fragments were obtained. One of the first known peptide hormones—bradykinin Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg—has been synthesised with the aid of the nitrophenol polymer[124] in an overall yield of 39% (65.3% relative to the protected nonapeptide) and exhibited the full biological activity. Satisfactory results were obtained in the synthesis of pentadecapeptides using insoluble *N*-hydroxysuccinimide polymers,[89,96,101] 4-hydroxy-3-nitrobenzylpolystyrene,[69,161] and polymeric *N*-hydroxybenzotriazole.[67,84,110,111] Fragments of oxytocin and pentagastrin,[162,163] thyroliberin,[110] the substrates for pig elastase,[164] the pentapeptide fragment of ox carboxypeptidase A,[96] taftsin and its analogues,[98,165] luliberin,[67,166] fragments of ACTH,[161] the *C*-terminal half of α-thymosin,[111] the 26–33 fragment of cholecystokinin,[98] and leucine-enkephalin [84] were synthesised in this way. The use of polymeric *N*-hydroxysuccinimide esters of t-butoxycarbonyl-L-aminoacids proved convenient in the synthesis of the diastereoisomeric dipeptides used in the enantiomeric analysis of aminoacids.[97,145,147,167] The possibility of the repeated employment of the polymeric reagent, the ease of standardising all the mechanical operations, and also their simplicity are significant advantages in routine analysis. Polymeric activated esters have also been used to acylate biogenic and synthetic amines. The high yields and ease of purification of the resulting amides made it possible to employ them successfully in the synthesis of physiologically active aminoacid derivatives of β-phenylethylamine,[168] penicillins and cephalosporins,[166] aminoacyl- and peptidyl-nucleotides,[169] and acylaminophosphonic acid.[170]

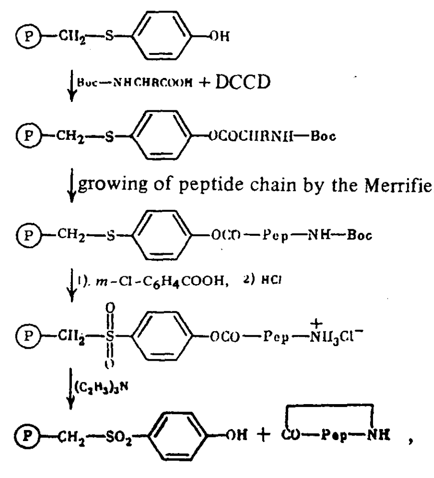
Cyclic peptides are usually obtained by the intramolecular condensation of linear peptides and, in order to suppress the competing intermolecular interactions, the reaction is carried out under the conditions of high dilution.[47] However, as a rule, even under these conditions, an appreciable amount of oligomeric side products is formed. In order to solve this problem, it has been suggested that peptide chains be fixed to an insoluble carrier after which intermolecular aminolysis is to be carried out.[27] The polymer serves in this case as a separator for the peptide chains, so that the unimolecular reaction should become the dominant process. Two versions of the application of monomers for this purpose are possible. In the first version the peptide chain was added to the polymer via a functional side group.[171] In the second version a polymer-activator was used for cyclisation:





Pep = peptide, Z-N = protecting group .

The first stage included the formation of the polymeric activated ester of the *N*-protected peptide. Nitrophenol polymers were used exclusively for this purpose,[27,84] while the condensing agent was DCCD. The yields were fairly low at this stage. However, one should bear in mind that, in order to reduce side reactions to a minimum, the content of acyl residues in the polymer should not be high. In the subsequent stages the *N*-protecting group was removed under acid conditions and the amino-group was deprotonated by an organic base, after which the polymer was maintained in the swollen state for the required time.[27] A series of simple cyclic di-, tri-, and tetra-peptides have been obtained in this way in a yield of 60–80%.[60] In order to obtain cyclic peptides, a linear peptide was initially synthesised by the solid phase method,[31] the ester bond in the peptide-polymer was then activated, and the cyclisation was finally carried out by the method indicated above[27] (yield 40–60%):



where Boc = t-butoxycarbonyl, DCCD = dicyclohexylcarbodiimide, R = side group of the aminoacid, and Pep = peptide.

The "selective activation" principle[§] has been used in a number of other studies for the synthesis of both cyclic and linear peptides.[172–175] The application of oxidants for the labilisation of the peptidyl–polymer bond limits the choice of peptides for the synthesis, because in this case they must not contain a readily oxidisable aminoacid (methionine, cysteine, or tryptophan).

The idea that peptide chains and the reacting groups in the polymer are fully isolated from one another in space and that their interaction is extremely limited has been criticised in a number of investigations.[43,176] Many facts indicated that, even in the case of polymers with a relatively high degree of cross-linking, the internal mobility of the polymeric segments cannot be eliminated.[177]

The question of the influence of the condensation method and of the nature of the polymer-activator on the degree of racemisation of the peptide synthesised has been hardly touched upon in the literature.[178] One should distinguish racemisation proceeding during the activation of the carboxy-component by the polymer-activator and the racemisation in the aminolysis of the activated ester.[139,179] The methods for the formation of the peptide bond have come to be evaluated in this respect by the synthesis and analysis (liquid chromatography[76]) of a "test peptide", where readily racemised acylaminoacids are used as the carboxy-component.[180] The degree of racemisation in the synthesis of the model peptide Z-Gly-L-Ala-L-Leu-OBzl has been estimated[178] (the Izumiya test[181]) by the method of polymeric reagents, which consisted of polymeric esters based on 4-hydroxy-3-nitropolystyrene[27,124] and polymeric *N*-hydroxysuccinimide.[89] The authors compared this with the racemisation occurring when the usual low-molecular-weight condensing agents are employed. Polymeric Z-Gly-L-Ala esters have been obtained with the aid of DCCD and the aminolysis reactions carried out in dimethoxymethane. Diastereoisomeric analysis of the deblocked tripeptide showed that the content of the D-isomer was 6.4% for the *N*-hydroxysuccinimide polymer and 37.4% for the nitrophenol polymer. On the other hand, when DCCD or DCCD with *N*-hydroxysuccinimide were used as condensing agents for the formation of the peptide bond in solution, the amounts of the D-isomer were 24.6 and 2.8% respectively. The data obtained were of the integral type as regards the polymers and the differential estimation of the influence of various factors on the racemisation from experimental data is difficult. The above results[178] are therefore valuable only in the practical sense. It is evident, for example, that the *N*-hydroxysuccinimide polymer is preferable to the nitrophenol polymer from the standpoint of racemisation. When polymer-activated aminoacids with protecting groups of the urethane type are used, the probability of racemisation is minimal, with certain exceptions.[182] For this reason, in most studies where such derivatives were employed, the racemisation was either not estimated during the synthesis or the peptides synthesised were compared with optically pure authentic specimens. Racemisation was not usually observed. This factor made it possible to use the *N*-hydroxysuccinimide polymeric reagents for the enantiomeric analysis of aminoacids.[97,145,147,168]

The attempt to employ the optically active polymeric 3-hydroxyhydroxyhydrantoin for asymmetrically selective peptide synthesis is noteworthy.[114] Two versions of the synthesis of the dipeptide Z-Gly-Ala-OC$_2$H$_5$ from DL-Ala-OC$_2$H$_5$ were achieved in the above study. In the first version the corresponding activated Z-Gly ester was obtained in the preliminary step by the DCCD method and in the second the polymer was used as an additive in condensation by the same method. In the first case the dipeptide obtained contained 54.6% of the L-aminoacid and in the second case 72.6%. This effect was accounted for by the interaction of the D-isomer with the 3-hydroxyhydantoin group in the polymer, which increased the amount of the L-isomer in the solution.

VI. POLYMERIC CONDENSING AGENTS

The use of dehydrating agents makes it possible to simplify greatly the working procedures associated with the formation of the peptide bond. Carbodiimides are usually employed

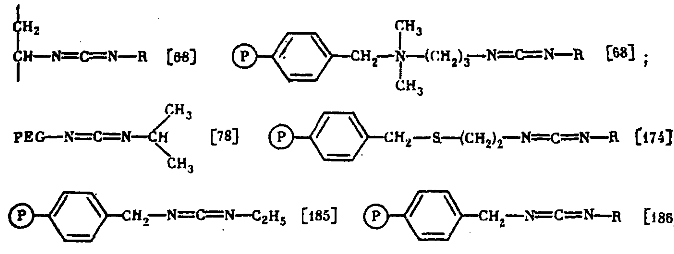
---

[§] In non-Soviet literature different terms are used for the principle: the "safety-catch principle" [176] and "*a posteriori* activation".[177]

for this purpose.[183] The polymeric reagent with the functional group indicated has been known for a comparatively long time:[184]

$$[-(CH_2)_6-N=C=N-]_n \ ,$$

Data for a series of cross-linked[68,174,185,186] and soluble[78] polymeric carbodiimides having the following structures appeared:



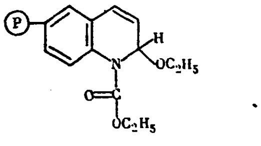
PEG = poly(ethylene glycol), R = alkyl.

For this synthesis, the polymer containing primarily amino-groups was usually treated with the corresponding isocyanate and the resulting polymer-bound urea was dehydrated. Cross-linked polystyrenes have been used as carriers as a rule.

The advantage achieved when such polymers are used may be imagined to consist in a more complete activation of the carboxy-component if the condensing agent is taken in excess and both this agent and its conversion products can be readily removed from the peptide in solution.

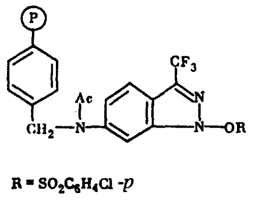
The practical application of classical peptide synthesis and also studies on the kinetics and mechanism of peptide condensation with the aid of DCCD have shown that such reactions have complex mechanisms.[187,188] A side reaction involving the formation of *N*-acylurea, leading to the loss of the carboxy-component, has been frequently observed under these conditions. This side reaction occurred also in the case of a polymeric analogue,[186] which precluded its complete regeneration. The formation of symmetrical anhydrides[188] can also hinder the purification of the final product.

A condensing agent based on polyvinylquinoline[189,190] activates selectively the carboxy-component, converting it into a mixed anhydride of ethoxycarbonic acid:

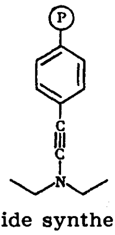


An analogous low-molecular-weight reagent, *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline, had been used earlier in the classical and solid phase methods of synthesis.[130,131]

A further two polymeric condensing agents have been obtained from chloromethylated polystyrene, namely polymer-bound indazole[191] and aynamine:[192]



$R = SO_2C_6H_4Cl\text{-}p$



There is little information about peptide synthesis with the aid of polymeric condensing agents and only several di- and tri-peptides were synthesised in the above studies. Tests for racemisation[189,190] showed that it occurs at the level of low-molecular-weight analogues. The advantages of these reagents became more clearly defined when they were used in other fields of organic synthesis, for example, for the oxidation of alcohols,[193] for the preparation of symmetrical anhydrides[186] and esters, including activated esters.[184]

VII. CONCLUSION

In essence, in any approaches to peptide synthesis one of the reactants is used in excess to ensure the completion of the reaction. The method of polymeric reagents has the advantage that it makes it possible to simplify the purification of the reaction product—the excess polymeric reagent and the deacylated polymer-activator can be readily separated from the low-molecular-weight reactant. In addition, the majority of the known polymer-activators can be used repeatedly, since they are readily regenerated. In particular, the inclusion of the activating components in the polymer makes it involatile and removes its toxicity and unpleasant small. By taking into account the specific features of the microenvironment of the reaction groups and the possibility of modelling high dilution conditions by their separation, it is possible to solve a series of problems which are difficult to solve with the aid of other methods of peptide synthesis.

In the practical application of any method, the prospect of its automation is always attractive. As regards the method of polymeric reagents, the column version of the automation of peptide synthesis has been most frequently forecast.[194] In this case each stage in the formation of the peptide bond requires a separate column with a polymer-activated carboxy-component.

The main purpose of the column is to obtain at the outlet the pure product in a quantitative yield. However, studies in the authors' laboratory[195] showed that a (2-4)-fold excess of poly-*N*-hydroxysuccinimide reagents relative to the amino-component and low rates of elution did not lead to the required required result: the product required additional purification. This is apparently associated with the inadequately high rate of reaction and the absence of fractionation in the case of comparatively low and similar molecular weights of the dissolved components of the reaction mixture. A higher excess of the polymeric reagent in trivial aminolysis reactions is undesirable. Furthermore, the automated method should include a further two stages involving the concentration of the solutions and *N*-deblocking, which are fairly difficult to automate. However, attempts have been made, for example, to employ polymers for the removal of a series of *N*-protecting groups: Nps,[85] Boc,[196] and Fmoc.[197,198] The above considerations apparently complicate the automation of the method of polymeric reagents; virtually no studies on this subject have been described in the literature. A complicating factor is also the fact that industrial manufacture of the polymeric reagents has not so far been initiated, although these are as a rule fairly stable compounds which are convenient to store and transport.

The limits of the applicability of the method of polymeric reagents in relation to the synthesis of high-molecular-weight peptides have not so far been determined. However, it is apparently more most useful to obtain by this method a comparatively small peptide containing 15–20 aminoacid residues (in order to avoid diffusional complications) with subsequent combination of the resulting fragments in solution using either chemical or enzymic methods.

During the preparation of the review for publication, the communication of Patchornik and co-workers appeared in which they describe approaches to the methodology of peptide synthesis using a "mediator" (Mediator Methodology) in a two-polymer system.[199] Also published was a review by the same authors on polymeric transferring agents[200] and polymeric activated esters based on a high-molecular-weight 1-hydroxy-2-pyrrolidinone[201] were proposed.

Variants of Thin-layer Chromatography with Controlled Flow of the Mobile Phase

V.G.Berezkin and V.V.Buzaev

The review is devoted to the methods for controlling the flow of the mobile phase which have been developing successfully in thin-layer chromatography (TLC). Their use makes it possible to eliminate some of the principal disadvantages of the traditional TLC with retention of the majority of its advantages. The continuous variant, the continuous variant with flow type detection, the centrifugal variant of TLC, and also the variant of TLC under pressure are examined. It is shown that control of the flow of the mobile phase makes it possible not only to employ TLC successfully for the selection of separation conditions in column liquid chromatography (CLC) but also to approach CLC as regards performance and speed. At the same time it gives rise to new possibilities for the automation of TLC.
The bibliography includes 143 references.

III. Continuous combined (two-stage) TLC 384
IV. Continuous single-stage TLC with flow detection 385
V. Continuous TLC with a moving attached layer of sorbent 388
VI. Centrifugal TLC 389
VII. Thin-layer chromatography under pressure 390

I. INTRODUCTION

The method of thin-layer chromatography, proposed in 1938 by the Soviet scientists Izmailov and Shraiber,[1] is at present one of the principal procedures in liquid chromatography. It is used in the study of organic[2] and inorganic[3] substances and has found applications in biochemistry and pharmacology,[4,5] in medicine,[6] and in the analysis of the environment,[7] polymers,[8] etc. Such wide-scale application of TLC can be accounted for by the following advantages of this method: (1) the simplicity of the equipment and of the experimental methods, (2) the possibility of altering purposefully and relatively simply a large number of parameters optimising thereby the separation process, (3) economy, (4) the possibility of separating simultaneously and independently a large number of samples in the course of a single determination (up to 20 samples). Important features of TLC such as the possibility of the rapid and simple replacement of the mobile and stationary phases, which determine the selectivity of the method,[4,9-15] and of using the two-dimensional separation technique,[4,9,10,16] which significantly increases the real resolving power of the method must also be specially emphasised. The advantages of TLC include also the fact that on a plate it is possible to analyse all the mixture components and not only those which have reached the detector, as happens in column chromatography.

The commonest variant of liquid chromatography is at the present time column liquid chromatography (CLC) and especially its modern version—high performance liquid chromatography (HPLC). However, the features of TLC mentioned above ensure that it has many advantages over CLC, which have also been responsible for the fairly wide scale employment of TLC in analytical practice. Furthermore, after comparing CLC and TLC, certain investigators give preference to the latter.[17-19] It has been suggested in a review[20] that, although HPLC is superior to high performance TLC (HPTLC) as regards efficiency and the number of components separated, nevertheless the difference between them is not fundamental.

However, compared with HPLC, traditional TLC suffers also from certain disadvantages; (1) a lower reproducibility of the retention parameters, (2) usually a longer separation time, and (3) the existence of certain complicating factors which may have a negative influence on the reproducibility of the chromatographic process (for example, the separation into layers of the solution of the multicomponent mobile phases as they move through the sorption layer,[21] which has been observed in many instances, and the evaporation and adsorption of the vapour of the mobile phase), and (4) a more laborious and complex automation of the entire process—from the introduction of the sample and the preparation of the chromatographic plate up to the quantitative assessment of the results obtained.

The majority of the disadvantages of traditional TLC are associated with the use of a non-stationary virtually uncontrolled flow of the mobile phase (see, for example, Refs. 4, 9, 10, and 22-24). The flow rate of the mobile phase in the layer varies signigicantly during elution and the distance traversed by the front of the mobile phase Z_f is quadratically related to the elution time t:[9,22-25]

$$Z_f^2 = kt \;, \tag{1}$$

where k is the rate constant, which depends on the nature of the mobile and stationary phases.

It follows from Eqn.(1) that the rate of movement of the mobile phase front diminishes appreciably as one moves away from the site where the eluent is supplied. It is also essential to note that the pressure drop caused by capillary forces precludes the achievment of optimum rates of movement of the mobile phase throughout the elution zone. For this reason, elution on most of the plate takes place in traditional TLC at rates below the optimum values.

The non-stationary nature of the flow of the mobile phase, the formation of an unsaturated zone in the region of the eluent near the front, in which the content of the solvent relative to the sorbent differs significantly from the equilibrium value,[9,25-27] and the processes involving the evaporation and adsorption of the components of the mobile phase[28] have an appreciable negative influence on the effectiveness of the separation, the reproducibility of the retention parameters, and the chromatographic process time. A number of studies[29−33] have been devoted to the optimisation of the chromatographic process in TLC, mainly by means of the concerted selection of the sorbent, the mobile phase, and the length of the chromatographic plate. In our view the creation of, firstly, a stationary flow, and, secondly, the optimum flow of the mobile phase, or one approaching the optimum, also plays an important role in the optimisation of the separation process in TLC. The use and development of elution methods which make it possible to obtain a stable flow of the mobile phase (which it is desirable to contol) is one of the promising trends in TLC, because, in combination with the known methods for the optimisation of separation conditions,[29−33] it helps to overcome the principal disadvantages of the traditional TLC, among those enumerated above, retaining at the same time most of its advantages. This is why the present review is devoted to the consideration of methods of TLC with a controlled flow of the mobile phase (TLC-CF).

II. CLASSIFICATION OF TLC METHODS WITH CONTROLLED FLOW OF THE MOBILE PHASE

Variants of TLC in which a stationary flow of the mobile phase, controlled only by employing special methods involving elution and action on the chromatographic system by various physical forces can also be usefully included among TLC-CF methods. Among the variants of TLC-CF known at the present time, it is possible to distinguish two groups: continuous TLC methods and TLC methods with forced flow of the mobile phase. Such subdivision is caused primarily by the difference between the forces responsible for the movement of the mobile phase. In the first group of methods, these are capillary forces. This group includes the continuous combined (two stage), the continuous single-stage (flow), and the continuous TLC methods with a moving attached layer of the sorbent.

In continuous two-stage TLC the sample is deposited on the dry sorbent after which the mobile phase is eluted up to the point where it is removed from the bed under the conditions of the usual TLC with a variable rate of elution (first stage); next, until the end of separation, the rate of elution remains constant (second stage). The rate of elution in the second stage depends on the length of the elution zone, i.e. on the distance between the site where the eluent is supplied and the site where it is removed.

In continuous single-stage TLC the sample is injected directly into the steady flow of the mobile phase. The rate of elution from the instant of the introduction of the sample up to the end of its separation is constant.

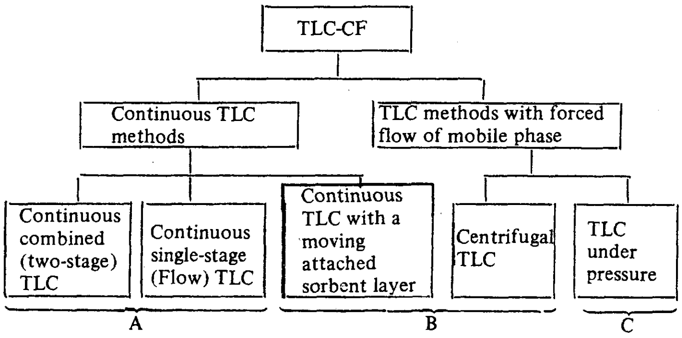
In the third method of this group, the sorbent, attached to a flexible support, moves in the direction opposite to that of the component to be separated. The sample can be deposited on the dry sorbent or can be injected into the flow of the mobile phase.

The term "forced flow TLC" was introduced by Kalász[34] quite recently. It has been used directly to designate the method of TLC under pressure (TLC-P),[35] in which the movement of the mobile phase in the sorbent layer, as in HPLC, is achieved as a result of the excess pressure at the entry of the eluent into the chromatographic system. However, we think that it is more useful to include in the concept of "forced flow TLC" (TLC-FF) all the variants of TLC in which any external factor, for example, the centrifugal force or a magnetic field, acting on the given chromatographic system, determines the character of the movement of the mobile phase. Accordingly, centrifugal TLC, where the eluent moves mainly under the influence of centrifugal forces, has been assigned by the present authors to TLC methods with forced flow of the mobile phase (TLC-FF), like TLC-P.

We may note that descending TLC,[36] in which the force of gravity increases the rate of movement of the mobile phase compared with the ascending and horizontal variants of elution, could also be included in TLC-FF. However, because of the week influence of the gravitational component on elution,[37] this method is regarded only as a variant of continuous TLC.

A classification of the methods of TLC-CF is presented below. It demonstrates the possibilities of different variants of TLC-CF as regards the control of the flow of the mobile phase. In the TLC-P method (group C) the range of flow rates generated is virtually the same as in HPLC. The use of group B methods shortens the time of analysis by a factor of 2–5 and that of group A methods by a factor of 1.5–3 compared with traditional TLC.

Scheme



It is noteworthy that this proposed subdivision of TLC-CF methods into two groups is fairly arbitrary. For example, continuous elution conditions are realised in both centrifugal TLC and in TLC-P.

Table 1. Principal variants of liquid chromatography.

Characteristic	Traditional TLC	TLC with a controlled flow of mobile phase	CLC
Type of sorption system used	open	open or closed	closed
Cause of movement of mobile phase in sorption layer	capillary forces	capillary forces or pressure drop across layer	pressure drop
Flow rate of mobile phase lengthwise along the layer	variable	constant (controlled)	constant (controlled)
Possibility of controlling the flow of mobile phase	does not exist	exists	exists
Method of detecting components	on sorbent layer (static)	static and dynamic	in stream of mobile phase (dynamic)
Detection sensitivity*	high	high	high
Reproducibility	moderate	high	high
Number of samples analysed simultaneously	large	large	limited (usually one)
Use of sorption layer	single**	single**	repeated
Consumption of sorbent in series of analyses	large	minimal	minimal

---

*CLC has the following advantages over traditional TLC: 1) absence of sorbent in the detection zone and 2) long light path in the measuring cell.

**Certain types of chromatographic plates in TLC can be used repeatedly after regeneration.

The principal variants of liquid chromatography are compared in Table 1 in terms of the sorption system employed, the character of the forces responsible for the movement of the mobile phase, etc.

III. CONTINUOUS COMBINED (TWO-STAGE) TLC

The term "continuous chromatography" is used in TLC in two senses. Firstly, in order to designate the process involving the separation of the sample which is continuously supplied into the chromatographic system. In continuous separation the mobile phase, on the one hand, and the sample and the sorbent layer, on the other, move in different directions. This method was first proposed by Martin[38] in planar (paper) chromatography and was realised by Guiochon et al.[29] Secondly the term is used to designate the variant of TLC in which only the flow of the mobile phase is continuous and the volume of this phase is greater than that necessary to wet the sorbent throughout the length of the chromatographic plate. Here and henceforth we shall only use the second meaning of the term "continuous chromatography".

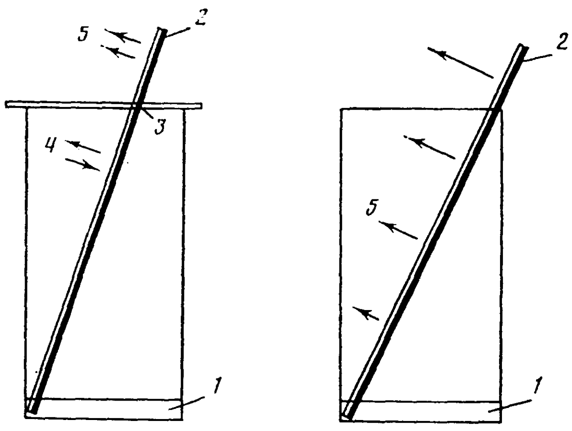
The principal aim of continuous TLC is the improvement of the separation of the mixture analysed by increaseing the distance over which the components to be separated migrate.

The initial variant of continuous TLC was the combined (two-stage) method. It was first used[40] in ascending chromatography on a free layer of alumina. The component to be separated was deposited on a dry layer of sorbent and elution was then carried out. The mobile phase was evaporated from one end of the chromatographic plate. In this case the separation process proceeds in exactly the same way as in the usual TLC after the attainment of the edge of the plate. The eluent reaches the edge of the plate, as stationary flow of the mobile phase is established along the sorbent layer. The flow rate is determined by the rate of migration of the front of the mobile phase at the end of the elution zone. Changes in the rate of movement of the solvent for the given combination of the mobile and stationary phases can be achieved by altering the length of the elution zone. [In a recently published study† an attempt was made to optimise the separation conditions in continuous TLC as a function of the rate constant of the movement of the eluent, the degree of separation, and the R_f for the components separated.]

Somewhat later Stanley and Vannier[41] and Mistryukov[42] developed novel and elegant methods for descending two-stage continuous TLC. Interesting procedures for the application of this variant of TLC have also been described in other communications.[43,44] However, the method involving constant flow of the mobile phase, proposed by Truter and Van Den Eijnden[45-47] and also the method of the gradient flow of the mobile phase or the evaporation method[48,49] are most frequently used. The differences between them are illustrated fairly clearly in Fig.1.

In order to carry out continuous TLC under identical conditions, Truter[45,47] suggested that a special lid be employed for the chromatographic chamber with a slit in which the plate is inserted. The mobile phase rapidly evaporates outside the limits of the chamber. Later a similar design was proposed independently by Van Den Eijnden[46] and was successfully applied in subsequent investigations.[50]

We may note certain useful modifications of Truter's method. In one investigation[51] a layer of charcoal was proposed to accelerate the process involving the "removal" of the mobile phase from the end of the chromatographic plate. The use of a paper wick for the removal of the eluent from the plate and for its supply through a slit to the outside of the chamber for the purpose of subsequent evaporation has been described.[52,53] The sorbent itself can be used to collect the mobile phase by placing a thick layer of the former ("roller") on the edge of the chromatographic plate.[54-56]



a *b*

Figure 1. Continuous TLC methods:[20] *a*) the method of the constant flow rate of the mobile phase;[45-47] *b*) the method of the flow rate gradient of the mobile phase along the layer:[48,49] 1) mobile phase; 2) thin-layer plate on which separation takes place; 3) slit in the lid of the chamber through which the upper end of the plate passes; 4) equilibrium in the sorption and desorption of the mobile phase vapour (the gas phase in the chamber is saturated by the mobile phase vapour); 5) evaporation of the mobile phase from the plate (a flow rate gradient of the mobile phase arises as a result of evaporation along the plate).

Thus a chamber saturated by the vapour of the mobile phase is used in Truter's method (Fig.1*a*) and its modifications and the solvent is evaporated outside its limits. For this reason, the rate of movement of the mobile phase along the plate is constant within the chamber.

Subsequently, chambers with a small volume of the gas phase came to be widely used. The first chamber of this type was proposed by Brenner and Niederwieser[57] specially for continuous TLC.[57] It was subsequently significantly improved by a number of investigators.[58-62] In our view, a novel chamber distinguished by simplicity and convenience in use, described by Soczewiński and co-workers,[61,62] merits special attention.

In the second known variant of continuous TLC (Fig.1*b*), the mobile phase is evaporated from the chromatographic plate already in the separation zone and during separation.[48,49] As a result of the partial evaporation of the eluent, the rate of movement of the mobile phase diminishes from the beginning to the end of the plate. This negative flow rate gradient results in a decrease of the width of the band (the band is compressed) and the separation is improved, which is especially important for the analysis of impurities. However, the main disadvantage of this interesting variant of continuous chromatography is inadequate reproducibility of the experimental conditions, which is naturally reflected also in the

---

reproducibility of the retention parameters, the effectiveness, and the separation factors for the compound analysed.

Subsequently a new method, based on the intensification of the evaporation process—the so called "hot plate" method—was proposed and developed.[63,64] In this method a zone of increased temperature is created on the plate where accelerated evaporation results in an appreciable gradient of the flow rate of the mobile phase, leading to the compression of the chromatographic bands.

The variants of continuous TLC described (the evaporation and hot plate method) can be usefully employed, in our view, mainly for the concentration of impurities in analysis.

In the practical application of continuous chromatography, the isothermal variant is most often used.

All the variants examined presuppose a two-stage continuous TLC scheme. The presence of the first chromatographic stage and the deposition of the specimen to be separated on the dry sorbent greatly reduce the reproducibility and effectiveness of the continuous TLC method. Apart from this, the separation conditions selected with the aid of this method are fairly difficult to use in HPLC. This in fact stimulated the development of the single-stage continuous TLC method in which the sample is injected directly into the flow of mobile phase.[65] An important feature of this method is the detection of the components to be separated in the course of elution as in HPLC. For this reason, the single-stage continuous TLC will be considered in greater detail below in the Section devoted to the single-stage TLC with flow detection.

The continuous TLC method with sample injection into the stream of eluent is frequently referred to as flow TLC,[66] and the two-stage variant as continuous TLC. The concepts of "two- and single-stage continuous TLC" introduced in this review reflect the significant differences between these variants of TLC. This is necessary also because in the literature the flow variant is frequently referred to as continuous and conversely, although, as shown above, they differ fundamentally.

IV. CONTINUOUS SINGLE-STAGE TLC WITH FLOW DETECTION

An important independent stage in any chromatographic method is the assessment of the results of separation or the detection stage. In continuous TLC the following procedures can be used to determine the qualitative and quantitative compositions of the mixture analysed: (1) scanning (optical) of the plate with the separated chromatographic bands (see, for example, Refs.23 and 24), (2) continuous measurement of the concentrations of the compounds analysed in the moving eluent on the chromatographic plate or beyond it, and (3) a combination of both procedures: a method of detection in the flow of mobile phase for "light" components and a scanning method for "heavy" components or in general for components which are not eluted under the given conditions.

The first and third procedures appear to us more laborious compared with the second but they are optimal in the solution of many analytical problems. At the present time scanning is the commonest method for the automatic assessment of the results of separation in TLC.

The application of the second method actually implies the creation of a liquid-type thin-layer flow chromatograph. The role of the column in the latter is fulfilled by the thin-layer plate whose absorption layer is open from at least one side. Since in our view unjustifiably little attention has been devoted in the literature to the second variant of continuous TLC, although it makes it possible to reduce significantly the amount of labour involved in TLC whilst retaining its traditional advantages, it appears useful to discuss this method in greater detail. Previously it was considered only in a monograph[67] and in a review.[68]

The consideration of the method of continuous TLC with flow detection in a review devoted to different ways of controlling the mobile phase can be justified by the fact that the single-stage continuous (flow) TLC method was first devised precisely as a variant of continuous TLC with flow detection. The application of a flow detector assisted in a more successful development of continuous TLC.

The method of continuous TLC was initially developed for the rapid selection of experimental conditions in column liquid chromatography.[65]

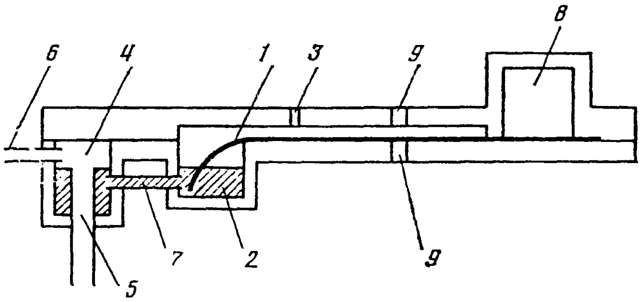

Figure 2. Schematic illustration of the first thin-layer chromatograph:[65] 1) TLC plate on a flexible transparent support; 2) reservoir for the mobile liquid phase; 3) aperture in the cover plate for the introduction of the sample onto the chromatographic plate; 4) preliminary chamber for the mobile phase with the drain tube *5*; 6) tube for the supply of the mobile phase; 7) connecting tube; 8) reduced pressure chamber for the evaporation of the mobile phase; 9) apertures for detection.

The thin-layer chromatograph employed by Schmid et al.[65] is shown in Fig.2. The constancy of the supply of the mobile phase is ensured by maintaining a virtually constant level of liquid in the working reservoir *2*, which communicates with the chamber *4*. The sample is injected from a micropipette via the aperture *3* in the upper lid. We may note that, in order to compensate for the possible errors in the measurement, a double chromatographic system is used. The two parts of a single flexible thin-layer plate work independently: in the chromatograph there are two apertures in the upper lid for the injection of the samples analysed and two apertures for the light guides with the aid of which the results of separation are recorded. The light guides, connected to a light source, are fitted with a green filter (550 nm). A photoresistor is used as the radiation detector. The liquid mobile phase is removed from the plate in chamber *8* under vacuum. The distance between the site of sample injection and the detection region is about 4 cm.

Fig.3 presents as an example the chromatogram of a mixture of dyes obtained on a thin-layer chromatograph of the first type. The parameters of the chromatographic bands of the dyes separated are listed in Table 2.[65] Taking into account the fact that the data presented in Table 2 refer to a short length of the layer (4 cm), they must be regarded as entirely satisfactory. For comparison, we may note that the columns used in the initial period of the development of gas–liquid chromatography were characterised by an efficiency close to that given in Table 2.

The method of continuous TLC with flow detection has been subjected to a general assessment.[69] It was shown that the continous-eluent planar chromatography can be used to separate both organic and inorganic compounds and that not only inorganic but also organic adsorbents, including ion-exchange adsorbents, can be employed as the stationary planar phase. In many instances it is useful to employ chromatographic paper as the sorbent in planar chromatography. Different gradient methods for the improvement of separation and, in particular, methods based on the use of sorption layers of different shape are of interest.[70,71]

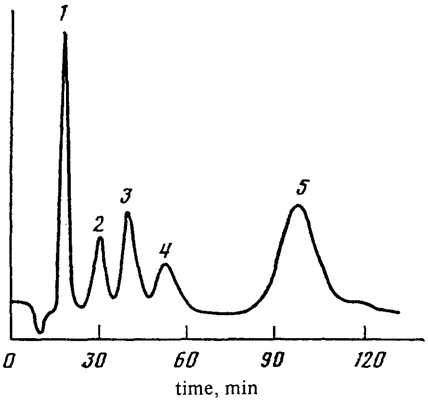

Figure 3. Chromatogram of a mixture of azo-dyes obtained on the first thin-layer chromatograph;[65] separation conditions: stationary phase—"Polygram Sil C" TLC plate, thickness of silica gel layer 0.25 mm, mobile phase—toluene mixed with 2% of ethanol; the designation of the peaks correspond to the numbers of the dyes in Table 2.

Table 2. Characteristics of the separation of azo-dyes under the conditions of continuous TLC with flow detection (mobile phase—toluene).[65]

Dye	t, min	c, mm	N, t.p.
N-Ethyl-1-[(*p*-phenylazophenyl)azo]-2-naphthylamine	17.5	4.5	648
1-[(*p*-n-Butylphenyl)azo]-2-naphthol	39	10	654
1-[(*p*-Methoxyphenyl)azo]-2-naphthol	61	17	501
1-[(*m*-Methoxyphenyl)azo]-2-naphthol	90	25	506
1-[(*o*-Methoxyphenyl)azo]-2-naphthol	162	41	683

Notation: t is the retention time, c the width of the separated component band, and N the number of theoretical plates (t.p.).

Continuous planar chromatography with flow detection makes it possible to employ the advantages of two main methods of liquid chromatography: the planar method characterised by flexibility and ease of replacement of the column-plate, economy, etc. and the column method which ensures, a high reproducibility of the retention parameters, a high degree of automation of the process, etc.

The method of continuous-eluent chromatography with flow detection can be applied in two versions: version I—the specimen analysed is deposited on the dry sorption layer and elution is then carried out by means of a flow of the mobile phase (the traditional method of sample deposition in TLC) and the components separated are detected by means of a flow detector; version II—the specimen analysed is deposited on the sorption layer wetted by the moving mobile phase and the components separated are detected by the flow detector (the method used in continuous TLC[61]).

In order to assess these versions of sample injection in continuous TLC, two series of measurements, comprising seven repeated separations on the same plate, were carried out.[69] The average rates of movement of azo-dyes on the TLC plate obtained using both versions as well as the reproducibility of these quantities are presented in Table 3.[69] The maximum deviation of the rate of movement of the chromatographic band from its average value (ψ_{max}, %) was used as the characteristic of the reproducibility. The measurements were performed using two mobile phases: benzene and toluene. Table 3 shows that the linear rate of migration of the chromatographic band (or the retention parameter) is reproducible, under conditions where the sample is injected into the stream of eluent (version II), with a random error 6–10 times smaller than in the deposition of the sample on the dry sorbent layer (version I). The time of analysis, determined from the retention time of the last extra component, was the same for both versions, but the retention times of light components are shorter for version I, apparently because of the higher flow rate in the initial period of the spreading of the mobile phase through the dry sorbent and the presence of a region of unsaturation near the solvent front.

Table 3. The average rates of migration of azo-dyes U_a on the chromatographic plate and the characteristic of their reproducibility $\psi_{max} = (\Delta U_{max}/\bar{U}_a) \times 100\%$ under the conditions of continuous TLC with the substance analysed introduced onto the dry layer of sorbent (variant I) and on the sorption layer wetted by the moving eluent (variant II).[69]

Sorbent (stationary phase)	Azo-dye	$\bar{U}_a$, mm min^{-1}				ψ_{max}, %	
		benzene (I)	toluene (I)	benzene (II)	toluene (II)	benzene (I)	toluene (I)
KSK silica gel + 5% of gypsum	*1*	1.82	1.70	1.27	0.99	22	2
	2	0.95	0.37	0.69	0,66	20	0
	3	0.57	0.46	0,54	0.38	7	2
	4	0,42	0.32	0,41	0,28	12	2
	5	0.30	0.21	0.30	0,20	10	0
Kieselgel 60F 254	*1*	2.40	2,18	2,00	0.92	16	1
	2	1.72	0.71	1,33	0,42	21	1
	3	0.90	0.33	0,67	0,24	13	0
	4	0.50	0.22	0,45	0.18	8	2
	5	0.30	0.10	0.31	0.11	4	2
Silpearl + 5% of gypsum	*1*	3.87	2.50	2.29	2.00	13	1
	2	1.56	0.92	1,21	0.88	16	1
	3	1.04	0,58	0.89	0,51	11	0
	4	0.65	0.33	0,60	0.30	8	2
	5	0.48	0,22	0,48	0,22	6	0

Notation: ΔU_{max} is the maximum deviation from the average rate of migration of the azo-dye in a series of experiments; 1) azobenzene; 2) Dimethyl Yellow; 3) *p*-methoxyazobenzene; 4) *p*-aminoazobenzene; 5) Sudan-III.

Analogous results have been obtained in the separation of aminoacids. Chromatograms of mixtures of dyes and aminoacids are presented in Fig. 4. The variation of the base line in the region of light (weakly retained) components on chromatograms *a* and *c* can be accounted for by the fact that, when the sample analysed is deposited on the dry sorbent, the arrival at the detector of the front of the mobile phase is accompoanied by a gradual alteration of the signal as a result of the movement through the detector of the unsaturation zone with a variable content of the eluent. When the sample is deposited on the sorbent layer and the stream of eluent is moving at a constant rate, this phenomenon is naturally not observed (chromatograms *b* and *d*).

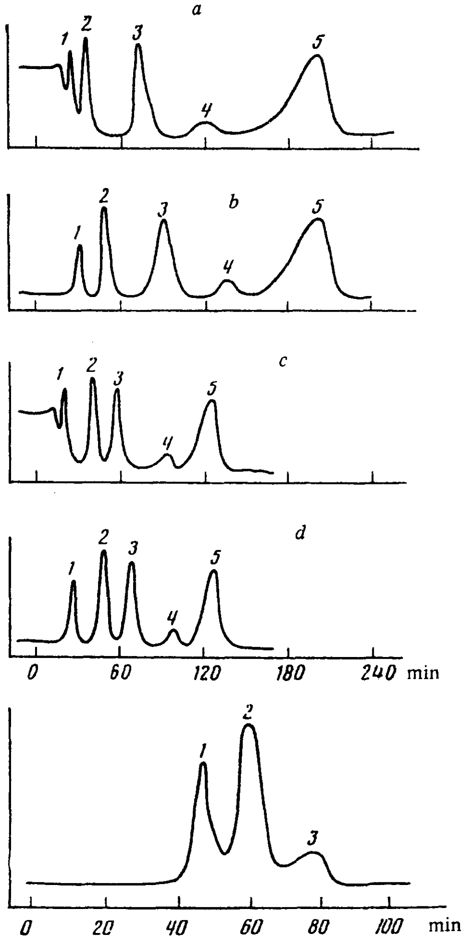

Figure 4. Chromatograms of mixtures of azo-dyes and amino-acids obtained on a thin-layer chromatograph:[69] *a*)–*d*) separation of a mixture of five azo-dyes (the designations are indicated in Table 3) on plates with "Kieselgel 60F 254" silica gel from the Merck Company (*a* and *b*) and "Silpearl" silica gel from the Cavalier Company (*c* and *d*); mobile phase—benzene, 600 nl sample introduced onto the dry layer of sorbent (*a* and *c*) or onto a layer of sorbent with a moving stream of eluent (*b* and *d*); *e*) separation of a mixture of 4-aminosalicylic acid (1), tryptophan (2), and histidine (3); stationary phase—"Silpearl" silica gel + 5% of gypsum, mobile phase—70 : 30 ethanol–water mixture; sample introduced onto the layer of sorbent with a flowing eluent; distance from the point of sample injection to detection zone 40 mm.

Since in the case where the sample is injected on the sorbent layer with the eluent in continuous TLC with flow detection (CTLC-FD) the separation process does not differ in essence from those occurring in column chromatography, this version of TLC is apparently one of the most rational procedures for the selection of optimum separation conditions in liquid column chromatography, to which attention was drawn by Schmid and Cramer.[65] The possibilities of CTLC-FD as regards the optimisation of separation conditions have been demonstrated in relation to the analysis of a mixture of dyes.[72] However, in our view, this method is undoubtedly also of independent importance. For this reason, we may note some of its positive features. Firstly, CTLC-FD makes it possible to replace the mobile and stationary phases easily and simply. Secondly, the method permits the analysis of specimens containing components which are not in fact eluted, since the periodic replacement of the thin-layer plate presents no difficulties. Thirdly, the method approaches column chromatography as regards the level of automation.

It is important to note that the injection of the sample into the stream of mobile phase beyond the line of the solvent front makes it possible to obtain more symmetrical peaks.[62] Thus this method of sample injection is of interest also for the usual variants of TLC. CTLC-FD occupies an intermediate position between the two- and single-stage variants of continuous TLC, since the eluent flow has not yet reached a steady state despite the specimen being injected into it.

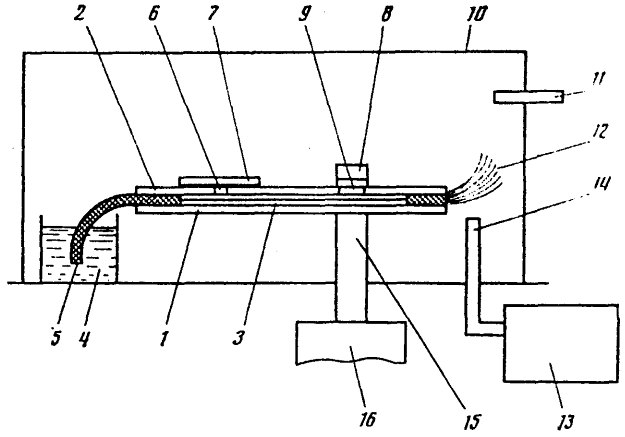

Figure 5. Schematic illustration of a thin-layer chromatograph:[69] 1) base (lower lid) of the chamber for the thin-layer plate; 2) upper lid of the chamber; 3) plate with sorption layer; 4) compartment for the mobile phase; 5) paper wick; 6) window for the introduction of the sample to be analysed; 7) lid; 8) radioluminescent light source; 9) slit diaphragm; 10) opaque jacket; 11) tube for the removal of air with the mobile phase vapour; 12) wick for the evaporation of the mobile phase; 13) air microcompressor; 14) pipeline for the supply of air; 15) light guide; 16) photoelectric multiplier.

The design of the apparatus is important in any experimental method. A thin-layer chromatograph, differing somewhat from the first instrument,[65] has been described by Berezkin et al.[69] This liquid-type chromatograph is illustrated schematically in Fig.5. A wick exposed to a strem of air and not an evacuated chamber, as in the study of Schmid et al.,[65] is used here to remove the solvent from the chromatographic plate. The employment of the wick for the supply of solvent to the plate permitted a greater variety of types of plates which can be used in the thin-layer chromatograph. In particular, in this instrument one can employ plates on a solid support. The use of a radioluminescent light source[73] permitted a simplification of the design and the employment of sources with different maxima in their emission spectra permitted the expansion of the region of applicability of the spectral detector. Not only glass but quartz plates are used as the material of the support for the adsorption layer, which creates the possibility of measurements in the ultraviolet part of the spectrum.[69] Other solutions have also been described.[74] They are based on the use of a small aperture in the sorption layer on the plate, which is usually opaque, as the optical microcuvette of the detector, where the concentrations of the compounds separated in the stream of mobile phase are measured. The filling of this aperture by the mobile phase does not entail an appreciable distortion of the chromatographic bands of the components separated. Fig.6 illustrates the possible types of microcuvettes in a thin-layer chromatographic plate.[74] The application of microcuvettes increases the sensitivity of the determination by a factor of 1.5–10 compared with variants in which there is a thin layer of sorbent in the path of the measured emission.[75] The diameter of the microcuvette does not exceed 1–3 mm. The possibility of using microcuvettes for the electrochemical detection of compounds separated has also been noted.[75]

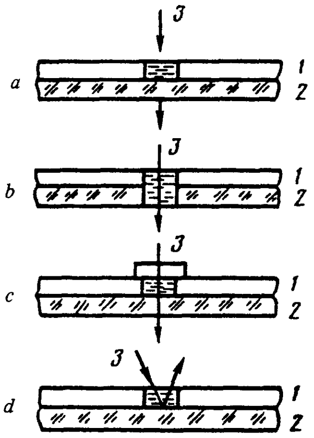

Figure 6. Types of optical flow microcuvettes in the TLC plate:[74] *a*) microcuvette in the sorption layer; *b*) microcuvette in the sorption layer and the support; *c*) closed microcuvette in the sorption layer; *d*) microcuvette in the sorption layer deposited on a support with a reflecting surface; 1) sorption layer; 2) support; 3) direction of light flux.

The efficiency of the separation when plates prepared in the laboratory with a thickness of the layer of 0.4 mm and a working length of the layer of 100 mm are used was $N = 700$ theoretical plates for the Sudan dye. The use of a plate from the Merck Company for high performance TLC made it possible to increase the efficiency to 3450 theoretical plates (for a working length of the layer of 60 mm).[69] This is significantly greater than the value obtained by Schmid et al.[65]

An interesting and promising trend in the development of flow TLC is its use for the separation of various compounds on various mobile phases consisting of two and more components. In chromatography under the conditions of single-stage continuous TLC, the "separation into layers" of the components of the mobile phase is unlikely, in contrast to traditional TLC.[21] This makes it possible to employ complex mobile phases for the separation of various sytems[72,76,77] and also to carry out the separation under the conditions of gradient elution.[78] The method and theory of continuous TLC separation using multicomponent mobile phases have been described in a recent study#. In the same investigation it was also shown that the data on separation obtained by continuous TLC agree satisfactorily with the results of separation by the HPLC method and can therefore be usefully employed for the optimisation of the separation conditions in HPLC.

The CTLC-FD method can be used successfully to estimate the separating properties of solvent powders,[79] which leads to yet another possibility, in principle, of employing TLC for physicochemical measurements.

We believe that, in analysing the prospects for the development of continuous TLC with flow detection, one should turn ones attention to the possibility of using slightly modified standard equipment for CTLC-FD, for example, a chromatograph with a U-chamber[80] as well as detectors based on the employment of laser-excited fluorescence,[81] photoionisation,[82] photoacoustic spectroscopy,[83] etc.

V. CONTINUOUS TLC WITH A MOVING ATTACHED LAYER OF SORBENT

A way[29,32,84] of increasing the efficiency of the separation per unit time is to increase the rate of elution and the distance over which the separation takes place. High flow rates of the mobile phase and high rates of continuous TLC can be achieved by shortening the elution zone,[37] which decreases in its turn the total number of effective theoretical plates. Separation in continuous TLC using a long elution zone entails a considerable fall in the flow rate of the eluent and hence a significant decrease of the specific efficiency.

Saunders and Snyder[85] have proposed an interesting solution of the problem of increasing the specific and general efficiency by increasing the rate of elution with a simultaneous increase of the distance over which the components separated migrate in the course of analysis under the conditions of continuous TLC. They developed a method in which an infinite strip on which the sorbent has been deposited moves in the direction opposite to that of the movement of the eluting substances. This method has been called drum TLC.[85] It is based on the fact that in the course of elution the distance between the front of the mobile phase and the site where it is supplied remains unchanged. By maintaining this distance as small as possible, one achieves high rates of elution. The separation in drum TLC takes place in the following manner. The plate on a flexible base is attached to a cylinder, the specimen to be separated is deposited, and then the cylinder is lowered into the eluent in such a way that the specimen remains above the surface of the liquid eluent. After the front of the mobile phase has reached the evaporation line, the drum is made to rotate against the direction of the migration of the eluent at a rate equal to that of the frontal migration but having the opposite sign. Thus the separating layer migrates relative to the spot and the immersion and

---

#E.Soczewiński, in "Planar Chromatography", Vol.1 (Edited by R.E.Kaiser), Huethig, Heidelberg, 1986, p.79.

evaporation (of the front) lines at the same rate. Consequently the components separated can be eluted through a sorption layer of any length at a fairly high rate. The authors[85] showed that the method of drum TLC is a more effective and shorter analytical procedure than the traditional and usual continuous TLC and its efficiency is also superior to that of centrifugal TLC.

However, drum TLC, which gives rise to highly effective and rapid separation, suffers from a series of limitations. Firstly, this method makes it possible to separate only substances which differ only slightly in their R_f. Secondly, it is fairly difficult to maintain the necessary rate of rotation of the drum in the separation of colourless substances. Nevertheless, this method, which is relatively unsuitable for the separation of multicomponent mixtures consisting of substances with markedly different R_f, can prove to be extremely effective for the separation and analysis of substances having similar properties, for example, optical isomers.

A principle analogous to that employed in drum TLC has been used in the method of three-chamber TLC.[86] In this case the chromatography is achieved on a long looped foil strip coated by a thin layer of sorbent. During its movement, the foil enters the elution device consisting of three glass chambers (Fig.7).

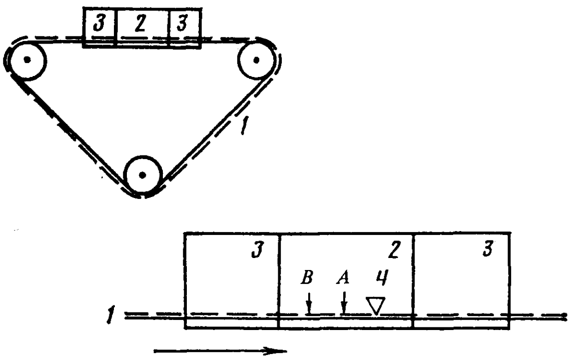

Figure 7. Schematic illustration of three-chamber TLC:[86] 1) foil with chromatographic layer; 2) main chamber; 3) lateral chambers; 4) channel for the supply of the solvent; A) and B) substances to be separated.

The separation takes place in the middle chamber. The other two serve for the evaporation of the solvent from the layer of sorbent. The rate of movement of the foil with the adsorbent is regulated by means of an electric motor connected to rollers. The mixture separated is deposited on the sorbent and placed in the middle chamber through which eluent is then supplied. During chromatography, the rate of movement of the strip should be such that the component to be determined is at the same distance from the eluent front throughout. At the end of the chromatographic process, the speed of the chromatogram is increased and all the components separated are moved in succession to the side opposite to that where the eluent is supplied. After drying each chromatographic band, a clear cut separation of the specimen over a comparatively short distance is achieved.

A method similar to drum TLC has been described by Halpaap and Bausch.[87] In this method the film with the sorbent layer is rewound from one coil to another coil underneath. As in drum TLC, the latter is immersed in the reservoir with the eluent. In this case the separation section is much longer than the circumference of the cylinder in drum TLC. The authors[87] carried out the separation process on sections of the sorption layer of different lengths.

It is noteworthy that the continuous TLC methods considered here are variants of eluent chromatography with the layer of sorbent moving relative to the point of supply of the eluent.[88,89]

VI. CENTRIFUGAL TLC

Centrifugal chromatography, first proposed[90] as a variant of paper chromatography, was subsequently used in TLC.[91,92] This method is applied in two versions: the linear and radial versions.[85] In the radial or circular version of the centrifugal TLC, the system chromatographed rotates about its axis so that the movement of the mobile phase is accelerated by centrifugal forces, as in the linear version. In the radial centrifugal TLC, the mobile phase is supplied to the centre of a circular sorption system. The flow rate of the mobile phase can be regulated by means of a micropump. According to the authors,[85] centrifugal forces play the same role as pressure in HPLC.

In linear centrifugal TLC, the quantity equivalent to pressure in HPLC can be expressed by the relation[85]

$$P = \rho\omega^2 Z_f^2/2 , \qquad (2)$$

where ρ is the density of the mobile phase, ω the angular velocity of the plate, and Z_f the distance from the point of supply to the front of the mobile phase.

On the basis of the foregoing, centrifugal TLC can be classified as a TLC method with a controlled forced flow. The flow is stabilised by employing continuous TLC conditions and the rate of elution is regulated by the rate of rotation of the support. We may note that the rate of elution is directly proportional to the square of the angular velocity.[85]

A detailed critical review on centrifugal chromatography,[93] written in 1964, has not lost its importance today. The authors[4] believe that the economy of time in the elution of thin-layer chromatograms by centrifugal TLC is not very great. It is impossible to agree fully with this view. For very long separations, this method is undoubtedly economically justified and it has continued to be used in analytical practice in recent years: the reversed phase centrifugal TLC has been used successfully for the separation of polar compounds of plant origin § and the ion-exchange version of centrifugal TLC has been employed for the determination of Fe, Co, Ni, Cu, Hg, and other metals ¶. Different aspects of the application of centrifugal TLC have been discussed in a number of studies.[94–96] The possibilities of centrifugal TLC for preparative separation have been demonstrated by Stahl and Müller,[97] who showed that the specific sample charge in this method can amount to between 10 and 1000 mg per millimetre of the thickness of the absorption layer for one compound. The results of a detailed study[97] are of interest not only for preparative but also for analytical chromatography. Fig.8 [97] illustrates the dependence of the separation time on the overall flow rate of the mobile phase. It follows from the data presented that an increase in the flow rate of the mobile phase leads to a significant shortening of the chromatographic process, which is particularly pronounced in the region of low rates. Fig.9 [97] presents the dependence of the separation

factors for hydrazones (dyes) on the volume rate of supply of the mobile phase and the rate of rotation of the chromatographic system. The maximum resolution for the average flow rate of the mobile phase (5.2–3.5 ml min^{-1}) was obtained in the region of relatively low rates of rotation of the chromatographic system (~750 rev min^{-1}).

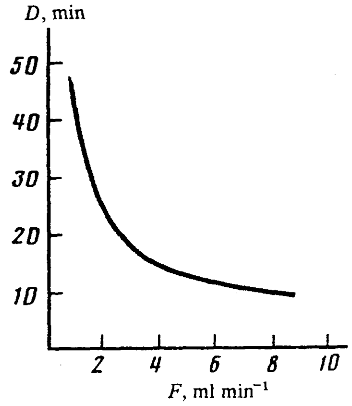

Figure 8. Dependence of the separation time D on the volume flow rate of the mobile phase F; experimental conditions: stationary phase—silica gel 60 with 1.5% of acronal, mobile phase—80:20 hexane–ethyl acetate mixture, rate of rotation 750 rev min^{-1}.[97]

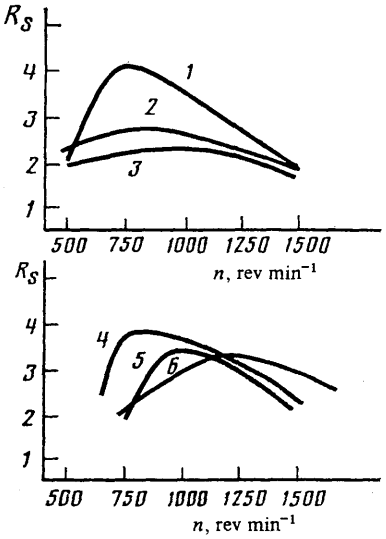

Figure 9. Dependence of the separation factor R_S for hydrazone dyes on the rate of rotation of the chromatographic system n;[97] experimental conditions: stationary phase—silica gel 60 with 1.5% of acronal, mobile phase—80:20 hexane–ethyl acetate mixture, volume rate of supply of mobile phase to the chromatographic system (ml min^{-1}): 1) 3.5; 2) 2.1; 3) 1.1; 4) 5.2; 5) 7.1; 6) 8.8.

In comparing preparative centrifugal TLC with traditional preparative TLC and column chromatography, the authors[97] arrived at the justified conclusion that this method has definite advantages.

Attention should be drawn to the recent appearance of several new methods and variants of apparatus involving centrifugal TLC.[98–100] A new method of planar preparative chromatography—sequential centrifugal layer chromatography (SCLS)—has been described.[98] According to the authors of the method, it combines the advantages of preparative and analytical centrifugal, antiradial, and sequential TLC. The apparatus for SCLC makes it possible to carry out circular chromatography with centrifugation at different rates of rotation. The supply of the eluent to any point on the plate makes it possible to separate additionally the individual components using individual mobile phases. Furthermore, there is a possibility of carrying out antiradial chromatography under the influence of capillary forces. Thus the SCLC method is in fact a hybrid procedure which expands the possibilities of centrifugal TLC.

A new centrifugal countercurrent chromatograph for partition chromatography has been proposed by Japanese investigators.[99] A rapid preparative separation of a series of mixtures of aminoacids, sugars, and saturated aliphatic acids has been achieved with its aid.

The possibilities of centrifugal TLC for a significant increase of the flow rate of the mobile phase in HPTLC have been demonstrated.[101] It has been shown that the results obtained in three-minute separation with centrifugation are equivalent to 12-minute separation with the aid of the usual circular TLC.

The method of centrifugal paper chromatography, its possibilities, and the prospects for its development have been considered in a review.[102]

The possibility of obtaining high flow rates of the mobile phase in centrifugal chromatography are limited. It is believed[85] that the use of rates of rotation at which pressures above 1 atm are created [see Eqn.(2)] would cause the rupture of the column of solvent and the mixing of air with the solvent at the point of its introduction. Yet another limitation is associated with the application of an open layer of sorbent in centrifugal chromatography: the increase in the resistance of the layer of sorbent with increase in the rate of elution can lead to the "spilling" of the eluent through the sorbent. This is in fact why centrifugal chromatography does not permit the attainment of the same high flow rates of the mobile phase as in HPLC.

VII. THIN-LAYER CHROMATOGRAPHY UNDER PRESSURE

The simplest, effective, and traditional method of attaining a high flow rate of the mobile phase or the layer of sorbent involves the creation of an excess pressure at the start of the sorption layer. However, an enclosed layer must be used to apply this method. This solution was proposed for TLC in 1977 by Hungarian investigators.[35] In fact, this is a variant of thin-layer column liquid chromatography, because the column contains a thin layer of sorbent. Thin-layer plates with an enclosed layer were known earlier in planar chromatography (see, for example, Refs.103–105), but they were not used in liquid chromatography.

A schematic illustration of a simple and novel apparatus[35,106,107] for TLC under pressure is presented in Fig.10. It is especially noteworthy that standard plates of any type can be used in this apparatus. The support of the chromatographic plate serves as the lower wall of the planar column, while the upper wall consists of the polymeric film-membrane *8*, which is clamped to the adsorption layer *6* of the plate *7* under the pressure of gas or liquid. The pressure at the inlet to a planar chromatographic column should naturally be lower than the external pressure used to clamp the polymer film to the adsorption layer in order to form a closed chromatographic system—"column". Owing to edge effects, which significantly disturb the front of the mobile phase and disorganise the solvent stream under the conditions of increased pressure, in applying the linear TLC-P method it is essential to use either special plates with the sorption layer on a silica gel, alumina, or talc base[108] alternatively a material inert towards the given mobile phase must be deposited on the edges of standard plates. Paraffin or various plastics are used as materials of this kind. Fig.11 illustrates plates for TLC-P. In order to form the linear front of the mobile phase over the adsorption layer of the TLC plate, an insert with a channel connected to the aperture through which the solvent is supplied to the planar chromatographic system is introduced. The channel can be made also directly in the adsorption layer having removed part of the sorbent.[109] Under the conditions of increased pressure, the solvent very rapidly fills the capillary channel, which thus becomes a linear source of the solvent and actually fulfills in TLC-P the role of a small bath with a mobile phase used in the usual TLC. Fig.11 illustrates two versions of linear TLC on standard plates: *a*—elution in one direction and *b*—elution in two opposite directions. Two dimensional separation,[110] which is known to be characterised by the maximum peak capacity compared with other TLC methods, can be achieved by means of TLC-P.

Other variants of traditional TLC, differing in the form of the sorption layer, can also be used successfully in the TLC-P method: the triangular,[71] anti-circular,[111] and circular[23] variants. The use of circular chromatography in this variant of TLC has been described, for example, in Refs.107, 109, and 112. It is apparently simplest to apply this variant of TLC-P in practice, since there is virtually no need to cover the edge of the plate by any material. The samples analysed are usually deposited on the plate in a preliminary step before the plate is placed in the TLC-P apparatus. A number of studies[113–116] have been devoted to questions of the optimisation of the operating conditions in TLC-P. Kalász and Nagy[116] believe that the optimum linear flow rate of the mobile phase depends on the size of the particles of the sorption layer and is in the range 0.10–0.28 mm s^{-1}. The TLC-P method was subsequently developed in other investigations.[117–120]

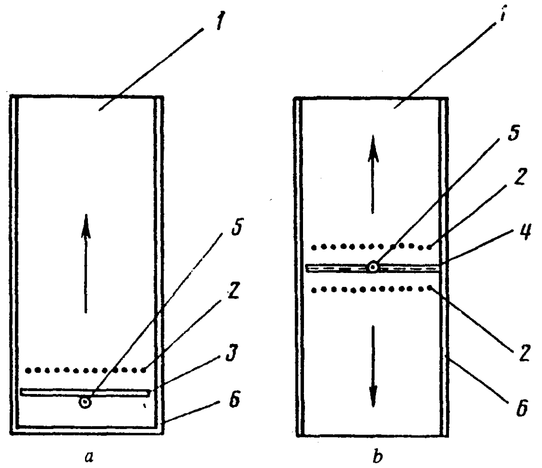

Figure 11. Linear elution in one direction (*a*) and in two opposite directions (*b*) in TLC-P:[109] 1) chromatographic plate; 2) region of deposition of samples analysed on the sorbent layer; 3) capillary channel in the adsorption layer for the organisation of the linear mobile phase front; 4) insert with a capillary channel for the mobile phase; 5) inlet for eluent; 6) edge impregnated with inert material.

The characteristics of the movement of the mobile phase front in TLC-P differ from those familiar in traditional TLC, for which a quadratic law holds[9,22–25] [see Eqn.(1)], while in the vicinity of the front there is an unsaturation zone.[7,27] It has been established (see, for example, Lengyel et al.[109]) that the following equation is valid for linear TLC-P:

$$Z_f = k_{\mathrm{TLC\text{-}P}}t, \qquad (3)$$

where Z_f is the distance of the solvent front from the line at which the mobile phase is introduced, t the time, and $k_{\mathrm{TLC\text{-}P}}$ a constant. This relation holds under the following conditions: (1) the volume rate of supply of the mobile phase in

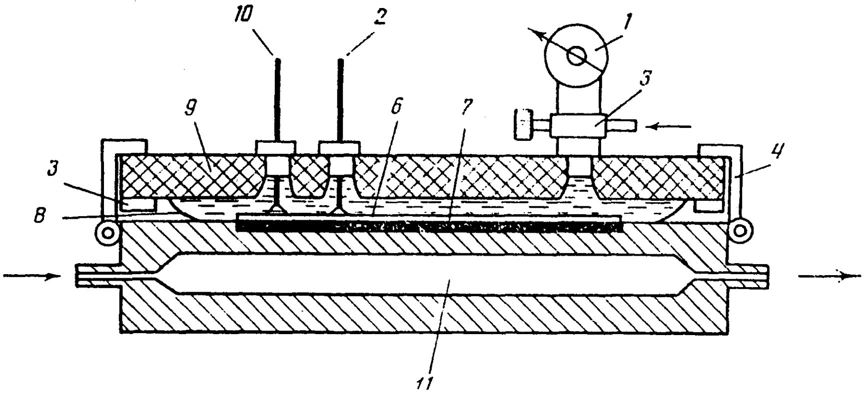

Figure 10. Schematic illustration of the apparatus for TLC under pressure:[106] 1) manometer; 2) device for the introduction of the specimen to be analysed under pressure; 3) inlet for gas or liquid; 4) clamps; 5) sealing washer; 6) sorbent layer; 7) glass or plastic support; 8) polymer membrane; 9) transparent lik; 10) device for the introduction of the mobile phase; 11) thermostatic device.

the chromatographic system F is constant and (2) the layer of sorbent is regularly packed so that its width is b, its thickness d, and the free volume fraction is β. The time t during which the mobile phase front migrates over a distance Z_f is defined by the relation

$$t=(Z_f b d\beta)/F\,,$$

whence

$$Z_f=(F/bd\beta)\,t\,. \tag{4}$$

It follows from Eqns.(3) and (4) that

$$U_f=k_{\mathrm{TCL\text{-}P}}=F/bd\beta,$$

where U_f is the linear rate of migration of the front.

Knowing the parameters b, d, and β of the sorption layer and also the volume rate of supply of the mobile phase to the system, it is possible to determine the linear rate of supply of the mobile phase.

On the basis of material balance equations, the following relations can be formulated for circular TLC-P:

$$t=\pi Z_{f\text{-}r}^2 d\beta/F\,,$$

where Z_{f-r} is the radius of the mobile phase front on the chromatogram and

$$Z_{f\text{-}r}=\left(\frac{Ft}{\pi d\beta}\right)^{1/2}, \tag{5}$$

$$U_{f\text{-}r}=\frac{dZ_{f\text{-}r}}{dt}=\frac{1}{2}\left(\frac{F}{\pi d\beta t}\right)^{1/2},$$

or

$$U_{f\text{-}r}=\frac{1}{2}\,\frac{F}{\pi d\beta Z_{f\text{-}r}}\,.$$

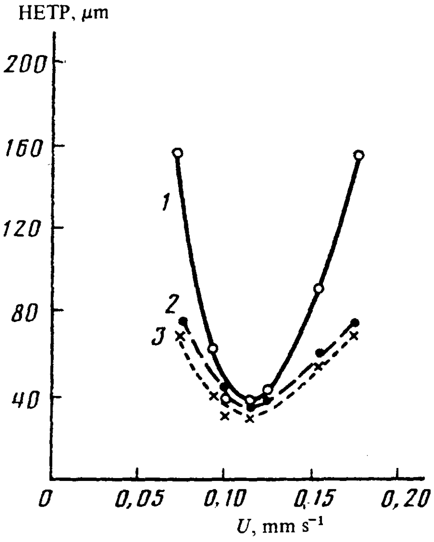

Figure 12. Dependence of the HETP on the linear flow rate of the mobile phase U;[131] stationary phase—200 × 200 mm plate (Fixion 50 × 8), mobile phase—sodium citrate buffer at pH 4.2; 1) arginine; 2) lysine; 3) histidine.

Thus the linear flow rate of the liquid mobile phase under the conditions of circular TLC-P is inversely proportional to Z_{f-r}. Consequently, under these conditions, the linear rate of migration of the eluent is not constant, decreasing as the point of the measurement moves away from the site at which the mobile phase is introduced. However, it is known that the efficiency of a chromatographic system, characterised by the height equivalent to the theoretical plate (HETP), depends significantly on the linear rate of migration of the mobile phase and this dependence has a sharp optimum. As an example, we may quote the dependence of the HETP on the linear flow rate of the mobile phase (see Fig.12). It follows from Fig.12 that the HETP depends fairly markedly on the linear rate of migration of the mobile phase. It therefore appears useful to carry out the chromatographic separation at a constant linear rate also in circular chromatography. This condition can be achieved by programming the flow rate of the eluent.

Since the flow rate of the mobile phase decreases as the front moves in the known variants of circular TLC-P, the HETP increases. As an example, Fig.13 presents data for the variation of the HETP as a function of the distance traversed by the mobile phase front. Evidently in linear TLC-P the efficiency hardly changes but it diminishes sharply when the elution methods traditional for TLC are used. It is noteworthy that the maximum efficiency is also attained in the case of linear TLC-P.

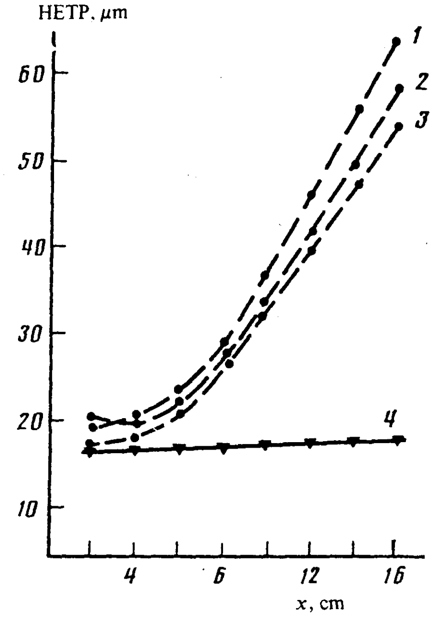

Figure 13. Dependence of the HETP on the distance traversed by the mobile phase front x [126] under the conditions of traditional TLC (curves 1–3) and TLC-P (curve 4): 1) unsaturated chamber; 2) ultramicrochamber; 3) saturated chamber; experimental conditions: stationary phase–silica gel 60 with 5 μm grain size, mobile phase—methylene chloride, sorbate—Butter Yellow dye.

Fig.14 presents two densitograms (chromatograms) for a mixture of compounds used as doping agents.[121] All the compounds are separated satisfactorily by the TLC-P method (Fig.14*a*) after 25 min; when traditional TLC is used (Fig. 14*b*), certain compounds cannot be separated at all (for example, compounds 2 and 3 and 5 and 6), while others are separated unsatisfactorily (for example, compounds 3 and 4 and 7 and 6), the separation time amounting to 95 min (almost four times more than in TLC-P).

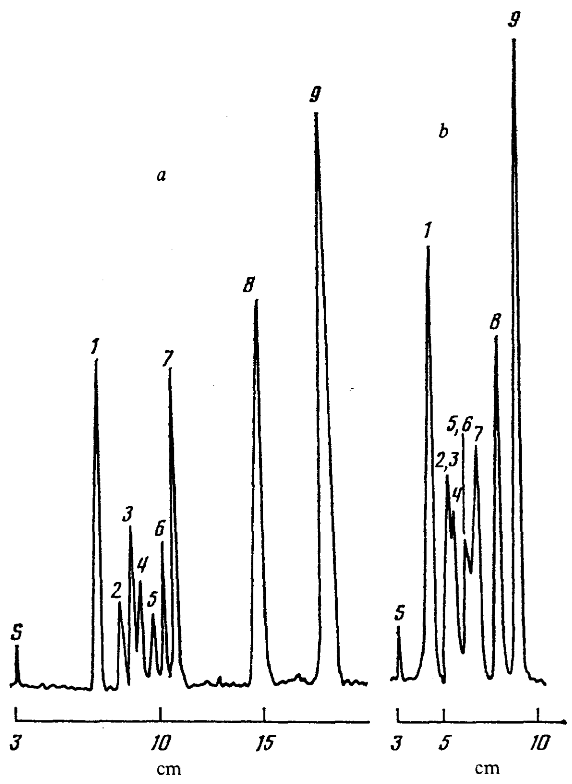

Figure 14. Separation of doping agents by TLC-P (*a*) and traditional TLC (*b*) methods:[121] 1) strychnine; 2) ephedrine; 3) methamphetamine; 4) phenmetrazine; 5) methylphenidate; 6) amphetamine; 7) desopimon; 8) coramin; 9) caffeine; S—start; stationary phase—silica gel 60 from the Merck Company, mobile phase—25 : 17 : 8 : 4 : 6 1-butanol—chloroform—ethyl ethyl ketone—water—acetic acid mixture; flow rate (for TLC- 0.85 cm min^{-1}.

Table 4. Some examples of the practical use of thin-layer chromatography under pressure.[108]

Compound analysed	Mobile phase
Essential oil	methylene chloride or benzene
Lipophilic dye	methylene chloride
Corticosteroids	nitromethane
Bile acids and their derivatives	ethyl acetate
Ergot alkaloids	acetonitrile
Dinitrophenylhydrazones of aliphatic aldehydes	diisopropyl ether
Essential oil	benzene–ethyl acetate (98 : 2)
Adducts of dimedone with aliphatic aldehydes	chloroform–ethyl acetate (95 : 5)
Aminoacids derived from nucleic acid bases, nucleosides	n-butyl alcohol–glacial acetic acid–water (4 : 1 : 1)
Poppy alkaloids	acetonitrile–water mixtures
Digitalis alkaloids	acetonitrile–water mixtures
Dinitrophenylhydrazones of aliphatic aldehydes	methanol–water and acetonitrile–water mixtures

The TLC-P method suffers from no limitations as regards the type of compounds to be analysed and is used to separate compounds of different classes: aminoacids and their derivatives,[122–124] the aflatoxins B_1, B_2, C_1, C_2, and M_1,[125] dyes,[126] and organic acids and their derivatives.[127] This method is used in reversed phase[128–130] and ion exchange TLC[131] and in phytochemistry.[132] Certain classes of compounds separated and the systems of mobile phases used for their separation are presented in Table 4. The possibilities of the TLC-P method have also been discussed in other studies.[133–142]

A variant of TLC-P different from that employed by Hungarian investigators[106,107] has been recently proposed by Kaiser and Rieder.[143] In this case the plate is positioned on a thermostatted base with the sorption layer downwards and is clamped to the latter with the successive deposition from above onto the support of the plate of a layer of silicon rubber and a thermostatted coating using a press developing a force up to 20 tonnes. The eluent is supplied from below onto the sorption layer at the centre of the plate or along its periphery. In the former case the circular version of TLC-P is achieved and in the second the antiradial version obtains. The eluent passes from a vessel, in which an excess pressure is established by supplying an inert gas at a high pressure. The main advantage of this variant of the device for TLC-P is the possibility of the relatively simple application of antiradial TLC-P.

The extensive experience gained in the development and study of the possibilities of the TLC-P method makes it possible to recommend it for a wide range of applications. At the present time Hungarian specialists have initiated the manufacture of commercial apparatus for TLC-P.[108,114,136,140]

In considering the prospects for the TLC-P method, we should like to draw attention to the usefulness of its variant with flow detection. When this method is employed for preparative separation, it is desirable to use one detector placed behind the sorption layer. We may note that we are unaware of studies in which the possibilities of the TLC-P method have been assessed as regards preparative separation, although this aspect of its practical application appears to be of great interest.

The variant of continuous TLC-P with a series of independent detectors, in which the chromatographic plate functions as a set of individual columns arranged in parallel, for the simultaneous and independent separation of a series of samples is promising for analytical separation.

Analysis of Polycyclic Aromatic Hydrocarbons by High Performance Liquid Chromatography

V.P.Dmitrikov, O.G.Larionov, and V.M.Nabivach

The review gives a systematic account of a survey of data on the high performance liquid chromatography of polycyclic aromatic hydrocarbons using phases of normal polarity and reversed phases. The factors influencing the parameters of the chromatographic separation of the above compounds are examined and the conditions for the analysis of polycyclic aromatic hydrocarbons in objects within the environment are presented.
The bibliography includes 318 references.

VI. Analysis of PAH in various systems within the environment 404

I. INTRODUCTION

The monitoring of the content of polycyclic aromatic hydrocarbons (PAH) in various objects in the environment is very important. Since it has been demonstrated that the carcinogenic and mutagenic action of certain PAH depends on their composition and structure, the exact knowledge of the structure of each component of the complex mixture of PAH is essential for the determination of the total carcinogenic (mutagenic) potential of the test specimen.[1,2]

With increase of the intensity of man's action on nature during the XXth century, the entry of PAH into the environment has become more pronounced at an increasing rate. The principal anthropogenic sources of PAH are[3] internal combustion engines, boiler engines operating on solid and liquid fuels, metal casting, chemical, coke, and shale industries, self-igniting coal bearing rock, etc. Thus the exhaust gas from internal combustion engines contains more than 200 different components of which 160 are carcinogenic. In city air with intense automobile traffic and metallurgical and coke-chemical industries, the content of PAH can reach 1.5–2.5 μg/100 m^3 of air.[4] It has been suggested that the contribution of tobacco smoking to the overall level of the accumulation of PAH is small but has a very dangerous effect on human health.[5,6] More than 170 carcinogenic substances have been detected in tobacco smoke.[4] At the same time the accumulation of PAH in the Planet's biosphere is expressed by the impressive overall figure of 5000 tonnes annually;[7,8] PAH have been detected also in the air and atmospheric dust of industrially developed cities, in drinking water, in industrial waste water, in various marine organisms and deposits, in the work places of certain industries, in food products, etc.

The content of 3,4-benzopyrene, which is comparatively easy to determine, can serve as a fairly reliable criterion for the estimation of the overall content of PAH in objects in the environment.[2,7] Approximately 80% of 3,4-benzopyrene released can be transported over a distance in excess of 100 km and can influence the state of the environment in non-industrial regions.[8] During winter, the content of PAH in the atmosphere is usually several times greater than in the summer.[9]

Analysis of PAH is important for the hygienic assessment of the quality of the environment for the determination of the source of contamination by carcinogenic substances.[10] The possibility of direct analysis of PAH in various objects of the environment is determined primarily by the sensitivity of the method[11] and in many cases preliminary concentration of the sample is necessary. The most promising analytical methods for PAH are capillary and gas–liquid chromatography (GLC) and high performance liquid chromatography (HPLC).[5] The possibilities of capillary GLC become increasingly limited with increase of the molecular weight of the PAH and the method is unsuitable for the analysis of samples containing six and more aromatic nuclei in the molecule. Similar limitations apply to a much lesser extent to the analysis of PAH by the HPLC method and in recent years there has been an increase in the number of publications on the HPLC of various PAH.[5,10,12–24]

The present review covers the literature on the analysis of PAH by the HPLC method published between 1973 and 1983 inclusive and partly the literature in 1984–1985; the analytical methods using normal-polarity and reversed phases, gradient elution, and highly sensitive detection systems are examined. The review does not include studies on the separation of PAH using exclusion or ion-exchange chromatography.

II. SEPARATION BY NORMAL-PHASE CHROMATOGRAPHY

During many years, alumina and silica gel were the commonest sorbents for the separation of PAH. Microdisperse[25] or surface-porous silica gels[26] are most often used nowadays. Thin-layer chromatographic data obtains using saturated hydrocarbons as the mobile phases (MP) are as a rule employed for the selection of conditions in the preparation of PAH on packed columns. In the analysis of PAH with high molecular weights, the MP are modified by activating additives in order to intensify their eluting properties.[27–31]

In one of the first studies on the HPLC of PAH,[32] it was shown that a mixture of substances ranging from naphthalene to 1,2-benzopyrene is effectively separated on a 300 × 3 mm column filled with Spherosil XOA 400 (MP = iso-octane and cyclohexane). The sensitivity of the determination of the individual components with UV detection (at wavelengths of 250 and 220 nm) is approximately to within 2 ng.

The earlier attempts to correlate the chromatographic parameters with the structure of the PAH molecules are presented in a monograph.[21] It was noted that the content of unsubstituted PAH increases with increase of the molecular weight and of the number of carbon atoms in the molecule; with increase of the length of aliphatic side chains, the content of PA also increases as a rule.[33-37] The relation between the capacity factor of the test substance k', the adsorption energy S_a^0, and other parameters is:[21]

$$\lg k' = \lg V_a + \alpha (S_a^0 - A_s \varepsilon^0)\,, \tag{1}$$

where V_a is the volume of the adsorbent in the column, α the adsorption activity of the adsorbent, A_s the size of the adsorbate molecule, and ε_0 the eluting power of the mobile phase. When pentane is used as the MP, $\varepsilon^0 = 0$ and the expression simplifies:

$$\lg k' = \lg V_a + \alpha S_a^0\ . \tag{2}$$

The adsorption energy S^0 can be expressed by the equation[126]

$$S^0 = \sum_i Q_i^0 + \sum_i q_i^0\ , \tag{3}$$

where Q_i^0 are the additive contributions of the individual groups of the molecule to the overall adsorption energy and q_i^0 are the contributions determined taking into account the possibility of the interaction between the groups indicated. The retention parameters of alkylnaphthalenes and alkylphenanthrenes are described satisfactorily by Eqn.(2) only for compounds with unbranched groups; the presence of secondary alkyl groups induces a significant discrepancy between the experimental and calculated data.[33]

A systematic study of the chromatographic behaviour of alkylnaphthalenes and alkylphenanthrenes has been undertaken by Popl et al.,[33,38] who established that Snyder's empirical formula

$$S^0 = 0.31\, nC_a\ , \tag{4}$$

where C_a is the number of aromatic carbon atoms in the molecule, holds vigorously in the alumina–pentane system only for arenes whose molecules contain 1–3 aromatic nuclei; on passing to PAH with four nuclei and non-planar PAH, the deviations become considerable. The relation expressed by Eqn.(4) breaks down on passing from straight-chain groups to branched groups owing to steric hindrance to the adsorption of such compounds.

Acid–base interactions influence significantly the sorption process. The adsorption energies on sorbents of the type Al_2O_3 increase appreciably for PA with acidic hydrogen atoms (indene, fluorene, and benzofluorenes) and low ionisation potentials (anthracene, naphthacene, and pentacene).[38] The acidity of the Al_2O_3 surface influences significantly the retention sequence of the components and, when the standardisation of the sorbent is adequately reliable, this phenomenon can be used successfully for both group[39] and individual analyses.[40]

Alumina and silica gel differ significantly in their sorption characteristics owing to the different acidities and structures of their surfaces.[22,43-46] These differences are fairly clearly manifested in relation to the separation of the anthracene–fluoroanthene pair.[41,42] It is believed that the sorption of PAH on Al_2O_3 is determined by electrostatic interactions and that on SiO_2 by hydrogen bonds. Detailed investigation of the characteristics of the separation of PAH on different brands of silica gel has shown that the capacity coefficient depends on the difference between the changes in free energies,[47] partition coefficients, specific surfaces, packing densities of the sorbent, and the proportions of its particles of different size.[48,49] The alkyl groups in naphthalenes and phenanthrenes influence differently their sorption on Al_2O_3 and SiO_2.[33,50,51] It is noteworthy that certain cyclic aromatic compounds have retention parameters close to those of aromatic polymethyl-substituted hydrocarbons containing identical numbers of carbon atoms. This phenomenon has not so far been convincingly explained.

Isomers of PAH with substituents in different positions have significantly different Kovac indices.[38] For the same number of carbon atoms in a series of aromatic hydrocarbons, the retention indices either differ significantly, as, for example, in 1,4- and 2,3-dimethylnaphthalenes and 1- and 2-phenylnaphthalenes, or are approximately the same as in 1,7- and 1,3-dimethylnaphthalenes and 1- and 9-methylphenanthrenes. In the latter case liquid chromatography on reversed phases with a careful selection of the eluent can be usefully employed for separation.

Other sorbents are also used in the analysis of PAH. Thus isomeric benzopyrenes and coronene have been separated[52,53] on columns with cellulose acetate and polyamide. Cellulose[54] and macroporous polystyrene[55] are also employed to separate PAH. One must assume that mixed partition and adsorption processes occur for these and similar sorbents.[56] A significant disadvantage of these fillers is their low mechanical strength and it is therefore useful to deposit them on strong carriers. The deposition of picric acid,[57] melamine polymerisate,[58] Bentone,[34,59] and carbon black[60,315] on silica gel and the use of such deposits for the separation of aromatic hydrocarbons by the HPLC method have been described in a number of studies. A new packing material, namely porous carbon glass, has been proposed recently.[61] Using methylene chloride with the addition of 0.1% of 1,3-terphenyl as the MP, it has been possible to separate successfully into individual components a mixture consisting of five PAH. The modification of hexane by more polar solvents has been examined on Silasorb 600 silica gel.[301]

III. THE USE OF CHEMICALLY MODIFIED SORBENTS

One of the main criteria of the reliability of chromatographic determination is the reproducibility of the retention parameters. Classical adsorbents are modified even in the presence of a very small water content in the MP. The retention times of the components vary within wide limits because the chromatographic column is in a non-equilibrium state.[62] Difficulties therefore arise in the use of gradient elution, for example, in the analysis of high-molecular-weight PAH.[63]

The deficiencies of liquid–liquid partition chromatography are frequently more significant than its advantages. The stationary phases fixed on the carrier become unstable when MP with similar polarities are used; the instability is manifested to an even greater extent when a gradient MP with highly polar eluents is employed.[64] The separation of PAH exclusively on chemically bound stationary phases will be considered below because ~80% of all the separations by the HPLC method are carried out on such sorbents.[65]

1. Separation on Reversed Phases

In separation on reversed phases (RP) a non-polar adsorbent and a polar eluent are used. This system is universal for PAH, their reaction products, and their heterocyclic analogues. In this variant of liquid chromatography, the retention of the components is inversely proportional to their polarity and is determined both by the non-polar non-specific sorbate–sorbent interaction and by the polar specific sorbate–eluent interaction.[14] In the analysis of PAH on RP, the relations between such interactions are frequently fairly complex. With increase of the chain length of the MP, the capacity factors rapidly fall (Fig.1) which significantly complicates the analysis of multicomponent PAH mixtures.[66]

As a consequence of the unique properties and the wide availability of octadecylsilane (ODS) reversed phases, the majority of the analyses of PAH have been carried out on such phases. Sorbents with RP are also used for the determination of vapour pressures of various PAH by the HPLC method under dynamic conditions.[67] When silica gel is treated with octadecylsilanes, its specific surface diminishes; it has been suggested that the silica gel pores are then not only narrowed but are also frequently blocked by the RP groups.[68]

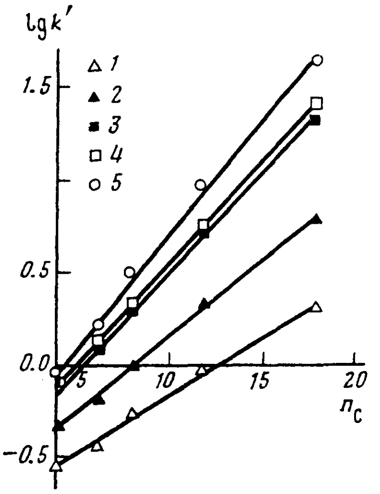

Figure 1. Dependence of the capacity factors of various aromatic hydrocarbons on the length of the chain grafted to the surface of the Spherosil silica gel in an amount of 2.1 μmol m^2 [55] (70: 30 methanol–water mobile phase): *1*) benzene; *2*) naphthalene; *3*) phenanthrene; *4*) anthracene; *5*) pyrene.[55]

Under identical conditions (identical RP composition, eluent flow rate, temperature, and column size), the retention times of PAH on a column with Nucleosil C_{18} are approximately twice as great as on Nucleosil C_8.[21] It is believed that PAH molecules are retained on the bound RP by van der Waals forces and that the bond strength increases with increase of the length of the side chain.

As early as 1973, Sleight[69] derived equations relating the capacity factor and the number of carbon atoms in both unsubstituted and substituted PAH; the methanol–water system was used as the MP. For unsubstituted PAH, the relation is linear along the section from benzene to benzopyrene isomers and is described by the equation

$$\lg k' = a + bC_N\ , \tag{5}$$

where k' is the capacity factor, C_N is the number of carbon atoms in the molecule, and a and b are constants. The introduction of alkyl substituents into the PAH molecule entails an appreciable increase in the retention of the component. This relation is characteristic not only of alkylbenzenes but also of alkylnaphthalenes and alkylphenanthrenes and is likewise described by a linear equation.[69]

Attempts to find correlations between the retention parameters of PAH on ODS phases and the composition and structure of the adsorbate have been made.[70–73,99] Thus a relation has been found[73] between the retention parameter and the geometry of the sorbed molecules for 84 alkylated and non-alkylated PAH. The ratio L/B, where L is the length and B width of the rectangle into which the PAH molecule can be "inscribed" taking into account the bond lengths and the covalent radii of the atoms, served as the criterion for the estimation of sorbability. In almost all cases the elution sequence of the isomeric PAH could be predicted with the aid of this relation: the retention increases with increase of the ratio L/B.

In order to estimate the retention of PAH on RP, the relation between the capacity factors k' and molecular binding χ, taking into account the steric structure of the PAH molecule and the bond orders, has also been employed.[75] The correlation factor F,[74,75] which takes into account the number of double bonds and the number of primary and secondary carbon atoms, has likewise been used to predict the chromatographic properties of the PAH determined. The factors F and χ have been calculated for 34 alkyl-substituted and partly reduced PAH.[75] It has been shown that the retention indices calculated on a computer taking into account these and other parameters can be used to predict the chromatographic behaviour of unknown PAH.[76]

A definite relation has been observed[77] between the retention and the physical properties of PAH. For columns containing different RP, the type of molecules, their structure, and their hydrophobic properties are of the main importance.

Table 1. Thermodynamic characteristics of the sorption of various PAH.

No.	Substance	$-\Delta H^0$, kJ mol^{-1}	$-\Delta S^{0*}$, J mol^{-1}K^{-1}
	Group A		
1	*o*-Terphenyl	8.3	17
2	Anthracene	16.0	43
3	*m*-Terphenyl	11.3	25
4	Fluoranthene	16.9	44
5	1,1-Binaphthyl	13.3	30
6	Triphenylene	18.9	48
7	Chrysene	23.5	62
8	1,3,5-Triphenylbenzene	12.5	23
9	4-Methylpyrene	21.8	55
10	9,10-Dimethyl-1,2-benzoanthracene	21.6	52
11	3,4-Benzofluoranthene	26.6	68
12	9,10-Diphenylanthracene	16.6	32
13	1,2,5,6-Dibenzoanthracene	30.7	79
	Group B		
14	*p*-Terphenyl	18.3	47
15	2,3-Benzofluorene	18.5	47
16	Bifluorenyl	18.0	45
17	1-Phenylnaphthalene	13.1	33
18	3-Methylphenanthrene	14.2	35
9	4-Methylpyrene	21.8	55
19	3-Methylpyrene	21.6	55
20	1,2-Benzoanthracene	22.4	59
	Group C		
21	2-Phenylanthracene	25.4	66
22	2,2′-Binaphthyl	21.9	55
23	9-Phenylanthracene	15.2	35
24	4,4′-Dimethylbiphenyl	14.4	36
25	2-Phenylnaphthalene	15.5	40
26	1-Benzylnaphthalene	10.8	27
27	Phenanthrene	13.3	35
28	Biphenyl	9.1	25
29	Naphthalene	13.3	40

*The entropy changes have been calculated under conditions such that V_S is equivalent to the volume of the sorbent in the column.

The elucidation of the mechanism of the retention of PAH on ODS phases has been prevented by the fact that until recently it was fairly difficult to follow the degree of surface coverage of the sorbent by the reversed phase; as a result, together with the RP monolayers, polymolecular layers appeared, which actually led to the reversal of the elution sequence of PAH from the column.[78-80] Sorbents with identical types of grafted phases can differ appreciably in their selectivity even if they have been manufactured in the same factory.[81,82] New generation sorbents, namely ODS-3, are almost free from the above disadvantages.[83] The influence of the degree of coverage of the sorbent by the reversed phase on the separation of the PAH can be seen in relation to the retention of the isomeric 1,2-benzoanthracene–1,2-benzophenanthrene pair. On monolayer reversed phases, 1,2-benzophenanthrene is eluted before 1,2-benzoanthracene, while on polymolecular layers the reverse order obtains. For pairs such as anthracene–phenanthrene, pyrene–fluoroanthene, and 1,2-benzopyrene–1,2-benzoanthracene, the separation factors α increase on passing from monolayer to polymolecular layer RP.[58]

The characteristics of the retention of PAH on columns with different degrees of coverage of the sorbent by ODS groups differ significantly. Thus, on a monolayer column with an ODS phase, polyphenylarenes are retained more strongly than condensed PAH.[73,78] It has been shown[84] that two series-connected columns filled with sorbents having different ODS group contents on the surface exhibit the same selectivity in relation to PAH as columns filled with mixed ODS sorbents at different concentrations. Data on the retention of PAH on C_{13} RP, grafted to silica gel,[85-90] surface-porous materials,[85,91,92] porous glass,[86] etc.[93-95] are available in the literature.

The retention of unsubstituted PAH and their homologues is influenced significantly by the composition of the MP,[96] which actually makes it possible to alter the elution sequence of the components (Table 1).[69] In studies with reversed phases, the methanol–water and acetonitrile–water systems are usually employed.[97] In certain cases the separation of complex PAH mixtures and individual pairs, for example, 1,5-naphthalenophanes,[103] is improved by modifying the mobile phase by additives containing sodium sulphonates and perchlorates[98,100] or silver ions (0.001–0.02 M);[101,102] the silica gel surface is treated with cetyltrimethylammonium bromide.[104]

With the increase of temperature, not only are the peaks narrowed but the duration of analysis is reduced. The use of a temperature gradient also makes it possible to separate substances eluted under isothermal conditions in the form of one peak and for certain pairs of compounds the reverse elution order is observed. With increase of the separation temperature, the retention of more condensed PAH diminishes at a higher rate compared with less condensed PAH.[105] The use of plots of the relation $\ln K = f(1/T)$ and of the Gibbs equation permits the calculation of the entropy and enthalpy factors and the estimation of their contributions to the overall retention and the sorption mechanism:

$$\Delta G^0 = -RT \ln K = -RT \ln \frac{c_s^x}{c_m^x} = -RT \ln \frac{V_r - V_m}{V_s}, \qquad (6)$$

where ΔG^0 is the free energy of the transfer of the sorbate between the phases, K the partition coefficient assumed equal to the equilibrium distribution constant, c_S^x the concentration of the sorbate X in the adsorbent, c_m^x the concentration of the sorbate X in the MP, V_r the retention volume, V_m the "dead" volume, and V_S the overall volume of the stationary phase or the overall surface area of the sorbent.

Data obtained using silica gel for grafted ODS groups and the 80:20 acetonitrile–water MP are presented in Table 1.[105] The negative enthalpy changes indicate a high probability of the transition of the sample from the MP to the sorbed state. The absolute entropy change increases with increase of adsorbability. For more condensed PAH, a more rigorous elution sequence on the column is observed. With increase of temperature, the entropy differences become dominant, which alters significantly the partition coefficients of the PAH. Thus the components of the pairs separated with appreciably different entropies (Table 1, group A) are eluted in the reverse sequence, while for components in group B with similar or identical entropies, the usual elution sequence is obtained. We may note that, in order to separate components 18, 23, and 27 (Table 1), characterised by identical ΔS^0 but different ΔH^0, the "enthalpy" factor assumes a decisive role. On the other hand, for components 5, 27, and 29 with identical ΔH^0, one may postulate the "entropy" mechanism of the separation process. The separation of a mixture of components with different thermodynamic parameters is determined by the relative contributions of the factors indicated. In this case it is extremely difficult to predict beforehand the results of the chromatographic separation.

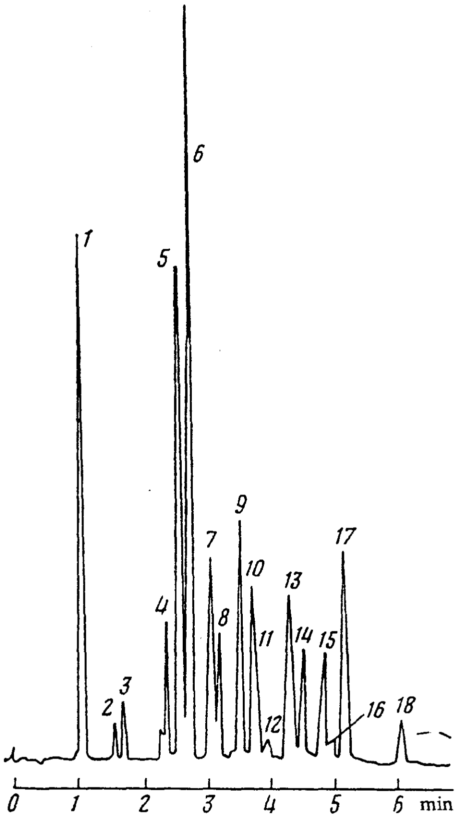

Figure 2. Separation of PAH on a column (125 cm × 4.6 mm) filled with the μ-Bondapak C_{18} sorbent (5 μm) (acetonitrile–water mobile phase; linear concentration gradient of 60–100% of acetonitrile in water over a period of 5 min; eluent flow rate 4 ml min^{-1}; UV detector, 254 mm):[121] *1)* benzene; *2)* admixture; *3)* naphthalene; *4)* fluorene + acenaphthene; *5)* phenanthrene; *6)* anthracene; *7)* fluoranthene; *8)* pyrene; *9)* 3,4-benzofluoranthene; *10)* chrysene; *11)* 1,2-benzanthracene; *12)* admixture; *13)* 1,2-benzopyrene + perylene; *14)* 3,4-benzopyrene; *15)* 1,2,5,6-dibenzoanthracene; *16)* 1,2,3,4-dibenzoanthracene; *17)* 1,12-benzoperylene + 2,3-o-phenylenepyrene; *18)* coronene.

The selection of the composition of the mobile phase and temperature plays an important role in the optimisation of the PAH separation process.[126] By virtue of their exceptional stability, columns with bound RP are widely used in the analysis of PAH by HPLC. The PAH present in carbon black, with molecular weights up to 448, have been successfully separated on such columns.[106] It has been shown that alkylnaphthalenes can be analysed on carbon black.[107] Examples of the gradient elution of PAH mixtures have been fairly widely described in the literature. By altering the composition of their MP, it is possible to achieve not only an acceptable separation and retention but also a change in the elution sequence. With increase of the content of the organic component in the MP, PAH having increasingly higher molecular weights are eluted.[108,109] Both linear and non-linear gradients have been used. The advantages of the employment of the gradient technique in the analysis of PAC have been demonstrated in a number of studies.[110,111,112] For the effective separation of heavy PAH with a molecular weight up to 450, the tetrahydrofuran–acetonitrile–methanol–water four-component gradient system has been proposed.[113]

The separation of PAC on the high performance Vydac 201 TP, C_{18} column (linear gradient; acetonitrile–water MP) has been carried out.[78] The same composition of the MP under gradient conditions has been used for the separation of a model mixture of PAH ranging from coronene to bicoronyl on a column containing Nucleosil 5 C_{18} [114] and also for other PAH mixtures.[115–119] A gradient anhydrous MP, for example a methylene chloride–acetonitrile mixture, can sometimes be usefully employed for the analysis of PAH.[120] The gradient elution of a mixture containing 18 different PAH is illustrated in Fig. 2.[121]

A programmed variation of the flow rate or temperature is sometimes used to improve separation.[21] However, the latter exerts a significantly smaller influence on the retention parameters in liquid chromatography than in gas chromatography.

High resolution chromatography on RP can be readily achieved with gradient elution and the rapid return of such columns to the initial equilibrium and the rapid change to the new composition of the MP makes them very convenient to operate.

The separation of high-molecular-weight PAH in both the normal and reversed phase variants requires a careful selection of the MP. In many studies using isocratic and gradient elution, it has been possible to separate PAH with molecular weights of 400–600.[122–124]

2. Separation on Sorbents with Grafted Polar Groups

Sorbents with grafted polar groups (SGPG) are being increasingly used for the separation of PAH. The groups in alkyl(aryl)silanes, used to modify the surfaces of classical sorbents, contain one or several polar groups (NH_2, NO_2, OH, CN, etc.). The bound organic layer of polar stationary phases is monomeric because the mass transfer across the layer proceeds at a high rate and the mass transfer along the layer becomes minimal. By selecting SGPG with different functional groups, it is possible to vary widely the sorption characteristics.[125] In other words, the separation on SGPG combines the advantages of partition and sorption chromatography. The concentration of functional groups on the silica gel surface is as a rule 3–4 group on 100 Å.[126] The properties of various polar phases suitable for the separation of PAH have been compared.[127]

The mechanism of the retention of PAH on SGPG is fairly complex. Here one must take into account the interaction between the π-electron systems of the sample components and various structures on the polar surface.[128] Unsubstituted PAH are eluted in order of increasing molecular weight[129] and ponents which cannot be separated on a non-polar RP.[130]

The characteristics of the retention of more than 90 unsubstituted and alkyl-substituted PAH on a polar phase containing amino-groups have been described.[78] It was noted that the retention of the PAH increases with increasing number of aromatic nuclei in the molecule. In contrast to the usual columns with RP, the presence of alkyl groups in the PAH molecules influences only insignificantly the retention sequence, which makes it possible to use the above phase for preliminary fractionation in the analysis of complex mixtures. Furthermore, the use of volatile non-polar MP facilitates the concentration of the collected fractions.

The separation of PAH on a polar phase containing aminopropyl groups has been investigated.[131,132] The non-polar MP were cyclohexane and the polar phases were methanol–water or acetonitrile–water mixtures. In the former cases the separation was attributed to the interaction of the unshared electron pair of the N atom and the π-electrons of the PAH and in the latter to the partition effect due to the employment of MP of high polarity and the mixed adsorption-partition effects in MP with a lower polarity.

A complex mixture of aromatic hydrocarbons and alcohols, which included also naphthalene and anthracene, has been successfully separated[133] on a column with aminated Lichrosorb.

The retention parameters of 32 PAH on the usual columns with silica gel and on columns with SGPG have been compared[134] and considerable differences in the retention volumes and capacity coefficients have been detected. According to the authors, the cyclic amide SGPG phase interacts with the PAH via both the normal-phase and reversed-phase mechanisms, exhibiting at the same time specific features in the separation process. This results in a significant change in the separation factors for the individual pairs and in the elution sequence of the components. Thus, on a normal-phase sorbent, 9,10-diphenylanthracene and phenanthrene emerge as a single peak, while on SGPG these compounds are separated (the selectivity was 3), phenanthrene emerging first.

PAH have been analysed on grafted phases containing nitrile, diol, ethyl, quaternary ammonium, and amino- and diamino-groups.[135,136,296] The phase with diamino-groups proved to be the most selective. The use of a system comprising two columns—one with a polar phase and another with a non-polar phase—is even more promising for the study of complex PAH mixtures.[137] The characteristics of the separation of a number of PAH, their nitrogen-containing analogues, and biaryls have been investigated[71] on silica gel modified with polar nitrophenyl groups. For each of these groups of compounds analysed, a linear relation was observed between the logarithm of the retention of the components and the number of carbon atoms in the molecule. Furthermore, the PAH were readily separated from their nitrogen-containing analogues owing to the greater polarity of the latter. In a number of studies Nucleosil 100-5 NO_2 has been used successfully for the analysis of heavy PAH.[138–140]

Blumer et al.[141] separated coal tar on a nitrophenyl phase into more than 100 components. In contrast to capillary gas chromatography, where only 30% of the composition of the resin can be determined, on the nitrophenyl phase up to 70% of the composition has been isolated by the HPLC method. Using the nitrophenyl phase, it has been possible to separate PAH of complex composition with molecular weights up to 600.[122] It has been found[142] that, under HPLC conditions, the nitrophenyl phase is preferable for the analysis of PAH present in dust to the amine phase and RP C_{18}. The characteristics of the retention of PAC on the nitrophenyl phase have not so far been investigated in detail.

Phases with other polar groups, for example, nitrofluoreneimine,[143,144] picramidopropyl,[145] 3-(2,4-dinitroanilino)-propyl,[146] and phthalimidopropyl[147] groups, are also suitable for the separation of PAH. With the aid of the last phase, 1,12-benzofluoranthene and perylene were separated and the reverse elution sequence of the components of the binary 3,4-benzopyrene–1,2-benzopyrene mixture was noted compared with the C_{18} phase. Stationary SGPG phases, forming charge-transfer complexes with PAH, are entirely suitable for the separation of complex PAC mixtures into di-, tri-, and poly-aromatic compounds.[148]

Studies of the relation between the capacity factor k' and the molecular structure of PAH have been published.[149,313,318] A sufficiently distinct regularity in the deviation of the k' (Table 2) on passing from different silica gels with grafted phases to pure silica gel has not been observed on phases of different polarity in the separation of a number of PAH. Examination of the selectivity in relation to pairs of compounds difficult to separate has also revealed a scatter of the relevant values. For example, in the separation of the anthracene–phenanthrene pair the selectivity assumes values from 0.94 to 1.46, while for the anthracene–fluorene pair it ranges from 1.09 to 2.30, etc. The use of other factors (F and L/B) for the calculation of the capacity factor is fruitful when these are present simultaneously in an equation of the type

$$k'=aF+b(L/B)+c\ , \qquad (7)$$

where F = number of double bonds + number of primary and secondary carbon atoms—0.5 (for a non-aromatic nucleus) and a, b, and c are column constants.

Table 2. Characteristics of the retention of PAH on various stationary phases.[149]

Substance	F	L/B	Capacity factor, k'						
			C_2	C_p	C_8	C_{18}	S_{N_1}	S_{N_2}	S
Benzene	3.0	1.10	1.89	2.00	1.48	1.05	0.48	0.19	0.48
Naphthalene	5.0	1.24	3.01	3.55	2.22	1.67	1.42	0.50	1.06
Fluorene	6.5	1.57	4.40	5.29	2.89	2.44	2.68	0.76	1.92
Acenaphthylene	5.5	1.08	3.35	4.24	2.49	2.03	2.58	0.93	1.48
Anthracene	7.0	1.57	4.81	6.27	3.36	3.20	3.47	1.75	2.16
Phenanthrene	7.0	1.46	4.49	5.86	3.14	2.99	3.68	1.20	1.70
Pyrene	8.0	1.27	5.56	7.47	3.80	3.97	5.55	1.68	2.40
Fluoranthene	8.0	1.27	5.59	7.42	3.80	3.97	5,55	1.68	2.40
Chrysene	9,0	1,72	7.13	10.4	4.88	5.93	9.03	2,50	3.44
Naphthacene	9.0	1.89	8.28	11.4	5.27	7.18	8.71	2.54	3.31
Triphenylene	9.0	1,12	6.45	9.34	4.67	5.48	9.19	2.63	3.11
3,4-Benzopyrene	10.0	1,50	9.06	13.8	6.75	9.86	11,8	3.70	3.98

Notation: C_2 = dimethylsilica gel, C_p = phenylsilica gel, C_8 = octylsilica gel, C_{18} = octadecylsilica gel, S_{N_1} = Fine SIL-NH_2, S_{N_2} = Lichrosorb-NH_2, and S = pure silica gel.

A reliable method for predicting the parameters of the chromatographic retention of various PAH has been proposed;[256] a high correlation coefficient (0.97–0.99) was obtained in all cases. The authors began with the fact that the logarithm of the capacity factor of the molecule can be represented as the sum of the logarithms of the capacity factor of its constituent fragments. The method is suitable for any type of chromatographic separation (adsorption, partition, or a mixed type). For the majority of PAH, the calculated capacity factors are satisfactorily correlated with experimental data over a wide range of polarities of the mobile and stationary phases. The isomeric 2,7- and 2,6-dimethylnaphthalenes are exceptions, but this in no way reduces the advantages of the new method, which can be extended to PAH derivatives after the appropriate correction of the calculated data.

IV. THE APPLICATION OF MICROPACKED AND CAPILLARY COLUMNS FOR THE ANALYSIS OF PAH

The increase of the molecular weight of PAH leads to a rapid increase of the number of isomers, which requires the application of high performance columns and a more careful selection of the MP. The efficiency of the system can be increased by connecting several columns in series.[151] However, this entails an increase of the pressure drop and of the duration of the analysis. Furthermore, a large pressure drop entails the heating of the silica gel particles owing to friction, which leads to additional spreading of the peak.[150]

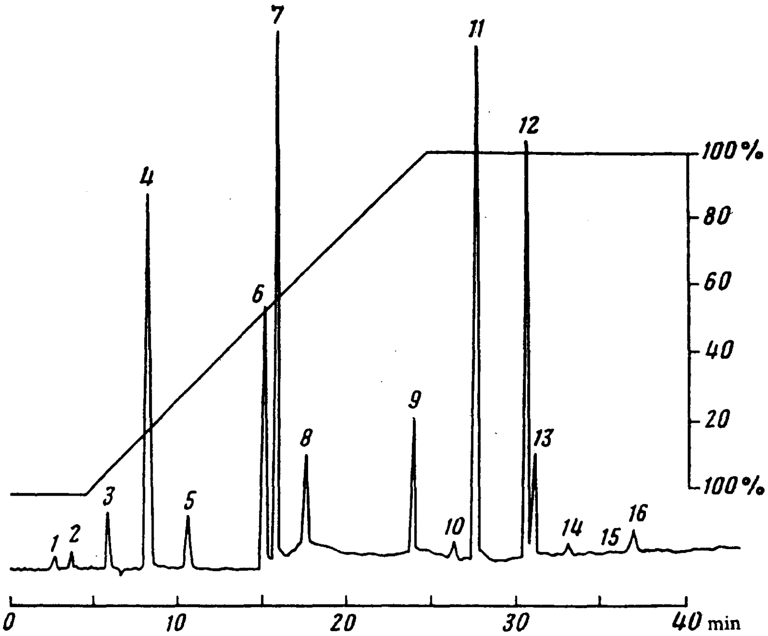
Micropacked, capillary, and microcapillary columns are being increasingly used nowadays for the analysis of complex PAH mixtures. These columns have a number of advantages, which include (1) the possibility of employing a combination of a chromatograph with a mass-spectrometer or a flame-ionisation detector, (2) high efficiency (more than 10^5 theoretical plates), which permits the separation of extremely complex mixtures, (3) a decrease of the consumption of the MP by a factor greater than 20, which permits a much wider use of expensive and toxic solvents, (4) an increase of the sensitivity of the determination of the components by a factor greater than 20, and (5) the need for very small amounts of the specimen in the analysis (less than 1 μl). Microcolumn liquid chromatographs, with the aid of which it is possible to solve a wide variety of research and technical problems, have received wide recognition in our country and abroad. Soviet investigators have used successfully the Ob'-4 and Milikhrom chromatographs for the analysis of PAC.[152]

Packed microcolumns are quite efficient. For example, a 1 m × 1 mm column filled with Partisil ODS/10 μm has an efficiency up to 30 000 theoretical plates (t.p.). A complex mixture of PAH extracted from coal has been separated on this column.[312] A battery of 14 series-connected columns of this kind has an efficiency of 650 000 t.p.[153] A multicomponent mixture of PAH has been separated on 100 × 0.12 mm and 100 × 0.340 mm ultramicrocolumns filled with ODS SC-01 silica gel.[154,155]

Capillary packed columns have an even greater efficiency,[156] which is calculated from the relation $H \leq 3d_p$ (d_p is the particle diameter). Thus the efficiency of a 1 m× 320 μm column filled with ODS silica gel (particle size 3 μm) is 110 000 t.p.; a 2 m × 300 μm column with the same filler has an even greater efficiency—144 000 t.p. (with respect to pyrene for k' = 10). Both columns have been used successfully for the identification of PAC contaminating the environment.[153,157]

A capillary column whose inner surface has been treated with silicone SE-30 proved to be highly efficient for the analysis of a model mixture of PAH.[158,308] The heavy aromatic fraction of coal tar has been separated[159-161] on a 55 m × 70 μm column filled with alumina (particle size 30 μm) having grafted ODS groups. The use of a glass capillary column on the inner surface of which a layer of silica gel modified by cetyltrimethylammonium bromide has been deposited[162,310] is also promising. The separation of PAH on such a column proceeds similarly to the separation on a capillary column with grafted ODS groups.

In order to reduce the duration of analysis, it is useful to employ gradient elution for the separation of PAH having a complex composition.[163,164,311] An example of such separation on a packed capillary column is illustrated in Fig.3.



3. Gradient separation of PAH on a 66 cm × 250 μm column filled with Vydoc 201 TP silica gel (5 μm).[163] The variation of the composition of the MP during analysis is shown above: *A*) 65% acetonitrile + 35% water; *B*) 80% acetonitrile + 20% dimethoxyethane. Sample composition (the amount in ng is given in brackets): *1*) naphthalene (20); *2*) acenaphthylene (4); *3*) acenaphthene (20); *4*) fluorene (4); *5*) phenanthrene (2); *6*) anthracene (2); *7*) fluoranthene (4); *8*) pyrene (2); *9*) 1,2-benzoanthracene (2); *10*) chrysene (2); *11*) 3,4-benzofluoranthene (4); *12*) 1,12-benzofluoranthene (2); *13*) 3,4-benzopyrene (2, detectable minimum amount 50 pg); *14*) 1,2,5,6-dibenzoanthracene (4); *15*) 1,12-benzoperylene (4); *16*) 2,3-*o*-phenylenepyrene.

Microcolumns and capillary columns with MP of different polarity have been used to separate PAH in supercritical (fluid) chromatography. Hydrocarbons (pentane, butane, and isobutane), dimethyl ether, carbon dioxide, nitrous oxide, etc. have been used as the MP. Multicomponent PAH mixtures[166–168] as well as the PAC present in soot,[306] in the exhaust gases of automobiles,[169] and in coal tar[170] have been successfully separated with the aid of microcolumn liquid chromatography.

Despite their evident advantages, capillary columns are being fairly slowly introduced into chromatographic practice. The reasons are failure to develop as yet a reproducible method for the preparation of these columns, the absolute need for a new system for the introduction of the sample, inadequately improved pumps working at very high pressures, and, in addition, the need for very small flow cells in the detection of the components, for which one can usefully employ the "tail" section of a glass column. Micropacked columns are extremely promising.[171,172]

V. DETECTION SYSTEMS

The principal advantages of the analysis of PAH by the HPLC method are due to the possibility of employing highly sensitive and selective detectors. The molecules of aromatic compounds are known to be capable of absorbing ultraviolet light and certain PAH exhibit an intense fluorescence. Detectors working in accordance with the above principles have come to be widely used in the analysis of PAH by liquid chromatography.[173] Aromatic solvents cannot be used as MP, but this does not create difficulties in the selection of the eluent. There are fairly numerous different solvents which exhibit a minimal absorption at the wavelength employed for detection.

1. Ultraviolet Detectors

Although various PAH and their analogues differ somewhat in the absorption of UV light at fixed wavelengths, the detection of substances in amounts not exceeding several nanogrammes is quite feasible. The use of UV spectrophotometers permits the selection of the optimum wavelength for the detection of specific components of PAH.[174] A UV detector with a variable wavelength is quite often used to increase the selectivity.[175–177] The complete UV spectra have been used[114] to identify PAH after separation by HPLC. For analysis, it is useful to measure the relative absorption of PAH at several wavelengths.[178,179] The advantages of UV scanning with stopped flow for identification of PAH peaks have been demonstrated.[180,181] By altering the wavelength in the UV region it is possible to control successfully the content of, for example, 3,4-benzopyrene in the presence of perylene at 290 nm or of pyrene in the presence of fluoranthene at 360 nm.[175] Detection with a variable wavelength under the conditions of reversed phase separation[182] make it possible to detect fairly readily 3,4-benzopyrene in coal tar.

In order to determine the maximum number of components, it is useful to employ rapid scanning and multi-wavelength detectors[183–185] with Fourier transformation.[186] The sensitivity of the determination of PAH can be increased by using weakly pulsating pumps. Pumps of the syringe type which do not give rise to pulsations in the flow are best for this purpose.[187]

Definite information can be obtained by using two combined detectors tuned to different wavelengths[188,189] and also by combining UV detectors with a fluorimetric detector.[190–192] The sensitivity of the determination of PAH can be increased with the aid of a detector based on the use of the Cherenkov effect,[193], etc,[194–197]

2. Fluorimetric Detectors

The rapid growth of the manufacture of fluorimetric detectors for HPLC is due to their selectivity with respect to condensed PAH[198,199] and high sensitivity.[173,200,201] The analysis of admixtures whose amount does not exceed 10–100 pg then becomes entirely realistic. It is believed[202–204] that PAH detection limits below 10^{-12} M are entirely attainable when laser-excited fluorescence is employed. At the same time the use of fluorescence detection can sometimes lead to inaccurate estimates of mixture compositions, because the signal intensities at different wavelengths are not the same. Under these conditions, the signals of a series of PAH components can diminish appreciably and can even disappear.[205]

Fluorimetric filters and spectrofluorimeters are used to determine PAH in air-borne dust,[176] in the exhaust gases from diesel engines,[204] in cigarette smoke,[206] and in various petroleums and oils.[207–209] The fluorescence peak intensity rations under different conditions of the excitation of the fluorescence have been used to identify 17 different PAH present in food, water, and tobacco smoke.[210]

In certain studies attempts have been made to improve the technique of the fluorimetric detection of PAH in systems in the environment.[211–214] In particular, the use of a narrow-band filter greatly improved the sensitivity of the determinations of the readily separated PAH; however, for poorly separated peaks, the best results are given by a monochromator.[211] A two-photon laser fluorescence detector[215–217] and a detector based on β-induced fluorescence[218] have been used successfully to analyse various asphaltenes.

The sensitivity of a fluorescence detector increased significantly when an MP with added dodecyl sulphate was used.[219] The selective extinction of the fluorescence of certain PAH in the presence of nitromethane has been investigated.[198,220,221] The addition of 0.5% of nitromethane to the MP significantly extinguishes the fluorescence of non-fluoranthene PAH (the fluorescence of anthracene is not fully extinguished).[220]

Table 3. Conditions in the analysis of PAH contained in various objects within the environment.

Object of analysis	Sorbent	Composition of mobile phase	Detector	References
Petroleum	Bio-Sil ODS-10	methanol - water, G	UV	[257]
Petroleum	Spherisorb C_{18}	methanol - water (80 : 20)	F	[258] ([230, 259, 260])
Petroleum, shale, coal liquefaction products	Chromegabond $(NH_2)_2$	hexane - methylene chloride, G	UV	[261]
Ditto	Woelm alumina	hexane - methylene chloride, G	UV	[261]
"	2,4-dinitroanilinopropylsilica gel	hexane - methylene chloride, G	UV	[261]
Bitumens, motor oils	Partisil 5	hexane	UV	[262] ([263])
Ditto	Corasil C_{18}	methanol - water (75 : 25)	UV, F	[264] ([265])
Heavy petroleum fractions, coal tar	Nucleosil NO_2, NH_2, CN, SA, Lichrosorb Si 60, Alox T; Spherisorb A5U	hexane; hexane - methylene chloride, G	UV	[266] ([304])
Coal tar, pitch	Lichrosorb, μPorasil	cyclohexane	UV	[182]
Ditto	μBondapak, C_{18}	acetonitrile - water (60 : 40)	UV	[182]
Coal tar	alumina C_{18}	acetonitrile, acetonitrile - dichloroethane, G	F	[160] ([307])
Coal pitch	Lichrosorb RP-8	water - acetonitrile - dimethylformamide, G	UV	[123]
Ditto	Nucleosil 100-5NO_2	hexane - chloroform, G	UV	[140] ([267])
Coal tar and petroleum processing products	HC-ODS	tetrahydrofuran-acetonitrile (70 : 30)	UV, F	[268]
Ditto	PAH/10	acetonitrile - water, G	F	[268] ([31, 191])
Coal liquefaction products	μBondapak, C_{18}	methanol - water (65 : 35)	UV	[74, 269]
Ditto	Partisil PXS 10/25 ODS	acetonitrile - water (70 : 30)	F	[203] ([239, 240, 270, 271, 317])
PAC hydrogenation products	Lichrosorb RP-18	methanol - water, G	UV	[272]
Tobacco smoke	Micropak C-H "Varian"	methanol - water, G	UV	[6]
Air contaminants	Vydac 201 TP	acetonitrile - water (70 : 30)	F	[273]
Ditto	Fine SIL C18-10	acetonitrile - water (70 : 30)	F	[274]
"	Lichrosorb NH_2	iso-octane	UV	[142]
"	Nucleosil 5 NO_2	iso-octane - methylene chloride (9 : 1)	UV	[142]
"	Lichrosorb RP-18	acetonitrile - water (85 : 15)	UV	[142] ([9, 81, 118, 119, 176, 187, 192, 205 - 281])
Water contaminants	Lichrosorb RP-18	methanol - water (85 : 15)	F	[282]
Ditto	PAC 254-400 "Contron"	methanol, acetonitrile	UV	[283]
"	Perkin-Elmer HC-ODS	acetonitrile - water, G	UV	[201]
"	Perkin-Elmer HC-ODS	aqueous solution of acetonitrile (38%) and methanol (15%)	F	[284]
"	μBondapak C_{18}	acetonitrile - water (80 : 20)	F	[285] ([286-290, 309])
Deposits on sea bottom, marine organisms	Lichrosorb RP-18	acetonitrile-water, G	UV	[291] ([292-295])
Exhaust gases from engines	Lichrosorb RP-18	acetonitrile-water (80:20)	UV	[296]
Ditto	Zorbax TM ODS	methanol-water (8:1)	F	[85]
"	Spherisorb ODS	methanol-water, G	UV	[297] ([250, 298-300, 316])
Automobile fuel	Fine SIL C_{18}-10	acetonitrile-water (80:20)	F	[302]
Barley malt	Zorbax ODS	methanol-acetonitrile-water, G	UV, F	[303]

Notation: G = gradient elution, UV = ultraviolet detector, F = fluorimetric detector. The additional literature relevant to the object of analysis is indicated in round brackets.

Only the peaks of PAH of the fluoranthene series, namely fluoranthene, 3,4-benzofluoranthene, and 11,12-benzofluoranthene, remain on the chromatogram (Fig.4). The addition of a fluorophor, for example, aniline, to the MP makes it possible to detect both fluorescent and non-fluorescent PAH.[222]

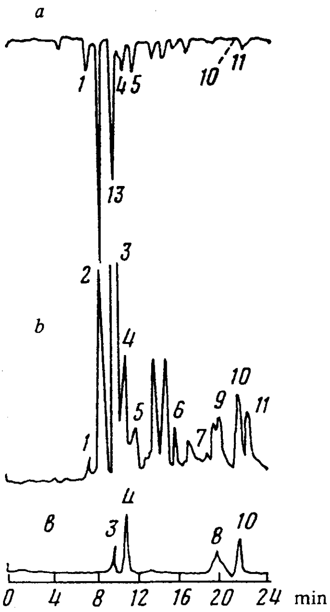


Figure 4. Separation of an extract from coal tar on a reversed phase: *a*) detection at 254 nm; *b*) fluorescence detection; *c*) detection with fluorimetric quenching (0.5% of nitromethane in the MP).[200] Column filled with Vydoc 201 TP silica gel (10 μm); mobile phase—linear gradient of 50—100% of acetonitrile in water over a period of 25 min; eluent flow rate 2 ml min^{-1}. Sample composition: *1*) fluorene; *2*) phenanthrene; *3*) anthracene; *4*) fluoranthene; *5*) pyrene; *6*) 10,11-benzofluoranthene; *7*) 1,2-benzopyrene; *8*) 3,4-benzofluoranthene; *9*) perylene; *10*) 11,12-benzofluoranthene; *11*) 3,4-benzopyrene.

Multichannel rapidly scanning spectrometers have been employed[223] for the detection of eluates containing PAH, for example, for the determination of the origin of oil slicks.[223] A fluorimetric detector combined with computer techniques and a data bank has been used successfully for the analysis of complex PAH mixtures.[224] The employment of a rapidly scanning device with a photodiode detector and a computer is promising for the optimisation of the composition of the MP.[314]

3. Other Detection Methods

The HPLC and mass-spectrometric methods have been combined successfully in recent years for the separation and identification of complex PAH mixtures.[225–231] This approach proved to be fruitful for the analysis of both model mixtures[154, 232–236] and coal liquefaction products containing heavy aromatic hydrocarbons.[237–240]

Various ionisation procedures which make it possible to differentiate isomeric PAH are used to detect mass-spectrometrically the PAH eluted from the column, namely electron impact, chemical ionisation, and, much more rarely, field ionisation and field desorption. The reliability of the method is determined both by the selection of the ionisation procedure and of suitable masses, which are characteristic for the substances to be determined.[5,241] Detectors employing proton magnetic resonance,[242] IR spectroscopy,[243] and other spectroscopic methods combined with computer techniques[244] and Fourier transformation[186] have also been described.

It is noteworthy that even the use of the most selective and effective columns in the analysis by the HPLC method does not permit the complete separation of isomeric PAH in complex mixtures. For a greater reliability of the data obtained, it is useful to combine HPLC with gas chromatography and mass spectrometry[160,245–251] and also various spectroscopic methods,[6, 252–255] which makes it possible to increase significantly the amount of information derivable from the analytical results.[256]

VI. ANALYSIS OF PAH IN VARIOUS OBJECTS WITHIN THE ENVIRONMENT

Table 3 presents the conditions for the analysis of PAH contained in various objects within the environment. It is seen that the use of adsorption chromatography permits the solution of a very limited range of problems. Furthermore, the long duration of the analytical cycle is a significant disadvantage in routine analyses of complex mixtures.

---o0o---

It follows from the data described that the separation of PAH on reversed phases grafted to the spherical particles of wide-pore silica gel having a small diameter (3—5 μm) is much more effective (when both non-polar and polar grafted groups and appropriate eluents are employed). Gradient elution can be usefully applied in the study of PAH forming part of the composition of petroleum, coal tar, the products of their processing, and contaminated water and air. Good results have been obtained following the combined application of UV and fluorescence detectors. Computer techniques make it possible to detect, in particular, the UV spectra of individual PAH in the course of chromatographic separation and to compare them with the available information. Methods in which HPLC is used in combination with mass spectrometry, ^{1}H NMR, ^{13}C NMR, and other methods have been developed for the identification of unknown PAH. Computer techniques can then make it possible to reduce to a minimum the time consumed in comparing the data obtained and to increase the accuracy of the analytical determination.

Detailed Kinetic Mechanism of the Combustion of Homogeneous Gaseous Mixtures with Participation of Oxygen-containing Oxidants

V.Ya.Baevich

The kinetic mechanisms of the oxidation and combustion of hydrogen, methane, methyl alcohol, acetylene, ethylene, ethane, and methylamine, using oxygen as well as hydrogen peroxide and nitric acid as oxidants, are discussed. The calculated and experimental data obtained under static conditions, in a flow, during flame propagation, and in shock tubes are compared. The bibliography includes 184 references.

I. INTRODUCTION

The aim of the present review is a joint examination of the available kinetic schemes for the oxidation of hydrogen, hydrocarbons, and their derivatives, which permit the construction of fairly general detailed kinetic mechanisms (DKM) of oxidation and combustion processes. It has been found that, despite the individual differences between the initial molecules of the fuel and the oxidant, the atomic composition of such molecules is important for the course of the reaction. Depending on this composition, the same or different intermediate species are formed which determine the character of the interaction. Even when all the reaction channels are not know accurately and despite extremely approximate values of the rate constants being frequently employed, it is possible to achieve by computation a fairly satisfactory description of the kinetics of experimental processes.

We may note that, although the questions analysed below are of intrinsic importance, they constitute a small part of the general kinetic theory whose foundations have been laid in a number of fundamental monographs and textbooks (see, for example, Refs. 1–10).

The number of fuels and oxidants used in practice and important for the theory of combustion processes is very large. Fuels having a complex multicomponent composition are usually employed. However, at the present time one may hope to be able to construct detailed kinetic mechanisms only for an extremely limited number of simplest fuel–oxidant pairs, which are the subject of the exposition below. Complex compositions can be modelled by simpler ones but even the latter have frequently a direct practical application.

II. HYDROGEN AND HYDROGEN PEROXIDE

The principal characteristics of the DKM of combustion can be illustrated in relation to the oxidation of hydrogen. The mechanism of the oxidation of hydrogen has become one of the first DKM in the study of which many fundamental postulates of chemical kinetics were developed and tested, including the theory of branched processes.[1,2,6,7,11-19]

Extensive experimental data referring to the oxidation of hydrogen, mainly in the region of the ignition peninsula, and all the known fundamental elementary stages of the process were described, i.e. in essence a DKM had been constructed, already in a monograph of Nalbandyan and Voevodskii[8] and then in the studies of Semenov[1] and Kondrat'ev[7] [Table 1, reactions† (1), (-4), (-6), (7), (-8), (-11), (-14a), and (-83)].

In these studies it is possible to find all the fundamental features of simple and branched chain hydrogen oxidation reactions (as well as the oxidation reactions of hydrocarbons and other combustible substances), including those accompanied by a rise of temperature, and the relevant communications give compilations of numerous experimental and calculated data and comparisons which provide a quantitative justification of the theory. A general solution of many ignition problems can be found with the aid of the following approximate system of equations:[2,7,16]

$$\frac{\mathrm{d}n_j}{\mathrm{d}t}=\sum_i w_{ij} \ , \tag{I}$$

$$\rho C\frac{\mathrm{d}T}{\mathrm{d}t}=\sum_{ij} h_{ij}w_{ij}+\frac{\varkappa S}{V}(T-T_c) \ , \tag{II}$$

where n_j is the concentration of species j, t the time, T the temperature, ρ the density, C the heat capacity, and ω_{ij} and h_{ij} are respectively the rate and heat of reaction in the ith elementary step with participation of the jth component, κ is the coefficient of heat evolution in the wall of the reaction vessel, S and V are respectively the surface and volume of the reaction vessel, and T_c is the temperature of the vessel wall. The usual initial conditions apply: $t = 0$, $n_j = n_{j0}$, and $T = T_0$.

Later communications contain a series of revisions which specify in greater detail the mechanism of the combustion of hydrogen. Thus a mechanism has been proposed[17] for the oxidation of hydrogen under conditions remote from the ignition peninsula, namely under detonation conditions characterised by high temperatures and pressures. For this reason, a number of bi- and tri-molecular processes involving the recombination of active centres, which in this case play a significant role owing to the high concentration of atoms and radicals, have been included in the mechanism [Table 1, reactions (11)–(13), (19), and (83)].

It has been established[18,19] that the mechanism of the ignition reaction of hydrogen–oxygen mixtures, proposed by Nalbandyan and Voevodskii[8] and supplemented by recombination processes of the kind described above is very suitable for the description of the propagation of a laminar flame. This follows from a comparison of the calculated and experimental data for the rate of heat evolution Σhw in the reaction zone at low pressures P (Fig.1). A theoretical basis for such calculations is provided by the system of equations describing the stationary one-dimensional propagation of the flame:[2,7,16]

$$\frac{\mathrm{d}}{\mathrm{d}x}D_j\rho\frac{\mathrm{d}(n_j/\rho)}{\mathrm{d}x}-\rho_0u_n\frac{\mathrm{d}(n_j/\rho)}{\mathrm{d}x}+\sum_i w_{ij}=0 \ , \tag{III}$$

$$\frac{\mathrm{d}}{\mathrm{d}x}\lambda\frac{\mathrm{d}T}{\mathrm{d}x}-\rho_0u_n\frac{\mathrm{d}CT}{\mathrm{d}x}+\sum_{ij} h_{ij}w_{ij}=0 \ , \tag{IV}$$

where x is the coordinate of the propagation of the flame, λ the thermal conductivity, u_n the laminar rate of propagation of the flame, ρ_0 and ρ are respectively the initial and current densities, and D_j is the diffusion coefficient of the jth component of the chemical reactions. The boundary conditions at $x = 0$ and $x = 1$ (end of the reaction zone) are as follows:

$$\left(T-\frac{\lambda}{\rho_0u_nC}\frac{\mathrm{d}T}{\mathrm{d}x}\right)\bigg|_{x=0}=T_0;\quad\left(n_j-\frac{\rho D_j}{u_n\rho_0}\frac{\mathrm{d}n_j}{\mathrm{d}x}\right)\bigg|_{x=0}=n_{j0};$$

$$\frac{\mathrm{d}T}{\mathrm{d}x}\bigg|_{x=l}=0;\ \frac{\mathrm{d}n_j}{\mathrm{d}x}\bigg|_{x=l}=0 \ .$$

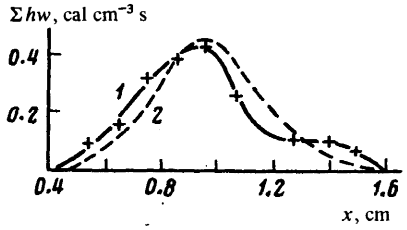

Figure 1. Dependence of the rate of heat evolution on the coordinates in the reaction zone;[19] $[H_2]_0 = 7.2\%$, $[O_2]_0 = 92.8\%$, $T = 295$ K, $P = 0.068$ atm, rate of propagation of the flame $u_n = 19.6$ cm s^{-1}: *1*) experiment; *2*) calculation (here and henceforth volume percentages are quoted).

The rate of heat evolution profile was calculated from the material balance equations (III) in which the terms describing the appearance and consumption of each substance were set up on the basis of the kinetic scheme [Table 1, reactions (1), (-4), (-6), (7), (11), (12), (17), and (28)]. Readings of the non-inertial resistance thermometer on a spherical bomb with central ignition were used to determine $T(x)$.[18]

Here it is necessary to make certain general remarks concerning the rate constants. For certain reactions, these quantities have been frequently measured by different workers and fairly similar results have been obtained. However, frequently there is a large scatter in the experimental values. In such cases (and these are in the majority) it is sometimes difficult to find arguments for the justification of the *a priori* selection of the value of the rate constant and the problem is solved by comparing the calculated data with the results of experiments carried out under different initial conditions. Special attention has been devoted in the present review to such comparisons. Furthermore, we may note that processes corresponding to the exothermic direction of the reaction are regarded as forward processes, while those involving the endothermic direction of the reaction are regarded as reverse processes. Strictly speaking, it is necessary to take into account all the forward and reverse processes. However, in each specific calculation one needs to consider only those which contribute appreciably to the development of the process.

---

† Here and henceforth M is any third species removing or supplying energy; the minus sign refers to the reverse reaction.

Table 1. Combustion mechanisms.

*The reactions are grouped in terms of substances; the numbering used in the original papers has been retained.

**The combination of the Arrhenius parameters of these processes selected for the description of cold flames.[94]

The mechanisms indicated above describe satisfactorily the course of the reaction in an atomic-oxygen hydrogen flame when oxygen atoms and molecular hydrogen are rapidly mixed in the stream.[95] An important part of the scheme, particularly at pressures close to and above the second limit, are reactions involving hydrogen peroxide.[96] The latter is formed during the oxidation of H_2 as an intermediate and the allowance for such reactions makes it possible to achieve a satisfactory agreement between the calculated and experimental second ignition limits.[96]

A fairly universal DKM, describing the hydrogen oxidation and combustion reaction over a wide range of temperatures, pressures, and mixture compositions, should apparently contain a greater number of elementary steps than in the calculations quoted above. It should consist of at least three parts including (a) chain initiation, propagation, branching, and linear termination processes when the rate of termination is proportional to the concentration of the active centre (with a power exponent of unity under all conditions), (b) quadratic termination processes the rate of which is proportional to the square of the concentration of the active centre, i.e. recombination reactions (at high concentrations of the active species at high temperatures and for high degrees of combustion), and (c) reactions involving hydrogen peroxide, which make a large contribution at high pressures.

A fairly detailed mechanism, incorporating more than 20 processes satisfying the above requirements, has been described in a number of communications[2,97–99] (the first 22 forward and reverse processes in Table 1). The validity of this DKM has been tested by a series of calculations modelling the self-ignition and combustion in the spreading flame.

In self-ignition, the initial reaction stage is not outwardly manifested in any way and a sharp increase in the rate of reaction and evolution of heat, passing into explosion, are observed only after a certain time, called the self-ignition delay, has elapsed. Calculation of the self-ignition delay time makes it possible to follow the initial stages of the reaction, where the concentration of the initial reactants hardly changes.

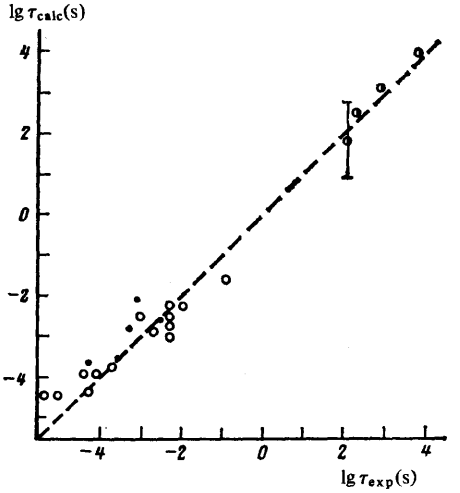

Figure 2. Comparison of the calculated[30,46,97,98] and experimental self-ignition delays; $[H_2]_0$ = 1–8%, $[CH_4]_0$ = 2–33%, $[O_2]_0$ = 1–67%, T = 696–2130 K, P = 0.167–5 atm (according to the data in Refs.100–112).

An example of a comparison of hydrogen ignition delays, measured and calculated on the basis of the DKM on the assumption that a purely branched chain process takes place, is given in Fig.2 (filled symbols). The delays were calculated with the aid of a standard program by solving a system of material balance equations (I). A sharp increase in the rate of the chemical reaction, indicating the occurrence of self-ignition, was adopted as a criterion at the end of the delay. The experimental data refer to the temperature range 979–2130 K and the pressure range 0.23–5 atm. Evidently the discrepancy between the measured and calculated delay does not exceed one order of magnitude.

We shall now proceed to the examination of reactions in a mixture containing hydrogen peroxide as the initial reactant. Since hydrogen peroxide occurs in the DKM (Table 1), the latter can be used without any changes. The mechanisms of the reactions of H_2O_2 have been investigated in a number of studies. Thus the rate constant for reaction (−28) has been determined[113] for the conditions prevailing at the beginning of the thermal decomposition of H_2O_2 (Table 1). In another study[32] the investigation was carried out under flow conditions at low pressures. The authors determined the important rate constants for reactions of H_2O_2 with hydrogen and oxygen atoms. Under these constants, calculations have been performed[27] on the basis of the DKM for the conditions of the experiment adopted in previous calculations.[32,113] Thus the experimental[32] and calculated concentrations of H_2, H, O, O_2, H_2O, and H_2O_2 in the reaction of H_2O_2 with O (453 K, 0.124 atm) were compared; a comparison was also made of the experimental[113] and calculated $[H_2O_2]$ and $[HO_2]/[H_2O_2]_0$ in the H_2O_2 decomposition reaction (1060 K, 6.2 atm) as a function of the reaction time and of the yield of H_2O_2 as a function of its initial concentration in the reaction of the peroxide with the products of a discharge in a hydrogen–oxygen mixture containing hydrogen atoms $\{[H]_0$ = 0.04%$\}$ and hydroxy-radicals $\{[OH]_0$ = 0.0114%$\}$ at 803 K, a pressure of 0.01 atm, and for a reaction time of 1.7 ms. It was found that the calculations permit a qualitatively correct description of the course of the reaction of H_2O_2 in the temperature range 453–1060 K and in the pressure range 0.01 to 6.2 atm.

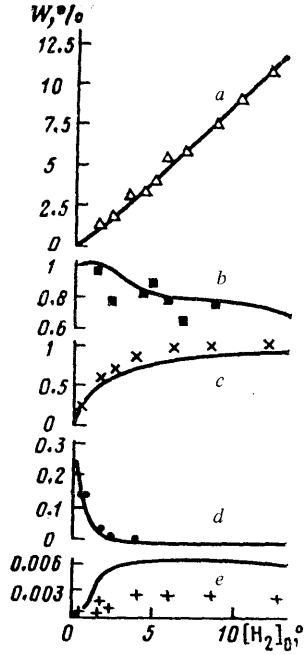

Figure 3. Dependence of the yield of the reaction products on the initial H_2 concentration for the oxygen atomic flame with hydrogen;[28] $[O]_0$ = 0.5%, $[O_2]_0$ = 0.82%, T = 1169 K, P = 0.01 atm, t = 2.5 ms: symbols—experiment; lines—calculation; a) H_2; b) O_2; c) H; d) O; e) OH.

It has been shown[27] that failure to take into account the reactions of hydrogen peroxide at 803–1038 K near the ignition peninsula in the combustion of hydrogen–oxygen mixtures can lead to appreciable errors, but at temperatures above 1200 K these reactions can be disregarded.

As the kinetics and rate constants for different stages are refined, it becomes possible to obtain a more accurate and reliable description of the hydrogen combustion process. This can be seen from the comparison of the calculated and experimental yields of the products obtained for the atomic-oxygen hydrogen flame[28] (Fig.3).

The results of numerous studies on the mechanism of the combustion of hydrogen are also presented in a review,[114] in a monograph,[115] a number of communications,[116–118] etc. They consider the mechanisms involving virtually the same reactions as those listed in Table 1. Thus one may note the unity of the views of different investigators concerning the principal processes in the DKM of the oxidation of hydrogen. We may also note that algorithms have been proposed in a number of studies, for example in Refs.115 and 116, for the identification of the reactions important under the specific conditions considered and for the construction of abbreviated kinetic schemes.

III. C_1–C_2 HYDROCARBONS AND METHANOL

1. The Combustion of Methane

The experience gained in the study of the mechanism of the combustion of hydrogen has shown that the chemical reaction can be described with a satisfactory accuracy under most varied conditions. The next step as regards complexity involves the construction of the DKM for the oxidation and combustion of methane (including the combustion of carbon monoxide and formaldehyde appearing as intermediates).

Extensive experimental data on the kinetics of the oxidation of methane, referring mainly to the region of low temperatures (below 900 K), have been examined in monographs and communications.[1,6,12,13,111,112,119,120]

On the basis of data for the low-temperature oxidation and high-temperature processes in flames, a number of workers[43,48,121–123] demonstrated that reactions involving the active centres of the hydrogen–oxygen flame (OH, H, and O) and molecular hydrogen play an important role in the conversion of methane. Thus, according to Westenberg and Fristrom,[121] the methane oxidation reaction# in the flame proceeds as follows:

$$CH_4+OH\rightarrow CH_3+H_2O, \qquad (31)$$

$$CH_4+O\rightarrow CH_3+OH, \qquad (35)$$

$$CH_3+O_2\rightarrow H_2CO+OH, \qquad (57)$$

$$H_2CO+OH\rightarrow HCO+H_2O. \qquad (43)$$

$$HCO+OH\rightarrow CO+H_2O, \qquad (68)$$

$$CO+OH\rightarrow CO_2+H, \qquad (21)$$

$$H+H_2O\rightarrow OH+H_2, \qquad (-1)$$

$$O+H_2\rightarrow OH+H, \qquad (-6)$$

$$OH+OH\rightarrow H_2O+O, \qquad (9)$$

$$H+O_2\rightarrow OH+O, \qquad (-4)$$

$$O+O+M\rightarrow O_2+M. \qquad (12)$$

The basis of the mechanism formulated here is the reactions of the active centres O and OH with the initial methane and the reactions ensuring the degenerate chain branching by hydrogen. The principal direction of the transformation corresponds to the sequence

$$CH_4\rightarrow CH_3\rightarrow H_2CO\rightarrow HCO\rightarrow CO\rightarrow CO_2.$$

Molecular hydrogen and water also appear during the reaction.

Quantitative calculations, carried out approximately within the framework of the mechanism described above, enabled a number of workers[124–126] to describe satisfactorily the experi-experimental data.

In a number of studies[30,97–99] an attempt was made also simultaneously to elucidate to what extent the reaction scheme based on a mechanism similar to that described above but including a greater number of possible elementary steps with participation of species involved in the scheme proposed by Westenberg and Fristrom[121] may be universal. It is essential to elucidate also the contributions of these new reactions to the DKM and to determine whether their introduction is really necessary. The scheme under test is wholly based on the DKM of the oxidation of hydrogen and numerous probable but as yet uninvestigated reactions of the radicals generated during the combustion of methane (CH_3, CH_2, CH, and HCO) have been introduced. The possible elementary steps were selected taking into account their probable rates on the basis of the following rules: all reactions (apart from several active centre initiation reactions) with a high activation energy were excluded; also excluded were almost all the reactions accompanied by a change in multiplicity (in conformity with the Wigner rule). Analysis showed that the methane oxidation pathway leading to the final product involving the CH species is less probable than other possible pathways and this species and its reactions were not therefore included in the scheme.

Ultimately the kinetic mechanism incorporating processes ranging from (1) to (74) in Table 1 was adopted. It does not include several well known reactions. Among them in the recombination of methyl radicals with formation of ethane, which takes place in accordance with the equation

$$CH_3+CH_3\rightarrow C_2H_6. \qquad (2c)$$

Analogous processes lead to the formation of other hydrocarbons. These reactions are followed by the interactions of hydrocarbons with the active centres, etc. Allowance for all these reactions entailed a very great increase in the complexity of the mechanism. In the proposed scheme chain termination as a result of the recombination of methyl radicals is simulated by reaction (42).

The rate constants were taken from the literature sources and, when these were lacking, the activation energy was determined from semiempirical formulae:[1] for exothermic reac-reactions, $E = 11.5 - 0.25h$ for $h \leq 46$ and $E = 0$ for $h > 46$; for endothermic reactions, $E = 11.5 + 0.75h$ (h is the heat of reaction in kcal mol^{-1} [127]). The pre-exponential factor A for a bimolecular reaction is approximately 10^{-11} cm^3 $molecule^{-1}$ s^{-1} (6×10^9 litre mol^{-1} s^{-1}). The values of A and E for the reverse reactions have been calculated from the equilibrium constants given by Gurvich et al.[127] If the activation energy for the endothermic process is smaller than h for the reaction, then the activation energy for the reverse process is found to be negative. In this case an extremely high rate constant may be obtained at low temperatures. This is a consequence of the deviation of the temperature variation of the rate constant from the Arrhenius straight line and must be taken into account in the calculations at low temperatures. Naturally, the parameters of the rate constants thus obtained

---

#Here and henceforth the numbers of reactions are given in accordance with Table 1.

constitute only an extremely rough and approximate estimate. The values of A and E obtained in the calculations have been corrected when necessary. Clearly, in the presence of a large number of roughly estimated parameters the correction can also be fairly approximate. The total number of elementary reactions in the initial version of the DKM reached 86 (the forward and reverse processes).[30]

The DKM obtained was tested primarily in the calculation of the arrest of the self-inflammation over a wide range of initial conditions: temperatures from 979 to 2130 K, pressures from 0.167 to 3 atm (Fig.2, open symbols). At the same time, the yields of products in the shock tube and in the atomic flame of methane were modelled. The products formed in such a flame (0.01 atm) have been analysed in greater detail by Basevich et al.[37]

Comparison of all these calculations with experiments yielded yielded more or less satisfactory results. An acceptable agreement has been obtained in the description of the propagation of the methane flame.[128] In the latter case the calculation was performed using Eqn.(III) on the assumption of a stepwise temperature rise in the combustion zone:

$$x<0,\ T=T_0\ ,$$
$$x\geqslant 0,\ T=T_c.$$

The values of T_c and the rates of propagation of the flame were specified on the basis of experimental data.[129] Account was taken only of reactions which make the greatest contribution to the process under specific conditions of the calculation.

The extension of the DKM described above to the low-temperature region did not require any fundamental changes.[46] It has been possible to calculate the reaction half-lives in satisfactory agreement with experiment up to hundreds of minutes (Fig.2, half-filled symbols). The processes significant for the DKM, whose contribution to the yield of products throughout the range of calculated conditions is either between 10 and 100% (approximately 30–40 elementary steps including certain forward and reverse reactions) or between 1 and 10% (a further approximately 30 processes) have been selected on the basis of the calculations performed. If account is taken of the possible occurrence of the above reactions in the forward and reverse directions, then one obtains 2 × 55 processes including also processes (5d) and (4d), which were added later—see below. We may note that the processes have been selected by Basevich et al.[46] by comparing the integrals of the rate of reaction over the periods covered by the calculation:

$$I=\int_{\tau} w_{ij}\,dt\,. \qquad \text{(V)}$$

Such comparison showed that methane is consumed mainly in the processes

$$CH_4+OH\rightarrow CH_3+H_2O \qquad (31)$$

and

$$CH_4+H\rightarrow CH_3+H_2. \qquad (33)$$

The main source of H atoms is the reaction

$$H_2+OH\rightarrow H_2O+H\,. \qquad (1)$$

Water is formed in the reactions

$$CH_4+OH\rightarrow CH_3+H_2O, \qquad (31)$$

$$H_2CO+OH\rightarrow HCO+H_2O, \qquad (43)$$

and

$$H_2+OH\rightarrow H_2O+H. \qquad (1)$$

Carbon monoxide is obtained in the processes

$$HCO+M\rightarrow H+CO+M \qquad (-66)$$

and

$$HCO+O_2\rightarrow CO+HO_2\ , \qquad (70)$$

while carbon dioxide is produced in the reactions

$$CO+OH\rightarrow CO_2+H, \qquad (21)$$

and

$$CO+HO_2\rightarrow CO_2+OH. \qquad (24)$$

The greatest yield of hydrogen is obtained from the process

$$CH_4+H\rightarrow CH_3+H_2\,. \qquad (33)$$

Degenerate branching takes place at the H_2O_2, H_2, and H_2CO molecules. After the selection of the leading reactions steps, it was found that at 700–1000 K the rate of branching is a maximum due to the process

$$H_2O_2+M=OH+OH+M\,, \qquad (-28)$$

while at T > 1200 K the main branching process becomes the reaction

$$H+O_2=OH+O. \qquad (-4)$$

The addition of reactions (87)–(91) and (2c) from Table 1 to the kinetic scheme for the combustion of methane proposed by Basevich et al.[46] makes it possible to model, on the basis of Eqns.(I) and (II), the reaction in the region of cold flames and the cold-flame flash[94] observed by Vanpee[130] (here it is necessary to take into account the thermal regime in the reaction). Furthermore, it is necessary to modify the Arrhenius parameters of the rate constants for stage (57) which had given rise to doubts (the new values are A = 1.56 × 10^9 litre mol^{-1} s^{-1} and E = 25 kcal mol^{-1}). Analysis of the solution showed[94] that the mechanism of the cold flame includes the initial activation of the oxidation reaction and subsequent inhibition owing to the thermal decomposition of the peroxy-radical, the formation of formaldehyde from the latter, and the interaction of formaldehyde with the leading active centres. Additional tests showed that the changes in the kinetic parameters introduced for the description of the cold flame do not affect the calculated characteristics of the reaction outside this region.

Criteria have been proposed[131] for the estimation of the accuracy of the calculations based on the DKM for the combustion of methane. Quantities characterising the deviation of the experimental parameters X_{exp} from the calculated X_{calc}, i.e.

$$pM=\lg\left(X_{calc}/X_{exp}\right)$$

have been calculated for the eight DKM for the oxidation of methane proposed in the literature. The induction period, the coefficient in the exponent defining the growth of the concentration of CO_2 during the induction period (β_{CO_2}), and the analogous coefficient for the chemiluminescence of the excited radical CH* (β_{CH^*}) and the CO molecule (β_{CO}) (Table 2) were adopted as the parameters. The values of pM obtained,[132] corresponding to the DKM for the oxidation of methane proposed by Basevich et al.[46], are presented in Table 2; the average logarithm of the deviation of the calculated quantities is 0.03 and the mean square logarithm of the deviation is 0.33 (the deviation corresponds to a coefficient of ~2). In general, these deviations are not worse than the values calculated by Olsen and Gardiner[131] especially since the experimental parameters selected by the authors[131] were in no way optimised.

Table 2. Comparison of the calculated and experimental parameters of the oxidation of methane.

Parameter X	T, K	P, atm	Composition, % (remainder-Ar)			Value of X		pM	
			CH_4	CO	O_2	experiment*	calculation (Ref.132)	from Ref.132	from Ref.131
τ, s	1750	0.28	1.67	—	3.33	$1.38\cdot10^{-3}$	$0.34\cdot10^{-3}$	−0.61	−0.72÷0.56

$d[CH_3]/dt$, mol $cm^{-3}s^{-1}$	1820	10	1	—	2	$3.9\cdot10^{-4}$	$3.5\cdot10^{-4}$	−0.05	
$\Delta[CH_4]_{rel}$	2200	0.25	9	—	1	0.017	0.0081	−0.32	−0.8÷0.02
$\Delta[CH_4]_{rel}$	2500	0.25	9	—	1	0.01	0.014	0.15	

Notation: τ is the induction period, Δt_{max} the time from the start of the reaction until the attainment of $\{[CO][O]\}_{max}$, and $\Delta[CH_4]_{rel}$ is the change in the relative concentration after $(0.2-2)\times10^{-4}$ s.

*According to Olson and Gardiner.[131]

A kinetic mechanism of the combustion of methane has also been described in other communications,[117,133–137] etc.

2. Combustion of Methyl Alcohol

The study of the combustion of CH_3OH is important intrinsically and also because methanol is usually formed as a side product in the combustion of methane and other hydrocarbons. A possible mechanism of the oxidation of methanol has been examined[51] in relation to its flame with atomic oxygen. We shall now turn to the kinetics of this process.

In the primary step of the interaction of oxygen atoms with methanol, the CH_2OH radical and the hydroxylradical are apparently formed.[138,139] Formaldehyde, which has also been considered[140] as a primary product, appears in our view in a subsequent elementary step involving the interaction of CH_2OH with O and H atoms, with the hydroxylradical, and molecular oxygen. Qualitatively the same picture holds also in the case where the methoxyradical is obtain instead of the alcohol radical.

There are no grounds for the belief that the subsequent course of the reactions of formaldehyde and the resulting molecular hydrogen involves any specific stages characteristic solely of the oxidation of methanol. It most probably involves the same processes by which they react as intermediates in the oxidation of methane. This has been confirmed by the study of the characteristic features of the formation of carbon monoxide, hydroxylradicals, and atomic hydrogen in the course of the O + CH_3OH reactions.

Thus, a quantitative description of the interaction of methanol with oxygen atoms requires the addition of the processes specified above of the reactions of methanol and the radical [Table 1, reactions (1a)–(9a)]. Among these reactions, at the beginning of the investigation[51] only the rate constants for reactions (1a) and (3a) were known. For the remaining seven reactions, the rate constants were adopted on the basis of semiempirical estimates. In the CH_3OH reaction mechanism these processes are then followed[51] by the reactions of formaldehyde and its formyl radical, carbon monoxide, and hydrogen. At sufficiently high temperatures, this mechanism presupposes the occurrence of a chain reaction, formaldehyde and hydrogen playing the role of intermediates ensuring degenerate branching.

On the basis of this mechanism, kinetic calculations have been made of the yields of all the analysed reaction products at a constant temperature and pressure.[51] Qualitative agreement between calculation and experiment has been observed. The maximum coefficient of deviation does not exceed 5.

The calculations performed make it possible to estimate the role of individual steps in the overall mechanism of the oxidation of CH_3OH.[51] We shall now consider the reactions of methanol and its radical. The interaction of CH_3OH with with oxygen atoms [reaction (1a)] initiates oxidation and its rate determines to a large extent also the degree of reaction. However, the reactions of CH_3OH with OH [reaction (2a)] and H [reaction (3a)], formed during the reaction, also influence the yields of all the products although to a much smaller extent. Thus an increase of the rate constant k_{2a} by an order of magnitude alters the yield of H_2CO, CO, and H by 5–9%. The increase of the rate constant k_{3a} (according to the data of Aders[141]) alters the yields of H_2CO, CO, and H_2 by 5–20%. The yields of all the products depend especially strongly on the rate constants for the reactions of CH_2OH with O, H, and OH; when these quantities are varied within the limits of one order of magnitude, the corresponding yields change from several to hundredths per cent. The reaction of CH_2OH with O_2 is less important: the analogous change in the constant alters the yields of products by less than 10%. The high activation energies for reactions (−4a) and (−5a) show that they can play a significant role only in the absence of initiation and at high temperatures. Calculations have shown that, under the given conditions, the reactions of hydrogen peroxide also influence the yields of all the products albeit only slightly.[51]

The kinetic mechanism of the combustion of methanol has likewise been considered in other studies.[137,142,143]

3. The Combustion of Acetylene

Kinetic mechanisms of the oxidation of acetylene have been proposed in a number of studies (for example in Refs.144 to 147) and the rate constants of certain elementary stages have been determined. Although these mechanisms differ, they also have much in common. According to the majority of investigators, the main reactions involving the consumption of acetylene in the combustion of weak mixtures are

$$O+C_2H_2\rightarrow CO+CH_2 \qquad (1d)$$

and

$$OH+C_2H_2\rightarrow CO+CH_3\ . \qquad (2d)$$

In addition, there is no doubt that other reactions in which acetylene is consumed also occur, in particular, the reaction of H atoms with C_2H_2. Presumably the kinetics of the subsequent reactions of the carbon monoxide and methyl and methylene radicals formed in the stages (1d) and (2d) are similar to those which obtain in the combustion of methane. This makes it possible to construct a theoretical scheme for the oxidation of acetylene–oxygen mixtures, based on the general ideas concerning the combustion of methane, which is sufficiently complete for the description of all the main reaction products.[49] However, this scheme is unsuitable for the description of the combustion of rich mixtures of acetylene and of its cracking, since this process includes heterogeneous stages which have not been investigated.

According to Basevich et al.[49], the combustion of acetylene begins with two reactions in which it is consumed [reactions (1d) and (2d)] and this is followed by branching as a result of the reactions

$$CH_2+O_2\rightarrow CO+OH+H \qquad (5d)$$

and

$$CH_2+O_2\rightarrow CO_2+2H \qquad (4d)$$

(see Table 1). The second reaction has been discussed in the literature (for example, in Refs.147 and 148). Calculations have shown[49] that the inclusion of even one of them ensures the necessary rate of propagation of the flame. The subsequent part of the mechanism corresponds to the DKM for methane [reactions (1)–(14), (14a), (17), (17a), (17d), (19), (21), (24), (26), (27), (28), (29a), (30)–(33), (35), (42)–(45), (46a), (47), (48), (54), (57), (59), (66), (68), (69), (70), (70a), (83), and (1d)–(5d) in Table 1].

This mechanism is applicable also in the region of relatively low temperatures, since the reactions of hydrogen peroxide, which play an appreciable role in the region $T < 1200$ K, are fairly completely represented here. Table 1 also indicates the Arrhenius parameters of the rate constants for reactions (1d) and (2d) taken from the literature. The rate constants for reactions (5d) and (4d) were selected by calculation. A stepwise temperature rise in the reaction zone is postulated. The calculations were performed for the conditions used in the study of Eberius et al.[147], in which the yields of the final and intermediate products generated in a planar acetylene flame were obtained. In these experiments the conditions were as follows: $[C_2H_2]_0 = 7.2\%$, $[O_2]_0 = 89.2\%$, the remainder comprising He and Ar; $P = 0.0144$ atm and $T = 960$ K. It follows from the comparison of the experimental and calculated[49] profiles that, when no account is taken of reactions (5d) and (4d), it is essential to adopt a somewhat high rate constant for the reaction

$$CO+OH\rightarrow CO_2+H\ . \qquad (21)$$

On the other hand, if one adopts an "average" rate of reaction (21) with the Arrhenius parameters $A = 2.9 \times 10^9$ litre $mol^{-1}\ s^{-1}$ and $E = 5.7$ kcal mol^{-1},[34] then it is necessary to include step (5d) or (4d) with a fairly high rate constant ($\sim 1.8 \times 10^6$ litre $mol^{-1}\ s^{-1}$). It is noteworthy that the inclusion of reaction (5d) or (4d) in the methane oxidation mechanism hardly affects the calculated rate of combustion of methane, since in this case the formation of CH_2 is a side reaction.

The calculated and experimental concentrations of the products in the reaction zone agree well with one another and one may conclude that the mechanism is reliable and that the choice of reaction rate constants is correct. One can also conclude that the mechanisms of the oxidation of acetylene and methane are similar, which permits the use of a single approach to their description.

The kinetic mechanism of the combustion of acetylene has also been described in other communications.[117,137,149,150]

4. The Combustion of Ethylene

Experiments have shown[151–153] that the C=C bond is broken in the oxidation of ethylene by oxygen atoms and that products characteristic of the combustion of methane are formed. This makes it possible to construct a theoretical scheme for the combustion of a weak ethylene–oxygen mixture which is sufficiently complete for the description of the yields of all the main reaction products.[57] A broader and more detailed mechanism of the reaction, necessary for the description of the combustion of rich mixtures, remains, however, outside such a scheme.

The most probable primary steps in this reaction involve the interaction of C_2H_4 with oxygen atoms and hydroxylradicals. The former is apparently the main reaction, since in weak mixtures the concentration of atomic oxygen is usually highest. According to the literature,[151–153] the reaction of C_2H_4 with oxygen atoms proceeds in accordance with the equation

$$C_2H_4+O\rightarrow CH_3+HCO. \qquad (1b)$$

The less important reactions of C_2H_4 have also been less thoroughly investigated. The reaction of C_2H_4 with OH is of this kind and three possible pathways have been proposed for it:[57]

$$C_2H_4+OH\rightarrow CH_3+H_2CO\ , \qquad (2b)$$

$$C_2H_4+OH\rightarrow CH_4+HCO\ , \qquad (2b')$$

$$C_2H_4+OH\rightarrow C_2H_3+H_2O\ . \qquad (2b'')$$

Analytical data have shown[151] that the formation of acetylene C_2H_2 and of the vinyl radical C_2H_3 has been observed in the combustion of ethylene. As already mentioned, the main pathway in the reaction of C_2H_4 in weak mixtures apparently leads immediately to the rupture of the C=C bond, it follows that the formation of C_2H_2 and C_2H_3 is a side process. For this reason, without risking the distortion of the overall picture of the oxidation of C_2H_4, one may attempt to describe in a general form the kinetics of their formation and consumption which have been investigated to only a fairly slight extent. Certain possible reaction pathways, proposed previously by various investigators, were selected for a quantitative test,[57] namely the formation of C_2H_3 via reactions (2b″) and

$$C_2H_4+H\rightarrow C_2H_3+H_2\ , \qquad (-3b)$$

$$C_2H_4+O_2\rightarrow C_2H_3+HO_2 \qquad (-4b)$$

and its consumption via the reactions

$$C_2H_3+O\rightarrow CH_3+CO\ , \qquad (6b)$$

$$C_2H_3+OH\rightarrow CH_3+HCO\ , \qquad (7b)$$

$$C_2H_3+H \rightarrow C_2H_2+H_2\,, \qquad (8b)$$

$$C_2H_3+O_2 \rightarrow C_2H_2+HO_2\,. \qquad (9b)$$

The possible ethylene decomposition reaction

$$C_2H_4+M \rightarrow C_2H_2+H_2+M\,. \qquad (-5b)$$

must be added to the last two reactions, which lead to the formation of acetylene.

The Arrhenius parameters of the reaction rate constants, which in general differ from one another, were known for only three of the processes enumerated above [reactions (1b), (2b), and (5b)]. The values of *A* and *E* for reaction (1b) were taken from Basevich et al.[57], who obtained them by averaging the data from a number of studies;[151–153] those for reaction (2b) were taken from Greiner's data[58] and those for reaction (−5b) were obtained from Kozlov and Knorre[59] (Table 1). Semiempirical estimates were adopted for the remaining reactions. C_2H_2, CH_4, CH_3, H_2CO, HCO, CO, H_2, HO_2, and H_2O, whose further reactions were considered above, are formed in the reactions enumerated. For this reason, the subsequent part of the mechanism involves the DKM for acetylene and methane [in the study of Basevich et al.[57] these were reactions (1b)–(9b), (1d), (2d), (5d), (1)–(14), (14a), (17), (17a), (17d), (19), (21), (24), (26), (27), (28), (29a), (30), (31)–(35), (38), (39), (40), (42)–(45), (46a), (47), (48), (50), (53)–(57), (59), (65), (66)–(69), (70), (70a), (71), (72), (74), (83), (86) from Table 1].

The kinetic curves were calculated[57] for the experimental conditions adopted by Peeters and Mahnen,[151] who provided the most detailed data on the compositions of the ten final and intermediate products generated in a planar ethylene plane. The conditions in these experiments were as follows: $[C_2H_4]_0 = 6.55\%$, $[O_2]_0 = 33.45\%$, $P = 0.0535$ atm, and $T = 1900$ K. The calculated and experimental concentrations agreed in order of magnitude, the agreement being best on the assumption of a single channel in reaction (2b). Hence one may conclude that the reliability of the reaction mechanism underlying the calculation is fairly high.

Naturally the analytical results depend to a large extent on the choice of the reactions and rate constants; however, despite this they are of interest. The contributions of different elementary processes can be most conveniently estimated from the integral *I* [see Eqn.(V)]. The main pathway leading to the consumption of ethylene is, as was in fact assumed, reaction (1b); reaction (2b) has the lowest rate. The replacement of reaction (2b) by (2b′) makes the calculated concentration of methane higher by almost two orders of magnitude. The reaction pathway (2b″) yields a calculated concentration $[C_2H_3]$ twenty times higher than the experimental value. If account is taken only of the interaction of C_2H_4 with O and OH [reactions (1b) and (2b)] and at the same time all the processes associated with the reactions of C_2H_3 and C_2H_2 [(3b)–(9b), (1d), and (2d)], then one obtains in this instance the concentrations of products which agree in order of magnitude with their experimental values {naturally in this calculation it is assumed that $[C_2H_3] = [C_2H_2] = 0$}.

The main process responsible for the appearance of acetylene is

$$C_2H_4+M \rightarrow C_2H_2+H_2+M\,, \qquad (-5b)$$

while the reaction

$$C_2H_4+H \rightarrow C_2H_3+H_2 \qquad (-3b)$$

is responsible for the appearance of the C_2H_3 radical. The main processes leading to their consumption are respectively

$$C_2H_2+O \rightarrow CH_2+CO \qquad (1d)$$

and

$$C_2H_3+O_2 \rightarrow C_2H_2+HO_2\,. \qquad (9b)$$

It is important to note that the fastest branching process under the given conditions, as in the vast majority of cases of high-temperature oxidation of hydrocarbons, is the reaction

$$H+O_2 \rightarrow OH+O\,, \qquad (-4)$$

while the main source of hydrogen atoms is the process

$$HCO+M \rightarrow H+CO+M\,. \qquad (-66)$$

Examination of the overall results of the calculations and their comparison with kinetic data for methane and acetylene flames apparently permit the conclusion that the mechanisms of the combustion of various hydrocarbons are very similar and that hydrogen plays an important role as an intermediate oxidation product.

The kinetic mechanism of the combustion of ethylene has also been considered in other communications,[117,137,154,155] etc.

5. The Combustion of Ethane

The search for reaction schemes describing the combustion of all the more complex hydrocarbons (C_2H_6, C_3H_8, etc.) is important for both chemical kinetics and for practical purposes. The proposed mechanisms are apparently still not yet sufficiently schematic and are conventional in character. The mechanism of the combustion of ethane must naturally include the scheme for the oxidation of yet another stable intermediate—acetaldehyde.

At an early stage of the development of the DKM, two more or less detailed mechanisms of the combustion of ethane were proposed and analysed quantitatively. In one of them,[156] the dissociation of the carbon–carbon bond with formation of methyl radicals was considered as the primary step:

$$C_2H_6 \rightarrow CH_3+CH_3\,. \qquad (-2c)$$

The formation of CH_3 is characteristic also of the oxidation of methane. The author[156] therefore assumed that the subsequent reactions fully correspond to the mechanism of the oxidation of CH_4. The arbitrary nature of this solution is evident, because the rate of decomposition of C_2H_6 can in general be lower than the rate of its reaction with the principal active centres of the reaction—the hydroxylradical OH and the H and O atoms. In a second study[157] the primary reactions considered in the oxidation of ethane involved its interaction with OH, H, O, and O_2, leading to the abstraction of a hydrogen atom and the formation of hydrocarbon molecules and radicals, which in their turn react in the same way. According to this mechanism,[157] the carbon chain is ruptured only in the interaction of the C_2H_2 and C_2H formed with O and O_2 respectively, which leads to the appearance of CH_2, CO, and CHO. Thus the extremely probable reactions of the ethyl radical, which involve the rupture of the C–C bond or the formation of oxygen-containing species, were altogether excluded from consideration.

The mechanism of the combustion of ethane considered below was proposed by Basevich and Kogarko[64] and is based on the probable analogy of the mechanisms of the combustion of C_2H_6 and CH_4; in it additional allowance was made for a large number of reactions proposed previously by various workers, including those associated with acetaldehyde [Table 1, reactions (2c)–(28c)]. In the first six reactions [reactions (2c)–(7c)], the decomposition of ethane as well as the formation of ethyl radicals are postulated. Next, in contrast to the study of Cooke and Williams,[157] certain possible reaction pathways, involving the interaction of C_2H_5 with OH, H, and O and leading to the rupture of the C–C bond and the formation of alkyl radicals and oxygen-containing species [reactions (8c)–(11c)], were introduced.

When the reaction of C_2H_5 with the O_2 proceeds by analogy with the reaction between CH_3 and O_2, it can afford CH_3CHO and OH or, when the C–C bond is ruptured, H_2CO and CH_3O are formed [reactions (12c) and (13c)]. It has been suggested that CH_3CHO then reacts with dissociation of the C–C bond [reactions (−17c) and (−20c)] and with abstraction of the latter in the unimolecular reaction (−21c) or in reactions with H and O [reactions (22c) and (23c)]. The next group of reactions [reactions (24c)–(28c)] agrees in broad outline with the direction of the transformation via ethylene described by Cooke and Williams.[157]

All the processes described above result in the formation of products (H_2, H_2O_2, H_2CO, HCO, CH_4, CH_3, CH_2, CH_3O, C_2H_4, and CO) which also occur in the mechanisms of the combustion of CH_4, CH_3OH, C_2H_2, and C_2H_4; the list of the elementary processes involved in the oxidation of C_2H_6 should therefore be supplemented by the reactions of the latter compounds.

Table 1 indicates the Arrhenius parameters of the rate constants for the above reactions. The values of *A* and *E* were taken from the literature sources quoted, were selected in the calculations, or were estimated approximately from semiempirical formulae.

At sufficiently high temperatures, the mechanism proposed presupposes the occurrence of a branched chain reaction, hydrogen playing the role of the intermediate ensuring degenerate branching.

Calculations[64] have been carried out for two main versions. In the first account was taken of all the reactions involved in the mechanism. In order to elucidate whether the ethane dehydrogenation pathway[157] is the rate determining pathway in ethane combustion and whether the experimentally observed reaction products can be formed, in principle, without following this pathway, in the second version of the calculation all the reactions of the ethyl radical leading to the formation of ethylene were excluded. For the eight products investigated, a qualitative agreement has in general been observed between calculation and experiment.

The published literature data make possible an additional test of the mechanism considered. It follows from the theoretical analysis of the results of experimental studies of the atomic oxygen flame of ethane,[158] the oxidation of $CH_3.CHO$,[159,160] and the ignition delays[157,161,162,163] that the oxidation pathway involving the reactions of C_2H_5 with dissociation of the C–C bond and the formation of alkyl radicals and oxygen-containing species is entirely feasible, like the dehydrogenation pathway. The simultaneous occurrence of the reaction via both channels is extremely likely; however, it is difficult to trace the details of the process by observing the overall kinetics. Judging from the value of the integral *I*, the main substances participating in the reaction (substances whose concentrations are comparable in order of magnitude with the concentrations of the initial compounds consumed and of their reaction partners) are, according to the second version of the calculation, C_2H_6, OH, H, O, HO_2, HCO, CH_3, H_2, H_2O, H_2O_2, CO, CO_2, H_2CO, C_2H_5, O_2, and CH_4. Considerations of the values of *I* permits the conclusion that ethane is consumed mainly in its reaction with OH, H, O, and M. On self-ignition at low temperatures, the highest branching rate is given by the process

$$H_2O_2+M\rightarrow OH+OH+M, \tag{-28}$$

while at high temperatures (>1200 K) the reaction is

$$H+O_2\rightarrow OH+O. \tag{-4}$$

The dissociation of the C–C bond in the atomic flame takes place via the reaction

$$C_2H_5+O\rightarrow CH_3+H_2CO, \tag{11c}$$

while in the remaining cases it occurs in the reactions of C_2H_5 with O_2 and OH and in the decomposition of CH_3CHO. Atomic hydrogen is formed in the reaction

$$O+OH\rightarrow O_2+H \tag{4}$$

or in the decomposition of the formyl radical,

$$HCO+M\rightarrow H+CO+M, \tag{-66}$$

while molecular hydrogen is formed in the reaction of H with C_2H_6, CH_4, and H_2CO. Water appears as a result of the reactions of C_2H_6, H_2, and H_2CO with OH; carbon monoxide is produced by the reaction of HCO with O_2 and M, and carbon dioxide is formed by the reaction of CO with OH and HO_2. Thus the reaction mechanism is in many respects similar to the mechanism of the combustion of CH_4, by analogy with which it has in fact been constructed.

The lack of experimental data at the present time precludes a rigorous selection of the reaction pathways and of all the elementary steps. Table 1 does not include many of the known reactions. There is no doubt that the mechanism discussed must be regarded as preliminary, requiring confirmation and refinement on the basis of a wide variety of experimental data.

The kinetic mechanism of the combustion of ethane has also been analysed in other studies,[137,164,165] etc.

IV. NITROGEN-CONTAINING COMPOUNDS

Methylamine is the simplest amine among those used in the combustion technology independently or as a fuel additive. The knowledge of the mechanisms of the combustion of such compounds is essential for the description of the energy evolution and for the understanding of the kinetics of the formation of the final products, some of which are environmentally undesirable.

The H–C–N–O system is very complex but the availability of data on the kinetics of the combustion of H_2 and C_1–C_2 hydrocarbons with O_2 justifies attempts to construct the combustion mechanism also in this involved case. The construction of a mechanism of the combustion of methylamine is considered below in relation to the atomic oxygen flame.[69] The initial endeavour of the authors[69] to make do with a small number of reactions was unsuccessful; for this reason, subsequently their efforts were directed to the construction of a more or less detailed mechanism.

By analogy with many of the known reactions involving oxygen atoms, one can assume that the abstraction of a hydrogen atom from the molecule being oxidised is extremely probable in the primary step. The C–H bond (93.7 kcal mol^{-1}) is stronger than the N–H bond (87.2 kcal mol^{-1}).[166] One can therefore postulate that the hydrogen abstraction reaction proceeds in accordance with the equation

$$O+CH_3NH_2\rightarrow CH_3NH+OH. \tag{2.1}$$

The hydroxylradical formed in reaction (2.1) and the atomic hydrogen obtained via the reaction

$$O+OH\rightarrow O_2+H \tag{4}$$

can react with the initial molecules in the processes

$$OH+CH_3NH_2\rightarrow CH_3NH+H_2O, \tag{2.2}$$

$$H+CH_3NH_2\rightarrow CH_3NH+H_2. \tag{2.3}$$

The reactions involving the generation of active centres, i.e.

$$CH_3NH_2\rightarrow CH_3+NH_2, \tag{-2.4}$$

$$CH_3NH_2+O_2\rightarrow CH_3NH+HO_2. \tag{-2.5}$$

may be important for self-ignition at high temperatures and in the presence of O_2. Further reactions can be represented only very tentatively. Atomic oxygen and also H, OH, and O_2 can give rise ultimately to species of the type CH_3, CH_3O, CH_4, HNO, NH, and NH_2 on interaction with CH_3NH. However, there are no objective criteria which would make it possible to discover, on the basis of the available experimental data, the processes leading to their formation. For this reason, the reactions presented below should probably be regarded as overall processes:

$$CH_3NH+O \rightarrow CH_3O+NH\ , \qquad (2.6)$$

$$CH_3NH+OH \rightarrow CH_4+HNO\ , \qquad (2.7)$$

$$CH_3NH+H \rightarrow CH_3+NH_2\ , \qquad (2.8)$$

$$CH_3NH+O_2 \rightarrow CH_3O+HNO\ . \qquad (2.9)$$

Starting with the set of species formed in these reactions, it is possible to formulate the subsequent processes (they are also included in Table 1). The reactions of CH_4 and CH_3 in the presence of atomic oxygen were considered earlier in the methane oxidation scheme and, together with the corresponding parameters, they can be usefully adopted as a component of the mechanisms investigated. This also applies to the reactions of the CH_3O radical.

The reactions of the NH, NH_2, and HNO species formed in the processes enumerated above have also been frequently considered by various investigators (for example, by Albers et al.[78]). The rate constants for some of them are known and are presented in Table 1 [see reactions (2.10) to (2.27)]. They include processes involving the possible formation of NH_3. This part of the scheme should describe also the oxidation of NH_3 constituting, together with the reactions in the H–O system, an important part of the DKM for the H–N–O system.

The combustion of rich mixtures of hydrocarbons, particularly nitrogen-containing hydrocarbons, is known to be accompanied by the formation of HCN and NH_3.[167] HCN is formed in large amounts also when NH_3 is added to hydrocarbons. Consequently one may assume that the interaction of the NH_2, N, and NH species, characteristic of the combustion of ammonia, with intermediates in the combustion of hydrocarbons, can also lead to the formation of HCN, as in the combustion of amines, including CH_3NH_2. Part of the kinetic scheme describing the formation of HCN and its oxidation reactions actually corresponds tentatively to this feature [see Table 1, reactions (2.28)–(2.40)].

Reactions (2.41) and (2.42), put forward by Fenimore,[167] make it possible to explain the formation (in the reverse reaction) of HCN and the so called "fast" NO in hydrocarbon flames. On the one hand, atmospheric nitrogen and, on the other, the CH_2 and CH species participate in these processes. The first species occurs in the methane oxidation scheme; the appearance of the second and its consumption were described by reactions (95)–(99), which constitute the continuation of the methane part of the scheme (see the first half of Table 1). The Arrhenius parameters of these processes are indicated on the basis of the estimates of Basevich et al.[50]

Processes responsible for the formation of NO in the high-temperature oxidation of methane in air [reactions (1.12) to (1.15)] (the so called extended Zel'dovich mechanism[168]) are characteristic of this species. Reactions (1.3)–(1.10) take place over a wide temperature range and lead to the formation and decomposition of NO.[89] Reaction (1.11) should also be apparently included here.

Basevich et al.[69] used as far as possible the rate constants for the forward or reverse reactions available in the literature (for the relevant references, see Table 1); in certain cases the Arrhenius parameters were estimated semiempirically. After the initial selection, the parameters listed in Table 1 were used in all subsequent calculations.

The mechanism examined was used[69] in the calculations of the kinetics of the combustion of CH_3NH_2 in an atomic oxygen flame and a fairly satisfactory agreement between experiment and calculations was achieved.

The proportions of the principal reaction products (other than CH_3NH_2, O, and O_2), whose final concentration amountec to not less than 10% of the CH_3NH_2 consumed, can be calculated. These products include H_2, CO , H, CH_4, NO, H_2O, H_2CO, N_2, and NH_3, which are thus the principal species of the kinetic scheme for the given conditions.

Next, the contribution of each elementary step to the reactions of CH_3NH_2 and the individually selected reaction components was calculated.[69] The primary reaction (2.1) involves the consumption of 12–20% of oxygen atoms. The relative contribution of reactions (2.2) and (2.3), involving the consumption of CH_3NH_2 by reaction with OH and H, to its overall reaction is 22–45%. Nitric oxide is formed mainly via the reactions

$$N+OH \rightarrow NO+H\ , \qquad (1.15$$

$$N+O_2 \rightarrow NO+H\ , \qquad (1.13$$

and also

$$HNO+O \rightarrow NO+OH\ , \qquad (2.21$$

$$NH+OH \rightarrow NO+H_2\ . \qquad (2.23$$

The contributions of these reactions diminish in the above order but have similar magnitudes. The contributions of the reactions

$$CH_3+N \rightarrow HCN+H_2\ , \qquad (2.29)$$

$$CH_2+NH \rightarrow HCN+H_2 \qquad (2.28$$

to the formation of HCN are also virtually within the limits of one order of magnitude. In the processes indicated above, the reactions

$$NH+H \rightarrow N+H_2\ , \qquad (2.24)$$

$$NH+O \rightarrow N+OH\ , \qquad (2.25)$$

$$NH_2+NH \rightarrow NH_3+N\ , \qquad (2.16)$$

$$NH+NH \rightarrow NH_2+N \qquad (2.27)$$

play the role of the source of atomic nitrogen. NH_3 is formed via the reactions

$$NH_2+HO_2 \rightarrow NH_3+O_2\ , \qquad (2.11)$$

$$NH_2+H_2 \rightarrow NH_3+H\ . \qquad (-2.18)$$

The rapid reaction

$$NH_2+OH \rightarrow NH_3+O \qquad (2.12)$$

is ineffective owing to the faster occurrence of the reverse process.

A satisfactory agreement has also been found on comparing the calculated and experimental data obtained under the conditions of atmospheric flames[167,169] and experiments with added ammonia.[170]

The insufficiency of experimental data and the complexity of the system considered preclude at the present time a rigorous selection of reaction pathways and all the elementary steps. Table 1 does not include many of the known reactions. There is no doubt that the mechanism discussed should be regarded as a first approximation. This applies especially to the part described by Eqns.(2.6)–(2.9). It is necessary to refine the character of the process and the reaction rate constant.

A kinetic mechanism of the combustion of nitrogen-containing compounds have also been proposed in other studies,[171,172] etc.

The kinetics of combustion in the H–C–N–O system have found an application in the analysis of the environmental consequences of combustion processes and in the search for possible ways of reducing the concentrations of harmful products. Two main reactions leading to the formation of nitric oxide from atmospheric nitrogen [(1.12) and (1.13)] were found to be unspecified in a fundamental study.[168] As already stated, the above mechanism[168] is usually considered jointly with the rapid reaction (1.15). The contribution of reaction (1.15) to the formation of NO has been shown by calculations to be frequently not inferior to the contribution of reaction (1.13) and is sometimes even greater.[173] Under practical conditions, the NO concentration can reach hundredths and thousandths of parts per million owing to the relatively high temperatures and long (more than 0.1 s) residence times of the gas at high temperatures. In the absence of nitrogen in the fuel itself, the above mechanism of the formation of NO is the main one.

Under laboratory conditions, which are distinguished as a rule by low temperatures (<2000 K) and short residence times of the gas (less than 10–20 ms), the yield of NO amounts to several, several tens, and (rarely) 100 parts per million. Under these conditions, the approximations underlying the theory[168] are insufficiently valid and for this reason differences are observed between the theoretical and experimental nitric oxide concentrations: there is insufficient time for the attainment of equilibrium and the actual concentrations of atomic oxygen can exceed significantly those corresponding to thermodynamic equilibrium. Calculations using the DKM have shown that more NO is usually obtained under these conditions.[174–176] However, this applies solely to hydrocarbons. The calculations for hydrogen–air flames have fully confirmed the theoretical and experimental data,[168] which indicates the possibility of excluding the reaction zone from consideration. The calculations have also shown that, up to pressures of 100 atm, the amount of NO formed in the reaction zone of the H_2 flame even at an initial temperature of 600 K is extremely insignificant owing to the short residence times.

Under laboratory conditions, the abrupt formation of nitric oxide in the reaction zone on combustion of hydrocarbons was first observed by Fenimore.[173] It was noted that, under the experimental conditions, the formation of NO includes two stages: the rapid stage in the reaction zone and the slow stage in the flame gases. The mechanism of the formation of NO via reactions (1.12)–(1.15) operates in both stages. The authors[177] concluded that in the case of hydrocarbons the mechanism (1.12)–(1.15) describes the combustion of weak mixtures with a coefficient of the excess of air $\alpha \geq 1.3$.

Data for rich mixtures with a large discrepancy between the unduly low calculated and experimental NO concentrations, indicating that the mechanism of the formation of nitrogen oxide is in this instance apparently more complex and is not confined to the scheme (1.12)–(1.15), have been frequently quoted in the literature. Special experiments have been carried out,[178] in which the yields of NO were compared under identical conditions in hydrogen–oxygen–nitrogen flames without and with addition of acetylene. In the latter case more nitric oxide is formed and there is reason to believe that its formation is promoted by the reactions of hydrocarbon radicals with nitrogen (Table 1, DKM for the H–C–N–O system), although these NO formation pathways have not as yet been adequately investigated. We may note that the concentrations of "fast" NO do not exceed 100 to 120 p.p.m.[179] In the latter studies the authors specially optimise the experimental conditions in order to obtain the maximum yield of this species.

Finally, there exists yet another source of the formation of nitrogen oxides on combustion. This is the nitrogen which forms part of the composition of fuel and impurity molecules. Experiments have shown[180] that, depending on the combustion conditions and the composition of the fuel mixture, between 10 and 90% of the fuel nitrogen is converted into nitric oxide; the remainder (in rich mixtures) forms ammonia and HCN as well as nitrogen molecules (see the above scheme for the H–C–N–O which was formulated to account for the formation of NO from the fuel nitrogen, requires a more detailed specification and justification. The possible role of N atoms in this process, which have been discovered by Basevich et al.[69], has also been pointed out by Miller et al.[172]

V. THE APPLICATION OF H_2O_2 AND HNO_3 AS OXIDANTS

The use of hydrogen peroxide as oxidants instead of oxygen is based on the relative ease of its thermal decomposition with formation of two hydroxylradicals. The oxidation of the corresponding mixtures begins at the temperature of the onset of appareciable decomposition of hydrogen peroxide.[9] It was stated above that hydrogen peroxide is an essential component of the DKM of the oxidation of hydrogen and hydrocarbons and the kinetic mechanism where H_2O_2 functions as the oxidant is therefore identical with the mechanism of the reaction in the oxygen system.

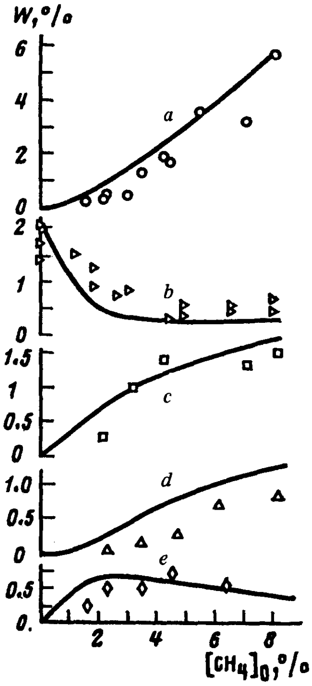

Figure 4. Dependence of the yield of the products of the reaction of CH_4 with HNO_3 on the initial methane concentration;[88] $[HNO_3]_0 = 7\%$, $T = 1067$ K, $P = 0.01$ atm, $t = 5$ ms: symbols—experiment; lines—calculation; *a*) CH_4; *b*) NO_2; c) CO; d) H_2; *e*) CO_2.

The calculated and experimental data were compared under flow conditions for the CH_4–H_2O_2 [33] and H_2–H_2O_2 [28] systems. The presence of a certain initial concentration $[O_2]_0$ as a consequence of the presence of O_2 in liquid H_2O_2, which, when vaporised by bubbling, generated the necessary H_2O_2 concentration in the gas phase, was noted in the experiments. A satisfactory agreement between the experimental and calculated data was achieved in both cases.

Nitric acid also readily decomposes with formation of nitrogen dioxide and a hydroxylradical[181,182] and is therefore used as the oxidant.[183,184] The hydroxylradical obtained reacts again with nitric acid to form the highly reactive NO_3 radical and water [reactions (1.1) and (1.2) in Table 1]. Examination of the above processes together with the DKM for the H—N—O system made it possible to analyse the kinetics of the interaction of hydrogen with nitric acid.[28] The reaction proceeds fairly rapidly but, as a consequence of the high rate of destruction of OH, H, and O in the gas samples of the EPR spectrometer due to the presence of nitrogen-containing products, the concentration of these radicals could not be recorded.

Certain experimental data referring to the reaction of CH_4 with HNO_3 under flow conditions are presented in Fig.4.[88] The reaction begins at the temperature corresponding to the onset of the decomposition of HNO_3. The calculated kinetic curves describe satisfactorily the experimental relations obtained when the initial methane content is varied.

---o0o---

The theoretical studies described above were not the only ones performed with the aid of the DKM. They have been used to calculate the ignition delays, the rates of propagation and the stabilisation limits of flames, in the study of promotion and chemi-ionisation phenomena and of the composition of the products in the technological formation of acetylene and the synthesis gas from methane, in the estimation of the concentrations of various environmentally undesirable components, and in other cases, including the conditions in a turbulent medium. The results of the available calculations demonstrate their more or less satisfactory agreement with experimental data. The specific DKM presented in Table 1 serves merely as the first approximation and requires further refinement.

The first stage in the construction of the detailed kinetic mechanisms, where their possibilities and the accuracy of the calculations based on them have become clear has apparently now been completed. The next stage in the construction of the DKM will probably involve a careful analysis of the individual elementary steps and the real reaction channels and also an increase in the accuracy of the estimation of the rate constants. The aim of this stage will be a transition from qualitative estimates obtained nowadays to a quantitatively accurate *a priori* calculation.

A Quantitative Concept of the Permeability to Hydrogen of Passivating Layers on a Metal at the Apex of the Crack in the Corrosion-induced Cracking of Constructional Materials

V.A.Marichev

A general theoretical and methodological approach to the determination of the role of the local anodic dissolution and hydrogen-induced embrittlement in the corrosion-induced cracking of various constructional materials is examined. The possibility of the quantitative estimation of the role of the hydrogen-induced embrittlement in the corrosion-induced cracking of high-strength steels and titanium, aluminium, magnesium, and zirconium alloys is demonstrated. A quantitative concept of the permeability of hydrogen of passivating layers on a metal at the apex of a crack, which has made it possible to determine quantitatively for the first time the relation between the critical concentration of hydrogen and the stress intensity coefficient in the hydrogen-induced embrittlement of steels and titanium and aluminium alloys, has been developed on the basis of several postulates. Two new methods for the investigation of the adsorption of hydrogen and anions at the apex of the crack in corrosion-induced cracking, based on this concept, are proposed.

The bibliography includes 47 references.

I. INTRODUCTION

There is at present no unique concept concerning the mechanism of the growth of cracks in corrosion-induced cracking (CIC) on any specific alloy—electrolyte system. There is an even greater lack of a generally accepted theoretical and methodological approach to the determination of the mechanism of the growth of cracks which would be applicable to any constructional materials regardless of their composition and structural state. The majority of studies have been characterised by a one-sided approach to the determination of the CIC mechanism—whilst justifying the leading role of one of the possible mechanisms, the authors fail to consider or reject the possibility of the growth of cracks via other, competing mechanisms. An attempt has been made[1-3] to develop a general electrochemical method for the determination of the CIC mechanism using the following initial postulates. At the apex of the crack there is a possibility of the simultaneous occurrence of two main processes—local anodic dissolution (LAD) and hydrogen-induced embrittlement (HIE), the role of each of which depends on the composition of the alloy and the electrolyte, the heat treatment of the alloy, the potential, etc. and also on the rate of growth of the crack V and the stress intensity coefficient K. The coefficient V is regarded as an index of the extent to which the properties of the metal at the apex of the crack approach those of a freshly formed surface and defines the permeability of the passivating films to hydrogen. The different types of influence of cathodic polarisation on the growth of cracks observed in the study of high-strength martensite steels[1] serve as an experimental basis of the ideas concerning the CIC mechanism developed in the above studies.[1-3] This phenomenon consists in the fact that, other conditions being equal, the same cathodic polarisation retards the growth of cracks if the initial V and K at the corrosion potential are below certain critical values and accelerates the growth of cracks if they are above such values. The physical significance of the concept of the "critical rate of growth of the crack" is as follows. With increase of V, the time required for the formation of passivating layers on the metal at the top of the crack, which constitute barriers to the penetration of hydrogen into the metal, diminishes. Regardless of the value of V, cathodic polarisation increases the rate of the electrochemical evolution of hydrogen. However, for coefficients V below the critical value, the films formed on the metal hinder the penetration of hydrogen into the latter, the attainment of the critical concentration of hydrogen, and the onset of the HIE. On the other hand, cathodic polarisation suppresses the LAD and, as shown by experiment, reduces V. When the critical and higher values of V are reached, passivating films can no longer effectively prevent the penetration of hydrogen into the metal and for this reason cathodic polarisation accelerates the growth of cracks via the HIE mechanism although it does reduce the rate of local dissolution.

The critical rate of growth of the crack V_{cr} and the corresponding critical stress intensity coefficient K_{HIE} are quantitative indices of the role of the LAD and HIE in the growth of the cracks; for $V < V_{cr}$ and $K < K_{HIE}$, the main CIC mechanism involves the LAD; for $V > V_{cr}$ and $K > K_{HIE}$, the mechanism is based on the HIE. The values of V_{cr} and K_{HIE} depend on the composition of the alloy and the electrolyte, the cathodic polarisation potential, etc. Changes in the alloy—electrolyte system reducing the stability of the passivating layers at the apex of the crack or the critical concentration of hydrogen should diminish V_{cr} and K_{HIE}, i.e. should enhance the role of the HIE in the CIC. This hypothesis was confirmed experimentally in the determination of the dependence of V_{cr} and K_{HIE} in the CIC of high-strength steels on the content in the electrolyte of chlorides, agents promoting such saturations with hydrogen, and oxidants and also the dependence of these quantities on the heat treatment of the steels.[1,2]

Although the ideas which we have developed[1–3] about the CIC mechanism suffer from no limitations associated with the composition of the alloy or the electrolyte, they cannot be transferred mechanically to all materials without demonstrating experimentally that cathodic polarisation exerts different types of influence on the growth of cracks in the CIC of these materials, as for high-strength steels. As the above ideas were generalised, they were subjected to tests. In particular, it was assumed *a priori* that, when any alloy (or group of alloys with a specific base) tends to undergo HIE in the absence of a corrosion medium but at the same time cathodic polarisation always has the same effect on its CIC, it is possible to alter the CIC conditions in such a way that cathodic polarisation exerts different types of effect on V for this alloy. For example, it is known that austenite steels and titanium, zirconium, magnesium, and alluminium alloys tend to undergo internal HIE but, in CIC in 0.5 M NaCl solution, cathodic polarisation only retards the growth of cracks in these materials.[2] This means that in the NaCl solution the main CIC mechanism involves LAD, while HIE does not play an appreciable role although it can occur. On the other hand, one can postulate the existence of conditions for these materials such that HIE plays an appreciable or main role in the CIC. Indeed electrolytes have been selected in which cathodic polarisation in the CIC of the above materials influenced the growth of cracks in different ways; for V and K below their critical values, it reduced V, increasing it after the attainment of such values.[2–4]

The agreement between the theoretical prediction and the experimental fact of the different types of influence of cathodic polarisation on the growth of cracks in the CIC of austenite high-strength steels and titanium, zirconium, magnesium, and aluminium alloys[2–4] suggests that this feature is common to all CIC processes and makes it possible to formulate a general theoretical and methodological approach to the determination of the role of LAD and HIE in the CIC of constructional materials regardless of their base and the composition of the electrolyte. According to this approach, the unambiguous influence of cathodic polarisation (i.e. only retardation or only acceleration of the growth of cracks regardless of the values of V and K) should be regarded as a special case of its varying influence on V, reflecting the independence of the leading CIC mechanism of V and K. More detailed arguments in support of this postulate can be found in another communication.[2]

The ideas about the CIC mechanism developed in a series of studies[1–4] are mainly qualitative. In the present review a quantitative concept of the permeability to hydrogen of passivating layers on a metal at the apex of the crack, which makes it possible to establish a relation between the electrochemical CIC conditions, the coefficients V_{cr} and K_{HIE}, and the critical concentration of hydrogen in the HIE, has been formulated on the basis of the extension and analysis of these ideas.

II. RELATION BETWEEN THE CRITICAL CONCENTRATION OF HYDROGEN AND THE CRITICAL STRESS INTENSITY COEFFICIENT IN THE HYDROGEN-INDUCED EMBRITTLEMENT OF CONSTRUCTIONAL MATERIALS

The fundamental concepts of the theory of the HIE of constructional materials are the critical concentration of hydrogen c_{cr} and the critical stress intensity coefficient in HIE, K_{HIE}. The value of K_{HIE} can be determined experimentally both in the HIE in gaseous hydrogen and in electrolyte solution under CIC conditions. However, none of the methods of physicochemical analysis and none of the HIE theories have so far been developed sufficiently to permit the experimental or computational determination of the absolute values of c_{cr} (there is no generally accepted physical model of the HIE; models of the distribution of stresses ahead of the apex of the crack are in the state of development; the configuration of the apex of the crack and the location of the breakdown zone in the HIE relative to the top of the crack are unknown, etc.[2,5]). The question of the relation between c_{cr} and K_{HIE} is extremely important for the theory of HIE and was frequently discussed previously.[2,5–9] However, at the present time only the following qualitative relation can be regarded as established: the higher K_{HIE}, the lower c_{cr} and conversely.

The method for the investigation of the relation between c_{cr} and K_{HIE} proposed by the present author[10] follows from general ideas about the CIC mechanism[1–4] and is based on the possibility of the quantitative estimation of the role of HIE in CIC by means of the experimental determination of the values of V_{cr} and the corresponding critical stress intensity coefficients K_{HIE}. These values depend on the electrolyte composition, the heat treatment and the structure and strength of the alloy, the pH of the medium, the presence of agents promoting saturation with hydrogen, the process temperature, the potential of the specimen, and also the nature and the ratio of the concentrations of the corrosive and passivating ions. The last factor is particularly important because this ratio defines, like V, the permeability to hydrogen of the film of the metal at the top of the crack.

The main postulate of the HIE theory states[2] that the crack grows when the critical hydrogen concentration c_{cr} is established ahead of its apex and the critical value of the stress intensity coefficient K_{HIE} has been attained. Having supplemented this condition by stating that c_{cr} decreases with increase of K_{HIE}, one can formulate the equation

$$c_{cr}K_{HIE}^{n} = \text{const.} \tag{1}$$

This relation, proposed in Ref.11, is one of the possible formulations of the criterion of breakdown in HIE and is not based on any specific physical model of HIE. Formally it is close to the power relation examined by Van Leeuwen[9] within the framework of the decohesive theory of HIE.[8]

The penetration of hydrogen into the metal ahead of the apex of the crack growing under the CIC conditions includes several successive steps:

(1) The occurrence of an electrochemical reaction as a result of which a definite concentration (degree of surface coverage) of adsorbed hydrogen atoms θ is established on the surface of the passivating film.

(2) The penetration of the hydrogen adsorbed on the surface of the film through the latter and the establishment of a certain concentration c_{ms} of hydrogen in the surface layer of the metal at the apex of the crack at the metal–film boundary. This concentration is determined by the permeability of the film to hydrogen: $c_{ms} = \theta\alpha$. The dimensionless quantity shows what proportion of the hydrogen adsorbed on the passivating film penetrates through the latter and is responsible for the HIE.

(3) The attainment of a critical concentration of hydrogen $c_{cr} = c_{ms}\xi = \theta\alpha\xi$ directly at the apex of the crack ($\xi = 1$) or at a certain distance from it ($\xi < 1$), the distance being unimportant, since the given formal treatment is not associated with any specific physical model of HIE. The requirements that the HIE mechanism remains unaltered when the experimental conditions are changed (for example, when the cathodic polarisation potential or the concentration of chloride ions are changed) and that the transport coefficient ξ remains constant are significant.

The HIE mechanism is determined by the properties of the metal–hydrogen system and is independent of the electrochemical conditions at the apex of the crack which influence the HIE kinetics in CIC. The coefficient ξ depends on the diffusion coefficient of hydrogen in the metal, the distance of the breakdown zone from the apex of the crack, and the diffusion time, i.e. on the duration of the cathodic polarisation in the determination of the values of K_{HIE}. For a constant cathodic polarisation time, ξ = const. for the given alloy.

The constancy of the cathodic polarisation time is ensured by the method used to determine K_{HIE},[10] which consists of the following steps. The specimen in the electrolyte at a certain initial potential E_i (for example the corrosion potential E_{cor}) is stressed until the attainment of an arbitrary coefficient K, is maintained in this state for 300 s, and is then subjected to cathodic polarisation until the attainment of the potential E_{cp}. If the cathodic polarisation induces an acceleration of the growth of the crack up to 150 s, the specimen is again polarised to E_i, K is reduced by 3–5%, and, after being maintained at E_i the specimen is polarised to E_{cp}. If the cathodic polarisation does not accelerate the growth of the crack in the course of 150 s, then K is increased by 3–5% and the above operations are repeated. Thus, using the method of successive approximations, K_{HIE} is determined as the minimum value of K for which cathodic polarisation to E_{cp} accelerates the growth of the crack up to 150 s. The relative errors in the determination of K_{HIE} and V_{cr} are 4 and 10% respectively.[10]

The quantities θ and α depend on the compositions of the alloy and the electrolyte, the pH, temperature, the potentials E_i and E_{cp}, etc. Other conditions being equal, the permeability to hydrogen is proportional to the rate of growth of the crack and the concentration of the corrosive anion, for example the chloride ion $[Cl^-]$, adsorbed on the film at the top of the crack. It is assumed that the adsorption of chloride ions from solution is described by the Langmuir isotherm at low coverages: $[Cl^-] = \beta(Cl^-)$, where β is the adsorption coefficient and (Cl^-) and $[Cl^-]$ are the concentrations of chloride ions in solution and adsorbed on the film respectively. It is also assumed that, when $V \leq 0.01$ mm h^{-1}, the permeability of the film to hydrogen is independent of the rate of growth of the crack and, when $V > 0.01$ mm h^{-1}, it is proportional to V.[10]

These ideas about the permeability to hydrogen of passivating films on the metal on top of the crack growing under CIC conditions are based on the present author's data;[2,3] in the absence of halide ions, it proved impossible to induce the HIE of aluminium, titanium, and zirconium alloys under CIC conditions even for $K \cong K_{IC}$ (where K_{IC} is the critical stress intensity coefficient in the absence of corrosion medium) and a cathodic polarisation potential E_{cp} up to -4 V (relative to n.h.e.†), while for certain ratios of the concentrations of passivator and depassivotor ions optimal for each material the acceleration of the growth of cracks under cathodic polarisation (i.e. HIE and CIC) is observed for $K_{HIE} \leq 0.03$, K_{IC}, and $E = -0.7$ V. For the materials investigated previously,[2,3] the quantity α can be neglected in the absence of corrosive ions, but, for high-strength steels this cannot be done in the general case, since their CIC via the HIE mechanism can occur, for example, in distilled water. However, even for high-strength steels it is possible to establish conditions (by selecting the composition of the electrolyte and the cathodic polarisation potential) under which the permeability of the film to hydrogen is determined by the concentration of the corrosive ions in the electrolyte also at the top of the crack. In this Section only such conditions will in fact be considered; the permeability of steels to hydrogen is discussed in greater detail in Section III.

Taking into account the above assumptions concerning the critical parameters describing quantitatively the role of HIE in CIC (V_{cr} and K_{HIE}, the criterion for the HIE in the alloy–hydrogen system (1) can be used also as the criterion of the HIE in CIC having formulated it in the form

$$\theta\alpha\xi K^n_{HIE} = \text{const}, \tag{2}$$

$$\theta\xi\beta(Cl^-)V_{cr}K^n_{HIE} = \text{const}, \tag{3}$$

$$\lg[(Cl^-)V_{cr}] = \text{const} - n\lg K_{HIE}. \tag{4}$$

The constant coefficients ξ and β in Eqn.(3) are unknown and it is therefore impossible to determine the permeability of the film to hydrogen in absolute units. However, the exponent n in the power relation (1) between the critical concentration of hydrogen and the stress intensity coefficient can be determined from the slope of the linear plot in terms of the variables of Eqn.(4).

In conformity with the assumptions made, the power exponent n in Eqns.(1)–(4) characterises the HIE in the alloy–hydrogen system and is in no way related to the corrosion stability of the alloy in any particular electrolyte. Hence it follows that n may depend on the composition, structure, and the conditions of the heat treatment of the alloy and on temperature but should be independent of any electrochemical parameters of the electrolyte.[10] The experimental test of these conclusions shows that the assumptions made in the derivation of Eqns.(1)–(4) are valid. In particular, the observed value of n should be independent of the method of introduction of hydrogen into the specimen: for the same material, the exponent n should be identical for HIE under CIC conditions and in an atmosphere of gaseous hydrogen. For HIE in CIC, the exponent n should not be influenced by the nature of the solvent, the concentrations of the passivator and depassivator ions, the pH, the cathodic polarisation potential, and similar factors, although variation of these parameters does influence significantly V_{cr}, K_{HIE}, θ, and other terms in Eqns.(2)–(4).

Since n is independent of the electrochemical parameters of the solution, all the data obtained for one material in different solutions may be plotted on a single curve. In each series of experiments where only the concentration (Cl^-) is varied, the solution with the maximum value of (Cl^-) is selected as the standard.[10] Then, for this series, Eqn.(4) is transformed into

$$\lg\frac{[V_{cr}(Cl^-)]_x}{[V_{cr}(Cl^-)]_{st}} = \lg\frac{\alpha_x}{\alpha_{cr}} = -n\lg\frac{K_{HIE,x}}{K_{HIE,st}}, \tag{5}$$

where the subscripts "st" and "x" correspond to the standard in variable concentrations (Cl^-).

The validity of Eqn.(5) was tested in a study[10] in which the dependence of K_{HIE} and V_{cr} on the concentrations of chloride, bromide, and sulphate ions was obtained in various buffer solutions in the CIC of aluminium and titanium alloys and four high-strength martensite steels. These data, treated in accordance with Eqn.(5), are presented in Fig.1; it is seen that, despite the considerable scatter, the experimental points for each material do indeed fit on a straight line. The slopes of the straight lines (i.e. the power exponents n) for the aluminium alloy, the titanium alloys, and the high-strength steels are respectively 2.1, 3.0, and 5.5. As assumed, n for each material is independent of the electrochemical parameters associated with the electrolyte; however, within the limits of experimental error, it was impossible to

---

†Here and henceforth the potentials are given throughout relative to the normal hydrogen electrode (n.h.e.).

observe the dependence of *n* not only on the conditions in the heat treatment of the steel but also on the composition, structure, and strength of titanium α-alloys and the high-strength martensite and martensitically ageing steels.

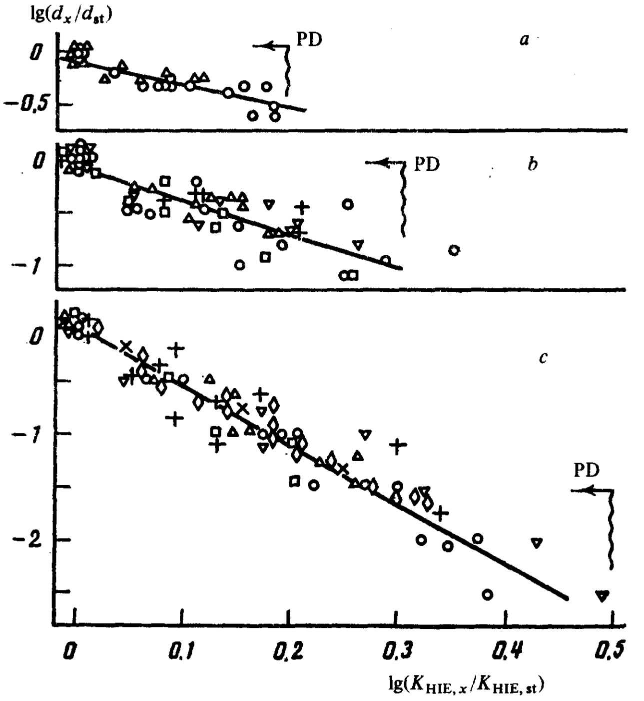

Figure 1. Dependence of K_{HIE} in the CIC of aluminium (*a*), and titanium (*b*) alloys and high-strength steels (*c*) on the permeability to hydrogen of the passivating films at the apex of the crack; PD—planar deformation boundary. The different symbols correspond to different alloys, different heat treatment conditions, and different electrolyte compositions.[10]

One can apparently conclude that the exponent *n* in Eqn.(1) is a characteristic parameter of the HIE of the alloys and depends solely on the nature of the metal on which the alloy is based. One cannot rule out the possibility that the different values of *n* for aluminium and titanium alloys and high-strength steels reflect different mechanisms of the HIE of these materials. We may note that, with increase of the tendency of the materials towards HIE in the series aluminium alloys–titanium alloys–high-strength steels, the exponent *n* also increases. Unfortunately, there are no data concerning the influence of the type of lattice on *n*; such data can be obtained by studying with the aid of the method described titanium β-alloys and high-strength austenite steels.

As stated above, in the model considered the exponent *n* should not be influenced by the method of introduction of hydrogen into the alloy. The validity of this postulate can be tested by comparing the value $n = 5.5$ obtained[10] for high-strength steels (under the conditions of HIE in CIC) with the value of *n* under the conditions of gas-phase HIE. There are fairly numerous literature data on the dependence of the K_{HIE} of high-strength steels on the hydrogen pressure, but they are unsuitable for the determination of *n*, because they refer mainly to the range of high (in excess of 1 atm) pressures at which one can postulate the maximum degree of surface coverage by adsorbed hydrogen atoms. Virtually the only study in which the dependence of K_{HIE} (for high-strength martensite steel 4340) on hydrogen pressure was determined (in the range 0.1–1000 mmHg) is that of Oriani and Josephic.[8] The data from this investigation, treated in terms of Eqn.(5), are designated in Fig.1c by rhombuses; they fall within the scatter band of the HIE data in the CIC of other high-strength steels. The exponent *n*, determined independently from the results of the above investigation,[8] is 5.1 and is virtually identical with the value $n = 5.5 \pm 0.5$ found for HIE in CIC.[10]

Despite the fact that Eqns.(1)–(5) are empirical and are not based on any specific physical model of HIE, the values of *n* obtained[10] can be useful in the development of physical ideas about the mechanism of the HIE of various materials. In particular, the identity of the values of *n* for the HIE in the CIC of high-strength steels and for their HIE in a gaseous medium makes it possible to assume that the HIE of these materials has the same mechanism.

The derivation of Eqns.(1)–(5) is based on several postulates (the applicability of the proposed criterion of breakdown in HIE, the direct proportionality of the permeability to hydrogen to the rate of growth of the crack and to the concentration of chloride ions adsorbed on the film, and the independence of θ of [Cl$^-$], which do not conflict with the known theoretical ideas but cannot be justified analytically or tested experimentally. For example, it is impossible to test by an independent procedure the values of *n* obtained,[10] because only qualitative ideas about the relation between c_{cr} and K_{HIE} have been developed in the HIE theory. Nevertheless the concept of the permeability of passivating layers on the metal to hydrogen at the top of the crack, developed by Marichev,[10] permits predictions for certain values of *n* which can be tested experimentally (see Sections III and IV).

III. THE PERMEABILITY TO HYDROGEN OF PASSIVATING LAYERS ON A METAL AT THE APEX OF THE CRACK IN CORROSION-INDUCED CRACKING

The permeability to hydrogen α was formally introduced above dimensionless quantity showing which part of the hydrogen adsorbed on the passivating film penetrates through it onto the metal–film interface and is responsible for the occurrence of HIE. The mechanism of the permeability to hydrogen has not yet been fully elucidated but one can assume that the diffusional transport of hydrogen through the passivating film does not play the main role. Thus in the CIC of aluminium and titanium alloys for $K > K_{HIE}$ the acceleration of the growth of the cracks after the cathodic polarisation has been switched on takes place after 1 s, while for $K < K_{HIE}$ under the same CIC conditions acceleration was not observed even after more than 10^4 s. Furthermore, the occurrence of the CIC of these alloys via the HIE mechanism, for example, in 1 M CrO_3 has not been observed even for $K \cong K_{IC}$, but, when 0.01 M NaCl is introduced, HIE takes place at a high rate for low values of *K*. It appears unlikely that such small amounts of added chloride ions, which do not alter significantly the corrosion potential and do not cause the breakdown of the passive state of the alloys in 1 M CrO_3 solutions, should increase by several orders of magnitude the diffusion coefficient of hydrogen in the passivating film.

Since θ and the constant coefficients (except *n*) in Eqns. (2) and (3) are unknown, the absolute values of the permeability to hydrogen cannot be determined from data obtained in tests on the CIC (i.e. the quantities V_{cr} and K_{HIE}). However, having adopted $\alpha = 1$ for certain arbitrarily selected standard experimental conditions, it is possible to determine the relative changes in α_x when, for example, the concentration of chloride ions in the electrolyte is altered:

$$\alpha_x = \frac{V_{st}}{V_x}\left(\frac{K_{HIE,st}}{K_{HIE,x}}\right)^n . \qquad (6)$$

It is assumed that small changes in the composition of the electrolyte (as a rule by not more than 0.05 M of activator or passivator ions) do not affect the surface coverage θ of the film by adsorbed hydrogen, which depends mainly on the potential of the specimen and the pH of the electrolyte.[12]

The most complete information about the dependence of the permeability to hydrogen α of passivating layers on a metal at the top of the crack on the electrolyte composition can be obtained for high-strength steels, since in the course of their CIC the growth of cracks via the HIE mechanism at sufficiently negative cathodic polarisation potentials takes place in water and NaOH solutions not containing activating ions.[2] The following standard experimental conditions have been selected[13] for high-strength steels: NaOH solution at pH 10, cathodic polarisation potential for the determination of V_{cr} and K_{HIE} amounting to $E_{cp} = 0.8$ V, and the period from the instant when the cathodic polarisation is switched on to the instant of the acceleration of the growth of cracks via the HIE mechanism amounting to 150 s. This choice was dictated by the necessity to keep constant the pH of the electrolyte as its composition is changed (for example, the 0.03 M Na_2HPO_4 solution has pH 9.9), the appreciably insignificant corrosion of the steels investigated, and also the fact that in this electrolyte the critical HIE stress intensity coefficient is small for $E_{cp} = -0.8$ V. The latter significantly extends the possible limits of variation of the electrolyte composition, especially on introduction of passivators, since the increase of K_{HIE} induced by them should not lead to the breakdown of the passive planar deformation state of the specimens.[14] The corrosion potential of the steels studied was approximately 0.2 V in NaOH solution at pH 10 and −0.15 V in 0.03 M Na_2HPO_4 solution, changing insignificantly (by ±0.05 V) after the introduction of activator or passivator ions into these electrolytes at a concentration of 0.05 M.

Fig. 2 shows that the introduction of additional NaOH at a concentration of 0.03 M into the standard NaOH solution increases the permeability to hydrogen of the passivating films at the apex of the crack by a factor of 6, while the additional introduction of 0.01 M NaCl causes a further increase by a factor of 2. The addition of nitrate ions to these solutions lowers sharply the permeability to hydrogen, the decrease being more pronounced the lower the initial permeability. Thus, when 0.001 M $NaNO_3$ is introduced into the standard solution, the permeability to hydrogen diminishes by a factor of 15 (curve *1*), but it hardly changes when the solution contains also 0.01 NaCl (curve 3).

We must emphasise that not only nitrates but also other anions, mainly oxidants (chromates, nitrites, nitrobenzoates, etc.) can reduce α, but there is no correlation between the strength of the oxidant and the degree of its influence on the permeability to hydrogen. For example, the strongest oxidants investigated by the present author,[13] namely H_2O_2 and $Na_2S_2O_8$, at concentrations up to 0.1 M do not reduce α in the CIC of steel in the presence of 0.03 M Na_2HPO_4 (the latter actually increases significantly α, since its reduction entails the formation of sulphate, which, like the chloride ion, increases the permeability to hydrogen). The introduction into the same solution of 0.05 M $NaNO_3$, which is an appreciably weaker oxidant but effectively displaces chloride ions from the surface of the steel as a result of competitive adsorption,[13,15] lowers α by three orders of magnitude.

It is of interest to compare the role of phosphates and nitrates. Phosphates are assumed to be corrosion inhibitors; indeed in the presence of 0.03 M Na_2HPO_4, the corrosion potential increases by 0.05 V compared with the potential in NaOH and the corrosion of the specimens is almost fully suppressed but the permeability to hydrogen of the passivating layers at the top of the crack increases by 5–6. On the other hand, nitrates are believed to behave as corrosion activators (although there have been studies[16,17] demonstrating their inhibiting effect on the CIC process and corrosion fatigue), but they reduce α very markedly in solutions containing chlorides and sulphates and fully suppress the CIC of high-strength steels in a standard NaOH solution. In a series of prolonged (up to one month) experiments, it was shown that not only K_{HIE} but also K_{ISCC} (critical coefficient of the density of stresses in CIC) increases appreciably in the presence of nitrates.[13]

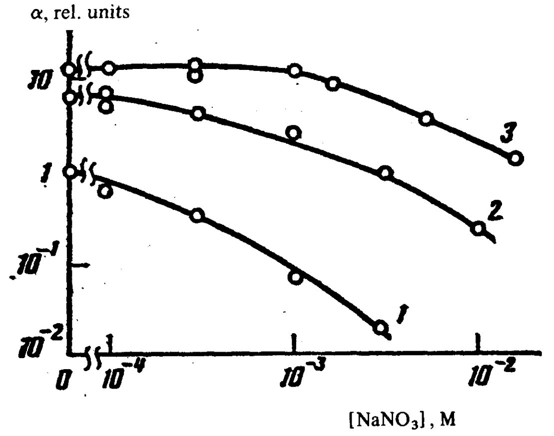

Figure 2. Dependence of the permeability to hydrogen, α, of passivating layers on a metal at the apex of the crack on the concentration of added $NaNO_3$ in the CIC of the steel 33Kh3NMFA in solutions at pH 10: *1*) NaOH; *2*) NaOH + 0.03 M Na_2HPO_4; *3*) NaOH + 0.03 Na_2HPO_4 + 0.01 M NaCl. The permeability to hydrogen in the NaOH solution was adopted as unity; $E_{cp} = -0.8$ V.[13]

It was subsequently established[15] that, when HIE conditions in distilled water are chosen as standard, all the anions investigated—the phosphate, acetate, borate, nitrate, hydroxide, and especially chloride and sulphate ions—increase the permeability of passivating films to hydrogen, i.e. they function as activators of the HIE of high-strength steels. The activating effect of anions on the HIE process depends significantly on the steel composition. Nitrates and other oxidants lower the permeability to hydrogen and increase HIE and hence they function as inhibitors of the HIE process only when they are introduced into solutions containing other anions, for example, chloride or sulphate ions, which activate the HIE of steel to a greater extent than nitrate ions.

One of the consequences of the concept of the permeability of passivating films to hydrogen has been the development of a method of study *in situ* of the adsorption of chloride ions (or other activator ions) on the film at the apex of the crack in the CIC of constructional materials.[15] The method consists in the experimental determination of K_{HIE} and V_{cr} under standard and real conditions and in the calculation of the relative changes in the concentration of chloride ions $[Cl^-]$ at the top of the crack. The standard condition is assumed to be $[Cl^-]_{st} = 1$. The real conditions differ in the concentrations of chloride or nitrate ions in the solution. It has been suggested that the constant coefficients in Eqns.(2) and (3) are identical for standard and real conditions. It follows from Eqns.(2) and (3) that

$$[Cl^-]_x = \frac{V_{st}}{V_x}\left(\frac{K_{HIE,st}}{K_{HIE,x}}\right)^n . \tag{7}$$

Within the framework of the assumptions made above, Eqn. (7) makes it possible to calculate the isotherms for the adsorption of chloride ions on the surface of the passivating film at the top of the crack growing in the CIC and also the decrease of $[Cl^-]$ as a result of competitive adsorption after the introduction of various extraneous anions, especially corrosion inhibitors, into the standard solutions.[15] This method can be used to investigate the adsorption of not only chloride ions but also of other anions in the presence of which the CIC of the alloy proceeds via the HIE mechanism. In the CIC of high-strength steels, it is possible to investigate by this method, for example, the adsorption of sulphate, phosphate, and other ions and the influence of inhibitors on the latter. For different constructional materials, the research technique is the same, but the exponent in Eqn.(7) varies (see above). The standard conditions (i.e. the material, the electrolyte composition, and the cathodic polarisation potential) are also different in the determination of the critical HIE parameters.

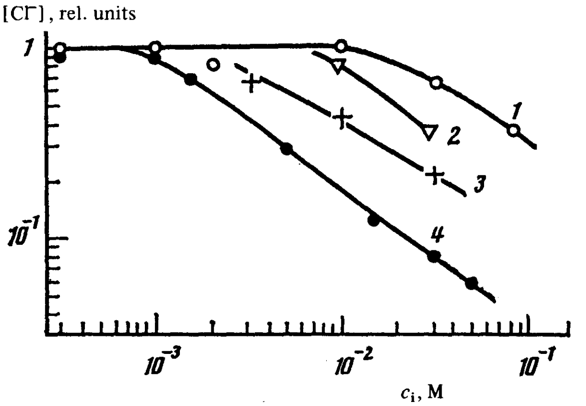

Figure 3. Dependence of the concentration of chloride ions adsorbed on the passivating film at the apex of the crack in the CIC of the steel 33Kh3NMFA in 0.03 M Na_2HPO_4 + 0.01 M NaCl solution on the concentration of inhibitors: *1*) $NaCrO_4$; *2*) hexamethyleneammonium 3,5-dinitrobenzoate (G-4); *3*) $NaNO_3$; *4*) $NaNO_3$; $[Cl^-] = 1$ in solution in the absence of inhibitors; $E_{cp} = -0.8$ V.[15]

Fig.3 presents certain results of a study of the competitive adsorption of chloride ions in the region of the apex of the crack in the presence of inhibitors in the CIC of different materials.[15,19] It shows that the introduction of oxidant anions into the standard solution hinders the adsorption of chloride ions, the nitrate ion, which has come to be regarded as an activator rather than an inhibitor of corrosion, being the most effective. Under the CIC conditions, this anion displaces chloride ions from the surface of the passivating film at the top of the crack much more vigorously than the known general corrosion inhibitors such as chromates, nitrites, and the organic G-4 inhibitor. This influence of nitrate is characteristic of the CIC of not only high-strength steels but also titanium and aluminium alloys.[19]

In this connection, mention should be made of the study[17] in which the CIC of high-strength steel was investigated in distilled water and it was shown that at high rates of growth of the crack nitrates are more effective as CIC inhibitors than nitrites, while chromates do not exhibit an inhibiting activity (at concentrations of 0.01 M). We may also mention a study[16] in which the possibility of the inhibition by nitrate of the corrosion fatigue of the high-strength aluminium alloy 7075 in a solution of chloride was demonstrated. It may be that the adsorption processes in the CIC exhibit a definite specificity which is in fact responsible for the highest adsorption capacity of the nitrate ion and the most effective displacement by the latter of chloride ions from the surface of the passivating film at the apex of the crack. As stated above, this is not associated with either the charges of the anions or with their oxidising capacity.

The above specificity has apparently no direct relation with oxo-ion reduction processes either, because the chromate ion influences the permeability to hydrogen less strongly than nitrate although it is not only reduced on the surface of iron but also enters into the composition of the passivating film in the form of Cr^{3+}.[18] In the CIC of aluminium alloys, the effectiveness of chromate is also greater than that of nitrate, vanadate, and molybdate,[19] although it has been established by electronic X-ray spectroscopy (ESCA) that it also enters into the composition of the film. The specificity of the adsorption processes in CIC affects also the behaviour of phosphate: being a general corrosion inhibitor, it increases the permeability to hydrogen of passivating films at the apex of the crack (Fig.2). The method for the study of adsorption at the apex of the crack examined above makes it possible to discover similar differences in the behaviour of oxo-ions in CIC and general corrosion; however, the formal ideas about the permeability to hydrogen, constituting its basis, proved insufficient to explain the specificity of the adsorption in CIC. The development of a physical model of the permeability to hydrogen is necessary for this purpose.

The competitive adsorption of chloride and nitrate ions in the CIC of steel A in solutions having the composition (0.001–0.01) M NaCl + (0–0.01) M $NaNO_3$ has been investigated in detail,[15] the results being presented in Fig.4. Fig.4*a* shows that an increase in the concentration of chloride ions in solution reduces sharply K_{HIE}, while an increase of the concentration of nitrate ions increases it. The higher the HIE activator (chloride ion) concentration, the higher the concentration of the HIE inhibitor (nitrate ion) inducing an increase of HIE. Under standard conditions, 0.01 M NaCl with $[Cl^-] = 1$, the relative changes in $[Cl^-]_x$ under real experimental conditions accompanying the changes in the chloride and nitrate ions in solution were calculated from the data in Fig.4*a* with the aid of Eqn.(7). The results of the calculations are presented in Fig.4*b* (curves *2*–*6*): evidently in the absence of nitrate ions the degree of adsorption of chloride ions increases in direct proportion to their concentration in solution, i.e. in the experimental concentration range the adsorption saturation on the surface of the passivating film at the top of the crack is not attained (curve *1*).

Assuming, as was done above in the derivation of Eqns. (2) and (7), that the adsorption of chloride and nitrate ions is described by the Langmuir isotherm, it is possible to calculate from curves *2*–*6* in Fig.4*b* the ratio *R* of the adsorption coefficient β of the chloride ions to the adsorption coefficient γ of the nitrate ions. If, following the introduction into the chloride solution at a certain concentration ((Cl^-)) of a definite amount of nitrate ions up to the concentration ((NO_3^-)), the initial concentration of the adsorbed ions $[Cl^-] = 1$ diminishes by a factor m, then it follows from the formal ideas about competitive adsorption[21] that

$$
\begin{aligned}
[Cl^-]_x &= \frac{1}{m} = \frac{\beta(Cl^-)}{1+\beta(Cl^-)+\gamma(NO_3^-)} , \\
[NO_3^-]_x &= 1-\frac{1}{m} = \frac{\gamma(NO_3^-)}{1+\beta(Cl^-)+\gamma(NO_3^-)} , \qquad (8) \\
R &= \beta/\gamma = \frac{(NO_3^-)}{(m-1)(Cl^-)} .
\end{aligned}
$$

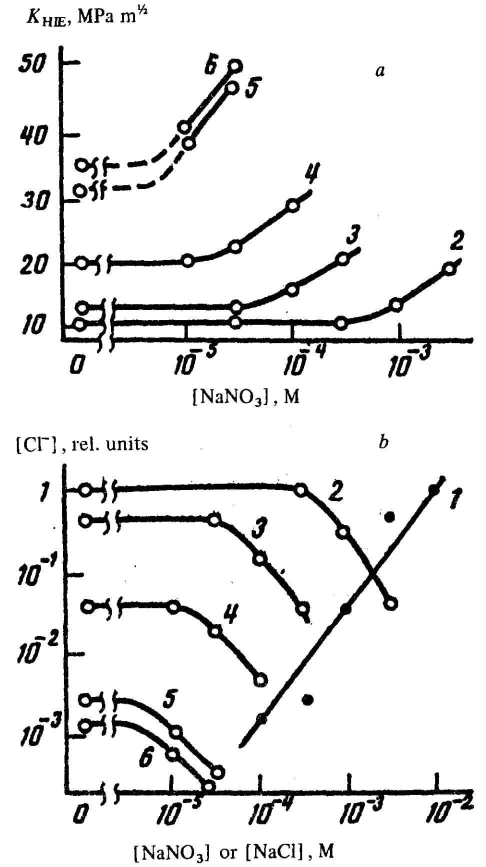

Figure 4. *a*) Dependence of K_{HIE} for the steel 02N18K9M5T on the NaNO₃ concentration in NaCl solutions at different molarities; *2*) 0.01; *3*) 0.003; *4*) 0.001; *5*) 0.0003; *6*) 0.0001; *b*) calculated dependence of the concentration of chloride ions adsorbed on the surface of the film at the apex of the crack on the NaNO₃ concentration in NaCl solutions: *1*) pure NaCl solutions; as in Fig. 4*a* above.[15]

It must be emphasised that, within the framework of the assumptions made, the absolute ratio of the adsorption coefficients of the HIE activators and adsorption is determined from Eqn. (8), although the change in the concentration of the adsorbed HIE activator ions can be determined from Eqn. (7) only in terms of relative units. The following adsorption coefficients of chloride and nitrate ions on the passivating film at the top of the crack in the CIC of steel in neutral solutions have been calculated from the data in Fig. 4*b* by Eqn. (8)[15] (in order of increasing initial NaCl concentrations): 0.06, 0.03, 0.03, 0.03, 0.07, i.e. $R = 0.04 \pm 0.01$. Similar calculations have been made for all the steel–electrolyte systems investigations in the above study;[15] it was established that the strongest inhibitor of HIE in the CIC of steels is the nitrate ion and that the adsorption coefficient ratios depend not only on the nature of the coadsorbed anions but also on the composition of the steel.

The method examined above can be used to investigate the theoretically and practically important question of the dependence of the adsorption of anions on the potential. This question has been examined comprehensively in theoretical electrochemistry but it is far from clear in corrosion theory. The point is that electrochemical studies are carried out on objects which are not corroded in the course of the experiment and which do not form passivating films—on noble metals, mercury, and amalgams. The dependence of the degree of adsorption on the potential under such conditions is determined by the ϕ potential (on a reduced scale), which characterises the charge of the electrode relative to the solution and the structure of the electrical double layer.[22]

Ideas about the adsorption of anions on noble metals are sometimes used in the study of the role of anions in the corrosion processes occurring on real constructional materials. This is apparently insufficiently justified, since no account is taken of the specificity of the interaction of the anions with the passivating films present inevitably on the surface of real alloys in weakly acid, neutral, and alkaline electrolytes on dissolution in the passive and active states and also in pitting, in the growth of cracks in the CIC and HIE, etc. As a rule, the increase of the surface activity of the anions in the sequence $F^- < Cl^- < Br^- < I^-$, observed in adsorption on mercury,[22] is not observed in the corrosion of iron, titanium, and aluminium alloys. For example, the activating capacity of anions in pitting on iron increases in the sequence $F^- < I^- < Br^- < Cl^-$ [23] and anions are adsorbed not only on the passivating film but are also incorporated in the latter.[24] The fluoride ion, which exhibits no surface activity at the mercury–aqueous solution interface, depassivates aluminium alloys most strongly although it does enter into the composition of the film.[25]

There are very few literature data for specific adsorption (especially for the dependence of the degree of adsorption on the potential) on metals of practical importance owing to the lack of a method for the investigation of adsorption in electrolytes *in situ*. The method of adsorption-enhanced Raman scattering (Raman spectroscopy) developed in recent years has been used successfully in the study of adsorption on noble metals.[26] The data obtained by this procedure for iron have been criticised.[27]

As stated above (see Section I), the K_{HIE} for each alloy–electrolyte system depends significantly on the duration and potential of the cathodic polarisation E_{cp} in the determination of K_{HIE} and also on the initial potential E_i at which the passivating layers are formed at the apex of the crack. Therefore, in the determination of the dependence K_{HIE} on the electrolyte composition, these values were constant. The present author[28] investigated the influence of E_{cp} and E_i on the competitive adsorption of anions in the CIC of martensitically ageing steel. The dependence of K_{HIE} on E_{cp} for E_i = const. and the dependence of K_{HIE} on E_i for E_{cp} = const. were determined experimentally for several solutions in which the concentration of the HIE inhibitor ions was varied at a constant concentration of HIE activator ions. Fig.5 shows that an increase of both the concentration of nitrate ions and of the potential E_{cp} increases K_{HIE} (curves *1*–*4*). The influence of the increase of the $NaNO_3$ concentration is caused by the decrease of the adsorption of the HIE activator (the chloride ion) as a result of competitive adsorption and the influence of the increase of E_{cp} is associated with the decrease of the degree of surface coverage by adsorbed hydrogen atoms at the apex of the crack. For each potential E_{cp}, the dependence of the concentration of the chloride ions adsorbed in the region of the apex of the crack (Cl^- on the concentration of nitrate ions in solution was calculated by Eqn.(7); it was shown that E_{cp} in the range from −0.4 to 1.0 V does not affect the adsorption of anions. The decrease of $[Cl^-]$ with increase of $[NO_3^-]$ for different values of E_{cp} is described by the same curve *5* from which the ratio of the adsorption coefficient of chloride and nitrate ions $R = 0.04$, independent of E_{cp}, was determined with the aid of Eqn.(8). An analogous conclusion can be reached on the basis of a study of the adsorption of $[B_4O_7^{2-}]$, namely that R virtually does not change when E_{cp} is varied in the range from −0.2 to −1.0 V for a constant value $E_i = E_{cor}$.

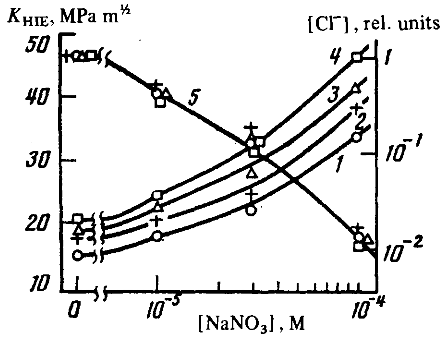

Figure 5. Dependence of K_{HIE} for the steel 02N18K9M5T in 0.0003 M NaCl solution (curves *1*–*4*) and of the concentration of chloride ions adsorbed on the film at the top of the crack (curve *5*) on the $NaNO_3$ concentration in solution at different cathodic polarisation potentials E_{cp} (V): *1*) −0.4; *2*) −0.6; *3*) −0.8; *4*) −1.0.[28]

The dependence of K_{HIE} on the cathodic polarisation potential E_{cp} and the absence of such dependence of R are not in conflict, because different standard values of K_{HIE} for a given E_{cp} for a solution not containing HIE inhibitor ions are used in the calculation of R for different values of E_{cp}. Brief cathodic polarisation does not apparently alter the composition and properties of the passivating film formed at the corrosion potential.

The initial potential E_i, at which the passivating film at the apex of the crack is formed, exerts a significant influence on the competitive adsorption of anions. At the constant potential $E_{cp} = -0.6$ V, the increase of E_i from zero to +0.8 V entails a marked decrease of the degree of adsorption of $B_4O_7^{2-}$ from solutions with identical concentrations of tetraborate and nitrate ions; the ratio of the adsorption coefficients of these anions R diminishes from 0.03 to 0.003.[28] Fig. 6 presents the dependence of R on the potentials E_{cp} and E_i for all the electrolytes investigated in the above study.[28] Evidently, for constant values of E_i, E_{cp} (curves *1* and *2*) hardly influences R, which depends mainly on E_i. This dependence is different for different pairs of competing anions. With increase of E_i, the ratio R for the $B_4O_7^{2-}/NO_3^-$ pair diminishes (curve *3*), that for the pair OH^-/CrO_4^{2-} hardly changes, while that for the pair OH^-/NO_3^- decreases in the range −0.2—+0.4 V and increases with increase of E_i to +0.7 V.

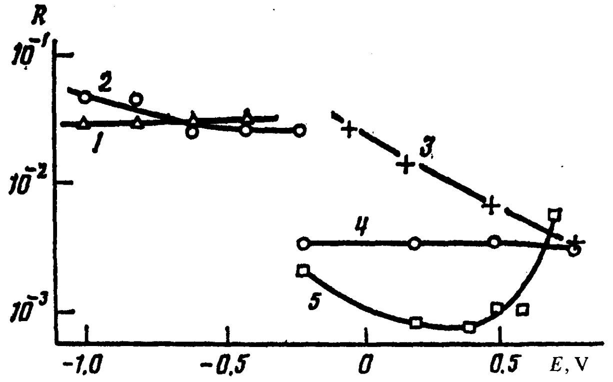

Figure 6. Dependence of the ratio R of the ion adsorption coefficients on E_{cp} (curves *1* and *2*) and E_i (curves *3*–*5*): *1*) Cl^-/NO_3^- pair; *2*) and *3*) $B_4O_7^{2-}/NO_3^-$ pair; *4*) OH^-/CrO_4^{2-} pair; *5*) OH^-/NO_3^- pair.[28]

The method described above makes it possible to calculate the ratio of the adsorption coefficients of two anions when they are present simultaneously in solution but it does not permit the calculation of the absolute adsorption coefficients of individual anions. Nevertheless, the activating or inhibiting capacity of different anions in relation to the HIE process at different potentials E_i in which the passivating film has been formed can be inferred qualitatively from data for the variation of K_{HIE} for the same steel in solutions with different concentrations of such anions. Thus it is seen from Fig.7 that, over the entire experimental range of potentials, the anion $B_4O_7^{2-}$, which does not activate the general and pitting corrosion of steels, increases the permeability of passivating films to hydrogen just as much as the chloride ion—the most active of the halide ions. The joint adsorption of $B_4O_7^{2-}$ and halide ions enhances their activating effect on the HIE process and the differences in the activating effects of different halide ions are virtually abolished. The ability of anions to activate the HIE process at potentials from −0.8 to +0.1 V increases in the sequence $F^- \ll I^- \cong Br^- < Cl^- \cong B_4O_7^{2-}$, while at a potential of +0.5 V it increases in the sequence $F^- \ll I^- \ll Br^- < B_4O_7^{2-} < Cl^-$ (Fig.7, curves *1*–*5*), i.e. halide ions increase the permeability of passivating films to hydrogen in the same sequence in which they activate pitting on iron and which is not the same as the sequence based on the increase of their surface activity and adsorption capacity on mercury.

The following facts are striking. The dependence of the adsorption of different anions on steel on the potential E_i (Figs.6 and 7) exhibits no anomalies at the zero-charge potential of iron (−0.4 V). The anions F^-, SO_4^{2-}, and NO_3^-, which are inactive or weakly active on the mercury–aqueous solution interface, are powerful activators of the corrosion of iron and steels. The adsorption capacity series for halide ions on mercury, which breaks down appreciably in corrosion, pitting, CIC, and HIE of constructional materials in neutral solutions,[15,23] holds in the corrosion of nickel in highly acid solutions at a high rate of dissolution,[29] where passivating films, constituting a separate phase, have apparently not formed on the electrode surface. These facts lead to the conclusion that concepts of the zero-charge potentials of the metals and of the ϕ potentials on the reduced scale (in the form in which they have been formulated in theoretical electrochemistry[22]) are inapplicable to corrosion processes occurring on the surfaces of passivating films. Indeed the zero-charge potential characterises the clean surface of the metal in the absence of specifically adsorbed ions and not the surface with a layer of oxides or hydroxides, which are always formed in the corrosion of technical metals and alloys in weakly acid, neutral, and alkaline solutions.

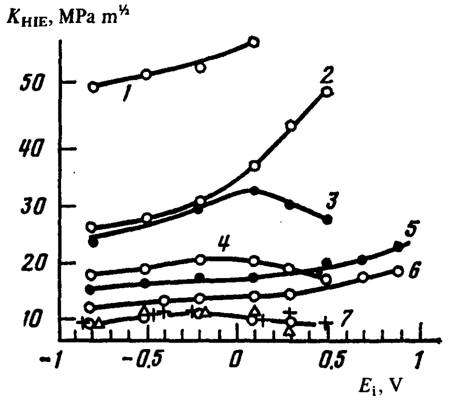

Figure 7. Dependence of K_{HIE} for steel A on the formation potential of the passivating film in solutions of different salts (concentration 0.001 M); *1)* NaF; *2)* NaI; *3)* NaBr; *4)* NaCl; *5)* $Na_2B_4O_7$; *6)* $Na_2B_4O_7$ + NaF; *7)* $Na_2B_4O_7$ + NaCl (or NaBr or NaI); $E_{cp} = -0.8$ V.[28]

Hoar[30] emphasises the disagreement between the zero-charge potentials on clean and oxidised metals in aqueous solutions and suggests that the zero charge potential of the oxidised metal is close to the pitting potential. The concept of the "pH of the zero charge potential (pH_0)* is used in the study of adsorption on oxide and oxidised metallic electrodes. It has been shown that anions are adsorbed on the surfaces of oxides at pH < pH_0 and that their adsorption is independent of the polarisation of the electrode over a wide range of potentials.[31] A tendency to use the concept of pH_0 in corrosion studies has arisen recently. For example, it has been shown[32] that in a chloride solution a decrease of pH_0 of aluminium (pH_0 = 9.1) when the latter is alloyed with molybdenum (pH_0 = 1.95) increases the pitting potential from −0.7 to −0.5 V.

The method for the investigation of adsorption on a passivating film proposed by the present author[15,28] makes it possible to obtain information *in situ* about the adsorption processes at the apex of the crack in the CIC at different potentials and is fairly sensitive (up to 10^{-5} g-ion litre^{-1} for chloride and nitrate ions). It can be used to study any constructional materials in the CIC of which HIE plays an important role. Some of the results of the calculations by this method, for example, data for the adsorption of chloride ions on the surface of a passivating film at the apex of the crack in the CIC of the AL27-1 aluminium alloys have been tested by the ESCA method. It follows from the calculated data that,[19] when $NaNO_3$ is introduced into the 0.5 M CrO_3 + 0.01 M NaCl solution at a concentration of 0.01 M, the concentration of chloride ions adsorbed on the passivating film diminishes by a factor of five. It has been established by the ESCA method that [Cl^-] is 1.5 at.% in the initial solution, while after the introduction of 0.01 M $NaNO_3$ it is not more than 0.5 at.%. This confirms the more general conclusion of the above study that, in the simultaneous presence of chloride and nitrate ions at equal concentrations (in the range 0.01–0.1 M) in 0.5 M CrO_3 solution, the adsorption of chloride ions on the passivating film is almost completely suppressed.

The competitive adsorption of anions in the CIC of the AL27-1 aluminium alloy and the study of adsorption by the ESCA method have been described in detail in studies[19,20] where it was shown, in particular, that the adsorption isotherm of chloride ions, calculated by Eqn.(7), is very close to the experimental isotherm obtained by the ESCA method. Extensive possibilities for experimental tests (by studying the adsorption, saturation with hydrogen, and permeability to hydrogen of thin films, etc.) have arisen as a result of the investigation of high-strength steels because in these materials it is possible to select conditions for the determination of K_{HIE} in the absence of the growth of the crack, i.e. when $K_{HIE} < K_{ISCC}$. The state of the surfaces of the model specimens, investigated, for example, by the ESCA method, is closer to the state of the real surface at the top of the stationary crack than under the conditions of its growth.

IV. THE DEGREE OF SURFACE COVERAGE OF THE PASSIVATING FILM ON A METAL AT THE APEX OF THE CRACK BY ADSORBED HYDROGEN ATOMS

The first two stages in the HIE process (the discharge of hydrogen ions and the adsorption of hydrogen atoms on the surface of the passivating film at the top of the crack until the attainment of a degree of surface coverage θ with subsequent transport of hydrogen through the film to the film–metal interface) are especially important, because each of them may become the rate-limiting stage in the HIE accompanying the CIC under certain conditions. It must be specially emphasised that the degree of such coverage of the film–solution interface by adsorbed hydrogen atoms can significantly exceed the degree of coverage of the nickel–metal interface, because passivating films are barriers to the penetration of hydrogen to the metal both in CIC and in gas-phase HIE, so that the boundary conditions for the diffusion of hydrogen in the metal are determined to a very large extent by the permeability of the film to hydrogen. For example, the presence of 2–3 monolayers of the oxide on the surface of tantalum reduces the rate of adsorption of hydrogen by a factor of 10^{10}.[33] The role of passivating films as barriers to the penetration of hydrogen into the metal is one of the few questions in the theory of CIC for which there is virtually no disagreement (in its qualitative treatment), but in the few studies[12,34,35] which have been devoted to the determination of θ for adsorption on iron, steel, and nickel the role of films is as a rule not considered.

The method for the determination of the degree of surface coverage θ by adsorbed hydrogen atoms of the film at the top of the crack in CIC[36] is based on the quantitative concept of the permeability of passivating films to hydrogen. In the study of the dependence of K_{HIE} and V_{cr} on the cathodic polarisation potential E_{cp} for the same alloy–electrolyte system, the coefficients in Eqns.(2) and (3), namely ξ, α, and β, can be regarded as constant; the dependence is then determined solely by the dependence of θ on the potential. Since the above constant coefficients in Eqns.(2) and (3) are unknown, the determination of the absolute values of θ from the results of corrosion-mechanical tests is impossible. However, having adopted $\theta = 1$ for certain standard conditions (the compositions of the alloy and the electrolyte and the potential E_{cp}), it is possible to determine the relative changes in θ_x as the potential is varied. It follows from Eqns.(2) and (3) that

$$\theta_x = \frac{V_{cr,st}}{V_{cr,x}}\left(\frac{K_{HIE,st}}{K_{HIE,x}}\right)^n . \qquad (9)$$

The standard potential for each alloy–electrolyte system is chosen arbitrarily (as a rule, this is the most negative potential in the series of experiments).

The dependence on the potential E_{cp} on the degree of coverage θ by hydrogen atoms of the surface of the passivating film on the metal at the apex of the crack in the CIC of the high-strength steels N18K9M5T, 40Kh13, and 38N4MFA and the VT20 titanium alloy has been investigated.[36] All the steel specimens and some of the titanium specimens were tested in the state of planar deformation (the exceptions where the thickness of the titanium specimens did not satisfy the formal requirements[14] will be noted below). The relative error in the experimental determination of K_{HIE} was 4%, while the error in the calculation of θ by Eqn.(9) was about 40%.

Fig.8 presents the dependence of the surface coverage by hydrogen atoms of the passivating film at the top of the crack on E_{cp} in the CIC of the steel 02N18K9M5T in different solutions at pH 10. Thus, in view of its high tendency to undergo HIE, this steel is particularly convenient for the investigation of such dependence, since its HIE under CIC conditions in alkaline solutions at $E_{cp} = -(0.2–0.8)$ V can be induced for $K \leq K_{ISCC}$, i.e. in the absence of the growth of cracks at the corrosion potential. This extends the range of the potentials investigated and reduced significantly the scatter of the values of θ, because in the calculation of θ one can disregard the critical rates of growth of the cracks and hence the errors in their measurement. The cathodic polarisation potential $E_{cp} = -0.8$ V was selected as standard for electrolytes. It must be emphasised that the adoption of $\theta = 1$ for standard conditions does not imply the assumption of the complete surface coverage of the film by adsorbed hydrogen, since the method employed does not permit the determination of the absolute values of θ. Presumably the coverage at $E_{cp} = 0.8$ V is close to the maximum, because at more negative potentials (down to −1 V) it hardly changes in all the electrolytes investigated. For the 0.03 M Na_2HPO_4 + 0.1 M NaCl solution (Fig.8, curve *1*), the region of weak dependence of θ on the potential ranges from −0.4 to −0.8 V. For electrolytes without chloride ions and for the solution having the composition 0.03 M Na_2HPO_4 + 0.05 M $NaNO_3$ + 0.1 M NaCl, in which the adsorption of chloride ions is significantly suppressed by nitrate ions, the decrease of θ with the increase of the potential can be described by the general curve *2*, for which $\Delta E/\Delta \lg\theta$ in the range from −0.3 to −0.8 V is 0.25 V. In the solution 0.03 M Na_2HPO_4 + 0.1 M NaCl, the decrease of θ with increase of the potential from −0.8 to −0.4 V is not quite so intense (curve *1*), but in the range from −0.4 to −0.2 V the rate of decrease of θ accelerates and curves *1* and *2* have approximately equal slopes.

A study[34] devoted to the determination of θ by the pulsed anodic polarisation of an iron electrode in the solution 0.0001 M NaOH + 0.1 M Na_2SO_4 (pH 9.5), i.e. under conditions close to those of the present author's study[36] (Fig.8, curve *1*), showed that in the potential range from −0.3 to −0.4 V, the coverage θ varies from 0.05 to 0.12 and $\Delta E/\Delta \lg\theta =$ 0.27 V. For nickel, the main alloying component on the steel 02N18K9M5T in an alkaline solution in the region of low (up to 0.3) coverages, this coefficient is 0.20 V.[35] The similarity of the values of $\Delta E/\Delta \lg\theta$ obtained under the initial conditions by direct electrochemical methods[34,35] to those obtained by the indirect computational method described in the present study can be regarded as evidence for the validity of the assumptions underlying the computational method.

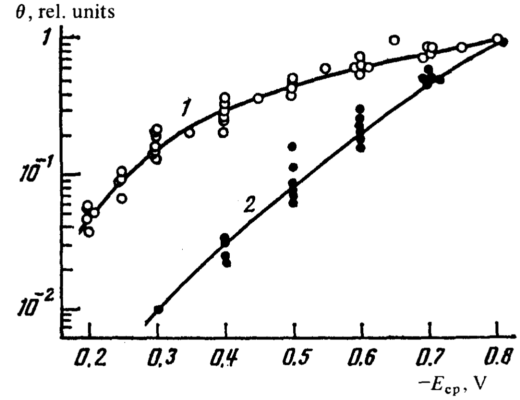

Figure 8. Dependence on the cathodic polarisation potential of the degree of surface coverage by adsorbed hydrogen atoms of the surface of the passivating film at the top of the crack under the conditions of the CIC of the steel 02N18K9M5T in solutions at pH 10: *1*) 0.03 M Na_2HPO_4 + 0.1 M NaCl; *2*) NaOH (or 0.03 M Na_2HPO_4) + 0.05 M $NaNO_3$ + 0.1 M NaCl.[36]

The concept of the permeability to hydrogen of the passivating layers on a metal at the apex of the crack in the CIC and the method for the determination of θ arising from it have no fundamental limitations associated with the nature of the material. They can be used for any alloy–electrolyte system in which there is a possibility of the growth of the crack via the HIE mechanism under CIC conditions and which is characterised by different types of influence of the cathodic polarisation on the growth of cracks, which constitutes the experimental basis for the determination of K_{HIE} and V_{cr}. Only high-strength steels satisfy these conditions in the CIC in the majority of aqueous solutions, but, by a suitable selection of the composition of the electrolyte, it is possible to extend significantly the range of such materials and to include in it austenite stainless high-strength steels and titanium, zirconium, and aluminium alloys (Section I). Their selection consists in seeking the optimum combination of the concentrations and nature of the electrolyte components—passivators and activators. The role of the passivator consists in hindering or fully suppressing the growth of cracks via the local dissolution mechanism, which increases K_{ISCC}, while the role of activators is to ensure the permeability of the passivating layers at the top of the crack to hydrogen sufficient for HIE. It has been established by means of such selection that solutions based on chromium trioxide are universal for the determination of the role of HIE in the CIC of various constructional materials. For example, different types of influence of cathodic polarisation on the growth of cracks in the CIC of high-strength steels and titanium and aluminium alloys can be observed in the solution 1 M CrO_3 + 0.1 M NaCl.[3,15,36]

V. HYDROGEN-INDUCED EMBRITTLEMENT IN CORROSION-INDUCED CRACKING AT POSITIVE POTENTIALS

Studies on HIE (in particular on the dependence of θ on E_{cp}) in solutions based on chromium trioxide are of special interest, because they make it possible to observe HIE at potentials $E_{cp} > 0$ (relative to the n.h.e.). In these solutions, the corrosion potentials of steels and titanium alloys are +(0.5–0.8) V, which permits the determination of K_{HIE} and V_{cr} over a wide range of cathodic polarisation potentials including extremely positive potentials.

It has come to be assumed that at positive potentials HIE is impossible,[37] because the electrochemical evolution of hydrogen is thermodynamically impossible. However, although in the majority of alloy–electrolyte systems HIE under CIC conditions is indeed observed at negative potentials, this view is not uncontroversial. Data have been published on HIE in the CIC of steels[38] and titanium alloys[8] at potentials in the range +(0.1–0.15) V in acid buffer solutions at pH 0–1, i.e. under conditions which rule out the additional acidification of the electrolyte in the crack owing to the hydrolysis of the corrosion products.

The theory of the hydrogen electrode deals with two consecutive electrochemical reactions: the discharge of hydrogen ions and the combination of hydrogen atoms into molecules with liberation of gaseous hydrogen via several possible mechanisms. As a result of the first reaction, absorbed hydrogen atoms capable of penetrating through the passivating layers and ultimately causing HIE, are formed on the electrode surface. This reaction is primary and is therefore most important for the HIE process. On metals which effectively adsorb and absorb hydrogen, it can lead to high surface coverages by hydrogen atoms at fairly high positive potentials (up to +0.4, 0.3, 0.27, and 0.21 V on platinum, palladium, rhodium, and nickel respectively[39]); at the zero charge potential relative to the n.h.e., the degree of surface coverage of these metals in 0.5 M H_2SO_4 solution is close to unity.[39–41] The hydrogen evolution reaction at negative potentials influences the HIE process in CIC insofar as the degree of surface coverage of the passivating film on the metal at the apex of the crack by adsorbed hydrogen atoms depends on the ratio of the rate constants for the discharge and hydrogen evolution reactions.

The hydrogen electrode theory does not take into account the adsorption energy of hydrogen atoms on the electrode surface although there are indications in the literature[40,42] that the overpotential of the hydrogen evolution reaction and the degree of surface coverage depend on the adsorption energy and on the presence of oxide layers on the metal surfaces. For example, the free energies of formation of TiH_2 and TiH are −87 and −63 kJ mol^{-1} respectively, which indicates the thermodynamic feasibility of the formation of the corresponding hydrides (and hence also of the adsorption of hydrogen atoms as the first stage in the hydride formation reaction) at potentials of +0.45 and +0.65 V respectively.[43] The enthalpy of adsorption of hydrogen on the clean iron surface ranges from −52 to −120 kJ mol^{-1} according to various data,[6,9,44] i.e. the formation of adsorbed hydrogen atoms on the iron surface when hydrogen ions are discharged in acid electrolyte is possible at potentials up to +(0.27–0.61) V (without taking into account the overpotential of the discharge reaction and the influence of passivating layers).

In connection with the question of the possibility of HIE at positive potentials under discussion, mention should be made of the increase of the sodium segregation potential in neutral and alkaline solutions on mercury:[45] the reversible sodium segregation potential is −2.71 V, but appreciable reduction of sodium ions with formation of an amalgam begins already at −1.2 V, i.e. at a potential more positive by 1.5 V than the standard value. This phenomenon, induced by the decrease of the free energy of sodium on formation of the amalgam, has apparently the same nature as the discharge of hydrogen ions at positive potentials on platinum, palladium, nickel, and other metals with a high hydrogen adsorption energy.

In the study of HIE in solutions based on chromium trioxide, the compositions and the concentrations of the solution components were selected empirically for each alloy on the basis of the following inter-related requirements:[15,36] (1) the ratio of the concentrations of the activators (NaCl and Na_2SO_4) to the passivator (CrO_3) concentration should be the maximum possible; (2) at the corrosion potential E_{cor} = +(0.5–0.8) V, the alloy must exist in a stable passive state; (3) the current density at the most negative (standard) cathodic polarisation potential should not exceed 0.3 mA cm^{-2}. The fulfilment of all these requirements ensures a high permeability of the passivating layers at the top of the crack to hydrogen, low (or zero) rates of growth of cracks via the LAD mechanism at the corrosion potential and for high values of K, as well as insignificant changes in the electrolyte composition after brief cathodic polarisation. For example, tests on the VT20 titanium alloy were performed in (0.5–2) M CrO_3 + 0.1 M NaCl solutions [pH 1–0, E_{cor} = +(0.75–0.85) V].[36] The dependence of K_{HIE} on E_{cp} was determined and the relative changes in θ were calculated from Eqn.(9). Fig.9 shows that in all electrolytes an increase of the potential from −0.4 to 0 V entails a smooth decrease of θ and then a sharp fall. It is noteworthy that the values of K_{HIE} corresponding to θ > 0.2 were obtained under planar deformation conditions and those corresponding to a lower value of θ were obtained under the conditions of a mixed strained state of the specimen. For this reason, the values of θ in the range 0.01–0.2 in Fig.9 may be somewhat too low.

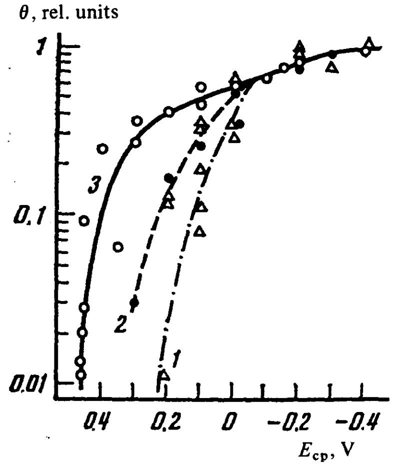

Figure 9. Dependence on the cathodic polarisation potential of the degree of surface coverage by adsorbed hydrogen of the surface of the passivating film at the top of the crack under the conditions of the CIC of the VT-20 titanium alloy in 0.1 M NaCl solutions with different amounts of added CrO_3: *1*) 2 M; *2*) 1 M; *3*) 0.5 M.[36]

In connection with the problem formulated—the investigation of the possibility of HIE at positive potentials—it is more important to emphasise that at potentials up to +0.45 V (see curve *3* in Fig. 9) the degree of surface coverage of the passivating film at the apex of the crack by adsorbed hydrogen atoms exceeds 0.01 and is sufficient to accelerate the growth of the cracks in the CIC of a titanium alloy via the HIE mechanism. The identity of the above potential with the standard potential for the formation of TiH_2 in acid solutions is apparently fortuitous and cannot be regarded as proof of the hydride mechanisms of the HIE of the VT20 alloy.

Compared with titanium, high-strength steels show a much smaller tendency to be passivated in chromium trioxide solutions and the chromate ion reduction reaction on the surface takes place more vigorously, so that the dependence of θ on E_{cp} in the HIE of high-strength steels was investigated in solutions with a lower concentration ratio $NaCl/CrO_3$ than for the VT20 alloy.[36]

Fig. 10 shows that θ falls sharply with increase of E_{cp}; however, at sufficiently positive potentials in the range +(0.1–0.5) V the values of θ are in the range 0.003–0.001 and are sufficient for the growth of cracks via the HIE mechanism. The possibility of determining such low values of θ by the method proposed by the present author[36] indicates its high sensitivity, which greatly exceeds the sensitivity of the known electrochemical methods. This is because in HIE of high-strength steels—materials showing the greatest tendency towards HIE for which the degree of surface coverage by hydrogen atoms ($\theta \cong 0.0001$) exceeds by several orders of magnitude the permeability to hydrogen—was used as the indicator of the presence of adsorbed hydrogen at the apex of the crack. Evidently the sensitivity of the metal should increase with increase of the strength of the steel (i.e. with increase of its tendency towards HIE) and as the values of K in the determination of θ approach K_{IC}.

In the above study[36] no account was taken of the possibility of a change in the pH of the electrolyte in the crack owing to hydrolytic processes and of the incomplete external cathodic polarisation at the top of the crack; as a result of the above processes, the true pH and the potential E_{cp} at the apex of the crack may be other than on the surfaces of the specimen. It is therefore necessary to emphasise that the titanium alloy and high-strength steels existed in the solutions of chromium trioxide in a stable passive state (i.e. the dissolution and hence the hydrolytic processes involving the dissolution products were virtually completely suppressed) and also that, at E_{cp} = +(0.2–0.5) V, the external polarisation current density did not exceed 10 μA cm^{-2}. The latter implies that, under the conditions of high electrical conductivity of the solution (pH 0) and the maximum opening of the crack at high $K \cong 0.9\ K_{IC}$, such currents could induce only a slight ohmic potential drop in the crack and the true potential at the apex of the crack should be more positive than the value of E_{cp} specified by the external cathodic polarisation.

The data in Figs. (9) and (10) can be regarded as experimental proof of the HIE of titanium alloys and high-strength steels at potentials significantly greater than zero relative to the n.h.e., i.e. under conditions where the electrochemical evolution of hydrogen is thermodynamically impossible, but, as shown above, one cannot rule out the possibility of the discharge of hydrogen ions and the formation of adsorbed hydrogen atoms on the surface of the passivating film.

The results described above justify the consideration of the discharge of hydrogen ions (without subsequent evolution of hydrogen) as a possible cathodic depolarisation process together with oxygen and hydrogen depolarisation processes. Judging from the high rates of growth of cracks in the HIE during CIC, the discharge of hydrogen ions may occur at a high rate over a wide range of potentials, including high positive potentials, but the adsorption nature of this process limits its depolarising capacity: for the maximum surface coverage (one hydrogen atom per metal atom), the amount of electricity consumed in the discharge process should not exceed 160–200 μC cm^{-2}) depending on the lattice constant of the metal. This implies that, in the usual corrosion processes, the discharge of hydrogen ions ceases rapidly and does not play an appreciable role as the cathodic depolarisation process, but in corrosion with constant renewal of the surface it can become an important cathodic process. It was shown above that, despite the low coverages θ at positive potentials, the discharge of hydrogen ions is in fact responsible for the growth of cracks via the HIE mechanism in CIC. In corrosion fatigue, corrosion wear, and rapid anodic dissolution, for example, under electrochemical polishing conditions or in chemical milling, the discharge of hydrogen ions (without the evolution of hydrogen) can play a significant role and can lead to the saturation of the metal with hydrogen.

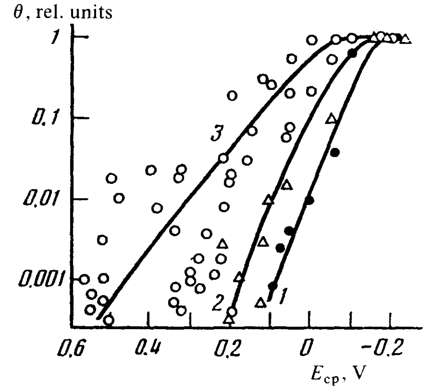

Figure 10. Dependence on the cathodic polarisation potential of the degree of surface coverage by hydrogen atoms of the surface of the passivating film at the top of the crack under the conditions of the CIC of the steels 4Kh13 (curve *1*) and 02N18K9M5T (curve *2*) in the 2 M CrO_3 + 0.1 M Na_2SO_4 + 0.003 M NaCl solution and of the steel 38N4MFA (curve *3*) in the 2 M CrO_3 + 0.02 M Na_2SO_4 solution.[36]

The role of the discharge of the hydrogen ions as the main cathodic process is apparently greatest on the freshly formed surfaces of the metal after a short (80–100 μs) time of their exposure to electrolytes. The study of corrosion and electrochemical properties of the freshly formed surfaces shows that, for many metals (iron, aluminium, titanium, etc.), the corrosion potential increases immediately after the cut and then sharply diminishes after 80–150 μs to values close to the standard potentials of the corresponding metals.[46] For lifetimes in the range 80–150 μs, the corrosion potential of the freshly formed surfaces in neutral solutions is as a rule more positive by 0.1–0.3 V than the hydrogen evolution potential and the current density of the anodic and cathodic processes reach several hundreds of mA cm^{-2}. It has been noted[46] that the nature of such an intense cathodic process is obscure because, owing to fusion-dependent limitations, this process cannot involve the reduction of the dissolved oxygen and the electrochemical evolution of hydrogen is thermodynamically impossible. Under these conditions, the discharge of hydrogen ions at positive potentials is the most likely cathodic process. It must be emphasised that, despite these limitations associated with its adsorption nature, this process can ensure the experimentally observed cathodic current densities (up to 1 A cm^{-2}) during periods up to 200 μs. In all cases the rate of the cathodic process on the freshly formed surfaces fell sharply owing to the formation of the primary passive film after brief exposures.[46]

The adsorption nature of the cathodic discharge of hydrogen ions makes it possible to account for certain characteristic features of the CIC and HIE of constructional materials in chromium trioxide solutions. These solutions, having the composition (0.5–2) M CrO_3 + (0.01–0.1) M NaCl, possess specific properties promoting the elucidation of the role of HIE in the CIC of different constructional materials. For example, only in this medium is it possible to observe HIE in the CIC of aluminium alloys,[3] while in the CIC of titanium alloys and high-strength steels in CrO_3 + NaCl solutions, K_{HIE} is much lower than in the presence of other oxidants.[36] As a rule, at sufficiently high cathodic polarisation potentials $K_{HIE} < K_{ISCC}$, i.e. passivating layers are formed in chromium trioxide solutions in the CIC at the top of the crack. These layers effectively suppress the growth of cracks via the LAD mechanism and at the same time exhibit a fairly high permeability to hydrogen.

In contrast to other oxo-ions, chromates are reduced on the surfaces of metals, as a result of which Cr^{3+} ions enter into the composition of the passivating film.[18] Studies by the ESCA method have shown[20] that the concentration of Cr^{3+} ions on the surface of the passivating film on the AL27-1 alloy in 0.5 M CrO_3 + 0.01 M NaCl solution is 5–6 at.%. It is known[3] that hydrogen is hardly adsorbed on aluminium oxides and hydroxides. It is also known[47] that the heat of adsorption of hydrogen on chromium oxide is very high. Presumably the Cr^{3+} ions entering into the composition of the passivating layers from aqueous chromate solutions generate effective adsorption centres on which hydrogen ions are discharged. Thus the passivating films in chromium trioxide solutions, which retain effective protecting properties and suppress CIC via the LAD mechanism, can promote the penetration of hydrogen into the metal and can facilitate CIC via the HIE mechanism.

---o0o---

In conclusion one should note that the quantitative concept of the permeability to hydrogen of passivating layers on a metal at the apex of the crack in the CIC of constructional materials, considered in the present review, is based on several postulates each of which separately does not conflict with known facts but cannot be fully justified theoretically or experimentally. Nevertheless, on the basis of this concept, it has been possible to reach *a priori* certain definite conclusions which have been confirmed experimentally.[10,13,15] This can be regarded as proof of the validity of the initial postulates of the concept considered and the method, arising from it, for the investigation *in situ* of the adsorption of activator ions on the passivating film at the apex of the crack in CIC, the method for the investigation of competitive adsorption, and the method for the determination of the dependence of the relative changes in the degree of surface coverage by the hydrogen adsorbed on the film on the cathodic polarisation potential. The above methods were used in the study of a wide range of processes which are of theoretical and practical importance (the development of physical ideas about the mechanism of HIE, the study of the strained state of the material at the apex of the crack, the study of inhibitors of corrosion, CIC, and HIE, the search for solutions for hydrotests, etc.).

Activation and Catalytic Reactions of Alkanes in Solutions of Metal Complexes

A.E.Shilov and G.B.Shul'pin

The reactions of saturated hydrocarbons and compounds modelling them with metal complexes, leading to the cleavage of the C-H and C-C bonds, are examined. In particular, processes which result in the formation of organometallic derivatives are described and the mechanism of the oxidation of alkanes by enzymes and their chemical models is discussed.
The bibliography includes 355 references.

VI. Conclusion	457

I. INTRODUCTION

The relatively low reactivity of saturated hydrocarbons is due to the absence of π and n electrons from their molecules and the low polarity of the C–H and C–C σ-bonds. At the same time, since paraffinic hydrocarbons (the store of which, especially methane, in nature is still large) are one of the types of chemical organic raw materials, the problem of their conversion into functional derivatives (alcohols, ketones, and acids) and also of the synthesis of olefins and aromatic hydrocarbons from alkanes is currently of very great importance. The hydrocracking and isomerisation reactions of paraffins, which make it possible to obtain valuable forms of motor fuel, are also of considerable practical importance. The main industrial processes in which alkanes are used as raw materials occur at high temperatures (above 150–200 °C), frequently in the presence of heterogeneous catalysts (for example, dehydrogenation, aromatisation, the reaction of methane with water which affords the CO + H_2 mixture, the cracking of methane to acetylene and hydrogen, nitration, fluorination by CoF_3, etc.). The radical-chain processes (photochemical chlorination by Cl_2, oxidation by molecular oxygen initiated by light or radicals, sulphochlorination, etc.), which are carried out at low temperatures, constitute a special field. However, the selectivity of these reactions is low and complex mixtures of products are usually formed. Finally, the ability of certain micro-organisms and higher animal cells to oxidise alkanes by oxygen at the usual temperature has long been known. Biological oxidation is usually selective. For example, certain micro-organisms oxidise only the terminal methyl group of hydrocarbons, converting it initially into an alcohol (ω-hydroxylation).

New homogeneous reactions of alkanes, occurring in solution or in the gas phase, have been discovered recently.[1] Thus the reactions of saturated hydrocarbons with electrophiles in solutions of strong acids or superacids have been discovered.[1,2] The proton, the attack of which on the alkane gives the alkonium ion $C_nH_{2n+3}^+$, which subsequently decomposes with cleavage of the C–H and C–C bonds, functions as the electrophilic species in solutions of the acids FSO_3H–SbF_5 or HF–SbF_5. The electrophilic substitution of hydrogen in alkanes by the nitro-group takes place under the influence of $NO_2^+PF_6^-$ in dichloromethane at room temperature, while the reaction of an alkane with Cl_2 in SbF_2–SO_2ClF takes place even at −78 °C. Solutions of fluoranil in HF–HF–SbF_5 oxidise methane, propane, and n-pentane.[3] The dissolution of H_2O_2 or O_3 in FSO_3H–SbF_5–SO_2ClF generates respectively the $H_3O_2^+$ and HO_3^+ species, which attack alkane molecules electrophilically resulting in the formation of various oxygen-containing derivatives. Like ozone, iodoxybenzene $PhIO_2$ oxidises aromatic alkyl-substituted hydrocarbons.[4] In reactions with electrophiles, the reactivity of the bonds in branched alkanes usually diminishes in the sequence 3° > C–C > 2° > 1° (where 1°, 2°, and 3° denote respectively the primary, secondary, and tertiary C–H bonds). In the reaction with $H_3O_2^+$, the reactivity varies in the sequence[2] 3° > 2° > 1° > C–C. An analogous behaviour has been observed also in the interaction of branched alkanes with radical and carbene species.[1] Thus hydroxylation of alkanes by peracids (for example, trifluoroperacetic)[1,5] also proceeds with the "normal" selectivity 3° > 2° > 1°, while the reaction with *cis*- or *trans*-1,2-dimethylcyclohexane proceeds with complete retention of the configuration. The reaction takes place via the "oxenoid" mechanism—with insertion of the oxygen atom in the C–H bond without the formation of intermediate free-radical or ionic species. Thus in all the reactions enumerated the reactants interacting with alkanes are to some extent electrophilic. The reaction of an alkane (methane, ethane, propane) with the phenylium ion $C_6H_5^+$ in the gas phase has been described recently.[6] The product of the insertion of the phenylium cation in the R–H bond of the alkane, resembling the familiar Wheland complex, which is converted into C_6H_5R after transferring H^+ to a base, is formed as an intermediate. The interaction of 1,10-B_{10}.$H_8(N_2)$ with a mixture of CO and CH_4 leads to the formation of $MeB_{10}H_7(CO)_2$ and $Me_2B_{10}H_6(CO)_2$, but the reaction mechanism has not been established.[7]

The first reaction of an alkane with a metal complex in which an organometallic compound, i.e. a derivative containing a metal–carbon bond,[9] is formed as an intermediate was discovered[8] in 1969. This reaction is responsible for the H–D exchange in methane, ethane, and higher alkanes in the C_nH_{2n+2}–D_2O–$PtCl_4^{2-}$ system. The ability of alkanes to be oxidised in the C_nH_{2n+2}–H_2O–$PtCl_4^{2-}$–$PtCl_6^{2-}$ system, also with the intermediate formation of organometallic σ-complex of platinum, was discovered somewhat later.[10] The characteristic features and mechanisms of these reactions have been studied in detail. Section II of the present review review is devoted to such reactions. New reactions in which the alkane molecule is activated in solution with a transition metal complex were discovered subsequently. The number of such reactions continues to increase and an increasing number of laboratories in various countries are becoming involved in the study of this rapidly developing field. Section III presents a survey of studies on this field carried out during the last decade. Major advances have been achieved recently in the understanding of the mechanism of the biological oxidation of alkanes. The studies on the chemical models of enzymes catalysing the oxidation of alkanes are developing vigorously. It is becoming clear that the active centres interacting with the C–H bond in the alkane include high-valence derivatives of a metal (usually iron). Reactions involving the direct oxidation of alkanes by high-valence metal compounds have been known for many years.[11,12] Section IV deals with the enzymic oxidation of alkanes and the oxidation of the latter by high-valence metal complexes, associated with the enzymic process. The review covers studies published mainly in the 1980's; earlier investigations were described in detail in other reviews.[13–18]

II. REACTIONS OF ALKANES WITH PLATINUM(II) AND PLATINUM(IV) COMPLEXES

The closest analogue of the activation of alkanes involving the dissociation of weakly polar strong C–H or C–C bonds is the activation of the H_2 molecule. Indeed the H_2 and CH_4 molecules exhibit a definite similarity, because they contain only σ-bonds (H–H or C–H), which have virtually identical homolytic dissociation energies $D(R{-}H)$ = 103–104 kcal mol^{-1} and are characterised by a high ionisation potential and a low electron affinity. At the end of the 1960's considerable advances were made in the solution of the problem of the activation of H_2 by metal complexes (see, for example, James[19]). The key stage of such activation is the oxidative addition of hydrogen in accordance with the scheme

$$M^n + H_2 \rightarrow H{-}M^{n+2}{-}H$$

On the basis of the similarity of the properties of H_2 and alkanes, it might have been supposed that the latter are also capable of being activated by metal complexes undergoing the oxidative addition reaction with the latter. As already mentioned, the first such system is represented by the platinum(II) chloride complex.[8] It was subsequently found that the platinum(IV) complex is capable of oxidising alkanes. Analogous reactions are known also for aromatic compounds.

1. Characteristic Features and Kinetics of the Reactions

(a) Deuterium Exchange in the Presence of Platinum(II) Complexes

When methane or another alkane is heated to ~100 °C in a sealed tube containing a solution of $PtCl_4^{2-}$ in the D_2O–CD_3COOD mixture, the hydrogen atoms in the alkane are replaced by deuterium.[1,8,13–17] The process also occurs in water but in the presence of acetic acid the rate of reaction increases by a factor of 30 (when account is taken of the solubility of alkanes in CH_3COOH). The reaction is of first order with respect to the hydrocarbon. The rate constant k for the deuterium exchange involving cyclohexane in the presence of various platinum(II) complexes decreases in the following sequence for $[C_6H_{12}]$ = 0.15 M, $[HClO_4]$ = 0.1 M, [Pt(II)] = 0.02 M, and 100 °C: K_2PtCl_4 (2.78), $K_2Pt(NO_2)Cl_3$ (0.366), $KPt(NH_3)Cl_3$ (0.777), $KPt(DMSO)Cl_3$ (0.056), $KPt.(py)Cl_3$ (0.025). The values of 10^3k (litre mol^{-1} s^{-1}) are given in brackets. When the anions X^- are added to the system, new complexes catalysing the H–D exchange in cyclohexane are formed via the reaction

$$S_2PtCl_2 + 2X^- \rightleftarrows X_2PtCl_2^{2-} + 2S\,.$$

The following rate constants for this reaction have been obtained (10^3k, litre mol^{-1} s^{-1}):[13] 6.30 (in the absence of X^-); 6.28 (in the presence of CF_3COO^-); 6.26 (F^-); 6.06 (SO_4^{2-}); 4.10 (Cl^-); 2.47 (Br^-); 0.394 (I^-); 0.115 (NO_2^-); 0.106 (CN^-). Ultimately this led to the establishment of the sequence based on the influence of the ligands in the platinum(II) complex on the rate of H–D exchange:[13]

$$PPh_3 \simeq py < DMSO < CN^- < NO_2^- < NH_3 < I^- < Br^- < Cl^- < F^- \simeq H_2O\,. \quad (1)$$

This sequence is the opposite to that based on the *trans*-effect of the corresponding ligands. The rate constants for the H–D exchange reaction catalysed by platinum(II) are described satisfactorily by the two-parameter equation

$$\lg(k/k_0) = \rho^*\sigma^* + n\psi\,, \quad (2)$$

where σ* is the Taft constant taking into account the polar influence, ψ the parameter characterising the conjugation of the substituent in the α-position relative to the H atom with the radical reaction centre, and n the number of substituents. The value ρ* = −1.4 indicates weak electron-accepting properties of the platinum(II) complex, while the presence of the resonance term may indicate that the C–H bond is dissociated homolytically. A linear correlation has also been observed between the logarithm of the rate of H–D exchange in hydrocarbons and their ionisation potentials.[13]

Unbranched alkanes are the most reactive in the H–D exchange reaction. On the other hand, in the exchange of branched hydrocarbons the "reverse" reactivity sequence is observed, i.e. 1° > 2° > 3°. Evidently this is associated with the strong influence of steric factors. The low rate of exchange in the methyl and methylene groups adjoining the t-butyl group in 2,2-dimethylpropane and 2,2-dimethylbutane can be explained in the same way. A characteristic feature of the reaction is multiple exchange—the alkane molecule can exchange several H atoms for D without leaving the coordination sphere of the metal complex. The multiple exchange parameter M for different alkanes varies in the range 1.4–1.7 and increases only slightly with decrease of the reaction temperature.

(b) Oxidation by Platinum(IV) Complexes

When a solution of H_2PtCl_6 and Na_2PtCl_4 in H_2O (or in aqueous CF_3COOH) is heated in the presence of alkanes (100–120 °C, 0.25–5 h), a mixture of isomeric alkyl chlorides, alcohols, trifluoroacetates, and ketones is formed, while platinum(IV) is reduced to platinum(II).[1,10,13–17] The kinetics of the reaction with participation of methane have been described in detail.[20] When cyclic alkanes (cyclohexane and decalin) are oxidised, aromatic hydrocarbons (benzene, naphthalene) are obtained. The π-complex of hex-1-ene with platinum(II) has been isolated[21] in 1% yield from the mixture of products formed in the reaction of H_2PtCl_6 with hexane in the CF_3COOH–H_2O mixture. Acetic acid is oxidised by a mixture of Pt(IV) + Pt(II) chloride complexes to chloroacetic acid. The reaction of $PtCl_6^{2-}$ with saturated hydrocarbons is catalysed by added $PtCl_4^{2-}$. In the absence of such additives, an induction period is observed, its duration decreasing with increase of the amount of added $PtCl_4^{2-}$. In the presence of heteropoly-acids, the platinum(II) formed in the reaction can be reoxidised by air and the oxidation of CH_4 to CH_3Cl (CH_3OH is then also oxidised) becomes catalytic.[22] Another catalytic system for the chlorination of alkanes contains K_2PtCl_4, H_2PtCl_6, and $HgSO_4$ immobilised on silica gel.[23]

As in deuterium exchange, the dependence of the rate of oxidation of alkanes (with a constant k_n) in the $PtCl_6^{2-}$ + $[PtCl_{4-n}(H_2O)_n]^{n-2}$ system passes through a maximum with increase of n (at $n = 2$), but in the case of isobutane $k_2 =$ 3.8 litre mol^{-1} s^{-1} differs insignificantly from k_3 and espepecially from k_1 (1.9 and 3.7 litre mol^{-1} s^{-1} respectively). The complexes with $n = 0$ and 4 are almost inactive in the reaction.[1] When the H–D exchange and oxidation reactions of cyclohexane in CF_3COOH catalysed by Pt(II) + Pt(IV) were compared, the following features were discovered:[24] the sum of the rates of the oxidation and H–D exchange reactions is independent of the concentrations of CF_3COOH and Pt(IV), but with increase of [Pt(IV)] keeping $[CF_3COOH] =$ const., the rate of oxidation rises, while with increase of $[CF_3COOH]$ for [Pt(IV)] = const. the rate of H–D exchange increases. These data show that the two processes have a common initial stage.

The oxidation reaction of alkanes containing between 1 and 4 carbon atoms in an aqueous medium is of first order with respect to the hydrocarbon and has a fractional order (0.77) with respect to platinum(II).[14] The activation energy (~20 kcal mol^{-1}) for the oxidation reactions of ethane, propane, or butane is approximately equal to the activation energy for the H–D exchange involving ethane (18.6 kcal mol^{-1}). The chlorination of acetic acid proved to be most convenient for kinetic study. The order of this reaction is unity with respect to platinum(II) and CH_3COOH. At low concentrations of the added Cl^- ions the rate of reaction is proportional to $[Cl^-]_{add}^{-1}$ while at high concentrations it is proportional to $[Cl^-]_{add}^{-2}$. The order of the reaction with respect to platinum(IV) varies from 0 to 1. The role of steric factors is strongly manifested in the reaction involving the oxidation of alkanes by the $PtCl_6^{2-}$ + $PtCl_4^{2-}$ system.[1,25] As for the system with $[H_2PtCl_6] = 0.02$ and $[K_2PtCl_4] =$ 0.05 M in water at 98 °C the oxidation rate constants diminish on passing from normal to branched hydrocarbons; for n-butane and 2-methylpropane, they are respectively 11.5 and 8.2 s^{-1}, for n-pentane, 2-methylbutane, and 2,2-dimethylpropane they are 15.3, 11.2, and 1.0 s^{-1}, and for n-octane and 2,2,4-trimethylpentane the corresponding values are 15.4 and 3.6 s^{-1}. In the series of normal alkanes, the oxidation rate constant increases with increase of the number of carbon atoms atoms: methane (1.6) < ethane (6.6) < propane (9.9). For C_5–C_8 n-hydrocarbons, k is approximately the same (~16 s^{-1}). The latter factor can be accounted for if it is assumed that the chlorine atom substitutes mainly the hydrogen atoms in the 1- and 2-positions in the chain on oxidation by the Pt(IV) + Pt(II) system. In general the number of active (capable of substituting their hydrogen atoms by Cl) carbon atoms n_a in the alkane C_nH_{2n+2} is defined by the formula[25] $n_a = n - n_{tert} - 5n_{quat}$, where n_{tert} and n_{quat} are the numbers of ternary and quaternary carbon atoms in the molecule respectively.

It has been found recently that, when a solution of H_2PtCl_6 and n-hexane in CH_3COOH is irradiated by light (λ > 300 nm) or γ-quanta, a π-complex of hex-1-ene with platinum(II), isolated in the form of the pyridine adduct $[CH_3(CH_2)_3.CH{=}CH_2]PtCl_2py$, is formed.[26-29] The yield of the π-complex in the γ-induced reaction reaches 17%. The photochemical reaction is of first order with respect to hexane.

2. Intermediate Organometallic Compounds

In earlier studies[1,13-17] it was postulated on the basis of the investigation of the kinetics of the reactions of alkanes with platinum complexes, and certain indirect evidence, that the interaction of alkanes with both platinum(II) and platinum(IV) leads to the intermediate formation of alkyl π-complexes of platinum. In recent years new indirect and direct evidence has been obtained for the involvement of these complexes in the process.

(a) The Stages in the H–D Exchange and Oxidation Reactions

The H–D exchange and oxidation reactions apparently begin with the attack by the reactive form of the platinum(II) complex on RH, which results in the formation of an alkylplatinum(II) σ-complex:

$$PtCl_4^{2-} \rightleftarrows PtCl_3^- + Cl^- \ , \qquad (3)$$

$$PtCl_3^- \rightleftarrows PtCl_2 + Cl^- \ , \qquad (4)$$

$$PtCl_2 + RH \rightleftarrows RPtCl + H^+ + Cl^- \ . \qquad (5)$$

In the absence of platinum(IV), the alkyl σ-derivative undergoes electrophilic attack by the D^+ ion (for the cleavage of the M–C bond by electrophiles—see, for example, Kochi[30]):

$$RPtCl + D^+ + Cl^- \rightarrow RD + PtCl_2 \ . \qquad (6)$$

On the other hand, if a platinum(IV) derivative is present in the system, it interacts with the platinum(II) σ-complex and converts it into an alkylplatinum(IV) σ-complex. The latter reacts with the nucleophile X (H_2O or Cl^-) and affords ROH or RCl:

$$RPt\,(II) + Pt\,(IV) \rightarrow RPt\,(IV) + Pt\,(II) \ , \qquad (7)$$

$$RPt\,(IV) + X^- \rightarrow RX + Pt\,(II) \ . \qquad (8)$$

At a temperature above 100 °C and a low platinum(IV) concentration the rate of reaction depends on [Pt(IV)] and on the acidity of the medium and stage (7) is apparently rate-limiting. The activation energy for this stage is low (~9 kcal mol^{-1}). At a temperature below 100 °C and for a low platinum(IV) concentration, the rate of the entire reaction is determined by the rate of stage (5). The activation energy for the reaction under the given conditions (~20 kcal mol^{-1} for C_2–C_4 alkanes) is naturally close to that for H–D exchange (18.6 kcal mol^{-1} for ethane).[14] Since the platinum(II) complex, used for the initial activation of RH, returns to the system in stage (7), the alkane oxidation reaction is catalytic with respect to platinum(II) and the platinum(IV) acts as an oxidant.

Evidence for the formation of intermediates or organometallic compounds in this process is presented below.

(b) Isolation of Aryl σ-Complexes and Their Properties

It is well known that transition metal complexes, in particular platinum complexes, are capable of cleaving the C–H bond intramolecularly with formation of cyclometallated compounds.[31,32] Compounds containing both sp^2-hybridised carbon atoms (aromatic rings) and groups with sp^3-hybridised carbon atoms (CH_2 and CH_3) are capable of entering into the cyclometallation reaction.[33-37] Calculation has shown[14] that the intramolecular metallation of the C–H bond should be 10^3–10^6 times faster than the intermolecular reaction.

In order to confirm the possibility of the formation of complexes with a C–Pt(IV) σ-bond in intermolecular reactions with $PtCl_6^{2-}$, use was made of aromatic compounds, since it was known that the reaction with benzene and other arenes gives rise to oxidation products (especially chlorobenzene) analogous to the alkane oxidation products and that aryl σ-complexes should be much more stable than the alkyl σ-complexes. It was found that heating of a solution of H_2PtCl_6 and an aromatic compound ArH in the CF_3COOH–H_2O mixture or in CH_3COOH leads to the formation of fairly stable aryl σ-complexes of platinum(IV) in yields up to 95%, which can be isolated in the form of anionic adducts with ammonia after chromatography on silica gel containing NH_3:[38–42]

$$ArH + PtCl_6^{2-} \xrightarrow[\text{2) } SiO_2 \cdot NH_3]{\text{1) } CF_3COOH-H_2O} [\sigma\text{-}ArPtCl_4NH_3]\,NH_4 \quad . \tag{9}$$

Complexes of naphthalene and *o*-nitrotoluene have been characterised by X-ray diffraction[38,43] and ^{195}Pt NMR spectra have been obtained for a number of complexes.[44] The kinetics of the accumulation of the complexes and of their decomposition, leading to the formation of ArAr, ArCl, and platinum(II), have been investigated.[42,45–48] The accumulation of the aryl σ-complex is accompanied by its *para–meta* isomerisation: if in the initial instant the substitution takes place mainly (to the extent of ~90%) in the *para*-position in toluene, then the statistical distribution $m:p = 2:1$ is gradually attained. The substituent does not enter the *ortho*-position for steric reasons. It has been established by the method of competing reactions[42,49] that the relative rates of reactions with participation of C_6H_5X decrease in the following sequence of X: OH (16), OCH_3 (8.5), CH_3 (3), C_2H_5 (2.7), OC_6H_5 (2.0), $CH(CH_3)_2$ (1.9), H (1.0), C_6H_5 (0.9), F (0.3), $COCH_3$ (0.1), COOH (0.09), Cl (0.08), NO_2 (0.04). The logarithms of these quantities are correlated with the Hammett constant σ and the Brown constant σ^+ (with the parameters $\rho = -3.0$ and $\rho^+ = -1.5$). On the basis of the data obtained, a mechanism has been proposed[42] for the reaction—electrophilic substitution in the aromatic ring.[48] In terms of its behaviour in the arene metallation reaction and also as regards the behaviour of the aryl σ-complexes formed in relation to nucleophiles (arenes, olefins),[50–53] platinum(IV) resembles palladium(II).[54] The gold(III) chloride complex apparently metallates arenes also via the electrophilic substitution mechanism.[55] Arenes interact with Na_2PtCl_4 on heating with a solution in $CF_3COOH-H_2O$ or CH_3COOH.[56] This apparently entails the formation of aryl σ-complexes of platinum(II) which are comparatively unstable but can be converted by treatment with H_2PtCl_6 into aryl σ-complexes of platinum(IV). Thus the platinum(II) chloride complex apparently behaves as an electrophile in the reaction with arenes. On the other hand, the reaction of arylplatinum(II) σ-complexes with $PtCl_6^{2-}$ can be regarded as a model of stage (7) in the oxidation of alkanes.

Reaction (9) can be induced not only by heating but also by light[26,28,48,57] or γ-irradiation.[27] The arenes C_6H_5X form the following series in terms of substituents X based on the variation of the relative rate of the photochemical reaction with $PtCl_6^{2-}$:[26] OH (8), OC_2H_5 (4.1), OCH_3 (4.0), OC_6H_5 (1.9), CH_3 (1.0). The logarithms of these quantities are correlated with the constants σ_n^+ ($\rho^+ = -1.5$). It has been suggested[48] that the radiation-induced reactions begin with electron transfer from the arene to platinum(IV) and then the Wheland complex is formed, as in the case of a thermal reaction.

All the reactions of arenes considered here apparently proceed by the electrophilic substitution mechanism postulating the delocalisation of the positive charge of the arene ring in the Wheland complex formed as an intermediate. Since such delocalisation is impossible for fully saturated hydrocarbons, the reaction with arene must be regarded merely as confirmation of the possibility of the formation of compounds with an M–C bond when alkanes are activated; on the other hand, the mechanisms of the interaction of the metal complexes with a C–H bond in alkanes and arenes should differ.

(c) Alkane σ-Complexes

The reactions involving the oxidative addition of alkyl halides to transition metal complexes containing phosphine or amine ligands, resulting in the formation of a compound with M–C bonds, are well known.[9,58] However, it has been found only recently[59] that the chloride complex $PtCl_4^{2-}$, not containing "stabilising" ligands, combines with CH_3I at room temperature in aqueous solution to form a methyl σ-complex of platinum(IV). An interesting feature of the reaction is that the sixth coordination site in the octahedral molecule of the product is occupied by water, while the I^- ion is bound to another molecule of the platinum(II) complex (PtI_2 is formed and precipitates). The reaction with C_2H_5I [60,61] and CH_3COCH_2I [62] proceeds analogously:

$$RI + PtCl_4^{2-} \xrightarrow{H_2O} RPtCl_4(H_2O)^- + I^- \quad . \tag{10}$$

In the presence of an excess of I^- ions at 80 °C, RI is converted rapidly and quantitatively into the alkane, the platinum(II) complex functioning as the catalyst:[63]

$$RI + I^- + H^+ \xrightarrow{Pt^{II}} RH + I_2 \quad . \tag{11}$$

The methyl σ-complex formed in reaction (10) ($R = CH_3$) eliminates CH_3Cl with formation of a platinum(II) complex:

$$CH_3PtCl_5^{2-} \rightarrow CH_3Cl + PtCl_4^{2-} \quad ; \tag{12}$$

$$CH_3PtCl_4(H_2O)^- + Cl^- \rightarrow CH_3Cl + PtCl_4^{2-} + H_2O \quad . \tag{13}$$

It has been concluded[64] on the basis of the kinetic parameters of the decomposition of the methylplatinum(IV) σ-complex that the steady-state concentration of this complex, formed in the reaction of CH_4 with the Pt(II) + Pt(IV) system at a methane pressure of 1.01×10^7 Pa, [Pt(II)] = 0.1 M, and 120 °C, should not exceed 10^{-6} M in aqueous solution. However, owing to the increase of the concentration of CH_4 and the higher rate of its reaction with platinum(II) in the $CF_3COOH-H_2O$ solution, this value may be higher by 1–2 orders of magnitude.

Similar alkyl σ-complexes of platinum(IV) can be obtained in the reaction of $PtCl_6^{2-}$ with certain alkyl derivatives of non-transition metals. Thus $PtCl_6^{2-}$ reacts slowly[65] with $(CH_3)_4Sn$ in CD_3COOD at room temperature with formation of $CH_3PtCl_5^{2-}$. The reaction is accelerated by the addition of $PtCl_4^{2-}$ and is of first order with respect to platinum(II):

$$(CH_3)_4Sn + PtCl_6^{2-} \xrightarrow{PtCl_4^{2-}} CH_3PtCl_5^{2-} + (CH_3)_3SnCl \quad . \tag{14}$$

In the absence of $PtCl_6^{2-}$, tetramethyltin reacts with Na_2PtCl_4 in aqueous acetone, also forming a methylplatinum(IV) σ-complex. The precipitation of metallic platinum is then observed. The reaction partly proceeds as oxidative addition of the components involved in the Me_3Sn-Me bond to platinum(II). As in the case of RI [reaction (10)], one component adds to the platinum(II) atom, while the other is bound by another platinum(II) species (reducing the latter):

$$(CH_3)_4Sn + 2PtCl_4^{2-} + H_2O \rightarrow CH_3PtCl_4(H_2O)^- + Pt + (CH_3)_3SnCl + 3Cl^- . \tag{15}$$

The reaction involving the transfer of the methyl group from methylcobalamine to platinum(IV) is likewise catalysed by a platinum(II) complex.[66] It is noteworthy that reaction (14) to a certain extent models the interaction of the Pt(IV) + Pt(II) system with saturated hydrocarbons. Reaction (15) probably also has features in common with the reaction of alkanes with the platinum(II) complex. The cleavage of the $Sn-CH_3$ bond by the $PtCl_6^{2-}$ complex is accelerated by light.[65] The formation of the complex $C_2H_5PtCl_5^{2-}$ (in addition to $CH_3.$ $.PtCl_5^{2-}$) has been observed by ^1H NMR in the photochemical reaction of $PtCl_6^{2-}$ with $(CH_3)_2Sn(C_2H_5)_2$ in CD_3COOD. Light apparently accelerates the conversion of the ethyl σ-complex into the ethylenic π-complex.

Thus the reactions in which there is a possibility of the formation of platinum(IV) derivatives and alkyl fragments containing a hydrogen atom in the β-position, mainly the photoinduced reactions of the ethyl derivatives of tin and germanium with $PtCl_6^{2-}$, oxidative addition of ethyl iodide or n-hexyl iodide to $PtCl_4^{2-}$, and thermal or photochemical reactions of hexane with $PtCl_6^{2-}$, lead to olefinic π-complexes of platinum(II). The most probable mechanism of the conversion of alkyl σ-complexes into olefinic π-complexes involves the β-elimination of hydrogen with reduction of platinum(IV) to platinum(II):

$$\mathrm{RCH_2CH_2PtCl_5^{2-}} \xrightarrow[-\mathrm{Cl}^-]{} \mathrm{(RCH{=}CH_2)}\underset{\displaystyle \mathrm{H}}{\mathrm{PtCl_4^{2-}}} \xrightarrow[-\mathrm{H}^+,\,-\mathrm{Cl}^-]{} \mathrm{(RCH{=}CH_2)PtCl_3^-}\,. \qquad (16)$$

The formation of the methyl σ-complex of platinum(IV) in the reaction of CH_4 with the Pt(II) + Pt(IV) system in H_2O has been demonstrated directly.[20] It was found that treatment of the reaction mixture, after the removal of methane from the latter, with sodium tetrahydroborate leads to the evolution of CH_4, formed on reduction of the complex $CH_3 . PtCl_5^{2-}$. The kinetic curve corresponding to the concentration of the methyl σ-complex determined in this way has a maximum corresponding to the same reaction time as the points of inflection on the kinetic curves for the consumption of $PtCl_6^{2-}$ or the accumulation of the final products (CH_3OH and CH_3Cl). The activation energy for the decomposition of the methyl σ-complex is 26 ± 2 kcal mol^{-1}, the decomposition rate constant at 120 °C is $0.14\ s^{-1}$, and the maximum concentration of the complex is 7.7×10^{-5} M. Hence it is possible to calculate the rate of decomposition of the complex at its maximum concentration (1.1×10^{-5} mol $litre^{-1}\ s^{-1}$), which is close to the maximum rate of consumption of platinum(IV) or accumulation of the product (1.0×10^{-5} mol $litre^{-1}\ s^{-1}$). Finally the σ-complex formed in the reaction with methane was characterised by the ^1H NMR spectrum, which proved to be identical with the spectrum of the complex obtained in reaction (10).

III. REACTIONS WITH COMPOUNDS OF OTHER METALS

As early as 1969, it was reported that the complex $H_3Co . (PPh_3)_3$ catalyses the H–D exchange between methane and D_2 in benzene solution.[8] Other hydride or low-valence metal complexes, inducing the H–D exchange in aromatic and aliphatic hydrocarbons, have been discovered in recent years. For example, processes of this kind have been described for the naphthalene–C_6D_6–$ReH_5(PMe_2Ph)_2$ [67] and H_2–C_6D_6–$ReH_7[P(C_6H_{11})_3]_2$ systems.[68] In solution in C_6D_6 the isopropyl or cyclohexyl groups R in the complexes $RuH_4 . (PR_3)_3$ are involved in the H–D exchange.[69] The photolysis of a solution of toluene or ethylbenzene in C_6D_6 in the presence of $CpMoH_3(Me_2PCH_2CH_2PMe_2)$ (Cp = cyclopentadienyl) leads to the substitution of H by D both in the aromatic ring and in the alkyl chain.[70] Under the influence of light, H–D exchange has been observed between $IrH_3(CO)(Ph_2PCH_2 . CH_2PPh_2)$ and C_6D_6.[71] The exchange between alkanes and D_2 is catalysed by the allyl hydride complex of rhodium immobilised on silica gel.[72,73] All the reactions enumerated apparently include the stage involving oxidative addition to the metal complex and in certain cases can begin with the elimination of H_2 from the hydride derivative.

In the presence of $TiCl_4$, Cp_2TiCl_2, or VCl_4, dimethylaluminium chloride exchanges the hydrogen atoms of the methyl group for deuterium atoms from CD_4.[74,75] CH_2D_2 is formed preferentially, CH_3D and CD_3H being produced in addition. The proposed reaction mechanism includes the reversible disproportionation of the methyl groups linked to the transition metal atom M, which leads to the formation of a carbenium complex, the latter combining in its turn with deuteriomethane. The electronic structures of the complexes H_nMCH_3 and H_mMCH_2 (M = Ti, V, or Cr) have been calculated by the LCAO-MO SCF method.[76] It was found that the capacity of these compounds for the formation of the carbenium complex ($MCH_3 \rightarrow MCH_2 + H_2$) varies in the sequence Ti < V < Cr.

Under the influence of Cp_2V, methane exchanges the hydrogen atoms for deuterium atoms from D_2 (the overall yield of CH_3D, CH_2D_2, CHD_3, and CD_4 is 2–6% after 24 h in the presence of 35% of methane and at a pressure of 250 mmHg; the product ratios are 1.0 : 0.2 : 0.3 : 0.12).[74,77,78] Benzene used as the solvent also enters into the H–D exchange reaction. The process mechanism includes the following stages:

$$\begin{gathered} M + CH_4 \rightleftarrows H{-}M{-}CH_3\,, \\ H{-}M{-}CH_3 + D_2 \rightleftarrows D{-}M{-}CH_3 \rightleftarrows H{-}M{-}CH_2D\,, \\ H{-}M{-}CH_3 + D_2 \rightleftarrows H{-}M{-}D + CH_3D\,, \\ M + D_2 \rightleftarrows D{-}M{-}D\,, \\ D{-}M{-}D + CH_4 \rightleftarrows D{-}M{-}H + CH_3D\,. \end{gathered} \qquad (17)$$

It is of interest that the H–D exchange between CD_4 and C_6H_6 under the influence of Cp_2V is strongly accelerated in the presence of ethylene, which may be associated with the fact that the addition of methane to the ethylene complex via the mechanism

$$M(\pi\text{-}CH_2{=}CH_2) + CD_4 \rightleftarrows CD_3{-}M{-}CH_2CH_2D \qquad (18)$$

is dynamically more favourable than the addition involving the formation of an alkyl hydride complex. In the CD_4–C_2H_4–C_6H_6 system the ethylene molecule plays the role of agent transferring deuterium from methane to benzene.

Iridium(III) and rhodium(III) chlorides catalyse the H–D exchange with the solvent (CH_3COOD–D_2O) in arenes and alkanes.[1,13–15,79] As for the platinum(II) complexes, multiple exchange is observed, arenes react faster than alkanes, and the exchange does not occur in the *ortho*-position in substituted arenes. Finally we may note that the interaction of alkanes with metal atoms or ions M (see, for example, Refs.80–87) leads to the cleavage of the C–H and C–C bonds and the formation of M–H and M–C bonds.

(a) Isolation of Alkyl Hydride Complexes

In certain cases the alkyl hydride complexes formed on oxidative addition (accompanied by the dissociation of a C–H bond) of arenes, alkyl groups linked to aromatic rings, and even alkanes are fairly stable and can be isolated. For example, on heating or photolysis, the complexes Cp_2WH_2, Cp_2WCO, and Cp_2WHCH_3 give rise to a coordination-unsaturated tungstocene species Cp_2W, which readily combines with aromatic or aromatic alkyl-substituted hydrocarbons.[88] For example, in the reaction with toluene the products are $Cp_2 . W(H)C_6H_4CH_3$ and $Cp_2W(CH_2Ph)C_6H_4CH_3$, i.e. tungsten is inserted both in a C–H bond in the aromatic ring and in a bond involving an sp^3-hybridised carbon atom. The thermal reaction of Cp_2W with mesitylene affords $Cp_2W(H)CH_2C_6H_3 . (CH_3)_2$. However, cyclohexane and neopentane do not give rise to insertion products in this instance. The oxidative addition of alkanes with formation of alkyl hydride complexes was first demonstrated directly in studies using iridium complexes. Thus the iridium dihydride derivative $Cp'Ir(H)_2 . PMe_3$ (Cp′ = pentamethylcyclopentadienyl) produces, after irradiation in solution in cyclohexane or neopentane, the complexes $Cp'(PMe_3)Ir(H)(C_6H_{11})$ and $Cp'(PMe_3)Ir(H) . CH_2C(CH_3)_3$ in a satisfactory yield.[89–91] Other saturated hydrocarbons and benzene also readily add to an iridium complex. The alkyl hydride complexes obtained have been characterised by ^1H and ^{13}C NMR and infrared spectra. By treatment with $CHBr_3$ at −60 °C, these complexes were converted into the more stable derivatives $Cp'(PMe_3)Ir(Br)R$. Irradiation of $Cp'Ir(H)_2PMe_3$ in the $C(CH_3)_4$ + C_6D_{12} mixture led to the formation of $Cp'(PMe_3)Ir(H)CH_2C(CH_3)_3$ and $Cp'.(PMe_3)Ir(D)C_6D_{11}$ with very small admixtures of cross-addition products. Thus both components involved in the R−H bond add to the same metal atom. The reaction of alkanes with the complex $Cp'Rh(H)_2PMe_3$ takes place analogously under irradiation conditions at a temperature below −30 °C.[89,92,93] It is of interest that the cyclopropyl hydride complex rearranges to the rhodacyclobutane derivative.[94] The relative rates of the reactions with various hydrocarbons have been determined by the method of competing reactions[89,92] (Table 1). The selectivity (both substrate and positional selectivity) proved to be much higher for the rhodium complex than in the case where an iridium complex was used. When the cyclohexyliridium hydride complex (I) or the n-pentyliridium hydride derivative (II) was heated for 50 h at 140 °C in a mixture of 91.5% of cyclohexane and 8.5% of n-pentane, the following equilibrium was established:

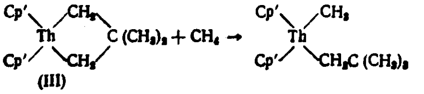
$$\underset{(I)}{Cp'(PMe_3)Ir(H)C_6H_{11}} + CH_3(CH_2)_3CH_3 \overset{K}{\rightleftarrows} \underset{(II)}{Cp'(PMe_3)Ir(H)(CH_2)_4CH_3} + C_6H_{12} \quad (19)$$

and the ratio (II):(I) was 1.0 ± 0.1. Hence the constant $K = [(II)][C_6H_{12}]/[(I)][n\text{-}C_5H_{12}] = 10.6$, which corresponds to $\Delta G^\circ = -2.0$ kcal mol^{-1}. It has been suggested that the entropy changes in the reaction are small and, assuming that the CH_2 and CH_3 bond energies in cyclohexane and n-pentane are 94.5 and 98 kcal mol^{-1} respectively, we find that the energy of the M−C bond in the complex (II) is higher by 5.5 kcal mol^{-1} than in the complex (I).[95] It follows from the estimates that the methyliridium hydride complex $Cp'.(PMe_3)Ir(H)CH_3$ should also be thermodynamically very stable. It was obtained in 58% yield on heating (at 140 to 150 °C) a solution of the complex (I) in cyclo-octane in the presence of methane (20 atm).[89,95]

Table 1. The relative rates of reaction of the complex $Cp'M(H)_2PMe_3$ with hydrocarbons via a C−H bond (irradiation at −60 °C).[89,92]

Hydrocarbon	Relative rate		Hydrocarbon	Relative rate	
	M=Rh	M=Ir		M=Rh	M=Ir
Benzene	19.5	3.9	Ethane	2.0	—
Cyclopropane	10.4	2.1	Cyclopentane	1.8	1.1
Hexane (1°)	5.9	2.7	Neopentane	—	1.14
Hexane (2°)	0.1	0.2	Cyclohexane	1.0	1.0
2-Methylpropane	3.6	—	Cyclodecane	—	0.23
Propane (1°)	2.6	1.5	Cycloheptane	0.14	—
Propane (2°)	0.1	0.3	Cyclo-octane	0.06	0.09
Ethylene	2.4	—			

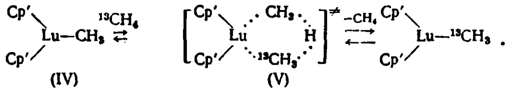
Irradiation of the solution of the carbonyl complex $Cp'Ir(CO)_2$ in perfluorohexane at room temperature in a CH_4 atmosphere (10 atm) led to the formation of $Cp'Ir(CO)(H)CH_3$ in 20% yield.[96] The study of the kinetics of the reaction of the complex $Cp'Rh(H)_2PMe_3$ with arenes and alkanes led to the conclusion that in the case of arenes the oxidative addition is preceded by the coordination of the aromatic hydrocarbons via one of the double bonds and that the $Rh-C_6H_5$ bond is more stable by approximately 13 kcal mol^{-1} than the $Rh-CH_3$ bond.[97] In reaction (20) of the cyclic derivative of thorium(III) with methane (60 °C, in cyclohexane) the methyl group is bound to the metal and hydrogen adds to the ligand carbon atom:[98]



(III)

(20)

This is confirmed by the fact that the reaction with CD_4 (which is 6 times slower than that with CH_4) leads to the formation of a deuteriated complex, evolving neopentane-d_1 after hydrolysis. The exchange reaction (21) of methane with a lutetium complex[99,100] apparently proceeds via a similar mechanism. It has been suggested that reaction (21) takes place via the transition state (V):



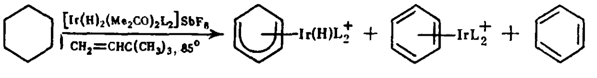
(IV) (V)

(21)

Since lutetium in the complex (IV) is in the +3 oxidation state, it is unlikely that the exchange with $^{13}CH_4$ takes place via the usual oxidative addition, since the latter should result in the formation of the alkyl-lutetium hydride complex (V). In the mechanism involving the transition state (V), the metal atom has electrophilic properties. The rhodium complex immobilised on silica gel, which reacts with methane, is also an electrophile.[101] The reaction proceeds via two pathways, one of which leads to a methylrhodium(III) hydride derivative. When the methylrhodium hydride complex is treated with chlorine, CH_3Cl is formed.

(b) Dehydrogenation of Alkanes

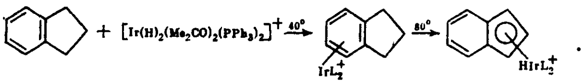
As already mentioned, platinum chloride complexes dehydrogenate alkanes. The complexes of certain metals in a low oxidation state can also abstract hydrogen from aliphatic substituents in phosphine ligands or alkanes. For example, the reaction of $[(cyclo\text{-}octene)_2MCl]_2$ (M = Rh or Ir) with tricyclohexylphosphine in boiling toluene leads to the formation of the derivative $[P(C_6H_{11})_3]M[P(C_6H_9)(C_6H_{11})_2]Cl$, in which the M atom is π-coordinated to the double bond in the cyclohexene group C_6H_9.[102] The cycloalkanes are dehydrogenated in the presence of 3,3-dimethylbutene by the cationic iridium complexes $[Ir(H)_2(Me_2CH)_2L_2]SbF_6$, where $L = PPh_3$ or $(p\text{-}FC_6H_4)_3P$.[103,104] The complex $[CpIr(H)L_2]SbF_6$ is formed from cyclopentane in 82% yield. Cyclohexane affords the mixture of the products (VI) and (VII) as well as benzene in yields of 5, 45, and 32% respectively:



$L = (p\text{-}FC_6H_4)_3P.$ (VI) (VII)

(22)

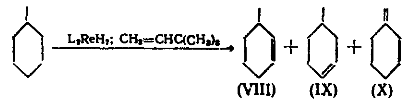
The reaction with cyclo-octane leads to the formation of $[Ir(COD)L_2]SbF_5$, where COD = 1,5-cyclo-octadiene and $L = (p\text{-}FC_6H_4)_3P$, in 75% yield. However, in the presence of 1,8-di(dimethylamino)naphthalene as the base, the process becomes catalytic (8 cycles) and its product is cyclo-octene. Iridium compounds with arenes ArH give rise to complexes which dehydrogenate cyclopentane with formation of a Cp derivative of iridium and the liberation of the free arene.[105] The indan dehydrogenation process is accompanied by an intramolecular rearrangement:[105]



(23)

All the reactions with cationic iridium complexes take place under homogeneous conditions. To demonstrate this, a special test was developed using dibenzo[*a*, *e*]cyclo-octatetrane, which makes it possible to detect the formation of a heterogeneous catalyst from the soluble complex.[106] It has been suggested that the dehydrogenation by the cationic complex includes the oxidative addition to the alkane via a C–H bond to the iridium atom with subsequent dehydrogenation.[103]

The dehydrogenation of alkanes has been studied in detail in relation to reactions with rhenium polyhydride complexes. Thus heating of a solution of L_2ReH_7 ($L = PAr_3$, where Ar = p-FC_6H_4, C_6H_5, or p-$CH_3C_6H_4$) in cycloalkane in the presence of 3,3-dimethylbutene leads to the formation of the complex $CpRe(H)_2L_2$ in the case of cyclopentane[107] or of cycloalkenes in the case of cyclohexane, cycloheptane, and cyclo-octane.[108] When low concentrations of the heptahydride and 3,3-dimethylbutene are used, the dehydrogenation reaction of the alkanes C_nH_{2n} (n = 6, 7, 8) becomes catalytic in relation to rhenium hydride (up to 9 cycles).[109] Under these conditions, methylcyclohexane produces a mixture of three olefins (no other products, for example benzene, have been detected):



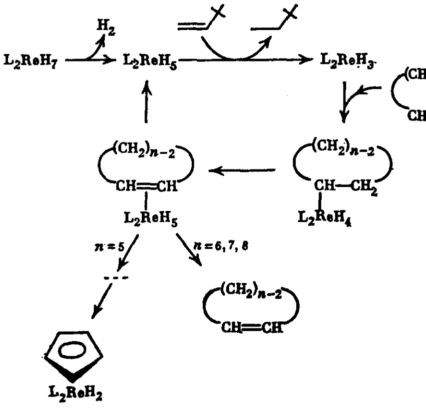
(24)

The ratio of the isomers (VIII), (IX), and (X) depends on the nature of the ligand L (Table 2).[109] The selectivity series $CH_3 > CH_2 > CH$ has been observed in the reaction, but for steric reasons the reagent does not attack the most shielded hydrogen atom (in CH_3 and 2- and 6-CH_2). In the case of the less bulky ligand Et_3P, the content of compound (X) increases at the expense of compound (IX). The proposed process mechanism (Scheme 1) includes the first stage involving the elimination of H_2 followed by the oxidative addition of RH to L_2ReH_3 and the β-elimination of the hydrogen atom with formation of an olefinic π-complex:

Table 2. The ratio of the isomers (in %) formed in reaction (24) as a function of the nature of the ligand L.[109]

L	(VIII)	(IX)	(X)
$(p\text{-}FC_6H_4)_3P$	29	65	6
Ph_3P	28	63	9
Et_3P	27	45	28

Scheme 1

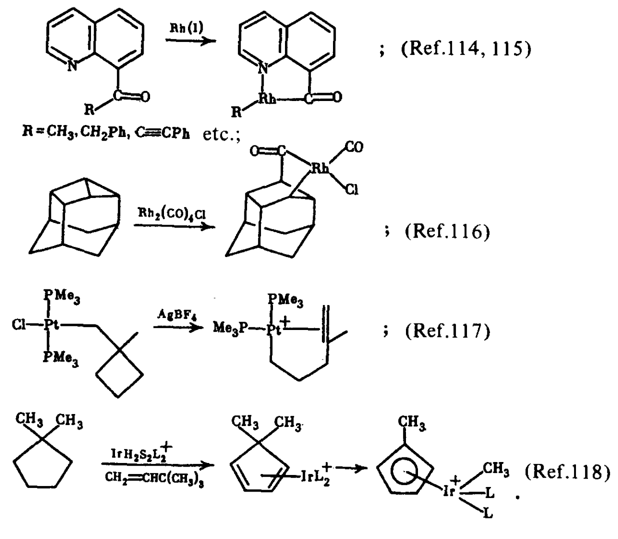


The reaction of $(PPh_3)_3ReH_7$ with n-alkanes leads to the formation of the diene complexes $(RCH=CH-CH=CH_2)Re\cdot(PPh_3)H_3$, which, on treatment with $(MeO)_3P$, give rise to alk-1-enes in yields of more than 95% and a selectivity in excess of 98%.[110] The polyhydrides of other metals, in particular, $(iso\text{-}Pr_3P)_2IrH_5$, $[(p\text{-}FC_6H_4)_3P]_2IrH_5$, and $[(p\text{-}FC_6H_4)_3P]_3RuH_4$ dehydrogenate catalytically (45 to 70 cycles) cyclo-octane to cyclo-octene in the presence of 3,3-dimethylbutene at 150 °C.[111] The dehydrogenation reaction can occur also under the influence of metal atoms. For example, the condensation of tungsten with cyclopentane and PMe_3 gives a 10% yield of $CpW(PMe_3)H_5$,[112] while the interaction of tungsten atoms with cyclohexane and PMe_3 affords the complex $C_6H_6W(H)_2(PMe_3)_2$.[113]

(c) The Cleavage of the C–C Bond

Compared with the C–H bond, the bond between carbon atoms in saturated fragments of alkane molecules is much more resistant to the action of metal complexes. Only reactions involving the opening of the cyclopropane ring and the insertion of Rh in the C–CO bond or bonds in saturated but strained cyclic hydrocarbons are known.[9] Certain examples of such reactions are presented in Scheme 2.

Scheme 2



An instance of the cleavage of a C–C bond in an alkane by metal complexes is known: when octane was heated at 180 °C for 15 h in an atmosphere of H_2 (50 atm) in the presence of $Re_2(CO)_{10}$ + $Al(C_2H_5)_3$, the hydrocarbon was hydrogenolysed with 48% conversion.[119] There are data showing that, in the presence of $Co_2(CO)_8$, the fragmentation of alkanes by γ-radiation is retarded and at the same time the complexes $Co_3(CO)_9CR$, where R = CH_3, C_2H_5, or $CH(CH_3)_2$, are formed.[120]

(d) The Hydroalkylation of Multiple Bonds by Alkanes

Like hydrogen (hydrogenolysis), methane can rupture a metal–alkyl bond (alkanolysis):

$$M-R+CH_4 \rightarrow M-CH_3+RH\ . \qquad (25)$$

The first examples of such reactions was the formation of ethane in the interaction of methane with organoaluminium compounds in the presence of $TiCl_4$, Cp_2TiCl_2, VCl_4, and other complexes.[74,75,121]

As already stated, the possibility of such processes was then demonstrated in the reaction of methane with lutetium and thorium complexes [reactions (20) and (21)]. Taking into account the occurrence of reaction (25), on the one hand, and knowing the mechanism of the multiple bond hydrogenation reaction, on the other, it is reasonable to postulate[74,121,122] the possibility of the addition of R–H to the multiple bond (hydroalkylation):

$$\begin{gathered} M + R{-}H \rightleftarrows H{-}M{-}R\ , \\ H{-}M{-}R + CH_2{=}CH_2 \rightleftarrows CH_3CH_2{-}M{-}R \rightarrow M + CH_3CH_2R\ , \\ CH_3CH_2{-}M{-}R + RH \rightarrow M{-}R + CH_3CH_2R\ . \end{gathered} \tag{26}$$

Indeed, in the reaction of methane with ethylene ($CH_4/C_2H_4 >$ 10, 20 °C, 10 h), propane is formed under the influence of the catalyst $Ti(OC_4H_9)_4 + Al(C_2H_5)_3$ in benzene in a yield of about 20% relative to ethylene.[122] Methane adds to acetylene with formation of propene when acted upon by $Al(C_2H_5)_3$ and and $Fe(acac)_3$ [74,121] or nickel stearate, naphthenate, and naphthenehydroxamate deposited on the surface of nickel hydroxide.[123]

IV. CHEMICAL MODELS OF THE BIOLOGICAL OXIDATION OF ALKANES

1. Enzymic Oxidation

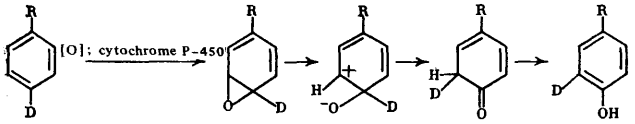
It is well known that various organic compounds, including alkanes, can be oxidised by oxygen in the cells of bacteria, insects, fish, warm-blooded animals, and man as well as higher plants. The group of enzymes catalysing the hydroxylation of CH-containing compounds by oxygen, namely oxygenases, can induce the insertion of only one oxygen atom from O_2 in the C–H bond, while the second oxygen atom is reduced with formation of water:

$$C{-}H + O_2 + AH_2 \rightarrow C{-}OH + H_2O + A\ . \tag{27}$$

In this case the enzymes are referred to as monoxygenases.[124–129] The hydrogen donors AH_2 are NADH, NADPH, the ascorbate anion, and other biological reductants. Certain monooxygenases contain cytochrome P-450—a protein which contains haem as the prosthetic group.[124–134]

(a) Oxidation with Participation of Cytochrome P-450

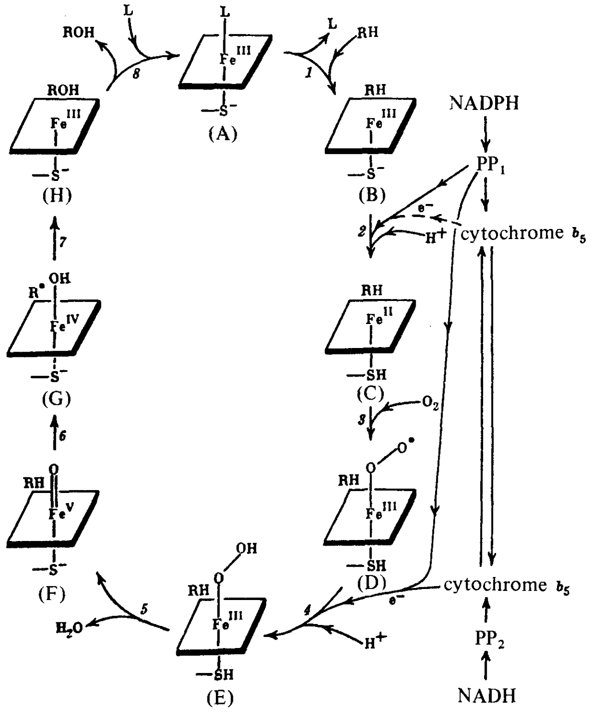
The oxidation of organic substrates by oxygen has been investigated in greatest detail in the liver cell microsomes of warm-blooded animals and also by bacterial monoxygenases containing cytochrome P-450. For example, the monoxygenases of the bacterium *Pseudomonas putida* hydroxylate camphor, while the monoxygenases from the mitochrondria and microsomes in the adrenal cortex cause the side chain of cholesterol to be split off with subsequent hydroxylation of the saturated C–H bonds. It is important that, in the presence of liver microsomes, alkanes and aliphatic acids are hydroxylated predominantly at the terminal (ω) carbon atom. The C–H bonds at the neighbouring (ω − 1) carbon atom of the aliphatic chain are much less reactive. Thus the oxidation of decanoic acid results in the formation of 92% of 10-hydroxydecanoic and 8% of 9-hydroxydecanoic acid. Since the oxidation in the ω- and (ω − 1)-positions is inhibited by carbon monoxide to different extents, presumably the C–H bond activation processes in these positions are catalysed by different monoxygenases. The isotope effect discovered in the hydroxylation of [11-D_2]lauric acid amounts to 3.6. On the other hand, monoxygenases are known (for example those isolated from rat liver microsomes) which hydroxylate alkanes with the "usual" selectivity (thus 1° : 2° : 3° = 1 : 15.4 : 113 for isopentane). A characteristic feature of the oxidation in the presence of monoxygenases is the retention of the configuration of the substrate. The hydroxylation of aromatic compounds proceeds as electrophilic substitution (the ratio $o:m:p$ = 59 : 13 : 28 for toluene) and is accompanied by the so called NIH shift. This phenomenon, consisting in the transfer of a hydrogen (deuterium) atom to a neighbouring position relative to that at which hydroxylation takes place, may be accounted for by the following scheme:



(28)

The oxidation of organic compounds RH by oxygen in the presence of cytochrome P-450 includes at least 8 stages (Scheme 3).[124] The following notation has been adopted in the scheme: PP_1 = NADPH-cytochrome P-450 reductase, PP_2 = NADH-cytochrome b_5 reductase, and S = cysteine residue.

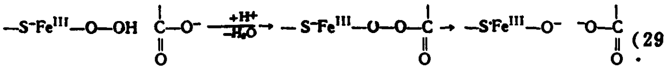
Scheme 3



The formation of the complex (B) in the first stage converts cytochrome P-450 from the low-spin form into the high-spin form. Reduction takes place in the second stage of the process, after which an O_2 molecule is coordinated to the Fe(II) atom. X-Ray diffraction analysis of the complex of myoglobin with O_2 showed that oxygen is coordinated in such a way that the molecular axis of O_2 forms an angle of 120° with the plane of the porphyrin ring [Pauling's structure (D)]. The fourth and fifth stages terminate with the reduction of the complex and the elimination of a water molecule. This results in the formation of the oxenoid (F), whose structure can be represented by several formulae:

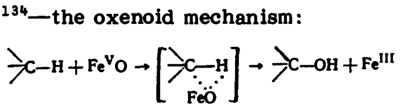
$$-S^{-}Fe^{V}O^{2-} \leftrightarrow -S^{-}Fe^{IV}O^{-} \leftrightarrow -S^{-}Fe^{III}O \leftrightarrow -S^{\cdot}Fe^{III}O^{-}\ .$$

The thiol ligand S^- behaves in this instance as an electron donor. The carboxy-group of one of the aminoacids of cytochrome P-450 and the intermediate acyl peroxide participate in the cleavage of the O–O bond:[124]



$$-S^-Fe^{III}-O-OH\quad -C(=O)-O^- \xrightarrow[-H_2O]{+H^+} -S^-Fe^{III}-O-O-C(=O)- \rightarrow -S^-Fe^{III}-O^-\quad {}^-O-C(=O)- \qquad (29)$$

The sixth stage consists in the rupture of a C–H bond in the substrate molecule. Two alternative mechanisms have been proposed[124,125,134]—the oxenoid mechanism:



$$>C-H + Fe^{V}O \rightarrow \left[>C-H \cdots FeO\right] \rightarrow >C-OH + Fe^{III} \qquad (30)$$

and the radical mechanism with subsequent recombination in the cage:

$$>C-H + OFe^{V} \rightarrow \left[>C^{\cdot}\ HOFe^{IV}\right] \rightarrow >C-OH + Fe^{III}\,. \qquad (31)$$

It may be that the real mechanism of the elementary process includes two stages, the first of which is close to the H atom abstraction mechanism but proceeds without the formation of radicals and the reaction terminates with formation of an alcohol.

(b) Methane Monoxygenases

The enzymes isolated from methane oxidising bacteria are known under the general name of methane monoxygenases.[1,135–137] The oxidation takes place in accordance with the scheme

$$CH_4 + O_2 + AH_2 \rightarrow CH_3OH + H_2O + A\ , \qquad (32)$$

where AH_2 = NADH or NADPH. The methane monoxygenases isolated from *Methylococcus capsulatus* and *Methylosinus trichosporium* contains proteins incorporating non-haem iron and possibly copper.[1] The enzymes also include cytochrome c, but its presence does not influence the activity of methane monoxygenases. The enzyme from *M. capsulatus* oxidises alkanes ranging from methane to butane and, as the chain length increases, the rate of oxidation falls. Pentane, cyclohexane, and aromatic hydrocarbons are not oxidised.[137] We may note that the activity maximum for cytochrome P-450 corresponds to alkanes containing 8 and 12 carbon atoms. The difference in the activity is apparently associated with the size of the hydrophobic pocket in the enzyme where oxidation takes place and not with a change in the reaction mechanism.

2. Chemical Models

(a) "Direct" Oxidation by High-Valence Metal Compounds

Aromatic, aromatic alkyl-substituted, and saturated hydrocarbons are oxidised by cobalt(III) compounds.[1,11,14,15,138,139] For example, cobalt(III) trifluoroacetate oxidises cyclohexane in solution in CF_3COOH at 30 °C in the course of 23 h to cyclohexyl trifluoroacetate in 35% yield. The proposed mechanism includes the formation of the $R^{\cdot}$ radical from the hydrocarbon RH under the conditions of the elimination of a proton synchronous with the reduction of cobalt(III):

$$RH + Co(III) \rightarrow R^{\cdot} + H^+ + Co(II)\ , \qquad (33)$$

or in the decomposition of the alkyl σ-complex of cobalt(III):

$$RH + CoX_3^+ \xrightarrow{-H^+} RCoX_3 \rightarrow R^{\cdot} + CoX_3\ . \qquad (34)$$

The radicals enter into further reactions leading to the formation of the final products. Numerous studies of the direct oxidation of alkanes and aromatic alkyl-substituted hydrocarbons by compounds of other high-valence metals are known. Thus, on interaction with manganese(III) or lead(IV) acetates in CF_3COOH, adamantane produces 1-adamantyl trifluoroacetate.[140] Lead(IV) acetate oxidises n-heptane and other alkanes at room temperature[12,141] and copper(III) complexes convert cyclohexane into cyclohexanol, cyclohexanone, and benzene in aqueous solution at room temperature.[142]

In highly acid media, in particular in concentrated H_2SO_4, certain complexes, for example those of palladium(II), platinum(III), and mercury(II), oxidise alkanes with formation of olefins, aromatic compounds, and carbonium ions.[143,144] The reactions with all oxidants in acid media apparently have a similar mechanism in the rate-limiting stage—homolytic cleavage of the C–H bond with participation of the ligand L:[143]

$$RH + L^-M^n \rightarrow R^{\cdot} + HL + M^{n-1}\ . \qquad (35)$$

(b) Oxidation by the Oxo-Compounds of High-Valence Metals

There is some similarity between the oxidation of alkanes and other compounds by monoxygenases, on the one hand, and the oxygen derivatives of high-valence metals, on the other. For example, the migration of the substituent, analogous to the NIH shift,[124] has been observed in the hydroxylation of arenes by the chromium(VI) derivatives $CrO_2(OAc)_2$.[124] The reactions of alkanes with chromium(VI) oxo-compounds apparently take place with the intermediate formation of radicals:

$$RH + O{=}Cr^{VI} \rightarrow R^{\cdot} + HO{-}Cr^{V}\ . \qquad (36)$$

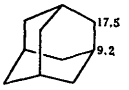
However, not all the radicals formed are liberated in the solution, since the oxidation of (+)-3-methylheptane by chromic acid involves the formation of (+)-3-methyl-3-heptanol with retention of configuration to the extent of 70–85%. The normal selectivity has been observed in the hydroxylation of branched alkanes. The addition of ruthenium(IV) or iridium(IV) chloride complexes increases the rate of the reaction leading to the formation of the chloroalkanes.[145–147] The selectivity of the oxidation in the presence of ruthenium(IV) (1° : 2° : 3° = 1 : 100 : 1000) is different from that in the oxidation catalysed by iridium(IV) (1 : 30 : 250); in the latter case, the primary C–H bond is relatively more reactive. One of the possible causes of the greater oxidising capacity of chromium(VI) compounds is the formation of the mixed complex $[Cl_4RuOCrO_3]^{3-}$.[147] Strong acids accelerate the reaction similarly (the rate of oxidation is proportional to the acidity of the medium), giving rise to protonated species, for example $O = Cr(OH)_3^+$ and $HCrO_3^+$. In solution in $CF_3.COOH$, permanganate oxidises alkanes at room temperature.[148] The cation MnO_3^+ is apparently the active species. The selectivity of the reaction corresponds to 1° : 2° : 3° = 1 : 60 : 2100. Finally, we may note that the ruthenium(IV) complex $[Ru(terpyridyl)(bipyridyl)(O)]^{2+}$ catalyses the electrochemical oxidation of aromatic alkyl-substituted hydrocarbons to alcohols, ketones, and acids.[149]

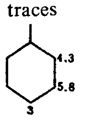
(c) Oxidation of Alkanes Coupled with the Oxidation of Metal Compounds

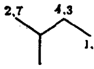
A whole series of systems hydroxylating organic substrates in a process coupled with the oxidation of a low-valence metal derivative by oxygen are regarded as chemical models of monoxygenases. Copper(I), titanium(III), molybdenum(O), molybdenum(III), iron(II), etc. compounds have been used for this purpose.[1] The hydroxylation of alkanes by oxygen in the presence of $SnCl_2$ in acetonitrile at room temperature has been studied in greatest detail.[1,150] The reaction selectivity corresponds to 1° : 2° : 3° = 1 : 5.1 : 12.5. It has been established that the interaction of O_2 with $SnCl_2$ involves a branched chain mechanism with formation of hydroxy-radicals, which react with alkanes.

(d) The GiF System

Molecular oxygen effectively oxidises alkanes in the presence of powdered iron, a carboxylic acid, pyridine, and water (the so called GiF system).[151] It was noted in the first studies that traces of H_2S initiate the reaction.[152,153] Soluble iron complexes are active in the system and zinc dust can be used as the source of electrons.[151,154] Oxidation in the course of 15–20 h at 30 °C leads to the formation of ketones and aldehydes (or an alcohol in the case of a tertiary C–H bond) with the following yields expressed as percentages (indicated by numbers opposite the corresponding positions within the molecule):







It has been suggested that the unusual selectivity of the oxidation reaction (the low reactivity of a weak tertiary bond compared with the primary and secondary bonds) is associated with the involvement in the process of a carbene complex of iron as an intermediate, but it has been shown[155,156] that the selectivity is independent of the nature of the metal. When copper, tin, and cobalt were used instead of iron, (and in general in the absence of a metal in the initiation of the oxidation) similar results were achieved. The unusual selectivity is apparently determined by the formation of the radicals $HO_2^{\bullet}$ or $RO_2^{\bullet}$ in the presence of pyridine and acid (part of the pyridine should be protonated). It has been suggested[155,156] that the "solvated oxygen cation" pyO^+ (or $pyO^{\ddagger}$), formed from $HO_2^{\bullet}$ or $RO_2^{\bullet}$ in the presence of protonated pyridine, is active in the oxidation of alkanes:

$$HO_2^{\bullet} + pyH^+ \rightleftarrows H_2O + pyO^+ \ . \qquad (37)$$

The pyO^+ species can react with the hydrocarbons as a three-electron oxidant with the elimination of H^+ from the carbon atom undergoing hydroxylation:

 (38)

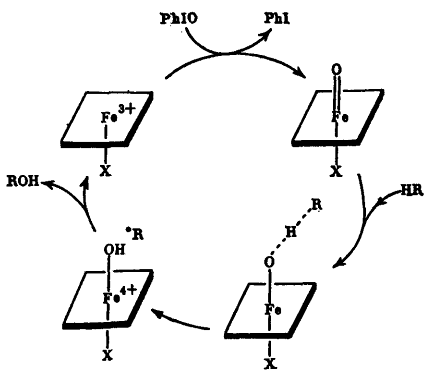
$$-\overset{|}{\underset{\displaystyle\overset{|}{H}}{C}}-H + pyO^+ \rightarrow -\overset{|}{\underset{\displaystyle\overset{|}{OH}}{C^{\bullet}}} + H^+ + py \ . \qquad (38)$$

The radical formed is converted into a ketone or an aldehyde on further oxidation or into an alcohol on reduction. Naturally, this mechanism does not operate in the case of a tertiary C–H bond, which may account for the unusual selectivity of the oxidation process.

(e) Oxidation by Metalloporphyrin Complexes of Oxygen

The closest models of the hydroxylating system based on cytochrome P-450 are oxygen derivatives of metalloporphyrins. Mainly oxidation with participation of iron and manganese complexes, using O_2, iodosobenzene PhIO, and KO_2 as sources of atomic oxygen, has been investigated.[157–170] The mechanism of the oxidation of alkanes catalysed by iron-porphyrins involves the initial oxidation of iron(III) with the simultaneous transfer of an oxygen atom to iron and the formation of the oxoferryl complex $[P{-}Fe^{IV}=O]^+$ (P = porphyrin), which affords an alcohol on reaction with RH (Scheme 4).

Scheme 4



The oxidation of cyclohexane by the PhIO + TPPFeCl system (TPP = tetraphenylporphyrin) leads to the formation of a mixture of cyclohexanol and cyclohexanone in proportions of 15 : 1 in 8% yield. The ratio 3° : 2° = 25–48 : 1. The oxoferryl complex can also be obtained by the interaction of the oxygen complex of iron(III) with the acylating agent AcX (X = OAc, Cl, or OH):[161,165]

$$[P{-}Fe^{III}O_2]^- + AcX \xrightarrow[-X^-]{} P{-}Fe^{III}{-}O{-}O{-}Ac \xrightarrow[-OAc^-]{} [P{-}Fe^{IV}{=}O]^{\ddagger} . \qquad (39)$$

It is of interest that the use of the tetramesitylporphyrin (TMP) complex, in which approach to the iron atom is sterically hindered, makes it possible to alter the selectivity.[165] Thus, whereas 1° : 2° : 3° = 1 : 12 : 40 for the hydroxylation of isopentane in the presence of the TPP-complex while C(1) : C(2) : C(3) = 1 : 10 : 10 for hexane, the corresponding ratios obtained in the presence of the TMP-complex were respectively 1 : 6 : 16 and 1 : 7 : 3. By increasing the steric shielding of the active centre, it is possible to achieve an even greater change in the selectivity. Particles of the tetrakis(p-hexadecyloxyphenyl)-porphyriniron chloride–PhIO–cyclodextrin system, dispersed in aqueous solution, were used as a model of the active centre of cytochrome P-450. Iron-porphyrin is incorporated in the liposomes formed by dimyristoylphosphatidylcholine. In the hydroxylation of hexane, we have the ratios C(3) : C(2) : C(1) = 1 : 1.8 : 0.59 when β-cyclodextrin is used and 1 : 2.1 : 0.77 for permethylated β-cyclodextrin.[166] These results confirm the hypothesis concerning the cause of the unusual selectivity observed in many instances of the biological oxidation of alkanes, according to which the high reactivity of the ω- and (ω – 1)–C–H bond is due to the steric hindrance generated around the active centre of cytochrome P-450.

The system based on the nickel(II) complex with a macrocyclic nitrogen-containing ligand, which hydroxylates arenes, is close to the metalloporphyrin models.[171] The complex forms an adduct with O_2 in aqueous solution, which then oxidises benzene.

V. THE MECHANISMS OF THE CLEAVAGE OF THE C–H BOND

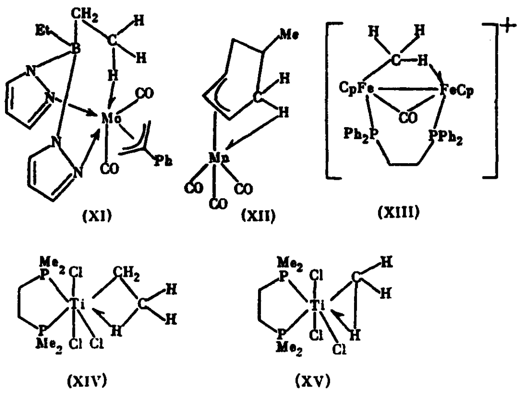
1. Saturated Hydrocarbons and Their Fragments as Ligands in Complexes

From the standpoint of the usual ideas, the formation of any complexes by saturated hydrocarbons is impossible owing to the lack of π or n-electrons in their molecules. However, compounds containing hydrogen and other three-centre bonds,[172] for example B...H...B and Al...CH_3...Al, are well known and fairly stable complexes of molecular hydrogen, namely $(iso\text{-}Pr_3P)_2(CO)_3W(H_2)$ [173] and $Cr(CO)_5(H_2)$,[174,175] have been characterised recently. If these data are taken into account, one can imagine the possibility of the existence of complexes of alkanes. On the other hand, bearing in mind that saturated hydrocarbons are extremely weak electron donors and poor electron acceptors,[176] one can postulate that alkane complexes should be extremely unstable. Thus, when iodine or oxygen is dissolved in saturated hydrocarbons, contact donor–acceptor complexes are formed,[177] the equilibrium formation constant of which is close to zero. The bond energy in these complexes is very low and both components are oriented with respect to one another in an arbitrary fashion. A quantum-chemical calculation for the $CH_4 + O_2$ system showed that,[178] if the C–H σ-bond is located along the axis of the π orbital of oxygen in such a way that the O...H distance is 2.05 Å, a minimum corresponding to a bond energy between the components of ~0.5 kcal mol^{-1} appears on the potential curve. The paramagnetic shifts of the ^{13}C NMR signals, induced by a nitroxy-radical (the di-t-butylnitroxy-radical) dissolved in the saturated hydrocarbon, indicate the formation of a complex between the radical and the alkane.[178,179] The paramagnetic shift $\Delta\delta$ diminishes on passing from the terminal atom of n-pentane to atoms in the 2- and 3-positions. Thus, at a radical concentration of 1 M, $\Delta\delta$ = 3.8, 2.4, and 2.3 p.p.m. respectively. In the case of 2,2-dimethylbutane, the paramagnetic shifts of the signal due to the CH_3 groups in the t-butyl and ethyl fragments are respectively 3.1 and 3.4 p.p.m., the shift for CH_2 amounts to 2.3 p.p.m., while for a quaternary carbon atom it is only 0.13 p.p.m. All the shifts are directed downfield, which indicates a transfer from the radical to the carbon atoms of alkanes having a positive spin density. The data presented led to the conclusion that an alkane forms a complex by interacting via its hydrogen atoms with the π orbital of the radical occupied by the unpaired electron and distributed approximately equally between the N and O atoms. According to the calculation for the model system $CH_3H...ONH_2$ by the INDO method,† the stabilisation energy of the complex for a O...H distance of ~2.0 Å does not exceed 1 kcal mol^{-1}.[181]

(a) Diffraction and Spectroscopic Studies

Fairly numerous complexes in which there is an intermolecular bond between the metal atom and one of the CH groups of the ligand according to X-ray diffraction data, confirmed by infrared and NMR spectra, have been discovered in recent years.[182] The bonds formed by saturated hydrocarbon fragments, especially methyl groups, are of special interest. It has been suggested[182] that such a bond be referred to as "agostic" and to designate it by half an arrow: C–H ⇀ M. Thus the term "agostic" bond refers to the case where the hydrogen atom is simultaneously bound covalently by a three-centre two-electron bond to carbon and transition metal atoms. Scheme 5 presents examples of complexes containing the agostic C–H ⇀ M bond. The presence of an agostic bond in the complexes has been demonstrated by X-ray diffraction (XD) and neutral diffraction (ND) methods.

Scheme 5



Certain distances in the crystal, determined by these methods, are presented in Table 3. When the agostic bond is formed, the C–H bond usually lengthens by 5–10%, but in the case where it is formed by the $C(sp^3)$–H fragment virtually no increase in length is observed. The M–H bond is also somewhat longer (by 15–20%) than in the usual hydride. The M–C bond length is always appreciably smaller than the sum of the van der Waals radii of M and C. The appearance of the agostic bond is reflected in the NMR spectra (upfield shift of the ^1H and ^{13}C signals) and IR spectra (decrease of the stretching vibration frequency of the C–H bond to 2700–2350 cm^{-1}). Thus a system with a C–H ⇀ M agostic bond is, as it were, on the reaction pathway between the C–H + M system and the alkyl hydride derivative C–M–H.

Table 3. Certain interatomic distances in complexes containing the agostic C–H ⇀ M bond.[182,183]

Complex	Method	Distance, A		
		C–H	M–H	M–C
(XI)	XD	0.97(8)	2.27(8)	3.06
(XII)	ND	1.19(1)	1.84(1)	2.34(1)
(XIII)	XD	1.06(4)	1.64(4)	2.101(3)
(XIV)	XD	1.02	2.29	2.516(10)
(XV)	XD	1.00(2)	2.03(4)	2.149(5)
(XV)	ND		2.45	

Dissolution of chromium trisacetylacetonate in 1-chlorobutane entails a paramagnetic shift of the ^{13}C signals of the solvent in the NMR spectra.[184] It is of interest that the shift $\Delta\delta$ along the chain initially diminishes and then again increases for the terminal CH_3 group; the ratios of the $\Delta\delta$ are C(1) : C(2) : C(3) : C(4) = 1.00 : 0.30 : 0.14 : 0.62. These results indicate the transfer of electron spin density from the complex to the methyl group of the chlorobutane coordinated to it and, since the complex is coordination-saturated, the interaction apparently takes place via the acetylacetonate ligand of the complex (outer-sphere coordination). The formation of adducts of cyclohexane with the paramagnetic bis[hydrotris(1-pyrazolyl)borato]cobalt(II) complex has been observed[185] by ^1H NMR.

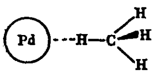
Finally the formation of methane, hexane, and methylcyclohexane complexes with the $Cr(CO)_5$ species in a matrix has been detected.[186–188]

---

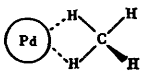
† For the description of different quantum-chemical methods for calculations on molecules, the molecular structure of coordination compounds, the symmetry-based classification of orbitals, etc., see, for example, Minkin et al.[180]

(b) Quantum-Chemical Calculations for Complex Formation

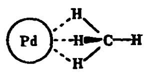
The problem of the coordination of saturated hydrocarbons or molecular fragments to metal complexes has recently attracted the attention of theoretical chemists. It has been suggested that the interaction of saturated C–H bonds with transition metals is due to the overlap of the diffuse outer orbitals of the transition metal with the localised orbitals of the saturated bond.[189,190] The simplest system modelling the interaction of the C–H bond with an unoccupied diffuse orbital of the metal is a CH_4 molecule coordinated to a palladium atom. A calculation has been carried out for this system by the non-empirical SCF MO method.[191] Three possible symmetrical structures, differing in the number of hydrogen atoms coordinated directly to the Pd atom, were examined: two structures with the C_{3v} symmetry [(XVI) and (XVIII)] and one with the C_{2v} symmetry [structure (XVII)]:



(XVI)



(XVII)



(XVIII)

The calculated $CH_4...Pd$ bond energies decrease in the sequence (XVI) > (XVII) > (XVIII), although they are similar for all three structures [8.4 and 7.3 kcal mol^{-1} for (XVI) and (XVIII) respectively]. Coordination leads to a slight transfer of electron density from methane (mainly from H atoms) to the 5*s* and 5*p* orbitals of palladium via a donor–acceptor mechanism; this entails some redistribution of electron density in the individual AO of both components. Thus the electron density in the $4d_{z^2}$ AO of the palladium atom decreases in all three structures. There is a simultaneous increase of electron density in the 5*s*, $5p_\pi$, and $5p_\sigma$ AO but the overall negative effective charge on palladium increases. The changes in the populations of the AO of methane (much smaller) show that the electron density is to some extent transferred also via a dative mechanism. Since a carbon and not a hydrogen atom plays the main role in structure (XVIII), where the methane molecule is oriented towards the palladium atom via three hydrogen atoms [the equilibrium Pd...H distance in (XVIII) is 2.2 Å against 1.7 Å in (XVI)], the dative transfer of electron density from palladium mainly to a carbon atom is most clearly expressed precisely in this structure.

It is of interest that the bond energy in the $Pd...H_2$ system, calculated by the same method, is almost twice as high as the bond energy in the methane complex. The donor–acceptor transfer in the alkane complex is much smaller than in the complex with H_2. On the other hand, in general, since the HOMO energy in CH_4 is higher than in H_2 (the ionisation potentials are 12.7 and 15.4 eV respectively), methane should be a better electron donor. However, according to the calculation, the opposite behaviour obtains. One can therefore conclude that the interaction is in this instance determined by the overlap of the corresponding orbitals and not by the difference between the energy levels.[189,191]

The electronic structure of complexes activating alkanes—square planar and pseudo-square chloride and aquochloride derivatives of platinum(II), as well as the interaction of these complexes with CH_4 have been investigated by the semiempirical MO-LCAO SCF method in the CNDO approximation.[192] Calculation for the complexes $[PtCl_{4-n}(H_2O)_n]^{n-2}$ with $n = 0, 1, 2, 3, 4$ and *trans*-$[PtCl_2(H_2O)(OH)]^-$ showed that the changes in their quantum-chemical characteristics are monotonic and are independent of the symmetry (thus the positive charge on platinum increases monotonically with the increase of *n*). It was concluded that, when the interaction of such complexes with an axial ligand is controlled by the LUMO, then this is an interaction with an *s* AO and to a lesser extent a d_{z^2} AO of platinum. The methane molecule was considered as the ligand and the calculation was performed for the $CH_4...PtCl_4^{2-}$, $CH_4...$*trans*-$PtCl_2(H_2O)(OH^-)$, $CH_4...$*trans*-$PtCl_2(H_2O)_2$, and $CH_4...Pt(H_2O)_4^{2+}$ systems. It was found that coordination involves a redistribution of electron density in CH_4, as a result of which the polarity of the CH bonds increases and the bonds (particularly those coordinated to Pt or an equatorial *acido*-ligand) are weakened. Furthermore, an increase in the free valence of the carbon atom of methane was noted. This actually results in the activation of the CH_4 molecule, facilitating the attack on the latter by polar species. Analysis of the distribution of electron density in methane complexes showed that the alkane is bound as a result of the interaction of the 1*s* AO of the hydrogen atoms and the 2*s* and $2p_z$ AO of the carbon atom with the 6*s* and $6p_z$ AO of platinum. Thus the involvement of the *d* AO of the metal in such complex formation is smaller than the involvement of the outer *s* and *p* AO. For virtually any mode of coordination of CH_4 to the platinum(II) complex (coordination via the vertex, edge, and face of the methane tetrahedron to platinum and also simultaneously to platinum and the acido-ligand was considered), the resulting transfer of electron density from methane entails its decrease at the H atoms. However, owing to the contribution by the dative interaction, the electron density on the carbon atom increases. It is essential to note that the acceleration of the H–D exchange reaction, observed experimentally after the replacement of the $PtCl_4^{2-}$ or $Pt(H_2O)_4^{2+}$ catalysts by $PtCl_2(H_2O)_2$, could not be related to any calculated quantum-chemical parameters. It was therefore postulated[192] that an optimum combination of the donor–acceptor and dative mechanisms of the transfer of electron density is essential for the effective alkane–platinum(II) complex interaction. Since the contribution of the former increases and that of the latter diminishes with increase of the positive charge on the complex, the optimum combination can be achieved for the complex with zero charge. Somewhat earlier the presence of a catalytic activity maximum for the complex $PtCl_2(H_2O)_2$ was attributed to the influence of the symmetry of the ligand environment.[193] On the basis of the hypothesis that the formation of a bond with the activated alkane takes place mainly on interaction with the d_{z^2} AO of the complex, the rates of reaction were correlated with the contribution by this orbital to the LUMO of the platinum(II) complex. Symmetry considerations led to the conclusion that, for $n = 0$ and $n = 4$, the LUMO of the complex is formed solely by the $d_{x^2-y^2}$ AO and cannot contain an admixture of the d_{z^2} state. As a consequence of the decrease of symmetry for $n = 1, 2, 3$, such admixture exists but the $n = 2$ complex occupies a special place (thus the contribution of the d_{z^2} AO orbital for the *trans*-isomer with $n = 2$ should be greatest). It is believed[192] that this approach, based on the crystal field theory, is insufficiently complete, since, according to the MO theory, the d_{z^2} AO of platinum participates in the binding of equatorial ligands even in highly symmetrical complexes, i.e. in these complexes too this orbital, being partly unoccupied, can be involved in the donor–acceptor interaction with the alkane.

The total energies have been calculated by the extended Hückel method[194] for alkanes coordinated to the $PtCl_3(H_2O)^-$ species and it has been shown that the coordination of the terminal atom, for example, in pentane, is most preferred. The MO analysis of the agostic interaction in the methyl complexes of metals has been carried out.[195]

2. Types of Reactions

(a) Electrophilic Substitution

Reactions involving the electrophilic substitution of hydrogen in arenes by metal complexes are known for transition metal complexes: Pd(II),[54] Au,[55,195–197] Pt(II),[56] Pt(IV),[38–49] and Rh(III).[198] This series can be extended if account is taken of the cyclometallation reactions.[31,32,199] Arenes are also readily metallated by compounds of the non-transition elements Hg(II), Tl(III), and Pb(IV). All these reactions apparently proceed with the intermediate formation of Wheland complexes. Less information is available about the electrophilic substitution of hydrogen involved in the formation of the C(sp^3)—H bond. For example, reaction (21) between methane and a lutetium(III) complex proceeds in this way. The oxidation of alkanes by palladium(II) complexes in acid media can proceed via the cyclic transition state in which palladium(II) behaves as the electrophile.[200,201] The saturated H_2 molecule can also be split by a transition metal ion via an electrophilic mechanism:[202]

$$H_2 + Cu^{2+} \rightarrow CuH^+ + H^+ \,. \qquad (39a)$$

Analysis of the thermodynamics of electrophilic substitution reactions

$$L_nM + RH \rightarrow L + L_{n-1}M^-—R + H^+ \qquad (40)$$

yielded[176] the expression

$$\Delta E = E_{M-L} - Q^c_L - Q^c_{L_{n-1}M} + Q^c_{L_nM} \qquad (41)$$

(where ΔE is the energy expenditure on the formation of the coordination vacancy and Q^C are the heats of solvation), from which it follows that substitution is favoured by a low bond energy E_{M-L} and a high heat of solvation $Q^C{}_L$.

(b) Oxidative Addition

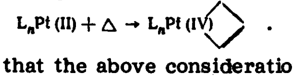
The interaction of arenes with low-valence transition metal complexes, leading to the formation of aryl σ-complexes, is a reaction involving the oxidative addition of the components involved in the Ar—H bond to the metal. The cleavage of the Ar—H bond is usually preceded by the formation of a coordination-unsaturated species via the elimination of hydride, alkyl, and halide ligands. An example of such a process is the insertion of Cp_2W in an aromatic C—H bond[88] (see Section III). The metal complex, to which arenes add via an oxidative mechanism, functions as a nucleophilic species. Thus in the reaction of the complex $HMNp(Me_2.PCH_2CH_2PMe_2)_2$ (Np = 2-naphthyl, M = Fe or Ru) with various arenes, the retarding effect of electron-donating substituents and the accelerating effect of electron-accepting substituents in the aromatic ring was noted. For example, the hydrogen atom in the *para*-position in toluene is 2.5 times more reactive than the D atom in C_6D_6 (where M = Fe).[203] Reactions involving the substitution of hydrogen in aromatic compounds by rhodium(I), iridium(I),[204] manganese(I),[205] rhodium(III), and iridium(III) [206] complexes, which exhibit nucleophilic properties, are known. Examples of the reactions of alkanes, which undoubtedly proceed as oxidative addition, were presented in Section III. The complexes inserted into the aromatic C—H bond are frequently capable of activating also the saturated hydrocarbons or the corresponding fragments via the same mechanism. For example, $HMN_p(Me_2PCH_2CH_2PMe_2)_2$ (M = Fe, Ru, or Os) is inserted oxidatively in the C—H bond of the methyl group of acetonitrile.[207] Estimation of the heat of oxidative addition via the mechanism[202]

$$L_nM + RH \rightarrow R—L_nM—H$$

demonstrated that this reaction is usually endothermic with $\Delta H \cong +10$ kcal mol^{-1} (the following typical dissociation energies were used for the calculation: $D_{M-H} = 60$, $D_{M-R} = 30$, and $D_{R-H} = 100$ kcal mol^{-1} [208]). Oxidative addition with cleavage of the C—C bond via the mechanism

$$L_nM + R—R \rightarrow R—L_nM—R$$

should be thermodynamically even less favourable. This does not apply to the cleavage of C—C bonds in strained hydrocarbons, for example, in the reaction[202]



(42)

It is noteworthy that the above considerations refer to complexes of the first transition series of metals, because there are no data on the bond energies in the complexes of heavier metals. The alkyl—metal bonds can be stronger in the case of heavy metals, although, for example, the D_{M-CH_3} for the M^+—CH_3 ions in the gas phase indicate the absence of a distinct tendency towards an increase of this parameter on passing from light to heavy metals within a given Group.[209] The calculated[210] $\bar{D}_{Pt-C} = 36$ kcal mol^{-1} [for *cis*-$Me_2Pt(PH_3)_2$] and $\bar{D}_{Pt-H} = 60$ kcal mol^{-1} [for *cis*-$(H)_2Pt(PH_3)_2$] made it possible to estimate the enthalpies of the oxidative addition to $Pt(PH_3)_2$ of hydrogen (−16 kcal mol^{-1}, exothermic reaction), methane via the CH_3—H bond (+9 kcal mol^{-1}, which agrees with Halpern's estimate[202]), and ethane via the CH_3—CH_3 bond (+19 kcal mol^{-1}, highly endothermic reaction). On the other hand, the complex *cis*-$OsHMe(CO)_4$ is apparently thermodynamically stable and does not exhibit a tendency towards intermolecular reductive elimination of CH_4 (see below). It has been suggested[202] that the $Os(CO)_4$ species, generated photochemically, is capable of combining oxidatively with the alkanes, this addition process being thermodynamically favourable. Thus the kinetic barrier to the oxidative addition of RH to low-valence metal complexes is fairly low and the inability of many 16-electron complexes to activate alkanes can be associated with the thermodynamic causes.[202] Indeed, the rate of addition of CH_4 to Cp′IrCO depends only very slightly on temperature.[211] The nature of L (CO + PMe_3) has little influence on the reactivity of the complexes Cp′IrL in relation to alkanes, which can also indicate that the activation barrier is low.[202] The energy of the oxidative addition of RH to L_nM is determined by the equation[176]

$$E_{M-R} + E_{M-H} - E_{R-H} \simeq E_{M-M} \qquad (43)$$

and hence can be estimated from E_{M-M}. The highest value of E_{M-M} has been obtained for platinum and in addition it has been shown that the reaction involving Group VIII and I transition metals is energetically favourable.

The components involved in saturated bonds can add oxidatively simultaneously to two metal complex molecules:

$$M + R—R + M \rightarrow 2M—R \,.$$

It may be that reaction (15) proceeds as two-centre oxidative addition of the components of the $(CH_3)_4Sn$ molecule, namely CH_3 and $Sn(CH_3)_3$, to two platinum(II) species. Finally, one cannot rule out the possibility that, in the interaction of the Pt(II) + Pt(IV) system with methane, the methyl group adds oxidatively to the platinum(II) in the molecule, forming $CH_3Pt(IV)$, while the second component, the hydride, reduces platinum(IV) to platinum(II). Information about the oxidative addition mechanism can be obtained from the study of the reverse process—reductive elimination.[212,213] For example, since the interaction of $OsH(CD_3)(CO)_4$ and $OsD.(CH_3)(CO)_4$ results in the formation of a mixture of CH_4, CH_3D, CD_3H, and CD_4, one may conclude that the reductive elimination proceeds as a bimolecular process:

$$2OsH(CH_3)(CO)_4 \rightarrow CH_4 + (OC)_4HOsOs(CH_3)(CO)_4 \,. \qquad (44)$$

However, the reaction is kinetically of first order, i.e. its rate-determining stage is unimolecular. In the presence of amines or phosphines (L = py, PPh_3, or PEt_3) a first order is also observed but the reaction proceeds as intramolecular elimination.[214] At the rate-determining stage, an intramolecular rearrangement takes place with insertion of CO in the $Os-CH_3$ bond. The acyl complex formed reacts in a rapid stage with a second molecule of the initial compound.

Processes involving the oxidative addition of the components involved in the saturated H–H or R–H bonds to metal complexes or metal atoms as well as the reductive elimination of RH have been investigated by quantum-chemical methods.[215–223] We shall consider the general case of the interaction of a metal complex with the simplest saturated molecule, namely H_2.[218] In the interaction of the bonding σ orbital of hydrogen with the unoccupied acceptor orbital of the complex and of the antibonding σ^* orbital with the occupied donor orbital, four orbitals of a new hydride derivative are generated. The two low-lying orbitals are filled with electrons, one being symmetrical and the other antisymmetrical relative to the twofold axis or the mirror symmetry plane. A symmetrical combination is formed, for the MH bond generated, from the occupied orbital of the hydrogen molecule and such electron transfer from $\sigma_g(H_2)$ to ML_n weakens the H–H bond and strengthens the M–H bond. The electron transfer in the opposite direction, namely donor orbital $\rightarrow \sigma_u^*$, also weakens H–H and strengthens M–H. One can assume that the occupied a_1 orbitals and the three degenerate t_2 orbitals in CH_4 correspond to the σ_g orbital of the hydrogen molecule. Since the energy of the t_2 orbital is greater by 2 eV than the energy of the $\sigma_g(H_2)$ orbitals, the CH_4 molecule is a somewhat stronger donor.

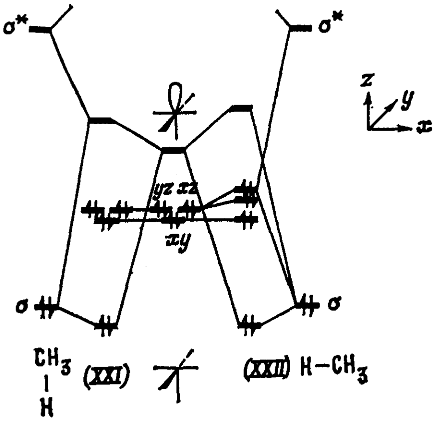


Figure 1. The interaction of orbitals in the formation of the structures (XXI) and (XXII).[218]

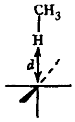
The total energy of the $H_2...Cr(CO)_5$ system has been calculated by the extended Hückel method.[218] The interaction energy is negative for both the perpendicular orientation (XIX) and the parallel orientation (XX) of the H_2 molecule approaching the $Cr(CO)_5$ fragment, which has the C_{4v} symmetry. However, in the case of the parallel approach of H_2 the energy of the system has a much more distinct minimum. When H_2 is replaced by CH_4, the curve for the perpendicular approach has approximately the same form but the parallel approach becomes extremely unfavourable.

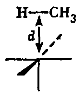
Whereas the d_{xz} orbital (which functions as the donor orbital in the complex) is lowered for (XX), in the case of CH_4 [structure (XXII)] the energies of both d_{xz} and d_{yz} orbitals increase (Fig.1).

(XIX)

(XX)



(XXI)



(XXII)

If the CH_4 approaches $Cr(CO)_5$ in such a way that the $H-CH_3$ axis forms an angle θ with the height of the pyramid, the structure is stable for $d(M-H) = 2.0$ Å and $\theta \leq 130°$. However, the perpendicular orientation ($\theta = 180°$) remains the most favourable. The reactions involving the oxidative addition of H_2 and CH_4 to $Rh(CO)_4^+$ and the corresponding isolobal complex CpRh(CO) and to the metallic surfaces of nickel and titanium have also been analysed.[218]

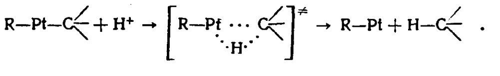
(c) The Mechanism with a Three-Centre Transition State

The first stage in the reaction of alkanes with the platinum(II) complex proceeds via a mechanism which cannot apparently be identified with either typical oxidative addition or the usual electrophilic substitution. Indeed the correlation (2) yields $\rho^* = -1.4$, indicating weak electrophilic properties of the metal complex. On the other hand, the series characterising the influence of ligands on the rate of the H–D exchange [reaction (1)] is the opposite to the *trans*-effect ligand series for the substitution reaction, which takes place with square platinum(II) complexes, but this does not agree with the mechanism involving the direct substitution of the ligand at platinum(II) by the alkane:

$$RH + Pt(II){-}Cl \rightarrow [H \cdots R \cdots Pt \cdots Cl]^{\neq} \rightarrow H^+ + RPt + Cl^- .$$

We may note that, in the cyclometallation of arenes, the rhodium(I) and iridium(I) complexes behave as nucleophiles, the palladium(II) complex exhibits electrophilic properties, and the platinum(II) complex occupies an intermediate position.[204]

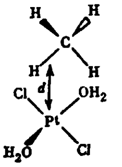
Presumably the reaction of the chloroaquoplatinum(II) complex with alkanes begins as oxidative addition, proceeds through a three-centre transition state, and terminates by the synchronous formation of a Pt–C bond with elimination of H^+ (which can be transferred to a H_2O molecule).[18,176,223] A similar mechanism has been proposed for the cyclometallation of 8-alkylquinolines by palladium(II).[224] It has also been suggested that the reverse process—the protolysis of the Pt(II)–C bond in alkyl and aryl complexes—involves a three-centre transition state:[225–227]



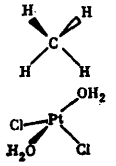
$$R{-}Pt{-}C\!\lessdot + H^+ \rightarrow \left[R{-}Pt \cdots \underset{\cdot\cdot H \cdot\cdot}{C}\!\lessdot\right]^{\neq} \rightarrow R{-}Pt + H{-}C\!\lessdot \quad (45)$$

At the same time the photolysis of the Pt–C bond in *trans*-$[PtH(CH_2CN)(PPh_3)_2]$ takes place in two stages: the oxidative addition of H^+ to the metal and the subsequent elimination of CH_3CN with formation of *trans*-$[PtHCl(PPh_3)_2]$.[228]

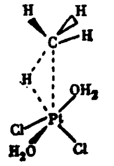
The cleavage of the C–H bond in methane by the *trans*-$PtCl_2(H_2O)_2$ complex has been subjected to quantum-chemical analysis by the extended Hückel method,[176,223] It was shown that the approach of CH_4 to the square planar platinum(II) complex [structure (XXIII)] leads to strong four-electron repulsion, the main cause of which is the interaction between the t_2 orbitals of methane and the occupied orbitals of the metal complex localised in the region of the free coordination site (HOMO consisting mainly of the d_{z^2} orbital and also the low-lying d_{yz} orbital). When the distance between the Pt atom and the centre of the C–H bond reaches $d = 2.8$ Å, the distortion of the metal complex [structure (XXIV)] lowers the repulsion energy. The composition of the HOMO then changes, namely the contribution of the d_{z^2} orbital diminishes and that of the $d_{x^2y^2}$ orbital increases, which entails a decrease of the electron density in the region of the free coordination site. The $d_{x^2-y^2}$ orbital is hybridised with the s, p_z, and d_{z^2} orbitals of the metal, as a result of which the low acceptor MO of the complex becomes extended in the axial direction.



(XXIII)



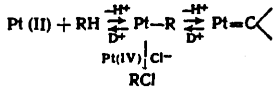
(XXIV)



(XXV)

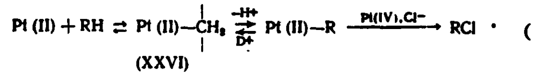
The overlap of the acceptor orbital with the σ orbital of the C–H bond increases and hence the contribution of the transfer of electron density via the donor–acceptor mechanism also increases. This is accompanied by the simultaneous increase of the dative interaction, the main contribution to which is made by the charge transfer from the d_{z^2} and d_{yz} orbitals to the σ* orbitals of methane. In the second stage, the deformation distortion of the methane molecule occurs starting with $d = 2.4$ Å and the repulsion energy diminishes still further. At the same time the angle of the displacement of the ligands from the plane of the complex increases from 10° to 36°. The populations of the Pt–C and Pt–H bonds reach 30–40% and the C–H bond is loosened to the extent of 20–30%. Under these conditions, the overlap of the d_{yz} and t_2 orbitals diminishes. Since an analogue of an unshared pair oriented towards the complex appears at the carbon atom, namely the $3a'$ component at the t_2 level (Fig. 2), the donor–acceptor interaction is enhanced. The transition state (XXV) arises for $d = 1.8$ Å, whereupon the Pt–C and Pt–H bond lengths reach the usual values and the angle of deviation of the ligand in the complex is 36°. When the C–H bond is extended by 0.28 Å, a maximum appears on the curve describing the energy of the system and the C–H, Pt–C, and Pt–H bonds become approximately equivalent. The extension of the C–H bond enhances both the donor–acceptor and dative interactions; the main contribution to the latter comes in this case from the transfer of electron density to the $3a_1$ component of the t_2^* level. This transfer plays a decisive role in the rupture of the C–H bond. It is noteworthy that, when the C–H bond is extended, the four-electron repulsion increases faster than the interactions of both types and only when CH_4 and the complex are close together do the repulsion and dative interaction energies become equalised. Calculation[223] has shown that, on passing from *trans*--$PtCl_2(H_2O)_2$ to $PtCl_4^{2-}$, the activation energy for the reaction with the alkane should increase by 0.24 eV, which agrees with the experimental data (these yield a difference ⩾0.17 eV). In the first stages of the process, up to the appearance of the transition state, the C–H bond is polarised, which increases the acidity of the hydrogen atom. This is apparently why in the presence of bases stronger than the platinum(II) complex, it is easier for the system to transfer hydrogen in the form of H^+ to the molecule of the base, which may be H_2O. Thus the reaction may be completed by the synchronous formation of the Pt–C bond and the elimination of H^+, i.e. can proceed as "soft" electrophilic substitution.

The study of the kinetics of the H–D exchange and of the oxidation of alkanes as well as the analysis of the multiple exchange parameter led to the hypothesis[229] that the reaction does not proceed via the alkyl–carbene mechanism



$$\mathrm{Pt(II)} + \mathrm{RH} \underset{D^+}{\overset{-H^+}{\rightleftarrows}} \underset{\mathrm{RCl}}{\underset{\downarrow\,\mathrm{Pt(IV)},\,\mathrm{Cl^-}}{\mathrm{Pt{-}R}}} \underset{D^+}{\overset{-H^+}{\rightleftarrows}} \mathrm{Pt{=}C}\!< \qquad (46)$$

but via the alkane–alkyl mechanism



$$\mathrm{Pt(II)} + \mathrm{RH} \rightleftarrows \underset{\mathrm{(XXVI)}}{\mathrm{Pt(II){-}CH_3}} \underset{D^+}{\overset{-H^+}{\rightleftarrows}} \mathrm{Pt(II){-}R} \xrightarrow{\mathrm{Pt(IV),Cl^-}} \mathrm{RCl}\ . \qquad (47)$$

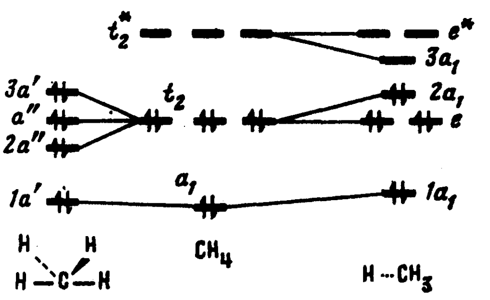


Figure 2. The change in the orbitals of the methane molecule on deformation of the angles and following an increase in the C–H bond length.[223]

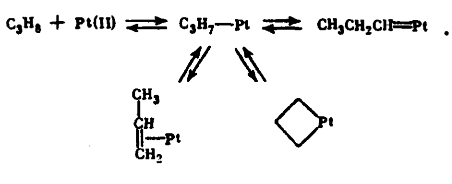
It has been suggested that the first kinetically significant intermediate in this reaction is the Pt(II)–alkane complex (XXVI), which is an analogue of alkonium ions of the type CH_5^+, whose formation is associated with the deformation of both the planar complex and of the tetrahedral hydrocarbon molecule. The multiple H–D exchange in alkanes under the influence of platinum(II) can also be due to the formation of olefinic π-complexes and metallocycles[1] (Scheme 6).

Scheme 6



(d) Cleavage with Formation of Radicals

In contrast to the activation of an alkane by a platinum(II) complex, the reaction of RH with Pd^{2+} may begin as electron transfer.[230] The hydroxylation of alkanes by oxygen complexes also proceeds with formation of radicals (see Section IV). In the latter case the interaction of the metal with the C–H bond takes place via a bridging ligand.[143,144,231,232] The formation of a benzylrhodium(III) σ-complex on interaction of the porphyrinrhodium dimer with toluene apparently begins with attack by the P–Rh(II)• radical species on the C–H bond.[233] The reaction of $PtCl_6^{2-}$ with hexane induced by light or γ-radiation[26–29] begins with the homolysis of the Pt–Cl bond in the excited species $[PtCl_6^{2-}]^*$,[234–236] which results in the formation of a platinum(III) complex and the $Cl^{\bullet}$ radical species. The latter can apparently attack the hexane molecule in the solvent (CH_3COOH) cage. The hexyl radical formed recombines with $Pt^{III}Cl_5^{2-}$ to produce a hexylplatinum(IV) σ-complex, which eliminates HCl reductively and is converted into the hexeneplatinum(II) π-complex. The hexyl radical can also be oxidised or can disproportionate with formation of hexene. The olefin readily reacts with[237] the platinum(II) or platinum(IV) chloride complex, affording the hexene π-derivative.

3. Polar, Orbital, and Steric Control

The reactions of metal complexes and other reagents with saturated compounds containing a C–H bond can be subdivided into three types depending on the factors which have a decisive effect on the course of the process. According to perturbation theory,[238] the total energy change ΔE on partial formation of a bond between the atom s of an electron-donating molecule S and the atom t of an electron-accepting molecule T in a solvent with an effective dielectric constant ε is expressed by an equation incorporating the electrostatic and covalent terms:

$$\Delta E = -\frac{q_s q_t}{R_{st}\varepsilon} + \frac{2(c_s^m c_t^n \Delta\beta_{st})^2}{E_m^* - E_n^*}, \qquad (48)$$

where q_s and q_t are the total charges on the atoms s and t in the isolated molecules, R_{st} is the distance between the atoms s and t, c_s^m and c_t^n are the coefficients of the corresponding AO, $\Delta\beta_{st}$ is the change in the resonance integral on interaction of the orbitals of the atoms s and t, and E^* are quantities characterising the energies of different MO in the isolated molecules.

When atoms carrying large opposite charges interact, an increase in the contribution of the first, electrostatic term in Eqn.(48) favours the reaction. If the difference between the energy levels of the occupied MO of the donor and the unoccupied MO of the acceptor is large, the contribution of the covalent term is insignificant. Interactions of this type refer to reactions controlled by the charge (polar control).[238] In order that alkanes, which are weak donors, should enter into reactions of this type, very strong acceptors are required. Here one can apparently include the reactions of alkanes with complexes of metals in a high oxidation state. The variation of the selectivity in the sequence 3° ≫ 2° ≫ 1° is characteristic of such processes involving alkanes. In this case the role of the medium (especially the acidity) is large. The C–H bond in arenes is cleaved much more readily than in alkanes. Clearly this class includes typical electrophilic substitution reactions. On the other hand, if the HOMO of the donor and the LUMO of the acceptor have very similar energies, the denominator $E_m^* - E_n^*$ becomes extremely small and the second term in Eqn.(48) is very large. Such processes are classified as orbital-controlled. The reactions of alkanes with complexes of metals in low and moderate oxidation states [for example platinum(II), iridium(I), and rhodium(I)] are close to this type. The energy of the metal–carbon bond formed and of the C–H bond ruptured should be particularly important in this connection. Polar factors are not then significant and the influence of the medium is usually small. Bearing in mind that the changes in the M–C and C–H bonds cancel out, the selectivity as regards the point of attack on the molecule is low and different molecules with the C–H bond have similar reactivities. Finally, steric factors can play a decisive role in the process. In this case the selectivity series are of the type 1° > 2° ≫ 3° and $\omega > (\omega - 1) \gg (\omega - 2)$; methane may prove to be the most reactive molecule. Biological oxidation is apparently closest to processes of this type, although steric factors are also clearly important in reactions involving metal complexes.

In the real processes involving alkanes account must be taken of all three factors. Their quantitative assessment for different reactions still needs to be carried out.

VI. CONCLUSION

During the 18 years which have elapsed since the discovery of the first reactions of alkanes in solutions of metal complexes, this field of chemistry has developed vigorously, particularly in recent times. There is no doubt that one may expect the discovery of new, especially catalytic, processes with participation of methane and its homologues, which will find practical applications. In its turn, this will intensify the interest in alkanes from the standpoint of their involvement in selective chemical processes and the new chemistry of alkanes thus established will be in line with the ever more urgent need for economy in the consumption of the existing resources of this chemical raw material on our planet, which have accumulated during the billions of years of its existence.

The rapid development of this field of chemistry is also reflected in the fact that, during the period required to prepare the manuscript of this review for the press, several tens of articles solely or partly devoted to the activation of the C–H bond in hydrocarbons and dealing with related problems have appeared in the literature. Reviews have been published on individual problems of the activation of alkanes by metal complexes.[239–244]

The reactions of the hydride, cyclopentadienyl, and other complexes of transition metals in a low oxidation state with alkanes,[245–252] olefins,[253–256] and arenes,[257–260] which proceed as a rule via the oxidative addition mechanism, have been investigated vigorously. The complexes catalyse the H–D exchange in methane[245,246] and benzene.[246,257] Organyl σ-derivatives can be isolated in the case of rhenium,[247,251] thorium,[248] iridium,[249,254–256,258] rhodium,[250] platinum,[252] iron,[253] and osmium[260] complexes. Evidence has been obtained that the addition of an alkane to the $C_5Me_5RhPMe_3$ species takes place with the intermediate formation of an alkane η^2-complex (with an agostic bond).[250] Factors promoting the initial activation of the C–H bond have been discussed.[261] The iridium hydride complex catalyses the thermal and photochemical alkane dehydrogenation reaction.[262] The possibility of hydromethylating carbon monoxide (with formation of acetaldehyde from CH_4 and CO or ethyl methyl ketone from CH_4, CO, and C_2H_4) in the presence of the Cp_2TiCl_2–$(CH_3)_2AlCl$ system has been demonstrated.[263] The reaction involving the "metathesis" of the σ-bonds between the pentamethylcyclopentadienylscandium complex Cp_2^*ScR and the hydrocarbons R'H ($^{13}CH_4$, arenes, and styrenes) via the mechanism $Cp_2^*ScR + R'H \rightleftharpoons Cp_2^*ScR' + RH$ has been described.[264] The bipyridyl complexes of platinum(II) catalyse the addition of methane to acetylene with formation of propene.[265] A number of studies[269–276] have been devoted to cyclomethylation (see the relevant reviews[266]) with cleavage of saturated and aromatic C–H bonds. The thermodynamic and kinetic parameters of the reversible cyclomethylation of the C–H alkyl bonds have been determined[273,274] and the intermolecular cleavage of such bonds in a chelate cobalt complex has been described.[275] The dimers of octaethylporphyrin complexes of rhodium[277] or iridium[278] react with aromatic alkyl-substituted compounds via an aliphatic C–H bond with the simultaneous formation of alkyl σ-derivatives and hydride derivatives (see also Wayland and Del Rossi[233]). The activation of

H–H and C–H bonds by ML_n species with the d^0 configuration, for example, Cp_2LuR, has been analysed by the extended Hückel method.[279] The interaction of the d^6 ML_5 fragments with H_2 involving the η^2-H_2 type of coordination of hydrogen to the metal and the formation of the dihydride derivative, has been investigated by the same method.[280] The dihydrogen complexes $M(CO)_3(PR_3)_2(\eta^2\text{-}H_2)$, where M = Mo or W, have been isolated and characterised.[281] The adducts of saturated hydrocarbons with the paramagnetic complexes $Cr(acac)_3$ and $Fe(acac)_3$ have been detected by ^{13}C NMR in solutions in $CHCl_3$ and CCl_4.[282]

Examples of the cleavage of C–C bonds by metal complexes have been described in a number of studies.[283–286] The reaction of pentamethylcyclopentadiene with $Mn_2(CO)_{10}$ proceeds, in particular, with the cleavage of a C–C bond, which results in the formation of tetramethylcyclopentadienyltricarbonylmanganese.[284] A compound containing a π-bond between iridium and monomethylcyclopentadiene is formed from 1,1-dimethylcyclopentane and the complex $[Ir.(H)_2(Me_2CO)_2L_2]^+$, where $L = (p\text{-}FC_6H_4)_3P$.[285] Cycloalkylrhodium hydride complexes rearrange to rhodacycloalkanes.[286] The reactions of alkanes with transition metal atoms, ions, and complexes in the gas phase and in the matrix at low temperature, which proceed with the cleavage of C–H and C–C bonds, have been described.[287–296]

The interaction of aromatic, alkyl-substituted aromatic, and saturated hydrocarbons with compounds of metals in a high oxidation state usually takes place as electrophilic substitution or involves the formation of radicals. Thus, detailed study of the reactions of arenes with the octaethylporphyrin complex of rhodium(III) in the presence of Ag^+ (this ion eliminates chlorine from the metal complex) has shown[297] that the aryl σ-derivative is formed on electrophilic substitution. The logarithms of the relative rates of methylation of substituted benzenes are correlated with the σ parameters ($\rho = -5.43$). It is of interest that photolysis of solutions of aryl σ-complexes in benzene leads to the homolytic cleavage of the Rh–C bond, which results in the formation of 4-substituted biphenyls.[297] A study has been devoted[298] to the mechanism of the methylation of arenes by mercury(II) and thallium(III) compounds. In a study of the products of the decomposition of the *meta*- and *para*-isomers of the tolylplatinum(IV) σ-complex, formed in the reaction between H_2PtCl_6 and toluene in aqueous CF_3COOH, it was observed that, together with the "expected" 3,3'-, 4,4'-, and 3,4'-bitolyl isomers, a large amount of the 2,3'- and 2,4'-bitolyls is formed after a long induction period.[299] Such products of *ortho*-substitution relative to the methyl group are apparently formed on interaction of *meta*- and *para*-platinised toluenes with free toluene present in solution. It has been shown[300,301] that the oxidation of methylbenzenes by palladium(II) complexes in an acid medium can occur via two pathways: electrophilic substitution in the arene ring with formation of an organometallic intermediate and one-electron transfer from the arene to the palladium atom with participation of the arene radical-cation as an intermediate. The oxidation of mesitylene by the $PtCl_6^{2-}$ ion, which leads to the formation of diarylmethane, apparently takes place with electron transfer.[302] Irradiation by light of a solution of anisole and the $OsCl_6^{2-}$, $IrCl_6^{2-}$, or $RhCl_3$ complex in acetic acid affords a mixture of bianisyl isomers.[303] It has been suggested that in the first stage of the reaction an electron is transferred from the arene to the excited metal complex species and the resulting radical-cation attacks a free anisole molecule.[303] When solutions of the $AuCl_4^-$ [304] or $PtCl_6^{2-}$ [305] ions are irradiated in the presence of alkanes, excited metal complex species are generated,[306] after which the Au–Cl or Pt–Cl bonds undergo homolysis with formation of Cl radical species, which chlorinate alkanes. In the case of $PtCl_6^{2-}$, a hexeneplatinum(II) π-complex is formed as a second reaction product[26–29,305] in addition to the chlorohexane isomers.[305] The reactions involving the free-radical halogenation of alkanes by halogeno-derivatives of hydrocarbons (for example, CCl_4) can be initiated by carbonyl complexes such as $Re_2(CO)_{10}$, $Cr(CO)_6$, etc.[307] The homolytic reactions involving the introduction of functional groups into oxygen-containing compounds are initiated by variable-valence metal derivatives.[308] It has been shown that the oxidation of toluene derivatives by oxygen, catalysed by cobalt acetate in the presence of NaBr, takes place in two stages and that in the first rapid stage chain propagation takes place via the reaction between the peroxy-radical and the cobalt bromide complex.[309] It has been suggested that hydrocarbons are oxidised by lead tetraacetate via a free-radical mechanism.[310] On the other hand, the acyloxylation of toluene by oxygen at the methyl group, catalysed by the $Pd(OAc)_2$–$Cu(OAc)_2$ system, is apparently heterolytic.[311] The activation of a C–H bond in allyldialkylruthenium(IV) complexes has been described.[312]

Several studies have been published on the oxygenation of hydrocarbons by oxygen-containing compounds of high-valence metals. Irradiation of polyoxotungstate by light in the presence of zerovalent platinum and an alkane involves the introduction of a functional group into the hydrocarbon.[313] It has been found that irradiation accelerates the oxidation of alkyl-substituted aromatic hydrocarbons, cyclohexane, and adamantane by oxo-complexes of chromium(VI) both in a homogeneous solution in acetic acid and in water in the presence of tetrabutylammonium bromide.[314] Chromyl trifluoroacetate proved to be an exceptionally powerful oxidising agent capable of oxidising alkanes to ketones at room temperature in solution in CCl_4.[315] Anhydrous $FeCl_3$ in dry acetonitrile activates hydrogen peroxide; the reaction of this system with cyclohexane gives rise to cyclohexyl chloride, cyclohexanol, and cyclohexanone.[316] It has been suggested that the process does not proceed via a radical mechanism. The kinetics and selectivity of the oxidation of alkanes to aromatic hydrocarbons by permanganate in aqueous solutions have been described.[317]

A series of further detailed studies of the Gif system have been published recently.[318–325] The system is effective in the oxidation of natural products, for example, steroids;[318,321–323]; the mechanism of the oxidation has been discussed.[320] The metallic zinc in the oxidising system can be replaced by a cathode (the electrochemical version has been called the Gif–Orsay system).[324,325]

Several studies[330–337] have been devoted to cytochrome P-450 and hydrocarbon oxidation reactions with its participation (see the relevant reviews[326–329]). Increasing attention has been paid to hydrocarbon oxidation reactions catalysed by metalloporphyrins, which model the action of cytochrome P-450 (see the relevant reviews[338–341]). It has been suggested that $KHSO_5$ [342] and NaOCl [343] be used as donors of atomic oxygen in such processes. The stage involving the cleavage of the O–O bond in the porphyrin derivative of iron has been observed;[344] the cleavage of this bond in the analogous manganese(III) complex can take place both heterolytically and homolytically.[345] A change in the selectivity of the oxidation of alkanes with increase of the steric shielding of the active centre of the metalloporphyrin catalyst has been demonstrated in a number of studies.[346–349] Hydrocarbons are oxidised by iodosobenzene in catalysis by phthalocyanine complexes of iron on a zeolite[350] or by oxygen in catalysis by haemin immobilised on the surface of silica.[351]

Finally we may mention several studies on the introduction of functional groups into alkanes without the involvement of metal complexes: photohydroxylation with the aid of H_2O_2,[352] oxidation by peracids[353] and ozone,[354] and the formation of carboxylic acids from alkanes and CO in the HF–SbF$_5$ mixture.[355]

Reactions of Carbonyl Compounds with Organic Derivatives of Alkali Metals and Hydride Reductants: the Effects of the Medium and the Cation

A.A.Solov'yanov and I.P.Beletskaya

The effects of the medium and the cation in the reactions of alkali metal salts of CH acids and hydride reductants with carbonyl compounds are analysed.
The bibliography includes 73 references.

I. INTRODUCTION

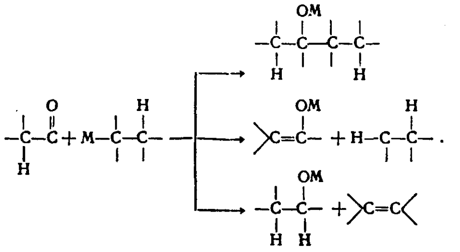
The reactions of carbonyl compounds with organometallic derivatives are widely used in synthetic organic chemistry as one of the main methods for the formation of the carbon–carbon bond. However, despite the enormous number of studies devoted to the practical development of syntheses on the basis of carbonyl compounds, until recently the existing ideas about the mechanisms of these processes were fairly vague. Systematic studies of the influence of the nature of the solvent and the size and charge of the cation on the kinetics and mechanisms of reactions with participation of carbonyl compounds began only in the last decade. Thus, the first model of the mechanism of the reactions of carbonyl compounds with organic derivatives of alkali metals, which is based on the extremely fruitful idea that the carbonyl group can be activated by the coordination of the oxygen atom to a metal cation and that the effective nucleophile (the group R of the organometallic compound) can be deactivated via association with formation of ion pairs, was constructed[1] in 1978. At the same time one must note that this, in essence, kinetic scheme clearly underestimates the thermodynamic factor known from other investigations, in particular, the fact that in the case of a thermodynamically sufficiently stable carbanion the addition to the carbonyl group can be reversible and the thermodynamic stability of the product should also depend on the cation and the solvent. Therefore, precisely at this time, when there has been a growth of interest in problems of the mechanism of the reactions of carbonyl compounds, it is necessary to perform a more detailed analysis of all the factors active in these processes in order to be able to base the formulation of the problems tackled in the later studies on the entire set of theoretical ideas in this field.

This review considers in the first place the reactions of organic derivatives of alkali metals with aldehydes and ketones, which lead to the formation of a C–C bond and for which data are available concerning the influence of the cation and the solvent on the rate and on the yield and composition of the products formed. Precisely for these reactions it is most often possible to relate the thermodynamic and kinetic parameters to the state of the organometallic compounds in solution (the type of ion pairs, the presence of free carbanions, the formation of associated species made up of ion pairs) and the ability of the cations to be coordinated to the carbonyl oxygen, which is of decisive importance for the determination of the process mechanism. An attempt has been made to consider critically the data in the original communications and to interpret them whenever possible from a single standpoint.

It is noteworthy that, from the standpoint of the effects of the medium on the cation, the reactions of organic derivatives of alkali (and alkaline earth) metals with carbonyl compounds and processes involving the reduction of the carbonyl group by alkali metal tetrahydroaluminates and tetrahydroborates have a great deal in common. Frequently the same workers have carried out parallel studies on processes of both types. For this reason, in certain cases, whenever this is necessary for the modelling of individual stages of the reaction or for the establishment of a more general picture, the review presents data on the reactivities of alkali metal enolates and cuprates and organomagnesium compounds and the hydride reduction reactions of the carbonyl group are also considered.

II. REACTIONS OF ORGANIC DERIVATIVES OF ALKALI METALS WITH ALDEHYDES

The reactions of organic derivatives of alkali metals and organomagnesium compounds with carbonyl compounds (aldehydes and ketones) can proceed in principle via three pathways:[2] addition, enolisation (when the carbonyl compound contains a sufficiently mobile proton), and reduction:



The relative contributions of each pathway are determined by the structure of the organometallic and carbonyl compounds, the charge and size of the metal ion M, the nature of the solvent, temperature, and certain other factors. It is simplest to analyse the influence of the reaction conditions on the reaction rate and the final result in the interaction of organic derivatives of alkali metal compounds with aldehydes where only addition products are formed as a rule. However, we shall begin this Section with one of the most important features of the reaction involving addition to the carbonyl group—its reversibility.

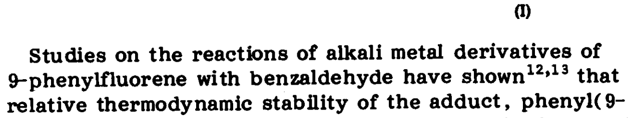
The idea of the reversibility of the nucleophilic addition to the carbonyl group probably arose in a study in 1950 of the kinetics of reactions in which organolithium compounds were chosen as nucleophiles.[3] The authors were able to explain the observed features only within the framework of a kinetic scheme including a rapid stage in which the alkoxide formed is cleaved into the initial reactants:

$$RM + {>}C{=}O \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} R{-}\overset{|}{\underset{|}{C}}{-}OM. \qquad (2)$$

Other investigators observed[4,5] that the ease of the analogous cleavage of alkoxides derived from β-hydroxyesters, namely $PhRC(OM)CH_2COOR'$ (where R = CH_3 and Ph and R′ = C_2H_5, iso-C_3H_7, or t-C_4H_9), obtained by the metallation of the corresponding OH acids by alkali metal amides in toluene, liquid ammonia, and diethyl and dibutyl ethers, depends greatly on the size of the counterion. Thus the yield of benzophenone obtained when $Ph_2C(OM)CH_2COOC_2H_5$ was kept in liquid ammonia for several hours amounted to 89 and 71% for M = Na and K but was 0% when M = Li. The alkoxides $Ph_2CHC(OM)Ph_2$, where M = Na or K, are also cleaved fairly readily in ether and liquid ammonia with formation[6,7] of benzophenone and the alkali metal derivative of diphenylmethane.

According to Cram's data,[8,9] the yield of the acetophenone formed on cleavage of alkoxides having the general formula $(C_2H_5)(CH_3)(Ph)C{-}C(CH_3)(Ph)(OM)$ in dimethyl sulphoxide (DMSO) increases sharply with increase in the radius of the alkali metal cation M: 25% for Li (24 h, 170 °C), 28% for Na (24 h, 75 °C), and 68% for K (12 h, 25 °C). The cleavage of alkali metal derivatives of trialkylcarbinols into the corresponding carbonyl compound and the organic derivative of the alkali metal takes place more effectively the greater the radius of the metal atom: Li < Na < K.[10]

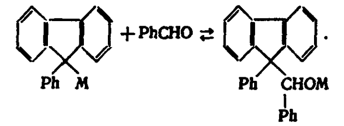
The thermodynamic stability of the alkali metal alkoxide depends not only on the size of the alkali metal cation but also on the solvent. This is indicated by the clear decrease of the yield of the adduct (I) obtained by the addition of 2-lithio-2-phenyl-1,3-dithiane to 4-t-butylcyclohexanone: 90% in cyclohexane, 75% in tetrahydrofuran (THF), and 0% in hexamethylphosphoramide (HMP)† and also by the quantitative decomposition of this compound (obtained beforehand in cyclohexane) into the initial reactants when the solvent is replaced by HMP:



(3)

(I)

Studies on the reactions of alkali metal derivatives of 9-phenylfluorene with benzaldehyde have shown[12,13] that the relative thermodynamic stability of the adduct, phenyl(9-phenyl-9-fluorenyl)alkoxide (II), diminishes simultaneously with increase of the radius of the metal atom and with increase of the polarity of the medium:



(4)

(II)

In dimethoxyethane (DME), the yield of compound (II) diminishes in the sequence Li ≅ Na > K > Cs and on passing from solvents of the ethereal type to dipolar aprotic solvents. In HMP the decomposition of compound (II) into the initial reactants takes place regardless of the size of the metal atom. HMP destabilises not only compounds (I) and (II) but also the lithium and caesium alkoxides formed[14,15] in reaction (5) of alkali metal salts of diphenylacetonitrile, 1,3-diphenylindene, 9-methoxycarbonylfluorene, and fluoradene with benzaldehyde. In DME in the presence of 3–4 mole % HMP, the yield of RPhCHOM does not exceed 5%:[15]

$$PhCHO + RM \overset{K}{\rightleftarrows} RPhCHOM. \qquad (5)$$

As a result of the possibility of the spectroscopic measurement of the concentration of the alkali metal salt of the CH acid at any stage of its reaction with benzaldehyde, in particular when the reaction system attains the equilibrium position, measurements were made for the first time[14–16] of the equilibrium constant *K* and a study was made of the factors influencing this quantity. In the reaction of alkali metal salts of 9-phenylfluorene with benzaldehyde in DME, the equilibrium constant decreases monotonically with increase of the HMP concentration. For the lithium salt, *K* = 208, 25, and 6 litre mol^{-1} at HMP concentrations of 5.6, 8.2 and 10.7 vol.% and for the sodium salt the constant is 39.6, and 0.7 litre mol^{-1} at HMP concentrations of 1.4, 3.5, and 10.7 vol.%. In conformity with the results of qualitative observations,[4–10] *K*(Li) > *K*(Na) in the reaction medium of the same composition (10.7 vol.% HMP), which is associated with the greater thermodynamic stability of the lithium alkoxides.

Table 1. The equilibrium constants for the reactions[14–16] of alkali metal salts with benzaldehyde in DME at 25 °C.

CH acid (RH)	pK_a[a]	*K*, litre mol^{-1} ($c = 10^{-4}$ M)		
		Li^+	K^+	Cs^+
9-Benzylfluorene	22.0	—	—	>100
1-Methyl-3-phenylindene	—	—	—	38
Ethyl diphenylacetate	22.4	—	—	29
Diphenylacetonitrile	17.8	23	15	22
9-Phenylfluorene	18.5	—	14	15
1,3-Diphenylindene	12.8	16	—	2.4
Fluoradene	10.5	7.2	2.8	2.2
9-Methoxycarbonylfluorene	10.4	1.8	—	0.25
9-Cyanofluorene	8.5	—	—	0.32

[a] The pK_a were taken from Petrov et al.[17]

Measurements of the equilibrium constant have also been performed[14–16] in DME for the reactions of benzaldehyde with alkali metal salts of CH acids of different structure, whose pK_a were varied within the range of approximately 14 units (Table 1). The common features in the variation of the equilibrium constant are then as follows: (1) the increase of *K* with decrease of the thermodynamic stability of the reacting carbanion (in the presence of a fixed

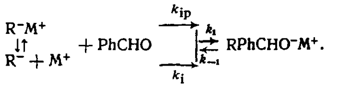
---

†The main reaction pathway in HMP is enolisation, which will be examined in detail in the next Section of the review.

cation) whose measure is the pK_a of the conjugate CH acid and (2) the decrease of K with increase of the radius of the alkali metal cation (for a fixed CH acid). The variation of K in the sequence Li > K > Cs agrees with the results of the study of the thermodynamic stability of alkali metal alkoxides of different structure.[4-10] At the same time, the shift of equilibrium (5) towards the initial reactants with increase of the thermodynamic stability of the carbanion is a fact which is difficult to justify without rigorous quantitative measurements, although intuitively it appears to be fairly natural.

On the basis of the results of studies of equilibrium (5), an energetic approach has been developed[13,15] to the determination of the relative thermodynamic stability of the adducts. In this approach, account is taken of the fact that the alkali metal salts of CH and OH acids are ionic compounds and that they exist in solution in the form of an equilibrium mixture of free carbanions, ion pairs, and even (in the case of alkali metal alkoxides) associated species made up of ion pairs. One of the main factors influencing the position of equilibrium (5) is the energy of the interaction of the charged fragments of the ion pair $RPhCHO^-M^+$: the smaller this energy, the lower the value of K. The interaction energy diminishes with increase of the radius of the cation and of the degree of its solvation (in the presence of HMP and crown polyethers[13])—the equilibrium constant diminishes correspondingly. It is of interest that calculation for the gas phase[18] demonstrates a clear decrease of the C–H bond energy in alkali metal methoxides $H{-}CH_2OM$ on passing from Na (333 kJ mol^{-1}) to K (326 kJ mol^{-1}); the energy of the C–H bond is even lower in the free methoxide anion (306 kJ mol^{-1}). Presumably the interaction in the ion pair–O^-M^+ influences analogously the C–R bond energy in the alkali metal alkoxides $\rangle C(OM){-}R$.

The study of the kinetics of the reactions of alkali metal salts of CH acids with benzaldehyde in DME established[14-16] that both free carbanions (rate constant k_i) and ion pairs (rate constant k_ip) participate in the stage involving addition to the carbonyl group:

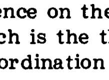


$$\left.\begin{matrix} R^-M^+ \\ \downarrow\uparrow \\ R^- + M^+ \end{matrix}\right. + PhCHO \begin{matrix} \xrightarrow{k_\mathrm{ip}} \\ \\ \xrightarrow[k_\mathrm{i}]{} \end{matrix} \Big| \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} RPhCHO^-M^+. \tag{6}$$

Since two types of ionic species participate in the reaction and the reactivity of the free carbanions is appreciably higher than that of the ion pairs, the observed reaction rate constant k_1 depends on the concentration of the alkali metal salts of the CH acid in a fairly complex manner. At the same time the reverse reaction (k_{-1}) takes place only with participation of complex ion pairs $RPhCHO^-M^+$ and the observed rate constant is independent of the concentrations of the reactants.

The features characterising the changes in the rate constants k_i and k_ip (Table 2) as a function of the radius of the alkali metal cation and the structure of the carbanion resemble those observed in nucleophilic aliphatic substitution reactions[19] with participation of alkali metal salts of CH acids. However, there are also significant differences. A common feature is the higher reactivity of free carbanions regardless of the variation of other factors, i.e. $k_\mathrm{i} > k_\mathrm{ip}$. Since in virtually all cases (with the exception of the lithio-derivatives of 1,3-diphenylindene and fluoradene)[19,20] the ion pairs of the alkali metal salts investigated are of the contact type, k_i exceeds k_ip approximately by two orders of magnitude. In a reaction system with solvate-separated ion pairs (1,3-diphenylindenyl-lithium), $k_\mathrm{i}/k_\mathrm{ip}$ is appreciably lower (~13).

A new factor, which was not encountered previously in the reactions of alkali metal salts of CH acids, is the dependence of the rate constant for the reaction of the free carbanion on the radius of the alkali metal caton when lithium and caesium salts are compared. In the case of alkali metal derivatives of diphenylacetonitrile, 1,3-diphenylindene, and fluoradene, $k_\mathrm{i}(Li^+)$ exceeds $k_\mathrm{i}(Cs^+)$ by a factor of 6–15, while for the reactions of alkali metal salts of 9-methoxycarbonylfluorene the difference between $k_\mathrm{i}(Li^+)$ and $k_\mathrm{i}(Cs^+)$ approaches two orders of magnitude. In order to account for this result,[14,15] one can invoke the idea, put forward by Lefour and Loupy,[1] that the carbonyl group is activated by the formation of a complex between the Li^+ cation and the oxygen atom:



Complex formation entails an increase in the electrophilicity of the carbonyl group, because there is an increase[1,21] in the positive charge on the carbon atom and a decrease of the LUMO energy. According to calculated data in two communications,[1,21] the formation of complexes between Li^+ and acroleine, benzaldehyde, acetophenone, and aliphatic aldehydes in the gas phase results in a decrease of the LUMO energy in these carbonyl compounds by 600–700 kJ mol^{-1}. Since there are experimental facts[21] indicating the possibility of controlling the reactions of carbonyl compounds and organic derivatives of alkali metals by means of the LUMO and HOMO energies, these calculations merit special attention. While coordination to Li^+ lowers[1] the energy of the LUMO of acroleine by 695 kJ mol^{-1}, coordination to Na^+ alters the LUMO energy by 454 kJ mol^{-1}. Large cations, for example Cs^+, have little influence on the LUMO energy of the carbonyl compound. Such is the theoretical assessment of the possibilities of the coordination of the cation to the carbonyl group.

Table 2. The rate constants[a] for the reactions involving the addition[15,16] of the free carbanions (k_i) and their ion pairs (k_ip) to the carbonyl group of benzaldehyde in DME at 25 °C.

CH acid	M^+	10^3k_i	10^5k_ip
9-Methylfluorene	Cs^+	310	840
Diphenyl(2-pyridyl)methane	Cs^+	170	570
Diphenylacetonitrile	Li^+	203	224
"	Cs^+	13.5	24.7
1,3-Diphenylindene	Li^+	8.8	66
"	Cs^+	0.85	0.34
Fluoradene	Li^+	4.66	—
"	Cs^+	0.83	1.33
9-Methoxycarbonylfluorene	Li^+	22.8	2.26
"	Cs^+	0.32	0.52
9-Cyanofluorene	Cs^+	0.14	0.24

---

[a] The dimensions of the constants are litre mol^{-1} s^{-1}.

Experimental data have confirmed[22-25] the possibility of the formation of complexes of Li^+ with aldehydes and ketones. However, these data have been obtained in studies in solutions in the carbonyl compounds themselves,[22] in acetonitrile,[23,24] and in aqueous alcoholic mixtures.[25] On the other hand, when one is dealing with the coordination of an alkali metal cation to the carbonyl group in solvents of the ethereal type, many questions arise. Firstly, there are no convincing thermodynamic data in support of such coordination. It is known that the basicity of ethereal solvents is as a rule higher than the basicity of carbonyl compounds. For example, the Kamlet–Taft basicity parameters B_{CT} [26] for acetone and cyclohexanone are respectively 0.37 and 0.41, while the values for ether and THF are respectively 0.49 and 0.47. The change in ΔH on formation of a complex between Li^+ and THF, DME, and glymes by 0.3–20 kJ mol^{-1} in absolute magnitude exceeds the corresponding parameter for the reaction of Li^+ with acetone.[27] Admittedly there are data[28] showing that the energies of the complex formation reactions of Li^+ with ether, formaldehyde, and acetaldehyde are similar: −163, −149, and −169 kJ mol^{-1} respectively.

Secondly, in the reaction medium the concentration of the carbonyl compound is usually lower by one–two orders of magnitude than the concentration of the ethereal solvent. Thus, even if the complex of the alkali metal cation with the carbonyl group is formed, its concentration should probably be small and should depend greatly on the reaction conditions.

At the present time the concept[1] of the formation of a complex of the alkali metal cation with the carbonyl group is widely used[21,29–35] also in the interpretation of the results of studies on reactions of lithio-derivatives with aldehydes and ketones. One can therefore mention also data obtained in the investigation of related systems. The fluoradenyl anion[36] and carbanions of the benzyl type[37] react with epoxyethane more slowly than their lithium ion pair because, according to the authors' hypothesis, the cation forming part of the composition of the ion pair cooperates with the opening of the epoxide ring by being coordinated to the oxygen atom.

Among the results obtained[16] in the study of the kinetics of the reactions of alkali metal salts of CH acids with benzaldehyde, yet another experimental fact is of great interest. The rate constants for the addition of the carbanions (k_i) and their caesium ion pairs (k_{ip}) to the carbonyl group vary in parallel with the rate constants for the reactions of the same species in nucleophilic aliphatic substitution processes. Furthermore, the logarithms of the nucleophilic addition and nucleophilic substitution rate constants are linearly related. This shows that the nucleophilic properties of the ionic species determine their reactivity in both processes.

Interesting effects of the medium and the cation have been observed[29] in the reactions of alkali metal derivatives of nitriles with benzaldehyde and its *para*-substituted derivatives. The yield of the adducts (III) in reaction (7) does not depend greatly on the size of the metal atom—98% for Li, 70% for Na, and 80% for K, but it nevertheless reaches its maximum value in the reaction with the lithium salt:

$$\mathrm{MCH_2CN + PhCHO \rightarrow \underset{(III)}{PhCH(CH_2CN)OM}}. \qquad (7)$$

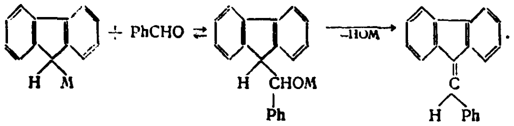
In the light of the foregoing examination of the interactions of alkali metal salts of CH acids with aldehydes, these data constitute indirect evidence for the reversibility of reaction (7), although the authors[29] make no mention of this important factor. Incidentally, if the equilibrium constants of reaction (7) are estimated by assuming that the initial reactant concentrations are 0.1 M,[29] then entirely reasonable values are obtained: 10^4 for Li, 80 for Na, and 200 litre mol^{-1} for K. Taking into account the fact that reaction (7) was carried out in THF and not in DME and at −80 °C and not at 25 °C (pK_a for acetonitrile is 24), the constants obtained agree fairly well with the data presented in Table 1. It is of interest that the variation of the equilibrium constant as a function of the cation ($Li^+ > K^+ > Na^+$) is of the same character both for the reactions of alkali metal salts of diphenylacetonitrile[15] and for the reactions of alkali metal salts of acetonitrile. Judging from the time required to complete reaction (7), its rate varies in the sequence Li > Na > K. This result (subject to the condition that both free carbanions and ion pairs or even associated species comprising ion pairs react in THF at an alkali metal salt concentration of 0.1 M) clearly indicate the involvement of the cation in the activation of the carbonyl group. This is confirmed by the decrease of the rate of reacton following the addition of cryptand 211 to the lithium salt of acetonitrile. However, the rate of reaction of KCH_2CN in the presence of cryptand 222 increases, which the authors[29] believe is also associated with the increase of the fraction of free carbanions. On the other hand, cryptand 221 does not influence the rate of reaction of $NaCH_2CN$, which the authors explained by the cancellation of two effects—on the one hand, the suppression of the activation of the carbonyl group and, on the other, the increase of the contribution of the reaction involving the more reactive free carbanions.

The half-life of the reaction of the lithium salt of *m*-chlorophenylacetonitrile with aromatic aldehydes in THF at −80 °C diminishes in the following sequence of X: CN (15 min) > H (10 min) > OCH_3 (5 min). When HMP is added, the sequence is reversed: CN (0.5 min) < H (2 min) < OCH_3 (45 min):

$$m\text{-}\mathrm{ClC_6H_4CH(CN)Li} + p\text{-}\mathrm{XC_6H_4CHO} \rightarrow m\text{-}\mathrm{ClC_6H_4}\underset{\substack{|\\ p\text{-}\mathrm{XC_6H_4CHOLi}}}{\mathrm{CH}}\mathrm{(CN)}. \qquad (8)$$

The rate of reaction of anisaldehyde diminishes, while other aldehydes react faster. The authors have interpreted these results[29] from the standpoint of the positions of the energy levels of the LUMO of the aldehyde relative to the HOMO of the carbanion assuming that, by virtue of the coordination of Li^+ to the carbonyl group, in THF the energies of the LUMO of all three aldehydes are equalised and are lower than the energies of the corresponding LUMO in a THF–HMP mixture, where such coordination does not occur.

The study of the reactions of alkali metal salts of fluorene with benzaldehyde under different conditions yielded[12,13] data concerning the influence of the solvent and the cation not only on the stage involving the addition of the nucleophile to the carbonyl group but also on the next stage in which a molecule of the alkali is eliminated, i.e. on the process modelling the crotonic condensation. In contrast to their 9-substituted derivatives, the unsubstituted fluorenyl salts [cf.Eqn.(4)] react with benzaldehyde in accordance with the following scheme:

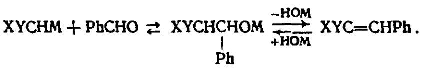


(IV) (V) (9)

The conversion of fluorenyl-lithium or fluoroenylsodium into the reaction products in ether and DME at concentrations of organic derivatives of alkali metals in the range 0.01–0.1 M and those of benzaldehyde in the range 0.03–0.4 M takes place over a period shorter than 1 s. The lithium and sodium salts of fluorene in HMP or its potassium, caesium and tetra-n-butylammonium salts in any of the solvents employed (ether, DME, HMP) react appreciably more slowly. Under these conditions, the complete consumption of the carbanion requires about 1 min. The retardation of the reactions in ether and DME in the presence of K^+, Cs^+, and Bu_4N^+ compared with Li^+ and Na^+ or the retardation of the reactions of fluorenyl-lithium and fluorenylsodium on passing to HMP (or after the introduction of solvating additives of the type of crown polyethers) is due to the appreciable shift of the equilibrium in the first stage of reaction (9) towards the initial reactants. In HMP or in the presence of large cations in ether and DME, the reactions considered in essence occur generally only because of the irreversible alkali elimination stage. For this reason, the only observed reaction product under these conditions is benzylidenefluorene (V).

In other cases the composition of the products depends on the competition between the first and second stages. A common feature is the increase in the yield of benzylidenefluorene with increase of the basicity (or with decrease of the thermodynamic stability) of the alkali metal alkoxide formed. The yield of benzylidenefluorine increases with increase of the polarity of the medium in the presence of the given cation (benzene < ether < DME < HMP in the presence of Li^+ and Na^+) and with increase of the radius of the cation in the given solvent. In DME: Li^+ (9%) < Na^+ (77%) < K^+, Cs^+, Bu_4N^+ (100%); in ether: Li^+ (16%) < Na^+ (70%) ≅ K^+ (69%); in benzene: Li^+ (0%) < Na^+ (23%) < Cs^+ (42%).

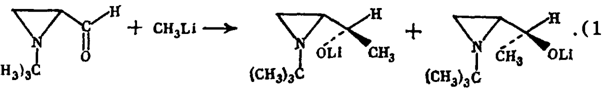
Whereas the elimination stage is irreversible in the reactions of alkali metal salts of fluorene and benzaldehyde, both stages are reversible in the Knoevenagel condensation [reaction (10)], where X and Y = CN or COOR:



$$XYCHM + PhCHO \rightleftarrows \underset{\displaystyle Ph}{XYCHCHOM} \underset{+HOM}{\overset{-HOM}{\rightleftarrows}} XYC{=}CHPh. \qquad (10)$$

For this reason, situations where both equilibria are fully displaced towards the initial reactants and the condensation product is not formed are entirely realistic. An example may be provided by the reaction[40] of sodiomalonic ester with benzaldehyde in ethanol. The condensation of $XYCH_2$ with carbonyl compounds is known to occur when amines are used as catalysts.[38,39]

Interesting results, which may indicate the coordination of the Li^+ cation to two heteroatoms of the carbonyl compound, have been obtained in a study of the reaction[31] of methyl-lithium with N-t-butyl-2-formylaziridine:

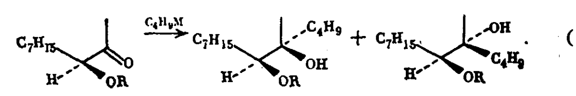


(11)

(VI) (VII)

A mixture of the stereoisomers (VI) and (VII), in which (VI) predominates (60%), is formed in THF. When LiBr is introduced into the reaction medium, at a concentration five times greater than that of methyl-lithium, the fraction of the isomer (VI) increases to 80%. The authors believe that the reaction proceeds via the formation of an intermediate complex from which the isomer (VI) should be formed with a higher probability.

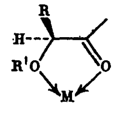
The coordination of the cation to oxygen ensures a high stereoselectivity also when organolithium and organomagnesium compounds interact with α-alkoxyaldehydes:[41,42]



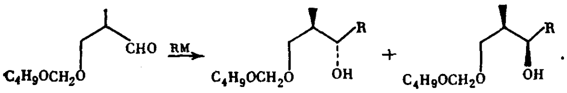
(12)

(VIII) (IX)

In reaction (12), which was carried out at −78 °C, the change in the nature of the solvent (n-hexane, chloroform, ether, THF) has little effect[42] on the ratio of the isomeric *threo*-product (VIII) and the *erythro*-product (IX): if M = Li and R = $CH_2OC_2H_4OCH_3$, the ratio (VIII)/(IX) varies from 3 to 0.7 (the smallest amount of the *threo*-isomer is formed in THF). If M = MgBr, the ratio (VIII)/(IX) increases to 9–14 in hexane, ether, and chloroform, and exceeds 100 in THF. The same high stereoselectivity [(VIII)/(IX) = 100 to 200] is observed[42] in THF in the analogous reaction of the organomagnesium compound if R = methoxymethyl, methylthiomethyl, benzyl, benzyloxymethyl, and furfurylmethyl. The authors suggest[42] that reaction (12) proceeds via the formation of an α-chelate (five-membered coordination complex), which is more stable for magnesium than for lithium.



α-Chelation is weakly manifested[41] in reactions (ether, −78 °C) of methyl-, vinyl-, and n-butyl-lithium and methylmagnesium bromide with β-alkoxyaldehyde:

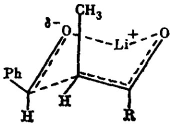


(13)

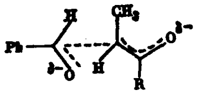
(X) (XI)

The ratio of the *threo*- and *erythro*-isomers formed (X)/(XI) varies in this instance only from 0.7 to 1.7. However, when lithium dimethyl- or di-n-butyl-cuprates are used in the reaction, the ratio (X)/(XI) increases respectively to 30 and 17. This ratio remains fairly high (12–20) also when the $C_4H_9OCH_2OCH_2$ group is replaced by $PhCH_2OCH_2$, $\overline{O(CH_2)_4C}HCH_2$, or $\overline{O(CH_2)_2OC}HCH_2$. It has been suggested[41] that the high stereoselectivity of the reactions of organocuprates with β-alkoxyaldehydes is due to β-chelation, i.e. the formation of an intermediate six-membered coordination complex. At the same time the stereoselectivity of the reactions of organocuprates with α-alkoxyaldehydes [for example, $PhCH_2OCH_2OCH(CH_3)CHO$] is low.[41] Unfortunately the nature of the distinct tendency of Grignard reagents towards α-chelation and of cuprates towards β-chelation in these reactions has not yet been established, although the excellent preparative possibilities associated with these effects are evident.

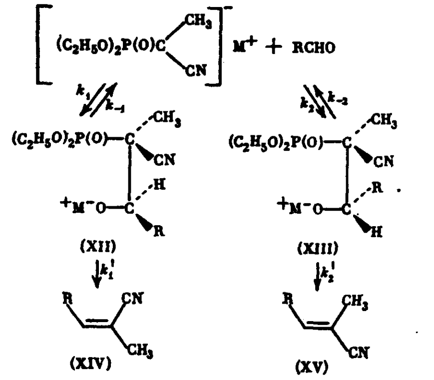
The *erythro*-aldol is formed exclusively[43] in the reaction of benzaldehyde with the lithium enolate of t-butyl ethyl ketone, while in the case of the lithium enolate of ethyl mesityl ketone, 92% of the *threo*-aldol and only 8% of the *erythro*-aldol is formed. The stereoselectivity of the first reaction does not change when HMP is introduced into the reaction medium, which the authors believe to be caused[43] by the formation of a six-membered transition state in which Li^+ is strongly bound to two oxygen atoms:



On the other hand, the use of the tetra-alkylammonium enolate of t-butyl ethyl ketone in this reaction is accompanied by the exclusive formation of the *threo*-aldol, which thus leads to the complete reversal of the stereoselectivity compared with the reaction in the presence of Li^+. In this case there is no possibility of the coordination of the cation to the oxygen atoms and they are thus both arranged in the transition state in such a way that the electrostatic repulsion between them is minimal:[43]



The conditions of the Horner–Emmons reaction also have an appreciable influence on the composition of the products formed (Table 3):[44,45]



(14)

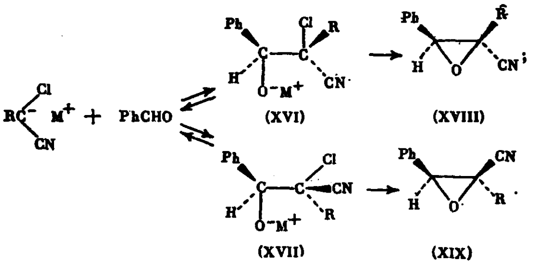
Table 3. The composition of the products of reaction (14) in THF as a function of temperature and the size of the alkali metal cation.[44,45]

R	t, °C	Li⁺			Na⁺			K⁺		
		$(XIV)^a/(XV)$	$(XIV)^b/(XV)$	k_{-1}/k_1'	$(XIV)^a/(XV)$	$(XIV)^b/(XV)$	$(XIV)^c/(XV)$	$(XIV)^a/(XV)$	$(XIV)^b/(XV)$	k_{-1}/k_1'
Ph	−78	0.43	3.0	0.6	1.0	—	—	9.0	19	1
	20	0.33	0.43	13	0.66^d	4^e	0.03^f	1.5	—	—
	65	0.25	0.33	15	0.54	—	—	1.0	1.5	4
p-$CH_3OC_6H_4$	−78	0.25	1.5	1	0.43	—	—	2.33	9.0	0.5
	20	0.25	—	—	0.43	—	—	1.5	—	—
	65	0.33	0.33	>40	0.64	—	—	1.02	1.02	>40

Remarks. Procedure followed in carrying out the reactions: [a]by mixing the initial reactants; [b]by starting with compound (XII): [c]by starting with compound (XIII); the ratios (XIV)/(XV) in HMP are [d]0.25, [e]16, and [f]0.02.

The aldol condensation stage in reaction (14) is reversible. For this reason, the product (XV) is formed, as shown by the authors,[44,45] not only on mixing the initial reactants but also when compound (XII), obtained by an independent procedure, is maintained in solution in THF or HMP (Table 3). Similarly, compound (XIV) can be obtained when compound (XIII) is kept in HMP or THF. The possibility of carrying out the experiment with compound (XII) or (XIII) obtained beforehand determines to a large extent the ratio of compounds (XIV) and (XV) formed ultimately. At low temperatures the decomposition of the alkoxides (XII) and (XIII) into the initial reactants (k_{-1}, k_{-2}) is relatively slow and this is why compounds (XIV) and (XV) are formed preferentially from compounds (XII) and (XIII) respectively. At high temperatures, the equilibration process is rapid (k_{-1}/k_1' and k_{-2}/k_2' are large), so that the product ratio (XIV)/(XV) is almost independent of the way in which the experiment is carried out (Table 3).

The epoxynitriles (XVIII) and (XIX) are formed in reaction (15) also via the reversible stage involving nucleophilic addition to the carbonyl group:[46]

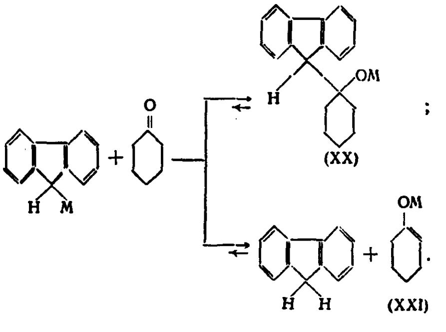


(15)

When a 1:1 mixture of compounds (XVII) and (XVI) synthesised beforehand is kept in HMP (Na⁺), benzene (Na⁺ and Li⁺), and THF (K⁺ and Li⁺), the ratio of the products formed (XIX)/(XVIII) is respectively >98, 0.43, 4.4, and 9. If PhCHO and RC(CN)(Cl)M are mixed, then compound (XIX) predominates among the products of reaction (15): the ratio (XIX)/(XVIII) exceeds 98 for Li⁺ in THF and benzene, while for Na⁺ in HMP and THF and for K⁺ in THF the ratio (XIX)/(XVIII) is respectively >98, 4, and 4. The only exception is the reaction of the sodium salt in benzene for which (XIX)/(XVII) is 0.18.

III. REACTIONS OF ORGANIC DERIVATIVES OF ALKALI METALS WITH KETONES

The reactions of organic derivatives of alkali and alkaline earth metals with ketones having a fairly mobile proton can lead to the formation[2] of both an adduct and an enolisation product. In this case detailed studies of the effects of the medium and the cation have been performed[12,47,48] in relation to the reactions of alkali metal salts of fluorene with cyclohexanone via the mechanism



(16)

In all the solvents investigated, the yield of the adduct (XX) increases with decrease of the radius of the cation. In DME: Bu_4N^+, Cs⁺, K⁺ (0%) < Na⁺ (5%) < Li⁺ (13%); in ether: Cs⁺ (0%) < Na⁺ (27%) < Li⁺ (72%); in benzene: Cs⁺ (7%) < Na⁺ (33%) < Li⁺ (80%). On the other hand, the yield of compound (XX) in the reactions of all the alkali metal salts investigated increases on passing to non-polar non-solvating media. HMP (0%) < DME (15%) < ether (72%) < benzene (80%) for Li⁺, DME (5%) < ether (27%) < benzene (33%) for Na⁺, and HMP, DME (0%) ≈ ether (0%) < benzene (7%) for Cs⁺. In HME the equilibrium is fully displaced towards the initial reactants. On the other hand, in the reaction of 2-lithio-1,3-dithiane and 2-lithio-2-phenyl-1,3-dithiane with 4-*t*-butylcyclohexanone, HMP has a somewhat different influence. In this solvent, the adduct (I) is not formed[11] and enolisation takes place instead:

(17)

Thus the enolate is not formed in the reaction of fluorenyllithium with cyclohexanone in HMP,[47,48] but enolisation does occur in reaction (17) in the same solvent. This apparent contradiction can be readily accounted for if one turns to the results obtained[49] in a study of the basicity of alkali metal enolates of cyclohexanone (and also cyclopentanone, ethyl methyl ketone, and acetophenone). In the presence of cryptands, the lithium, sodium, and potassium enolates of cyclohexanone ($pK_a = 18$) [50] metallate quantitatively triphenylmethane ($pK_a = 31.5$) [51] and diphenylmethane ($pK_a = 33$) [51] in THF, which is itself surprising merely on the basis of a comparison of the above pK_a for these compounds. The sharp increase of the basicity of the alkali metal enolates of cyclohexanone is caused by the fact that, in the presence of cryptands, they probably exist in the form of solvate-separated ion pairs (or even partly in the form of free enolate ions).

Thus it has been found that HMP, whose action is analogous to that of cryptands, increases the basicity of alkali metal enolates of cyclohexanone so much that they metallate quantitatively fluorene ($pK_a = 23$), fully displacing to the left the transprotonation equilibrium in scheme (16) (as well as the addition equilibrium). On the other hand, the pK_a for 1,3-dithianes are probably sufficiently high for enolisation in accordance with scheme (17). It is significant that enolisation does not occur in the reactions of alkali metal salts of fluorene with cyclohexanone also in DME[47,48] when the cations are K^+, Cs^+, or $(C_4H_9)_4N^+$. This shows that the basicity of the enolates increases also with increase of the radius of the cation.

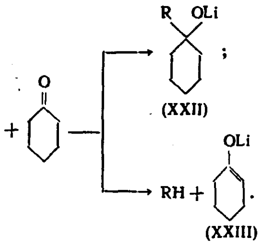
The yield of the adduct in the reactions of alkali metal salts of fluorene with cyclohexanone depends on the presence[47,48] of added inorganic lithium salts in the reaction system. Thus the yield of compound (XX) in the reaction of fluorenyllithium increases from 13 to 30% as a result of the introduction of $LiClO_4$ into DME. The yield of the product of the addition of propynyl-lithium to cyclohexanone or cyclopentanone increases analogously[52] to 80–90% under the influence of LiBr (in the absence of the salt, the yield varies in the range 40 to 60%).

LiBr exerts an unusual influence on the reaction of fluorenylpotassium and fluorenylcaesium with cyclohexanone in DME. The addition of this salt leads[48] to the instantaneous consumption of the carbanion but only the alkali metal enolate is formed in this process. The observed effect is probably determined in the first place by the occurrence of the exchange reaction[53,54]

$$RM + LiX \rightleftarrows RLi + MX. \qquad (18)$$

However, the absence of an adduct[48] suggests that LiBr activates not only the carbonyl group but also the α-CH bond of the ketone. On the other hand, the activated ketone enters preferentially into the enolisation reaction in this instance. This result agrees in general with the observed behaviour in the reactions of alkali metal salts of fluorene with cyclohexanone in DME: the yield of alkoxides in these reactions is always lower than that of the enolates.[47,48]

The interaction of alkyl organolithium compounds with cyclohexanone in ether or DME takes place[30,31] in accordance with scheme (19) which is analogous to scheme (16):



(19)

However, by virtue of the low CH acidity of RH ($pK_a > 40$) [55] and the high basicity of RLi, in this case both reaction pathways are apparently almost irreversible. The composition of the product is in this instance strongly influenced[30,31] by ionic and solvating additives. When cyclohexanone interacts with n-butyl-lithium, t-butyl-lithium, and ethynyl-lithium, the adducts (XXII) are formed rapidly in the first two instances and slowly in the last with a quantitative# yield.[30,31] In the presence of cryptand 211 in these reaction systems, enolisation takes place exclusively but, if apart from the cryptand, an equimolecular amount of LiBr is also introduced into the mixture, then compound (XXII) again becomes the only reaction product. In order to explain the results the authors used the concept of the activation of the carbonyl group by the formation of its complex with Li^+. The cryptand, which effectively binds Li^+, does not allow the cation to be coordinated to oxygen and LiBr plays the role of a donor of Li^+ ions capable of coordination.

A strong influence of the cryptand has been observed[30] also in a study of the reactions of n-butyl-lithium with the ethyl esters of benzoic, αα-dimethylpropionic, and α-methylpropionic acids. In ethereal solvents the alkyl-lithium compound adds to the carbonyl group while the addition of cryptand 211 fully inhibits the reaction and the initial esters can be isolated quantitatively from the reaction medium. Furthermore, it has been found[30] that cryptand 211 influences analogously also the reactions of alkyl-lithium compounds with carboxylic acids. In the presence of a large excess of n-butyl-lithium, it adds to the carbonyl group of benzoic, αα-dimethylpropionic, and α-methylpropionic acids (more precisely their lithium salts, which should be formed in the first stage). On the other hand, the cryptand precludes this addition owing to the absence, according to the authors,[30] of the coordination of Li^+ to the carbonyl oxygen atom.

The yield of the adduct can be increased[2] and that of the enolate decreased by lowering the reaction temperature. Whereas the addition of n-butyl-lithium to acetone, cyclohexanone, cyclopentanone, norcamphor, and acetophenone in ether at 0 °C proceeds respectively to the extent of 67, 82, 63, 76, and 73%, at −78 °C the respective yields are 80, 89, 75, 81, and 81%. Furthermore, it has been found that, in the reaction of t-butyl-lithium with various ketones, the yield of the adduct is lower (amounting to 50–70% depending on the structure of the ketone) than in the reaction with n-butyl-lithium and in the case of cyclohexanone it amounts to 53% (and not 100% as indicated by the studies of Perraud

---

#According to Van Rijn et al.[52], the yield of the products of the addition of n-butyl-lithium to cyclohexanone usually does not exceed 80%.

and Handel[30,31]). The relative increase of the yield of the adduct with increasing temperature can probably be caused by two factors—the lower activation energy for the addition of the alkyl-lithium compound to the carbonyl group compared with the proton transfer reaction and/or the higher thermodynamic stability of the alkoxide compared with the enolate. It is noteworthy that the fraction of the adduct increases[47] with increase of temperature also in the reaction of fluorenyl-lithium with cyclohexanone in DME.

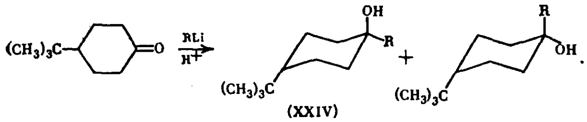
Analogously to the observations made[47,48] in the reactions of alkali metal salts of fluorene, an increase in the size of the cation lowers[2] the effectiveness of the addition reaction: t-butyl-lithium makes it possible to obtain 53% of 1-t-butyl-1-cyclohexanol, while t-butylsodium produces only 7% of this compound. According to O'Sullivan et al.[56], the yield of the adduct increases not only with decrease of the radius of the alkali metal cation but also on passing from organolithium, organosodium, and organopotassium derivatives to organomagnesium derivatives. In the reactions of a series of PhM with acetophenone, the ratio of the yield of the adduct to that of the enolisation product is 1:10 (hexane) for M = K, 1:1.4 (heptane) for M = Na, and 23:1 (ether) for M = Li. Enolisation does not occur at all when M = MgCl.[56]

In the synthesis of graft copolymers [in the reactions of polystyryl-lithium and polystyrylpotassium with poly(methyl methacrylate) and the copolymers of styrene with methyl vinyl ketone, acroleine, or methyl methacrylate], the degree of grafting (i.e. the fraction of the adduct) is always higher[57] when the reaction is carried out in non-polar media and not in THF and when the carbanion with the lithium counterion enters into the reaction with the carbonyl functional group. In the reaction of a carbanion of the benzyl type (the polystyryl anion) with 3-methyl-2-pentanone,[57] the yield of the adduct increases with decrease of the radius of the alkali metal cation (i.e. with increase of its affinity for oxygen) and on passing from THF to cyclohexane. Thus K^+ (20%) < Na^+ (50%) < Li^+ (73%) in THF and K^+ (48%) < Na^+ (59%) < Li^+ (79%) in cyclohexane. In this case too, the authors[57] believe that the addition is promoted by the coördination of Li^+ to the carbonyl group.

The addition of dimethylmagnesium to benzophenone has been investigated[58] in ether in the presence of various solvating additives. The authors established that dimethylmagnesium enters into the reaction in the form of 1:1 and 1:2 complexes with bidentate and monodentate solvating compounds respectively, the addition taking place without the elimination of ligands. Depending on the nature of the ligand, the reaction is accelerated (dimethyl ether, triethylamine, DME, HMP, β-methoxyethyldimethylamine) or retarded (THF, dioxan, tetramethylethylenediamine).

In the reactions of organomagnesium compounds with ketones, the composition of the products can be appreciably altered[59] by changing the nature of the medium, as happens in the case of organic derivatives of alkali metals. In the reaction of n-propylmagnesium bromide with diisopropyl ketone in ether, the ratio of the adduct and the reduction product is 37:63, increasing appreciably in benzene (to 64:36). An analogous situation has been observed in the reaction of n-propylmagnesium bromide with cyclohexyl isopropyl ketone (48:52 in ether and 86:14 in benzene) and with isopropyl propyl ketone (5:35 in ether and 13:61 in benzene). In the reaction with isopropyl propyl ketone, an appreciable amount of the enolisation product is also formed, its yield falling on passing from ether (60%) to benzene (26%).

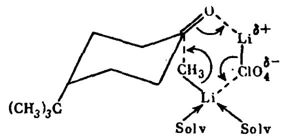
By varying the conditions in the reactions of organolithium compounds with 4-t-butylcyclohexanone [reaction (20)], it has been possible to alter,[60–62] albeit not within very wide limits, the ratio of the axial isomers (XXIV) and the equatorial isomers of the alcohols formed:



(XXIV)

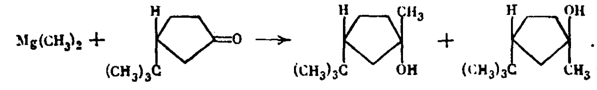
.(20)

In the reaction of methyl-lithium[61] in THF at −78 °C, the fraction of compound (XXIV) is 65–69%. The introduction of LiBr, LiI, $LiClO_4$, or $LiCu(CH_3)_2$ into the solution does not influence the yield of compound (XXIV). When the reaction is carried out in ether at −78 °C, the above additives make it possible to increase the fraction of compound (XXIV) to 87–92%.[61] The addition of $LiClO_4$ also increases somewhat[62] the yield of compound (XXIV) (from 58 to 69%) in the reaction of phenyl-lithium carried out under the same conditions. On the other hand, the increase of temperature from −78° to +5 °C lowers[60] the fraction of compound (XXIV)—for example, in the reaction of 4-t-butylcyclohexanone with n-butyl-lithium and s-butyl-lithium. The authors[60,61] believe that the influence of added inorganic lithium salts on temperature is manifested only when the reaction is performed in ether, because its complex forming effect does not greatly exceed the ability of the ketone to form a complex with Li^+. For this reason, in the reactions of a wide range of cyclic ketones with methyl-lithium in ether, the addition of lithium perchlorate should promote[62] the formation of a transition state from which only the axial isomer can be obtained.



It is noteworthy that it is very difficult to treat systematically the influence of the solvent on the stereoselectivity of the reactions of organolithium compounds with cyclic ketones, because each reaction system as a rule reacts in a fairly individual manner. In the reaction of ethynyl-lithium with 2-methylcyclohexanone,[63] the fraction of the axial alcohol is appreciably higher when the reaction is carried out in a non-polar solvent (benzene, 67%) than in THF (42%). The axial isomer is formed analogously in the reaction of ethylnyl-sodium[63] with a higher yield in benzene (53%) than in the polar THF–NH_3 mixture (41%). On the other hand, both in ether and in THF the product (XXIV) is formed[60] in virtually the same yield—69 and 65% respectively. In the reaction with 7-norbornene, n-butyl-lithium affords[64] 50% of the *endo*-isomer both in ether and in n-hexane. This is also true of the reaction of phenyl-lithium;[64] the yield of the *endo*-isomer is 72% in both solvents.

The solvent has an even weaker influence on the stereoselectivity of the reactions of organomagnesium compounds. In the reaction of dimethylmagnesium with 3-t-butylcyclopentanone, i.e.



(XXV)

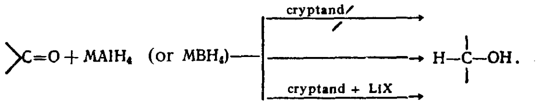
.(21)

the yield of the *cis*-isomer (XXV) is the same[65] in ether (53%), THF (52%), and anisole (54%). The yield of compound (XXV) is independent of the solvent (THF, anisole, ether); when methylmagnesium bromide reacts[65] with 3-t-butylcyclopentanone, the yield is again 53–54%.

The change of the cation in the reactions of organic derivatives of alkali metals with cyclic ketones has as a rule only a weak influence on the stereoselectivity, especially as the process takes place in a solvent which effectively solvates the alkali metal cations. The reaction of ethynyl-lithium and ethynylpotassium with 3-methylcyclohexanone in the THF–NH_3 mixture leads mainly to the equatorial isomer:[63] 82% (Li^+) and 80% (K^+). In the same medium but in the reaction of 2-methylcyclohexanone with $HC{\equiv}CM$ the yield of the equatorial isomer falls but a dependence on the cation cannot be observed:[63] 45% (Li^+), 41% (Na^+), and 44% (K^+). Only in benzene is the yield of the axial isomer somewhat higher[63] in the presence of Li^+ (67%) than in the presence of Na^+ (53%).

IV. THE HYDRIDE REDUCTION REACTIONS OF CARBONYL COMPOUNDS

Numerous studies[32–35,66–69] of the effects of the medium and the cation on the reduction of carbonyl compounds by alkali metal tetrahydroaluminates and tetrahydroborates have been published in recent years. The methodology of the majority of these investigations and their results are similar. They can be represented in the following form:

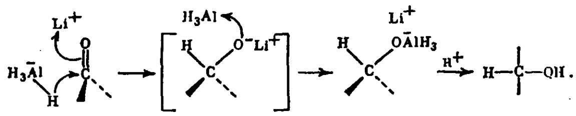


(22)

We shall examine initially the results obtained in the study of the reactions of alkali metal tetrahydroaluminates. In ethereal solvents (DME, THF, ether, diglyme), $MAlH_4$ (where M = Na or Li) reduces cyclohexanone,[32,33] 2-methylcyclohexanone,[66] 4-t-butylcyclohexanone,[66] cyclopentanone,[32] *N*-t-butylacetyl-2-aziridine,[35] α-chloropropiophenone,[67] benzaldehyde,[21] acetophenone,[21] p-methoxyacetophenone,[21] and compounds[32] having the general formula $C_2H_5C(O)X$, where X = H, OH, or C_2H_5, to the corresponding hydroxy-derivatives. In the present of cryptand 211 for M = Li and cryptand 221 for M = Na, hydroxycompounds are not formed[32,33,35,66,67] or, much more rarely,[21] the rate of their formation is sharply reduced. The rate of reduction is also lowered by the addition of crown ethers[68] and hexamethyltriethylenetetra-amine[34] but their effect is much weaker than that of cryptands.

Finally, if an inorganic lithium salt (LiBr, LiI, $LiClO_4$) [32,33,35] or sodium salt ($NaClO_4$) [33,35] is introduced into the reaction medium in addition to the cryptand, the effect of the latter is fully removed and quantitative reduction of the carbonyl compound is observed.

In order to account for the results, the idea of the activation of the carbonyl group as a result of the formation of a complex of the latter with an alkali metal cation has been used, as for the reactions involving organometallic compounds discussed above. For example, the reaction involving reduction by lithium tetrahydroaluminate has been described in this way:[33]



(23)

The reaction does not occur in the presence of cryptands, because the possibility of the formation of a complex between the alkali metal cation and the carbonyl group is then eliminated. On the other hand, if the reaction is carried out in the presence of equimolar amounts of lithium tetrahydroaluminate, the cryptand, and an inorganic lithium salt, then one equivalent of Li^+ ions not involving the complex remains for the activation of the carbonyl group.

It is surprising that no attention has been paid in any of the studies quoted to what may occur in the reaction mixture in the presence of the cryptand. After all the latter not only eliminates the possibility of the formation of a complex between the cation and the carbonyl group but in its presence there should be an appreciable increase of both the nucleophilicity and the basicity of the negatively charged tetrahydroaluminate fragment, which has been demonstrated by investigations of the reactions of organolithium compounds.[30,31] It is extremely likely that in the presence of cryptands $MAlH_4$ nevertheless reacts with ketones but via the transprotonation and not the addition mechanism, i.e. by enolising suitable carbonyl compounds. This has been confirmed indirectly by the finding that cyclohexanone is converted into the enolate under the influence of sodium, potassium, and lithium hydrides when cryptands are present in the reaction medium.[69] Yet another interesting question arises: is it possible to account for the influence of cryptands by the reversibility of the addition of the hydride to the carbonyl group? Although there is no experimental evidence in support of this claim, nevertheless this hypothesis is entirely reasonable.

The behaviour observed for the reactions of tetrahydroaluminates, discussed above, holds in general also for the reactions of alkali metal tetrahydroborates. Cryptands suppress the reduction of *N*-t-butylacetyl-2-aziridine,[35] cyclohexanone[33] and α-chloropropiophenone.[67] However, when $LiClO_4$ [33] or $NaClO_4$ [33,35] is introduced into the system together with the cryptand, the effect of the latter is removed. In contrast to $MAlH_4$, the reactions of MBH_4 can be carried out in hydroxylated solvents (water, alcohols) where the carbonyl group can be activated by the formation of hydrogen bonds with solvent molecules.[35,66,67,70] In methanol, *N*-t-butylacetyl-2-aziridine [35] is reduced rapidly by $NaBH_4$ regardless of whether the cryptand 221, $NaClO_4$, or $LiClO_4$ are present in the reaction medium. The addition of water to an ethereal solvent makes it possible to obtain the product of the addition of *N*-t-butylacetyl-2-aziridine,[35] α-chloropropiophenone,[67] 2-methylcyclohexanone,[66] and 4-t-butylcyclohexanone[66] even if the solvent contains the cryptand.

Lithium tetrahydroborate reacts faster with carbonyl componds than sodium tetrahydroborate, which has been observed in most varied solvents: pyridine,[71] isopropyl alcohol,[54,70] and water.[70] Thus $LiBH_4$ reduces ethyl benzoate in isopropyl alcohol, while $NaBH_4$ does not.[54] The rate constant for the reaction[70] of acetone with $LiBH_4$ in the same solvent (5×10^{-3} litre mol^{-1} s^{-1}) is almost three times as high as that for the reaction with $NaBH_4$ (1.5×10^{-3} litre mol^{-1} s^{-1}). However, in all cases this result is attributed to the more effective coordination of Li^+ (compared with Na^+) to the carbonyl group, which is sometimes believed[71] to be due to the higher nucleophilicity of the lithium ion pair (although without any special supporting evidence).

The importance of the activation of the carbonyl group is also indicated by data obtained in the study of the reduction of acetone[70] and esters[54] by tetrahydroborates. The reaction with $NaBH_4$ takes place only in water and alcohols and its rate increases with increase of the electron-donating capacity of the solvent: isopropyl alcohol < H_2O, ethanol. In acetonitrile, pyridine, DMF, and diglyme, $NaBH_4$ hardly reacts with acetone. Esters are not reduced by $NaBH_4$ [54] even in isopropyl alcohol. The addition of LiI and LiCl accelerates[70] the reduction of acetone by both $NaBH_4$ and

$LiBH_4$. In the presence of LiBr, ethyl acetate, ethyl stearate, ethyl benzoate, ethyl cinnamate, and ethyl *p*-chlorobenzoate begin to react with $NaBH_4$.[54] Here one must note that, whereas the acceleration of the reaction involving $LiBH_4$ can be accounted for solely by electrophilic catalysis, in the case of $NaBH_4$ inorganic lithium salts give rise to the possibility of cation exchange as well[54] [reaction (24)], so that subsequently the process can proceed with participation of $LiBH_4$:

$$NaBH_4 + LiX \rightleftarrows LiBH_4 + NaX. \qquad (24)$$

The reduction of esters by $NaBH_4$ can also be catalysed by $MgCl_2$ and $MgBr_2$.[54]

Contradictory data have been obtained concerning the catalytic role of amines. When acetone is reduced[70] by $LiBH_4$ and $NaBH_4$ in alcohols and diglyme, it is assumed that the latter do not affect the rate of reaction. On the other hand, under identical conditions (acetone in diglyme + $NaBH_4$) the acceleration of the reaction in the presence of the same triethylamine derivative has been observed.[54]

Among the communications[34,68,72] devoted to the investigation of the kinetics of the reduction of ketones by lithium and sodium tetrahydroaluminates, much attention has been devoted in the paper of Ashby et al.[72] to the investigation of the state of the tetrahydroaluminates in solution in THF. Measurements were made of the dissociation constants of $MAlH_4$ over a wide temperature range and the thermodynamic parameters of the dissociation reaction have been calculated. At 25 °C, $K_D = 6.9 \times 10^{-7}$, 2.1×10^{-7}, and 1.8×10^{-6} mol litre^{-1} for M = Li, Na, and Bu_4N respectively. The temperature dependence of the enthalpy and entropy of dissociation led to the conclusion[72] that the lithium ion pairs $MAlH_4$ are of the solvate-separated type, while the sodium ion pairs are mainly of the contact type.

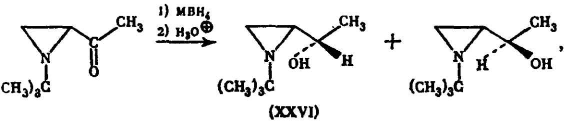
Ashby and Boone[34] used a second-order equation to describe the reactions involving the reduction of mesityl phenyl ketone by $LiAlH_4$ and $NaAlH_4$ in THF. However, this equation is inapplicable[20] if it is assumed[34] that the process takes place with participation of only the free ions or the free ions and the solvate-separated ion pairs.

At 25 °C the observed rate constant for the reaction of mesityl phenyl ketone with $LiAlH_4$ (0.595 litre mol^{-1} s^{-1}) is ten times greater than the rate constant for the reaction with $NaAlH_4$ (0.0587 litre mol^{-1} s^{-1}), which is caused, according to the authors,[34] by the effective activation of the carbonyl group by the lithium cation and not by the difference between the states of the above tetrahydroaluminates in solution. The activation parameters for the reaction of $LiAlH_4$ differ appreciably from the analogous parameters in the case of $NaAlH_4$: $\Delta H^{\neq} = 9.9$ and 17.5 kcal mol^{-1} respectively and $\Delta S^{\neq} = -26.2$ and -5.4 e.u. respectively, which is attributed[34] to the more intense interaction of the ketone with Li^+ in the activated complex.

Under the same conditions as for mesityl phenyl ketone, camphor was reduced[57] by $LiAlH_4$ and $NaAlH_4$. The reaction involving Li^+ is also much faster than that with Na^+, but its kinetic orders with respect to $LiAlH_4$ (1.0) and $NaAlH_4$ (0.73) are different. The authors explain this result by the dimerisation of $NaAlH_4$ (in their view lithium tetrahydroaluminate exists in the monomeric form in THF). However, one should note that the association of ion pairs usually intensifies[20] with decrease of the radius of the alkali metal cation. On the other hand, when the data of Ashby and Boone[34] are used, it is easy to explain the observed kinetic orders with respect to the tetrahydroaluminate. $LiAlH_4$ reacts in the form of free ions and solvate-separated ion pairs (these species usually have[19,20] comparable reactivities) and the order with respect to the tetrahydroaluminate should therefore be close to unity. $NaAlH_4$ is partly dissociated in THF [34] and reacts only in the form of H_4Al^-, so that the order with respect to this reactant should be fractional.[20]

In a study of the reduction of camphor by $LiAlH_4$, Wiegers and Smith[68] made a fairly strange observation: the reaction is retarded by both LiBr and crown polyether. In order to explain this finding, one may suppose that in this instance LiBr not only plays the role of the electrophilic catalyst but also suppresses the dissociation of $LiAlH_4$ via the common ion effect[20] and the latter effect is more important.

Data concerning the influence of the nature of the cation and the solvent on the stereochemistry of the reduction of carbonyl compounds have been obtained in a number of studies. The reaction of tetrahydroaluminates and tetrahydroborates with *N*-t-butylacetyl-2-aziridine, i.e.



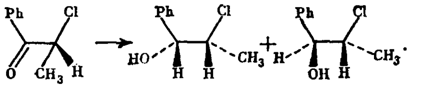
, (25)

(XXVI)

and the reaction of *N*-t-butyl-2-formylaziridine with methyllithium [cf.Eqn.(11)] result in the formation of two products.[35] In the absence of additives in diglyme, the product (XXVI) predominates (>98 and 92% in the reactions with $LiAlH_4$ and $LiBH_4$ and 80 and 70% in the reactions with $NaAlH_4$ and $NaBH_4$), which is due to the formation of a complex by the alkali metal cation with two heteroatoms of the substrate (see above). The yield of compound (XXVI) is greater in the case of Li^+ than Na^+, which is a consequence of the more effective complex formation with the cation having a smaller radius. In the presence of added cryptands and metal salts in diglyme, the stereochemical result is determined by the cation of the added salt, which indicates a high selectivity in the complex formation reaction of the cryptand. In the reaction involving $LiAlH_4$, together with cryptand 221 + NaI, the yield of compound (XXVI) is the same as in the reaction with $NaAlH_4$ in the absence of additives, while in the reaction with $NaBH_4$ + cryptand 221 + $LiClO_4$ the yield is the same as in the reaction with $LiBH_4$ in the absence of additives.

Since in the reduction of *N*-t-butylacetyl-2-aziridine by $NaBH_4$ in methanol the carbonyl group is activated not only by the alkali metal cation but also (no less effectively) by solvent molecules, the stereoselectivity of the reaction is low: the fraction of the product (XXVI) is about 40%.[35] Only in the presence of large amounts of $LiClO_4$ is it possible to increase the yield of compound (XXVI) to 90%.

The influence of the cation and the solvent on the stereoselectivity of the reduction of α-chloropropiophenone is not very pronounced:[67]



(XXVII)

The yield of compound (XXVII) increases with increase of the solvating capacity of the solvent (on passing from ether to DME) and in DME it diminishes only slightly with increase of the radius of the cation. In almost all cases the yield of compound (XXVII) under identical conditions is slightly higher in the reaction with $MAlH_4$ than in the reaction with MBH_4. The yield of compound (XXVII) is 72% ($LiAlH_4$) and 68% ($LiBH_4$) in ether, and 94% ($LiAlH_4$) and 91% ($LiBH_4$) in the presence of Li^+ and 90% ($NaAlH_4$) and 88% ($NaBH_4$) in the presence of Na^+ in DME. The stereoselectivity is almost the same in DME and methanol: in the reaction with $NaBH_4$, the yields of compound (XXVII) are respectively 88 and 85%. In both DME and methanol, the composition of the products is independent of the addition of inorganic solvents (LiBr, NaBr).

The reaction conditions, namely the variation of the solvent (ether, DME, methanol) and the cation (Li^+, Na^+) and the addition of LiBr, has the same weak influence on the stereochemistry of the reduction^{66} of 4-t-butylcyclohexanone and 2-methylcyclohexanone by alkali metal tetrahydroaluminates and tetrahydroborates. When the former ketone is reduced, the yield of the *cis*-isomer varies in the range 11 to 15%, while in the latter case it varies in the range 22–39%.

The stereochemistry of the reduction of carbonyl compounds has been examined in greater detail in Wigfield's review.^{73}

V. CONCLUSION

Analysis of the available literature data on the reactions of organic derivatives of alkali metals and alkali metal tetrahydroborates and tetrahydroaluminates with carbonyl compounds permits the perfectly definite conclusion that the rates of these reactions and the compositions of the products formed can be varied within wide limits by altering the nature of the medium and the metal atom. In certain cases the observed effects permit a quantitative treatment, but usually they can be understood only at a qualitative level, normally by resorting to the idea that the cation is coordinated to the carbonyl oxygen and other heteroatoms. Although the mechanisms of many of the processes investigated have not yet been elucidated in detail owing to the lack of sufficient quantitative data, nevertheless one can already speak of the existence of definite regularities, which may serve as a basis for the successful planning of preparative experiments. Thus it is quite evident that the stereoselectivity can be increased by lowering the polarity of the solvent and by decreasing the size of the alkali metal cation (sometimes by replacing organic derivatives of alkali metals by organomagnesium compounds). The thermodynamic stability of the adduct can be increased by the same procedures and hence its yield can be increased. On the other hand, in order to increase the rate of the nucleophilic addition of the organic derivative of the alkali metal, one must intensify the solvation of the cation, naturally without forgetting at the same time the important role of the cation in the activation of the carbonyl group.

One must assume that further studies on the reactions of organic derivatives of alkali metals with carbonyl compounds, carried out at an effective quantitative level, will permit the final formulation of the idea concerning the role of the various factors in these reactions and hence will make possible certain reliable predictions about the outcome of the process in each specific instance.

The Cope Aza-rearrangement in Organic Synthesis

N.M.Przheval'skii and I.I.Grandberg

The latest advances in the application of the Cope aza-rearrangement in organic synthesis are examined and the results of studies on the mechanism of the reaction and of its use in syntheses are surveyed.
The bibliography includes 147 references.

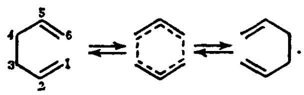
I. INTRODUCTION

Pericyclic reactions, including sigmatropic rearrangements, have attracted much attention by chemists in recent years.[1-3] In the first place this is because the [3, 3]sigmatropic shift, which embraces also the Cope rearrangement,[4] gives rise to a predictable regiostereoselectivity in the formation of new bonds.[5,6] No less important is also the fact that new approaches to the synthesis of a wide variety of heterocyclic and acyclic structures have been demonstrated and interesting stereochemical features of the rearrangement have been observed with the aid of this reaction.

In the present review we shall consider studies devoted to the theoretical and synthetic aspects of the Cope aza-rearrangement. Mainly studies carried out in 1978–1984, published after the review of Heimgartner et al.[7] which quotes the literature up to 1977 inclusive, are discussed. In certain instances earlier communications are invoked in order to preserve the integrity of the exposition.

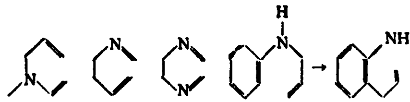
The thermal rearrangement of hexa-1,5-dienes (I), called the Cope rearrangement,[4] belongs to the class of [3, 3]sigmatropic processes[8] which proceed via the six-membered transition state (II):



(I) (II) (III)

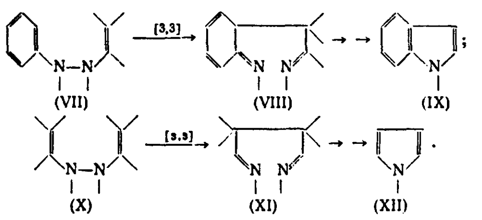
The replacement of one or several carbon atoms in the diene (I) by nitrogen leads to the corresponding aza-hexadiene systems (IVa–c), for the rearrangement of which the term the Cope aza-rearrangement has been proposed.[9]

When 3-azahexa-1,5-diene (V), in which one double bond is incorporated in an aromatic nucleus, undergoes the Cope rearrangement, then reactions of this type are frequently referred to as the Claisen (V) → (VI) amino-rearrangement.[10]



(IVa) (IVб) (IVв) (V) (VI)

On passing to 3,4-diazahexa-1,5-diene, systems of the type of the enehydrazine (VII) or dienehydrazine (X) are produced, whose rearrangement is a stage in the formation of the carbon—carbon bond in the Fischer indole synthesis[11,12] and the Piloty pyrrole synthesis:[13]



(VII) (VIII) (IX) (X) (XI) (XII)

The transformations (V) → (VI) and (VII) → (IX) can be regarded as the Cope 3-aza- and 3,4-diaza-rearrangements. A general classification of sigmatropic "Cope hetero-rearrangements" has been published.[14]

Apart from the reactions indicated, those involving systems of type (IV), containing heteroatoms (O, S) other than the nitrogen atom, i.e. the Cope oxaza- and thiaza-rearrangements, have been discussed.

The general postulates of the theory of sigmatropic rearrangements developed by Woodward and Hoffmann,[8] mainly for thermal non-catalytic reactions of hydrocarbons, were subsequently extended to both thermal and catalytic reactions of aliphatic and aromatic heterosystems.[15]

The following criteria were mainly used to assign these reactions to the concerted [3, 3]shift type: the first order of the reaction; the large negative activation entropies; comparatively small (by a factor of 20–30) changes in the rate after the introduction of electron-donating or electron-accepting substituents; the inversion of allyl groups; the retention of optical activity in the products when the initial molecule was optically active. The mechanism of the Cope 3-oxa-rearrangement of a series of allyl vinyl[17] and allyl aryl ethers[17] (the aliphatic and aromatic Claisen rearrangements), their thio-analogues,[18] (the Claisen thia-rearrangement), and the allyl esters of carboxylic acids,[19] for example, has been established with the aid of these criteria.

Numerous experimental data obtained in the course of these investigations demonstrated that the Cope rearrangements and the Cope hetero-rearrangements are much faster for charged or highly polarised systems.[1-3,7] Reactions of this type have been called charge-induced[20,21] and charge-accelerated[22] [3, 3]sigmatropic rearrangements.

The charge-induced reactions are in fact of greatest interest for the Cope aza-rearrangements, because they facilitate significantly the conditions under which they can be carried out and increase the yield of products.

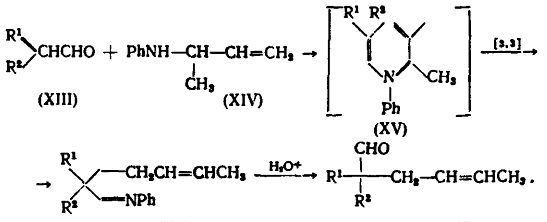
At the same time, as stated in a review,[7] the available information about the mechanism of these reactions is limited. Definite progress has been achieved in this respect only recently (see Sections II–VI).

II. THE COPE 3-AZA-REARRANGEMENT

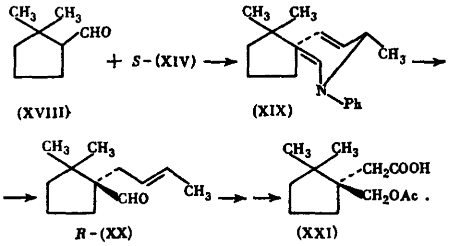
1. The Aliphatic Cope 3-Aza-rearrangement

One of the first examples of the aliphatic Cope 3-aza-rearrangement was described in a study[10] where it was shown that it proceeds via a transition state in the chair conformation. Since the thermal Cope 3-aza-rearrangement usually requires high temperatures, attempts have been made to achieve the reaction under mild conditions using Lewis acids,[23,24] sulphuric acid,[25] and $TiCl_4$ [26] as catalysts.

Thus the reaction of the aldehydes (XIII) with N-(1'methylallyl)-aniline (XIV) (benzene, $TiCl_4$) leads to the formation of the intermediate (XV) which rearranges to the imine (XVI), whose hydrolysis affords the aldehyde (XVII):



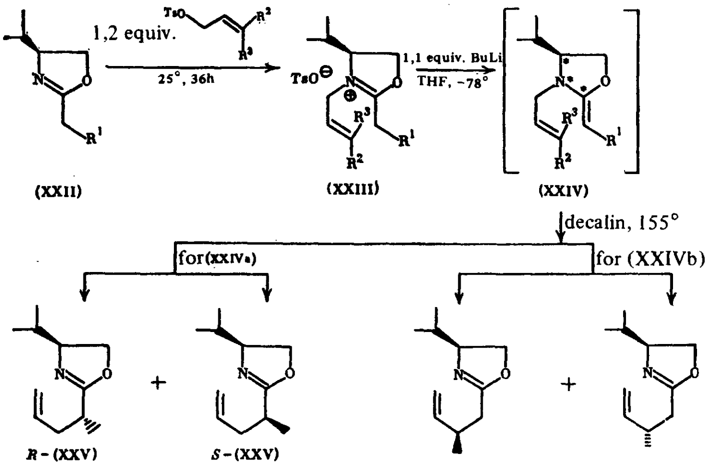
If the optically active amine S-(XIV) with $[\alpha]_D^{27} = 1.47°$ is introduced into the reaction with 2,2-dimethylcyclopentanaldehyde (XVIII), then the *trans*-aldehyde (XX) with $[\alpha]_D^{27} = -2.53°$ and having the R-configuration is formed via the intermediate S-(XIX):[26]



By reduction with sodium tetrahydroborate, acetylation, and oxidation with permanganate, compound (XX) was converted into the acid (XXI), which is an important intermediate in the synthesis of an optically active pheromone.[27]

One of the disadvantages of the above transformation (XV) → (XVII) is the necessity to employ optically pure allyl substrates in order to obtain optically pure products. Furthermore, the chirality in the initial optical centre is lost during the reaction. An attempt to overcome these difficulties has been made in a theoretically and synthetically important study[28] in which asymmetric induction was achieved in the Cope 3-aza-rearrangement by means of an auxiliary reagent. The authors began with the hypothesis that an auxiliary chiral centre bound covalently to the nitrogen atom would create a transition state bias in the Cope aza-rearrangement. In order to enhance to the maximum possible extent the topological influence of the auxiliary chiral reagent, this centre, the nitrogen atom, and the C(1) atom of the vinyl fragment (denoted by an asterisk) were incorporated in the five-membered oxazoline ring:

Scheme 1



(XXII) (XXIII) (XXIV)

R-(XXV) S-(XXV)

R-(XXV) : S-(XXV) = 87 : 13

(XXII)–(XXVI)

a) $R^1 = CH_3$, $R^2 = R^3 = H$

b) $R^2 = CH_3$, $R^1 = R^3 = H$

c) $R^3 = CH_3$, $R^1 = R^2 = H$

R-(XXVI) S-(XXVI)

R-(XXVI) : S-(XXVI) = 87 : 13 for XXIVb)

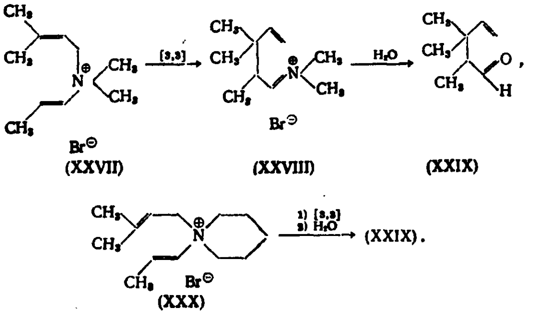
R-(XXVI) : S-(XXVI) = 14 : 86 for XXIVc)

The salts (XXIIIa–c) were obtained from the oxazolines (XXIIa–c) with the aid of allyl toluene-p-sulphonates. The neutralisation of the salts (XXIIIa–c) leads to the NO-acetals (XXIVa–c) which rearrange in decalin, without isolation, to the oxazolines (XXV) and (XXVI) in yields exceeding 85% (Scheme 1).

The diastereoselectivity of this Cope 3-aza-rearrangement was determined in the following manner. The oxazoline (XXV) was hydrolysed (3 N HCl 90 °C, 1.5 h) and the subsequent optical measurement showed that R-(−)-2-methylpent-4-enoic acid is formed in excess so that compound (XXIVa) rearranges predominantly to the oxazoline R-(XXV). The ratios of the diastereoisomeric oxazolines R-(XXV)/S-(XXV) and R-(XXVI)/S-(XXVI) were established by means of high-pressure liquid chromatography. Analysis of the high-resolution ^1H NMR spectra (500 MHz) of the N-methyl-oxazolinium salts obtained from compounds (XXV) and (XXVI) by methylation with dimethyl sulphate demonstrated that one of the diastereoisomers is present in 72–74% excess in the rearrangements (XXIVa) → R-(XXV), (XXIVb) → R-(XXVI), and (XXIVc) → S-(XXVI).

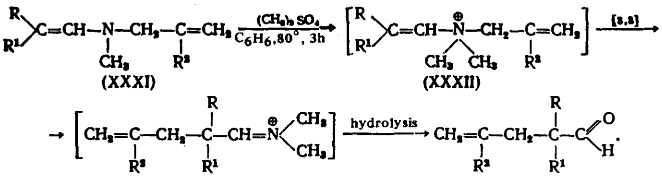
The rearrangement of the enammonium salt (XXVII) under mild conditions (20 °C) under the influence of bases has been described.[29] The hydrolysis of the resulting amine (XXVIII) leads to the aldehyde (XXIX):

Scheme 2



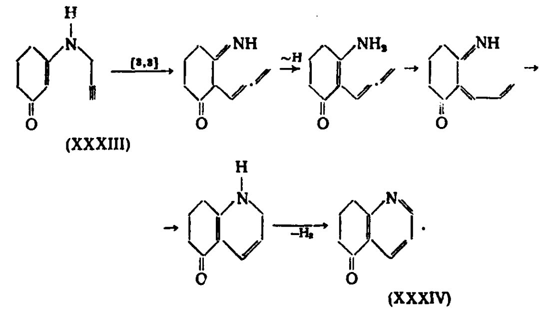
The aldehyde (XXIX) also arises as a result of the Cope 3-aza-rearrangement when a benzene solution of the bromo-derivative (XXX) is maintained at room temperature[29] (Scheme 2).

A promising method for the generation of the quaternary carbon centre under mild conditions with the aid of the Cope 3-aza-rearrangement of the enammonium salts (XXXII) has been proposed:[30]

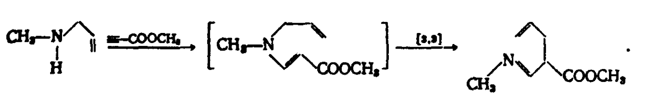


The advantage of this method over that proposed previously[31] is because the allylenamines (XXXI) were obtained by the selective *N*-alkylation of the corresponding allylamines, which made it possible to avoid the difficulties quoted by Opitz et al.[31] associated with the fact that, when vinylamines were used as the initial compounds for the synthesis of structures of type (XXXII), the formation of a mixture of isomers was observed as a result of the simultaneous occurrence of the *C*- and *N*-allylation reactions.

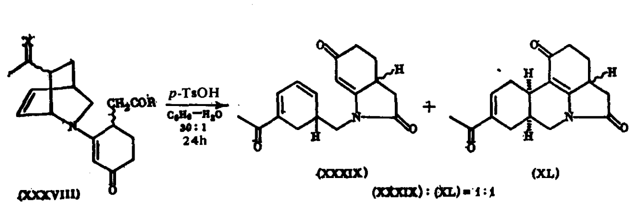
The Cope 3-aza-rearrangement has been used successfully to synthesise the pyridines (XXXIV) from the propargylvinylamines (XXXIII):[32]



The addition of the allylamine (XXXV) to methyl propionate with the subsequent Cope 3-aza-rearrangement of the intermediate (XXXVI) leads to the imine (XXXVII):[33]

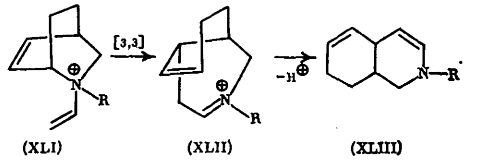


The acid-catalysed reaction of *N*-(β-cyclohexenoyl)isoquinuclidines (XXXVIII), leading to the tetracyclic skeleton of the type of lycorane (XL), has been described in a recently published study[34] in which the investigation[35-39] of the Cope aza-rearrangement initiated previously was continued.



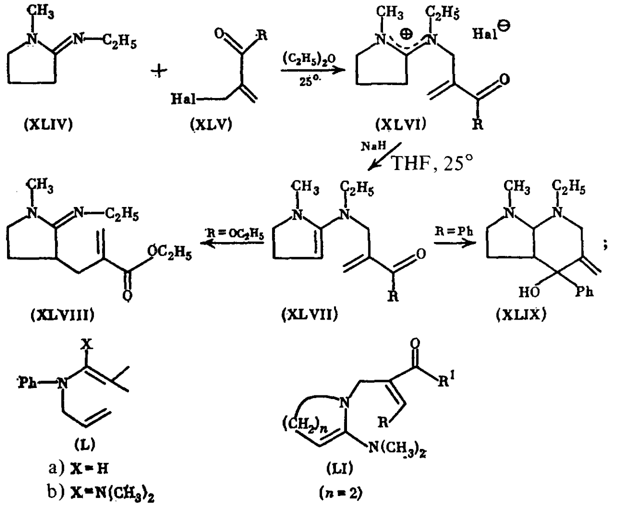
The lactam (XXXIX) is a precursor of the lactam (XL), since only compound (XL) is formed in 40% yield when the reaction is carried out over a period of 48 h.

It is assumed that the hexahydroisoquinoline ring (XLIII) is formed via the elimination of a proton from the intermediate (XLII), which arises from vinylisoquinuclidine (XLI) as a result of the Cope 3-aza-rearrangement:[35]



In certain cases the Cope aza-rearrangement may be accompanied by side reactions (see also Section III). Thus the rearrangement of the amidinium salt (XLVI) via the base (XLVII) leads both to the [3, 3]sigmatropic rearrangement product (XLVIII) and to the product (XLIX) of the intramolecular aldol addition[38] (Scheme 3).

Scheme 3



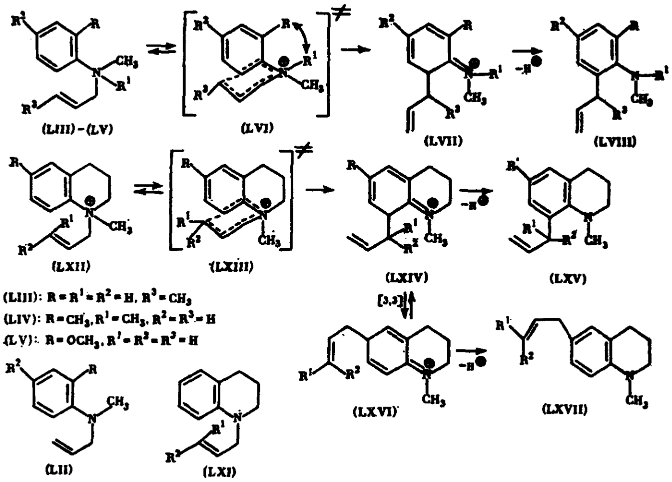
Systems of type (XLVII) merit attention from the standpoint of the elucidation of the influence of electronic factors on the Cope 3-aza-rearrangement, because they contain both electron-donating ($\rangle$N−CH$_3$) and electron-accepting ($-C\begin{smallmatrix}\nearrow R\\ \searrow O\end{smallmatrix}$) substituents. The dialkylamino-group is known to accelerate the Cope oxa-rearrangement.[2] On the other hand, the rearrangement of the amine (La) take place at 170 °C,[26] while that of the diamine (Lb) occurs at 280 °C.[39]

It might have been expected that the simultaneous presence of electron-donating and electron-accepting substituents in a system of type (L) would facilitate the Cope aza-rearrangement. However, it has been found that the rearrangement of the diene (LI), formed from the corresponding amidinium salt on treatment with sodium hydride, takes place even at room temperature and is 10^6–10^8 times faster than the rearrangement of the amine (Lb).[38]

2. Aromatic Cope 3-Aza-rearrangement

The influence of electronic and steric factors on the course of the aromatic Cope 3-aza-rearrangement of *N*-allylanilines [the base (LII) and the salts (LIII)–(LV)][40-42] and the corresponding tetrahydroquinolines (LXI) and (LXII)[42,43] has been investigated in a series of studies by Japanese workers[40–43] (Scheme 4):

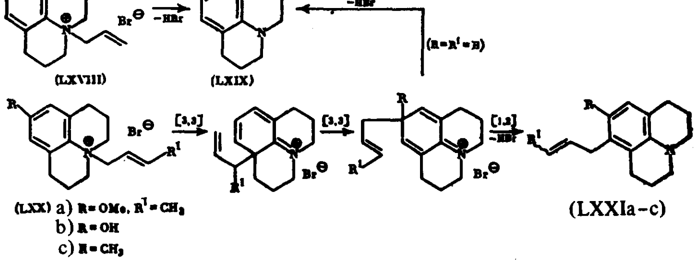
Scheme 4



The concerted reaction mechanism was confirmed in relation to the rearrangement of the *N*-crotyl salt (LIII) (2 : 1 glycerol–water mixture, 140 °C, 4 h). The reaction proceeds via the transition state (LVI) and the aniline (LVIII) with an inverted allyl group is formed. The rearrangement of the quinolines (LXII) takes place via the transition state (LXIII) in the chair conformation, leading to the intermediate (LXIV), from which the quinolines (LXV) and (LXVII) are formed. The intermediate (LXIV) may undergo the usual Cope rearrangement (LXIV) → (LXVI) → (LXVII), which leads to the formation of 6-substituted quinolines (LXVII) with a high stereoisomeric purity. In contrast to anilines with R=H and the quinolines (LXI) and (LXII), the *ortho*-substituted allylanilines (LIV), (LV) afford mainly deallylation and not rearrangement products, which can be accounted for by the steric interaction between the groups R and R^1 in the transition state (LVI).[42] The decrease in the yield of 8-allylquinolines (LXV) on passing from the unsubstituted to the mono- and di-methylallyl groups is associated with increase in the steric interaction of the alkyl groups with the proton in the 8-position in the quinoline ring in the transition state (LXIII).

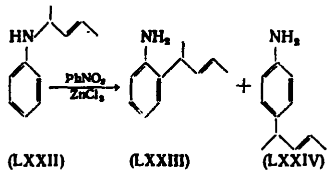
An interesting result has been obtained in the study of the Cope 3-aza-rearrangement of bromo-derivatives of the 4-allyljulolidines (LXVIII) and their 9-substituted analogues (LXXa to c)[41] (Scheme 5). The products (LXXIa-c), involving the rearrangement to the *meta*-position, were discovered first (the analogous Claisen *meta*-rearrangement is known for the reaction of allyl 2,4,6-trimethylphenyl ether in the presence of BCl$_3$ [44]):

Scheme 5



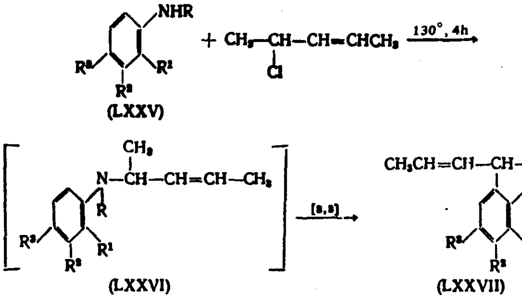
A mechanism involving two consecutive [3, 3]sigmatropic shifts [the transformation (LXVIII) → (LXIX) takes place analogously] and a [1, 2]shift with elimination of a hydrogen bromide molecule has been proposed for the rearrangement (LXX) → (LXXI) (Scheme 5).

The aromatic[45–51] Cope 3-aza-rearrangement of various N-alkenylanilines has been investigated. It has been shown that the rearrangement of *N*-(1-methyl-2-butenyl) aniline (LXXII) is catalysed by the hydrochlorides of aromatic amines and Lewis acids and that the best yield of the corresponding *ortho*- and *para*-alkenylanilines is attained in the presence of ZnCl$_2$ [the yield of (LXXIII) + (LXXIV) is 97%]:[45,50]



An analogous reaction has been achieved for octa,2,7-dienylaniline[46] and *N*-(1-methyl-2-butenyl)-2,5-xylidine.[51]

The rearrangement of *N*-alkenylanilines proved to be an effective method for the synthesis of various *C*-substituted anilines:[47,48]

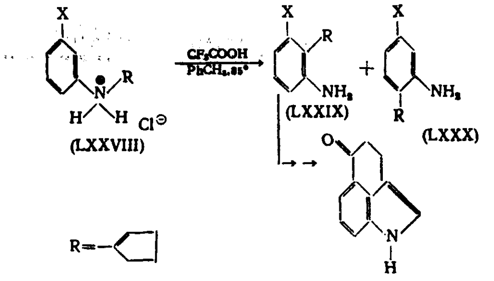


R^1 – R^3 = alkyl, halogen, OCH$_3$,
R = alkyl.

N-Alkenylanilines (LXXVI), formed in the reaction of substituted anilines (LXXV) with 4-chloro-*trans*-pent-2-ene, are immediately converted into the corresponding product (LXXVII) under the reaction conditions.

The kinetics of the acid-catalysed Cope 3-aza-rearrangement of various *N*-allylanilines of type (LXXV) in nitrobenzene have been investigated[49] and it has been shown that in all cases the rearrangement is accompanied by elimination, but that the contribution of the latter is different for different substituents. For equal initial concentrations of aniline and hydrochloric acid, the reaction is described by a first-order equation. The results have been explained from the standpoint of the formation of a contact ion pair from PhNHR.HCl, which can either undergo a rearrangement to 2-allylaniline in the solvent cage or elimination.

The influence of electron-accepting groups on the regioselectivity of the aromatic Cope 3-aza-rearrangement of *meta*-substituted anilinium salts, (LXXVIII) → (LXXIX) → (LXXX), has been studied:[52]

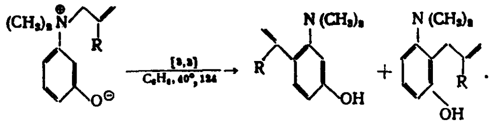


(LXXVIII) (LXXIX) (LXXX) (LXXXI)

	a	b	c	d	e
X	—C≡N	CO_2CH_3	NO_2	F	CF_3
(LXXIX):(LXXX)	2.9:1	(LXXIX) not detected	1:10	1:3.7	1:2

In all cases [with the exception of *m*-cyanoaniline (LXXVIIIa)], the preferential formation of products in the rearrangement to the *p*-position relative to the substituent X was observed. These data have been explained[52] by the steric influence of the group X, because the activation energy for the transition to the isomer (LXXIX) is lower than that for the transition to the isomer (LXXX).[53] The transformation (LXXVIIIa) → (LXXIXa) is of undoubted interest, since it permits the synthesis of the Uhle's ketone (LXXXI), which is a key intermediate on the way to ergot alkaloids.[54]

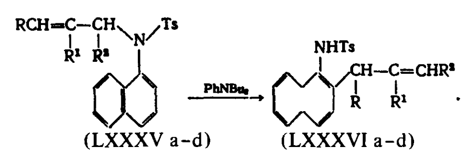
The [3, 3]sigmatropic rearrangement of the betaine (LXXXII) leads to a mixture of the phenols (LXXXIII) and (LXXXIV), the main product being the isomer (LXXXIII) [(LXXXIII):(LXXXIV) = 4:1].[55]



(LXXXII) (LXXXIII) (LXXXIV)

The exceptionally mild reaction conditions are associated with the possibility of the delocalisation of the charge in the course of the rearrangement.[55]

Japanese workers[56] investigated the influence of substituents in the allyl group on the thermal aromatic Cope 3-aza-rearrangement of *N*-allyl-*N*-tosyl-α-naphthylamines (LXXXV) → (LXXXVI):



(LXXXV a-d) (LXXXVI a-d)

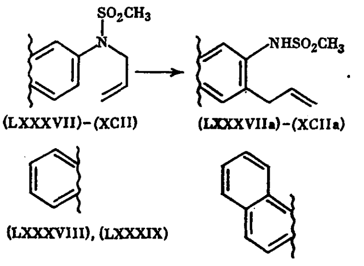
(LXXXV), (LXXXVI)

a) $R{=}R^1{=}H$, $R^2{=}CH_3$
b) $R{=}R^2{=}H$, $R^1{=}CH_3$
c) $R^1{=}R^2{=}H$, $R{=}CH_3$
d) $R^1{=}R^2{=}H$, $R{=}Ph$

The formation of the naphthylamines (LXXXVIa, c, d) from the amines (LXXXVa, c, d) indicates the concerted character of the rearrangement.

In the rearrangement of compounds (LXXXVb), (LXXXVc), and (LXXXVd), the corresponding 4-substituted naphthylamines are formed in addition. The *para*/*ortho* product ratio increases in the series of amines (LXXXVb) < (LXXXVc) < (LXXXVd), which supports the occurrence of consecutive [3, 3]sigmatropic shifts, whose driving force is the steric interaction between the tosylamino-group and the 1-substituted allyl group.

The influence of the aromatic ring on the rate of the thermal Cope 3-aza-rearrangement of *N*-allyl-*N*-methanesulphonylamines [the aniline (LXXXVII), the 1- and 2-naphthylamines (LXXXVIII) and (LXXXIX), and the 2-, 3-, and 9-phenanthrylamines (XC), (XCI), and (XCII)] in *NN*-dibutyl-aniline containing a small amount of triphenylphosphine has been studied:[57]



(LXXXVII)-(XCII) (LXXXVIIa)-(XCIIa)

(LXXXVIII), (LXXXIX)

(XC)-(XCII)

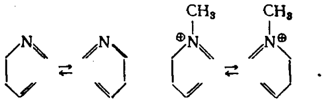
In all cases the rearrangement (LXXXVII) → (XCII) → (LXXXVIIa) → (XCIIa) obeys a first-order kinetic equation and has negative activation entropies, which suggested a concerted process mechanism.[57]

The highest rate of rearrangement has been observed for *N*-allyl-*N*-methanesulphonyl-1-naphthylamine (LXXXVIII) and *N*-allyl-*N*-methanesulphonyl-9-phenanthrylamine (XCII). The data (ln *k*) obtained are satisfactorily correlated ($r = 0.991$; $s = 0.290$) with the corresponding delocalisation energies.

An analogous correlation of the logarithms of the rate constants with the localisation energies has been observed also for the Claisen rearrangement of the corresponding o-allyl ethers of phenol, naphthol, and phenanthrol ($r = 0.999$; $s = 0.110$).[57]

III. THE COPE 2-AZA-REARRANGEMENT

The Cope 2-aza-rearrangement of 3-butenylimines (XCIII) is degenerate:

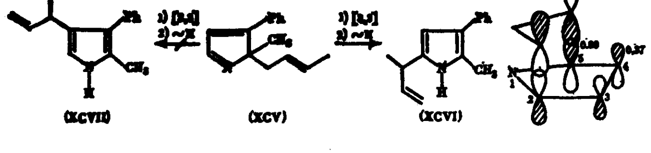


(XCIII) (XCIII) (XCIV) (XCIV)

The equilibrium position in substituted systems of type (XCIII) can be established on the basis of "secondary" structural factors such as, for example, steric interactions or the conjugation effect in the reactants and products.[7] A number of instances of rearrangements of systems (XCIII) and (XCIV) have been quoted in a review.[7] It has been established that, as a rule, iminium salts of type (XCIV) rearrange under much milder conditions than the isoelectronic type (I) Cope systems and the rearrangement is faster than the reaction of the uncharged imine (XCIII).[7]

One of the latest studies devoted to the comparative investigations of the Cope rearrangement and its 2-aza-analogue has been carried out by French investigators.[58] The thermolysis of the model 2*H*-pyrrole (XCV), which has no substituents in the 4- and 5- positions (170 °C, 3.5 h), led to the isolation in 90% yield of one product (XCVI), whose formation has been explained by the Cope 2-aza-rearrangement with subsequent migration of hydrogen:

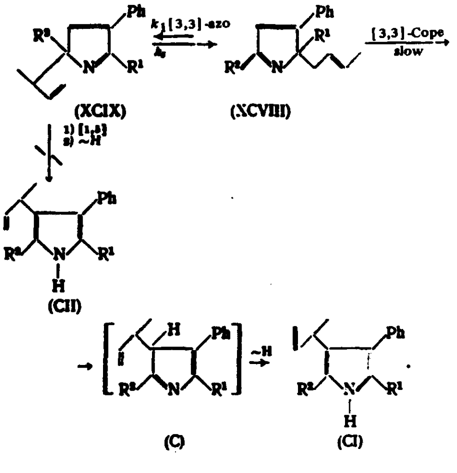
Scheme 6



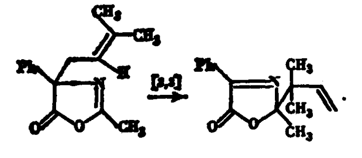
The following conclusions have been reached concerning the possibility of the migration of the *trans*-crotyl group.[58] If the 2*H*-pyrrole is unsubstituted in the 3- and 4-positions, then the [1, 5]shift to the 3-position takes place; when the 4-position is the only one remaining free, the Cope rearrangement [migration to C(4)] is observed; finally, when the 4- and 5-positions are free, only the Cope 2-aza-rearrangement [migration to C(5)] takes place. The absence of the Cope rearrangement (XCV) → (XCVII) has been explained by the difference in the interaction of the frontier orbitals of pyrrole and the allyl group in the two transition states leading respectively to the Cope reaction and the Cope 2-aza-reaction. The difference between the amplitudes of the atomic orbitals of the carbon atoms in the 4- and 5-positions demonstrates the possibility of the migration to the C(4) atom[58] (Scheme 6). The data obtained in the above study made it possible to account for earlier experimental observations.[59,60]

The finding that the thermolysis of the pyrrole (XCVIII) does not lead to the product (XCIX) of the Cope aza-rearrangement[60] can be logically explained by the following factors: firstly, the rate constant k_2 for the reversible isomerisation (XCVIII) ⇄ (XCIX) is higher than k_1; secondly, the slower Cope reaction converts the pyrole (XCVIII) into the 3*H*-pyrrole (C), which isomerises irreversibly to the pyrrole (CI); thirdly the 1,5-migration with formation of the pyrrole (CII) is not observed when the 3-position is substituted[58] (Scheme 7):

Scheme 7



The Cope 2-aza-rearrangement has been observed in the series of oxazoles.[61] Thus the thermolysis (162 °C, benzene) of allyl-substituted Δ^2-oxazolinones leads to the Δ^3-oxazolinone system:

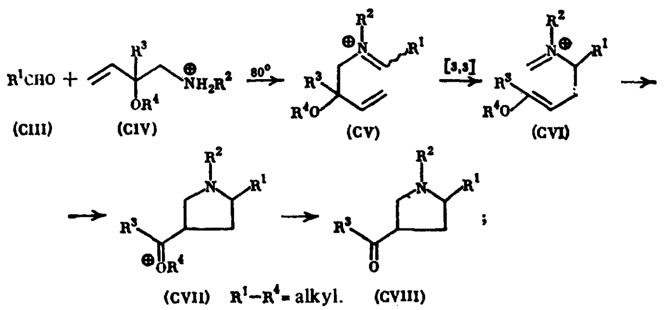


The formation of 2-(1,1-dimethyl-2-propenyl)-Δ^3-oxazolinone shows that the reaction proceeds via the [3, 3]sigmatropic and not the [1, 3]sigmatropic shift.[61]

In recent years the Cope 2-aza-rearrangement has been widely used by several groups of investigators for the synthesis of various heterocyclic systems.

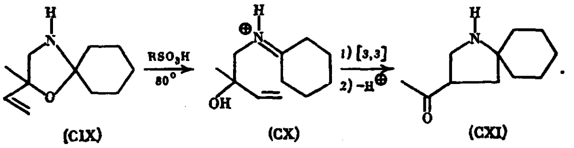
A series of studies[62-71] have been devoted to the "directed" Cope 2-aza-rearrangement of charged systems of type (XCIV). The condensation of the aldehyde (CIII) with salts of secondary amines (CIV) leads to the iminium salts (CV), which undergo the [3, 3]sigmatropic rearrangement to the intermediates (CVI), which are further transformed via the oxonium cation (CVII) into the acylpyrrolidines (CVIII) in 80 to 95% yield[62] (Scheme 8):

Scheme 8

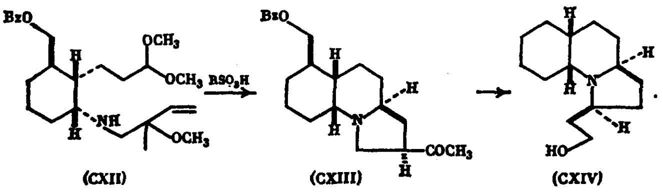


The reaction described constitutes a new method of synthesis of the pyrrolidine ring. The cationic Cope aza-rearrangement and the Mannich reaction have been used consecutively to synthesise poly-substituted pyrrolidines of type (CVIII) (isoprene) derivatives were used as the initial compounds).[69]

It has been shown[63] that the imminium ion (CX) [an analogue of the ion (CV)] can be generated from the oxazolidine precursor (CIX), which permitted the synthesis of substituted 1-aza-spiro-[4, 5]decanes (CXI):

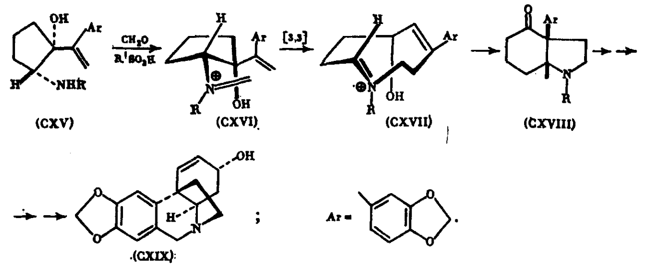


A reaction in which the iminium ion is formed intramolecularly has been used for the single-stage synthesis of the indolizine (CXIII) [(CXII) → (CXIII)],[70] which is a key compound on the way to the alkaloid DL-perhydrogenphyrotoxin (CXIV):



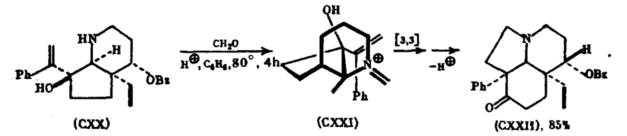
A novel method of synthesis of the pyrrolidine ring, involving the consecutive occurrence of two processes, namely ring expansion and contraction, has been demonstrated in the synthesis of *cis* 3a-aryl-octahydroindolones [Scheme 8, (CXV) → (CXVIII), R = $CHPh_2$].[64,66] This reaction makes it possible to achieve a new stereoselective synthesis of the alkaloid crinin (CXIX).

Scheme 8a



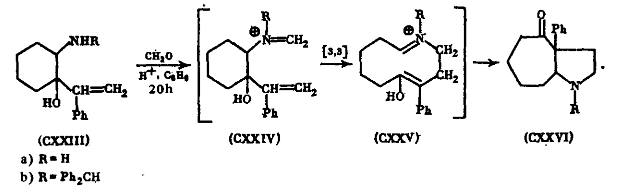
The formation of the *cis*-product (CXVIII) follows from the *trans*-orientation of the amino- and vinyl groups in the amine (CXV). As a result of such *trans*-disposition, the iminium ion undergoes the Cope 2-aza-rearrangement via the only possible transition state in the chair conformation, affording *trans*, *trans*-azacyclonona-1,6-diene (CXVII). The latter is converted stereospecifically into the *cis*-intermediate (CXVIII) after the intramolecular Mannich ring closure.

The above method of ring expansion with the subsequent formation of the pyrrolidine ring has been used successfully for the synthesis of the complex 9a-arylhydrolilodine system [(CXX) → (CXXII)], which is the basis of the *Aspidosperma* alkaloids:[65]



The synthetic possibilities of the cationic Cope 2-aza-rearrangement have also been demonstrated in relation to the stereospecific synthesis of *cis*- and *trans*-3a-aryl-4-oxodecahydrocyclohepta[*b*]pyrroles (CXXVI):[67,68,71]

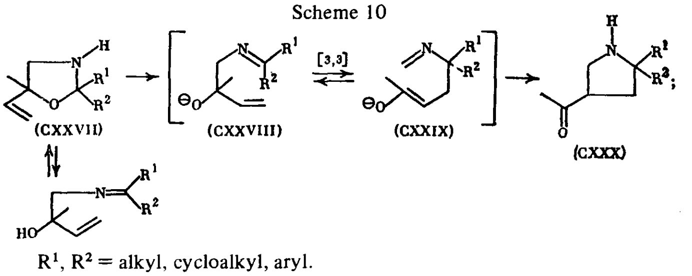
Scheme 9



In the case of the cyclohexanols (CXXIIIa, b), with the *trans*-disposition of the vinyl and amino-groups, the rearrangement leads to the *cis*-pyrrolidine (CXXVI) via the iminium cation (CXXIV) and the intermediate *trans*, *trans*-azacyclodeca-1,7-diene (CXXV) (cf. with Scheme 8a).

Instances of the Cope 2-aza-rearrangement enumerated above (see, for example, Overman and co-workers[62,63]) are either thermal or acid-catalysed processes. However, it has been shown[65] that the above rearrangement can be achieved under exceptionally mild conditions in the presence of a base (Scheme 10):

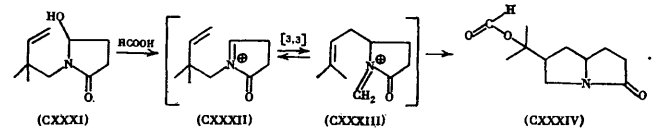
Scheme 10



R^1, R^2 = alkyl, cycloalkyl, aryl.

On heating in THF (at 25 °C) for 24 h in the presence of 1.5 equivalents of KH and 0.1 of an equivalent of 18-crown-6 ether, 5-vinyl-oxazolidines (CXXVII) give rise to the pyrrolidines (CXXX) in 50–90% yield. Potassium hydride converts the oxazolidine (CXXVII) into the intermediate (CXXVIII), which undergoes the [3,3]sigmatropic rearrangement to the enolate anion (CXXIX), which effects ring closure to 3-acetylpyrrolidine (CXXX) via the intramolecular endocyclic attack on the imino-group. The transformation (CXXVII) → (CXXX) constitutes the first example of the base catalysis of the Cope hydroxy-2-aza-rearrangement (the acceleration of the usual Cope hydroxy-rearrangement by bases is well-known[73–76]).

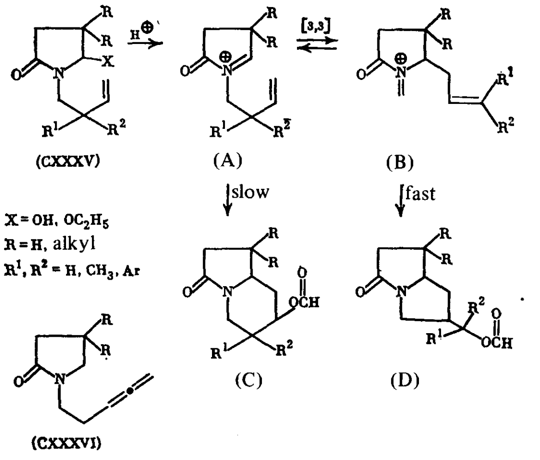
The Cope 2-aza-rearrangement of *N*-acyliminium salts has been used in a number of studies to synthesise heterocyclic systems.[77–81] A rearrangement of this kind was described for the first time in a study[77] where it was shown that treatment of the carbinolamide (CXXXI) with formic acid leads to the pyrrolizidinone (CXXXIV):



A key stage is the Cope 2-aza-rearrangement of the *N*-acyliminium ion (CXXXII) with the subsequent cyclisation of the intermediate (CXXXIII) to the formate (CXXXIV). Later this method was used to synthesise a series of pyrrolizidine bases.[78]

The mechanism of the Cope 2-aza-rearrangement of *N*-acyliminium salts has been investigated[79–81] and it has been established that the pyrrolidinones (CXXXV)–(CXXXVI) can react via two pathways in an acid medium.[79–81] One of them leads to the pyrrolizidine system (P)[80,81] and the other leads to the indolizidines (C) (Scheme 11).

Scheme 11



Both processes proceed via a stage involving the formation of the "secondary" iminium ion (A), which either undergoes the reversible Cope 2-aza-rearrangement to the "primary" iminium ion (B) and then rapidly cyclises (the relevant kinetic data have been published[81]) to the pyrrolizidine (D) or is immediately converted into the indolizidine (C) in a slow stage. The lactams (CXXXVI) containing an allene residue react analogously. The pathway followed in the reactions of the lactams (CXXXV) and (CXXXVI) and the ratio of the products (C) and (D) depend on the nature of the groups R, R^1, and R^2 in the pyrrole ring and in the allyl component of the molecule.[79-81]

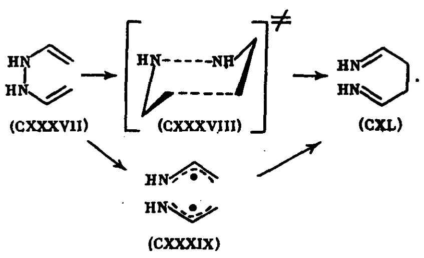
IV. THE COPE 3,4-DIAZA-REARRANGEMENT

As stated in the introduction, the Cope 3,4-diaza-rearrangement of the enehydrazines (VII) and (X) is in essence a stage in the formation of the C–C bond in the Fischer indole synthesis and in the Piloty pyrrole synthesis.

The idea that these reactions be considered from the standpoint of [3, 3]sigmatropic rearrangements was first put forward in two reviews.[11,13] A number of studies devoted to the elucidation of the mechanism of the thermal and acid-catalysed Cope 3,4-diaza-rearrangements have been discussed in a monograph.[7] New results demonstrating the validity of the approach to the mechanism of the rearrangement of enehydrazines from the standpoint of the theory of concerted processes have been obtained in recent years.

The rearrangement of the model divinylhydrazine (CXXXVII) has been investigated[82] by the MINDO/3 method (Scheme 12).

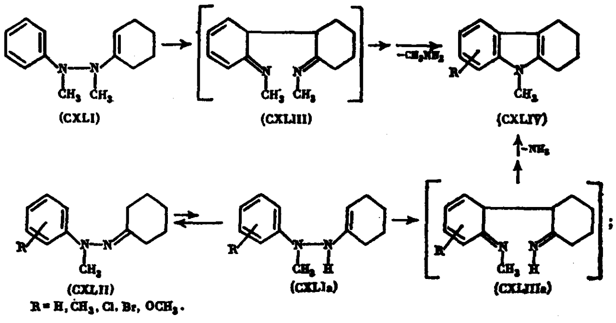
Scheme 12



The MINDO/3 calculation showed that the transition state (CXXXVIII) in the [3, 3]sigmatropic migration (CXXXVII) → (CXL) has the chair structure (C_2 symmetry), which indicated an analogy with the rearrangement of hexa-1,5-diene.[8] The multistage mechanism involving the formation of the radical pair (CXXXIX) is energetically less favourable (by 8.2 kcal mol^{-1}) than the concerted mechanism, but such a small difference between the energies of the two migration mechanisms does not allow the complete exclusion of homolysis from the general scheme of the rearrangement[82] (the concerted mechanism of the Cope rearrangement involving hexa-1,5-diene is more favourable to the extent of 33.4 kcal mol^{-1} than the multi-stage mechanism[83]).

Experimental confirmation of the concerted mechanism in the stage involving the formation of the carbon–carbon bond in the Fischer reaction, (CXLI) → (CXLIII) and (CXLIa) to (CXLIIIa), has been obtained on the basis of kinetic data for the rearrangement of *NN'*-dimethyl-*N*-phenyl-*N'*-(1-cyclohexenyl)hydrazine (CXLI) and substituted cyclohexanone *N*-methyl-phenylhydrazones (CXLII) to the tetrahydrocarbazoles (CXLIV)[82,84] (Scheme 13).

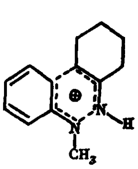
Scheme 13



It has been established that both the thermal and acid-catalysed rearrangements of the enehydrazine (CXLI) are faster than the corresponding reactions of the hydrazones (CXLII), which indicates a significant contribution by the stage (CXLII) → (CXLIa) to the overall rate of the process.[82] Substituents of different types and solvent polarity have little influence on the rate of conversion of the hydrazones (CXLII) into indoles, which proceeds in accordance with a first-order equation and in addition this reaction has fairly high negative activation entropies in all cases.[82,84]

The acidity of the medium has an appreciable influence on the rate of the transformations (CXLI) → (CXLIV) and (CXLII) → (CXLIV). Thus the factor by which the sulphuric acid-catalysed (two moles of acid per mole of reactant) rearrangement of the enehydrazine (CXLI) is accelerated compared with the thermal rearrangement at 60 °C is ~400,[82] which agrees with other data.[85,86]

This finding supports the charge-induced pericyclic reaction.[20] This reaction takes place so rapidly because the positive charge in the six-membered transition state (CXLV) is delocalised between the six atoms of the reacting system. An analogous acceleration has been observed in the aromatic Cope 3-aza-rearrangement (Section II).

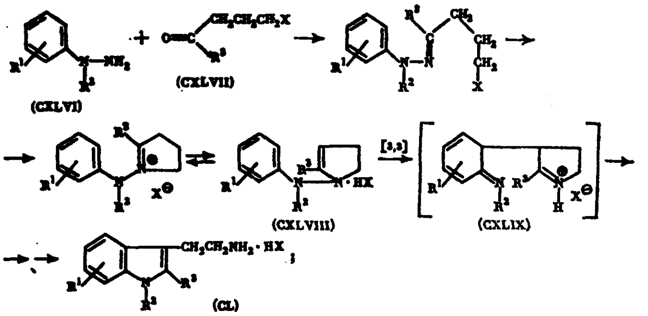


(CXLV)

The main stage in the synthesis of the tryptamines (CL) and related structures from γ-halogenocarbonyl compounds (CXLVII) (or their δ-analogues) and the arylhydrazines (CXLVI), namely the formation of the C–C bond via the reaction (CXLVIII) → (CXLIX), is also a type of the Cope 3,4-diaza-rearrangement and proceeds via the mechanism of the

[3,3]sigmatropic rearrangement (Scheme 14) (see the relevant review[87] and the literature quoted therein).

Scheme 14



$R^1 - R^3$ = alkyl, aryl, arylalkyl; X = halogen.

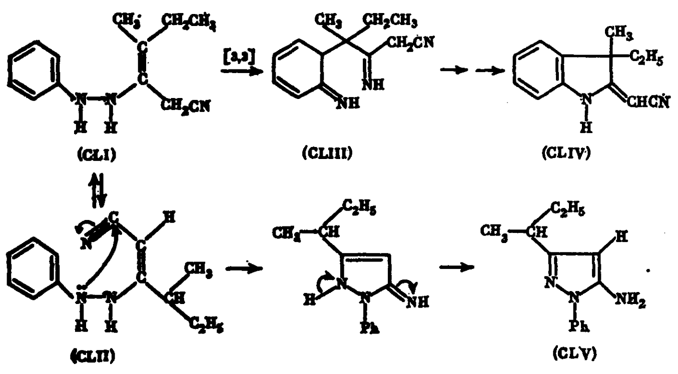
This reaction is a special case of the Fischer indole synthesis without the evolution of ammonia.

Numerous studies of various aspects of the mechanism of the Fischer reaction have been published in recent years. Thus the possibility of the formation of intermediates and their structures has been investigated by ^{13}C NMR,[88] ^{15}N NMR,[89] and mass spectrometry.[90] The influence of the electronic and steric factors on the direction of the indole formation reaction, its mechanism, and the ratio of the isomeric products has been studied.[91–100] The results of the comparative investigation of the Fischer indole synthesis and of the "anomalous" [3,5]- and [5,5]-sigmatropic rearrangement of various o-substituted arylhydrazones and also the migration of the substituents in these systems have been discussed in detail in a review[103] and recent communications.[102,103]

The authors of the above studies[91–103] adhere to the concept of the concerted character of the carbon–carbon bond formation stage in the Fischer reaction.

An interesting example of the Cope 3,4-diaza-rearrangement, namely (CLI) → (CLIII) has been observed for the adduct (CLI) formed in the reaction of phenylhydrazine with an allene nitrile[104] (Scheme 15):

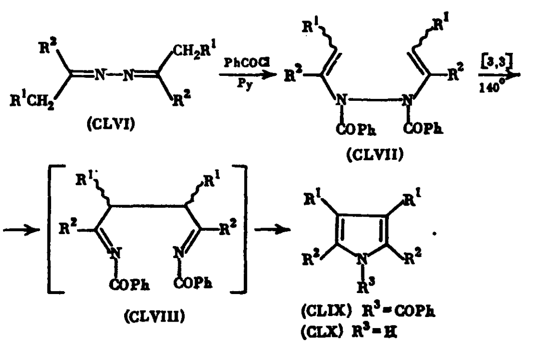
Scheme 15



Since the enehydrazine (CLII) (isolated in a pure state) does not undergo the [3,3]sigmatropic rearrangement and gives rise to the pyrazole (CLV), the formation of the indoline (CLIV) from this enehydrazine can be explained by the prototropic isomerisation (CLII) → (CLI) with the subsequent Cope 3,4-diaza-rearrangement.[104]

The latest advances in the chemistry of the enehydrazines of type (VIII), including their ability to undergo the Cope 3,4-diaza-rearrangement with formation of pyrrole systems, have been analysed in detail in a review.[105]

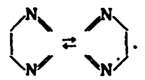
We shall mention only the study[106] in which a general method has been proposed for the synthesis of the pyrroles (CLIX) and (CLX) from the azines of the enolysable aldehydes and ketones (CLVI) via the concerted thermal rearrangement (CLVII) → (CLVIII) of the benzoyl derivatives (CLVII):



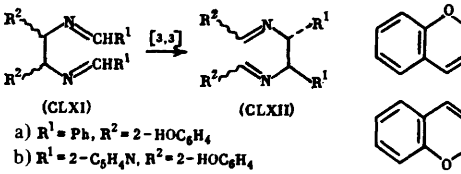
The dienehydrazines (CLVII), which are fairly stable compounds (characterised by ^{1}H NMR), have been used in the synthesis of the pyrroles (CLIX) without isolation. The hydrazinolysis of the latter made it possible to obtain readily the pyrroles (CLX).

V. THE COPE 2,5-, 2,3-, AND 1,3-DIAZA-REARRANGEMENTS

The Cope 2,5-diaza-rearrangement is in the general case a reversible process and in the absence of substituents is a degenerate process:



However, the directed Cope 2,5-diaza-rearrangement (CLXI) → (CLXII)[107] has been achieved for the double Schiff base (CLXI) containing the 2-hydroxyphenyl group (see also Heimgartner et al.[7]). The subsequent hydrolysis of the diimine (CLXII) leads to a carbonyl compound and *meso*-1,2-diaryl-1,2-ethylenediamine:

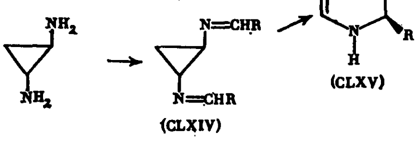


a) R^1 = Ph, R^2 = 2-HOC_6H_4
b) R^1 = 2-C_5H_4N, R^2 = 2-HOC_6H_4

In the given instance the relative stability of the diimines (CLXIIa) and (CLXIIb) is due to the presence of the intramolecular hydrogen bond between the imine nitrogen atom and the phenolic hydroxyl.

The possibility of the thermal Cope 2,5-diaza-rearrangement was first demonstrated in 1965 for *trans*-1,2-bis(benzylideneamino)cyclopropane (CLXIV, R = Ph); the reaction yielded 2,3-diphenyl-2,3-dihydro-1*H*,1,4-diazepine (CLXV)[108] (Scheme 16). However, the stereochemistry of the process remained unelucidated.

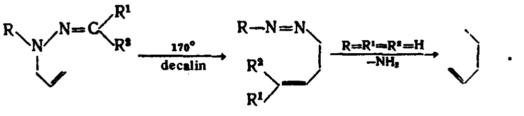
Scheme 16



The thermal rearrangement of the *cis*- and *trans*-bisimines (CLXIII) and (CLXIV) (R = t-butyl, phenyl, *p*-tolyl, or mesityl), formed from the corresponding diaminocyclopropanes, has been investigated.[109] It was found that in all cases the only reaction product is a *cis*-substituted dihydrodiazepine (CLXV). This result demonstrates that the Cope 2,5-diaza-rearrangement involves one structure with the same configuration at both C=N bonds [for the imine (CLXIII) this is the *EE*-configuration]. A strong influence of the t-butyl groups on the rearrangement of the bis-imines (CLXIII) and (CLXIV) has been observed. Thus the *cis*-imine (CLXIII, R = t-Bu) is only slowly converted into the diazepine (CLXV) at 100 °C (93 h, yield 49%), while the reaction of *cis*-diaminocyclopropane with benzaldehyde at 0 °C leads to a 90% yield of the diazepine (CLXV, R = Ph). This effect can be explained by the fact that, in the formation of the C(2)–C(3) bond in 2,3-dihydro-1,4-diazepine, the substituents must have an eclipsed disposition, and in the case of two t-butyl groups this destabilises the molecule to the extent of 63 kJ mol^{-1}.[109]

We may note that the Cope 2,5-diaza-rearrangement, illustrated in Scheme 16, constitutes one of the important preparative methods whereby it is possible to achieve ring expansion by four units at once with formation of a heterocyclic system (the Claisen rearrangement and the Cope hydroxy-rearrangement have also been studied for this purpose, but these processes involve the formation of carbocyclic compounds[110]).

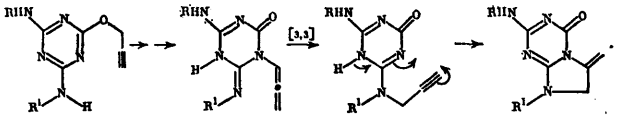
The Cope 2,3-diaza-rearrangement of *N*-alkyl-*N*-allylhydrazones (CLXVI) has been proposed for the preparative synthesis of the γδ-unsaturated azo-compounds (CLXVIII)[111] [the thermolysis of the hydrazone (CLXVII) led to the alkene (CLXIX)[112]]:



(CLXVI), (CLXVII) (CLXVIII) (CLXIX)
(CLXVII): R=R¹=R²=H

The Cope 2,3-diaza-rearrangement has also been observed in the vacuum pyrolysis of *N*-allyloxadiazolinones.[113] For charged systems, this reaction has not been described in the literature.

One of the stages in the thermal[114] and catalytic [$(CF_3COO)_2$][115] transformations of the propargyl ethers of hydroxytriazine (CLXX) into imidazo[1,2-*a*]-1,3,5-triazines (CLXXIII) can be regarded as the Cope 1,3-diaza-rearrangement (CLXXI) → (CLXXII):



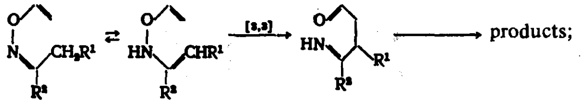
(CLXX) (CLXXI) (CLXXII) (CLXXIII)

VI. THE COPE POLYHETERO-REARRANGEMENTS

The rearrangements of systems containing oxygen and sulphur atoms in addition to nitrogen atoms, i.e. the Cope oxaza- and thiaza-rearrangements are considered in this section.

1. The Cope Oxaza-rearrangement

The [3,3]sigmatropic rearrangement in which the nitrogen–oxygen bond dissociates (thermal rearrangement or rearrangement in the presence of acids) was described in 1971 in relation to *O*-aryl- and *O*-vinyl-oximes:[116]

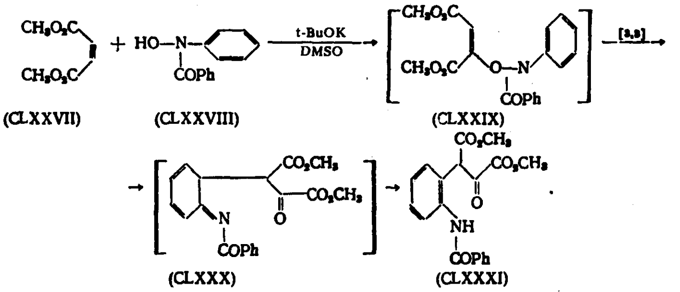


(CLXXIV) (CLXXV) (CLXXVI)
R^1, R^2 = H, alkyl, aryl.

Presumably the fairly severe reaction conditions are necessary only for the isomerisation of the oxime (CLXXIV) → (CLXXV), while the stage involving the rearrangement proper (CLXXV) → (CLXXVI) should occur spontaneously under mild conditions by virtue of the relatively weak and highly polar N–C bond.

Indeed it has been found that if the Cope hetero-system of type (CLXXIX) is produced directly by the addition of *N*-phenylbenzohydroxamic acid (CLXXVIII) to dimethyl acetylenedicarboxylate (CLXXVII), then the rearrangement (CLXXIX) → (CLXXX) takes place readily (20 °C, 1 h) and leads to the ester (CLXXXI) in a high yield[117] (Scheme 17):

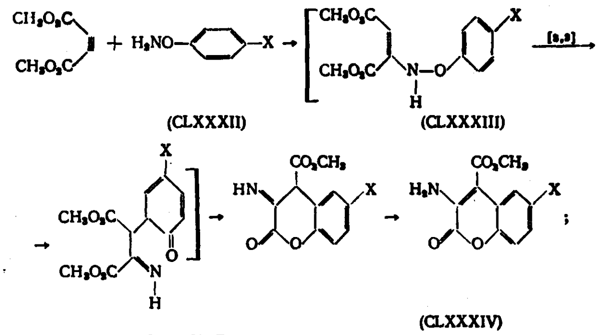
Scheme 17



(CLXXVII) (CLXXVIII) (CLXXIX) (CLXXX) (CLXXXI)

The addition of *p*-substituted *O*-arylhydroxylamines (CLXXXII) to)CLXXVII) (ethanol, 20 °C, 2 h) takes place in the absence of alkaline catalysts and the adduct (CLXXXIII) formed is converted via a stage involving the [3,3]sigmatropic shift into 3-aminocoumarins (CLXXXIV)[117] (Scheme 18):

Scheme 18

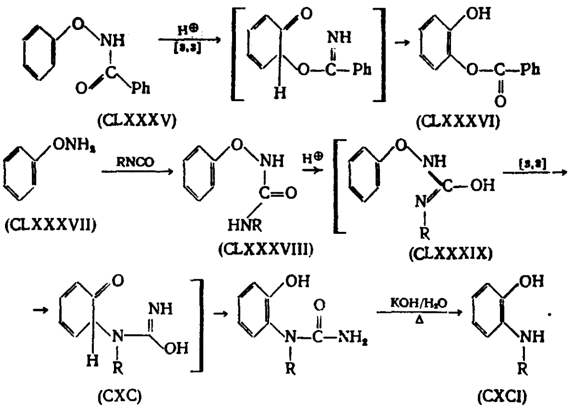


(CLXXXII) (CLXXXIII) (CLXXXIV)
X=H, CH_3, Cl, Br.

The acid-catalysed Cope oxaza-rearrangement is the principal stage in the reactions of derivatives of *O*-arylhydroxylamines described by a group of Japanese investigators[118,119]

(Scheme 19). It is of interest that the hetero-hexa-1,5-diene systems (CLXXXV) and (CLXXXIX) contain three heteroatoms, which increases their reactivity:

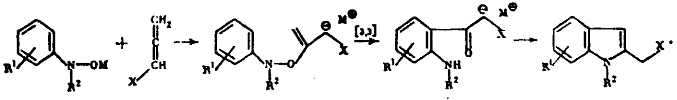
Scheme 19



Thus treatment of *N*-benzoyl-*O*-phenylhydroxylamine (CLXXXV) with a 5:1 mixture of trifluoroacetic and trifluoromethanesulphonic acids for 24 h at 20 °C leads to a high yield of *o*-hydroxyphenyl benzoate (CLXXXVI),[118] while the urea derivative (CLXXXVIII) readily gives rise to 2-alkylaminophenols (CXCI) in dichloromethane at room temperature.[119]

The Cope oxaza-rearrangement has been used in a number of instances for the synthesis of the indole ring.[120–123] 2-Substituted indoles (CXCVI) are readily formed from derivatives of *N*-phenylhydroxylamine (CXCII) and allenes with electron-accepting substituents (CXCIII).[120] The key stage in this synthesis is the formation of *o*-substituted anilines (CXCV) via the [3,3]sigmatropic rearrangement (CXCIV) → (CXCV) (Scheme 20):

Scheme 20



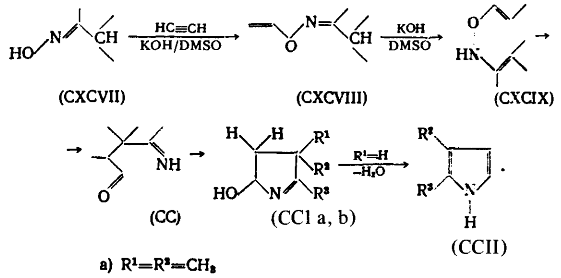
R^1 = H, 4-CH_3, 3-OH, 4-Cl; X = SO_2Ph
R^2 = $COCH_3$, $COCH_2Ph$, C_2H_5; M = Li, Na, K

The anilide (CXCV, R^1 = 4-CH_3, R^2 = $COCH_3$, X = So_2Ph) has been obtained in 90% yield from the corresponding salt of the hydroxamic acid (CXCII) at room temperature in the course of 10 min while in the reaction involving the use of *N*-alkylphenylhydroxylamines (R^1 = H, R^2 = C_2H_5) spontaneous conversion into the indole (CXCVI) was observed.

An additional cause of the extremely great ease of the Cope oxaza-rearrangement (CXCIV) → (CXCV) (apart from the lability of the N–O bond) is the presence in the molecule of compound (CXCIV) of a carbanionic centre, which is known to accelerate the Cope rearrangement[124] and the Cope hydroxy-rearrangement.[125] Derivatives of *N*-phenylhydroxylamine have also been used to synthesise 2,3-unsubstituted indoles,[121] pyrrolo[1,2-*a*]indole,[122,123] and 2-substituted *N*-acylindoles.[126,127] All the reactions indicated proceed via a stage involving the [3,3]sigmatropic shift, analogous to that illustrated in Scheme 20.

The Cope oxaza-rearrangement of derivatives of *N*-arylhydroxylamine has also been used for the regioselective acylamination of the benzene ring[128] and the synthesis of *o*-acyloxyanilides.[129]

Data confirming the concerted variant of the mechanism of the reaction involving the formation of pyrroles from ketoximes and acetylene[132] proposed previously[131] have been published:[130]

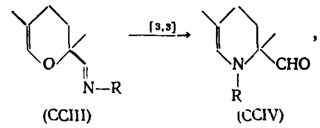


a) $R^1=R^2=CH_3$
b) R^1=H, R^2=iso-C_3H_7, R^3=Ph

The vinyloxyimine (CXCVIII), obtained from the ketoxime (CXCVII) and acetylene in the superbasic catalytic system KOH–dimethyl sulphoxide system, isomerises to the *ON*-divinylhydroxylamine (CXCIX), which undergoes the Cope oxaza-rearrangement to the intermediate (CC), which has been isolated in the form of the dihydropyrrole (CCI). On heating, the latter is readily converted into the pyrrole (CCII).[130]

Apart from the examples of the Cope oxaza-rearrangement, occurring with dissociation of the N–O bond, which has been described above, reactions are known for the hexa-1,5-diene system in which the nitrogen and oxygen atoms are not linked directly to one another.

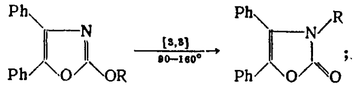
Thus dihydropyranimines (CCIII) have been made to undergo a thermal (200–250 °C) rearrangement to the aldehydes (CCIV) via the mechanism of the Cope oxaza-rearrangement:[133]



where R = s-butyl, benzyl, phenyl, or cyclohexyl.

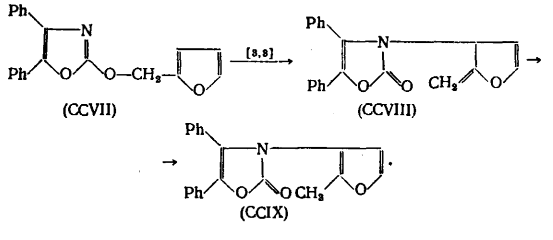
An analogous scheme has been proposed for the rearrangement of *O*-cyclohexynyl carbimidates.[134]

The thermal rearrangement of 2-allyloxyoxazoles (CCV) to 2-oxazolinones (CCVI) has been described:[135,136]



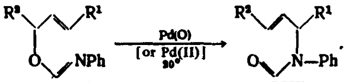
R = allyl, substituted allyl.

The hypothesis that the reaction (CCV) → (CCVI) proceeds via the stage of the [3,3]sigmatropic rearrangement has been confirmed by the isolation of the intermediate (CCVIII) on heating the oxazole (CCVII) in a benzene–pyridine mixture:[136]



On heating or in the presence of acids, the adduct (CCVIII) is converted into the oxazolinone (CCIX).

The use of the complex palladium catalysts $Pd(PPh_3)_4$ and $Pd(PhCN)_2Cl_2$ makes it possible to carry out the Cope oxaza-rearrangement under mild conditions.[137] *O*-allyl *N*-phenylformimidates (CCX) readily rearrange at room temperature to the corresponding *N*-allyl-*N*-phenylformamides (CCXI):



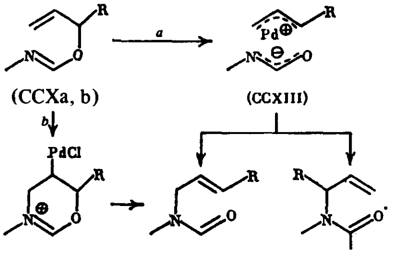
(CCX) (CCXI)

a) R^1=CH_3, R^2=H
b) R^1=H, R^2=CH_3

It has been shown that the regioselectivity of the rearrangement (CCX) → (CCXI) depends on the nature of the palladium complex. Thus catalysis by the palladium(II) complex of the rearrangement of the imidates (CCXa) and (CCXb) leads solely to the corresponding formamides (CCXIa) or (CCXIb), while a zerovalent palladium complex affords in both cases a 2:1 mixture of the products (CCXIa) and (CCXIb) (it is noteworthy that the stereochemistry of the process has not been rigorously established.

These results can be explained by two possible mechanisms of the interaction of the palladium complex with the hexadiene system (CCX)[137] (Scheme 21):

Scheme 21

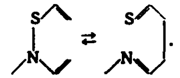


(CCXa, b) (CCXIII) (CCXII) (A) (B)

The zerovalent palladium complex catalyses the rearrangement proceeding via the formation of the allyl π-complex (CCXIII) by its oxidative addition to the C–O bond of the formimidate (pathway *a*). There is then a possibility of the formation of two isomers (A) and (B). On the other hand, the palladium(II) complex tends to form the six-membered intermediate (CCXII) (pathway *b*), which leads to only one product (A) [an analogous mechanism has been proposed for the Cope rearrangement catalysed by palladium(II)[138] and mercury(II)[139] complexes].

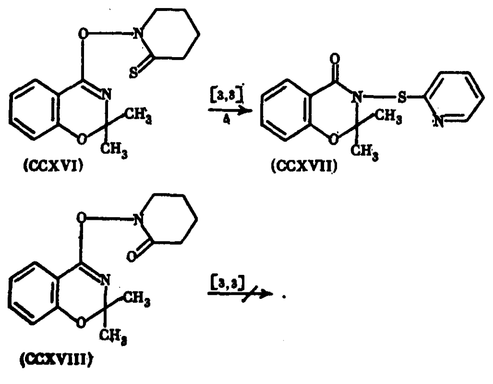
2. The Cope Thiaza-rearrangement

The Cope thiaza-rearrangement has a number of features which distinguish it from the oxaza-analogue. Firstly, systems of type (CCXIV), for which the transformation (CCXIV)→(CCXV) would be possible (see, for example, Padwa and Cohen[136]), are unknown:



(CCXIV) (CCXV)

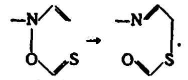
On the other hand, the formation of the S–N bond [i.e. the transition (CCXV) → (CCXIV), which has not been observed for the *ON*-system] via the thermal [3,3]sigmatropic rearrangement of the benzoxazine (CCXVI) to the benzoxazinone (CCXVII) has been described:[140]



(CCXVI) (CCXVII) (CCXVIII)

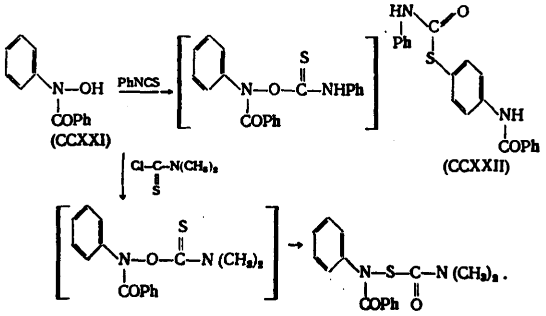
The possibility of the reaction (CCXVI) → (CCXVII) evidently arises not only from the presence of four heteroatoms and the labile N–O bond in the reacting system (CCXVI) but also from the adequate stability of the N–S bond formed, because the benzoxazine (CCXVIII) is not involved in a similar rearrangement.[140]

At the same time the attempts to achieve a concerted reaction of the type (CCXIX) → (CCXX) were unsuccessful:



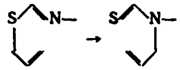
(CCXIX) (CCXX)

Thus the interaction of *N*-benzoyl-*N*-phenylhydroxylamine (CCXXI) with phenyl isothiocyanate[141] and dimethylthiocarbamoyl chloride[142] led to the formation of the products of the *n*-rearrangement [compound (CCXVII)] and 1,3-migration [compound (CCXXIII)] respectively, which virtually rules out a concerted mechanism:



(CCXXI) (CCXXII) (CCXXIII)

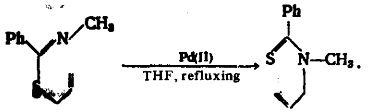
The rearrangement of *S* allyl thiomidates (CCXXIV) → (CCXXV) has been investigated in a number of studies:[143–147]



(CCXXIV) (CCXXV)

It has been shown[143] that the rearrangement of allylthiocaprolactam proceeds via a zwitter-ionic intermediate and not via a concerted mechanism.

Palladium(II) salts [$PdCl_2$ or $PdCl_2(PhCN)_2$ [144]] proved to be effective catalysts of the Cope thiaza-rearrangement of *S*-allyl thioimidates:

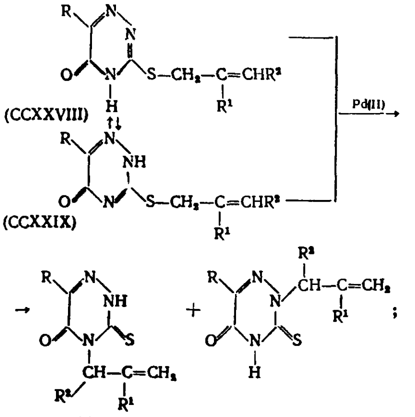


(CCXXVI) (CCXXVII)

Thus the *S*-allyl thioimidate (CCXXVI) is converted quantitatively into the *N*-allylthioamide (CCXXVII) in the presence of a bivalent palladium salt, while the usual thermal reaction (150 °C, decalin) leads only to the product of the isomerisation with respect to the double bond in the allyl group. The reaction mechanism proposed by the authors[147] includes the formation of a six-membered intermediate analogous to that presented in Scheme 21.

The Cope thiaza-rearrangement of 3-allylthio-4*H*-1,2,4-triazin-5-one (CCXXVIII) and 3-allylthio-2*H*-1,2,4-triazin-5-one (CCXXIX), catalysed by palladium(II) complexes, leads to a mixture of the thiones (CCXXX) and (CCXXXI) as a result of the tautomeric equilibrium (CCXXVIII) ⇄ (CCXXIX)[146,147] (Scheme 22).

Scheme 22



(CCXXVIII)
(CCXXIX)
(CCXXX) (CCXXXI)
R=H, Ph, CH_3; R^1=H, CH_3; R^2=H, CH_3.

During the preparation of the manuscript, a number of studies of the mechanism and synthetic use of the aliphatic[148–151] and aromatic[152–155] Cope 3-aza-rearrangements have been published. The Cope 2-aza-rearrangement has been investigated in relation to the cyclisation of *N*-acyliminium salts[156,157] and a series of oxazoline derivatives.[158] The fairly rare Cope 1-aza-rearrangement, achieved under the conditions of flash vacuum thermolysis, has been described.[159] The Cope oxaza-rearrangement has been investigated[160–162] and the thiaza-rearrangement has been used to synthesise condensed thiazole systems[163–164] and also for the synthesis of the indole ring.[165,166]

Thermotropic Liquid Crystal Polymers with Mesogenic Groups in the Main Chain

E.E.Pashkovskii

The present state of the synthesis and studies of the structure and properties of thermotropic liquid crystal polymers and copolymers with mesogenic groups in the main chain is examined and the thermodynamic and structural principles of the identification of the polymeric mesophases as well as the influence of the chemical structure of the mesogenic blocks and flexible spacers on the mesomorphic properties of the polymers are discussed.
The bibliography includes 93 references.

I. INTRODUCTION

The interest in the liquid crystal state of polymers which has arisen in the last decade is due to a large extent to the possibility of obtaining ultrastrong highly modular fibres based on polymers exhibiting mesomorphic properties.[1-9] In addition, the study of the nature of the polymeric liquid crystal (LC) state is of independent interest. The lyotropic mesomorphism of polymers has long been known and has been thoroughly investigated; the principal results obtained during the last 20 years in this field have been surveyed in a monograph.[1] Thermotropic LC polymers have been discovered recently and the main direction of studies in this field has been associated with the investigation of the LC state of polymers with mesogenic groups in the side branches.[5,6-8,10] The main idea underlying the creation of such polymers has been the combination of properties characteristic of polymers (including their ability to form films and fibres) with the properties of low-molecular-weight LC compounds. The LC properties were manifested only when the behaviour of the side chains is relatively autonomous. This means that the structural transformations occurring in such polymers at the level of mesogenic groups need not necessarily be associated with the behaviour of the main chain. The mesomorphic properties of such polymers can be in many respects similar to the properties of low-molecular-weight liquid crystals: indeed it has been found that the differences between the electro-optical properties over a wide range of polymers are quantitative but not qualitative.[10]

When the mesomorphic properties of polymers are determined by the structure of the main chain, the differences between the low-molecular-weight liquid crystals and polymers are qualitative, since the structure of the mesophase is found to be related to the macroconformations of the molecules. The LC state of linear polymers is directly related to the anisotropy of the properties induced by the chain structure of the molecules. It would seem that the presence of long chain molecules should give rise to the possibility of the appearance of the LC state in the majority of polymeric systems. Nevertheless the existence of structures exhibiting order intermediate between the types of order which obtain in the crystalline and isotropic states does not always justify the inclusion of such structures among LC structures. Such structures obtain in polyphosphazenes, in polytetrafluoroethylene, in polyethylene at a high pressure, and also on fusion of orientationally-crystallised flexible-chain polymers.[11] A common feature of such structures is a pseudo-hexagonal packing of the chains arising as a result of the appearance of the rotational degree of freedom around the long molecular axis. It is known that such "rotational-crystalline" states occur in many low-molecular-weight compounds[12] (for example, in normal hydrocarbons), and yet such compounds are not classified as liquid crystals. According to Wunderlich's classification, the mesomorphic structures occurring in flexible-chain polymers belong to the category of crystals with elements of conformational disorder.[11]

Thus the chain structure of polymeric molecules is not a sufficient condition for the manifestation of LC properties characterised by the presence of a high degree of orientation order in combination with total or partial absence of positional order.[13]

Orientational order occurs to the maximum extent in complex aromatic polyethers containing only *para*-substituted benzene rings. However, the high anisometry of the molecules increases the stability of the crystal lattice, so that the region in which the mesomorphic properties are manifested lies above the chemical decomposition temperature. One of the ways of reducing the melting point involves the introduction of asymmetric groups or substituents in the *ortho*- and *meta*-positions in the polymer chain,[14] which hinders the packing of the macromolecules in the crystal and lowers appreciably the melting point. The occurrence of mesomorphism in such systems is caused by the rigidity of the polymer chain, which in many respects engenders a similarity between the aromatic polyethers and lyotropic LC polymers such as aromatic polyamides. The high equilibrium rigidity of such polymers results in the appearance of the isotropic state only in the presence of a solvent, i.e. for truly rigid-chain polymers thermotropic mesomorphism is impossible.

According to Flory's theory,[15] which describes the orientational ordering of solutions of rigid-chain polymers, there is a maximum critical axial ratio $p = l/d$ (where l is the length of the molecule and d its diameter) above which the isotropic phase is absolutely unstable in the absence of solvent. The concept of the critical axial ratio, introduced for absolutely rigid rodlike molecules, retains its significance in the description of the ordering in a solution of freely jointed chains,[16] and the quantity $p = A/2d$ represents the anisometry of the

Kuhn segment having a length *A*. Thus the anisometry of a section of the chain with a length of the order of *A* is a criterion of the possibility of the appearance of thermotropic mesomorphism: thermotropic behaviour is observed for sufficiently flexible chain polymers for which the condition $A < 2pd$ holds. The increase in the molecular diameter by the introduction of asymmetric substituents or benzene rings in the *ortho*- and *meta*-positions can entail the complete loss of capacity for crystallisation and also the suppression of LC properties.

One of the most convenient methods of regulating the mesomorphic properties involves the introduction of flexible sections (spacers) into the mesomeric skeleton of the macromolecule. Thermotropic LC polymers, whose mesomorphic properties are determined by the structure of the main chain consisting of rigid mesogenic (*R* = rigid) and flexible (*F* = flexible) fragments (*RF*-polymers) constitute systems with a specific combination of the properties of flexible-chain polymers and low-molecular-weight liquid crystals. The synthesis of *RF*-polymers has given rise to a series of fundamentally new problems for both the physics of liquid crystals and for the physics and chemistry of polymers.

The principal problem among those described involves the elucidation of the relation between the thermotropic mesomorphism of polymers and the LC state of low-molecular-weight compounds, whose nature has been fairly thoroughly investigated.

This problem has the following aspects: is there a possibility of the classification of a structural type of polymeric mesophases on the basis of the classification of low-molecular-weight compounds; how are the properties of the polymers related to the properties of low-molecular-weight model compounds and how does the molecular-weight (MW) of the polymer influence its mesomorphic properties and for what values of MW are the specific features of the LC state realised; to what extent can the ideas and methods of study traditional in the physics of polymers be applied to thermotropic LC polymers.

This review analyses the studies of the synthesis and properties of *RF*-polymers in which the questions formulated above have been reflected; important fields such as electro-optics,[17] rheology, mechanical properties,[18,19] and dielectric properties have remained outside the framework of the review, since the study of these aspects of the thermotropic mesomorphism of *RF*-polymers is only just beginning.

II. CLASSIFICATION AND IDENTIFICATION OF THERMOTROPIC LIQUID CRYSTALS

Liquid crystals can be divided into three main types: nematic, cholesteric, and smectic.[20] In nematic liquid crystals the centres of gravity of the molecules are distributed at random and long-range order is observed only with respect to their orientation (Fig.1*a*). The cholesteric mesophase is illustrated schematically in Fig.1*b*. The centres of gravity of the molecules lie in layers without any order and in each layer, the director (i.e. the vector characterising the preferential direction of the long molecular axes) is located in the plane of the layer. On passing from one layer to the next, it rotates by a small angle and a structure with a helical order is formed overall. Smectic liquid crystals, where the centres of gravity are located in layers but the director is no longer in the plane of the layer, forming an angle with the latter, are the most ordered (Fig.1c). The thermodynamic and structural aspects of smectic mesomorphism have been described in two communications.[21,22]

The knowledge of the type of mesophase makes it possible to infer the behaviour of the substance as a function of the external conditions (temperature, pressure, and external field strength). The main question which arises in the study of newly synthesised LC compounds is therefore related to the elucidation of the type of mesophases formed by the given compound and also to the determination of the temperature limits of their existence.

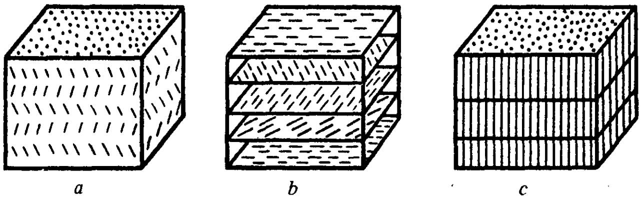

Figure 1. Structural types of mesophases: *a*) nematic; *b*) cholesteric; *c*) smectic.[20]

One of the commonest methods for the determination of the type of mesophase involves the observation of the optical textures of the liquid crystals in polarised light. A specific type of optical texture is associated with the behaviour of the director in the layer of the preparation, which is specific to the given type of liquid crystal. All the textures of LC compounds observed hitherto have been compiled in an atlas.[21] The most reliable identification method is X-ray diffraction, whose foundations in relation to low-molecular-weight liquid crystals have been described in a review;[23] the application of the diffraction methods in the study of mesomorphic polymers has been described by Blumstein.[3] The use of the given method for the identification of mesophases formed by *RF*-polymers is limited owing to the difficulty of obtaining specimens with a homogeneous orientation in a magnetic field.[24–26]

The foundations of the classification of the structural types of mesophases based on calorimetric data have been laid by Barall and Jonson,[27] who examined the ratio of the entropy of their transition from the LC state to the isotropic liquid melt (LC–I) ΔS_i to the overall entropy change in all the transitions undergone by the liquid crystal ΔS_T (this includes the polymorphic transformations in the crystalline phase). It was found that this quantity ($\Delta S_i/\Delta S_T$) is usually small for the nematic phase (of the order of 10^{-2}), while for the smectic phase it is an order of magnitude higher. Analysis of the thermodynamic parameters of the transition showed that calorimetric data can be used for the identification of liquid crystals.

The study of the phase equilibria in mixtures of LC compounds is an extension of the identification method. It is based on the hypothesis that two components can be infinitely miscible when their mesophases are isomorphous. For low-molecular-weight liquid crystals, there are extensive theoretical and experimental data concerning the character of the coexistence of the phases in binary mixtures.[28] The application of the given method to the investigation of polymers has been described in a series of recent studies.[29–31]

For polymeric mesomorphic systems, the problem of identification is greatly complicated, because so far there have been no classifications of polymeric liquid crystals which could satisfy investigators. For this reason, in most studies the authors either use the existing classification for low-molecular-weight compounds or they refrain from any definite conclusions about the type of mesophases. Furthermore, in the identification of polymeric liquid crystals there is a possibility that complications may arise due to kinetic causes, because observations are carried out under conditions remote from thermodynamic equilibrium. Thus the principal concepts accumulated in the study of low-molecular-weight compounds can be applied to the study of the mesomorphism of polymers only with caution since the nature of the polymeric mesophases may differ greatly from that of the low-molecular-weight liquid crystals.

III. THE ROLE OF FLEXIBLE SPACERS IN THE ORDERING OF LIQUID CRYSTAL POLYMERS

In 1975 de Gennes predicted the possibility of the existence of an enantiotropic nematic phase in polymer systems formed by linear flexible macromolecules containing mesogenic groups in the main chain.[32] The synthesis and mesomorphic properties of such polymers were reported at the same time.[33] Subsequently the above investigations developed in the USA, France, the USSR, and the Federal Republic of Germany, which led to the synthesis of tens of *RF*-polymers.[4,34]

According to Flory's theory,[35] for any flexible chain polymer the first (formal) crystallisation stage consists in the cooperative orientational ordering of the polymer chain. This state of orientational order can, however, be thermodynamically unstable in relation to the crystalline phase, which leads to spontaneous crystallisation. This process, leading to a "parallel arrangement" of the chains, corresponds to monotropic LC behaviour. The polyesters synthesised by Roviello and Sirigu are capable of forming an enantiotropic LC phase.[33,36]

The method of synthesis of *RF*-polymers is distinguished by an appreciable flexibility, since wide-scale variation of the chemical nature and molecular parameters of the spacers and mesogenic blocks has been postulated. Aliphatic polyenes of 4,4'-dihydroxy-αα'-dimethylbenzylideneazine with $n = 8$, 10, and 12 carbon atoms in the spacers [Table 1, compound (I)] have been investigated.[33] X-Ray diffraction studies have shown that these polymers are partly crystalline. With the aid of differential scanning calorimetry (DSC) and optical studies, it has been established that the polymers exhibit a first-order transition, which may be associated with the fusion of the crystal structure and also a transition from the LC state to the isotropic state. Comparative studies on the thermodynamic properties of polymers of different chemical nature and model low-molecular-weight compounds demonstrated an appreciable difference between the molar entropies of the LC–I transition.[36,37] For the low-molecular-weight models, this quantity was $\Delta S_i \cong 3$ J mol^{-1} K^{-1}, while for the polymers $\Delta S_i = 13$–16 J mol^{-1} K^{-1}. It has also been observed that ΔS_i is almost independent of the length of the flexible fragments, which has been attributed to the use of the representation of the nematic phase where the disordered flexible part of the chains behaves like an isotropic liquid, i.e. the chains are not involved in the formation of orientational order and can be regarded as solvent molecules. The same conclusions have been reached by other investigators[38] in the study of the temperature dependence of the molar volumes of a series of polymers with flexible spacers of different lengths. The contribution of aliphatic chains to the molar volume proved to be close to the molar volume of amorphous polyethylene, which supports the hypothesis of a disordered conformation of flexible spacers in the nematic phase. However, this conclusion must be made with caution, since the molar volume is not very sensitive to small conformational changes. The conformational state of spacers in different phase states for polymers based on terephthaloylbis(4-hydroxybenzoic) acid [Table 1, compound (II)] has been determined by IR spectroscopy.[39,40] Despite the fact that the conformational composition of the polymers in the LC and isotropic states is almost the same, the flexible-chain spacers in such polymers are partly oriented, i.e. play a definite role in the establishment of the LC order. The orientational order of the flexible sections Q_F is probably related to the redistribution of the rotational-isomeric forms in the LC state compared with the isotropic state. The parameter of the orientation of the mesogenic sections Q_R[†] is different from Q_F and $Q_R > Q_F$. When the length of the spacer is altered, Q_F hardly changes, which indicates a decisive contribution of the intermolecular interactions in the mesogenic sections of the macromolecule. It has been shown that Q_R and Q_F change in the temperature range corresponding to the existence of LC order; under these conditions, Q_R diminishes faster than Q_F, which is due to the temperature dependence of the intermolecular interaction in the mesogenic sections of the macromolecule.

Table 1. Chemical structures and transition temperatures of certain types of *RF*-polymers.

Structure of monomeric unit	*n*	Transition temperature, °C*	Refs.
 (I)	10	*C* 208 *N* 322 *I*	[33]
 (II)	10	*C* 223 *S* 297 *I*	[34]
 (III)	10	*C* 119 *N* 165 *I*	[41]
 (IV)	12	*C* 200 *I* (on heating), *I* 177 *N* 172 *C* (on cooling)	[49]

*C = crystalline phase, N = nematic phase, S = smectic phase, I = isotropic phase; the corresponding transition temperatures are shown between two symbols representing the phases.

[†] The order parameter $Q = \langle(3\cos^2\theta - 1)/2$, where θ is the angle between the rigid section of the chain (or a segment of the flexible fragment) and the anisotropy axis.

The temperature dependence of the order parameter of the polymer based on 4,4'-dihydroxy-2,2'-dimethylazoxybenzene and decamethylene glycol [Table 1, compound (III)] has been determined.[41] The authors note the unusually high order parameter in the transition to the isotropic state for the polymer compared with the low-molecular-weight nematic compound having the initial structure. For the given polymer, Q_R and Q_F vary in parallel and are almost identical. The transition from the isotropic to the LC state is accompanied by a sharp conformational alteration in the spacers: in the LC phase, they have the straight-chain conformation.

The results presented demonstrate the possibility of the operation of two different mechanisms of the ordering of the *RF*-polymers: in the first case, the stability of the mesophase is determined mainly by the intermolecular interaction of the mesogenic fragment and $Q_R > Q_F$, while in the second $Q_R \cong Q_F$, which indicates the decisive role of the macromolecular order. The second variant presupposes the virtually complete ordering of the flexible fragment.

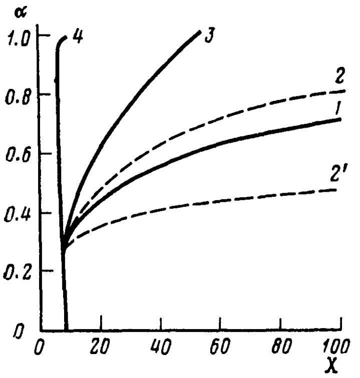

Figure 2. Phase diagram for the system of *RF*-macromolecules; α = volume fraction of flexible fragments; X = length of monomeric unit; flexibility parameter f_0; 1) 1.0; 2) and 2') 0.8; 3) 0.6; 4) 0.4.[42]

The role of the flexible spacers in the orientiational ordering has been examined in a number of studies.[42,43] On the basis of the Flory model for *RF*-polymers,[44] account has been taken of tendency of the LC phase for the flexible fragments to become oriented along the anisotropy axis. One of the most interesting results of this investigation is the conclusion that anisotropic phases of two types can exist as a function of the relative length of the flexible spacers and their rigidity. Fig.2 presents the phase diagram. The flexibility of the spacers f_0 is defined by the equation[35]

$$f_0=\frac{(z-2)\cdot\exp(-\varepsilon/kT)}{1+(z-2)\exp(-\varepsilon/kT)},$$

where z is the coordination number of the lattice and ε the difference between the free energies of the *trans*- and *gauche*-conformers. For an undiluted polymer, the conditions governing the stability of the isotropic phase is the inequality $f_0 > 0.63$. Curve *1* has been obtained without taking into account the finite flexibility of the flexible fragment. The nematic phase is thermodynamically stable in the region to the right of curve *1*. Curve *2* consists of two branches (*2* and *2'*), which corresponds to the fact that, for $f_0 = 0.8$ and also for any $f_0 > 0.63$, there is a possibility of an additional phase transition between two anisotropic phases: a highly ordered phase stable for low values of α and a phase with little order, which is stable for high values of α. When f_0 diminishes, the region of stability of the low-order anisotropic phase shifts towards higher values of α, disappearing at $f_0 = 0.63$. According to Flory,[35] when $f_0 < 0.63$, order obtains even for α = 1 (curves *3* and *4*).

Thus, for sufficiently rigid spacers, the behaviour of this system does not differ from that of a melt comprising rigid rods. For fully flexible spacers, there is a possibility of forming a low-order LC phase, and finally, for spacers with intermediate flexibility, either a highly ordered phase in which the flexible spacers participate in the overall ordering process or a low-order phase in which the spacers play the role of a solvent can be formed depending on the length of the spacers.

This result has been obtained in a somewhat different form by Birshtein and Kolegov,[45–47] who showed that, for polymer solutions containing *RF*-macromolecules, anisotropic phases of two types can exist: in the first case the ordering develops at the level of rigid segments and the chain retains overall the structure of a disordered coil (segmental ordering); in the second case the chain as a whole is ordered and intermolecular interactions ensure the loss of internal flexibility (macromolecular ordering). The occurrence of one or other type of ordering depends on the concentration of the rigid blocks in the solution and also on the mechanism of the flexibility. For the intermediate case of non-freely-jointed rigid blocks, an increase in the concentration of the solution initially entails a transition to the LC state by the segmental mechanism and only then, at high polymer concentrations, does macromolecular ordering occur.

Thus the main difference between the mesomorphisms of polymers and low-molecular-weight liquid crystals reduces to the possibility of the cooperative behaviour of the monomeric units, which depends in a specific manner on the chemical nature of the mesogenic fragments, on the length and nature of the flexible spacers, and also on the way in which they are joined to the mesogenic group. For this reason, the identification of the type of polymeric mesophase must include an analysis of the type of ordering on passing from the isotropic to the LC state. The occurrence of a particular type of ordering in the polymer system is, however, inevitably accompanied by the superposition of kinetic effects, which can greatly increase the uncertainty in the interpretation of the experimental results. The separation of the thermodynamic effects in the I–LC transition constitutes an interesting and important problem whose solution would be a major step towards the possibility of the technological use of *RF*-polymers.

The need to take into account the kinetics of the phase transitions of *RF*-polymers follows from ideas common to flexible-chain polymers, according to which there exist appreciable differences between the mechanisms of the fusion of flexible linear macromolecules and small rigid molecules.[48] These differences are associated with the decisive role of the conformational transformations in the phase transitions of flexible-chain polymers. For this reason, the thermodynamic parameters obtained in the study of phase transitions refer in most cases to the so-called irreversible fusion, i.e.

to fusion under conditions different from those in thermodynamic equilibrium.# The polymer (IV) (Table 1, $n = 12$), which exhibits monotropic mesomorphism, has been investigated.[49] Specimens of the polymer which have not undergone a preliminary heat treatment exhibited a "fictitious" enantiotropic mesomorphism. When the specimens were annealed, the melting point approached the equilibrium value, which proved to be higher than the temperature of the transition to the isotropic melt for the non-annealed specimens. Thus the LC behaviour is manifested by this polymer only under conditions remote from thermodynamic equilibrium. The equilibrium melting point of the polymer (II) (Table 1, $n = 10$) has been determined[50] and has been found to be appreciably higher than the observed melting point. Evidently, in order to understand the nature of the mesomorphism of the *RF*-polymers and also to discover a relation between chemical structure and mesomorphic properties, it is essential to know the equilibrium thermodynamic characteristics of the transition from the crystalline to the LC phase and of the LC–I transition.

Studies of the thermodynamic properties of polymers based on terephthaloylbis(4-hydroxybenzoic) acid[51] in dilute solution have shown that the behaviour of their *RF*-polymers is analogous to the behaviour of the usual flexible chain polymers, since the size of the Kuhn segment does not greatly exceed the size of the repeat unit. Studies on the conformations of the *RF*-macromolecules by measuring the magnetic double refraction established that, in a dilute solution and also in an isotropic melt, the molecules exist in coiled conformations.[52] The Cotton–Mouton constants for model low-molecular-weight compounds, *RF*-polymers, and flexible-chain polymers proved to be of the same order of magnitude and at the same time one–two orders of magnitude less than for aromatic *para*-polyamides and DNA.

Studies on the thermodynamic parameters of the I–LC transition of the polymer (III) ($n = 10$) with different molecular weights showed that ΔS_i increases sharply with increase of the MW, which indicates an increase of the contribution of the flexible spacers to the disordering process[53] (Fig.3). At the same time, the dependence on MW reaches saturation after the attainment of the MW corresponding to approximately 6–8 repeat units, i.e. the cooperative nature of the behaviour of the repeat units does not extend to the entire macromolecule. For high-molecular-weight specimens, the form of the ^1H NMR line for the nematic and crystalline phases was the same,[41] while for oligomeric specimens the spectra of the nematic phase were characterised by dipole splitting typical of homogeneously oriented nematic single crystals. For specimens with a high MW, a structural model of the "multidomain" type, postulating the existence of a marked spatial inhomogeneity, whose main source is the breakdown of orientation (disclination), has been proposed. It is natural to assume that the correlation radius of the orientation of the high-molecular-weight specimens does not exceed the length of 6–8 repeat units, which corresponds to the degree of polymerisation for which the dependence of ΔS_i on the MW reaches saturation. On the basis of magnetic double refraction data, thermodynamic studies, and NMR spectroscopy, it has been concluded that the I–LC transition in oligomeric specimens ($M_n = 1700$–4000) is characterised by a sharp conformational transformation of randomly coiled chains into chains, which are extended to a high degree. In the study of the thermodynamic properties of the *RF*-polymer combined with the measurement of the order parameter in the LC–I transition in the monomer–dimer–polymer series, similar results were obtained[54] (Table 2), and yet the authors nevertheless concluded that the polymeric mesophase has an intermediate degree of order, since, despite the fact that the order parameter of the polymer ($Q = 0.6$) is appreciably higher than for the monomeric compound, it is nevertheless insufficiently high to represent the nematic phase as a set of fully extended chains. The authors assume that, for purely thermodynamic reasons, the system of randomly packed chains undergoes a first-order transition to a nematic phase with an intermediate order.[55]

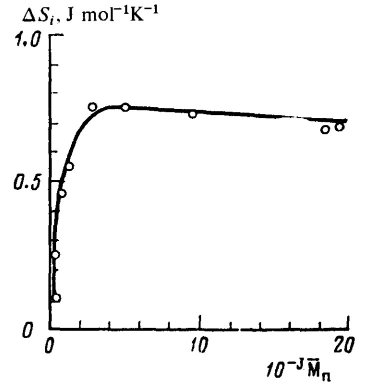

Figure 3. Dependence of the entropy of the LC–I transitions ΔS_i on the molecular weight of the polymers (III) (Table 1); ΔS_i has been referred to the fraction of rigid groups in the main chain.[53]

Table 2. Thermodynamic parameters of the LC–I transition for a nematic polymer, monomer, and dimer.[54]

Specimen*	T, °C	ΔH, kJ mol^{-1}	ΔS, J mol^{-1}K^{-1}	Q

Polymer —[—R$(CH_2)_{10}$—]— (V)	215	6.53	13.4	0.6

*R =
$$-O-C_6H_4-\underset{\underset{O}{\|}}{C}O-C_6H_4-O-$$

In a study of the thermodynamic properties of the copolymer of ethylene terephthalate with *p*-hydroxybenzoic acid, Krigbaum[56] reached the same conclusions. He showed that, even when, as suggested by Vol'kenshtein,[57] a correction associated with the torsional vibrations (on the assumption that they are fully excited in the nematic and isotropic phases) is introduced into the expression for the free energy, $\Delta S_i/\Delta S_T$ remains approximately 0.45, which is appreciably higher than the experimental value for the polymer investigated ($\Delta S_i/\Delta S_T = 0.11$). It was therefore suggested that

---

According to Wunderlich's terminology,[48] irreversible fusion is understood as transition from a metastable crystalline phase to a supercooled isotropic or LC phase and also as fusion accompanied by the superheating of the crystal. Here we employ the concept of irreversible fusion in its first meaning.

in the nematic phase the parameter f_0 is non-zero, i.e the mesophase is characterised by the presence of defects in the form of correlated bends in the chain. Thus the ratio $\Delta S_i/\Delta S_T$ deduced from the lattice model of the nematic phase with allowance for the modification mentioned above decreases from 1 to 0.59 or, when the contribution of the torsional vibration approaches the values calculated from polyethylene,[57] from 0.45 to 0.26. Furthermore, in the lattice model no account is taken of the contribution of the entropy change associated with the increase in volume on fusion. Allowance for this contribution should further diminish the $\Delta S_i/\Delta S_T$ predicted by the theory.

The study of Ianelli et al.[58] was devoted to the determination of the ratio $\Delta S_i/\Delta S_T$ for the polymer (IV) (Table 1) with n = 7 and 9–12 CH_2 groups in the spacers. The authors began with the hypothesis that the value of ΔS_i determined from direct calorimetric measurements correspond to equilibrium. ΔS_T was determined by studying the melting point depression of the polymers with formation of an isotropic melt in the presence of a low-molecular-weight solvent. The ratio $\Delta S_i/\Delta S_T$ amounted to 0.15–0.17 for even values of n and to 0.07–0.09 for odd values, which implies significant differences between the ordering mechanisms for polymers with odd and even numbers of carbon atoms in the spacers. ΔS_T for polymers is usually represented as the sum of three contributions:[59]

$$\Delta S_T = \Delta S_{\text{pos}} + \Delta S_{\text{or}} + \Delta S_{\text{conf}}$$

associated with the positional, orientational, and conformational disordering. For flexible-chain polymers, ΔS_{conf} exceeds all the remaining contributio s to ΔS_T; thus ΔS_{conf} amounts to 75% of the total entropy change for polyethylene[60] and to 65% for poly(ethylene terephthalate).[61] There are no data at present which would make possible analogous calculations for *RF*-polymers, but it is reasonable to suppose that in this case too the contribution of ΔS_{conf} to ΔS_T is decisive. The quantity ΔS_T calculated for each rigid group in the chain obeys the general rule for linear flexible-chain polymers (Table 3), which means that the nature of the isotropic melt for *RF*-polymers is the same as for flexible-chain polymers, which agrees well with the results of magnetic double refraction measurements.[52] Since ΔS_T calculated for each rigid group of the chain in *RF*-polymers is 6–8 J mol^{-1} K^{-1}, presumably the fusion of flexible-chain polymers and *RF*-polymers has the same character. If the conformational contribution to ΔS_T is decisive, the parameter $\Delta S_i/\Delta S_T$ can be regarded as a structural characteristic reflecting the degree of macromolecular order of the polymer chains in the LC phase.

The important role of the macromolecular order is manifested in the change of the thermodynamic properties in homologous series of polymers.§ Differences in the character of the changes in the parameters of the LC–I transition in the homologous series of monomeric, dimeric, and polymeric liquid crystals have been discovered.[62] In the homologous series of monomeric compounds, the usual variation of the mesomorphic properties with increase of the length of the alkyl groups is observed. For certain intermediate lengths, there is a transition from the nematic to the smectic mesophase accompanied by a sharp increase of the clarification entropy; the even–odd effect is most striking for the first homologues and becomes smoothed out with increase of the number of CH_2 groups in the aliphatic components. For the dimer, ΔS_i oscillates about the mean value intermediate between the ΔS_i for the polymer and the monomer and the even–odd alternation becomes more marked on moving from the lowest to the highest homologues (Fig.4). For the polymer, the even–odd alternation is very pronounced and, for all the even and all the odd homologues, the ΔS_i are almost identical. The pronounced even–odd effect for the polymers can be explained by the stronger relation, than in the low-molecular-weight liquid crystals, between the molecular structure of the aliphatic components and the mesomorphic properties. Two different types of ordering, observed for the polymers (III) with aliphatic spacers containing 2–14 carbon atoms, have been described.[63] The first type of ordering has been established for polymers with an even number of carbon atoms (n = 4, 6, 8, 10, 14) and the second for polymers with odd n = 5, 7, 9, 11, 13. The first type is characterised by a higher order parameter $Q = 0.75$ at the clarification point than the second, for which $Q = 0.59$. A high degree of order is achieved as a result of the extension of the spacers, which has been demonstrated by analysing the NMR line form.[41] The corresponding differences between the two types of ordering for polymers with even and odd numbers n are exhibited also in the analysis of thermodynamic data and X-ray diffraction data. The authors explained these features in the following way: the probably of the *trans*-conformation is higher for the first three even bonds, starting from the junction point with the mesogenic component. If both ends of the alkyl chain are fixed, the tendency towards an increase of the number of *trans*-conformers extends along the chain in opposite directions. For an even number of bonds (n is odd), interference results in a decrease of the average ratio of the *trans*- and *gauche*-conformers, while for an odd number of bonds (n is even) the ratio of these conformers actually increases.

Table 3. Thermodynamic characteristics of the C–LC, C–I, and LC–I transitions of flexible-chain and *RF*-polymers*.

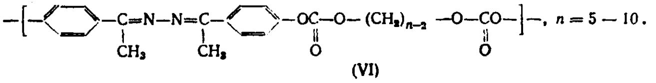
*T in °C, ΔH in kJ mol^{-1}, ΔS in J mol^{-1} K^{-1}; C–LC and C–I represent transitions from the crystalline to the LC and isotropic states respectively.

The thermodynamic aspects of the even-odd effect for the *RF*-polymers have been investigated in greatest detail by Roviello and Sirigu.[64] Fig.5 presents the dependence of ΔS_i on n for polymers of three types: (I) (Table 1, n = 6–12), (IV) (Table 1, n = 6–12), and



(VI)

In contrast to the polymers (I) and (IV), the polymers of the (VI) series show virtually no even-odd effect. This finding

---

§ Here and henceforth the concept of "homologous series" is that of a series of compounds (polymeric or monomeric) which differ from one another by the number of atoms in the flexible regions.

indicates the decisive role of the structure of the flexible spacers in determining the thermodynamic parameters of the LC–I transition. The replacement of the methylene groups in the spacers of the polymers (VI) by oxygen atoms probably lowers the conformational limitations imposed on the structure of the spacers by the nematic ordering. The authors assume that the question of the role of the flexible spacers in the LC ordering still remains open. Indeed, the study of the thermodynamic parameters of the LC–I transition in *RF*-polymers has shown that, since ΔS_i is characterised by an appreciable even-odd effect, the description of the LC order as a set of rigid rods connected by spacers, playing the role of a solvent, is illegitimate. On the other hand, the hypothesis of an appreciable role of the conformational transformations in the LC–I transition conflicts with the absence of a dependence of ΔS_i on *n* for even and odd values of *n*. If, as follows from the study of Martins et al.,[41] the flexible spacers in the LC phase were almost fully ordered, a marked dependence of ΔS_i on *n* should have been observed. It is essential to note that the estimation of the structure of the spacers by ^{1}H NMR involves the correct allowance for the dipolar contributions to the broadening of the lines due to the protons in the aliphatic and aromatic component, which can be achieved only on the basis of a more or less legitimate hypothesis about the conformations of the spacers. Recent results[65] have shown that the order parameter of the alkyl chains in the LC phase is not the same for the external and internal methylene groups (0.4 for the external groups and 0.3 for the internal groups). It is necessary to note that the studies were performed for a polymer with deuteriated spacers, which permitted the absolute determination of the order parameter of the spacers not requiring hypotheses about their conformational state. For this reason, the initial hypothesis of the stability of the complete ordering of the spacers is not sufficiently well founded.

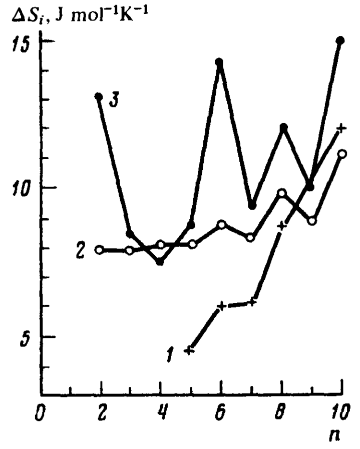


Figure 4. Dependence of the entropy of the LC—I transition ΔS_i on the number of carbon atoms *n* in the aliphatic components for the monomers (curve *1*), dimers (curve *2*), and polymers (curve *3*).[62]

Thus the nematic ordering of the *RF*-polymers differs greatly from the ordering of low-molecular-weight liquid crystals. The macromolecular ordering of the polymers, whose relation involves the cooperative nature of the dynamic behaviour of the mesogenic groups and depends on the chemical structure of the polymer and also on kinetic factors,¶ greatly complicates the task of identifying the polymeric liquid crystals and apparently entails the need to investigate the supermolecular liquid-crystal morphology of the polymers.

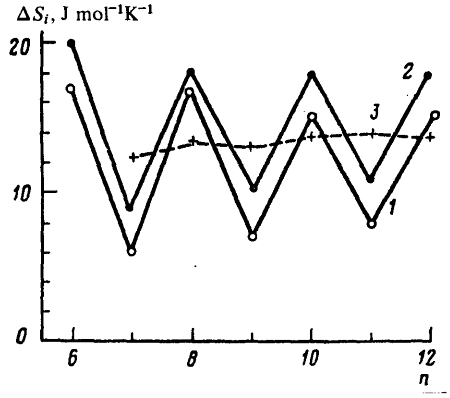

Figure 5. Dependence of the entropy of the LC–I transitions ΔS_i on the number *n* of atoms in the flexible spacers: 1) polymer (I); 2) polymer (IV); 3) polymer (VI).[64]

IV. THE INFLUENCE OF THE CHEMICAL STRUCTURE OF THE MESOGENIC BLOCKS AND FLEXIBLE SPACERS ON THE MESOMORPHIC PROPERTIES OF THE POLYMERS

There are literature data for the synthesis and properties of polymers with flexible spacers of different chemical nature—aliphatic,[33,34,68,69] oligo(ethylene oxide) (OEO), oligo(propylene oxide) (OPO),[70] and disiloxane spacers.[71] The influence of the structure of the mesogenic blocks has been examined in a number of studies.[68,72,73] However, it is as yet difficult to treat from a general standpoint the extensive experimental data concerning the elucidation of the relation between the mesomorphic properties and the chemical structure of the *RF*-polymers. The difficulties in the interpretation are associated with the fact that the mesomorphic properties are influenced by a series of factors such as the composition, inhomogeneity, MW, and the molecular weight distribution (MWD). In the study of polymers with high clarification temperatures, it is essential to take into account

---

¶ There are no direct indications in the literature that the LC–I transition is non-equilibrium in character. However, certain instances of the monotropic behaviour of the *RF*-polymers have been described.[49,66,67] The occurrence of conformational changes in flexible spacers in the transition to the isotropic melt should lead to the irreversibility of this transition. The small thermal hysteresis and the independence of ΔS_i of the conditions in the heat treatment of the specimens[50] may be a consequence of the kinetic stability of the mesophase and are not an unambiguous proof of its thermodynamic stability.

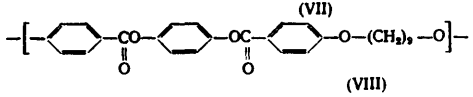
the possibility of chemical changes which leads to the breakdown of the regulatiry of the chain. Furthermore, the thermodynamic parameters obtained by direct calorimetric measurements do not in most cases correspond to equilibrium, which greatly hinders the elucidation of the relation between the chemical structure and mesomorphic properties.

The influence of the previous history of the polymeric specimens on their mesomorphic properties has been studied in greatest detail by Bilibin et al.,[34] Pashkovskii et al.,[50] Asrar et al.,[74] and Krigbaum and co-workers.[75,76] It has been established that the mesomorphic properties of the polymers depend greatly on the intrinsic viscosity of the specimens $[\eta]$. In the range $[\eta] < 0.4$ dl g^{-1}, the transition temperatures depend greatly on $[\eta]$; the dependence becomes weaker for $[\eta] > 0.4$ dl g^{-1}. Thus, in order to avoid an uncertainty in the interpretation of the experimental data, it is essential to work with specimens having sufficiently high molecular weights. This factor greatly reduces the value of the results obtained in the study of polymers with low $[\eta]$.

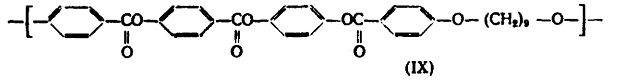
The influence of the MWD on the thermal characteristics of the polymers has not been studied in detail, but in a number of communications there are indications that the presence of a broad MWD affects primarily the parameters of the LC–I transition. The synthesis and properties of polymers based on 4-hydroxyphenyl-4-hydroxybenzoate have been described.[77] The transition to the isotropic melt in these polymers is characterised by a broad (50–60 °C) two-phase region, which is a result, according to the authors, of the segregation of the molecules of the specimen with respect to molecular weights in the nematic phase. The influence of the method of synthesis and the purity of the initial components on the properties of the polymers described in the above study[77] has been examined by Krigbaum et al.[76] It was shown that the presence of a broad region in which the isotropic and LC phases coexist is a consequence of the composition inhomogeneity of the polymer specimens, which is caused by the chosen method of synthesis. Krigbaum et al.[76] demonstrated that the correct choice of the methods of polycondensation and purification of the monomers make it possible to synthesise polymer specimens having a narrow two-phase region.

As for low-molecular-weight LC compounds, the mesomorphic properties of *RF*-polymers depend greatly on the chemical structure of the mesogenic blocks. Strzelecki et al.[72] synthesised and investigated the mesomorphic properties of polymers with mesogenic groups containing 2, 3, and 4 benzene rings with nonamethylene spacers:

(VII)

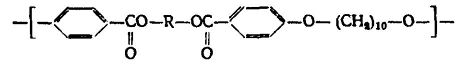


(VIII)

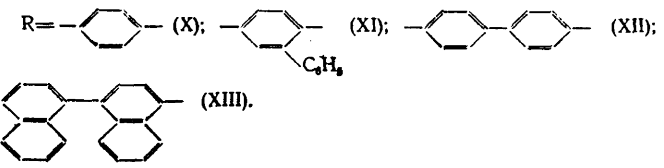


(IX)

The temperatures of the transitions to the isotropic melt for these polymers were respectively 200°, 305°, and 350 °C. The results of the above study[72] have been analysed[74] from the standpoint of the existing theories for low-molecular-weight nematogens, which make it possible to predict the clarification temperature as a function of the chemical structure of the molecules. Using the Flory–Ronca theory,[78] developed for monomeric molecules and taking into account the effects associated with the anisotropy of the molecular shape and with the anisotropy of the intermolecular interactions, the author concluded that the dependence of the clarification temperature T_i on the axial ratio of the rigid blocks is more pronounced for polymers than for the low-molecular-weight liquid crystals. A common conclusion is, however, the claim that existing theories are incapable of predicting the dependence of T_i on the axial ratio of the rigid component of the *RF*-polymers. The influence of the structure of the mesogenic component on the transition temperatures for the polymers (X)–(XIII), having different geometries of the mesogenic blocks and identical structures of the flexible chains, has been studied:[73]



where



It was shown that the clarification temperature and the range of existence of the nematic phase are much higher for the polymers (X) and (XII) than for the polymers (XI) and (XIII) respectively. The changes in the LC properties indicated take place as a consequence of the decrease of the anisometry of the rigid blocks after the introduction of asymmetric substituents.

Thus the character of the influence of the chemical nature of the mesogenic groups on the mesomorphic properties of the polymers is analogous to the influence of molecular structure on the properties of monomeric LC compounds. For low-molecular-weight liquid crystals, there are numerous data describing the relation between the mesomorphic properties and the molecular structure,[79] but there are as yet no criteria which would make it possible to predict the type and range of the existence of the mesophase for substances of a specific chemical nature. One of the most interesting and practically most important is the question of the relation between the structure of the mesogenic blocks and the type of their mesophase. The tendency to generate the smectic phase in low-molecular-weight liquid crystals is associated with the dominant role of the lateral intermolecular interaction compared with the end-face interactions.[5] This postulate is evidently valid also for *RF*-polymers: as can be seen from the data of Strzelecki and Van Lyuen,[80] the increase of the length of the flexible fragments of polymers entails, as for low-molecular-weight liquid crystals, the transition from nematic to smectic mesomorphism. Analogous results have been obtained by Bilibin et al.[81] and it was found that the tendency of polymers to generate the smectic phase is determined in many respect by the tendency of the low-molecular-weight model compounds having an analogous structure to generate this phase. However, the influence of the length of the flexible spacers on the tendency of the *RF*-polymers to generate the smectic phase cannot be explained from the standpoint of the characteristics of the homologous series of low-molecular-weight liquid crystals. A number of polymers based on 4,4′-dihydroxybiphenyl, in which all the even homologues exhibit smectic mesomorphism and the odd homologues exhibit nematic mesomorphism, have been investigated.[74] This indicates the specific role of the flexible spacers in the ordering of the *RF*-polymers.

The most important confirmation of the special role played by the flexible fragments in the generation of LC order in polymers is the marked dependence of the mesomorphic properties on the chemical nature of the spacers. The flexibility of the latter is a decisive factor influencing their clarification temperature. It has been shown that, for polymers with disiloxane spacers, the range of existence of the mesophase is much narrower and the clarification temperature is lower than for the polymer with decamethylene spacers.[71] Table 4 presents the thermodynamic parameters of the LC–I transition for a series of polymers whose rigid groups consist of aromatic triads and the chemical nature and lengths of the flexible spacers are different. For the polymers with disiloxane spacers (XIV), ΔS_i is greater and T_i appreciably lower than for the polymer with decamethylene spacers (XV), which indicates the decisive role of the entropy jump ΔS_i in the LC–I transition. The introduction of the oligo-oxyethylene spacers does not entail an appreciable decrease of ΔS_i compared with polymers containing oligomethylene spacers [(XIV) and (II), $n = 6$]. However, ΔS_i reflects not only the conformational features of the chains in the isotropic phase but also the structural features of the mesophase and for this reason unambiguous conclusions about the influence of ΔS_i on T_i can be made only on the basis of the knowledge of the structure of the LC and isotropic phases. It is of interest to note that, for polymers having spacers containing asymmetric centres (for example, the OOP spacers[70,81]), calorimetric measurements do not allow the determination of ΔH_i and T_i. Polymers with OOP spacers are non-crystallisable but there are no explicit indications of the suppression of their mesomorphic properties. In a number of studies, it has been reported[74,82,83] that polymers with OOP spacers are capable of forming a cholesteric mesophase. For low-molecular-weight nematic and cholesteric liquid crystals, the ΔS_i are virtually identical[25,26] and the significant difference between the thermodynamic properties of the nematic and cholesteric phases of *RF*-polymers can therefore be accounted for solely by the conformational features of the chains in each phase. The conformation of the chains in the cholesteric phase probably does not differ greatly from the conformation of a statistical coil, which explains the absence of a measurable entropy jump in the LC–I transition in polymers with OOP spacers.

Thus the variation of the chemical nature of the flexible spacers influences decisively the mesomorphic properties of *RF*-polymers. The character of the influence of the nature of the flexible components on the mesomorphic properties of the polymers cannot be understood from the standpoint of the traditional ideas about the mesomorphism of low-molecular weight compounds, since the structure of the polymeric mesophase is determined to a large extent by the conformational state of the macromolecules.

V. COPOLYMERS

The study of the properties of copolymers has attracted investigators for a number of reasons. The nematic states in copolymers have a wider region of stability than in the case of homopolymers.[84] It has been shown that LC polymers based on non-mesomorphic components can be obtained by copolycondensation.[85] The synthesis and properties of copolymers containing aliphatic fragments of different lengths have been reported.[38,84] It has been shown that, in terms of its structural and thermodynamic aspects, the mesophase of the copolymers is virtually identical with the mesophase of the homopolymers, which is indicated by DSC and X-ray diffraction data. The phase diagram for copolymers based on 4,4'-dihydroxy-αα'-dimethylbenzylideneazine, containing octo- and dodeca-methylene spacers, is presented in Fig.6*a* [Table 5, compound (XVII)]. The solidus lines (which have the form usual for eutectic diagrams) and the line representing the equilibrium between the nematic phase and the isotropic melt indicate the complete compatibility of the copolymer units in the LC phase. It has been established that copolymers with the equimolar composition have a very low degree of crystallinity and that under certain conditions it is possible to obtain specimens in the nematic vitreous state.

Copolymeric systems with one non-mesomorphic component, which, however, is capable of potential mesomorphism have been investigated[86] [Fig.6*b*, Table 5, compound (XVIII)]. When the content of the non-mesomorphic component is in the range $0 \leq m \leq 75$ mole %, the copolymers exhibit enantiotropic

mesomorphism. When the content of the non-mesomorphic component is greater, there is a possibility of the manifestation of only monotropic mesomorphism in the system. Extrapolation of the thermodynamic parameters for the LC–I transition to the 100% content of the non-mesomorphic component made it possible to determine the "potential" mesomorphic properties of the polymer containing only non-mesomorphic units.† Copolymers with two non-mesomorphic components, exhibiting potential mesomorphism, have been investigated [Fig.6c, Table 5, compound (XIX)].[85] Enantiotropic mesomorphism has been observed in the composition range 35 ≤ *m* ≤ 60 mole %. The manifestation of LC properties by copolymers becomes possible by virtue of the significant expansion of the region of stability of the mesophase. In this sense copolymers play the same role as mixtures of low-molecular-weight compounds with potential mesomorphic properties.

The synthesis of copolymers with a single non-mesomorphic component, which does not exhibit potential mesomorphism, has been described[87] [Fig.6*d*, Table 5, compound (XX)]. In contrast to those examined above, copolymers of this type are characterised by a broad two-phase region corresponding to the LC–I transition, which greatly expands with increase in the fraction of the non-mesomorphic component, which implies that there is partial segregation of the non-mesomorphic component.

Despite the outward similarity of the phase diagram presented in Fig.6 and the diagrams for mixtures of low-molecular-weight liquid crystals, the experimental data for copolymers cannot be understood from the standpoint of the characteristics known for low-molecular-weight systems. Furthermore, the study of the copolymers is complicated by the difficulty of obtaining phase equilibria, which greatly limits the progress in this field. Nevertheless, the need for more far-reaching study of the copolymers is evident because of their great practical importance. Copolymerisation is the most effective method of regulating mesomorphic properties and makes it possible to vary parameters important for applications, such as the degree of crystallinity, the glass point, and the mechanical characteristics of the given articles. From the standpoint of the use of *RF*-copolymers in the industrial manufacture of high-strength highly modular articles, systems analogous to that illustrated in Fig.6d are of greatest interest, since copolymers of this type make it possible to vary within wide limits the rheological characteristics of anisotropic melts.

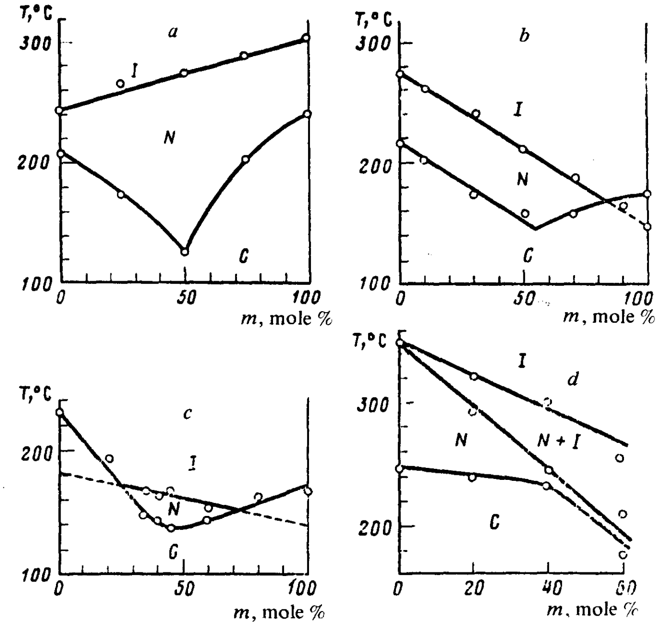

Figure 6. Phase diagrams for the copolymer systems presented in Table 5: *a*) (XVII); *b*) (XVIII); *c*) (XIX); *d*) (XX); *I*, *N*, and *C* = isotropic, nematic, and crystalline phases respectively; *m* = composition of the copolymer; *T* = temperature.[84–87]

---

† In this case the term "non-mesomorphic component" does not reflect the mesomorphic properties of the monomeric unit and is used in the sense that the homopolymer containing 100% of the non-mesomorphic units is also non-mesomorphic. Compounds for which the temperature of the transition from the crystalline to the isotropic state is higher than the clarification temperature are potentially mesomorphic.

Analysis of the data presented in the review permits the differentiation of three main trends in the study of *RF*-polymers: (1) the elucidation of the character of the influence of the chemical nature of the repeat unit on the mesomorphic properties of the polymers; (2) the study of the structure of the mesophases; (3) the determination of the relation between the molecular characteristics and the LC properties of the polymer. The value of the results obtained in the study of the structural characteristic features of the mesophases or of the influence of chemical structure on the properties of *RF*-polymers is greatly reduced if there are no corresponding data for the dependence of the mesomorphic properties on the molecular characteristics of the polymers. Nevertheless, whereas the first two research trends are fairly widely represented in the literature, the third is only in the initial stage of its development.

Thus an unambiguous interpretation of the experimental data is possible only for polymers with a rigorously defined composition, chemical structure, molecular weight, and molecular weight distribution.

An important feature of *RF*-polymers is the possibility of macromolecular ordering together with the establishment of orientational order at the level of individual segments. This accounts for the interest in the study of the behaviour of the flexible fragments in the I–LC transition. Many experimental data indicate a high activity of the spacers, which is one of the manifestations of the macromolecular ordering process.

Despite the major advances made in the synthesis and study of *RF*-polymers, the problem of the classification of the types of mesophases for the given system remains unsolved. Identification of the low-molecular-weight liquid crystals permits a comprehensive prediction of the behaviour of the given substance as a function of external conditions. The determination of the analogous characteristics of *RF*-polymers should include, apart from the determination of the type of mesophase at the segmental level, the determination of the geometrical characteristics of the chains in the LC phase, since these parameters in fact determine in many respects the macroscopic properties of the polymer. It therefore appears to be essential to develop research directed to the determination of the macroconformations of the chains of mesogenic polymers in the LC phase.

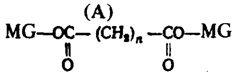
Linear thermotropic polymers capable of existing in the LC state at temperatures ranging from room temperature to 350–400 °C are known. Naturally such a wide range of the thermal stability of the polymeric mesophases gives rise to extensive possibilities for the application of *RF*-polymers in extremely varied fields of science and engineering. Applied studies of *RF*-polymers are directed mainly to the synthesis of fibres and films with improved strength characteristics and a high thermal stability. More far-reaching investigation of the nature of the LC state will undoubtedly open new pathways to the more extensive employment of *RF*-polymers in science and engineering. Furthermore, the interest in thermotropic linear polymers is of fundamental importance: like the study of monomeric liquid crystals, it has expanded our knowledge of the molecular structure of liquid crystals and the study of polymers deepens our understanding of the analogous features of polymer melts and crystals.

---o0o---

During the preparation of the review for the press, studies of fundamental importance were published. With the aid of the model of rotational-isomeric states,[88] a detailed investigation has been made of the conformational changes in the flexible fragment in the I–LC transition. It has been shown that the behaviour of the spacers during nematic ordering depends on the structure of the groups connecting the flexible fragments to the mesogenic groups (MG). Three types of connection of the spacers to the MG have been examined:

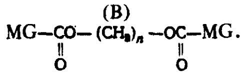
$$\mathrm{MG{-}O{-}(CH_2)_n{-}O{-}MG};$$

(A)



$$\mathrm{MG{-}\underset{\displaystyle O}{\underset{\|}{C}}O{-}(CH_2)_n{-}O\underset{\displaystyle O}{\underset{\|}{C}}{-}MG};$$

(B)



$$\mathrm{MG{-}\underset{\displaystyle O}{\underset{\|}{C}}O{-}(CH_2)_n{-}O\underset{\displaystyle O}{\underset{\|}{C}}{-}MG}.$$

(C)

The connections of the (A) and (B) types are preferred for the establishment of the nematic state, since they ensure highly "extended" spacers and a parallel arrangement of the MG without a significant decrease of the configurational partition function for the system. This explains the high conformational contribution to the overall entropy change ΔS_i for *RF*-polymers with connections of the (A) and (B) types and the fact that ΔS_i for polymeric nematic materials is higher by an order of magnitude than for low-molecular-weight materials. In case (C) the extended state of the spacers is unlikely and nematic ordering is therefore unfavourable. If, however, the nematic state does nevertheless obtain, the conformational contribution to ΔS_i is small, since the conformational structure of the spacers in the isotropic and LC phases is virtually the same. The principal conclusions of Yoon and Bruckner[88] have been confirmed experimentally[89] by ^{2}H NMR for a polymer with connections of type (A). The results of the IR spectroscopic study of the structure of the spacers for polymers with type (C) connections[39,40] also confirmed the theory.[88]

Blumstein[90] and Pashkovskii[91] paid particular attention to the study of the dependence of the parameters of the LC–I transition on the molecular weight taking into account the chemical structure of the end groups of the macromolecules. It has been shown that, in the region of low molecular weights, the structure of the end groups influences strongly the properties of *RF*-polymer specimens. This finding demonstrates the difficulty of interpreting the experimental data obtained in the early studies[68,70] for low-molecular-weight specimens.

Volino et al.[92] studied the structure of solutions of an *RF*-polymer in a low-molecular-weight nematic liquid crystal. Relations were obtained between the order parameter of the polymers Q_{RF} and the degree of polymerisation x. It was shown that Q_{RF} increases with increase in the parameter x, tending to the value of Q for a low-molecular-weight nematic material, which indicates the ideal "incorporation" of the polymer chains in the nematic medium. The data of Volino et al.[92] agree with the theory,[93] where it has been shown that flexible *RF*-polymer molecules can be rigid in the nematic phase, in contrast to the usual flexible-chain or comb-shaped LC polymers.

Thermal Polymerisation and Oligomerisation of Monomers

V.A.Kurbatov

Two competing types of thermal reactions of monomers of different classes, namely oligomerisation and polymerisation, are examined. The characteristics of the formation of the initiating radicals and of low-molecular-weight products (dimers and trimers) and of the inhibition of the thermal polymerisation by radical acceptors have been subjected to kinetic analysis. The mechanisms of the principal pathways in this process and the relations between them are discussed.
The bibliography includes 136 references.

I. INTRODUCTION

Thermal polymerisation† is the principal type of reactions of monomers; it proceeds exclusively under the influence of heat in the range of relatively low temperatures where the reactions involving the decomposition of the carbon skeleton of the molecule hardly occur. Its products are polymer and low-molecular-weight compounds—oligomers (dimers and trimers) having both linear and cyclic structures.

The importance of this study of thermopolymerisation is determined by practical and theoretical factors. Firstly, thermopolymerisation is an inseparable component of the overall polymerisation process occurring in the industrial isolation of monomers, which leads to the formation of polymer deposits and the breakdown of equipment. Secondly it is one of the methods of synthesis of polymers, for example styrene polymers. For this reason, the knowledge of the detailed features of the mechanism of the thermal reactions of monomers permits a more deliberate and better founded purposeful regulation of this reaction depending on the character of the problems undertaken. The mechanism of the generation of initiating radicals and oligomers, especially six-membered oligomers, is of theoretical interest. As regards the latter, two mechanisms of their formation have been discussed in the literature during a number of years: the synchronous and two-centre (biradical) mechanism.

The aim of the review was therefore to survey and analyse the literature data on the thermal reactions of various representatives of vinyl and acetylenic monomers, to discover the general features of these processes, and to attempt to formulate on this basis a single mechanism of the phenomenon under consideration. The need for the present review arose because, despite the fairly long history of the research into monomer reactions of this type, scarcely any attempts have been made to survey the available literature data which have accumulated during the last 20–30 years. In view of the fact that the cyclo-addition reactions constitute an independent branch of organic chemistry, as regards the latter we shall confine ourselves to conclusions which have a direct bearing on the topic of the present review.

II. MONOMERS OF THE VINYL-AROMATIC SERIES

1. Styrene and Its Derivatives

In the early studies, only the formation of the polymer was investigated. Reactions of both first and second order with respect to the monomer have been reported. The first exact reaction order, amounting to 2.5, was established by Flory[1] and then by Mayo and co-workers[2–5] and an expression has also been found for the rate of initiation:[2]

$$w_i\ (\text{mol litre}^{-1}\text{s}^{-1}) = 1.32\times10^{6}\exp(-121/RT)\,[M]^{3}$$

(here and henceforth M represents the monomer), which agrees well with the equation which we obtained on the basis of Flory's results.[1]

The reaction order obtained has been interpreted in different ways. Thus it has been assumed that the polymerisation is initiated by the radicals formed as a result of a trimolecular reaction of styrene, via a trimeric biradical, or by monoradicals arising from the latter (see Bagdasar'yan,[6] pp.9, 59). However, it has been shown[6,7] that biradicals cannot ensure the propagation of the chain process. This has also been confirmed by the polydispersity of the polymer, amounting to 1.8–2.0,[8] which is characteristic of monoradical initiation. Finally, special generation of the biradicals $C_6H_5\dot{C}HCH_2.$ $.CH_2\dot{C}HC_6H_5$ by the decomposition of the corresponding tetrahydropyridazine only slightly increased the rate of polymerisation of styrene.[9] The trimolecular reaction is regarded as unlikely because of the lack of a kinetic isotope effect in the polymerisation of ββ'-dideuteriostyrene.[10]

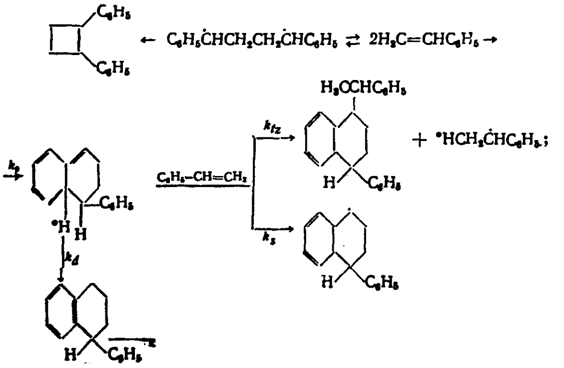
A qualitatively new stage in the development of a theory of thermopolymerisation was represented by Mayo's studies,[2,11] in which, together with the polymer, low-molecular-weight products L were detected, the rate of formation of which obeys a second order equation with respect to the monomer:

$$w_L\ (\text{mol litre}^{-1}\text{s}^{-1}) = 1.8\times10^{5}\exp(-95/RT)\,[M]^{2}.$$

---

† Henceforth we shall also use the term "thermopolymerisation", since it has become a traditional designation of this phenomenon.

Among the low-molecular-weight products, *cis*- and *trans*-diphenylcyclobutanes (DPCB), 1-phenyltetralin (PT), and 1-phenyl(phenylethyl)tetralin (PPET) were identified.[11-13] On this basis, Mayo proposed a new thermopolymerisation mechanism, according to which the primary product, 1-phenyl-1,2,3,9-tetrahydronaphthalene (PTHN), arising from a bimolecular reaction of styrene of the type of the Diels–Alder condensation, is responsible for the formation of the initiating radicals and oligomers. The set of reactions occurring under these conditions is described by the scheme



The expressions for the rates of initiation (w_i) and trimerisation (w_{tr}) arising from this scheme, i.e.

$$w_i=\frac{k_0k_s[M]^3}{k_d+(k_s+k_{tr})[M]};\ w_{tr}=\frac{k_0k_{tr}[M]^3}{k_d+(k_s+k_{tr})[M]}$$

are consistent with the experimental relations. The DPCB formation reaction is of second order with respect to styrene and is characterised by an activation energy of 104 kJ mol^{-1}.[12] It has been suggested that the high reactivity of PTHN is due to the lability of the hydrogen atom H*.[11,12]

The main evidence for this mechanism is believed to be the presence of the kinetic isotope effect in the initiation stage of the thermopolymerisation of *o*-dideuteriostyrenes,[14,15] the direct identification of PTHN by UV spectroscopy,[16-18] the absence among the reaction products of biradicals generated from diphenyltetrahydropyridazine and phenyltetralin,[19] and the manifestation of an initiating capacity by certain PTHN analogues.[20,21] An additional argument is provided by the ability of styrene dimers to regulate the molecular weight of the polymer;[8,22-24] it has been suggested that this role is played by PTHN.[25,26] Indeed the molecular weight of polystyrene and the concentration of PTHN exhibit an antiparallel time variation,[16,17] while compounds modelling PTHN are capable of playing the role of a chain transferring agent.[20,21]

Among the styrene derivatives, compounds substituted both in the aromatic ring and in the α- and β-positions in the side chain were investigated in the thermopolymerisation reaction. We shall consider initially derivatives of the first type. Data for the polymerisation of methylstyrenes have been published in a number of communications.[27-29] The activation energies for the overall process are 70, 80, and 70 kJ mol^{-1} for *o*-methylstyrene, *m*-methylstyrene, and vinylxylene respectively. Vinylmesitylene does not polymerise even in the presence of initiators. The thermopolymerisation of *p*-methoxystyrene has been investigated.[30] If it is supposed that the overall reaction order is also 2.5, it is possible to obtain an expression for the rate of initiation:

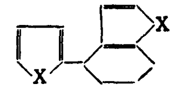
$$w_i\ (\text{mol litre}^{-1}\text{s}^{-1})=4.6\times10^7\exp(-125/RT)\ [M]^3.$$

The rate constant for the initiation of the polymerisation of o-chlorostyrene is described by an expression with the following parameters: E_i = 125 kJ mol^{-1} and A_i = 3.47 × 10^{10} litre^2 mol^2 s^{-1}.[31] For pentafluorostyrene, E_i = 84–92 kJ mol^{-1}.[32] Fairly numerous data are also available for other halogeno- and alkyl-halogeno-styrenes,[33-37] but the lack of information about the polymerisation rate constants precludes the calculation of the rate of initiation. Nevertheless, one may conclude that the variation within wide limits of the activation energies (by 37 kJ mol^{-1}) and pre-exponential factors for the rate constants (by 5 orders of magnitude) for the thermopolymerisation reactions of various styrenes is in the main a result of the variation of the corresponding parameters of the initiation stages.

The thermopolymerisation of styrenes containing substituents in the side chain has been little studied. It has been shown that α-methylstyrene polymerises only at high pressures.[38] Together with the polymer, a linear unsaturated α-methylstyrene dimer has been detected.[39] Only perfluorocyclobutane is formed from αββ′-trifluorostyrene,[40] while α-bromostyryl-1-phenylnaphthalene[41] and various chloro- and fluoro-styrenes are capable only of slow dimerisation.[42]

2. Other Vinyl-aromatic Monomers

The polymerisation of vinylthiophen (VT) and vinylfuran (VF) has been investigated.[44,45] Together with the polymer, a dimer having the structure



,

where X = O or S, is formed. Its yield is comparable to that of the polymer. The initiation process is characterised by third order with respect to the monomer, the activation energies being 117 and 125 kJ mol^{-1} for VT and VF respectively. The pre-exponential factors in the expressions for the VT and VF polymerisation rate constants were similar, amounting to 9 × 10^2 litre$^{3/2}$ mol$^{-3/2}$ s^{-1}. The data obtained are consistent with a polymerisation mechanism identical with that proposed by Mayo.

Analysis showed that the observed polymerisation rate constant is almost independent of the monomer concentration and the stage involving the conversion of the intermediate into trimers does not therefore exist. This is confirmed by the observation of only the dimer in the low-molecular-weight fraction,[45] from the yield of which it is possible to estimate approximately the dimerisation rate constant. At 130 °C the latter is approximately 1.6 × 10^{-6} litre mol^{-1}, i.e. is comparable to the rate constant for the oligomerisation of styrene.

The thermopolymerisation of vinylpyridines (VP) has been investigated in a number of studies.[32,46-48] Expressions describing the rate of initiation have been found for 4-VP and 2-methyl-5-VP:[46,48]

$$w_i\ (\text{mol litre}^{-1}\text{s}^{-1})=9.7\times10^{11}\exp(-133/RT)\ [M];$$
$$w_i\ (\text{mol litre}^{-1}\text{s}^{-1})=2.38\times10^{3}\exp(-88/RT)\ [M]^3.$$

The first order observed in the case of 4-VP is open to definite doubt. The surface of the glass probably exerts an influence in this instance, as noted by Onyon.[47] The overall rate constant is independent of the monomer concentration. An initiation activation energy similar to that found for 4-VP has been obtained also for 2-VP.[32] Aminov and co-workers[46,48] give preference to a biradical mechanism, although one cannot rule out the possibility of the formation of an intermediate similar to PTHN.

The thermopolymerisation of vinylpyridinium salts in aqueous solution proceeds via a radical-chain mechanism and the rate of reaction is proportional to $[M]^{2.2}$.[49]

Although the polymerisation of indene has not been subjected to kinetic analysis, nevertheless it has been shown that the rate of this process is lower than the rate of polymerisation of styrene and the degree of polymerisation ranges from 2 to 10, amounting on average to 4–6.[50] The rates of reaction at different temperatures, obtained in different studies, fit satisfactorily on a single linear Arrhenius plot and the activation energy is 94 kJ mol^{-1}.[51–54] There are no literature data for the relative kinetic chain propagation rate constant $k_p/k_t^{0.5}$, where k_p and k_t are the kinetic chain propagation and termination rate constants respectively. We calculated it using the data[54] for the polymerisation of indene initiated by benzoyl peroxide. The required constant was found to be given by the following expression

$$k_p k_t^{0.5}\ (\text{litre}^{1/2}\text{mol}^{-1/2}\text{s}^{-1/2}) = 3.2\times10^2 \exp(-33.6/RT).$$

The dependence of the degree of polymerisation on the initiator concentration (indene peroxide)[55] shows that the molecular weight of the polymer is regulated by chain transfer via the monomer. The calculated transfer constant was found to be 0.1. This can explain the low-molecular-weight of the polymer. The exact concentration-based measurement of the order of the polymerisation reaction with respect to the monomer was not carried out, but, according to an approximate estimate, it should be greater than 2. If it is assumed to be 2.5, then the pre-exponential factor in the expression for the initiation rate constant is 3.8 $\text{litre}^2\ \text{mol}^{-2}\ \text{s}^{-1}$ and the activation energy is 120 kJ mol^{-1}.

According to the data of different workers, the activation energies for the overall polymerisation (numerals designated by an asterisk) and initiation processes involving naphthalene derivatives are respectively 73*,[56] 71*,[32] and 123 kJ mol^{-1} [32] for α-vinylnaphthalene, 129* and 159* kJ mol^{-1} for acenaphthalene,[32] 76* kJ mol^{-1} for β-vinylnaphthalene, and 87* kJ mol^{-1} [56] for 6-vinyltetrahydronaphthalene. Decahydronaphthalene does not polymerise at 100 °C in the course of three days.[56]

If the order of the initiation stage of the polymerisation of α-vinylnaphthalene (α-VN) with respect to the monomer is three, then the rate constant can be calculated from the data of Koton and Kiseleva:[56]

$$k_i\ (\text{litre}^2\text{mol}^{-2}\text{s}^{-1}) = 4\times10^3 \exp(-73.0/RT)$$

(the polymerisation constants taken from Lipatov et al.[57] were used in the calculation).

3. The Kinetics and Mechanism of the Inhibition of the Thermopolymerisation of Styrene by Alkyl Radical Acceptors

The characteristic features of the inhibition of thermopolymerisation exhibit a number of significant differences from the initiated reaction. The relation between the inhibitor concentration and the induction period is usually non-linear.[58–62] The kinetic orders of the acceptor consumption reaction can be both zero[60,63–67] and unity[64,67] and in the former case the rates of destruction of different acceptors can differ by a factor of several tens and can greatly exceed the rate of initiation in the absence of acceptors.[63–69] The products of the thermal and initiated reactions are frequently different.

Thus the high-molecular-weight product formed in the initiated thermopolymerisation of styrene in the presence of quinones is a styrene–quinone copolymer, while the product of the non-initiated process is a styrene homopolymer.[70] The formation of 2 : 1 or 2 : 2 adducts of the monomer and the inhibitor (benzoquinone, sulphur, picric acid),[71,72] in which the dimeric styrene fragment has a linear structure, is a characteristic feature.

Details kinetic analysis of the thermopolymerisation inhibition process has shown[72] that the above features are caused by the reactions of the intermediate arising as a result of a bimolecular reaction of styrene:

$$\begin{gathered}
\text{M} + \text{M} \xrightarrow{k_0} \text{Z}, \\
\text{Z} \xrightarrow{k_d} \text{D}, \\
\text{M} + \text{Z} \xrightarrow{k_{tr}} \text{T}, \\
\text{M} + \text{Z} \xrightarrow{k_s} \dot{\text{R}}, \\
n\,\text{In} + \text{Z} \xrightarrow{k_b} \text{products}, \\
f\dot{\text{R}} + \text{In} \xrightarrow{k_{in}} \text{products},
\end{gathered}$$

where M, D, and T are the monomer, dimer, and trimer respectively, Z is the intermediate, In the inhibitor, n the stoichiometric coefficient, f the acceptance coefficient, and $\dot{\text{R}}$ the initiating radical. According to this scheme, the consumption of the inhibitor is defined by the expression

$$-\frac{d[\text{In}]}{dt} = k_0[\text{M}]^2 \frac{k_s[\text{M}]/f + nk_b[\text{In}]}{k_d + (k_{tr} + k_s)[\text{M}] + k_b[\text{In}]}.$$

Since $k_s[\text{M}]$ is fairly small, we obtain

$$-\frac{d[\text{In}]}{dt} \simeq \frac{nk_0k_b[\text{M}]^2[\text{In}]}{k_d + k_{tr}[\text{M}] + k_b[\text{In}]}.$$

Depending on the absolute values of the individual terms, two limiting cases can occur, where the inhibitor is consumed either in accordance with a zero order law at a rate $nk_0[\text{M}]^2$ and W_i/f or in accordance with a first-order law at a rate proportional to $nk_0k_b[\text{M}]^2/k_d + k_{tr}[\text{M}]$. This agrees with the experimental reaction orders (see above) and also shows that, depending on the conditions and the reaction time, the order may also assume intermediate values (between 0 and 1).

An equation relating the induction period τ to the inhibitor concentration was obtained in the same study:[72]

$$\tau = \frac{[\text{In}]_0}{nk_0[\text{M}]^2} + \frac{k_d + k_{tr}[\text{M}]}{nk_0k_b[\text{M}]^2} \ln \frac{nfk_0k_b[\text{M}]^2}{k_d + k_{tr}[\text{M}]w_i}[\text{In}]_0.$$

Depending on the initial inhibitor concentration, both a linear and a logarithmic relation between τ and $[\text{In}]_0$ can be obtained, which has been observed in practice. Furthermore, the above equation makes it possible to determine the reactivity of the intermediate towards the acceptor {the effective rate constant $k = nk_0k_b[\text{M}]^2/k_d + k_{tr}[\text{M}]$}, the rate of initiation, and the lower threshold of the rate constant for the reaction of the radicals, propagating the kinetic chains, with the inhibitor.

With the aid of this approach, we calculated the effective rate constants k for the interaction of the intermediate with various inhibitors (Table 1). A satisfactory agreement is observed between the values of k calculated from the induction period and from the consumption of the acceptor. A satisfactory agreement was also noted for the rate of initiation w_i and the inhibition rate constant k_{in} found in this way.[72] The constant k for different acceptors varies within the limits of one order of magnitude and has the maximum value for stable radicals. However, there are exceptions: Kolesch's radical# and tetramethyl-p-benzoquinone are consumed at a

---

1,3-Bis(diphenylene)-2-phenylallyl (BDPA)—see Pryor et al.[64] (cf.Table 1) (Ed.of Translation).

rate close to the rate of initiation and the interaction with the intermediate does not accordingly occur. It is of interest that, on passing to pentafluorostyrene, such reaction with Kolesch's radical becomes possible (Table 1).

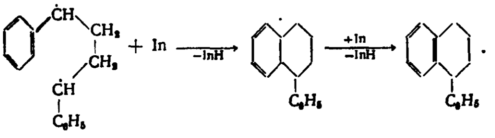
Table 1. The effective rate constants for the reactions of the intermediate with inhibitors.

Inhibitor	t, °C	$10^4 k$, s^{-1}	Method of determination
	Styrene (Ref.72)		
	75	1.67	from consumption of inhibitor
	80	1.67	from τ
Ditto	80	1—2	from consumption of inhibitor
$(C_2H_5OC_6H_4)_2N\dot{O}$	80	1.15	from τ
$(C_6H_5)_3\dot{C}$	100	0.71	from τ
 , where X = H	70	0.11	from τ
H	90	1.00	from consumption of inhibitor
Cl	80	0.14	from consumption of inhibitor
Br	80	0.17	from τ
I	80	0.36	from τ
	Pentafluorostyrene (Ref.64)		
Galvinoxyl	100	0.26	from consumption of inhibitor
Kolesch's radical	100	0.28	from consumption of inhibitor

There exist two hypotheses about the structure of the intermediate: according to one of them, it is PTHN and according to the other it is a biradical. We shall consider which hypothesis corresponds better to the thermopolymerisation inhibition data. The increase of the electronegativity of the halogen atoms in tetrahalogenobenzoquinone lowers the constant k (the reaction constant ρ is then -1).[72] On this basis, it was concluded that there exists a stage in which the halogenoquinone is subjected to the electrophilic attack by the intermediate.[72] The reactions of halogenoquinones with hydrocarbons are usually accompanied by the abstraction of hydrogen atoms. For example, 3,4,8,9-tetrahydronaphthalene, which is an analogue of PTHN, affords naphthalene on reaction with chloranil.[73] In such cases the reaction rate constant has the maximum value for quinones with the most electronegative substituents.[74] If the intermediate is PTHN, one may expect the opposite variation of the constant k on passing from chloranil to iodanil compared with that actually observed. For this reason, the occurrence of the process via a mechanism of the Diels–Alder type is ruled out.

The rate constant k for the reactions of methyl derivatives and p-benzoquinone diminishes with increase in the number of substituents and in the presence of four methyl groups cannot be measured. A similar trend has been observed in the series benzoquinone > naphthoquinone > anthraquinone.[71] This means that an unsubstituted ring carbon atom participates in the reaction of the intermediate with quinone. This conclusion has been confirmed quantitatively by the constancy of the values of k referred to a single reaction centre. An analogous deviation of the reactivity of methylquinones has been observed in reactions with methyl[75] and styryl[76] radicals; the specific constant then also remains invariant.

Since there are quantitative and qualitative analogies between the reactions of quinones with radicals and the intermediate, presumably the intermediate has a radical nature and hence should consist of a biradical. In practice it is unlikely that the rate constants for the reaction of Kolesch's radical with the intermediate would increase by 3–4 orders of magnitude on passing from H-PTHN to F-PTHN (pentafluorostyrene). It is also difficult to imagine the abstraction of a CH_3 group by diphenylpicrylhydrazyl from the PTHN formed from vinylmesitylene.[32] Finally, it has been established recently[77] that, when a nitroxy-radical is introduced at the beginning of the reaction, PTHN is not formed. On the other hand, the rate constant for its destruction in a pseudo-first order reaction with respect to Z is independent of the radical concentration. Hence PTHN is consumed unimolecularly, evidently isomerising to phenyltetralin, while the acceptor reacts with its precursor.[77] There is no doubt that this precursor can only be a biradical. Accordingly, the transfer of a hydrogen atom to the inhibitor is a result of disproportionation; the increased yield of phenyldihydronaphthalene under these conditions[66,78,79] is therefore determined by the reactions



One of the most convincing pieces of evidence for the existence of an intermediate of type PTHN is the conversion of nitroxy-radicals and DPPH radicals into hydroxylamine and hydrazine respectively.[66,78–80] However, hydroxylamine can also be formed as a result of the decomposition of its ether (recombination product).[81] On the other hand, the amount of hydroxylamine formed is only 20% of theoretical.[80] Without going into details, we may note that the change in the composition of the reaction products on treatment with DPPH, quoted by Kopecky and Hall[78] and Wiesner and Mehnert,[79] is inconsistent with the formation of an intermediate of the type of PTHN, since in this case one would expect anomalously high acceptance coefficients. Consequently the fact presented above cannot be regarded as rigorous proof of the involvement of PTHN in the reaction with stable radicals. The structure and composition of the products of the reactions of sulphur and benzoquinone are evidence against a bicyclic structure of the intermediate.[72]

Thus the structure of the products and the kinetics of the reactions of inhibitors fail to confirm, in our view, the concept of the triene structure of the intermediate and make it necessary to give preference to the hypothesis of its biradical nature.

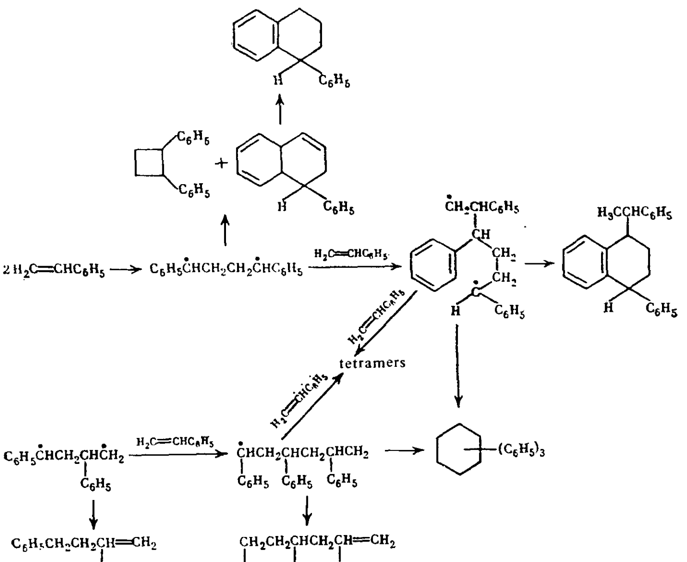
4. The Mechanism of the Thermopolymerisation of Styrene and Vinyl-aromatic Compounds

Since the main experimental data have been obtained for styrene, we shall initially analyse those concerning the mechanism of the thermopolymerisation of the above monomer.

Tetraline oligomers (PT, PPET), on the formation of which the current ideas about the thermopolymerisation mechanism are based, are not the only low-molecular-weight products of this process. Their yield is several times smaller than the overall yield of the oligomeric fraction. Together with these, linear unsaturated dimers and trimers have been identified: 1,3-diphenylbut-3-ene, 1,3,5-triphenylhex-5-ene, and triphenylcyclohexanes[11–13,82] and in the case of α-methylstyrene an unsaturated linear dimer.[46] This finding does not fit within the framework of Mayo's mechanism. In order to eliminate the contradiction, a number of workers postulated, taking into account the presence of the same olefinic compounds in the products of the thermal reaction of polystyrene, their pyrolytic formation under conditions of either chromatographic analysis[13] or direct polymerisation.[11,12]

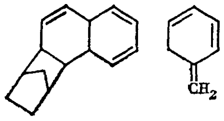
However, in the chromatography of solutions of polystyrene in ethylbenzene, subjected to preliminary heat treatment, oligomers were not detected.[72] The finding that the fraction of linear unsaturated oligomers of 1,3-diphenylbut-3-ene (DPB) and 1,3,5-triphenylhex-5-ene (TPH) decreases with increasing styrene concentration also conflicts with the above hypothesis.[12] Hence it follows that the low-molecular-weight compounds indicated are the main and not secondary thermopolymerisation products.

On the other hand, the presence of all the oligomers noted can be readily accounted for, without contradiction, within the framework of the biradical mechanism. Presumably the olifinic derivatives are formed as a result of the intramolecular disproportionation of the corresponding dimeric and trimeric biradicals, while cyclohexane derivatives are produced by their recombination and tetralin derivatives are formed via alkylation. Furthermore, the lowest biradicals can be converted into the highest by reaction with styrene molecules and then can give rise to oligomers in unimolecular reactions. This has been confirmed by the presence of tetramers among the polymerisation products[12,82] and agrees with the decrease of the fractional yield of DPB and TPH with increase in the concentration of styrene.



We shall now proceed to the discussion of the initiation mechanism. A kinetic isotope effect close to 2 has been found not only in the initiation reaction but also in the trimerisation reaction.[12] The rate of destruction of DPPH in the polymerisation of pentadeuteriostyrene is also smaller by a factor of two than in the reaction involving the non-deuteriated monomer. As already mentioned, this process is second order with respect to the monomer and its rate is limited by that of the stage involving the formation of the intermediate, which participates, according to current ideas, also in the initiation reaction. For this reason, the manifestation of isotope effects in the initiation reaction may be a consequence of their occurrence in the stage where the intermediate is formed. At the same time, on replacement of hydrogen by deuterium in the *ortho*-position, the kinetic isotope effect in the DPPH destruction process is 0.75 in the case of the thermopolymerisation reaction.[83] This indicates merely an uncertainty in the influence of the nature of the *ortho*-substituent on the formation of the intermediate, i.e. the given effect cannot be regarded as proof that the mechanism involving the generation of free radicals operates.

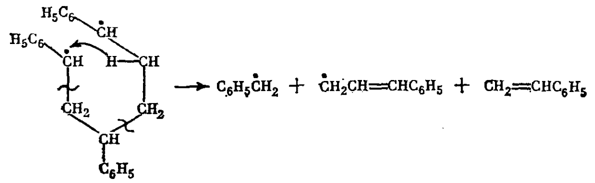
The PTHN concentration, established by UV spectroscopy, does not remain constant over several hours.[16,17] Consequently if PTHN were responsible for the formation of the initiating radicals, then the polymerisation process would not be stationary. For this reason, it is believed that[16,17] the isomer with the axial C_6H_5 group, assumed to be more reactive than the other isomers, participates in the initiation. However, as already mentioned, this intermediate should be produced via a biradical. Finally, the characteristic features of the formation of tetralin oligomers require that stationary conditions hold throughout the intermediate and not only in a fraction of the latter. It has been established[20] that close analogues of PTHN such as compounds of the type



only reduce the molecular weight of the polymer without influencing the rate of initiation. The increase of the latter has been noted only when markedly different model compounds, which can in principle themselves react with styrene to form biradicals, are used.

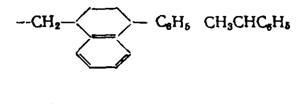
The capacity of pentafluorostyrene for thermopolymerisation cannot be explained on the basis of the structure of an intermediate of the type of PTHN. Indeed, in this case a fluorine atom should be abstracted from PTHN by a monomer molecule, which is extremely doubtful.

A possession of an initiating capacity (even though it is a weak capacity) by the biradical formed from cyclodiazo-compounds is of fundamental importance. We may note that the types of biradicals involved in the formation of monoradicals in thermopolymerisation can be various. The data of a study whose authors[84] concluded that the macromolecules have benzyl and phenylpropenyl end groups are extremely interesting in this sense. Clearly, PTHN cannot be their source. It is also unlikely that they arise in the thermal decomposition of dimers, since the rate of this reaction should be extremely low and the dimer $C_6H_5CH_2CH_2CH_2{=}CHC_6H_5$ has not been detected. Apparently the trimeric biradical



should be regarded as the source of initiating radicals.

In low-molecular-weight products of the thermopolymerisation of styrene in the presence of $FeCl_3$, the following fragments have been discovered:[85]



It has been suggested that they are due to the primary initiating radicals, which confirms Mayo's mechanism. However, they could be formed in other ways. Thus the phenyltetralin fragment can arise on chain transfer via PTHN and the phenylethyl fragment enters into the composition of the trimer.

We shall now confirm the available data on the polymerisation of styrene and other vinyl-aromatic compounds. The thermal reactions of these monomers are characterised by a series of common features: the formation of dimers having related structures (vinylthiophen, vinylfuran), the same order of the initiation reaction with respect to monomers, which is 3 (for VT, VF, 2-methyl-5-VP, and indene). It is noteworthy that also in the case of vinyl-aromatic compounds a dimeric intermediate participates in the formation of the initiating radicals. In principle, it can also be the adduct formed as a result of the Diels–Alder condensation. This possibility exists for VF, VT, VP, and β-VN, but is realisation in the case of indene, acenaphthalene, and α-VN is extremely problematical, since it requires the occurrence of fairly complex multistage rearrangements. One can therefore assume that there exists only one mechanism of the thermopolymerisation of all vinyl-aromatic monomers.

Thus the biradical mechanisms make it possible to account for the majority of experimental data, including those which do not fit within the framework of Mayo's mechanism.

Table 2. Kinetic parameters of the initiation process in the thermopolymerisation of acrylates.

Monomer	A_i, litre mol^{-1}s^{-1}	E_i, kJ mol^{-1}	t, °C	w_i, mol litre^{-1}s^{-1}	Refs.

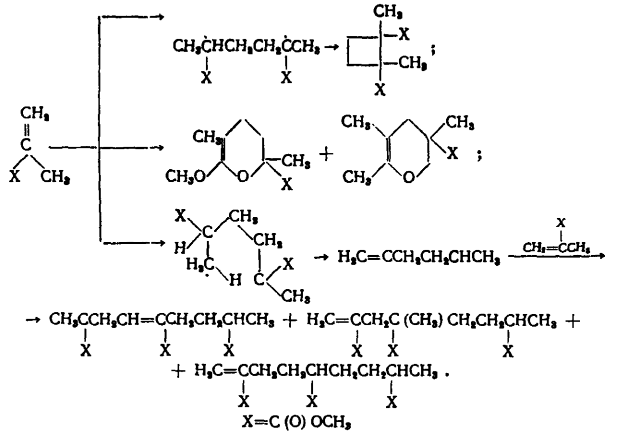
*Bimolecular initiation rate constants.

III. OXYGEN-CONTAINING MONOMERS

1. Acrylates

The kinetic data for bimolecular reactions initiating the polymerisation of acrylates in bulk, obtained in different studies or calculated by ourselves from published results, are presented in Table 2. In the analysis of the data in Table 2, the non-reproducibility of the rate of initiation of methyl methacrylate (MMA) is striking. It has been suggested[88] that this may be caused by the generation of an inhibitor in the thermal reaction. Indeed the rate of increase of viscosity for a fairly low degree of conversion diminishes as the process proceeds. Analysis shows that its reciprocal fits satisfactorily on the linear time plot. This is consistent with the hypothesis put forward by Bamford and Dewar.[88] The rate of initiation of the polymerisation of MMA at 0 °C [88] is fairly high (Table 2). According to the hypothesis of Stickler and Meyerhoff,[90] this can be caused by the accelerating effect of impurities, while pure MMA polymerises at a low rate. However, in this case one should expect a different type of time variation of the rate of increase of viscosity.

According to the data in Table 2, α-substituents (H, CH_3, C_2H_5, C_4H_9) do not exert a significant influence on w_i. An exception is Cl, whose introduction into the α-position increases the rate of initiation of polymerisation. The absolute rates of initiation quoted in a number of studies[86,87,89] differ from one another by three orders of magnitude. This can probably be explained by the causes noted above. Among the low-molecular-weight products, dimers of three types as well as linear trimers have been detected. These are formed via the following tentative mechanisms:

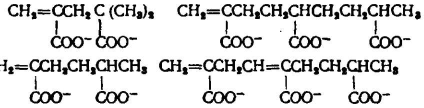


The main product is a linear dimer, the bimolecular rate constant for the formation of which is given by[91–94]

$$k\ (\text{litre mol}^{-1}\text{s}^{-1}) = 1{,}3\cdot10^{11}\exp(-107{,}2/RT).$$

Initiation is achieved as a result of the decomposition of the dimeric biradical.

In the polymerisation of methacrylic acid salts, the following products were identified in the solid phase:[95]



$CH_2{=}C(COO^-)CH_2C(COO^-)(CH_3)_2$ $CH_2{=}C(COO^-)CH_2CH_2CH(COO^-)CH_2CH_2CH(COO^-)CH_3$

$CH_2{=}C(COO^-)CH_2CH_2CH(COO^-)CH_3$ $CH_2{=}C(COO^-)CH_2CH{=}C(COO^-)CH_2CH_2CH(COO^-)CH_3$

A reaction mechanism has been proposed, in which the formation of biradicals is postulated in the first stage.[95]

The inhibition of the thermopolymerisation of acrylates by stable nitroxy-radicals—di(ethoxyphenyl)nitrogen oxide (I), the 4-hydroxy-2,2′,6,6′-tetramethylpiperidin-1-yloxy-radical (II), and the 4-benzoyl-2,2′,6,6′-tetramethylpiperidin-1-yloxy-radical—has been investigated.[86] In all cases, with the exception of methyl acrylate, the dependence of τ on $[In]_0$ is non-linear and resembles the corresponding dependence found for styrene. The results of the treatment of these data by Kurbatov's method[72] are presented in Table 3. Overall, a satisfactory agreement is observed between the rate constants calculated for different conditions. An exception is the value for the polymerisation of butyl methacrylate inhibited by compound (II). On the other hand, the values of w_i obtained using these compounds (I) and (II) agree satisfactorily. The linear dependence of τ on $[In]_0$ observed for the methyl acrylate–radical (I) pair shows that the radical is consumed in accordance with a zero-order law. The process rate constant is 6.75×10^{-9} mol litre^{-1} s^{-1}. This value exceeds almost by three orders of magnitude the rate of initiation found in experiments with the radical (III) and should therefore represent the product $nk_0[M]^2$.

The constant $k_{i,n}$ for the process involving MMA is much too high compared with that found under initiated conditions, while the value of w_i is consistent with that found by Lingnau and Meyerhoff.[89] The constants k for MMA and other monomers of this series are similar. This can be associated with the effect of strong secondary inhibition in the chain process or with the generation of an "internal" inhibitor, which reacts with alkyl radicals, as stated above. It is of interest that this feature is characteristic solely of MMA.

Table 3. The rates of initiation and the rate constants for the inhibition of the polymerisation of acrylates by nitroxy-radicals (calculated from data of Trubnikov et al.[86]).

Radical	k_{in}, litre mol^{-1}s^{-1}	k^*_{in}, litre mol^{-1}s^{-1}	w_i, mol litre^{-1}s^{-1}	10^4k, s^{-1}
		Butyl methacrylate, 80 °C		
(I)	$2.4\cdot10^6$	$5,7\cdot10^6$	$1.5\cdot10^{-11}$	2.7
(II)	$0.3\cdot10^6$	$30\cdot10^6$	$2.3\cdot10^{-11}$	0.60
		Methyl acrylate, 80 °C		
(I)	—	—	—	$\leqslant$0.1(88° C)
(III)	$4.8\cdot10^5$	$7\cdot10^5$	$3.2\cdot10^{-12}$	1.5
		Methyl methacrylate, 90 °C		
(II)	$460\cdot10^5$	$6\cdot10^5$	$4.0\cdot10^{-15}$	0.42

*The inhibition rate constants found under the conditions of initiated polymerisation.[86]

The set of data obtained in the analysis of the characteristics of the inhibition and of the composition and structure of the low-molecular-weight products shows that the thermopolymerisation of acrylate entails the formation of an intermediate, which reacts unimolecularly with the molecules of the inhibitor and the monomer. In the case considered such an intermediate can only be a dimeric biradical. By analogy with styrene, the formation of dimers in the scheme presented above can be represented as a result of its interaction with the monomer and the subsequent unimolecular disproportionation.

2. Vinyl Acetate

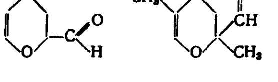
Calculated data based on the results of Starkweather and Taylor[96] have shown that the best agreement between the overall polymerisation rate constants is achieved when a kinetic order with respect to the monomer of 2.5 is adopted. One can then obtain the following expression for the rate of initiation (at 80–110 °C):

$$w_i\,(\text{mol litre}^{-1}\text{s}^{-1})=4.8\cdot10^{18}\exp(-167.2/kT)\,[M]^3.$$

It is close to that found[1] by another method. This means that the initiating radicals are formed in the thermopolymerisation of vinyl acetate with participation of monomer molecules.

3. Acrolein, Methacrolein, and Acrylic Acid

The primary products of the reaction of aldehydes are the corresponding dihydropyrans, formed as a result of 2,4-cycloaddition:[97–100]



Acrylic acid gives rise to a linear unsaturated dimer—acryloylhydracrylic acid.[99] Only the acrolein dimer is formed in the presence of hydroquinone.[99] The activation energy for the thermopolymerisation is 65.4 kJ mol^{-1}. In the presence of an amine inhibitor (whose structure and concentration have not been reported), it increases to 118.8 kJ mol^{-1}.[98] On this basis, it has been concluded that the inhibitor is active in the dimerisation stage.[98]

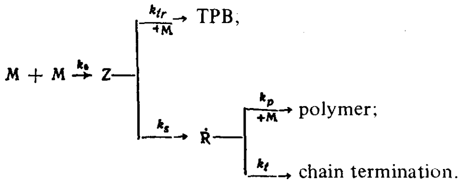
If the reaction takes place under inhibited conditions, the increment in the observed activation energy should be $0.5(E_i + E_t) - E_{in}$, where E_i, E_t, and E_{in} are the activation energies for initiation, chain termination, and the interaction of radicals with the inhibitor. For $E_{in} \cong 15$–25 kJ mol^{-1}, the quantity E_i, calculated on the basis of experiments with and without participation of the inhibitor, is 12–140 kJ mol^{-1} (the values of E_p and E_t were taken from Ham[101]), which means that the thermopolymerisation of acrolein proceeds via a radical-chain mechanism and that dimerisation is the accompanying process.

IV. MONOMERS OF THE ACETYLENE SERIES

Among the products of the thermopolymerisation of vinylacetylene, diethynylcyclobutane and the polymer which is a polyene according to the latest data[103,104] were detected.[102] The kinetic studies were performed in relation to ethynylaromatic compounds: phenylacetylene (PA), 5-ethynyl-2-methylpyridine,[105,106] and 3-ethynylphenyl phenyl ether.[107]

Apart from the polymer, 1,3,5- and 1,2,4-triphenylbenzenes (TPB),[106] whose overall yield was ~10%, were found among the products of the reaction involving PA. Since the overall rate of polymerisation is described by a kinetic equation whose order is close to two, it has been suggested that the initiators are biradicals or more precisely that one of the isomers is formed by the "tail to tail" combination of two monomer molecules, since the lowest activation energy is then expected; TPB arises as a result of the interaction of the biradicals with a monomer molecule.[106]

Analysis of the above data[106] shows that, both for PA and ethynylpyridine, the observed polymerisation rate constant, calculated subject to the condition that the reaction is of second order, is not invariant and depends on the monomer concentration. The relation $[M]^3/w = a + b[M]$, where a and b are constants, hold satisfactorily under these conditions (Fig.1). This result conflicts with the mechanism of the initiation of polymerisation by biradicals. The present author's analysis of the kinetic schemes has shown that unimolecular and bimolecular destruction of biradicals should correspond not to second order with respect to the monomer but to a higher or lower order. Hence the experimental reaction order and the dependence of the rate constant on the monomer concentration lead to the conclusion that the initiation reaction involves the formation of an intermediate Z. On this basis, one can postulate that the polymerisation mechanism is described by the following scheme:



According to this scheme, the intermediate gives rise to initiating radicals in the unimolecular reaction and to TPB in the bimolecular reaction. Chain termination takes place linearly, as has been established by Pickard and Jones.[107]

Under conditions stationary with respect to Z and $\dot{R}$, the expressions for the rate of polymerisation and trimerisation are as follows:

$$w = \frac{k_0 k_p k_s [M]^3}{k_t (k_s + k_{tr} [M])}; \tag{1}$$

$$w_{tr} = \frac{k_0 k_{tr} [M]^3}{k_s + k_{tr} [M]}. \tag{2}$$

Evidently the former agrees with the empirical relation.

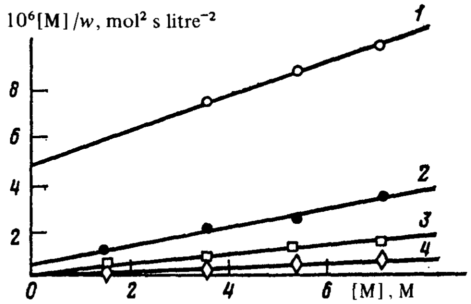


Figure 1. Dependence of the reciprocal of the measured third order rate constant for the polymerisation of phenylacetylene on its concentration at different temperatures (°C): 1) 125; 2) 140; 3) 155; 4) 170 (according to the data of Bantsyrev et al.[106]).

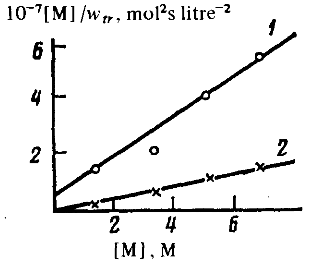

Figure 2. Dependence of the reciprocal of the third order rate constant for the formation of 1,2,4-triphenylbenzene (line 1), and 1,3,5-triphenylbenzene (line 2) at 140 °C on the phenylacetylene concentration (according to the data of Bantsyrev et al.[106]).

Treatment in terms of the second equation of data on the rate of formation of TPB isomers, which can be calculated from the results of Bantsyrev et al.,[106] confirms the validity of the proposed mechanism (Fig.2). The difference between the slopes of the linear relations in Fig.2 indicates unequal rates of generation of the precursors of the different TPB isomers. The constant k_0 is 1.5×10^{-7} litre mol^{-1} s^{-1} for 1,2,4-TPB and 5×10^{-7} litre mol^{-1} s^{-1} for 1,3,5-TPB. The straight line corresponding to 1,3,5-TPB intersects the ordinate axis near zero; consequently k_s/k_{tr} is vanishingly small. Thus the intermediate preceding 1,3,5-TPB does not participate in the initiating reaction. For 1,2,4-TPB, the above quantity, estimated from kinetic data for both polymerisation and trimerisation, is 5–6 mol litre^{-1}.

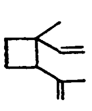
As regards the nature of the intermediate, there is no doubt that it is a biradical. Thus two types of paramagnetic species were detected by EPR in the thermopolymerisation of PA in the presence of spin trapping agents.[108] Analysis of the spectra permitted the conclusion that they arise as a result of the acceptance of the polymeric monoradical and biradical.

V. DIENE MONOMERS

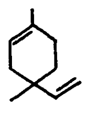
1. Derivatives of Butadiene and Cyclic Dienes

The majority of publications concerning the thermal reactions of hydrocarbons of the divinyl series refer to the study of low-molecular-weight cyclic products formed as a result of the [2 + 4]cycloaddition. The polymerisation kinetics have been investigated only in a few early studies and to an extremely limited extent. We shall deal here with data which are of fundamental interest.

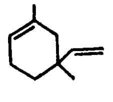
The thermal reactions of diene hydrocarbons of the divinyl series were accompanied by the formation of a polymer and dimers of three main types: derivatives of cyclobutane, vinylcyclohex-3-ene, and cyclo-octa-1,5-diene. Mainly 1-vinylcyclohex-3-ene and 4–5% of 1,2-divinylcyclobutane are formed from divinyl itself.[109] Isoprene gives rise to all the possible dimers:[110,111]



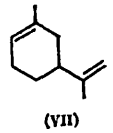
(IV)



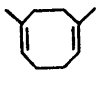
(V)



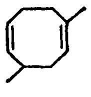
(VI)



(VII)



(VIII)



(IX)

The low-molecular-weight products of the reaction of *cis*-piperylene are only the six- and eight-membered dimers, while *trans*-piperylene gives rise to 80% of four-membered products.[111] The biisopropenyl dimer consists exclusively of dimethyl-4,6-dimenthene.[112]

The polymerisation of methylallenes leads to the formation of dimethylenecyclobutanes, which subsequently participate in secondary reactions.[113] Cyclopentadiene dimerises with an activation energy of 69 kJ mol^{-1} and the reaction is reversible.[111,114] Trimers are formed in a very small amount as a result of the cycloaddition of the monomer to the dimer.[115] Cyclohexadiene reacts via two pathways: dimerisation and polymerisation.[116]

The polymerisation reaction of all the dienes investigated is of second order with respect to the monomer. This order persists also when the reaction is carried out in dimethylformamide.[117] The results of kinetic studies are presented in Table 4. Since the overall polymerisation is a second order reaction, we may conclude that the initiation is a bimolecular process. Assuming that the activation energy for the bimolecular termination of the kinetic chains E_t is close to 8 kJ mol^{-1}, while $A_t = 10^7 - 10^8$ litre mol^{-1} s^{-1} as for the majority of monomers, we obtain $E_i \cong 92$ kJ mol^{-1} and $A_i \cong 8$ to 80 litre mol^{-1} s^{-1} for isoprene, while the corresponding values for biisopropenyl are 88 kJ mol^{-1} and 0.1–1 litre mol^{-1} s^{-1} respectively. The constants k_p were taken from Kauffmann et al.[16] (p.120) and Starinchikova and Svetlov[127] (p.342). Since the pre-exponential factors A_i found are fairly low, one can assume that the initiation rate constant is an effective quantity. This is possible only when the radicals are formed via an intermediate Z, which is also converted competitively, for example, into dimers. The reaction mechanism can be formally represented schematically as follows:

$$\begin{tikzcd} & & \dot{R}\,; \\ M + M \arrow[r, "k_0"] & Z \arrow[ur, "k_s"] \arrow[dr, "k_d"'] & \\ & & D. \end{tikzcd}$$

According to this scheme, the rate of initiation is defined by the expression

$$w_i = k_0 k_s [M]^2/(k_s + k_d).$$

Then, assuming that $k_s \ll k_d$ and adopting $E_d \cong 84-92$ kJ mol^{-1} and $A_d \cong 10^6-10^7$ litre mol^{-1} s^{-1}, we obtain $E_s - E_d \cong 0$ and $A_s/A_d \cong 10^{-6}-10^{-4}$. It is noteworthy that no measurements were made of the initiation reaction order on the basis of concentration; one cannot rule out that it amounts to 2.5 and that the rate constant k_s actually characterises a bimolecular process.

Table 4. Kinetic parameters of the reactions involving the formation of polymers (P) and dimers (D) from diene monomers.

Monomer	Reaction product	E, kJ mol^{-1}	A, litre mol^{-1}s^{-1}	Refs.
Isoprene	(VII)	94	$1.8 \cdot 10^7$	[118]
»	(V) + (VI) *	90	$1.4 \cdot 10^6$	[118]

Cyclohexa-1,3-diene	D	86	$4 \cdot 10^4$	[116]
»	P	96,5	$1.7 \cdot 10^5$	[116]

*Gapon[118] called this product the second dimer, while according to Nazarov et al.[110] it is a mixture of compounds (V) and (VI).

In our view the intermediate is none other than a biradical. The formation of biradicals in the thermopolymerisation of dienes has been confirmed by the presence of four-membered cyclic dimers. It has been established[119] that the volume of the transition state in the dimerisation of isoprene is greater by 21–23 cm^3 mol^{-1} than the volume of the dimer. On passing from six-membered rings to the corresponding linear hydrocarbons, the same increase in specific volume occurs. On this basis, it has been concluded that the intermediate is indeed a biradical. The dimerisation of 1,4-dideuteriobutadiene is accompanied by a decrease of the stereospecificity of the dienophile component by 10%.[121]

2. Chloroprene

The thermopolymerisation of chloroprene is accompanied by the formation of products of the same type as for other 1,3-dienes, namely compounds corresponding to divinylcyclobutane (X),[122] two vinylcyclohexene (XI) isomers, and cyclooctadiene.[123] The first two products predominate at high temperatures (95 °C) and the compound of type (X) isomerises to (XI). The polymer is linear *cis*-polychloroprene.[124] The dimers and the polymer are formed in accordance with a second-order law at different rates and with different activation energies; the latter differ little for the 4- and 6-membered isomers, amounting to 84–86 kJ mol^{-1}.[124,125] Typical inhibitors suppress the formation of the polymer but do not affect dimerisation,[124] DPPH being converted under these conditions into the corresponding hydrazine.

However, a number of significant differences make it necessary to regard the mechanism of the thermopolymerisation of chloroprene as extremely stereospecific and different from the mechanism of the reactions of other dienes. At the end of the induction period, associated with the exhaustion of the inhibitor, the concentration of the dimer falls, tending to ~1 wt.%, while the polymer is formed at a constant rate.[125] If the reaction is carried out without an inhibitor, then the concentration of dimers increases from a certain initial value to a limiting value, which is also close to 1 wt.%. These findings enabled the authors[124] to reach the unusual conclusion that the polymer is formed exclusively from the dimer; there is no doubt about its validity.

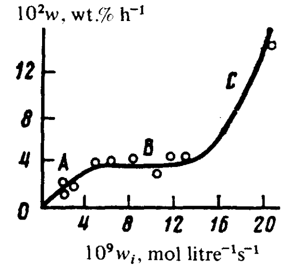

Figure 3. Dependence of the rate of polymerisation of chloroprene on the rate of initiation at 35 °C.[125]

The method used in the preliminary treatment of the monomer, especially, the degree of elimination of oxygen from the latter and the degree of its reduction, exerts the main influence on the rate of polymerisation. Chloroprene dimers do not polymerise, but the introduction of the monomer renders this process possible. The authors[125] suggested that the polymerisation initiator is an oxidised form of the monomer, which is not determined as the peroxide. The relation between the rates of polymerisation and initiation of chloroprene (the latter was estimated from the consumption of DPPH) is characterised by the presence of different sections *A*, *B*, and C (Fig.3) whose existence has been explained as follows.[125] After the careful removal of oxygen, the concentration of catalytic species Y is small and the rate of polymerisation is lower than that of dimerisation. Indeed, along section *A*, the sum of the concentrations of the dimers and the polymer is approximately equal to the concentration of the dimers formed in the presence of the inhibitor. Along section *B*, the rate of polymerisation is constant and equal to the rate of dimerisation in the presence of the inhibitor regardless of the rate of initiation. This means that [Y] is large and the rate of conversion of the dimers into the polymer is much higher than the rate of their formation. In order to explain section C of the curve, the monomer brought into contact with oxygen was employed and there is no doubt that the increase in the rate of polymerisation in this region is associated with the influence of a polyperoxide.[126]

Taking into account all the facts described, one may conclude that the monomer contains catalytic species which lead to the polymerisation of the dimers via ring opening. In the presence of inhibitors, these species are not destroyed. Therefore, there should exist an active centre (I), originating from the catalytic compound Y. It participates in the kinetic chain propagation and termination reactions and in the latter case the catalyst Y is regenerated.

We believe that the following mechanism is most probable:

$$\mathrm{M}+\mathrm{M}\xrightarrow{k_0}\mathrm{D};\qquad \mathrm{D}+\mathrm{Y}\xrightarrow{k_s}\mathrm{I};\quad \mathrm{D}+\mathrm{I}\xrightarrow{k_p}\mathrm{P};\quad \mathrm{I}\xrightarrow{k_t}\text{chain termination.}$$

The steady concentration of dimers can be found from the equation which follows from the above scheme:

$$0.5\left(\frac{k_t}{k_0k_pk_s[\mathrm{Y}][\mathrm{M}]^2}\right)^{0.5}\ln\frac{([\mathrm{D}]_{st}+[\mathrm{D}])([\mathrm{D}]_{st}-[\mathrm{D}]_0)}{([\mathrm{D}]_{st}-[\mathrm{D}])([\mathrm{D}]_{st}+[\mathrm{D}]_0)}=t, \qquad (3)$$

where $[\mathrm{D}]_{st}$ is the stationary concentration of the dimer.

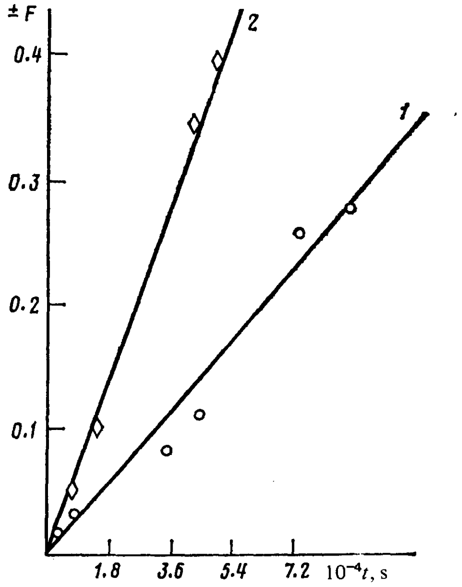

Figure 4. Semilogarithmic representation of the kinetics of the attainment of a stationary chloroprene concentration (at 35 °C): 1) calculation based on the accumulation of the dimer; 2) calculated based on the consumption of the dimer (according to the data of Billingham et al.[125]).

Calculation of the change in the concentration of the dimers by this equation both in experiments with the inhibitor and without it makes it possible to obtain the linear relations presented in Fig.4. In the second case, the sign of the function

$$F=\ln\frac{([\mathrm{D}]_{st}+[\mathrm{D}])([\mathrm{D}]_{st}-[\mathrm{D}]_0)}{([\mathrm{D}]_{st}-[\mathrm{D}])([\mathrm{D}]_{st}+[\mathrm{D}]_0)}$$

is negative. Since it is impossible to determine $[\mathrm{D}]_{st}$ accurately from the data presented, we assumed that it is approximately 1%. If it is ~1.5%, then the sign of F becomes positive. Evidently the authors[125] used monomer specimens with different concentrations [Y], which determine $[\mathrm{D}]_{st}$. The validity of the formal relations, which also show that $[\mathrm{I}] \ll [\mathrm{Y}]$, is of fundamental importance.

Within the framework of the scheme presented above, the rate of polymerisation is described by the expression

$$w=\frac{k_pk_s}{k_t}[\mathrm{Y}][\mathrm{D}]^2. \qquad (4)$$

After substituting in Eqn.(4) the expression for the steady concentration of the dimers, we obtain

$$w=\frac{k_pk_s}{k_t}[\mathrm{Y}][\mathrm{D}]_{st}\left(\frac{\beta e^{-\alpha t}-1}{\beta e^{\alpha t}+1}\right),$$

where

$$\alpha=2\left(\frac{k_0k_pk_s[\mathrm{Y}][\mathrm{M}]^2}{k_t}\right)^{0.5};\quad \beta=\frac{[\mathrm{D}]_{st}+[\mathrm{D}]_0}{[\mathrm{D}]_{st}-[\mathrm{D}]_0}.$$

Since

$$[\mathrm{D}]_{st}=\left(\frac{k_0k_t[\mathrm{M}]^2}{k_pk_s[\mathrm{Y}]}\right),$$

it follows that, for large values of [Y], $w = k_0[\mathrm{M}]^2$.

Two questions are of decisive important for the mechanism of the thermopolymerisation of chloroprene: (a) the nature of the catalytic species and of the active centre; (b) the mechanism of the ring opening. It is as yet difficult to give a definite answer to these questions.

On the grounds that substances tending to undergo homolytic reactions exhibit an inhibiting activity, presumably I is a radical in nature and diphenylpicrylhydrazine is formed as a result of a disproportionation reaction. Then the interaction of the dimer and Y should result in the formation of an extremely specific radical, which reacts with the dimer but not with the monomer. The equality of the rates of dimerisation and polymerisation suggests either the involvement of the dimers of all types in the second process or the establishment of equilibrium between them via the intermediate. There exists also the view that the rearrangement proceeds via the formation of a biradical.[121] This may explain the observed characteristics of the polymerisation, although the mechanism of the stabilisation of the biradicals by the catalytic species is obscure.

3. Divinyl Sulphide

The elementary units of the polymer macromolecules formed from divinyl sulphide have the thiophane structure.[127] The order of the overall polymerisation reaction with respect to the monomer is 2.1 and the activation energy is 50.2 kJ mol^{-1}. The activation energy for thermal initiation (62 kJ mol^{-1}) and the pre-exponential factor for the rate constant (~10^3 litre mol^{-1} s^{-1}) can be estimated from the data of Starinchikova and Svetlov.[127]

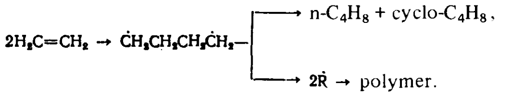
VI. ETHYLENE

The thermal reactions of ethylene have been investigated in the gas and liquid phases. At temperatures below 400 °C, polymerisation mainly takes place[128] (p.125). The primary reaction products detected consisted of 31.7% of butenes, 12.6% of cyclobutanes, and also propene and higher olefins. The activation energy for the formation of lower hydrocarbons is 475 kJ mol^{-1}. The kinetic order of the polymerisation reaction with respect to ethylene at sufficiently high conversions is close to two but at early stages it amounts to 2.3 to 2.5.[129]

The polymerisation of ethylene in solution in naphthalene is characterised by a kinetic order of 2.6, an activation energy of 170 kJ mol^{-1}, and a pre-exponential factor of $10^{10.1}$ litre mol^{-1} s^{-1}.[129] It has been suggested[129] that the reaction order observed is determined by the stage involving the formation of the intermediate. It is believed[128] that the initiating radicals arise when a hydrogen atom is transferred from one ethylene molecule to another. The observed activation energy for the initiation stage is consistent with this hypothesis but one cannot rule out the possibility of the formation of the tetramethylene biradical as the intermediate.[128]

The data of Russell and Hottel[129] permit the conclusion that the order of the initiation reaction with respect to ethylene is 3. When w_i (mol litre^{-1} s^{-1}) = $10^{15}\exp(-272/RT)\,[\mathrm{M}]^3$.

Bearing in mind that the reaction considered is of third order and also taking into account the formation of cyclobutane and butene, its mechanism can be represented by the following scheme involving the tetramethylene biradical:



$$2H_2C{=}CH_2 \rightarrow \dot{C}H_2CH_2CH_2\dot{C}H_2 - \begin{cases} \rightarrow n\text{-}C_4H_8 + \text{cyclo-}C_4H_8, \\ \rightarrow 2\dot{R} \rightarrow \text{polymer.} \end{cases}$$

Chlorotrifluoroethylene and tetrafluoroethylene give rise to only the corresponding cyclobutane derivatives.[130]

VII. CONCLUSION

Analysis of the results of the study of the thermopolymerisation of monomers of different classes permits certain general conclusions concerning the mechanism of this reaction.

The low-molecular-weight products of the given process can be various but as a rule they are dimers. Phenylacetylene gives rise to the trimer only. Mixtures of different dimers and trimers are produced from styrene and MMA and tetramers have also been detected.

The polymerisation of all monomers, with the exception of chloroprene, proceeds in accordance with the classical radical-chain mechanism. The initiating radicals are generated via an intermediate which is in most cases a biradical. Although the formation of PTHN as an intermediate has in fact been postulated for styrene, a number of results conflict with this hypothesis. There is probably no point in assuming a special exceptional mechanism for this monomer, which does not exhibit any anomalous properties. The third order of the initiation stage with respect to the monomer shows that the radicals are formed as a result of the interaction of the dimeric biradical with the monomer, which subsequently decomposes, producing, for example, in the case of styrene, the benzyl and phenylpropenyl radicals. Judging from the fairly low pre-exponential factors in the expressions for the initiation rate constants, the third kinetic order is to be expected for MMA, isoprene, bi-isopropenyl, indene, and divinyl sulphate. The primary radical is then preferentially converted into the dimer, which is confirmed in many instances either by the absence of trimers or by their low yield. On the other hand, when the competing reaction of the biradical with the monomer takes place to an appreciable extent, the reaction order may become less than three, falling to two. In order to establish the true reaction order, detailed kinetic studies are required and these have been by no means always carried out. In contrast to other monomers, in the polymerisation of phenylacetylene monoradicals arise in the decomposition of a dimeric biradical, whose reaction with the monomer leads to the formation of triphenylbenzene. The initiating radicals are not formed at all or are formed with a low yield in the thermopolymerisation of trifluorostyrene and acrylonitrile[101] (p.221), whose only products are the corresponding four-membered dimers.[131] A similar situation has been observed for α- and β-halogenostyrenes.

It is noteworthy that, when the classical values of the pre-exponential factors are used for the rate constants for the elementary stages involved in the initiation process, it is impossible to account for the high pre-exponential factors in the expression for the initiation rate constants for monomers such as ethylene and vinyl acetate, which amount to ~10^{15} and 10^{18} litre^2 mol^{-2} s^{-1} respectively. On the other hand, this can be explained by the fairly low values of A for the stages where the biradicals are converted into low-molecular-weight compounds or for their reversible decomposition with formation of the monomer and, on the other, by the more complex expression for the overall rate constant, which is determined by the characteristic features of the mechanism.

In contrast to other methods of generating similar reactive species, such as the decomposition of cyclic diazo-compounds or the thermolysis of cyclobutanes, in the thermal reaction of the monomers there is a possibility of the formation of biradicals with different configurations. It has been noted correctly[121] that the "uncoiled" forms of biradicals are less susceptible to unimolecular recombination, since for the occurrence of the latter it is essential that the biradical should assume a cyclic form, from which the cyclic dimer can be readily produced. Indeed, inhibitors do not influence the formation of diphenylcyclobutane in the decomposition of tetrahydropyridazines and in the thermal reaction of styrene.[19] The rate of generation of the initiating monoradicals is also extremely low. Biradicals in an acyclic conformation are capable of reacting unimolecularly also via disproportionation and alkylation. There is also a possibility of a bimolecular reaction, for example, the reaction with the monomer. Judging from data of Kirchner and Burhholz,[12] the ratio k_d/k_{tr} for styrene should be 2.3. Since the deviation from the zero order of the DPPH destruction reaction occurs at the concentration (DPPH) ≅ 10^{-5} M,[63] it follows that $k_b/k_{tr} \cong 8.7 \times 10^5$.

The rate constants for the destruction of biradicals generated in the photochemical reactions of ketones (Norrish type 2 reactions) in the presence of various acceptors (oxygen, bipyridyl hydrochloride, dibutyl selenoketone) are (4–6) × 10^9 mol^{-1} s^{-1},[132,133] i.e. exceed significantly in absolute magnitude the constants known for monoradicals. A similar phenomenon had been observed earlier for nitroxy-biradicals.[134] In order to account for this finding, the concept of the adiabatic nature of the reactions was resorted to[134] (pp.378, 386). If it is assumed that the rate constants for the reactions of the dimeric styrene biradicals with DPPH are also diffusion dependent, it is possible to calculate $k_{tr} \cong 5 \times 10^3$ litre mol^{-1} s^{-1} and $k_d \cong 10^4$ s^{-1}. The latter quantity may be too low, but even in the case of cyclic biradicals, whose conversion into a state favourable for recombination requires virtually no rotation about the C–C bonds, there exists a competing reaction with divinyl.[135]

The question whether the initiating radicals and all the low-molecular-weight compounds are formed via the same intermediate is of fundamental importance. There is perhaps no doubt that this is true (a) for styrene, because it is supported by evidence obtained in the study of the thermopolymerisation kinetics, the structures of the compounds produced, and the influence of radical acceptors and (b) for monomers whose thermopolymerisation gives rise preferentially to oligomers with a linear structure, which are formed via an intermediate (methacrylates).

However, for the monomers giving rise to low-molecular-weight 2,4-cycloaddition products, the answer to the question posed above is not unambiguous. The possibility of the formation of small amounts of four-membered or linear dimers cannot be ruled out even in those cases where the main product is a six-membered compound (2,3-dimethylbutadiene). On the other hand, there exists the hypothesis that 2,4-cycloaddition reactions take place via two competing mechanisms: synchronous and biradical.[136] The second pathway may be responsible for the initiation of the polymerisation. According to most investigators, the activation energy for the biradical process should be significantly higher than for the synchronous process[121] and its contribution should be correspondingly lower.

Thus in the given case the problem also reduces to the familiar problem of the mechanism of pericyclic reactions. Having analysed numerous facts, Firestone[121] concluded that the biradical mechanism makes it possible to explain virtually all the experimental data, while the synchronous mechanism is inconsistent with many of them.

Overall, one may conclude that there exists a general mechanism of the thermal reactions of many monomers. Specific differences may be observed for individual representatives of substances of this kind.

The Electronic Structure of Superhalogens and Superalkalies

G.L.Gutsev and A.I.Boldyrev

Molecular systems with anomalous values of the first ionisation ptoentials or electron affinity have been examined. On the basis of the results of calculations by the DV-X_α method it has been possible to relate the values of the electron affinity and the first ionisation potential to the characteristic features of the electronic structure of these compounds. The analysis carried out has made it possible to distinguish two large classes of chemical compound: with an anomalously high electron affinity (superhalogens) and with anomalously low first ionisation potentials (superalkalies). Estimates of the maximum possible electron affinity of chemical compounds have been given, and ways of finding these systems have been outlined. Various possible manifestations of high electron affinity and low first ionisation potentials in the physicochemical properties of superhalogens and superalkalies have been examined.

I. INTRODUCTION

Molecular systems exhibiting extremal characteristics are of particular interest from both theoretical and practical viewpoints. The theoretical study of these systems facilitates the appearance of new fundamental ideas on the physicochemical properties of matter, and the use of these systems in technology extends considerably the range of constructional materials.

The electron affinity (EA) and the first ionisation potential (IP) are the most important characteristics of molecules, so that molecules exhibiting the maximum values of the EA or the minimum values of the IP are of particular interest for chemistry. Systems with high EA play an important role in the synthesis of compounds of new classes. For example, the synthesis of the compound $Xe^+[PtF_6]^-$,[1,2] with which the chemistry of the noble gases began, was carried out using platinum hexafluoride PtF_6, which has a high EA. Subsequently, systems with high EA have been used to synthesise many new compounds, such as $XeF^+[RuF_6]^-$, $XeF_5^+[RuF_6]^-$,[3] $Xe_2F_3^+[AsF_6]^-$,[4] $KrF^+[SbF_6]^-$,[5] and many others,[6-12] and also compounds containing clusters of non-transition elements of the type Te_4^{2+}, Bi_5^{3+}, and S_8^{2+} as cations.[13]

Systems with high EA have recently been used as a basis for the synthesis of organic superconductors,[14-20] and also to modify the electronic structure of conjugated polymers (polymer doping) [21-25] and graphite (intercalation of graphite).[26] Systems with low first IP are also important for preparing new compounds, and the first salts of this type, $Li_3O^+[NO]^-$ and $Li_3O^+[NO_2]^-$ have already been synthesised.[27-29]

The anomalous EA and IP values are apparently related to the characteristic features of the electronic structure of the chemical compounds, so that it is of undoubted interest to study the electronic structure of molecular systems exhibiting anomalously high EA values and anomalously low IP values. This problem is dealt with in the present review.

II. ELECTRON AFFINITY

The electron affinity of a molecule or radical is defined as the decrease in the energy of the system when one electron is added. For molecules it is possible to distinguish two types of EA: adiabatic and vertical. The adiabatic EA of a neutral molecule is the difference between the total energies of the neutral system for its equilibrium geometry (R_e) and the negatively charged system, again for the equilibrium geometry (R_e^-):

$$\mathrm{EA}_{\mathrm{ad}} = E(R_e) - E^-(R_e^-) \qquad (1)$$

The vertical EA is the difference between the total energies of the neutral and charged systems for the equilibrium geometry of the neutral system (R_e):

$$\mathrm{EA}_{\mathrm{vert}} = E(R_e) - E^-(R_e) \qquad (2)$$

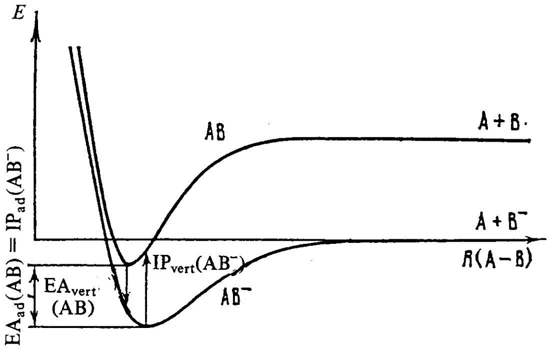

Figure 1. Diagram illustrating the definition of adiabatic and vertical EA and IP for the case of a diatomic molecule AB (R is the distance between the atoms A and B).

Moreover, for a negatively charged system it is possible to define the upper ionisation potential (IP), which also may be vertical and adiabatic. The adiabatic IP of a negative ion is equal to the difference between the total energies of the neutral system for its equilibrium geometry and the negatively charged ion for its equilibrium geometry:

$$\mathrm{IP}_{\mathrm{ad}} = -[E^-(R_e^-) - E(R_e)] \qquad (3)$$

Eqn.(3) shows that the adiabatic IP of a negative ion coincides exactly with the adiabatic EA of the neutral molecule. The vertical IP is equal to the difference between the total energies of the charged system and the neutral system for the equilibrium geometry of the ion:

$$\mathrm{IP}_{\mathrm{vert}} = -[E^-(R_e^-) - E(R_e^-)] \qquad (4)$$

The vertical IP of a negative ion differs from the vertical EA of the neutral system. The difference between the vertical and adiabatic values of the EA and IP is called the adiabatic correction.

$$\begin{aligned}\mathrm{EA}_{\mathrm{ad}} &= \mathrm{EA}_{\mathrm{vert}} + \Delta\mathrm{EA}_{\mathrm{ad}}\\ \mathrm{IP}_{\mathrm{ad}} &= \mathrm{IP}_{\mathrm{vert}} + \Delta\mathrm{IP}_{\mathrm{ad}}\end{aligned} \qquad (5)$$

These definitions of the EA and IP are illustrated graphically in Fig.1.

It should be emphasised that in practice, all three experimental values of $\mathrm{EA}_{\mathrm{ad}}$, $\mathrm{EA}_{\mathrm{vert}}$, and $\mathrm{IP}_{\mathrm{vert}}$ are not known simultaneously for any system. The values are equal to within the adiabatic corrections, however, so that is is necessary to consider in more detail the estimation of the values of these corrections. An analysis of the experimental photoelectron spectra of the molecules SF_6, C_6H_6, MoF_6, WF_6, and UF_6[30] showed that $\Delta\mathrm{IP}_{\mathrm{ad}}$ is generally small (usually 0.1–0.2 eV) and does not exceed 0.5 eV. The experimental photoelectron spectra of BrF_5 and IF_5[31] also indicate that the difference between $\mathrm{IP}_{\mathrm{ad}}$ and $\mathrm{IP}_{\mathrm{vert}}$ is small (0.4–0.6 eV).

The low values of the adiabatic corrections for these molecules are related to the fact that the electron is removed from non-bonding molecular orbitals (MO). Approximately the same $\Delta\mathrm{EA}_{\mathrm{ad}}$ values should be expected in those cases where the additional electron occupies a non-bonding MO. In those cases where the electron enters an antibonding MO, however, the value of the adiabatic correction may reach 1.5–3 eV. According to non-empirical calculations of the electronic structure of the SF_6 molecule and the SF_6^- anion, allowance for geometric relaxation in the bond lengths of the SF_6 molecule leads to an increase in the EA by 2.5 eV.[32] Calculations of the EA of the molecules PF_5, AsF_5, and SbF_5 by the present authors show that for these molecules, $\Delta\mathrm{EA}_{\mathrm{ad}} \cong 2.8$ eV, and that the negative ion has a square pyramidal structure, whereas the neutral molecule has a trigonal bipyramidal structure.

Thus in the case where the additional electron occupies a non-bonding MO, the adiabatic correction is small (~0.5 eV). If the treatment is restricted to an error of 0.5 eV (this can be done in those cases where the EA value is small), then to determine the EA it is sufficient to know one of the quantities $\mathrm{EA}_{\mathrm{ad}}$, $\mathrm{EA}_{\mathrm{vert}}$, or $\mathrm{IP}_{\mathrm{vert}}$. In this approximation, the problem of calculating the EA is simplified considerably, since it is possible to replace the geometry of the radicals, which is often unknown, by the geometry of negative ions with closed shells, which is known from crystallographic data for corresponding salts.

Thus for systems of the type being discussed, it is possible to distinguish two levels of the study of EA. The first level corresponds to a crude estimate of the EA, when the difference between the values of $\mathrm{EA}_{\mathrm{ad}}$, $\mathrm{EA}_{\mathrm{vert}}$, and $\mathrm{IP}_{\mathrm{vert}}$ is neglected. At this level, the errors in the estimation of the EA may reach 0.5–1.0 eV. At the second level, it is necessary to take account of $\Delta\mathrm{EA}_{\mathrm{ad}}$ and $\Delta\mathrm{IP}_{\mathrm{ad}}$, and in the comparison with the experimentally determined values it is necessary to take account of the conditions under which the experiment was carried out. At the second level, the errors should not exceed 0.1–0.2 eV. At present, it is apparently possible to reach the second level of the determination of electron affinity for small radicals, but for most systems, existing theoretical methods make it necessary to restrict the treatment to the first level.

When the additional electron occupies an antibonding MO, all three quantities ($\mathrm{EA}_{\mathrm{ad}}$, $\mathrm{EA}_{\mathrm{vert}}$, and $\mathrm{IP}_{\mathrm{vert}}$) may differ considerably, and they must be examined separately.

A large number of methods are used for the experimental determination of the EA: photo-ionisation,[33,34] surface ionisation,[35,36] fragmentation by electron impact,[34] molecular photodissociation,[34] equilibrium sublimation,[37] radiative addition of an electron,[37] measurement of crystal lattice energies,[37] charge-transfer reactions,[38,39] photosensitive ionisation,[34] and others.[40,41] The greatest experimental success[34,40] has been achieved by the laser photo-ionisation of negatively charged systems, but it is applicable only to substances which can be obtained in the gas phase in a sufficient concentration. In spite of the wide range of experimental methods, the results of the determination of the EA in early studies often do not agree with one another. For example, for the NO_2 radical the experimentally determined EA values lie in the range 1.6–4.0 eV; according to some authors, $EA(NO_2) > 3.613$ eV, and according to others, $EA(NO_2) < 3.063$ eV.[38,39]

An alternative method of estimating EA is provided by quantum-chemical calculations. One of the most important aims of both experimental and theoretical studies of EA is undoubtedly the search for simple models which would make it possible to predict qualitatively whether an EA has a high or a low value. The study of systems having anomalously high EA is of particular interest.

The direct calculation of EA is a difficult problem in quantum chemistry. The use of Koopmans' theorem[42] or the ΔSCF procedure[43] to estimate EA gives values which often differ from the experimental values by 2–3 eV.[44] The use of non-empirical methods with allowance for correlation[44–49] makes it possible to calculate EA with an accuracy of 0.1 to 0.2 eV, but their application at present is restricted to small molecules.

X_α methods, which make it possible to examine comparatively large systems, have recently begun to be used for EA calculations.[44]

Calculations of the electronic structure of a large number of molecules by X_α methods show that these methods are very effective for large systems and practically always ensure the correct order of magnitude of the calculated IP values with comparatively small deviations from the experimental IP values. The X_α calculation procedure has been described in sufficient detail,[44,50–55] and will not be described in the present work.

Among the elements of the periodic system, halogen atoms have the highest EA (3.0–3.6 eV). In molecules and polyatomic radicals, as a result of collective effects, the EA may be higher than the EA of the halogens. These systems are called superhalogens.

III. ELECTRONIC STRUCTURE OF SUPERHALOGENS

In the examination of systems with anomalously high EA values, two problems arise. Firstly, it is necessary to outline the range of molecules which can be regarded as superhalogens. Secondly, it is necessary to determine the highest EA values that molecular systems in general can have, and also the specific cases in which maximum EA values can be expected.

Simple qualitative ideas relating the EA value to the characteristics of the electronic structures of chemical compounds have been formulated.[56–58] These ideas make it possible to distinguish a class of compound with high EA; the arguments on which they are based will be discussed in detail below.

For the development of models it is natural to use the orbital approach, which is widely employed to interpret electronic, photoelectron, and X-ray electron spectra, and which also forms the basis of the Woodward–Hoffman rules, according to which the energies of the MO formed by AO of the same type should lie in the following order: ε(bonding) > ε(non-bonding) > ε(antibonding). Thus the value of the EA can be related to the structure of the lowest unoccupied MO (LUMO) of the neutral system, which generally accepts the additional electron on formation of an anion, and the value of the first IP of the anion can be related to the structure of its highest occupied MO (HOMO). This gives the corresponding order: IP(bonding) > IP(non-bonding) > IP(antibonding), that is the EA value depends on the type of HOMO of the anion.

A second important factor influencing the magnitude of the EA of a molecule is the value of the EA of the atoms making up the molecule. The higher the EA of the atoms, the higher may be the EA of the compound as a whole. It is therefore possible to have cases where, in spite of the antibonding character of the HOMO of the anion, and as a result of the high EA of the atoms making up the molecule, the EA of the whole molecule will be greater than that of a molecule for which the HOMO of the anion is non-bonding or even antibonding, but in which the values of the EA of the individual atoms are low.

A third important factor influencing the value of the EA of a molecule is the degree of delocalisation of the "additional" electron. According to traditional ideas,[59] the smaller the fraction of an electron $\delta\bar{e}$, added to an atom, the easier it is for the atom to retain it. In the limiting case, when $\delta\bar{e} \to 0$, the IP of the anion approaches the IP of the neutral molecule, which is fairly high. Thus the EA should increase with increase in the extent of the delocalisation of the electron over an increasing number of electronegative atoms making up the molecule.

Calculations by the present authors for the model system $F + \delta\bar{e}$, where $\delta\bar{e} = 0.1, 0.2, \ldots 1.0$ show that the ratio $[E(F + \delta\bar{e}) - E(F^-)]/\delta\bar{e}$, where E is the total energy, increases with decrease in $\delta\bar{e}$. The greatest contribution to the difference in the energies is made by the energies of attraction to the nucleus and interelectron repulsion, and the contributions from the kinetic and exchange energies are small. The electron affinity of the F atom is determined by the energy of the HOMO of the anion, which in turn is determined by the overall potential. Increase in $\delta\bar{e}$ is accompanied by an increase in the shielding of the nucleus, that is the effective charge of the nucleus decreases, leading to a decrease in the energy of the level determining the EA.

In addition to these basic factors, the value of the EA is also influenced by various other specific factors, which will be discussed below. The above three factors are sufficient, however, to formulate the conditions which must be satisfied by systems with anomalous EA or IP values. These limiting cases and the possible consequences of anomalous IP and EA values for chemistry will be discussed in detail below.

The ideas presented above can be applied first to molecules and radicals of the type MX_k. For the EA of these systems to be high, it is necessary that the ligands X be electronegative atoms with high EA, for example halogen or oxygen atoms. Moreover, it is desirable that the HOMO of the corresponding anion be bonding. If however the ligands are halogen or oxygen atoms (and in general if the ligand atoms have many electrons), the HOMO of the compounds are either non-bonding or antibonding. When the HOMO is non-bonding, the EA of the compound MX_k will be greater than the EA of the ligand atoms X as a consequence of the high EA of the atoms and the effect of charge delocalisation.

It should be noted that in those cases where the HOMO, from its symmetry, is antibonding, but the actual contribution of the central M to this orbital is very small (that is, it is essentially non-bonding), high EA can be expected for MX_k. An additional reason for the appearance of high EA values is observed in compounds MX_k where the ligands X are halogen or oxygen atoms and the central atom M has a positive charge which ensures additional stabilisation of the electron delocalised over the ligands. Calculations carried out[56] for a system consisting of an F^- ion with a point positive charge, separated from the F^- nucleus by 3.0 a.u., showed that increase in the point charge by +0.1 e increases the EA of the F atom by ~1 eV. Thus the greater the charge on the M atom, the greater may be the EA.

The above ideas on the relationship between the magnitude of the EA and the electronic structure of a compound can be presented in the language of localised MO. If in an ion MX_k^- with electronegative ligands the central atom does not have lone pairs of electrons (LPE), while the radical MX_k does not contain unpaired electrons localised on the M atom, and all the valence electrons are distributed among the localised MO of the bonds and the LPE of the ligands X, the additional electron will be delocalised over the electronegative ligands, and the first IP of the ion MX_k^- should be high. On the other hand, if the central atom of the anion has LPE (or unpaired electrons) and these electrons are involved in the ionisation, then as a consequence of the low EA of the M atom, the first IP of the MX_k^- ion will be comparatively low.

The influence of the additional electron on the electronic and geometric structure of a molecule MX_k depends on whether the M atom is a transition or non-transition element. In compounds MX_k, where k is the maximum valence of the M atom, the additional electron is generally accepted by an antibonding MO. If M is a non-transition atom, the ion MX_k^- is deformed in such a way that this electron becomes part of an LPE of the M atom (or in the case of radicals becomes the unpaired electron of the M atom). For example, if an electron is added to the linear BeF_2 molecule, the electron occupies an antibonding MO, and the BeF_2^- ion undergoes an angular deformation,[60] which decreases the antibonding action of this MO. In this case the additional electron becomes an unpaired electron of the Be atom.

In contrast to this, the geometry of the molecules and radicals of transition metals generally does not change when antibonding HOMO are filled with electrons. For example, in the series of hexafluorides from ReF_6^- to AuF_6^-, the antibonding HOMO $4t_{2g}$ is filled successively, but the geometry of the molecules remains octahedral.[61–63]

It is therefore appropriate to examine the systems MX_k separately for the cases where M is a non-transition element and where M is a transition metal.

1. Superhalogens Containing *sp*-Elements

According to the above ideas, in systems MX_k where k is smaller than or equal to the maximum valence of the atom M, an additional electron is accepted either by an antibonding MO or by a non-bonding MO of the central atom (that is forms part of an LPE of the M atom). In both cases the EA of the entire molecule or radical is low, because of the low EA of the M atom. The results of *ab initio* calculations with allowance for correlation[44,64,65] and experimental data[66,67] confirm this conclusion. On the other hand, in radicals of the type MX_{k+1}, where k is the maximum valence of the M atom, an additional electron enters a non-bonding MO of the ligands, to which the AO of the central atom does not contribute for symmetry reasons, and the delocalisation of this electron over ligands with high EA leads to a high EA for the radical.

According to calculations of the electronic structure of the radicals BeF_3, BF_4, MgF_3, AlF_4, SiF_5, PF_6 [56–58] and $BeCl_3$, BCl_4, $MgCl_3$, $AlCl_4$, $SiCl_5$, PCl_6 [68,69] by the discrete variation (DV) X_α method, the EA of these radicals is greater than 3.5 eV, and they can all be described as superhalogens. The same is true of systems $MX_{(k+1)/2}$, where X is a divalent oxygen atom, and k the maximum valence of the atom M. Estimates based on calculations of the electronic structure of the radicals BO_2, NO_3, AlO_2, PO_3, and ClO_4 [56–58] indicate that the EA of these systems are greater than 3.5 eV. Thus radicals of this type can also be described as superhalogens.

To emphasise the importance of high ligand EA values for the production of high EA in compounds MX_{k+1}, radicals whose HOMO are bonding can be considered. It might seem that in this case the ionisation potential from the HOMO of the anions MH_{k+1}^- should be fairly high; however, the estimated values of the first IP according to Koopmans (which, judging overall, are 1.0–1.5 eV too high) for BeH_3^-, BH_4^-, MgH_3^-, and AlH_4^- [70,71] are lower than those for the corresponding ions MF_{k+1}^-,[71,72] whose HOMO are non-bonding. The reason for this is evidently the low EA of the H atom.

It is thus possible to outline the range of molecules containing *sp*-elements which must undoubtedly be classified as superhalogens. These are radicals of the type MX_{k+1} where X is a halogen atom, and of the type $MX_{(k+1)/2}$, where X is an oxygen atom. Various other individual molecules can of course have fairly high EA. Examples are provided by the compounds $SeHal_6$ and $TeHal_6$,[73–75] which are of the type MX_k, where k is the maximum valence of the M atom. The additional electron in the ions MX_k^- occupies an antibonding HOMO, and the EA of the MX_k molecules should be low. This is the case, for example, for SF_6, whose EA is only 0.5–0.7 eV.[41,66] For SeF_6 and TeF_6, however, the EA is nevertheless fairly high (3.0 ± 0.2 eV and 3.34 ± 0.2 eV respectively).[76] This is related to the high polarity of the Se–F and Te–F bonds, as a consequence of which, although the HOMO have antibonding character with respect to the central atom–ligand interaction, the actual contribution to these MO from the AO of the central M atom is very small. In fact, the LUMO of SeF_6 and TeF_6 are non-bonding ligand MO, and this leads to high EA values for these molecules. It may be noted that the ions SeF_6^- and TeF_6^-, like the "metallic" octahedra MoF_6^- and WF_6^-, in which the additional electron again occupies antibonding HOMO, preserve the octahedral configurations.[77,78]

The difference in the EA values in the series of valence-isoelectronic molecules SF_6–SeF_6–TeF_6 has a marked influence on their chemical properties. Thus SF_6, which has a low EA, is stable in the gas phase, whereas SeF_6 and TeF_6, which have high EA, are not detected in the gas phase. On the other hand, the $SeCl_6^{2-}$ and $TeCl_6^{2-}$ anions form stable crystalline salts, whereas the corresponding salts with the SCl_6^{2-} anion have not been obtained.

In addition to SeF_6 and TeF_6, other molecules of the type MX_k, where M represents atoms of IV, V, and subsequent periods, may have fairly high EA. For example, the adiabatic EA, calculated by the DV-X_α method by the present authors, are 0.7 eV and 2.5 eV for the molecules PF_5 and SbF_5 respectively, and for AsF_5 the values lie in the range 1.9–2.9 eV. These are much lower than the values obtained from thermochemical data:[26] ~3.5 eV for PF_5, ≥ 5.3 eV for AsF_5, and ≥ 6.4 eV for SbF_5. The values given in Ref. 26 are apparently far too high. Further experimental studies of the EA of pentafluorides by up-to-date physical methods are required.

The EA of superhalogens of the type MX_{k+1} should increase with increase in k as a consequence of the delocalisation of the additional electron over a larger number of ligands. Thus in the series MgF_3 (~3.8 eV) < AlF_4 (~6.1 eV) < SiF_5 (~6.3 eV) < PF_6 (~6.6 eV) and AlO_2 (~3.4 eV) < PO_3 (~4.4 eV) < ClO_4 (~6.3 eV), the EA increases from 3.8 eV to 6.6 eV in the first case and from 3.4 eV to 6.3 eV in the second.[44] Extremal EA values should also be expected for MX_k with $k > 6$, but increase in k may also lead to a decrease in the EA. In particular, in the series $MgCl_3$ (~4.5 eV)–$AlCl_4$ (~5.2 eV)–$SiCl_5$ (~4.4 eV)–PCl_6 (~4.0 eV), beginning from $AlCl_4$ the EA decrease as a consequence of the strong repulsion of the ligands.[68,69] This last feature is related to the fact that the HOMO in the ions MX_{k+1}^- is non-bonding with respect to the central atom–ligand interaction, whereas with respect to the ligand–ligand interaction it has antibonding character. When *k* is sufficiently large, the mutual repulsion of the ligands predominates over the effect of electron delocalisation, leading to a decrease in the EA. For the optimum values of *k*, the effect of ligand–ligand antibonding is slight, and does not predominate over the delocalisation of the additional electron, and this leads to an increase in the EA. Of the superhalogens containing *sp*-elements which have been studied up to the present, the optimum ratio of antibonding and stabilisation is achieved for AsF_6 and SbF_6, which have high EA (~7 eV).[44]

The adiabatic EA is usually understood to be the difference between the total energies of the stable configurations of the anion and the neutral system. Available experimental data[40, 78–81] and the results of non-empirical calculations[82,83] indicate that the isolated anions MF_{k+1}^-, where *k* is the maximum formal valence of the central atom M, are energetically stable with respect to monomolecular dissociation to MF_k and F^-. Published estimates[78–83] of the energy of this dissociation are fairly high, 80–120 kcal $mole^{-1}$. At the same time, experimental data[84] indicate that MF_{k+1} radicals either have a very low energy of dissociation to MF_k + F or are generally unstable. It should be noted that the adiabatic EA of a radical can be determined even when it is unstable, since the necessary condition for the existence of EA is the existence of a stable negative ion. In this case the first IP_{vert} of the anion gives the upper limit of the EA_{ad} values of the neutral system.

The low energetic stability of MF_{k+1} radicals compared with the corresponding anions MF_{k+1}^- does not agree with the traditional ideas of the method of molecular orbitals, according to which the stability of a molecular system with respect to monomolecular dissociation should increase if the electron is removed from an antibonding MO, decrease if the electron is removed from a bonding MO, and remain unchanged if the electron is removed from a non-bonding MO. In all anions of the type MF_{k+1}^-, the highest occupied MO is non-bonding with respect to the central atom–ligand interaction, and consists only of ligand AO,[85] so that the removal of an electron from the HOMO of the anion should not lead to significant destabilisation of the resulting radical.

To investigate the reason for this discrepancy between the prediction based on the qualitative concepts of MO theory and available experimental data, the electronic structures of the anions BF_4^- and AlF_4^- and of the corresponding radicals BF_4 and AlF_4 were calculated by the discrete variation X_α method in the present work.

Data on the geometric structure are available only for the anions, and the calculated non-empirical equilibrium bond lengths in the isolated anions,[82] $R(B–F) = 1.43$ Å and $R(Al–F) = 1.72$ Å, are close to the corresponding values for the anions in inorganic salts:[86–88] $R(B–F) = 1.37–1.39$ Å and $R(Al–F) = 1.69–1.70$ Å. The equilibrium bond lengths in the anions, calculated by the DV-X_α method by the present authors, are $R(B–F) = 1.44$ Å and $R(Al–F) = 1.69$ Å, in good agreement with the above values. There are no published data on the geometric structure of the radicals BF_4 and AlF_4, so that their equilibrium bond lengths were optimised by the DV-X_α method assuming that they have a tetrahedral structure. The potential curves have minima in both cases, corresponding to the bond lengths $R(B–F) = 1.44$ Å and $R(Al–F) = 1.69$ Å. Thus the calculated bond lengths for the tetrahedral configurations of the radicals and anions practically coincide. The existence of minima on the potential curves of the radicals naturally does not mean that they are energetically stable with respect to monomolecular decomposition. To resolve the question of the stability of the radicals, it is necessary to carry out additional calculations of the total potential surfaces by non-empirical methods with allowance for correlation energy. These calculations cannot be carried out at present, because of the extremely large expenditure of machine time required. Although the present calculations do not make it possible to reach any conclusion about the stability of the radicals MF_{k+1}, they can be used to investigate the reasons for the destabilisation of these radicals.

The removal of an electron from a non-bonding MO of an anion should not in principle lead to destabilisation of the resulting radical if the composition of all the other MO remains unchanged. Since in the case being considered there is appreciable destabilisation of the radicals, it is natural to expect that this is the result of changes in the composition of the bonding MO as a result of electronic relaxation. The nature of the changes in the valence MO can be investigated using the data in Table 1, which gives the composition of these MO for both radicals and anions, for the equilibrium values of the bond lengths.

Table 1. Characteristics of the molecular orbitals of BF_4, BF_4^-, AlF_4, and AlF_4^-; the Mulliken populations of the bonding MO (*q*), the charges on the atoms (*Q*), and the overlap populations [*Q*(M–F)] for BF_4, BF_4^-, AlF_4, and AlF_4^- (in fractions of e).

Parameter	BF_4		BF_4^-		Parameter	AlF_4		AlF_4^-	
	B	ΣF	B	ΣF		Al	ΣF	Al	ΣF
$q(4t_2)$	0.22	5.78	0.26	5.74	$q(5t_2)$	0.37	5.63	0.48	5.52
$q(3t_2)$	1.03	4.97	1.11	4.89	$q(4t_2)$	0.63	5,37	0.72	5,28
$q(4a_1)$	0.39	1.61	0.40	1,60	$q(5a_1)$	0,36	1.64	0.36	1,64
Q_F	−0,23		−0.40		Q_F	−0.28		−0.45	
Q_B	+0.91		+0.61		Q_{Al}	+1.13		+0.78	
Q(B–F)	+0.47		+0,59		Q(Al–F)	+0,51		+0.62	
Q(F–F)	−0.05		−0.07		Q(F–F)	−0.01		−0.01	

It can be seen that the removal of an electron from the HOMO of the anion leads to a decrease in the contribution of the AO of the central atom to the bonding MO by ~0.3 e, and this explains the low stability of the radicals, compared with the corresponding anions. The reasons why ionisation from a non-bonding purely ligand HOMO of the anion leads to this rearrangement of electron density in the resulting radical can be understood on the basis of model representations of superhalogens in which the framework of fluorine atoms in the superhalogens has a high collective electronegativity. Thus if the process of ionisation of the anion is arbitrarily divided into two stages corresponding to the removal of an electron from the HOMO without change in the composition of any of the MO and the subsequent relaxation of the MO, then the loss of an electron by the framework of fluorine atoms in the first stage of the ionisation is partly compensated by the transfer of ~0.3 electron from the central atom.

A similar decrease in the energetic stability of the radicals compared with the corresponding anions should also be observed in all other systems of the type MF_{k+1} and MF_{k+1}^-.

2. Superhalogens Containing Transition Metals

In transition metal compounds of the type MX_k, the filling of antibonding HOMO generally does not lead to distortion of the geometry of highly symmetrical configurations, so that the behaviour of the EA of these systems may show a number of characteristic features.[89–94] The dependence of the EA on the electronic structure of transition metal hexafluorides can be considered in more detail. It is appropriate to begin the examination with the hexafluorides of the 5*d*-metals, since the characteristic features of the electronic structure are revealed most clearly in this case. Table 2 gives the IP from the valence MO. It can be seen that on going from Hf to Hg there is a change from the filling of a non-bonding purely ligand HOMO of the $1t_{1g}$ type (Hf, Ta) to the filling of an antibonding MO of the $4t_{2g}$ type, antibonding with respect to the central atom–ligand interaction (W–Au) and then to the filling of the next antibonding MO of the $6e_g$ type (Hg).

Table 2. Valence ionisation potentials (eV) of the negative ions of the hexafluorides of metals of the third transition series.[90]

MO	Spin*	HfF_6^-	TaF_6^-	WF_6^-	ReF_6^-	OsF_6^-	IrF_6^-	PtF_6^-	AuF_6^-	HgF_6^-

*The letters l and h denote transitions into the low-spin and high-spin final states of MF_6 respectively.

The data in Table 2 reveal the following characteristic features of the change in the IP from the valence MO in the series being considered. Firstly, it is irregular : the IP decreases sharply on going from TaF_6^- to WF_6^-, after which it increases regularly from WF_6^- to AuF_6^-, and decreases again on going to HgF_6^-. Secondly, the IP of the "ligand" $1t_{1g}$–$8a_{1g}$ MO remain practically unchanged. Thirdly, the IP from the bonding $3t_{2g}$ and $5e_g$ MO increase almost regularly, although the change in their energies on going along the series is smaller than the change in the energies of the 5d AO [90,92] of the corresponding central atoms.

The reason for this behaviour of the IP can be understood by analysing the composition and symmetry of the MO. For Hf and Ta hexafluorides, the HOMO is a non-bonding ligand orbital, and the EA of these compounds is high as a consequence of the delocalisation of the additional electron over the six strongly electronegative F atoms, in accordance with the above ideas on the superhalogens containing *sp*-elements. The EA of these two hexafluorides are close to the EA of the most electronegative superhalogens among compounds of the *sp*-elements: AsF_6 and SbF_6. On going to WF_6, the EA decreases, due to the filling by electrons of a HOMO of antibonding type; the energy gap between the nearest $4t_{2g}$ and $1t_{1g}$ MO is ~4 eV. Since the $4t_{2g}$ MO is antibonding, it might have been expected that its subsequent filling would lead to a decrease in the EA in the series being considered. Instead of this, however, there is a regular increase in the EA,[90] which reaches ~7 eV for AuF_6, and the gap between the $4t_{2g}$ and $1t_{1g}$ MO practically disappears.

The composition of the $4t_{2g}$ MO can be analysed in more detail. The nature of this orbital changes in the hexafluoride series[90] from appreciably antibonding (WF_6^-) to non-bonding (AuF_6^-). With decrease in the antibonding, its energy decreases, approaching the energy of the non-bonding MO of the ligands ($1t_{1g}$, $9t_{1u}$, $2t_{2u}$), and the EA for AuF_6 is close to the EA for TaF_6, in which the additional electron occupies a $1t_{1g}$ MO which is purely ligand from symmetry. On going from AuF_6^- to HgF_6^-, the next $6e_g$ MO is filled, accompanied by a decrease in EA, due chiefly to the extensive splitting of the $6e_g$–$4t_{2g}$ orbitals under the influence of the ligand field, since the $6e_g$ MO is essentially a ligand orbital. Thus the contribution of the 5*d* AO to the $6e_g$ MO is ~25%, and practically coincides with the contribution of the 5*d* AO to the $4t_{2g}$ MO of the AuF_6^- anion.[90] At the same time, an increase in the Hg–F overlap population is observed for HgF_6^-, compared with AuF_6^-.

It is of interest to relate the change in the EA in the series of hexafluorides Hf–Hg to the energy of the atomic 5*d* levels. On going along this series, the energy of the 5*d* AO decreases,[90,92] leading to stabilisation of the $3t_{2g}$ and $5e_g$ MO, and these MO are transformed to an increasing extent into non-bonding 5*d* AO. In other words, the 5*d* electrons tend to be localised close to the central atom M, leading to a decrease in the population of the 5*d* AO in the higher orbitals $4t_{2g}$ and $6e_g$ and to the approach of the $4t_{2g}$ MO to the ligand MO. This conclusion is confirmed by the decrease in the overlap population from WF_6^- to AuF_6^- and by its increase on going to HgF_6^-, since in this case the 5*d* electrons, for symmetry reasons, are forced to partly occupy the antibonding $6e_g$ MO.

The principal features of the electronic structure are the same for the hexafluorides of the 4*d* metals and the hexafluorides of the 5d metals, but some differences are also observed. Firstly, the block of valence MO of the ligand type for the hexafluorides of the 4*d* metals on the whole lie slightly higher (by 0.3–0.5 eV) than those for the 5d metals. This agrees with available experimental data on the IP of the compounds MoF_6 and WF_6,[30] which differ by ~0.3 eV. Moreover, the HOMO of the t_{2g} type for MoF_6^- lies 1.3 eV closer to the block of valence MO than in the case of WF_6^-, as a result of which the EA for MoF_6 is ~1 eV higher. The calculated differences between the IP of the $4t_{2g}$ and $1t_{1g}$ levels for WF_6^- and the IP of the $3t_{2g}$ and $1t_{1g}$ levels for MoF_6^- agree with the difference between the energies of the first optical transitions for the compounds MoF_6 and WF_6 [$\Delta\nu_1(WF_6) - \Delta\nu_1(MoF_6) = 1.33$ eV [95]]. The lower energy of the upper t_{2g} MO in MoF_6^- compared with WF_6^- is related to the lower degree of antibonding character of this MO, and this in turn is due to the higher energy of the 4*d* AO of the Mo atom.[90,92]

With further filling of the HOMO of the t_{2g} type, the degree of antibonding character of this MO in the 4*d* hexafluorides is again lower than in the 5d hexafluorides, leading to its more rapid approach to the block of ligand MO. Moreover, for AgF_6^-, where the $3t_{2g}$ HOMO is fully occupied, the energy of this MO is lower than the energies of the purely ligand $1t_{1g}$ and $1t_{2u}$ MO. For AuF_6^-,[90] this inversion of the levels is not observed. The sequence order of the MO in AgF_6^- does not agree with the traditional picture of the energy sequence for MO of different character (see above): ε(bonding) > ε(non-bonding) > ε(antibonding). This contradiction is eliminated, however, in a more detailed analysis of the nodal structure of the valence MO, represented schematically in Fig. 2. It can be seen that the $3t_{2g}$ MO is an antibonding MO of the π-type with respect to the central atom–ligand interaction, and a bonding MO of the σ-type with respect to the ligand–ligand interaction; the $1t_{1g}$ MO is σ-antibonding and purely ligand from symmetry; and $7t_{1u}$ and $1t_{2u}$ MO are orbitals of the π-type, and the first contains a small contribution from the central atom, whereas the second is a purely ligand antibonding MO.

On going from MoF_6^- to AgF_6^-, the contribution of the M atom to the $3t_{2g}$ MO decreases sharply, and in AgF_6^- the entire block of $3t_{2g}$–$1t_{2u}$ MO can be regarded as purely ligand, and the central atom–ligand interaction can be neglected.[92] In this case, from the ligand–ligand interactions and in accordance with classical ideas, the following sequence of MO energies can be expected: $3t_{2g}$ (bonding MO of the σ-type) > $7t_{1u}$ (antibonding, π-type) > $1t_{2u}$ (antibonding, π-type) > $1t_{1g}$ (antibonding, σ-type). This MO sequence is in fact observed for AgF_6^- and CdF_6^-, that is the electronic structure of the hexafluorides at the end of the 4*d* metal series is determined by purely ligand interactions.

The principal characteristic features of the change in the EA and IP in the series of 3*d* metal hexafluorides are on the whole the same as in the series of 4*d* and 5*d* metal hexafluorides,[90,92] although they are less clearly defined. In particular, the antibonding HOMO of the $2t_{2g}$ type in CrF_6^- lies only 1.5 eV above the block of purely ligand MO, whereas the corresponding values for the $3t_{2g}$ and $4t_{2g}$ MO in MoF_6^- and WF_6^- are 3.8 eV and 5.1 eV respectively. On further filling of the $2t_{2g}$ MO in the anions of the 3*d* element hexafluorides, its energy rapidly approaches the energies of the ligand MO, and inversion with respect to the $1t_{1g}$ MO takes place at FeF_6^-, whereas the corresponding inversion of the $3t_{2g}$ and $1t_{1g}$ MO is observed only at the end of the 4*d* series, for AgF_6^-. This behaviour of the $2t_{2g}$ MO is related to its lower antibonding character, compared with the $3t_{2g}$ MO for the 4*d* element hexafluorides, resulting from the higher energies of the 3*d* AO of the atoms in the first transition series. A decrease in the antibonding character of the HOMO of the t_{2g} type with increase in the energy of the atomic *d*-orbitals was also observed on going from the hexafluorides of the 5*d* elements to the hexafluorides of the 4*d* elements, although to a smaller extent than on going from the hexafluorides of the 4*d* elements to the hexafluorides of the 3*d* elements. In this connection it should be noted that small changes in the energies of the atomic *d*-orbitals lead to fairly large changes in the energies of HOMO of the t_{2g} type. The small contribution of the central atom to the HOMO of the hexafluorides of the 3*d* elements leads to high values (6–7 eV) of the EA for the entire series (with the exception of CrF_6, whose EA is also fairly high, 5.0–5.5 eV).

The above detailed analysis of the relationship between EA and electronic structure shows that the hexafluorides of the *d*-elements differ significantly from the fluorides of the *sp*-elements; practically all transition metal hexafluorides (with the possible exception of WF_6) can be regarded as superhalogens. At the same time, the dependence of the value of the EA on the electronic structure in each specific case is fairly complex. Nevertheless, it can be stated that among the hexafluorides of the 4*d* and 5*d* metals, the highest EA will be shown by those in which the HOMO is almost completely filled (that is NbF_6, TaF_6, AgF_6, and AuF_6). The hexafluorides of the 3*d* metals almost all have high EA.[44]

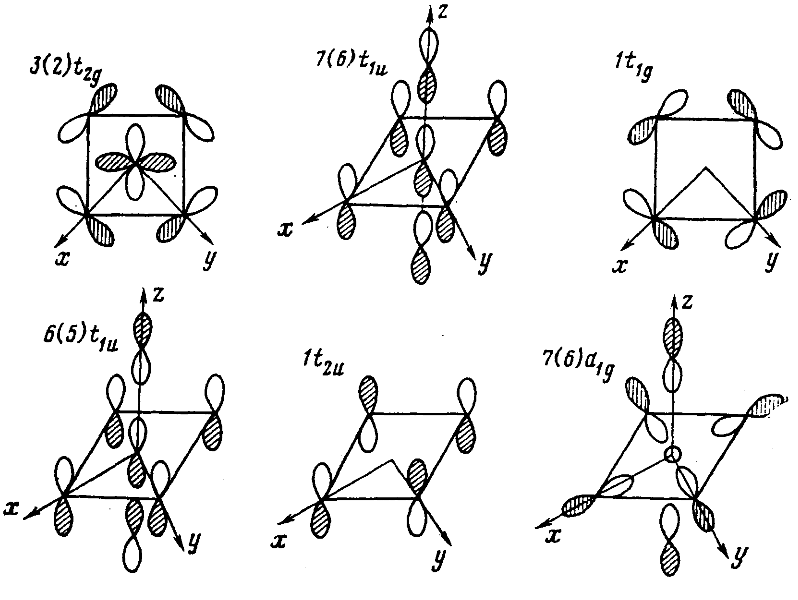

Figure 2. Schematic representation of the highest valence MO of transition metal hexafluorides.[92]

As noted above, in the estimation of EA_{ad} for systems in which the additional electron enters an antibonding MO it is necessary to investigate the dependence of the first IP_{vert} of the anion on the M–F bond length. To investigate this relationship, the electronic structure of the anions CrF_6^- and AgF_6^- has been calculated.[92] The distances R(Cr–F) = 1.75 Å and 1.85 Å and R(Ag–F) = 1.85 Å and 1.98 Å were used in the calculations. The calculations showed that the change in the IP from the HOMO of CrF_6^- does not exceed 0.5 eV, and that from the HOMO of the anion AgF_6^- does not exceed 0.15 eV. It may therefore be expected that for other transition metal hexafluorides, small changes in the interatomic distances will not lead to changes in the EA value exceeding 0.5 eV. The influence of R(M–F) on the EA value is a maximum for the atoms of group VI, since the HOMO of their hexafluorides has the most antibonding character with respect to the central atom–ligand interaction, and decreases in the same sense as the decrease in the antibonding towards the end of the period.

Tetra-anions MX_4^-, where X = F, O, and Cl, are also encountered in salts. It is therefore of interest to study the dependence of the EA of these anions on the characteristic features of their electronic structure. The tetraoxyanions can be considered as an example. The orbital energies of the tetraoxyanions of the 4*d* metals are given in Table 3. The following characteristic features of the change in the IP from the valence MO can be observed on going along the series. Firstly, the change is irregular: the IP value decreases on going from TcO_4^- to RuO_4^-, then increases from RuO_4^- to AgO_4^-, and decreases again on going to CdO_4^-. Secondly, the IP of the block of "ligand" $1t_1$, $8t_2$, and $7a_1$ MO remain practically unchanged on going along the series, like the IP of the $6t_2$ and $6a_1$ orbitals, formed predominantly by the 2*s* orbitals of the O atom. Thirdly, the IP of the bonding $7t_2$ and $2e$ MO increase regularly along the series.

Table 3. One-electron energies (eV) of the valence MO of 4*d*-metal tetraoxyanions.[94]

Anion (configuration)	MoO_4^- ($1t_1^5$)		TcO_4^- (closed)	RuO_4^- ($3e^1$)		RhO_4^- ($3e^2$)		PdO_4^- ($3e^3$)		AgO_4^- (closed)	CdO_4^- ($9t_2^1$)	
Spin	α	β	α=β	α	β	α	β	α	β	α=β	α	β
$9t_2$	—	—	—	—	—	—	—	—	—	—	3.4	—
$3e$	—	—	—	3.1	—	3.8	—	4.1	3.5	4.4	4.4	4.3
$1t_1$	5.6	4.8	4.9	4.8	4.5	5.1	4.2	4.8	4.2	4.7	4.5	4.3
$8t_2$	5.8	5.4	5.5	5.5	5.2	5.7	5.0	5.5	5.1	5.4	5.5	5.0
$7a_1$	6.2	5.8	6.2	6.0	5.8	6.0	5.6	5.8	5.5	5.8	6.3	5.5
$7t_2$	8.3	8.0	8.7	9.0	8.8	9.3	9.2	10.2	10.1	12.4	15.6	15.3
$2e$	8.3	7.9	8.5	9.0	8.7	10.0	9.3	10.7	10.5	13.6	17.8	17.8
$6t_2$	20.9	20.3	20.5	20.4	20.1	20.7	19.9	20.4	20.1	20.4	20.6	20.1
$6a_1$	21.1	20.5	20.6	20.6	20.2	20.7	20.0	20.5	20.1	20.5	21.0	20.6

Overall, the characteristic features of the change in the valence IP in the series of oxyanions are approximately the same as in the hexafluoride series. A difference is that in the tetraoxyanions, a HOMO of the *e* type is filled first, and the filling of the antibonding MO of symmetry t_2 begins from CdO_4^-. Moreover, the actual EA values for the tetra-oxides and their abrupt changes on going to the filling of antibonding MO of the *e* and t_2 types are appreciably smaller than for the hexafluorides. The changes in the upper valence IP on going along the series of 3*d* metal tetraoxyanions are similar to the changes in the upper valence IP in the series of 4*d* metals. As in the case of the hexafluorides of the 3*d* and 4*d* metals, however, the actual EA values for the tetra-oxides of the 3*d* metals are greater, and the abrupt changes on going to the filling of the antibonding MO are smaller, than in the case of the tetra-oxides of the 4*d* metals. On the whole, the EA values for the tetra-oxides are greater (3.5–5.0 eV), and practically all transition metal oxyanions, with the possible exception of RuO_4, can be classified as superhalogens.

A similar analysis of the dependence of the EA on electronic structure can be carried out for pentafluorides MF_5, tetrafluorides MF_4, trifluorides and trioxides MX_3, difluorides and dioxides MX_2, etc. High EA are shown not only by superhalogens of the type MX_{k+1}, where k is the maximum formal valence of the metal and X is a monovalent ligand, but also by systems of the type MX_k if the antibonding HOMO of the corresponding anion is completely or almost completely filled.

3. The Search for Systems with the Maximum Possible Electron Affinity

Theoretical studies of superhalogens and various experimental estimates show that chemical compounds may have very high EA, exceeding the EA of halogen atoms. Two questions naturally arise: what is the maximum EA that superhalogens can have, and among which systems should they be sought? According to the above ideas, these systems should contain as ligands the maximum possible number of fluorine atoms, since the energy of the HOMO of the anions of these systems would approach the energy of the HOMO of neutral fluorides, as a consequence of the delocalisation of the additional electron over a large number of ligands. Thus the value of the first IP of neutral fluorides can be regarded as the upper limit of the maximum possible EA values. According to available experimental data, the first IP in the fluoride series SF_6, WF_6, SiF_6, CF_4,[30] etc. are 15–17 eV, so that the value 17 eV can be taken as the upper limit of EA values for chemical compounds.

Various ways of searching for systems with maximum EA may be noted. One way is to increase the number of ligands in mononuclear systems of the type MF_{k+1}. However, with increase in the number of ligands, beginning from a certain value of k, the effects of destabilisation of the HOMO of the ion MF_{k+1}^- as a result of inter-ligand repulsion may predominate over the stabilising effects of delocalisation, so that further increase in the EA will not take place, as for example in the chlorides of the *sp*-elements examined above. Another possible way to increase the number of ligands is by changing to polynuclear superhalogens, of the type Al_2F_7, Sb_2F_{11}, or in general M_nX_{nk+1}. In these systems, inter-ligand repulsion does not increase with increase in the number of ligands, and as a result of the maximum delocalisation of the electron, the EA of these systems may approach the maximum possible value. These ideas are of course qualitative, and indicate only the trends in the change in the EA, and to obtain quantitative estimates it is necessary to carry out calculations for each specific case.

To follow the trend in the change in the EA with increase in the number of ligands, it is possible to use the results of calculations by the DV-X_α method of the electronic structure of the anions MnF_8^- and TcF_8^- (mononuclear anions of the type MF_{k+1}^-) and $Al_2F_7^-$, $P_2F_{11}^-$, $As_2F_{11}^-$, and $V_2F_{11}^-$ (dinuclear anions of the type $M_2F_{2k+1}^-$).[96,97] The geometric structure of the dinuclear anions is shown in Fig.3.

In the series of mononuclear anions ScF_4–VF_6–MnF_8, the EA increases sharply on going from ScF_4 (4.8 eV) to VF_6 (6.7 eV), and then remains unchanged on going from MnF_8

(6.7 eV). On going from NbF_6 (6.8 eV) to TcF_8 (5.8 eV), it even decreases. This indicates that the optimum combination of stabilising and destabilising factors to achieve the highest EA values in mononuclear complexes is obtained in the six-coordinate fluorides. Further increase in the number of ligands does not lead to an increase in the EA, because of the increase in the strength of the inter-ligand repulsion. Calculations by the DV-X_α method indicate that the maximum EA in mononuclear complexes (TaF_6 and AuF_6) is 7–8 eV.[90]

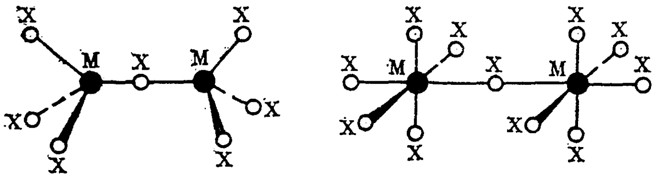

Figure 3. Geometric structure of dinuclear superhalogens.

On going from the mononuclear to the corresponding dinuclear complexes, the EA increases systematically by 1–2 eV. Thus for example the EA values for AlF_4 and Al_2F_7 are 6.1 eV and 7.5 eV, for PF_6 and P_2F_{11} 6.7 eV and 8.6 eV, for AsF_6 and As_2F_{11} 7.2 eV and 8.6 eV, and for VF_6 and V_2F_{11} 6.7 eV and 8.0 eV respectively.[90] Thus the maximum EA for dinuclear systems is apparently 9–10 eV. In particular, these EA values may be shown by the systems Ta_2F_{11} and Au_2F_{11}. Thus the change from mononuclear to polynuclear superhalogens is a promising way of searching for systems with the maximum possible EA values. Polynuclear superhalogens whose EA are more than twice the EA of halogen atoms should rather be called hyperhalogens. They may be used to obtain new classes of salt with non-traditional cations. Stable salts with Ar^+ cations may possibly be obtained using complex polynuclear hyperhalogens.

Table 4. Theoretical estimates of the EA of various superhalogens, obtained by the DV-X_α method*.[44]

Radical	EA, eV	Radical	EA, eV	Radical	EA, eV

4. Characteristic Physicochemical Properties of Superhalogens

Molecules with high EA show a whole series of fundamentally important distinguishing properties. Thus the high EA of $SeCl_6$ and $TeCl_6$ makes possible the existence of the anions $SeCl_6^{2-}$ and $TeCl_6^{2-}$, which are unusual from the traditional chemical viewpoint.

A high EA makes it possible to obtain fundamentally new salts with unusual cations, such as $O_2^+[PtF_6]^-$, $XeF_5^+[PtF_6]^-$, $Xe_2F_{11}^+[AuF_6]^-$, etc.[1–12] The molecules O_2, XeF_5, and Xe_2F_{11} have high IP, so that to obtain salts with their cations it is necessary to use superhalogens with anomalously high EA, such as, for example, PtF_6, AuF_6, etc. Thus superhalogens open up extensive possibilities for the synthesis of new non-traditional salts with both organic and inorganic cations.

Another unusual property of systems containing superhalogen groups is related to the high IP of the anions of superhalogens. Compounds in the gas phase in most cases dissociate homolytically, to give a pair of neutral fragments. This rule may not extend to molecules containing superhalogens, however. Thus the values of the IP of the alkali metals are 3.9–5.4 eV, and the EA of superhalogens may exceed these values. In these cases, heterolytic dissociation may be more favourable. For example, the salt Cs–AlF_4

dissociates to Cs^+ and AlF_4^-, and not to Cs and AlF_4. This heterolytic dissociation makes it possible to obtain a low-temperature molecular plasma by simple heating, and this in turn ensures increased conductivity of the vapours of these salts. The gas-phase mixtures of $NaAlCl_4$ and $KAlCl_4$ with $AlCl_3$–Al_2Cl_6 [116] have electrical conductivity values which are fairly high for gases, amounting to 10^{-11}–10^{-6} Ω^{-1} cm^{-1} in the temperature range 500–900 K. The partial pressure of ions in the gas reaches 10^{-8} atm at a partial pressure of $NaAlCl_4$ of 0.1 atm.

Superhalogens are widely used to modify the electronic characteristics of one-dimensional and two-dimensional organic compounds to obtain materials with metallic conductivity, and also organic superconductors.[14–26] All organic superconductors obtained up to the present contain superhalogens anions as counter-ions. It is suggested that the geometric structure of the anion is important for the conversion of quasi-one-dimensional organic systems to the superconducting state.[18] Thus for the synthesis of new organic superconductors with a higher critical temperature T_c it is necessary to have a wide range of superhalogens with different geometric structures.†

On the other hand, the class of counter-ions suitable for obtaining organic superconductors can be extended considerably using the cations of superalkalies, since the quasi-one-dimensional stacks of organic conjugated molecules forming the starting material have not only donor but also acceptor properties. The synthesis of organic systems using superalkali cations as counter-ions would extend considerably the range of organic semiconductors, metals, and superconductors, and would also be extremely interesting for theoretical chemistry.

IV. ELECTRONIC STRUCTURE OF SUPERALKALIES

After the detection of the large class of molecular systems having high EA (superhalogens) there arose the question, which is important for extending the concept of electronegativity and electropositivity, of the lowest possible IP values of neutral molecules and radicals, that is the EA of the corresponding singly charged cations. Among the elements of the periodic system, the lowest first IP are shown by alkali metal atoms, so that systems whose first IP are lower than those for alkali metal atoms are naturally called superalkalies.

From the ideas presented in section II, it follows that to achieve a low first IP of a neutral system of the type ML_{k+1}, it is necessary that the HOMO be antibonding with respect to the central atom–ligand interaction, and, in addition, that the ligands have low upper IP. In this case, on formation of the compound ML_{k+1}, the electrons of the L atoms will enter an antibonding MO, and the energy of their bond in the ML_{k+1} molecule will be lower than in the isolated L atom. It should therefore be promising to look for "superalkalies" in the class of systems ML_{k+1}, where L are alkali metal atoms.

To verify this suggestion, the DV-X_α method was used[117,118] to calculate the electronic structure of a number of radicals of this type. Table 7 gives the results of the calculation of the first IP of radicals ML_{k+1}, and also available experimental estimates. The IP of the radicals were calculated for the equilibrium geometry of the corresponding cations, that is the values of the first IP of the radicals ML_{k+1} given in Table 7 are equal to EA_{vert} for the cations ML_{k+1}^+. Clementi's double-exponent (DE) basis set was used in the calculations.[117,118] It was shown for the typical superalkalies $ClNa_2$ and PNa_4 that expansion of the DE basis set by including polarisation (3*d*) and diffuse (3*s*, 3*p*) functions of the central atom, and also polarisation (3*p*) functions of the ligand atoms, leads to only slight changes (~0.1 eV) in the first IP and the composition of the HOMO.

Table 7. First ionisation potentials (eV) of superalkali radicals.

Radical	Experiment	Calculation (Refs.117,118)
FLi_2	—	3.6
$ClNa_2$	4,15±0.20 [119]	3.7
FNa_2	—	3.7
FCs_2	—	2,6
$ClCs_2$	—	2,3
OLi_3	4,54±0,20 [120]	3.4*
ONa_3	3,90±0.15 [121]	3.5
OK_3	3,65±0.04 [121]	—
ONa_4	3,95±0.10 [121]	—
OK_4	3.62±0.04 [121]	—
SLi_3	—	3,2
SNa_3	—	3,3
NLi_4	—	3.6
NNa_4	—	3.7
PLi_4	—	3.0
PNa_4	—	3.2
NH_4^{**}	4,6 [125] 4,73±0,06 [126]	4.1

Non-empirical calculation with allowance for correlation energy (MP2/6-311) [122] gives the value 3.37 eV.

**See Ref. 123 and references therein up to 1984; non-empirical calculation with allowance for correlation energy[124] (SDFI) gives the values IP_{ad} = 4.41 eV and IP_{vert} = 4.43 eV.

Note. Numbers in square brackets denote references (Ed. of Translation).

The coefficients of the LCAO expansion of the valence MO in the DE basis set for the radicals FLi_2, OLi_3, and NLi_4 are given in Ref. 118. The MO have a similar structure for other radicals of corresponding types. According to Ref. 118, the doubly occupied MO consist chiefly of the AO of the central atom, whereas the highest half-filled MO consist chiefly of the AO of the ligands. For these radicals, the HOMO are antibonding with respect to the central atom–ligand interaction, and according to traditional views of the structure of MO its energy should be higher than the energies of the AO of both the central atom and the ligands. In fact, in all cases the IP of the radicals (see Table 7) are lower than the IP of the alkali metal atoms, which lie in the range 3.9–5.4 eV for Cs–Li. Thus the ML_{k+1} cations being considered must be regarded as superalkalies, since the first IP of the corresponding radicals are lower than the first IP of alkali metal atoms.

The above radicals were chosen so that it would be possible to follow the change in the IP with change in the ligand L and the central atom along a sub-group, and also with increase in the number of ligands. The replacement of Li by Na leads to small changes in the IP, and no regular trends could be established from the results of the calculations. The replacement of Na by Cs in the series FNa_2–FCs_2 and $ClNa_2$–$ClCs_2$, however, leads to a significant decrease in the IP. When a ligand is replaced by a heavier ligand from the same sub-group, a decrease in the EA of the corresponding cation should apparently be expected. The replacement of the

---

†In view of the importance of the tetrahedral structure of the counter-ion for increasing T_c (for example ClO_4^- [18]), the anions of transition metal tetra-oxides can be recommended as counter-ions for the production of new superconductors.

central atom by a heavier atom from the same sub-group will also lead to a decrease in the EA, although the relative changes are small. With increase in the number of ligands in series of the type FLi_2^+–OLi_3^+–NLi_4^+, the EA on the whole decreases, although the decrease is small. For the EA of the cation to be small, it is not necessary that the IP of the ligands be low. If the antibonding of the HOMO is strong, the energy of the binding of an electron in the neutral system ML_{k+1} may be low, in spite of a high EA for the cation L^+.

Another type of molecular radical ML_{k+1} with low values of the first IP may be provided by Rydberg radicals, in which the additional (relative to the corresponding cation) electron enters a Rydberg AO of the central atom. In this case, since the Rydberg AO of the M atom are fairly high, the IP from these AO should be low. An example of these systems may be provided by ammonium radicals NR_4, where R is an organic group. For the simplest system NH_4, detailed *ab initio* calculations have been carried out with variation of the geometry of the cation NH_4^+ and the radical NH_4 separately, and with allowance for the correlation energy by the configuration interaction method with the addition of Rydberg orbitals to the basis set.[127] These calculations showed that the HOMO in NH_4 consist chiefly of the Rydberg AO of the N atom, and the value of IP_{ad} for the NH_4 radical (or EA_{ad} for the NH_4^+ cation) is 4.3 eV. This value shows good agreement with the experimental estimates 4.6 ± 0.2 eV [125] and 4.73 ± 0.06 eV.[126] Other radicals NR_4 for which R has electron-donor properties should have even lower IP, and all these radicals can apparently be classified as alkalies or superalkalies.

Both superalkalies and Rydberg radicals are stable with respect to monomolecular dissociation,[119–126] although the dissociation energy is relatively low. At the same time the corresponding cations are extremely stable with respect to monomolecular dissociation. Thus the dissociation energy of $ONa_3^+ \rightarrow ONa_2 + Na^+$ is 87 kcal mole^{-1},[122] and that of $NH_4^+ \rightarrow NH_3 + H^+$ is 217 kcal mole^{-1}.[124]

The low EA of "superalkali" cations indicates the possibility of synthesising new classes of salt in which the anions are molecular systems with low EA. The first salts of this type, $LiO_3^+NO^-$ and $Li_3O^+NO_2^-$, have already been synthesised, and X-ray diffraction has confirmed that they contain Li_3O^+ cations.[27–29] Superalkali cations can form salts in cases where the formation of the corresponding salts with alkali metal atoms may be energetically unfavourable either because of the relatively high IP of the metal atom or because of steric hindrance. Salts consisting of superalkali cations and superhalogen anions can apparently have very low heterolytic dissociation energies, and this is of interest from the viewpoint of the physics of low-temperature molecular plasma.

In recent years, *ab initio* calculations have revealed a new class of so-called hyperlithium compounds OLi_4, OLi_5, CLi_5, CLi_6, etc.[128–132], in which the formal valence of the central atom is greater than the maximum classical valence. According to the calculations, the first IP of these compounds are relatively low, and these systems can also apparently be regarded as superalkalies. The question of the existence and energetics of hyperlithium compounds requires further theoretical and experimental studies, however.

---o0o---

The rapid extension of the possibilities provided by computing techniques suggest that in the near future it will be possible to calculate the electron affinity and ionisation potentials of chemical compounds of increasing complexity. Nevertheless, qualitative models which would make it possible to estimate these quantities without laborious calculations are of considerable interest. The analysis carried out in the present review has shown the existence of two important classes of chemical compound: with anomalously high EA (superhalogens) and with anomalously low first IP (superalkalies). Both classes of compound are of considerable interest for theoretical chemistry, since they extend the traditional concepts of the electronegativity and electropositivity of chemical groups. At the same time these compounds are important for practical purposes, for example for the synthesis of new chemical compounds and in the planned search for new dopants to increase the electrical conductivity of polymers, and also new counter-ions for the production of organic superconductors.

It is hoped that the above discussion of the electronic structure of superhalogens and superalkalies will attract the attention of experimental workers and find further theoretical development.

The Reactions of Azoxybenzenes in Acids. The Mechanism of the Wallach Rearrangement

G.G.Furin

Data concerning the use of various acids to effect the Wallach rearrangement in the series of azoxybenzenes are analysed and the influence of the chemical nature and position of the substituents on the reactions of azoxybenzenes in the presence of acids, including the Wallach rearrangement and side processes, are examined. Data obtained in the study of the mechanism of the Wallach rearrangement by kinetic and tracer atom methods are discussed and the effect of Lewis acids and UV radiation on azoxybenzenes is considered.

The bibliography includes 63 references.

I. INTRODUCTION

Organic compounds with a nitrogen-containing functional group play an exceptionally important role in natural and technological processes. Such compounds include medicinal preparations, dyes, pesticides, explosives, etc. The great theoretical and practical importance of these compounds has stimulated the study of the chemical properties of nitrogen-containing functional groups. Among organic nitrogen compounds, azoxybenzenes occupy a special place. As a result of their high thermal and chemical stabilities, all the compounds containing a nitrogen atom attached to the benzene ring can be ultimately converted into azoxybenzenes via oxidation or reduction regardless of the valence state of the nitrogen in the functional group (see, for example, Yandovskii et al.[1]).

On the other hand, the known instances of reversible reactions of azoxybenzenes are fairly few. This has aroused interest in the Wallach rearrangement, discovered more than one hundred years ago, which consists in the conversion of azoxybenzene into 4-hydroxy- and 2-hydroxy-azobenzenes on treatment with concentrated sulphuric acid. The availability of the starting materials and the simplicity of the conditions promoted the wide-scale employment and detailed study of the Wallach rearrangement, which is nowadays included among the principal synthetic methods of organic chemistry. The Wallach rearrangement has been investigated in special detail in relation to azoxybenzene itself: the fundamental features of its occurrence have been discovered and its mechanism has been seemingly elucidated. However, the data obtained in the studies during the last decade have shown that, even when the reaction conditions and the structures of the initial azoxybenzenes are altered only slightly, processes unrelated to the Wallach rearrangement proper begin to occur. Unusual reactions were then observed of the kind which it would perhaps be impossible to predict *a priori* at the present level of development of chemistry. It was also found that the mechanism of the rearrangement is more complex than appeared previously.

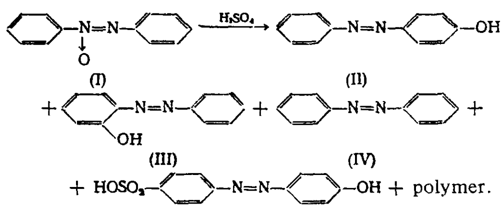
New data require the reconsideration of the accumulated results for a more adequate understanding of the situation which has arisen as regards the study and treatment of the Wallach rearrangement. Analysis of experimental data relevant to the Wallach rearrangement has been frequently carried out in a number of review articles and monographs and both individual aspects of this reaction and the reaction as a whole have been considered.[2-4] Japanese investigators, in Yamamoto's[5,6] and Oae's[7] schools, have made a major contribution to the discovery of the principal features of the Wallach rearrangement and the principal original studies in this field are due to these investigators. The fundamental investigations of Shemyakin's school, carried out by the tracer atom (^{15}N, ^{18}O) methods[8-10] have played a large role in the understanding of the mechanism of the rearrangement.[8-10] Data on the kinetics of the Wallach rearrangement have been obtained.[4,11]

Despite the large number of studies devoted to the mechanism of the Wallach rearrangement, a single view concerning the rearrangement has not so far been elaborated. One of the key questions, concerning the identification of the cationoid species responsible for the rearrangement, has remained unresolved. Olah et al.[12] put forward the hypothesis, shared by many chemists, that this species is a dication generated by the dehydrated diprotonated form of azoxybenzene. The data of the last few years, obtained in the study of the synthetic aspects of the Wallach rearrangement and its mechanism, are analysed in the present review. Earlier investigations are discussed only in those cases where this is required for the understanding of the new data.

II. THE INFLUENCE OF THE NATURE OF THE ACID AND THE ACIDITY FUNCTION OF THE MEDIUM ON THE ACID-CATALYSED REARRANGEMENT OF AZOXYBENZENES

In the course of the study of the behaviour of azoxybenzene in concentrated sulphuric acid, Wallach observed the formation of 4-hydroxyazobenzene together with 2-hydroxyazobenzene and other products (Scheme 1). Somewhat later, this result was confirmed by a number of workers who concluded that its character is general.[2,3]

Scheme 1



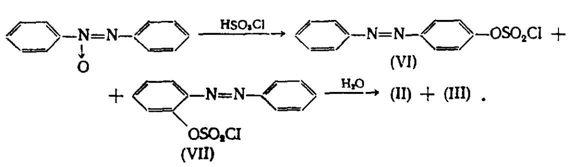
Kinetic data have shown that the rate of the rearrangement depends significantly on the acidity of the medium.[4] Thus, on passing from 75% ($-H_0 = 6.65$) to 99.99% ($-H_0 = 11.9$) sulphuric acid (at 25 °C), the rate constant increases by five orders of magnitude.

At the present time the range of acids used for the Wallach rearrangement is fairly large, starting with sulphuric acid ($-H_0 = 11.93$) and ending with the 1:1 HSO_3F-SbF_5 mixture ($-H_0 = 19.5$). There exist also individual examples of the employment of mixtures of acids (for example, toluene-*p*-sulphonic acid–acetic anhydride). However, these acid systems have no special advantages over sulphuric acid. Sulphuric acid (at a concentration >80%) is employed as a rule for the rearrangement. The product ratio (*ortho*:*para*) is 0.02%. It has been shown[13] that at these sulphuric acid concentrations the solvated proton H_3O^+ is not a sufficiently strong acid to catalyse the reaction considered. Stronger acids (H_2SO_4 and $H_3SO_4^+$) play the role of the catalyst under these conditions.

It has been suggested[11] that the product of the rearrangement of azoxybenzene in concentrated sulphuric acid is azobenzene-4-hydrogen sulphate, whose hydrolysis affords 4-hydroxyazobenzene. Indeed azobenzene-4-hydrogen sulphate hydrolyses in sulphuric acid with formation of 4-hydroxyazobenzene. It has been shown that under these conditions the nitrogen atom of the azo-group is initially protonated, which is followed by the slow protonation of the oxygen atom bound to the benzene ring, and finally the C–S bond is cleaved. The idea of the intermediate formation of 4-substituted esters with their subsequent hydrolysis to 4-hydroxyazobenzene was used to account for the processes occurring in different acids.[3,4]

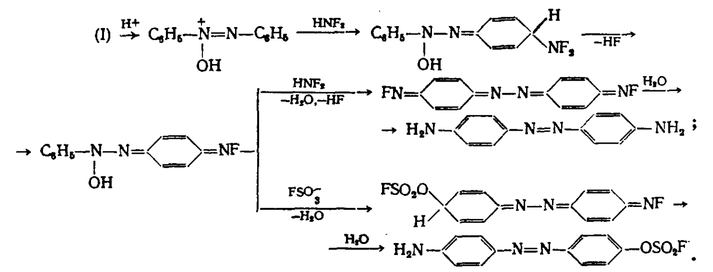
Dissolution of azoxybenzene in HSO_3Cl at −10 °C leads to the formation of its esters (VI) and (VII) (the *ortho*:*para* ratio is 0.51), which are readily hydrolysed by weak alkalis (Scheme 2):[14,15]

Scheme 2



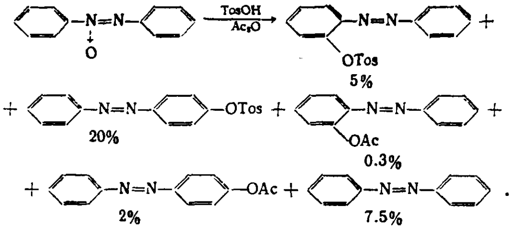
As in concentrated sulphuric acid, the rearrangement in HSO_3F leads to the preferential formation of the *para*-substituted product (II).[15,16]

The presence in the acid system of different anions, whose nucleophilicity has a decisive influence on the character of the products formed, is exceptionally important. For example, when the Wallach rearrangement is carried out in HSO_3F with added HNF_2, the products are 4-fluorosulphonyloxyazobenzene (17–35%), 4,4′-diaminoazobenzene (16–45%), and 4-amino-4′-fluorosulphonyloxyazobenzene (5–20%).[16] The amino-derivatives are formed via the intermediate fluoroimines:



When the Wallach rearrangement is performed in a mixture of acids containing different anions, different products are formed, for example both toluene-*p*-sulphonates and acetates are formed in the toluene-*p*-sulphonic acid–acetic anhydride mixture. This shows that in the second stage of the rearrangement the cationoid species generated from azoxybenzene interacts with the anion of the medium.[17] The *para*-substituted product predominates in this case too (Scheme 3).

Scheme 3



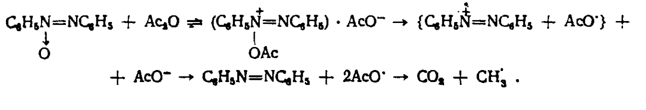
This demonstrates the important role of the second stage of the reaction, which consists in the attack by the nucleophile of the medium on the most electrophilic centre in the intermediate cationoid species responsible for the Wallach rearrangement.

When azoxybenzene is treated with 80% polyphosphoric acid, a mixture of 2-hydroxy- and 4-hydroxy-azobenzenes with an *ortho*:*para* ratio of 1.7 is formed (the yields of products are 26 and 11.8% respectively).[6] In addition 15.1% of azobenzene is produced.

When azoxybenzene is treated with toluene-*p*-sulphonic acid and polyphosphoric acid, azobenzene, the product of the reduction of azoxybenzene, is formed in appreciable amounts, which is extremely unexpected and difficult to explain. It has been shown[18] that azobenzene is the main product resulting from the treatment of azoxybenzene with the (1:1) ($HF-SbF_5$)–SO_2 mixture at −50 °C (yield 68–72%); the usual product of the Wallach rearrangement, namely 4-hydroxyazobenzene, is obtained in a yield less than 10%, while 2-hydroxyazobenzene is not detected at all. These data show that the nature of the acid used to effect the Wallach rearrangement influences not only the *ortho*:*para* ratio but also the course of the process itself, which is probably due to the difference in the reactivities of the species generated from azoxybenzene under the influence of different acids.

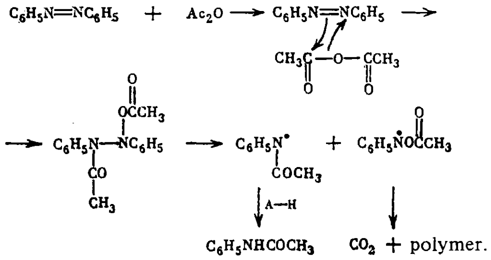
Azoxybenzene does not change in acetic acid at temperatures in the range 20–190 °C, while the addition of acetic anhydride leads to the formation of acetic acid and acetanilide in 70% yield (when the reactants are used in proportions of 1:5). On the other hand, for the equimolar reactant ratio, a complex mixture of products is formed in the system: azobenzene (60%), acetanilide (13%), acetic acid (63%), CO_2 (95%), CO (14%), and CH_4 (2%).[19] The authors suggest the following reaction mechanism (Scheme 4):

Scheme 4



$$C_6H_5\underset{\underset{O}{\downarrow}}{N}=NC_6H_5 + Ac_2O \rightleftharpoons (C_6H_5\underset{\underset{OAc}{|}}{\overset{+}{N}}=NC_6H_5)\cdot AcO^- \to \{C_6H_5\overset{+}{\dot{N}}=NC_6H_5 + AcO^\cdot\} + AcO^- \to C_6H_5N=NC_6H_5 + 2AcO^\cdot \to CO_2 + CH_3^\cdot\,.$$

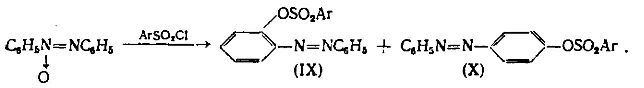
The acetanilide and CO_2 are obtained from azobenzene, which has been demonstrated independently by treating azobenzene with acetic anhydride. It has been suggested that the reaction proceeds as follows:



The usual products of the Wallach rearrangement, namely 2-hydroxy- and 4-hydroxy-azobenzenes, are formed from azoxybenzene in small yields in trichloroacetic acid in the presence of acetic anhydride.[20]

Thus the first feature of an acid system containing electrophilic CH_3CO^+ species is that reduction products and not the products of the Wallach rearrangements are formed, and the second feature is the possibility of catalysis of the Wallach rearrangement not only by H^+ but also by other cationoid species. The first stage under these conditions is attack by the cationoid species on the oxygen atom of the azoxy-group. Indeed, it has been found that, when azoxybenzene is heated with arenesulphonyl chlorides, the arenesulphonic esters (IX) and (X), the products of the Wallach rearrangement, are formed.[21] The *ortho* : *para* ratio then varies as a function of the nature of the arenesulphonyl chloride employed (Scheme 5):

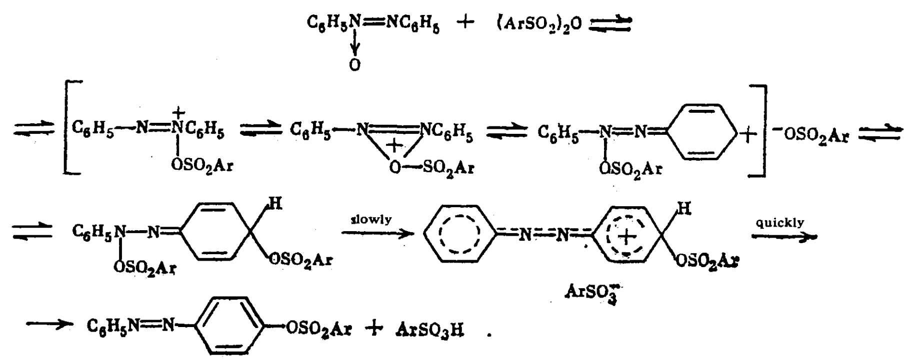
Scheme 5



Ar	(IX) Yield of (IX), %	(X) Yield of (X), %
$4\text{-}NO_2C_6N_4$	59.7	24.8
$4\text{-}BrC_6N_4$	28.8	36.8
$4\text{-}CH_3C_6N_4$	0.6	61.4
CH_3SO_2Cl	—	63.8

The rearrangement of azoxybenzenes proceeds also on treatment with the anhydrides of benzenesulphonic acids[22] (Table 1). However, the *para*-substituted product is formed exclusively in this case in high yields (Table 2). It has been suggested[22] that the reaction proceeds in accordance with Scheme 6.

Scheme 6



The kinetic data (in the presence of an excess of arenesulphonic acid anhydride, the reaction is of pseudo-first order, $E_a = 22.4$ kcal mol^{-1}, and $\Delta S^{\neq} = -14.2$ e.u.) and especially the influence of substituents both in the azoxybenzene ($\rho = -1.5$) and in the arenesulphonic acid anhydride ($\rho = +1.3$) on the rate of reaction show that the overall rate of this reaction is determined by the stage involving the cleavage of the N—C bond.[22]

Table 1. The reactions of azoxybenzene with sulphonic acid anhydrides.[22]

Anhydride	Reaction product	Yield, %
Tos_2O	$4\text{-}TosOC_6H_4N{=}NC_6H_5$	92
$(C_6H_5SO_2)_2O$	$4\text{-}C_6H_5SO_2OC_6H_4N{=}NC_6H_5$	92

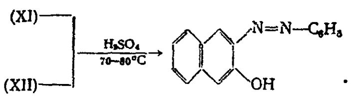
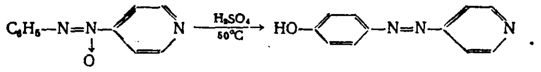
		70

Like azoxybenzene, azoxy-compounds of the naphthalene series undergo the Wallach rearrangement.[23,24] It has been shown that, when 2-naphthyl-*ONN*-azoxybenzene (XI), 2-naphthyl-*NNO*-azoxybenzene (XII), 1,1′-azoxynaphthalene, 1,2′-*ONN*-azoxynaphthalene, and 2,2′-azoxynaphthalene are treated with sulphuric acid (at a concentration in the range 60—93%), the Wallach rearrangement is observed and the corresponding hydroxyazo-derivatives are formed, the site of attack by the nucleophile being the *ortho*-position in the naphthalene nucleus:



On the other hand, the introduction of the dimethylamino-group into the benzene ring, for example in the case of 2-naphthyl-*ONN*-azoxy(4′-dimethylaminobenzene), prevents the Wallach rearrangement in 70% sulphuric acid (as a result of the protonation of its nitrogen atom).[25] However, at a sulphuric acid concentration of 97—99.9% protonation at the substituent does not prevent the rearrangement.[26] Thus 4-pyridyl-*NNO*-azoxybenzene affords under these conditions 4-(4′-hydroxyphenylazo)-pyridine. However, 4-pyridyl-*ONN*-azoxybenzene does not rearrange under these conditions, which indicates the importance also of the very structure of the azoxy-derivative for the acid-catalysed rearrangement:



Analogous characteristics have been discovered also for the isomeric (α- and β-) 4-(phenylazoxy)pyridine *N*-oxides.[27] Kinetic data for the rearrangement of 4-pyridyl-*NNO*-azoxybenzene have shown that, on passing from 98.46% to 99.91% sulphuric acid, the rate constant increases by two orders of magnitude.[26]

Thus the character of the acid employed has a significant influence on the products of the Wallach rearrangement.

III. THE INFLUENCE OF SUBSTITUENTS ON THE WALLACH REARRANGEMENT

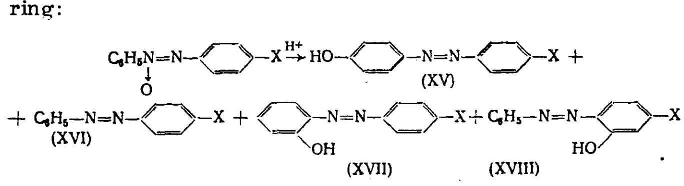
The introduction of electron-accepting substituents in the azoxybenzene molecule reduces the electron-donating capacity of the oxygen atom of the azoxy-group and increases the electron-accepting capacity of the carbon atoms in the benzene rings (Table 3).[28]

Table 3. The basicities of 4-substituted *NNO*-azoxybenzenes.[28]

X	pK_a	X	pK_a
OCH_3	-6.10 ± 0.04	H	-6.45 ± 0.05
OC_2H_5	-6.04 ± 0.03	Br	-7.01 ± 0.04
CH_3	-6.04 ± 0.03	NO_2	-9.83 ± 0.07

For this reason, substituents influence both the rate of the Wallach rearrangement and the nature of the products, so that the study of the influence of the chemical nature and position of the substituent in azoxybenzene on the reactivity and the type of products under the conditions of the Wallach rearrangement is extremely important for the question under consideration. In particular, this applies to those cases where structural factors hinder the Wallach rearrangement and the character of the acid system can promote other processes. Indeed, it will be seen from the data presented below that in many instances unexpected products are formed, which can be explained both from the standpoint of the stabilising influence of the substituent on the cationoid species and on the basis of the character of the electrophilic intermediate generated.

We shall consider in the first place the influence of the halogen in the 2- and 4-positions on the Wallach rearrangement. When 4-halogenoazobenzenes are treated with sulphuric acid, the main products are 4-halogeno-4-hydroxyazobenzenes, i.e. the OH group is in the unsubstituted benzene ring:



The ratio of the products varies little as a function of the structure of 4-halogenoazoxybenzene, i.e. as a function of whether it is the α- or β-isomer [4-halogeno-*ONN*-azoxybenzene (XIII) or 4-halogeno-*NNO*-azoxybenzene (XIV)] (Table 4).[29]

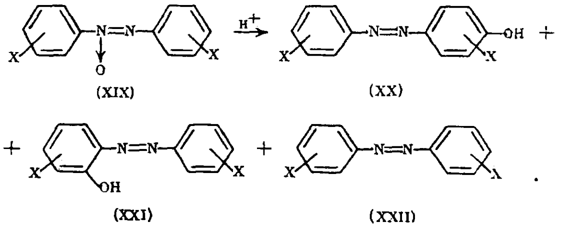
In the case of azoxybenzenes where the halogen atoms are in the 2,2′- and 3,3′-positions, treatment with different acids leads to the products of the Wallach rearrangement (4-hydroxydihalogenoazobenzenes) together with appreciable amounts of the corresponding dihalogenoazobenzenes (Table 5):



The Wallach rearrangement takes place selectively in the *para*-position. However, when both *para*-positions in the benzene ring are occupied, it takes place in the *ortho*-position. At the same time detailed study of the products of the reaction of 4,4'-dihalogenoazoxybenzenes in 92% sulphuric acid revealed a number of unexpected substances, among which compounds (XXV), (XXVI), and (XXVIII) were found.[28] The yields of the products are presented in Table 6.

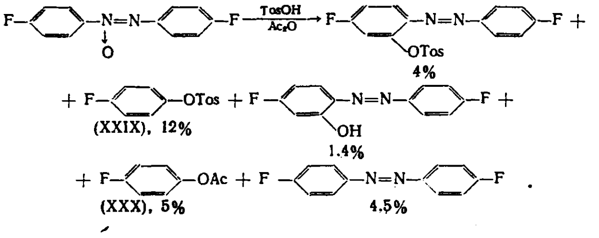
The pathways leading to their formation will be examined below. The data in Table 6 illustrate the influence of the nature of the halogen on the character of the products of the reactions of azoxybenzenes in sulphuric acid. In all cases, azobenzenes are formed in appreciable amounts and, when X = F or I, compounds of type (XXVI) are absent from the products. In the case of 4,4'-difluoroazoxybenzene, the influence of the acidity of the medium on the ratio of the reaction products was also observed. Thus, on passing from 85% to 98% sulphuric acid, the yield of the products (XXV) and (XXVIII) increases and the yield of compound (XXVII) falls sharply. Treatment of 4,4'-difluoroazoxybenzene with toluene-*p*-sulphonic acid in the presence of acetic anhydride leads to the products (XXIX) and (XXX) as a result of the interaction of the anions of the medium with the 4-fluorophenyl cation.[17] This presupposes the cleavage of the C–N bond in the protonated form of 4,4'-difluoroazoxybenzene and the subsequent conversion of the 4-fluorobenzenediazonium cation into the 4-fluorophenyl cation:

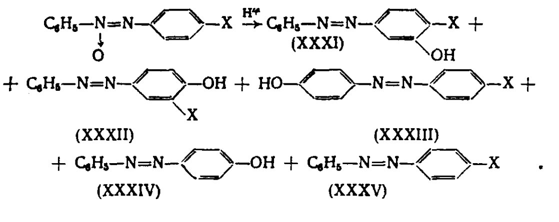


Naturally the formation of these products and their reactions do not take place in the same way in different media. Treatment of 4,4'-dichloroazoxybenzene with the TosOH–Ac_2O acid system at 100 °C leads to a complex mixture of products: 2-tosyloxy-4,4'-dichloroazoxybenzene (3%), 4,4'-dichloroazobenzene (5.5%), 4-chlorophenyl toluene-*p*-sulphonate (0.5%), and 4,4'-dichloro-2'-hydroxyazobenzene (0.5%).

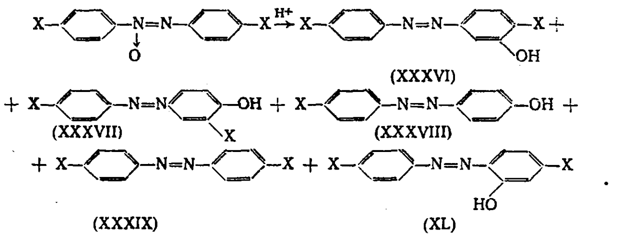
The accumulation of halogen atoms in the benzene ring tends to increase the content of azobenzenes. Thus 59% of 4,4'-dichloroazobenzene is formed from 4,4'-dichloroazoxybenzene in 90% sulphuric acid, while 2,2',4,4'-tetrachloroazoxybenzene gives rise to 76.8% of 2,2',4,4'-tetrachloroazobenzene. The exclusive formation of the products of the reduction of 2,2',4,4'-tetrachloroazoxybenzene is observed also in other acids—chlorosulphonic acid and 80% polyphosphoric acid.[31] However, account must be taken of the role of the nature of the acid in the overall set of reactions of azoxybenzene in acid media. Thus it has been shown[32] that 2,2',3,3',5,5',6,6'-octafluoroazoxybenzene does not undergo the Wallach rearrangement on treatment with HSO_3F, HF, and H_2SO_4, whereas the formation of the products of this rearrangement, namely 4-chlorosulphonyloxy-2,2',3,3',5,5',6,6'-octafluoroazobenzene, is observed in HSO_3Cl, although it is slow. On the other hand, treatment with the very strong 1 : 1 HSO_3F–SbF_5 acid mixture at 20 °C leads to the formation of only 2,2',3,3',5,5',6,6'-octafluoroazobenzene after hydrolysis. We may note that azoxybenzenes for which the Wallach rearrangement is impossible, for example, decafluoroazoxybenzene and 4,4'-dimethyloctafluoroazoxybenzene, give rise to decafluoroazobenzene and 4,4'-dimethyloctafluoroazobenzene respectively in this acid system.

Thus the data presented indicates the importance for the Wallach rearrangement of factors such as the position of the substituent in the benzene ring, the nature of the acid, the presence of active nucleophiles in the system, and the reaction conditions. It is therefore natural to expect that the same features as for the halogeno-substituents will be observed also for other substituents, such as the alkyl, alkoxy-, nitro-, carboxy-, etc. groups.

Indeed, treatment of 4-alkylazoxybenzene with sulphuric acid leads to the formation of both the usual products of the Wallach rearrangement (XXXIII) and the "anomalous" compounds (XXXI), (XXXII), and (XXXIV)[33] and their ratio varies with the character of the alkyl substituent. Thus compound (XXXI) predominates for the CH_3 substituent, whereas compound (XXXIV) is formed exclusively for $CH(CH_3)_2$ and $C(CH_3)_3$. This may be associated with the ability of the group X to be split off in the form of the cationoid species from the product of the addition of the anion in the second stage of the Wallach rearrangement:



The formation of "anomalous" products was to be expected also for 4,4'-dialkylazoxybenzenes. In fact, when such azoxybenzenes are treated with sulphuric acid, compounds (XXXVI), (XXXVII), and (XXXVIII) are formed together with the azo-compounds (XXXIX) and the 2-hydroxyazo-compounds (XL).[30] However, the ratios of these products depend significantly on the character of the alkyl substituents. Thus, on passing from CH_3 to the $C(CH_3)_3$ group, the yield of 4,4'-dialkylazobenzenes increases by a factor of 2 and that of compounds of type (XXXVIII) by a factor of 51. On the other hand, compounds (XXXVI) and (XXXVII) are obtained only in trace amounts from azoxybenzenes containing the $CH(CH_3)_2$ and $C(CH_3)_3$ groups. These features can be explained by the ability of the alkyl group to form stable carbonium ions:

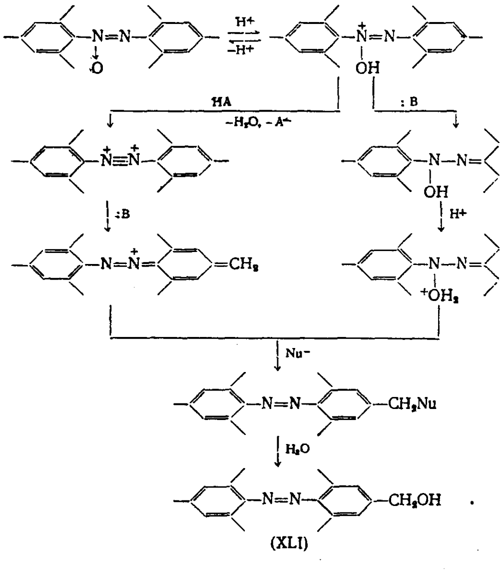


The features which can be accounted for by the ability of the alkyl group to form stable carbonium ions are also manifested here.

The use of a softer acid (trichloroacetic acid), which is used together with acetic anhydride, leads to the formation of the normal products of the Wallach rearrangement from 2,2′-dimethyl- and 4,4′-dimethyl-azoxybenzenes, namely 4-hydroxy- and 2-hydroxy-azobenzenes, in good yields.[5]

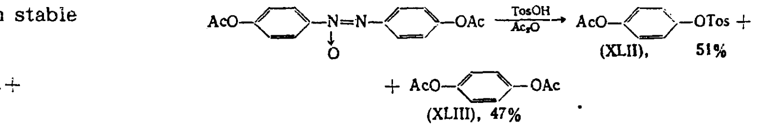
2,2′,4,4′,6,6′-Hexamethylazoxybenzene, for which the Wallach rearrangement is impossible, rearranges in a different way on treatment with concentrated sulphuric acid, i.e. the OH group is now located at the carbon atom of the methyl group in the *para*-position and 4-(hydroxymethyl)-2,2′,4′,6,6′-pentamethylazobenzene (XLI) is formed (in 91.5% yield in 85.6% sulphuric acid.[34–36] It has been suggested that the rearrangement proceeds in this case in accordance with Scheme 7.

Scheme 7



(XLI)

It has been found[37] that the reaction of 4,4′-dimethoxyazoxybenzene with the toluene-*p*-sulphonic acid—acetic anhydride mixture at 100 °C affords 3-acetoxy-4,4′-dimethoxyazobenzene (42%), 4,4′-dimethoxy-2-tosyloxyazobenzene (3.5%), and 4,4′-dimethoxyazobenzene (32%). 4-Methoxyazoxybenzene produces 3-acetoxy-4-methoxyazobenzene (38%), 4-methoxy-4′-tosyloxyazobenzene (5.6%), and 4-methoxyazobenzene (42%) in this acid system together with a small amount of the products of the hydrolysis of the esters, for example, 3-hydroxy-4-methoxyazobenzene.[37] Furthermore, the dissolution of 4,4′-diacetoxyazoxybenzene in the same acid system altogether fails to give rise to the product of the Wallach rearrangement and the exclusive formation of the products of 1-*unco*-substitution and the evolution of nitrogen are observed:[17]



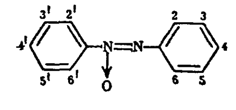
Similarly, 2,2′-diacetoxyazoxybenzene gives rise to 2-acetoxyphenyl toluene-*p*-sulphonate (41%), 1,2-phenylene diacetate (18%), and 2,2′-diacetoxy-4-tosyloxyazobenzene (16%). We may note that, in the case where the anhydride of toluene-*p*-sulphonic acid in acetonitrile is used, refluxing for 2 h produces compound (XLII) in 16% yield, while in sulphuric acid in the presence of acetic anhydride at 100 °C, compound (XLIII) is formed after 1 h (yield 35%).

4-Acetoxy-*ONN*-azoxybenzene and 4-acetoxy-*NNO*-azoxybenzene (XLIV) behave in the same way in acetic anhydride (100 °C, 2 h) as in TosOH, the only difference between them being that the β-isomer reacts more slowly:[17]

$$(\mathrm{XLIV}) \xrightarrow[\mathrm{Ac_2O}]{\mathrm{TosOH}} \underset{77\%}{(\mathrm{XLII})} + \underset{9\%}{(\mathrm{XLIII})} + \underset{18\%}{C_6H_5OTos} + \underset{72\%}{C_6H_5OAc}\ .$$

The behaviour in acids of azoxybenzenes containing electron-accepting substituents in the 4,4′-positions differs from that examined above. Thus treatment of 4,4′-dinitro- and 4,4′-dicarboxy-azoxybenzenes with concentrated sulphuric acid yields the products of the Wallach rearrangement—the corresponding 2-hydroxyazobenzenes.[37] 4,4′-Dinitro-4,4′-dicarboxy-azobenzenes are formed in very low yields. On the other hand, the presence of the CH_3CO group results in the formation of an azo-compound in which the CH_3CO group has been replaced by the OH group.

Table 7. Kinetics of the reaction of azoxybenzene with sulphuric acid (at 30 °C).[42]



X	$10^7 k$, s^{-1}			pK_a
	$[H_2SO_4]$ = 83.6%	$[H_2SO_4]$ = 90%	$[H_2SO_4]$ = 98%

4-NO_2	—	3.5	320	—6.18
3-NO_2	0.28	6.5	684	—6.33
4′-NO_2	—	300	33 300	—6,21
3′-NO_2	9	450	38 000	—6.47
H	200	1 280	9 170	—5.13
3,3′-$(OCH_3)_2$	110	1 350	—	—5.15
4-Br	467	2 920	—	—5.03
4-OH	6120	33 000	—	—5.21

The presence of the NO_2 group in only one benzene ring (the α- and β-isomers) leads to the rearrangement product in which the OH group is in the other benzene ring. Thus 4-hydroxy-4′-nitroazobenzene is formed in 83% yield in 92% sulphuric acid.[6,38] When HSO_3Cl is used, a mixture of products is formed from the α- and β-isomeric 4-nitroazoxybenzenes: 4-hydroxy-4′-nitroazobenzene, 2-hydroxy-4′-nitroazobenzene, and 4-nitroazobenzene.[39] Comparison of these data with the results obtained in concentrated sulphuric acid shows an increase of the *ortho* : *para* ratio for HSO_3Cl.[39]

The presence of a substituent in the 4-position, for example, CH_3CO,[33] AcNH, CH_3COO, and $(CH_3)_2N \rightarrow O$[40] prevents the Wallach rearrangement. Thus azoxybenzene with the $(CH_3)_2N \rightarrow O$ substituent gives rise to a 55.1% yield of

4-hydroxy-4′-dimethylaminoazobenzene in 100% sulphuric acid, which is the first example of the involvement of tertiary amine *N*-oxides in the Wallach rearrangement. If the reactant ratio is 1 : 1, the overall yield of 2-hydroxy- and 4-hydroxy-4′-dimethylaminoazobenzenes is ~22%, and for the 4 : 1 ratio, where there is a significant deficiency of acid, the Wallach rearrangement does not take place. In this case the tertiary amine *N*-oxide is reduced with formation of a mixture of α- and β-isomers of 4-dimethylamino-*ONN*-azoxybenzene. A similar reaction in an acid medium has been observed also for *N*-pentafluorophenylpiperidine oxide.[41]

Kinetic data for the influence of the nature and position of the substituent in the benzene ring on the rate of rearrangement indicate its dependence on the acidity function of the medium and the pK_a of the initial azoxybenzene (Table 7).[42]

The electron-accepting properties of the substituent in the 4-position in the benzene ring apparently exert an appreciable influence on the rate of the Wallach rearrangement. According to the results of kinetic studies, the rate of rearrangement is proportion to $[H^+]^2$.[4] Because of this, the presence of an electron-donating group, whose heteroatom is capable of interacting with the proton should lower the rate of rearrangement and should lead to the necessity for the employment of a stronger acid system. Indeed, it has been shown[25] that 4-dimethylamino-1-naphthyl-*ONN*-azoxybenzene does not undergo the Wallach rearrangement in 70% sulphuric acid; only protonation at the dimethylamino-group takes place under these conditions.

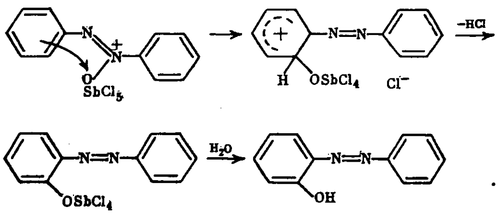
IV. THE EFFECT OF LEWIS ACIDS ON AZOXYBENZENES

The study of the reactions of azoxybenzenes with Lewis acids showed that 1 : 1 complexes are formed initially, giving rise to azobenzene as the main product on heating. Thus treatment of azoxybenzene with PCl_3 produces a 95% yield of azobenzene.[43] On the other hand, $AlCl_3$ and $FeCl_3$ afford 4-chloroazobenzene in yields of 83 and 63% respectively. If the reaction of $AlCl_3$ is carried out in SO_2Cl_2, then 4,4′-dichloroazobenzene is obtained in 70% yield, while in $SOCl_2$ a mixture of products is formed: 4-chloroazobenzene (3.1%), 4,4′-dichloroazobenzene (5.2%), and azobenzene (75.3%).[43] The reaction in nitromethane gives rise to 65% of 4-chloroazobenzene, 4% of 4,4′-dichloroazobenzene, 6% of 2-chloroazobenzene, 18% of 2,4-dichloroazobenzene, and 48% of 2,4′-dichloroazobenzene.[44]

When the reaction of azoxybenzene with $ZnBr_2$, $FeCl_3$, $AlCl_3$, and $TiCl_4$ is carried out in nitromethane, refluxing affords azobenzene as the main product and its amount increases with increase of the strength of the Lewis acid, the products of the Wallach rearrangement being obtained in trace amounts.[45]

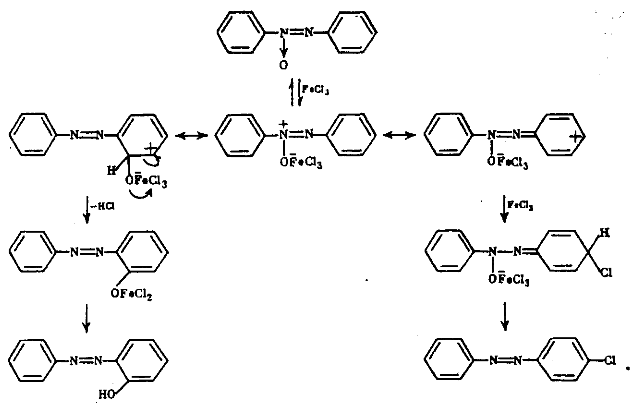
The structure of the reaction products can be influenced decisively by coordination. Thus thermolysis of the complexes of azoxybenzene with $SbCl_5$ leads selectively to an *ortho*-substituted product of the Wallach rearrangement.[45–47] It has been suggested that the reaction proceeds in accordance with Scheme 8:

Scheme 8



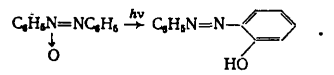
The reactions of substituted azoxybenzenes with $FeCl_3$ [48] or $AlCl_3$ [49] lead exclusively to the formation of reduction products—substituted azobenzenes. 4′-Chloro-2-hydroxyazobenzene and 4-chloroazobenzene have been obtained in proportions of ~1 : 1 only from 4-chloro-*NNO*-azoxybenzene (β-isomer). The formation of the corresponding chloro-derivatives of azobenzenes is striking and can be accounted for in terms of Scheme 9:

Scheme 9



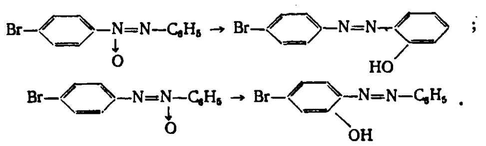
V. THE PHOTO- AND THERMO-INITIATED WALLACH REARRANGEMENT

In 1925 Cumming observed that irradiation of a solution of azoxybenzene in ethanol with UV light from a mercury lamp leads to the formation of 2-hydroxyazobenzene:

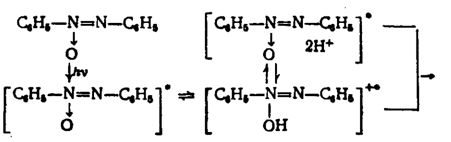


28%

It has been shown[48] that, on exposure of solutions of a number of asymmetrically substituted azoxybenzenes and benzene to sunlight, the oxygen atom of the azoxy-group is transferred to the benzene ring linked to the −N= fragment of the azoxy-group. Since the −N= valence angle is 120°, the oxygen atom is closest to the *ortho*-position of the neighbouring ring. For example, in the rearrangement of α- and β-isomeric 4-bromo-*NNO*-azoxybenzenes, the hydroxy-group is transferred to the benzene ring which in the initial compound was not bound to the NO fragment:



These facts lead to the conclusion that the photoinitiated Wallach rearrangement is intramolecular in character. It has been postulated[49] that it proceeds as follows:

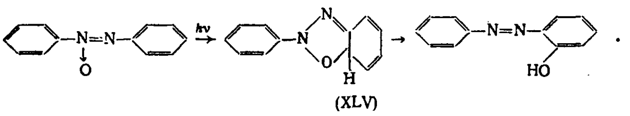


(III) .

With the aid of azoxybenzene labelled with ^{15}N at the site of the nitrogen atom of the azoxy-group not linked to the oxygen atom, it has been shown[9] that the equalisation of the isotope composition of the nitrogen is not observed for 2-hydroxyazobenzene and the labelled atom is in the benzene ring containing the hydroxy-group. With the aid of ^{18}O-labelled azoxybenzene, it has been demonstrated[8] that the isotope composition of the oxygen of the hydroxy-group in the 2-hydroxyazobenzene produced does not differ from that of the oxygen of the azoxy-group of the initial azoxybenzene. Consequently, in this rearrangement the hydroxy-group of 2-hydroxyazobenzene is formed from the oxygen of the azoxy-group and the reaction is intramolecular. Hence one may conclude that the rearrangement of azoxybenzene to 2-hydroxyazobenzene bypasses the symmetrisation stage and the benzene ring remote from the $=\underset{\downarrow \atop O}{N}-$ group is hydroxylated.

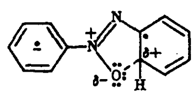
On the other hand, when [1-^{14}C]azoxybenzene in ethanol is irradiated, the distribution of the ^{14}C isotope label in the reaction products is inconsistent with an intramolecular rearrangement alone.[21] Thus the specific radioactivity of ^{14}C in the rearranged product is below that of the starting material.[21] This presupposes the simultaneous occurrence of α—β isomerisation and has been indicated also by the results of another study[50] where it was shown that irradiation of α- and β-4-methoxyazoxybenzenes in sulphuric acid results in the formation of 2-hydroxy-4-methoxyazobenzene. The rates of the Wallach rearrangement and α—β isomerisation depend on the character of the substituents in the benzene ring.

The photochemical reactions of 2,2′,6,6′-tetramethyl- and 2,6-dimethyl-*NNO*-azoxybenzenes have been studied in detail;[51] it has been concluded that the nucleophilic attack by the O atom of the azoxy-group on the benzene ring with the intermediate formation of compound (XLV) is more likely than the homolytic abstraction of an H atom from the *ortho*-position with subsequent transfer of the OH group. This conclusion has been confirmed by measurements of the quantum yields of the photochemical reaction and by the study of the isotope effect in the photoisomerisation of [D_{10}]azoxybenzene. The rate-limiting stage of the photochemical reaction of azoxy-compounds is probably the intramolecular migration of an H atom and not the formation of compound (XLV):

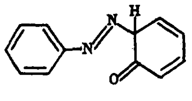


The nature of the substituent and its position in the benzene ring influence significantly the quantum yield of the photochemical reaction of substituted azoxybenzene. Thus the quantum yields in the rearrangements of 4-methyl- and 4-trifluoromethyl-*NNO*-azoxybenzenes are 0.37 and 1.70, while the corresponding yields for 3,5-dimethyl- and 3,5-bis(trifluoromethyl)-*NNO*-azoxybenzenes are 0.80 and 2.5 respectively.[52]

In their discussion of the pathways leading to the formation of compound (XLV), the authors[52] begin with the hypothesis that, on π,π* excitation of azoxybenzene, the less stable singlet state is converted into the more stable triplet state (XLVI) as a result of the interaction in the electronically excited state of the electrophilic oxygen radical and the electron-enriched remote benzene ring.

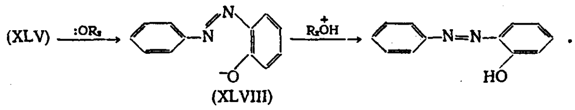


(XLVI)



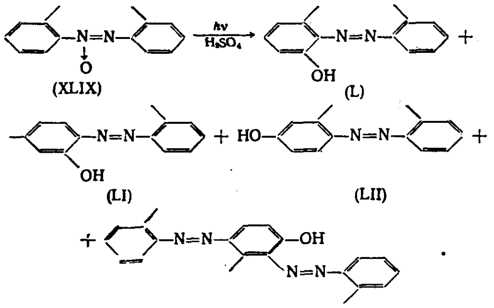
(XLVII)

In the presence of moderately basic solvents, for example, ethanol or diethyl ether, compound (XLV) is converted into the reaction product (III) via the anion (XLVIII):



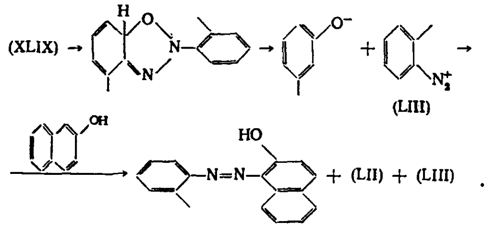
The formation of side products of the photochemical reaction has been attributed to the intermediate (XLVII) obtained from compound (XLV) by the intramolecular hydride 1,2-shift. A diazonium ion is formed from compound (XLVII), having been detected by the coupling reaction with β-naphthol.[52] Naturally, the above discussion is general so that one cannot claim to be able to explain many details of the process.

Interesting data have been obtained in the study of the photochemical reaction of 2,2′-dimethylazoxybenzene (XLIX)[53] in which unexpected products are formed:



The authors demonstrated (by adding β-naphthol to the system) the involvement of the arenediazonium cation (LIII) in this reaction (Scheme 10):

Scheme 10



It has been demonstrated[54] that, when 4- and 4′-substituted methoxy- and dimethylamino-derivatives of azoxybenzene are irradiated, 2- and 2′-hydroxyazobenzenes are formed. The authors suggest that the reaction proceeds via the intermediate formation of compounds of type (XLV).

If azoxybenzene is heated to 250 °C, its exothermic decomposition takes place and tarry substances are obtained together with azobenzene; 4-hydroxy- and 2-hydroxy-azobenzenes are formed in insignificant amounts.[55] The thermal reactions of azoxybenzenes have been investigated in detail.[56]

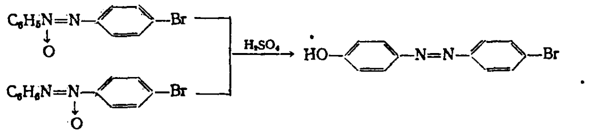
VI. THE MECHANISM OF THE WALLACH REARRANGEMENT

Up to the 1960's, the studies on the Wallach rearrangement were concentrated mainly on its synthetic aspects and virtually no attention was devoted to the mechanism of this reaction. The hypotheses put forward concerning the mechanism of the Wallach rearrangement were speculative and were not supported by experimental data. Only after the fundamental investigations of Shemyakin's school[8–10] and Buncel's kinetic measurements[4] were the first well-founded ideas concerning the mechanism of the Wallach rearrangement formulated. However, despite the large number of publications on this topic, after the above studies no serious step of any kind was taken towards the understanding of the mechanism of the Wallach rearrangement. On the contrary, a number of experimental data which could not be explained were published. The complexity of the study of the Wallach rearrangement was caused primarily by the possibility of the formation of a multiplicity of intermediates on dissolution of azoxybenzene in acid, each of which can influence the subsequent course of the reaction. The question of which cationoid species determines the rate of the Wallach rearrangement remains unresolved.

In the study of certain acid-catalysed rearrangements, for example the rearrangements of diazoaminobenzenes to phenylhydroxylamines, it was concluded that the mode of substitution in the benzene ring can be used to achieve the understanding of their mechanism. Thus mainly the *para*-substituted products should be formed via the intermolecular mechanism while the intramolecular mechanism gives rise mainly to *ortho*-substituted products. In those cases where 4-hydroxyazobenzenes are formed exclusively from azoxybenzenes, an intermolecular mechanism of the Wallach rearrangement might have been postulated. We shall deal with certain aspects of the mechanism of the Wallach rearrangement.

1. Acid-Catalysed α-β Isomerisation of Azoxybenzenes

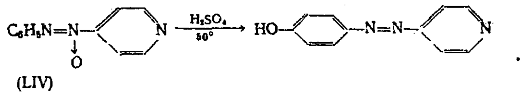
Both the α- and β-isomers of 4-bromoazoxybenzenes undergo an acid-catalysed rearrangement and the same product is formed: 4-bromo-4′-hydroxyazobenzene. Thus the hydroxy-group is in both cases in the *para*-position relative to the unsubstituted benzene ring:



This has also been observed for the α- and β-isomers of 4-methoxyazoxybenzenes. On the other hand, it has been unexpectedly observed that the main product of the reactions of the α- and β-isomers of 4-methylazoxybenzenes corresponds to the migration of the oxygen atom to the *ortho*-position in the unsubstituted benzene ring.[57] In a later study[58] it was shown that the α- and β-isomers of 4-methylazoxybenzene in 80–90% sulphuric acid form only 2-hydroxy-4-methylazobenzene, while the α- and β-isomers of 4-nitroazoxybenzene afford 4-hydroxy-4′-nitroazobenzene. 4-Bromo-*ONN*-azoxybenzene does not undergo the Wallach rearrangement, while 4-bromo-*NNO*-azoxybenzene gives rise to 4-bromo-2-hydroxyazobenzene under these conditions.

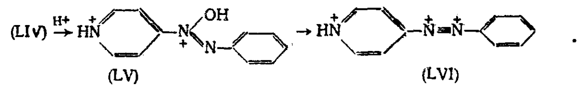
It has been found that the rates of rearrangement of the isomers are different and depend on the character of the substituent in the benzene ring. The use of identical conditions for the rearrangement of the α- and β-isomeric azoxybenzenes showed that the rate of rearrangement of α-isomers is higher for the CH_3 substituent and lower for the NO_2 and Br substituents. The ratio of the rates of rearrangement of α- and β-isomeric azoxybenzenes depends also on the acidity of the medium employed.

An example of an extremely large difference between the rates of rearrangement of the α- and β-isomers has been observed[26] for 4-[benzene-α(β)-azoxy]pyridines (LIV):



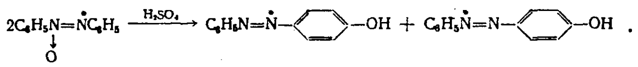
(LIV)

In this case only the β-isomer (LIV) undergoes rearrangement, while the α-isomer remains unchanged, which has been used to isolate it in a pure state. Kinetic measurements showed that the formation of the intermediate species (LVI) (the triprotonated form), as a result of the protonation of the nitrogen atom of the pyridine ring and the azoxy-group, is the rate-determining stage of the reaction:



(LV) (LVI)

Whether or not the α–β isomerisation is intramolecular can be elucidated by studying the behaviour in acids of azoxybenzenes labelled at one of the nitrogen or carbon atoms by the ^{15}N or ^{14}C isotopes. These data can also provide an answer to the question which of the benzene rings does the hydroxy-group enter in the Wallach rearrangement. Shemyakin et al.[9] used azoxybenzene labelled with the ^{15}N isotope at one of the nitrogen atoms of the azoxy-group. They found that the formation of 4-azoxyazobenzene is accompanied by the complete equalisation of the isotope compositions of the nitrogen in both positions and they concluded that both benzene rings are hydroxylated to the same extent:

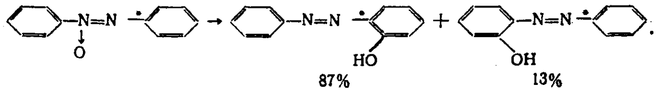


It has been established[9] that the observed equalisation of the distribution of the isotope label takes place during the period of the Wallach rearrangement itself and not before it. It has been demonstrated that the rearrangement of azoxybenzenes is not preceded by reversible isomerisation and that the rearrangement is not coupled with the preliminary conversion of the azoxybenzene to azobenzene, which is then hydroxylated.

The equalisation of the isotope compositions of the nitrogen in the final rearrangement product can indicate that the α–β isomerisation proceeds via a stage involving the formation of a free cation, which exists independently. Shemyakin et al.[9] suggested that this can be the oxonium cation (LVII), which is in fact responsible for the Wallach rearrangement.

(LVII)

These conclusions received some confirmation in a study[59] whose authors used azoxybenzene labelled with ^{14}C at the carbon atom linked to the nitrogen atom of the azoxy-group:



However, the ratio of the products formed is 87 : 13, which throws doubt on the necessity for the intermediate formation of the oxonium cation and its role in the mechanism of the Wallach rearrangement, confirming the possibility of the isomerisation of azoxybenzenes in an acid medium via the corresponding intermediate. Later these results were confirmed on the same object by other workers.[58] There is now no doubt that the acid catalysed α–β isomerisation is a general property of azoxybenzenes and proceeds independently of the Wallach rearrangement. It may be that this isomerisation takes place via the species (LVII).

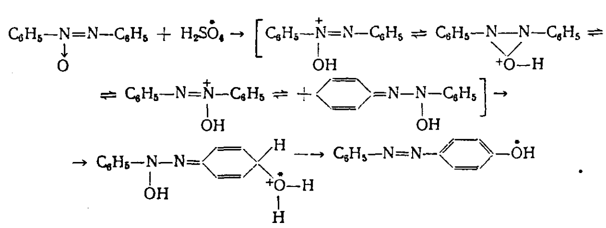
2. Data Obtained By the Tracer Atom (^{15}N, ^{18}O, ^{14}C) Method

An important factor in the understanding of the mechanism of the Wallach rearrangement was the solution of the problem whether it is intermolecular or intramolecular. It has been shown[9] that, in the reaction of azoxybenzene (labelled with the ^{15}N isotope) with acetic anhydride (at 230–240 °C) the formation of only 2-hydroxyazobenzene is observed, in which the distribution of the ^{15}N isotope label is not equalised. This shows that the rearrangement proceeds via an intramolecular mechanism.

4-Bromo-*ONN*-azoxybenzene, 4-nitro-*NNO*-azoxybenzene, and 3,3′-dinitro-azoxybenzene have been used as objects of study in two investigations.[8,10] They were subjected to the Wallach rearrangement in sulphuric acid labelled with the ^{18}O isotope under conditions where it is possible to isolate a certain amount of the initial azoxybenzene which failed to react. The isotope composition of the hydroxy-group in the rearrangement product is the same as that of the oxygen in the acid medium. This demonstrates the intermolecular mechanism of the rearrangement.

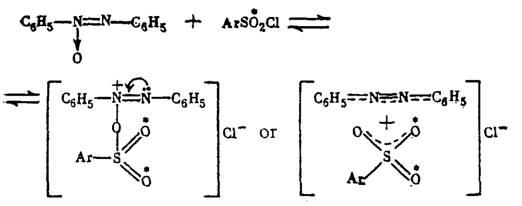
The validity of this conclusion and its independence of the conditions employed, the number of substituents, and their character and positions in the molecule have been confirmed in a study[60] whose authors proposed the mechanism of the Wallach rearrangement illustrated in Scheme 11:

Scheme 11



However, this picture, which is at first sight understandable, becomes much more complex after careful critical analysis. In the first place, the hypothesis that the structure of the monoprotonated form changes in the course of the reaction and even more so the hypothesis that intermediates are formed have not been rigorously proved. Subsequently, the intermolecular mechanism of the Wallach rearrangement was confirmed also for other acid systems. Thus it has been established[22] that, when azoxybenzene is treated with the anhydride of [^{18}O]-labelled benzenesulphonic acid, the oxygen atom of the acid system is found in the hydroxy-group of the final reaction products.

In the reaction of azoxybenzene with [^{18}O]-labelled benzenesulphonyl chloride, which leads to the Wallach rearrangement in the *ortho*-position, the ^{18}O isotope enters the hydroxy-group of the final product.[22] This indicates the intramolecular character of the rearrangement. However, the ^{18}O content in the final product is smaller than its content in benzenesulphonyl chloride, which can be accounted for by the formation of compounds (LVIII) and (LIX). This can also explain the decrease of the ^{18}O content in the *para*-substituted product of the Wallach rearrangement.



(LVIII) (LIX)

When [^{18}O]-labelled azoxybenzene is used in the Wallach rearrangement, the product is 4-hydroxyazobenzene, in which the ^{18}O content is ~10%.[1] When 4-methyl-*ONN*-azoxybenzene and 2-methyl-*ONN*-azoxybenzene are treated with 80% sulphuric acid, an insignificant amount of ^{18}O is also observed in the product of the Wallach rearrangement.

On the other hand, the study of the rearrangement of 4,4′-dimethylazoxybenzene in concentrated [^{18}O]-labelled sulphuric acid showed that 2-hydroxy-4,4-dimethylazobenzene contains ~70% of ^{18}O.[10] Hence it follows that the product of the Wallach rearrangement of azoxybenzenes is obtained via two mechanisms—intermolecular and intramolecular. Thus the conditions under which the Wallach rearrangement is carried out, the nature of the substituents in the benzene ring, and their positions can influence significantly the ratio of the rates of the process via these two mechanisms. In essence, the problem dealt with here is of central importance for the understanding of the mechanisms of other acid-catalysed rearrangements of nitrogen-containing aromatic compounds. This should be borne in mind in formulating a general mechanism of the Wallach rearrangement.

3. The Generation and Structure of the Intermediate Species When Azoxybenzenes are Treated with Acids

In the first studies of the Wallach rearrangement, it was already suggested that both the initial azoxybenzene and the intermediates formed in the course of the rearrangement may be protonated. On the basis of their own data, according to which the equalisation of the distribution of the ^{15}N label in the final rearrangement product should occur in a symmetrical structure, Shemyakin and co-workers[8] examined the possibility of the formation of compounds (LX)–(LXIII) in the Wallach rearrangement:

$C_6H_5-\underset{HO}{N}-\underset{OH}{N}-C_6H_5$

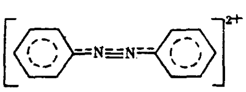
(LX)

$C_6H_5-N\equiv N-C_6H_5$

(IV)

$C_6H_5-\overset{+}{N}\equiv\overset{+}{N}-C_6H_5$

(LXI)



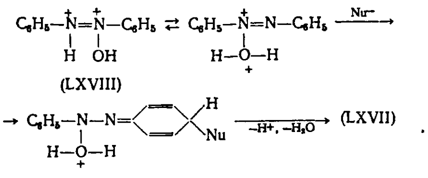
(LXII)

(LXIII)

The *NN*-diol (LX), proposed by Wohl,[61] apparently cannot be formed under the conditions of the Wallach rearrangement, because the hydration necessary for its formation cannot occur in strong acids such as HSO_3F and HSO_3Cl. Shemyakin and co-workers[9] showed that azobenzene (IV) is not an intermediate in the Wallach rearrangement, because the addition of azoxybenzene containing only the ^{14}N isotope to [^{15}N]azoxybenzene under the conditions of the rearrangement did not lead to the dilution of the isotope label in the reaction product—4-hydroxyazobenzene.[9] The structure of the oxide (LXIII) initially explained satisfactorily the experimental data. However, results were later obtained which are difficult to account for from these standpoints. It was found that an increase of the concentration of sulphuric acid from

75.3 to 99.99% increases the rate of rearrangement by five orders of magnitude, which indicated an extremely important role of the acidity of the medium. Indeed, kinetic studies of the Wallach rearrangement by Buncel[4] showed that a two proton process takes place. For this reason, the rate-limiting stage of the rearrangement must be the state involving the generation of dicationoid species.

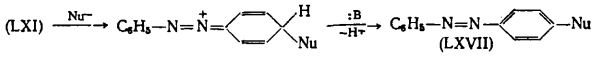
The diprotonated form of azoxybenzene and the dication (LXI) or (LXII), generated by the dehydration of the diprotonated form, are mainly discussed in the literature. The diprotonated form (LXVIII) can be responsible for the Wallach rearrangement, since the reaction of the anion with the medium (or water) results in the formation of the rearrangement product:



(LXVIII)

(LXVII)

On the other hand, the dication (LXI), generated from the diprotonated form of azoxybenzene by dehydration, also affords the products of the rearrangement (LXVII):



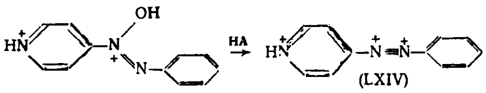
(LXI)

(LXVII)

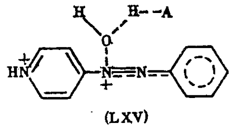
Naturally the question arose which intermediate species are in fact generated in each acid system. The application of ^1H NMR enabled Olah et al.[12] to trace, in relation to azoxybenzene and 4,4′-dichloroazoxybenzene, all the intermediate stages in the Wallach rearrangement—the generation of the mono- and di-protonated forms of azoxybenzene and the formation of a dication of type (LXI). Using ^{19}F and ^{15}N NMR, these intermediate species have been detected analogously[18,63] for decafluoro- and 2,2′,3,3′,5,5′,6,6′-octafluoroazoxybenzenes.

However, one should note that NMR spectroscopy makes it possible to detect only sufficiently long-lived carbonium ions. The data indicated do not therefore necessarily reflect the true picture because the rate-limiting stage may be the generation of a short-lived carbonium ion which is highly reactive. Nevertheless, Olah suggested that a dication of type (LXI) is responsible for the Wallach rearrangement. A number of investigators share this view and the results obtained in the study of the Wallach rearrangement are treated within the framework of Olah's concept. For example, Buncel and Cox[35] invoked the idea of the generation of a cation of type (LXI) to explain the results of the reaction of 2,2′,4,4′,6,6′-hexamethylazoxybenzene with concentrated sulphuric acid (see Scheme 7).

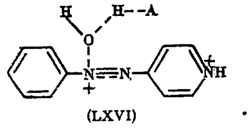
A pathway leading to the rearrangement via the generation of the intermediate trication (LXIV) from the diprotonated form has been put forward.[26] The rate-limiting stage is then the generation process. The authors used this in fact to account for the differences between the rates of rearrangement of the α- and β-isomeric 4-(phenylazoxy)-pyridines. Indeed the formation of the transition state (LXV) from the β-isomer is an energetically favourable process owing to the delocalisation of the charge by the benzene ring, while the transition state derived from the α-isomer (LXIV) is unfavourable from this point of view: [26]



(LXIV)



(LXV)



(LXVI)

The formation of the final product can be readily explained from this standpoint, but the explanation of many other facts encounters difficulties due to the lack of information about the structure of the complexes formed under the real process conditions and about their reactivity. Thus it has been concluded[23] that there is a difference in the pathways leading to the Wallach rearrangement as a function of the acidity of the medium. In relatively weak acids (for example in sulphuric acid at a concentration less than 80%), azoxybenzene is initially protonated at the oxygen atom in the equilibrium stage which is followed by the reversible attack of the nucleophile (probably HSO_4^-) with formation of a substrate of the quinonoid type. Next follows the protonation of this compound at the oxygen atom. In the rate-limiting stage attack by the base takes place (for example by HSO_4^-) with the concerted elimination of water and subsequent rapid hydrolysis, which leads to the final product.

In acids stronger than 80% sulphuric acid, the protonation of the oxygen atom of the azoxy-group is followed by the rate-limiting proton transfer from the undissociated form of the acid (usually acid catalysis) with subsequent elimination of water and the formation of a dication of type (LXV), which is subjected to rapid nucleophilic attack leading to the final product. The claim by Olah et al.[12] that 4-hydroxyazobenzene is formed in the hydrolysis of the dication generated by treating azoxybenzene with $HF—SbF_5—SO$ at −50 °C has been considered as an important argument in support of the formation of a dication of type (LXI). However, the reaction has been studied in detail[18] and it has been found that, under the conditions of the generation of a dication of type (LXI), hydrolysis affords azobenzene in 68–72% yield, while 4-hydroxyazobenzene is formed in small amounts.

We shall quote yet another example of the correction of old experimental data based on a careful analysis of the products of the Wallach rearrangement. It has been reported[57] that treatment of 4-bromoazoxybenzene with with sulphuric acid results in the formation of only 4-bromo-4′-hydroxyazobenzene. However, this study was repeated[29] and it was found that the main product of this reaction is 4-bromoazobenzene, while 4-bromo-4′-hydroxyazobenzene is formed in small amounts.

In contrast to the data of Lukashevich and Kurdyumova,[14] it has been concluded[6] that treatment of azoxybenzene with HSO_3Cl at −10 °C leads to the formation of 26.5% of azobenzene (previously 5% had been found), which appears somewhat strange. We reproduced this reaction and showed that the amount of azobenzene formed is ~5%.[18] Since azobenzene and azobenzene-4-chlorosulphonate have the same R_f, it is difficult to follow by thin-layer chromatography the completeness of the hydrolysis of the sulphate by an aqueous solution of ammonia (as was done by Yamamoto et al.[6]) and the value 26.5% probably refers to a mixture of two substances.

The fact that, as electron-accepting substituents, which reduce the pK_a of azoxybenzenes with a parallel decrease of the capacity of the substrate for diprotonation, are introduced into the benzene ring, the fraction of the azo-compound obtained—the product of the reduction of azoxybenzene—increases, has not so far been explained.

Owing to the probability of the attack by the nucleophile on both benzene rings, in the case of a dication of type (LXI), labelled with ^{14}C in one of the benzene rings, products of the Wallach rearrangement with identical contents of the

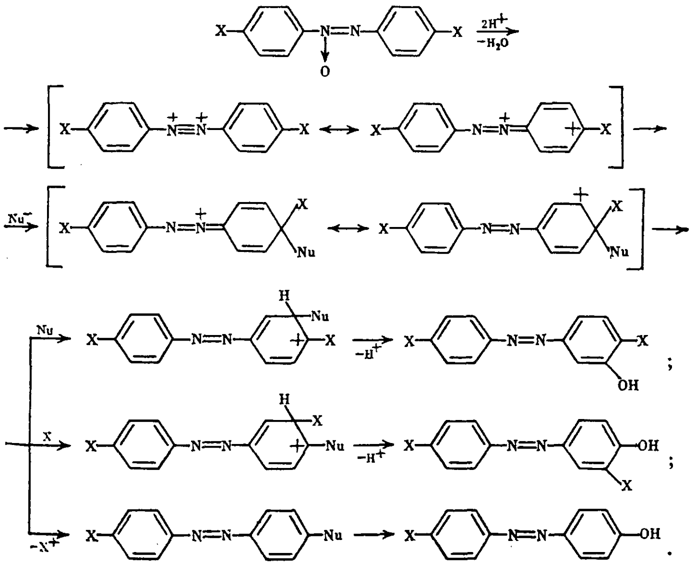
^{14}C label in both rings should be obtained. However, it has been shown for the reaction of [^{14}C]azoxybenzene in sulphuric acid[60] or in the anhydride of benzenesulphonic acid[22] that the ratio of the ^{14}C contents in the benzene rings differs somewhat from 1 : 1. On the other hand, in the diprotonated form of azoxybenzene the shielding of the carbon atoms of both rings, which parallels the magnitude of the positive charge on the atom, is somewhat different (see the ^{13}C NMR data for the diprotonated form of decafluoroazoxybenzene[18]). The small difference in the shielding of the carbon atom can explain the experimental data for the distribution of the ^{14}C label. These factors can indicate that the true intermediate species determining the course of the Wallach rearrangement is the diprotonated form of azoxybenzene.

Owing to the lack of direct experimental evidence, the above conclusions are to a large extent tentative and hence they do not rule out, in principle, other possible explanations.

4. The Interpretation of the "Anomalous" Processes Accompanying the Classical Wallach Rearrangement

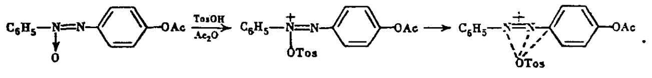
The formation of "anomalous" products on treatment of 4-alkyl- and 4,4′-dialkyl-azoxybenzenes with acids was noted above.[30,33] Assuming the generation of a dication of type (LXI), the appearance of these products can be explained in the following way (Scheme 12):

Scheme 12



The initial diprotonation with subsequent elimination of water leads to the formation of a dication which is attacked by the nucleophile at the carbon atom in the *para*-position. The resulting σ-complex, in which there is a considerable positive charge on C(3), is then converted into the reaction products via several pathways: (a) into 4-hydroxyazobenzene (XXXIII) via the elimination of X^+; (b) into 3-hydroxyazobenzene (XXXI) via a rearrangement with migration of Nu to the 3-position; (c) into 4-hydroxyazobenzene (XXXII) via a rearrangement with migration of X to the 3-position. The ability of X to migrate increases with increase of the electron density at the α-C atom. The group X is readily eliminated if it is able to form a stable carbonium ion [for example, the product (XXXIII) is formed for X = iso–Pr and t–Bu, while the ease of migration of the CH_3 and CH_3CH_2 groups leads to products of type (XXXII)]. The cationoid character of the Wallach rearrangement has been confirmed by these data.

The formation of complex mixtures of products when the Wallach rearrangement is carried out in the toluene-*p*-sulphonic acid–acetic anhydride system can be explained without the concept of the generation of a dication of type (LXI) but via the initial attack of the electrophile from the medium on the oxygen atom of the azoxy-group with subsequent formation of the intermediate (LXVII):[17]



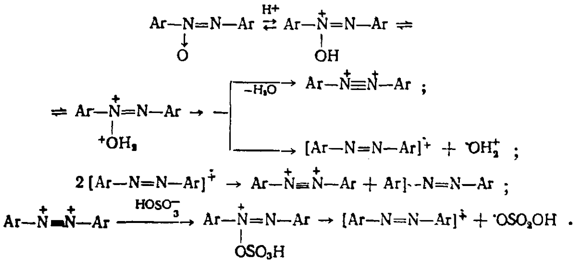
(LXVII)

In the cation (LXVII) there is a possibility of attack also in the *unco*-position. In this case a benzenediazonium cation is formed. Its formation has been confirmed by the reaction with toluene, which yields the corresponding biphenyls. It also affords C_6H_5OAc and C_6H_5OTos via the reaction of the intermediate phenyl cation with the anion of the medium.

It has been demonstrated by spectroscopic methods and by the azo-coupling reaction with dimethylaniline[58] that, when decafluoroazoxybenzene is kept in HSO_3Cl for 200 h, the pentafluorobenzenediazonium cation and chloropentafluorobenzene are formed:

$$\underset{\downarrow\atop O}{C_6F_5—N}{=}N—C_6F_5 \xrightarrow{HSO_3Cl} C_6F_5Cl + [C_6F_5—N{\equiv}N]^+ \cdot OSO_2Cl^- .$$

As noted above, the Wallach rearrangement affords in many instances azobenzene, sometimes in predominant amounts. The information about the pathways leading to their formation is fragmentary and frequently contradictory. It has been suggested[19,29] that they are obtained as a result of the disproportionation of the diprotonated form of azoxybenzene, which leads to the azobenzene radical-cation:



$$\underset{\downarrow\atop O}{Ar—N}{=}N—Ar \overset{H^+}{\rightleftarrows} \underset{|\atop OH}{Ar—\overset{+}{N}}{=}N—Ar \rightleftharpoons$$

$$\rightleftharpoons \underset{|\atop {}^+OH_2}{Ar—\overset{+}{N}}{=}N—Ar \to \begin{cases} \xrightarrow{-H_2O} Ar—\overset{+}{N}{\equiv}\overset{+}{N}—Ar ; \\ \longrightarrow [Ar—N{=}N—Ar]^{\dot{+}} + {}^{\cdot}OH_2^+ ; \end{cases}$$

$$2\,[Ar—N{=}N—Ar]^{\dot{+}} \to Ar—\overset{+}{N}{\equiv}\overset{+}{N}—Ar + Ar]\text{-}—N{=}N—Ar ;$$

$$Ar—\overset{+}{N}{\equiv}\overset{+}{N}—Ar \xrightarrow{HOSO_3^-} \underset{|\atop OSO_3H}{Ar—\overset{+}{N}}{=}N—Ar \to [Ar—N{=}N—Ar]^{\dot{+}} + {}^{\cdot}OSO_2OH .$$

By analogy with the reactions of diaryl sulphoxides in sulphuric acid, where the radical-cations of diaryl sulphides were detected by EPR, and the degree of their racemisation was determined using the ^{18}O isotope,[62] Oae and co-workers[19,29] attempted to detect the azobenzene radical-cation but they were unsuccessful. On the other hand, it has been shown for polyfluoroazoxybenzenes[32,63] that azobenzenes are formed only in those cases where dications of type (LXI) are observed, according to ^{19}F and ^{15}N NMR data in the 1 : 1 HF–SbF_5 or 1 : 1 HSO_3F–SbF_5 systems.

If the scheme put forward by Oae and co-workers[19,29] is adopted, then after a time one should observe the diprotonated forms of azobenzenes. However, it has been shown[32] that the signal is 13.6 p.p.m., referring to the diprotonated form of decafluoroazobenzene, is not observed for a solution of decafluoroazoxybenzene in the 1 : 1 HSO_3F–SbF_5 mixture allowed to stand for 20 h at 20 °C, while hydrolysis leads to the formation of decafluoroazobenzene. It has been suggested[32] that the formation of decafluoroazobenzene in this reaction is due to the pronounced oxidising properties of the type (LXI) dication, which oxidises water to hydrogen peroxide, as a result of which the dication itself is reduced to decafluoroazobenzene.

In all cases of the generation of type (LXI) dications from azoxybenzenes, hydrolysis results in the formation of the corresponding azobenzenes. For example, on treatment with the 1 : 1 $(HF-SbF_5)-SO_2$ mixture of 4,4′-difluoroazoxybenzene (−50 °C, 10 min) and 2,2′,4,4′-tetrafluoroazoxybenzene (−10 °C, 30 min), the ^1H NMR spectra revealed the presence of the H_3O^+ cation and the hydrolysis of such solutions results in the formation of 4,4′-difluoro- or 2,2′,4,4′-tetrafluoroazobenzene. The diprotonated form of azoxybenzene is incapable of leading to azobenzenes and the starting materials are recovered in all cases. Thus the dissolution of 4,4′-bis(trifluoromethyl)octafluoroazoxybenzene in the 1 : 1 HSO_3F-SbF_5 or 1 : 1 $HF-SbF_5$ system leads only to the diprotonated form at 20 °C according to ^1H and ^{19}F NMR spectra, while after 50 h signals due to the protons of the H_3O^+ cation appear in the ^1H NMR spectrum. Hydrolysis of this solution leads only to the starting material.

It has been shown[18] that in superacids, where nucleophiles exhibit a low reactivity, the generation of the diprotonated form of azoxybenzene is an insufficient condition for the occurrence of the Wallach rearrangement; the presence of active nucleophilic species is necessary in addition. Thus, in contrast to the reaction in HSO_3Cl, the Wallach rearrangement has not been observed for 2,2′,3,3′,5,5′,6,6′-octafluoroazoxybenzene in the 1 : 1 $(HSO_3F-SbF_3)-SO_2ClF$ (at −40 °C) or 1 : 1 $(HF-SbF_5)-SO_2$ (at −60 °C) systems, where the diprotonated form of azoxybenzene is detected.

We believe that the scheme in which azobenzenes are formed via a dication of type (LXI) on treatment of azoxybenzenes with acids, while the product of the Wallach rearrangement is formed as a result of the reaction of the diprotonated form of azoxybenzene with the nucleophile of the medium, is more likely.

---o0o---

The survey of data on the Wallach rearrangement permits certain general conclusions. Firstly, its mechanism has not yet been ultimately elucidated. Secondly, similar rearrangements are apparently possible in systems having the N → O group and capable of splitting off water on protonation, generating cationoid species. For example, one may expect that the *N*-oxides of tertiary aromatic amines and *C*N–diarylnitrones undergo a rearrangement in acid media which is of the same type as the Wallach rearrangement.

Thus, in order to understand the entire set of processes occurring in the Wallach rearrangement it is still necessary to solve fairly numerous complex problems. The necessity to proceed to a detailed investigation of the mechanism of the Wallach rearrangement has become self-evident. The solution of this problem can only be achieved by a combined method involving the use of modern physical research techniques. It is possible to differentiate two main groups of problems. One is associated with the study by a spectroscopic method of the electronic structures of the electrophilic species generated in the course of the rearrangement. The other concerns the determination of their true role in the Wallach rearrangement, especially in the rate-limiting stage. There is no doubt that further study of the mechanism of the Wallach rearrangement will significantly expand our ideas about molecular rearrangements.

The Synthesis of Saturated Cyclic Sulphides

E.N.Karaulova

New syntheses of saturated cyclic sulphides and their functional derivatives are examined. Attention is concentrated on the mode of reaction, the purity of the target products, their yields, and the relation between the structure and properties of cyclic sulphides.

The bibliography includes 142 references.

I. INTRODUCTION

During the last 10–15 years there has been a sharp growth of the number of studies on the chemistry of organic sulphur compounds. The chemistry of saturated cyclic sulphides has been developing vigorously. They are important models in the study of heteroatomic compounds in petroleum and also serve as the starting materials for the synthesis of polymers, polyfunctional biologically active compounds, and extractants for heavy metals.

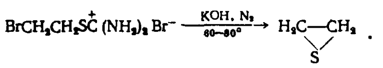
New synthesis of saturated cyclic sulphides during the period 1970–1984 are described in the present review. The yields of the sulphides are indicated (except in those cases where they are not given in the studies quoted or the method of synthesis is not preparative). If reviews or monographs on the relevant topic have been published during the above period, only the most important studies, mainly those published subsequently, are considered.

II. MONOCYCLIC SULPHIDES

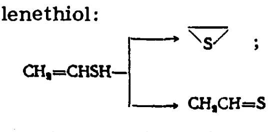
1. Thiirans

The syntheses of thiirans published up to 1976 have been examined in a monograph.[1] The methods of synthesis of thiirans are described systematically in this book in accordance with the types of the ring formation reactions (including the homolytic ring closure via the C=C or C=S bond and heterolytic ring closure as a result of anionotropic or cationotropic transformations). The most important methods of synthesis of thiirans published up to 1980 have been described in a brief review.[2]

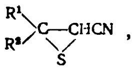
Thiirans have been obtained recently by cyclising S-(2-bromoethyl)isothiuronium bromide on heating with aqueous alkali:[3]



It has been shown[4] that up to 30% of thiiran is formed in the synthesis of ethylenethiol from vinyl chloride and hydrogen sulphide in the vapour phase, probably as a result of the isomerisation of ethylenethiol:

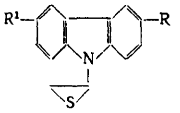


The nitriles of substituted thioglycidic acids



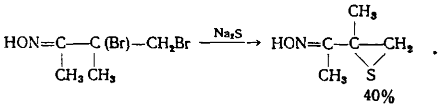
where $R^1 = H$, CH_3, or C_2H_5 and $R^2 = CH_3$ or C_6H_5, have been synthesised[5] by a familiar method involving the condensation of epoxides with potassium thiocyanate; to prevent the desulphurisation of these compounds, it is recommended that the reaction be carried out at pH 6.3–7.

The preparation of carbazolylthiirans with electron-accepting substituents in the carbazole fragment has been described:[6]

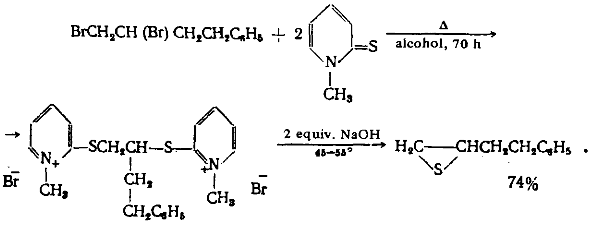


$R=H$, $R^1=Cl$, Br, NO_2; $R=R^1=Br$ or $COCH_3$.

It used to be assumed that the interaction of vicinal dihalogenoalkanes with sodium sulphide leads only to polymers.[1] However, it has been possible recently to achieve the synthesis of thiirans from 1,2-dibromoalkanes. When the oxime of 3,4-dibromo-3-methyl-2-butanone was allowed to react with an excess of sodium sulphide in acetone at 20 °C, 2-(α-hydroxyiminoethyl)-2-methylthiiran was obtained:[7]

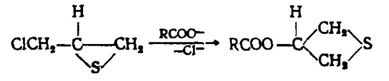


Japanese chemists[8] proposed a method of synthesis of 2-phenylethylthiacycloalkanes from 1-phenylethyl-ω-dibromoalkanes and N-methyl-2(1H)-pyridinethione; thus phenylethylthiiran has been obtained from 1-phenylethyl-1,2-dibromethane:

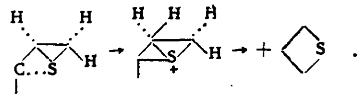


2. Thietans

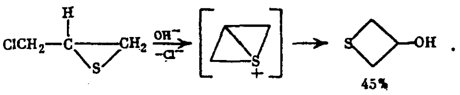
Certain methods of synthesis of thietans (mainly arylthietans) have been examined in the review by Vedejs and Kraft.[2] Nuretdinova and Arbuzov and co-workers investigated the conditions governing the formation of thiiran and thietan derivatives on treatment of ethylthiohalogenohydrins with nucleophiles.[9,10] They found, that, when chloromethylthiiran is treated with sodium and potassium acetates, chloroacetates, methylacrylates, and benzoates in aqueous solutions, 3-acyloxythietans are formed exclusively:



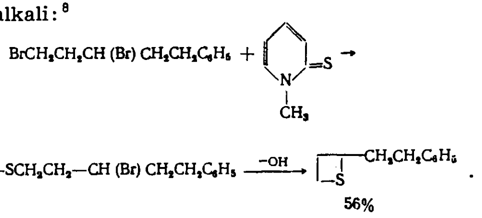
The thiiran–thietan rearrangement then takes place and its mechanism was related by the authors to the formation of an intermediate non-classical thiabicyclobutane cation: the cationotropic transformations of the latter leads, according to Fokin and Kolomiets,[1] to thietan derivatives:



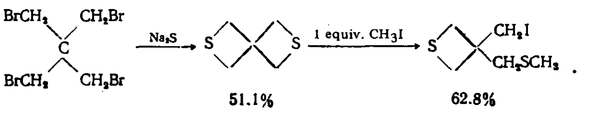
It has been suggested[1] that the conversion of epithiochlorohydrin into 3-hydroxythietan on treatment with aqueous alkali proceeds via the same mechanism:[11]



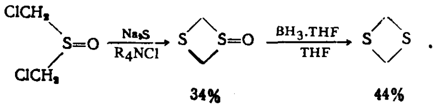
2-Phenylethylthietan can be obtained by prolonged heating of 3,5-dibromo-1-phenylpentane with *N*-methyl-2(1*H*)-pyridinethione and subsequent treatment of the reaction product with aqueous alkali:[8]



A thietan derivative, namely dithiaspiroheptane, has been synthesised by the cyclocondensation of pentaerythrityl bromide with sodium sulphide in aqueous alcohol; on treatment with methyl iodide, the product is converted into 3-iodomethyl-3-methyl-thiomethylthietan:[12]

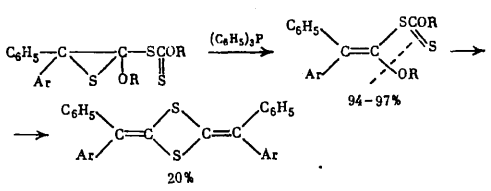


1,3-Diethetan was obtained for the first time in 1982[13] and its properties were investigated. Bis(chloromethyl) sulphoxide cyclises to 1,3-dithietan oxide on treatment with sodium sulphide in an aqueous medium in the presence of a phase transfer catalyst—tricaprilylmethylammonium chloride [the analogous reaction with bis(chloromethyl) sulphide yields only a polymer]. 1,3-Dithietan oxide was reduced to 1,3-dithietan at room temperature by treatment with the borane–tetrahydrofuran complex:

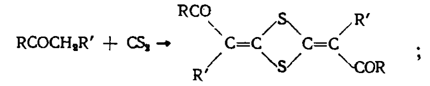


On prolonged storage, 1,3-dithietan is converted into the thioformaldehyde trimer.

1,3-Dithietan derivatives (thioketen dimers) have been obtained[14] by the mild desulphurisation of 2-acylthio-2-alkoxythiirans by tertiary phosphines and subsequent thermolysis of the thioketenals in accordance with the following scheme:

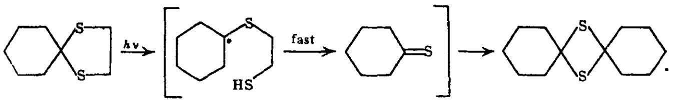


Thioketenal dimers (desaurins) can be obtained in moderate yields by heating carbonyl compounds with carbon disulphide in the presence of potassium hydroxide:[15]

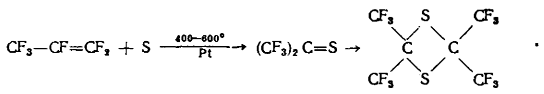


$R=C_6H_5, CH_3;\ R'=H, C_6H_5$.

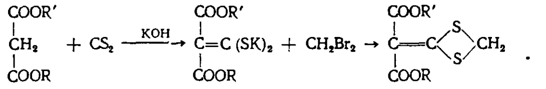
Cyclohexanone thioacetal is converted into spiro-1,3-dithietan on exposure to UV light; the reaction proceeds via a radical mechanism with the intermediate elimination of the radical $\cdot CH_2CH_2SH$ and the formation of cyclohexanethione, which dimerises to spiro-1,3-dithietan:[16]



Hexafluorothioacetone also dimerises to a substituted dithietan:[17]



Dithietanylidenemalonates have been patented as fungicides; it has been recommended that they be obtained by treating malonic acid esters with carbon disulphide in the presence of alkalies; the reaction products are treated with a dihalogenomethane,[18] for example:

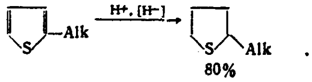


The yields of the required products are 52.8–88%.

3. Thiolans

The syntheses of alkyl- and aryl-thiolans and alkyl- and aryl-thianes, known up to 1969, have been examined in a monograph.[19] Since then new methods of synthesis of the thiolans described previously have been proposed and existing methods have been improved. The purities of the required sulphides have been established by means of gas chromatography and spectroscopic methods. Many thiolans and thianes characterised previously, before the use of these analytical methods, undoubtedly contained considerable admixtures of structural isomers. This must be taken into account in dealing with old data, in particular, with syntheses where dibromoalkanes served as the precursors of thiolans and thianes.

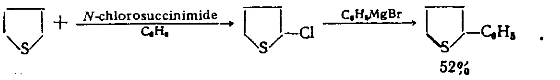
A new method of synthesis of thiolans, including the first member of the series—thiolan itself, involves the ionic hydrogenation of thiophen derivatives.[20] It consists in the successive addition of a proton and hydride ion to the double bonds. Thiophens are acted upon by a trialkylsilane in trifluoroacetic acid:



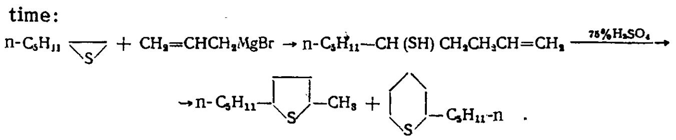
Subsequently the hydrogenating systems were modified[21]—treatment of the corresponding thiophens with the HSi.$(C_2H_5)_3$–HCl/$AlCl_3$ system in methylene chloride produced thiolan, 2-ethylthiolan, 2,5-dimethylthiolan, and, for the first time, 2,5-diphenylthiolan in yields of 25, 80, 75, and 66% respectively. Questions concerning the stereochemistry of disubstituted thiolans were not dealt with by the authors of the above communication.[21]

In order to obtain cyclic sulphides, Crumbie and Ridey[22] hydrolysed alkylthiuronium salts, which is a method widely used previously for the synthesis of alkanethiols. The reaction of 1-chloro-4-iodobutane and one equivalent of thiourea in alcohol yielded 2-(4-chlorobutyl)thiuronium iodide, which was immediately treated with dilute sodium hydroxide. This led to the synthesis of thiolan in 49% yield.

A novel general method of synthesis of 2-substituted cyclic sulphides has been proposed.[23] When unsubstituted cyclic sulphides are chlorinated with *N*-chlorosuccinimide under mild conditions, 2-chlorothiacycloalkanes are formed and are then converted on treatment with methyl- or phenyl-magnesium bromide into 2-substituted thiacycloalkanes (without an admixture of isomers with a different number of members in the ring). 2-Methylthiolan, and for the first time, 2-phenylthiolan were synthesised in this way in satisfactory yields:

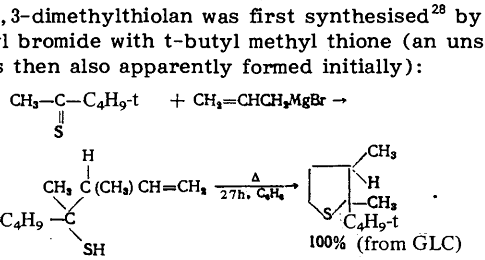


Extremely promising methods of synthesis of thiolans and thianes are based on the cyclisation of unsaturated mercaptans. The use of these reactions makes it possible to develop a general method of synthesis of five- or six-membered cyclic sulphides.[24] The method is based on the interaction of thiirans with allylmagnesium bromide or its homologues, which leads to $\gamma\delta$-unsaturated thiols. Intramolecular cyclisation of the latter via an ionic mechanism leads to sulphides with a five-membered ring and cyclisation via a free-radical mechanism results in the formation of sulphides with six-membered rings; their mixture is usually formed. 2-Methyl-3-n-pentyl- and 2-methyl-3-n-octyl-thiolans,[25] 2-methyl-4-phenylthiolan,[26] and 2-methyl-5-n-pentylthiolan[27] were obtained in accordance with the same scheme for the first time:

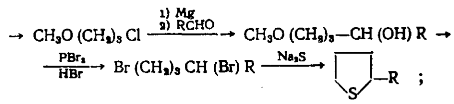


The overall yield of sulphides was 47% and the content of disubstituted thiolans (in the mixture) was 82%.

2-t-Butyl-2,3-dimethylthiolan was first synthesised[28] by treating crotyl bromide with t-butyl methyl thione (an unsaturated thiol is then also apparently formed initially):

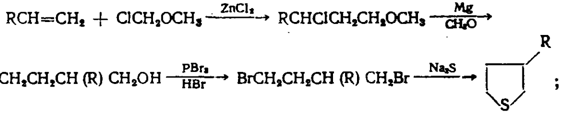


Dibromoalkanes, which are precursors of 2- or 3-substituted thiolans, have been synthesised from chloroalkyl methyl ethers.[29,30] In order to obtain α-substituted 1,4-dibromobutanes, the synthesis was begun with propane-1,3-diol; the substituent was introduced by treating with the corresponding aldehyde the Grignard reagent derived from chloropropyl methyl ether:



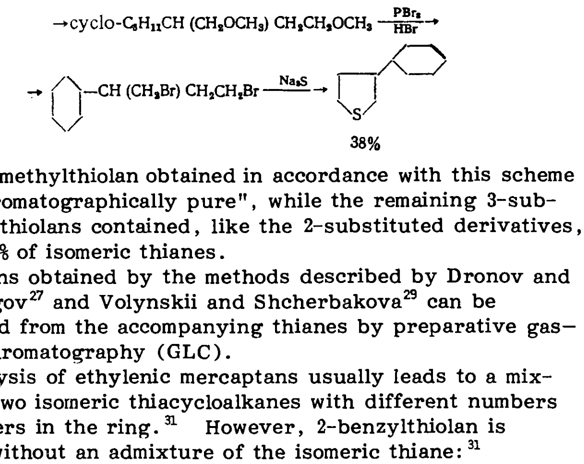
$R = n\text{-}C_3H_7, n\text{-}C_4H_9, n\text{-}C_6H_{13}, C_6H_5.$

The yields of 2-substituted thiolans were 50-80% relative to the dibromides and 27–53% relative to 3-chloropropyl methyl ether. The alkylthiolans obtained in accordance with this scheme contained 17–30% of alkylthianes (with a correspondingly shorter substituent), formed as a result of the cyclisation of the isomeric dibromoalkanes (the bromination method used by the authors leads to a mixture of dibromides which is difficult to resolve). β-Substituted 1,4-dibromobutanes were synthesised from α-olefins:



$R{=}CH_3, C_4H_9, C_5H_{11}, C_6H_{13}$.

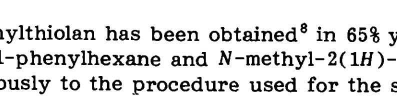
3-n-Butyl- and 3-n-hexyl-thiolans were obtained for the first time. The yields of 3-substituted thiolans (relative to the dibromides) were 64–81%. Volynskii and Shcherbakova[29,30] synthesised for the first time also 3-cyclohexylthiolan using the more readily available styrene rather than vinylcyclohexane:



The 3-methylthiolan obtained in accordance with this scheme was "chromatographically pure", while the remaining 3-substituted thiolans contained, like the 2-substituted derivatives, about 20% of isomeric thianes.

Thiolans obtained by the methods described by Dronov and Krivonogov[27] and Volynskii and Shcherbakova[29] can be separated from the accompanying thianes by preparative gas-liquid chromatography (GLC).

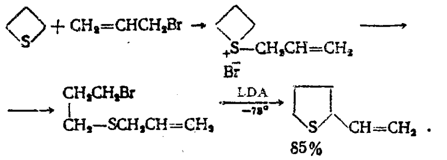
Photolysis of ethylenic mercaptans usually leads to a mixture of two isomeric thiacycloalkanes with different numbers of members in the ring.[31] However, 2-benzylthiolan is formed without an admixture of the isomeric thiane:[31]



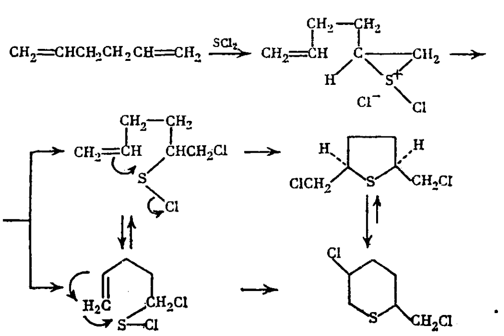
2-Phenylethylthiolan has been obtained[8] in 65% yield from 3,6-dibromo-1-phenylhexane and *N*-methyl-2(1*H*)-pyridinethione analogously to the procedure used for the synthesis of 2-phenylethylthietan described above.

New functional derivatives of thiolan have been obtained both from the corresponding acyclic precursors and by introducing functional groups into thiolans.

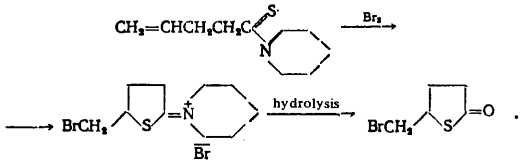
2-Vinylthiolan has been obtained from thietan and allyl bromide.[32] The allylthietanium bromide formed on interaction of these reactants is unstable and rearranges to allyl 3-bromopropyl sulphide, which is converted into 2-vinylthiolan on treatment with lithium diisopropylamide (LDA):



It has been shown recently[33] that, contrary to Lautenschlager's data,[34] the reactions of sulphhr dichloride with hexadiene are not regiospecific. This results in the formation of *cis*-2,5-dichloromethylthiolan and 5-chloro-2-chloromethylthiane (60:40). At 20 °C isomerisation takes place gradually and at thermodynamic equilibrium the ratio is 35:65 and the overall yield of adducts is 80%. However, they could be separated only after the preliminary oxidation to sulphones (the latter were separated by fractional crystallisation):

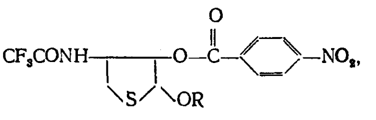


5-Substituted 2-thiolanones are obtained[35] by brominating or iodinating the thioamides of allylacetic acid, which entails heterocyclisation and the formation of halogenomethylpentamethyleneimmoniathiolan halides in yields up to 81%, for example:



The initial thioamides are obtained by refluxing the amides $CH_2 = CHCH_2CH_2CONR_2$ [NR_2 = piperidinyl, morpholinyl, $NHCH_2C_6H_5$, $N(CH_3)_2$, or $NHCH_3$] with P_2S_5 in benzene; it has been established that the "iodocyclisation" reaction is of first order with respect to iodine and thioamides.

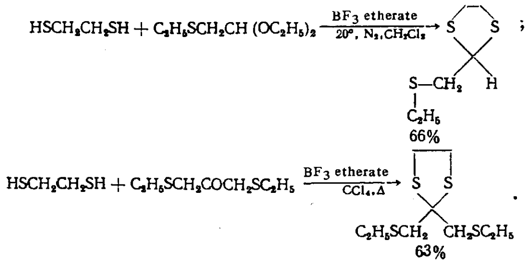
The starting materials for the synthesis of adriamycin analogues, namely the trisubstituted thiolans



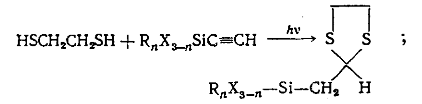
where R = $COCH_3$, $CH(CH_3)_2$, or cyclohexyl, have been obtained[36] from 3,4-dihydroxythiolan by means of successive reduction, trifluoroacylation, esterification, and alkoxylation.

Certain formation reactions of dithiolans and trithiocarbonates, derived from 1,3-dithiolan-2-thiones, have been described in a monograph.[1]

Numerous 2-substituted 1,3-dithiolans have been synthesised in recent years. The heterocycle is usually constructed from ethane-1,2-dithiol. The condensation of this dithiol with the diethylacetal of 2-(ethylthio)acetaldehyde or with 3,7-dithia-5-nonanone yielded 2-(ethylthiomethyl)- and 2,2-di(ethylthiomethyl)-1,3-dithiolan:[37]

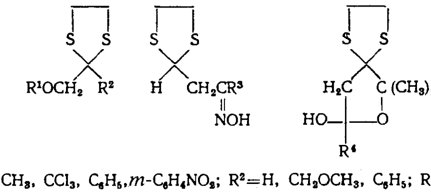


2-Silyl-1,3-dithiolans are formed on photochemical interaction of ethane-1,2-dithiol with ethynylsilanes:[38]



n=1—3, R=Alk, X=Cl, AlkO, AcO .

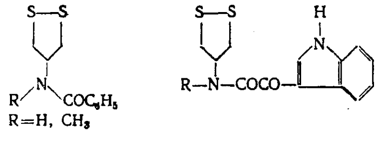
2-Substituted 1,3-dithiolans have been synthesised in order to obtain compounds with fungicidal properties:[39]



R^1=CH_3, CCl_3, C_6H_5, *m*-$C_6H_4NO_2$; R^2=H, CH_2OCH_3, C_6H_5; R^3=C_6H_5, 2-thienyl; R^4 = 2-furyl, 2-thienyl.

Among these compounds, spiro-1,3-dithiolans, especially the compound with R^4 = 2-thienyl, proved to be extremely active against phytophthora on tomatoes.

4-*N*-Acyl-1,2-dithiolans have also been synthesised by the direct acylation of 4-amino-1,2-dithiolans in order to obtain biologically active preparations:[40]



4. Thianes

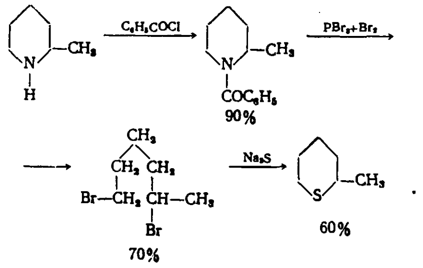
During the last 15 years many new mono- and poly-alkyl and mono- and poly-aryl-thianes have been synthesised.

The first member of the series (thiane) has been obtained by two new procedures: in 80% yield from 1-chloro-5-iodopentane and thiourea, analogously to the procedure described above[22] for thiolan, and in 76% yield from ethylene sulphide and allyl-magnesium bromide[41] (in accordance with the procedure proposed a year earlier[24]). Kondo and Negishi[41] directed the cyclisation of the initially formed thiol towards the formation of thianes by the following procedure: magnesium thiolate was decomposed with a solution of ammonium chloride and the resulting unpurified thiol was immediately refluxed in the presence of a radical reaction initiator—azobisisobutyronitrile.

3-Methyl-, 4-methyl- and (for the first time) 4-phenylthianes have been obtained in 70—74% yields by an analogous procedure involving the reaction of ethylene sulphide with methylallyl-, crotyl-, or cinnamyl-magnesium bromide.[41] 2-Methyl- and 2,2-dimethyl-thianes have been obtained in 60% yields from allylmagnesium bromide and propylene or isobutylene sulphide.[41] The absence of an admixture of the isomeric thiolans indicated the selective cleavage of the less sterically hindered C–S bond in the ethylene sulphides.[41]

The mixture containing 75% of 2-n-pentylthiane has been synthesised in 68.7% yield from allylmagnesium bromide and heptene sulphide;[27] the thiane was isolated by GLC (the intermediate decene-5-thiol was cyclised by exposure to UV radiation). 4-n-Pentylthiane (yield 47%) and 4-n-octylthiane (yield 44%) have been obtained analogously from ethylene sulphide and the corresponding alkenylmagnesium bromide, while 3-phenylthiane has been obtained from styrylethylene sulphide and allylmagnesium bromide in ~25% yield.[26]

2-Methyl, 4-methyl-, and 4-t-butyl-thianes have been synthesised from the corresponding alkylpiperidines in accordance with the scheme[42]

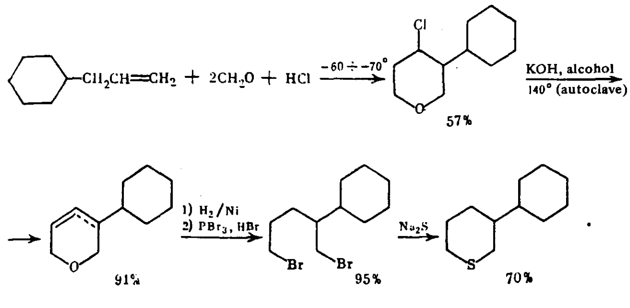


The synthesis includes only three stages (provided of course that alkylpiperidines are available).

2-Methylthiane and (for the first time) 2-phenylthiane have been obtained[23] from thiane in a manner analogous to the above synthesis of 2-phenylthiolan[23] (the yields were respectively 51 and 56%).

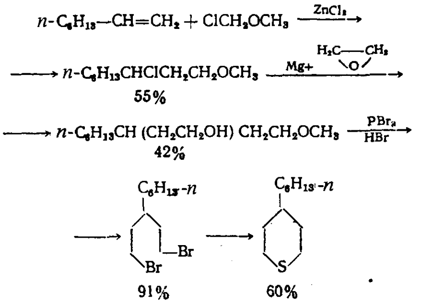
2-Phenylthiane has been synthesised[8] from 3,7-dibromo-1-phenylheptane and N-methyl-2(1H)-pyridinethione in 40% yield.

1,5-Dibromopentanes, which are precursors of 3- and 4-substituted thianes, have been obtained from α-olefins.[43,44] In order to obtain β-substituted 1,5-dibromopentanes, 3-alkyltetrahydropyrans were initially synthesised by condensing α-olefins with paraformaldehyde:[43]



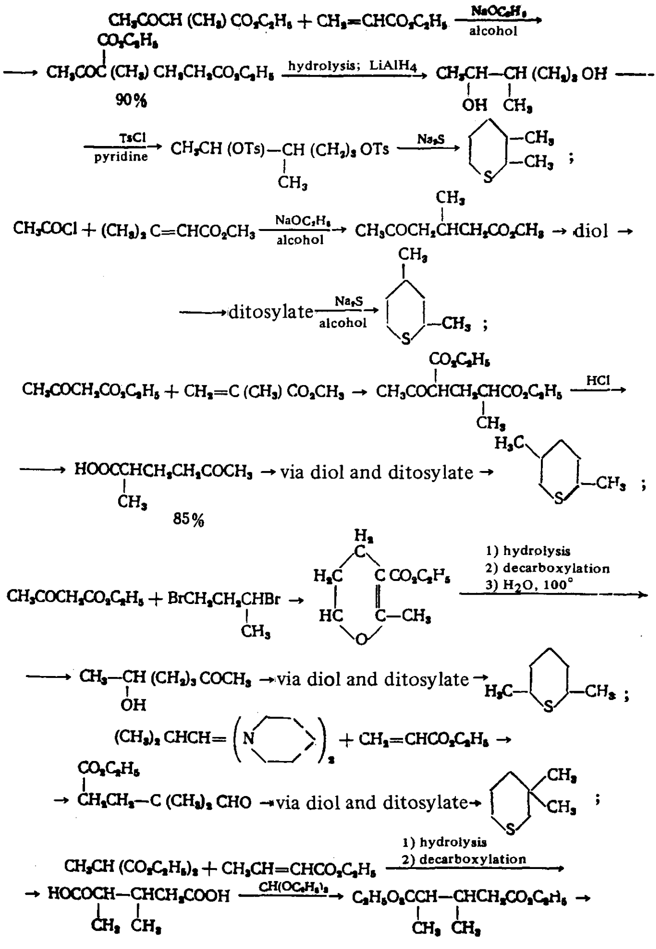
The authors modified the method of the opening of the tetrahydropyran ring having substituted sulphuric acid by phosphorus tribromide. The increase in the cost of the synthesis is compensated by the fact that the yield and purity of the dibromides are then significantly improved. This procedure has been used successfully by the authors in subsequent studies for the cleavage of ethers. 3-n-Butyl-, 3-n-hexyl- and (for the first time) 3-cyclohexyl-thianes were synthesised in accordance with the above scheme[43] in 85, 88, and 70% yields respectively.

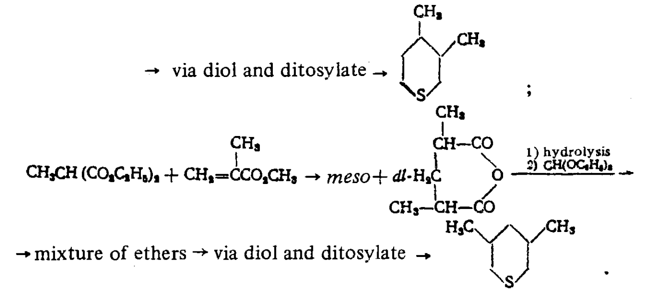
In the synthesis of γ-substituted 1,5-dibromopentanes, carbon chain extension was achieved by two procedures:[44]



Using this method, the authors[44] obtained 4-methyl-, 4n-butyl-, 4n-pentyl-, and 4-phenyl-thianes and also (for the first time) 4n-hexyl- and 4-cyclohexyl-thianes, the yields being respectively 86, 68, 80, 40, 60, and 70%.

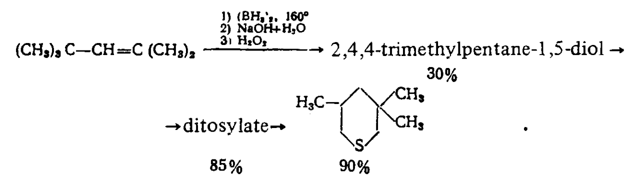
In order to investigate the conformations by ^{13}C NMR, extensive syntheses of dimethylthianes were carried out[42] in 1977; 13 thianes were synthesised for the first time, namely the *cis*- and *trans*-isomers of 2,3-, 2,4-, 2,5-, 2,6-, 3,4-, and 3,5-dimethylthianes and 3,3-dimethylthiane. All these compounds are obtained by reducing the corresponding precursors with lithium tetrahydroaluminate to 1,5-diols (90% yields), which were then converted into 1,5-di(toluene-p-sulphonate) (yields up to 80%) and their condensation with Na_2S afforded mixtures of the *cis*- and *trans*-substituted dimethylthianes (yields 65–85%). The stereoisomers were separated by preparative GLC. All the precursors of 1,5-diols were obtained from fully available compounds in accordance with the schemes



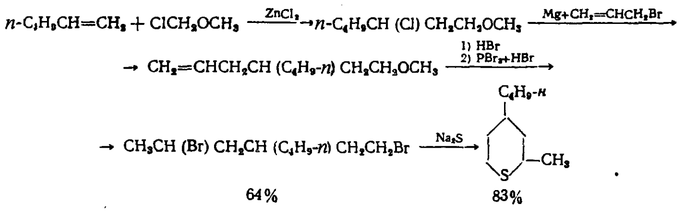


cis-3,5-Dimethylthiane can also be obtained without using preparative GLC: *meso*- and *dl*-dimethylglutaric anhydride are separated by crystallisation, the *meso*-form (yield 25%) is reduced with lithium tetrahydroaluminate to *meso*-2,4-dimethylpentane-1,5-diol and the latter is converted with PBr_3 into the dibromo-derivative (yield 80%), which is treated with Na_2S; the yield of 3,5-dimethylthiane is 75%.

The same workers[42] obtained for the first time 3,3,5-trimethylthiane in accordance with the scheme



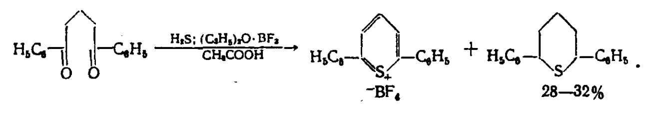
The authors[45] used the scheme proposed previously[44] for the synthesis of 4-substituted thianes in order to obtain 2,4-disubstituted thianes. The growth of the carbon chain, achieved with the aid of allyl bromide, made it possible to introduce a methyl group in the 2-position:



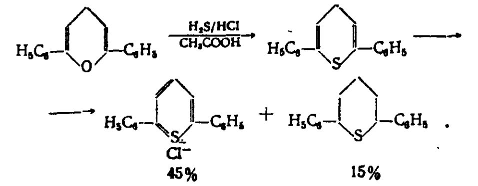
Using this scheme, the authors[45] synthesised for the first time 4-n-butyl-2-methyl-, 2-methyl-4-n-pentyl-, and 2-methyl-4-phenyl-thianes in the form of mixtures of *cis*- and *trans*-isomers (yields 83–87%): the stereoisomers of 2,4-dialkylthianes were separated by GLC. On the other hand, a mixture of the *cis*- and *trans*-2-methyl-4-phenylthianes was oxidised and the resulting mixture of stereoisomeric 1-oxides was separated by fractional crystallisation, after which the 1-oxides were reduced with lithium tetrahydroaluminate to *cis*- and *trans*-2-methyl-4-phenylthianes.[46] Having replaced hydrobromic acid by DBr, the same authors[46] obtained 2-monodeuterio-4-n-butylthiane in 74% yield by means of the same scheme.

2,2-Diphenylthiane was obtained for the first time by hydrogenating *gem*-diphenylthiacyclohexene over 10% Pd/C in a mixture of equal amounts of alcohol and ethyl acetate.[47] Hydrogenation of polyaryl(alkyl)-4*H*-thiopyrans over the same catalyst (in alcohol at 100 °C and a 5% atm hydrogen pressure) led to the corresponding polyaryl(alkyl)thiane—2,6-diphenyl-, 4-methyl-2,6-diphenyl, 2,4,6-triphenyl-, 3,5-dimethyl-2,6-diphenyl-, and 3-methyl-2,4,6-triphenylthianes—in 72–80% yields.[48]

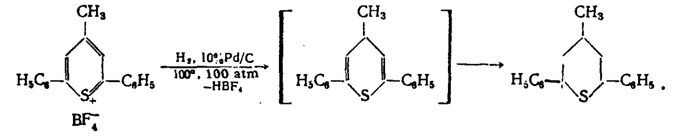
Several further preparative methods of synthesis of 2,6-disubstituted thianes have been proposed,[49,52] for example, from the corresponding 1,5-disubstituted pentane-1,5-diones:[49,50]



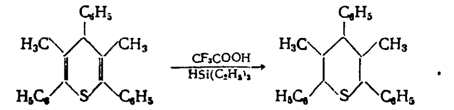
As shown by Kharchenko and Chalaya,[51] 2,6-diphenylthiane is formed as a result of the disproportionation of 2,6-diphenyl-4*H*-thiopyran:



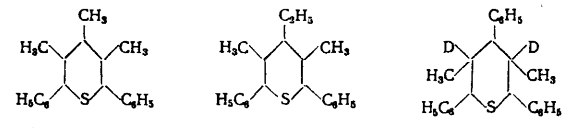
2,6-Diphenylthianes and thiapyrylium salts can be readily separated using their different solubilities in non-polar solvents. Diphenylthianes are also formed smoothly on hydrogenation of thiapyrylium salts[52] (yield 65–79%) with the initial formation of 4*H*-thiopyrans, for example:



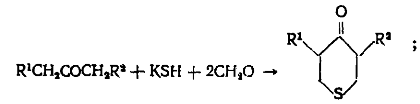
The ionic hydrogenation reaction can be used to obtain thianes from 4*H*-thiopyrans. The corresponding thianes have been obtained from polysubstituted 2,6-diphenyl-4*H*-thiopyrans by treatment with trifluoroacetic acid and an active hydride ion donor—triethylsilane:[53]



The use of CF_3COOD in ionic hydrogenation established that the double bond in 4*H*-thiopyrans is protonated in the C(3)- and C(5)-positions;[53] polysubstituted thianes were obtained for the first time in the above study:[53]



Few functional derivatives of thianes have been synthesised in recent years. A single-stage method of synthesis of disubstituted tetrahydro-1-thiopyran-4-ones has been proposed recently.[54] They were obtained by the thioalkylation reaction—the condensation of ketones containing at the carbonyl group two methylene groups having equal reactivities, with potassium hydrogen sulphide and formaldehyde in alcohol (with brief heating at 50 °C); the yields are 23–72.5%:

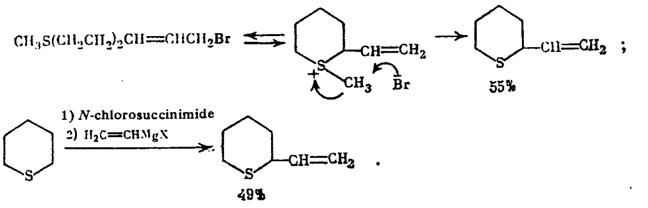


$R^1=R^2=C_2H_5,\ C_3H_7,\ n\text{-}C_4H_9,\ C_7H_{15};\ R^1=C_6H_5,\ R^2=CH_3.$

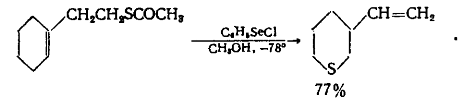
Ketosulphides are mixtures of stereoisomers with the *cis*-isomer predominating slightly; it is recommended that they be used as extractants for palladium ions.

When 6-dimethylamino-5-methylhex-2-en-4-one methiodide is treated with a solution of sodium sulphide at room temperature, 2,5-dimethyl-4-thianone is formed (yield 67%). 2,3-Dimethyl-4-thianone has been obtained analogously (yield 76%).[55]

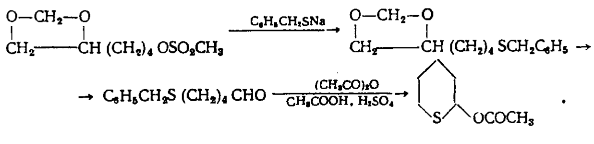
α-Vinylthiane has been obtained[56] by cyclising 7-bromohept-5-enyl methyl sulphide and also from thiane:



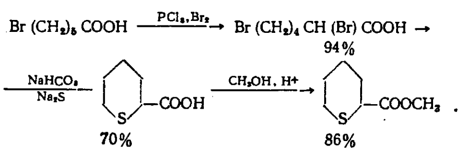
β-Vinylthiane is formed as a result of the cyclisation of acetylthioethylcyclohex-1-ene by treatment with benzeneselenyl chloride at a low temperature:[57]



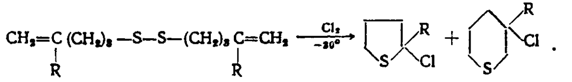
When butyl-lithium and then tetrahydrothiopyran-4-one are added to cyclopentadiene, fulvene—4-cyclopentadienylidenethiane—is formed as an unstable yellow liquid (yield 75%).[58] 2-Acetoxythiane has been synthesised by a fairly complex procedure:[59] the benzyl derivative was obtained from the methanesulphonate of the formal of hexane-1,2,6-triol and sodium benzylmercaptide and, after hydrolysis and oxidative cleavage, was converted into benzyl 4-formylbutyl sulphide; the latter was subjected to acetolysis in a mixture of acetic anhydride and acetic acid containing sulphuric acid:



There exists yet another method of synthesis of 2-acetoxythiane,[60] but the number of stages is likewise fairly large:

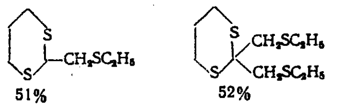


The chlorination of dipent-4-enyl disulphides yields a mixture of α-chlorothiolans and β-chlorothianes; when equilibrium is attained, the thianes predominate.[61] The reaction apparently proceeds via a stage involving the formation of unsaturated sulphenyl chloride:

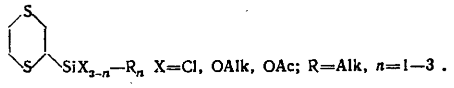


For R = H, the thiolan : thiane ratio is 80 : 20 (under the conditions of kinetic control) or 18 : 82 (under equilibrium conditions); for R = CH_3, the corresponding ratios are 95 : 5 and 4 : 96.

2-(Ethylthiomethyl)- and 2,2-di(ethylthiomethyl)-1,3-dithianes have been synthesised by the reaction of propane-1,3-dithiol with the diethylacetal of 2-ethylthioacetaldehyde or with 3,7-dithia-5-nonanone, analogously to the method described above for 1,3-dithiolans:[37]



The photochemical interaction of ethynylsilanes with ethane-1,2-dithiol results in the formation of 2-silyl-1,4-dithianes together with 1,3-dithiolans (see above):[38]



At −196 °C carbon monosulphide combines with hydrogen chloride to form the chloride of thioformic acid, which is rapidly converted into 2,4,6-trichloro-1,3,5-trithiane in ~50% yield on raising the temperature; 2,4,6-tribromo-1,3,5-trithiane has been obtained analogously by reaction with hydrogen bromide in ~75% yield.[62]

Some data on the relations between the structure and properties of the substituted thiolans and thianes. The dependence of the boiling points and retention volumes of alkylthiolans and alkylthianes (including the individual stereoisomers) on the number of substituents and their positions in the ring has been investigated.[63,64] Calculations showed that 2,4-dialkylthianes do not obey the Auwers–Skita rule—the *trans*-isomers have lower boiling points than the *cis*-isomers. Subsequently the applicability of the "reverse" Auwers–Skita rule to 2,4-disubstituted thianes (and to their 1,1-dioxides) was demonstrated experimentally in a number of investigations.[42,45,46]

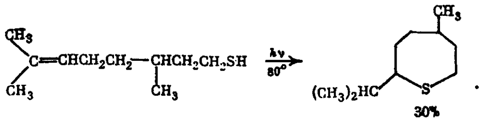
The characteristics of the chemical shift in the ^{13}C NMR spectra of methylthiolans have been examined;[65] the ^{13}C NMR spectra of thiane, twelve of its mono-di, and tri-methyl derivatives, 4-t-butylthiane, and two tetradeuteriothianes have been discussed by Willer and Eliel[42] and those of 1,3-dithianes by Eliel et al.[66] The ratios of the conformers in dimethylthianes and the conformational free energies of the methyl group in the 2-, 3-, and 4-positions in the thiane ring have been determined from the data obtained.

Krapivin and Perepelitchenko[67] investigated the ^{13}C NMR spectra of thianes with long alkyl (C_4–C_5) and aryl substituents and concluded that the steric disposition of substituents in 2,4-disubstituted thianes can be established from the chemical shifts of the ^{13}C nuclei in the 6-position in the thiane ring.

5. Sulphides Containing More Than Six Members in the Ring

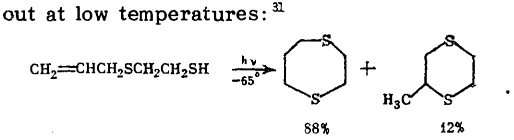
Thiepans have been synthesised by methods analogous to those examined above for thiolans and thianes. Thiepan has been obtained in 34% yield from 1-chloro-6-iodohexane and thiourea.[22] By treating thiepan with *N*-chlorosuccinimide in benzene, Tullen and Bennet[23] obtained α-chlorothiepan and treatment of the latter with methyl- or phenyl-magnesium bromide afforded 2-methylthiepan (yield 66%) and (for the first time) 2-phenylthiepan (yield 56%).

The photochemical cyclisation of 2,6-dimethyloct-2-ene-8-thiol results in the formation of 2-isopropyl-4-methylthiepan without an admixture of the stereoisomeric thiane:[31]



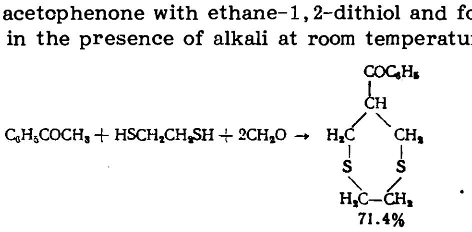
2-Phenylethylthiepan has been synthesised[8] from 3,8-dibromo-1-phenyloctane and N-methyl-2(1H)-pyridinethione in 56% yield.

A mixture of isomeric dithiacycloalkanes (overall yield 45%), with the 1,4-dithiepan predominating, is formed when the photochemical cyclisation of allyl 2-mercaptoethyl sulphide is carried out at low temperatures:[31]



2-(Ethylthiomethyl)- and 2,2-di(ethylthiomethyl)-1,3-dithiepans have been obtained from butane-1,4-dithiol by reaction of the latter with the diethylacetal of 2-ethylthioacetaldehyde or 3,7-dithia-5-nonanone respectively.[37]

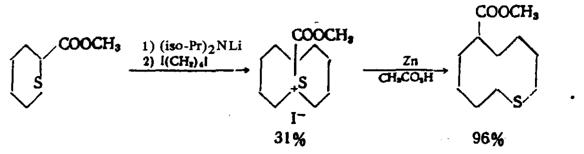
6-Benzoyl-1,4-dithiepan has been synthesised by thioalkylating acetophenone with ethane-1,2-dithiol and formaldehyde in the presence of alkali at room temperature:[68]



Numerous macrocyclic sulphur compounds, namely saturated macrocyclic sulphides, have been synthesised in recent years using noble metals as complex-forming agents and extractants. The methods of synthesis of a wide variety of macrocyclic sulphides, including saturated compounds, published up to 1974, have been examined in the review of Bradshaw and Hui.[69] The results of latter studies (1974–1983) have been very successfully surveyed in two other reviews.[70,71]

A modification of one of the methods of synthesis of macrocyclic sulphides, consisting in the interaction of ω-dihalides with ω-dimercaptans in an alkaline medium at high dilution,[69] merits consideration; instead of the usually employed alkali metal mercaptides, Setzer et al.[72] used a benzyltrimethylammonium salt, which led to a significant increase of the yield of the required products. Under the conditions of high dilution (in absolute methanol), benzyltrimethylammonium, di(2-mercaptoethyl) sulphide, and, simultaneously, 1,2-dibromoethane were made to react whilst heated. 1,4,7-Trithiacyclononane was obtained in 4.4% yield instead of the 0.04% yield obtained previously. Other analogous syntheses have been carried out (the yields expressed as percentages are indicated in brackets): 1,4-dithiepan (65) from ethane-1,2-dithiol and 1,3-dibromopropane; 1,5-dithiacyclooctane (46) from propane-1,3-dithiol and 1,3-dibromopropane; 1,4-dithiacyclooctane (14) from butane-1,4-dithiol and 1,2-dibromoethane; 1,5-dithiacyclononane (9) from the same dithiol and 1,3-dibromopropane; 1,6-dithiacyclodecane (1.5) from the same dithiol and 1,4-dibromobutane. 2-Phenylethylcyclononane has been obtained in 50% yield from 3,10-dibromo-1-phenyldecane and N-methyl-2(1H)-pyridine thione.[8]

6-Methoxycarbonylthiacyclodecane can be obtained fairly easily from 2-methoxycarbonylthiane via a bicyclic sulphonium salt:[60]



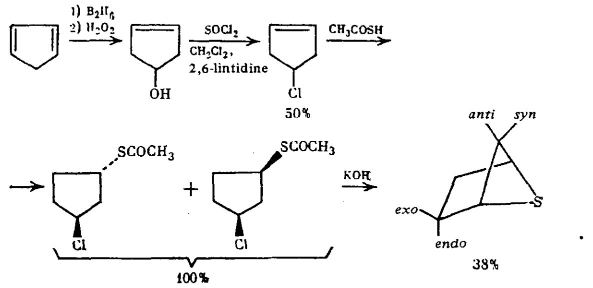
In discussions of the properties of macrocyclic sulphides, it has been noted[69,73] **that the melting points of thiacrown ethers increase with increase of the number of sulphur atoms** in each analogous series: the larger (compared with oxygen) sulphur atom renders the rings less mobile and the number of conformations in the liquid state and hence the entropy of fusion therefore decrease. Furthermore, the more symmetrical compounds have higher melting points. For the same number of sulphur atoms in the ring, the melting point regularly diminishes as the number of CH_2 groups separating the sulphur atoms rises and very large rings (containing more than 12 members) resemble two parallel chains linked at each end by methylene bridges or a sulphur atom.

III. POLYCYCLIC SULPHIDES

1. Thiabicycloalkanes

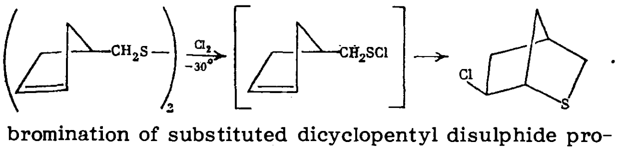
After the methods of synthesis of polycyclic sulphides had been surveyed in a monograph,[19] more than forty new thiabicycloalkanes have been obtained. These are mainly methyl- or phenyl-thiabicyclooctanes and also thiabicyclononanes—both unsubstituted and with methyl or aromatic substituents and thiabicyclodecanes with the same substituents. Most of the methods of synthesis of these compounds have been developed by Soviet workers.

Tabushi et al.[74] obtained the first representative of thiabicyclohexanes—5-thiabicyclo[2.1.1]hexane—from cyclopentadiene in accordance with the scheme

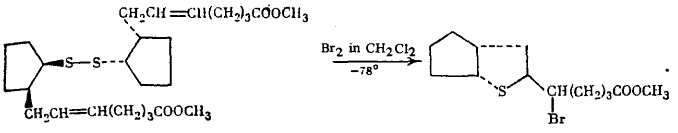


The addition of thioloacetic acid to chlorocyclopentene proceeds quantitatively and leads to a mixture of stereoisomeric 3-acetylthio-1-chlorocyclopentanes. The mixture is added to a boiling aqueous alcoholic solution of potassium hydroxide, whereupon the required product is formed from the *trans*-isomer (it is purified by preparative GLC).

6-*exo*-Chloro-2-thiabicyclo[2.2.1]heptane, its methyl analogue, and 7-*exo*-chloro-2-thiabicyclo[3.2.1]octane are obtained in quantitative yields by the intermolecular cyclisation of sulphenyl chlorides—the intermediates formed on chlorination of unsaturated disulphides at a low temperature:[75]

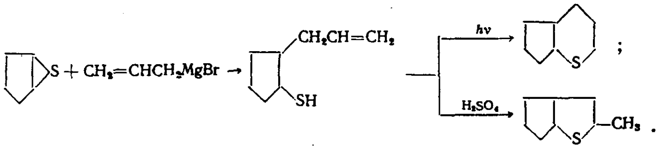


The bromination of substituted dicyclopentyl disulphide proceeds similarly—3-(1-bromo-4-methoxycarbonylbutyl)-2-thiabicyclo[3.3.0]octane has been obtained:[76]

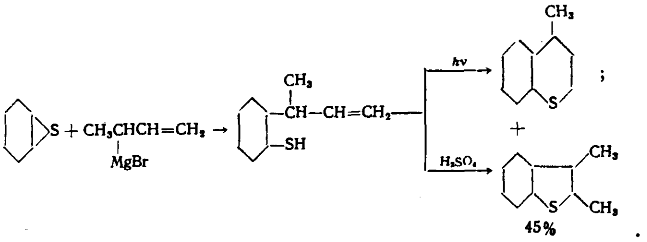


Thiabicyclooctanes, thiabicyclononanes, and thiabicyclodecanes have been synthesised successfully by condensing cycloalkene sulphides with allylmagnesium bromide and its derivatives. The reaction proceeds analogously to that examined above for thiolans and thianes.[24]

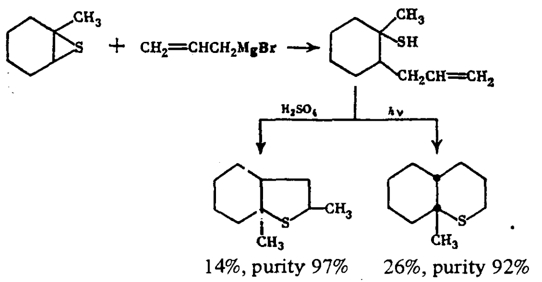
2-Allylcyclopentanethiol has been obtained from cyclopentene sulphide and allyl-magnesium bromide.[77] Its cyclisation on UV irradiation affords 2-thiabicyclo-[4.3.0]-nonane with an admixture of 3-methyl-2-thiabicyclo[3.3.0]-octane (ratio 97: 3, overall yield 42%). In cyclisation on treatment with sulphuric acid, the ratio of these structural isomers is reversed, but the overall yield of thiabicycloalkanes is low (13%). The authors explained this by the difficulty of the formation of two *trans*-joined five-membered rings:[78]



It has been shown[79] that 2-(α-methyl-β-propenyl)cyclohexanethiol is formed from cyclohexene sulphide and crotylmagnesium bromide, which reacts in the form of 3-magnesiobromobut-1-ene; its cyclisation on irradiation gives rise to a mixture of 8,9-dimethyl-7-thiabicyclo[4.3.0]nonane (2,3-dimethyl-1-thiahydrindan) and 5-methyl-2-thiabicyclo[4.4.0]-decane (4-methyl-1-thiadecalin) in an overall yield of 50%; cyclisation on treatment with sulphuric acid results in the selective formation of a thiahydrindan derivative. In both procedures the cyclisation is non-stereospecific. The pure structural isomers are obtained with the aid of GLC.



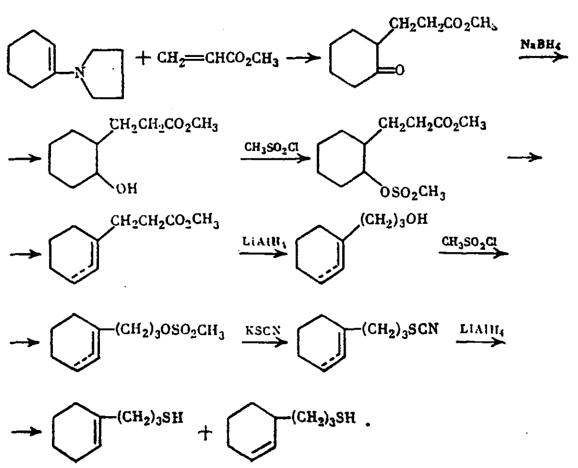
When 1-methylcyclohexene sulphide reacts with alkylmagnesium bromide, the C–S bond at the carbon atom attached to the larger number of hydrogen atoms is broken; the cyclisation of the thiol leads to thiabicycloalkanes with the methyl substituent at the ring junction in the *trans*-position relative to the angular hydrogen atom—6,8-dimethyl-7-thiabicyclo[4.3.0]nonane (2,8-dimethyl-1-thiahydrindan) and 1-methyl-2-thiabicyclo[4.4.0]decane (9-methyl-1-thiadecalin).[80] Although the yields are low for both cyclisation procedures, the processes are fairly selective. The subsequent purification via mercury complexes makes it possible to obtain "chromatographically pure" thiabicycloalkanes:



Fairly pure 8-methyl-7-thiabicyclo[4.2.0]nonane (2-methyl-1-thiahydrindan)[81] and 2-thiabicyclo[4.4.0]decane (1-thiadecalin)[41,81] have also been obtained in 52 and 67% yields from cyclohexene sulphide and allylmagnesium bromide; they were previously synthesised by another method.[19,82]

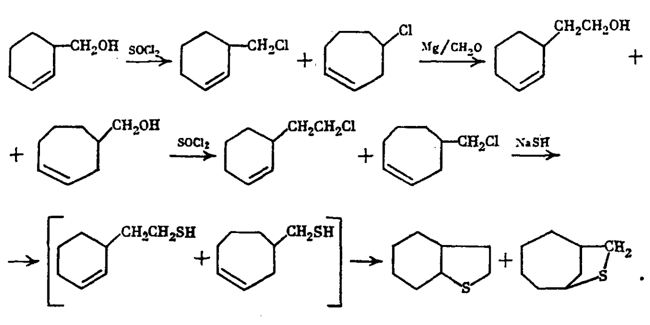
Claus and Vierhapper[83] used azobisisobutyronitrile for the radical cyclisation of *trans*-allyl cyclohexanethiols (cf. Kondo and Negishi[41]). 2-Thiabicyclo[4.4.0]decanes are then formed preferentially. With the aid of this initiator, 4-, 7-, and 10-methyl-*trans*-2-thiabicyclo[4.4.0]decanes were obtained for the first time. The same authors synthesised 4-, 6-, 8-, and 10-methyl-*cis*-2-thiabicyclo[4.4.0]decanes[83] using the fact that the radical cyclisation of 3-mercaptopropylcyclohexenes under the influence of the same initiator proceeds preferentially with formation of *cis*-joined thiabicyclodecanes.

The syntheses of such mercaptans are extremely laborious—for example a mixture of 1- and 3-(3-mercaptopropyl)cyclohexenes, cyclisation leads to *cis*-2-thiabicyclo[4.4.0]decanes, is obtained from pyrrolidinocyclohexene in 8 stages:



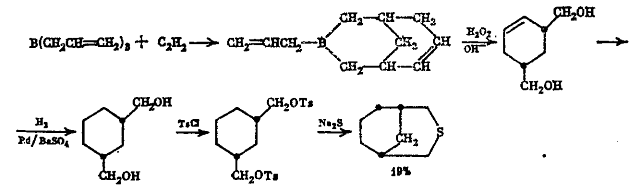
The content of *cis*-2-thiabicyclo[4.4.0]decane in the mixture after the cyclisation of there mercaptans is 68%. It is isolated by separating the complexes with mercury(II) chloride or by preparative GLC; methyl-*cis*-2-thiabicyclo[4.4.0]-decane has been obtained[83] using analogous schemes. The configurations and conformations of the compounds synthesised were identified[84] by means of ^{1}H and ^{13}C NMR spectroscopy.

Four unsubstituted bridged thiabicyclononanes have been synthesised. *cis*-7-Thiabicyclo[4.2.1]nonane mixed with *cis*-7-thiabicyclo[4.3.0]nonane (*cis*-1-thiahydrindan) was obtained[85] from 3-hydroxymethylcyclohexene according to the scheme

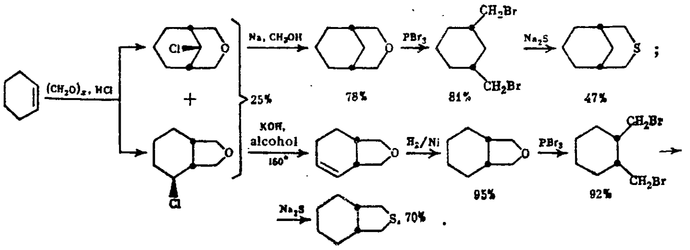


The formation of a mixture of such sulphides is a result of ring expansion on chlorination of hydroxymethylcyclohexene and also the cyclisation of thiols only at the nearest (relative to the substituent) end of the double bond. The overall yield of the mixture of sulphides in the last stage of the scheme is 90% and they are formed in approximately equal amounts; the mixture is separated by preparative GLC.

7-Thiabicyclo[3.3.1]nonane has been synthesised; its precursor—1,3-di(hydroxymethyl)cyclohexane—was obtained from acetylene and triallylborane:[86]



The same sulphide has been recently synthesised[87] by a simpler procedure:

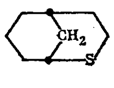


The second, isomeric chloromethylation product "was not wasted"—the authors used it to synthesise 8-thiabicyclo-[4.3.0]nonane, which had been previously obtained by Birch et al.[88] by a procedure involving a greater number of stages.

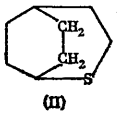
A two-stage method has been proposed for the synthesis of bridged thiabicyclooctanes and thiabicyclononanes from vinylcyclohexenes.[89,90] When vinylcyclohexenes interact with sulphur dichloride, intramolecular cyclisation adducts, namely isomeric dichlorothiabicycloalkanes, are formed (together with oligomeric products). The adducts are subjected to reductive dechlorination whereupon mixtures of thiabicycloalkanes are formed and are then resolved by preparative GLC.

In the course of the exchange of chlorine atoms for hydrogen, skeletal isomerisation takes place, the extent of which depends on the presence of methyl groups in the vinylcyclohexenes, their positions, the nature of the reducing agent, and the reduction conditions.

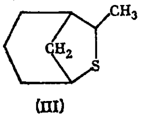
Unsubstituted thiabicycloalkanes have been obtained[89] from 4-vinylcyclohexene and sulphur dichloride on reduction by diisobutylaluminium (the yield of their mixture was 23%): 2-thiabicyclo[3.3.1]nonane (I) and 2-thiabicyclo[3.2.2]-nonane (II), and also methyl-substituted derivatives: *exo*- and *endo*-7-methyl-6-thiabicyclo[3.2.1]octanes (III) and 3-methyl-2-thiabicyclo[2.2.2]octane (IV):



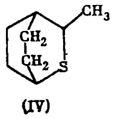
(I)



(II)

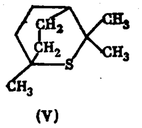


(III)

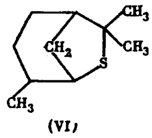


(IV)

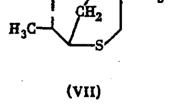
A mixture of thiabicycloalkanes (its yield was 86% after reductive dechlorination) has been synthesised analogously from 4-isopropenyl-1-methylcyclohexene.[90] 1,3,3-Dimethyl-2-thiabicyclo[2.2.0]octane (V), 4,7,7-trimethyl-6-thiacyclo-[3.2.1]—octane (VI), 4,8-dimethyl-2-thiabicyclo[3.3.1]-nonane (VII), and its epimer were isolated; the reduction of the adduct with sodium tetrahydroborate results in the formation also of considerable amounts of 1,4-dimethyl-2-thiabicyclo[3.2.2]nonane (VIII):



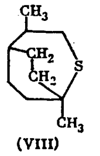
(V)



(VI)

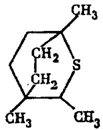


(VII)

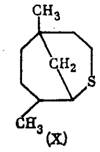


(VIII)

After the reduction of the adducts of sulphur dichloride and 1,4-dimethyl-4-vinyl-1-cyclohexene with diisobutylaluminium, a mixture of 1,3,4-trimethyl-2-thiabicyclo[2.2.2]-octane (IX) and 5,8-dimethyl-2-thiabicyclo[3.3.1]nonane (X) was obtained in proportions of 3 : 1 in 19% yield:

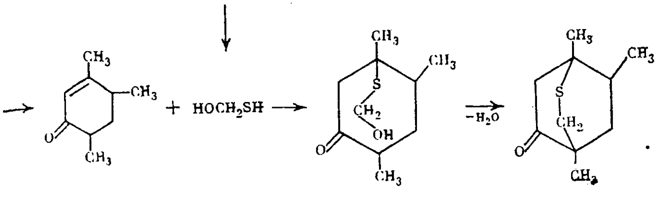


(IX)



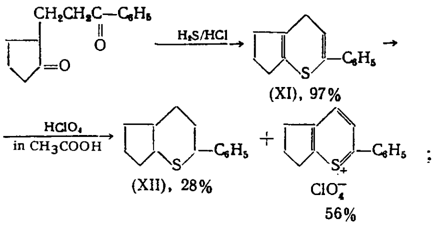
(X)

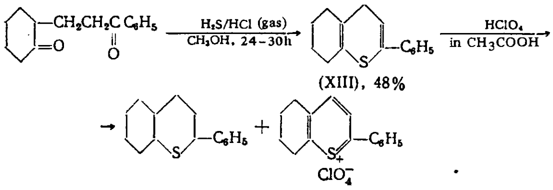
The thioalkylation of ethyl methyl ketone[91] makes it possible to obtain extremely simply (in one stage) 1,4,5-trimethyl-7-thiabicyclo[2.2.2]octan-2-one in 20% yield (the remainder consists of polymeric products):



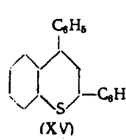
During the 1970's, the interaction of "semicyclic" 1,5-diketones with hydrogen sulphide in the presence of protic acids was investigated. The initial 1,5-diketones are obtained by the Michael reaction from cyclopentanone and arylideneacetophenones.[92] The reaction of diketones with hydrogen sulphide proceeds at room temperature. Aryl-substituted polymethylene-4*H*-thiapyrans are formed and in the presence of strong acids disproportionate to a mixture of polymethylenethiopyrylium salts and arylthiabicycloalkanes.[93] The latter are formed in low yields (of the order of 30%). However, the ease of their isolation from the mixture (readily separated from thiopyrylium salts by extraction with ethylhexane) makes up for this disadvantage.

Aryl-2-thiabicyclo[4.3.0]nonanes are obtained from cyclopentanone derivatives and aryl-2-thiabicyclo[4.4.0]decanes are synthesised from cyclohexanol derivatives, for example:[94]

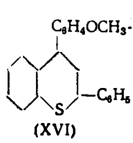




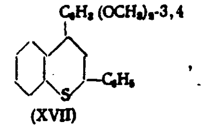
The compounds



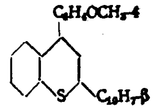
(XV)



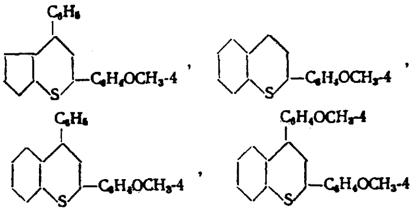
(XVI)



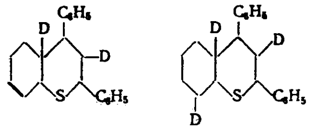
(XVIII)



have been obtained in the same way.[92,94] Compounds (XII) and (XIV)–(XVII) as well as other thiabicycloalkanes have been synthesised[95] in accordance with an analogous scheme from the corresponding 1,5-diketones and hydrogen sulphide, but in this case the reaction was in trifluoroacetic acid:

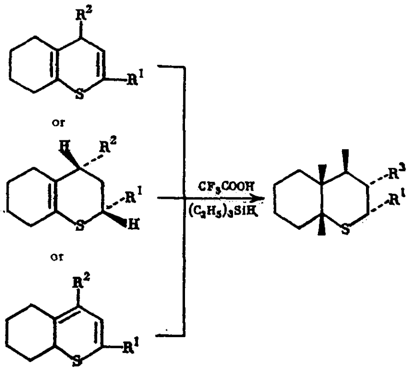


The study of the reaction of polymethylene-4H-thiopyrans with deuteriotrifluoroacetic acid[96] made it possible to establish the site of protonation in the disproportionation reaction; di- and tri-deuterio-3,5-diphenyl-2-thiabicyclo[4.4.0]decanes were then obtained for the first time:



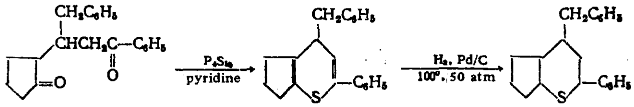
13%

Aryl-2-thiabicycloalkanes have been obtained in high yields by the catalytic hydrogenation (over Pd/C) of the corresponding 4H-thiopyrans, such as, for example, compounds (XI) and (XIII).[97] Compounds (XIV)–(XVII) have also been obtained by the ionic hydrogenation of condensed dihydro-4H- and dihydro-6H-thiopyrans (the yields were respectively 61, 60, 59, and 27%).[98] Regardless of the position of the double bond in the initial heterocycle and the degree of unsaturation, the *cis, cis, cis*-isomers are then formed:



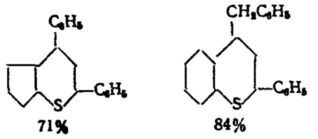
Compound (XV), obtained in 25% yield by the disproportionation of the corresponding thiopyran derivative, also has the *cis,cis,cis*-configuration.[99]

The initial condensed 4H-thiopyrans have also been synthesised from 1,5-diketones and P_4S_{10} by Kupranets's procedure,[92] for example:



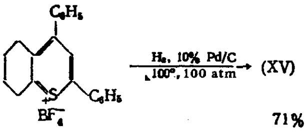
66%

Compounds (XII) and (XIV)–(XVII) as well as thiabicycloalkanes have been obtained analogously:[97,100]



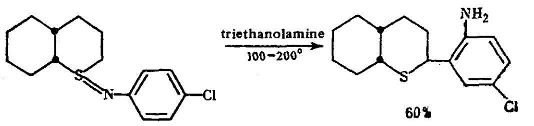
71% 84%

Hydrogenation of salts derived from arylthiochromylium also leads to thiabicycloalkanes:[52]



71%

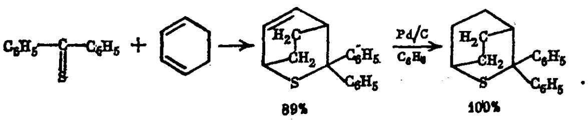
3-(2-Amino-5-chlorophenyl)-2-thiabicyclo[4.4.0]decanes can be obtained by the rearrangement of sulphimides—2-(p-chlorophenylimino)-2-thiabicyclo[4.4.0]decanes.[101] The synthesis and stereochemistry of the formation of the latter has been examined in detail in a review:[93]



60%

The product of the rearrangement is isolated by chromatography. The yields of the products of the rearrangement of sulphimides derived from methyl-2-thiabicyclo[4.4.0]decanes are 16–71% (depending on the conformation of the initial compound). If there is no steric hindrance, the rearrangement proceeds with a high degree of stereospecificity (>95%): shlphimides with an equatorial or axial S–N bond afford products with an equatorial or axial aryl substituent respectively.

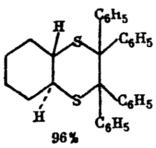
The initial compound for the synthesis of αα-disubstituted (relative to the sulphur atom) thiabicycloalkanes may be thiobenzophenone: its condensation with cyclohexa-1,3-diene led to the formation of 3,3-diphenyl-2-thiabicyclo[2.2.0]oct-5-ene which was then hydrogenated:[47]



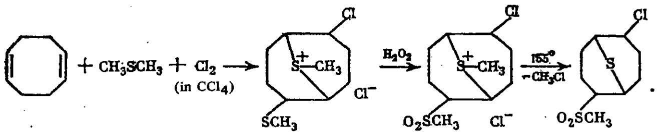
89% 100%

trans-2-Thiabicyclo[4.4.0]decan-5-one has been obtained in 50% yield from 1-(3-dimethylaminopropanoyl)cyclohexene and hydrogen sulphide in the presence of sodium acetate; the analogous reaction with 1-(3-dimethylaminobutanoyl)cyclohexene leads to the 3-methyl derivative in 78% yield.[102] These compounds can also be obtained from the methiodides of the above bases and sodium sulphide.[55,93]

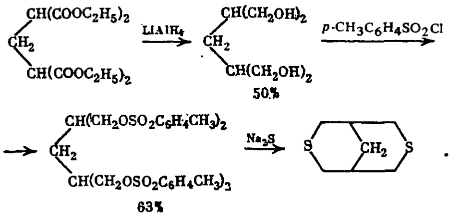
A review[103] devoted to the photocycloaddition of carbonyl compounds of olefins quotes the reaction of thiobenzophenone with cyclohexene which resulted in the formation of 3,3,4,4-tetraphenyl-2,5-dithiabicyclo[4.4.0]decane with a *trans*-junction between the rings:



The synthesis of pesticides based on 2-chloro-6-methanesulphonyl-9-thiabicyclo[3.3.1]nonane has been patented;[104] the nonane derivative was synthesised from cycloocta-1,5-diene and dimethyl sulphide in accordance with the scheme



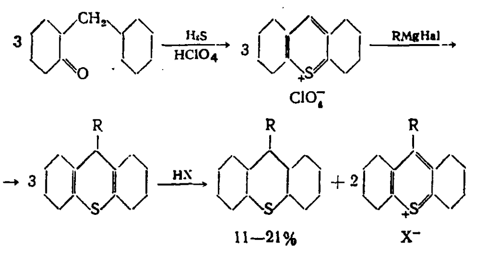
3,7-Dithiabicyclo[3.3.1]nonane has been synthesised[105] using the scheme



2. Thiatricycloalkanes

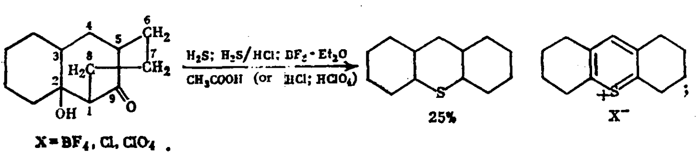
The synthesis of thiapolycycloalkanes with the aim of modelling the sulphur compounds in petroleum has acquired special importance in connection with the more extensive investigation of the composition and properties of the high-molecular-weight component of petroleum. However, in contrast to the syntheses of the thiamonocyclo- and thiabicycloalkanes, the methods of synthesis of thiapolycycloalkanes have developed little in recent years. This is apparently associated with the difficulty of constructing their bicyclic or tricyclic precursors.

The synthesis of perhydrothioxanthene from cyclohexylidenecyclohexanone has been examined in a monograph;[19] 9-substituted perhydrothioxanthenes have been obtained using the same scheme:[106,107]



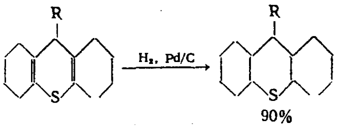
$R = C_2H_5, C_3H_7, C_6H_5$, $X = ClO_4, FeCl_4, Cl, CF_3COO, Br$,

Perhydrothioxanthene has also been obtained from 2-hydroxy-2,3-tetramethylenebicyclo[3.3.1]nonan-9-one:[108]



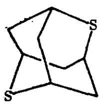
$X = BF_4, Cl, ClO_4$.

Perhydrothioxanthenes can be obtained in satisfactory yields by the catalytic hydrogenation of thioxanthylium salts[52] and also octahydrothioxanthenes:[97]

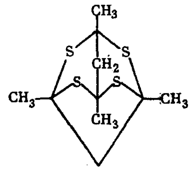


$R = H, CH_3$.

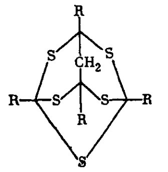
The syntheses of 2,6-dithiaadamantane (XVIII) from thiabicyclo[3.3.1]nona-2,6-diene, of tetrathiaadamantane (XIX) from dithioacetylacetone, and of tetrathiaadamantane, pentathiaadamantane (XX), and hexathiaadamantanes from β-dicarbonyl compounds and thioacetic acid have been considered in a review:[109]



(XVIII)

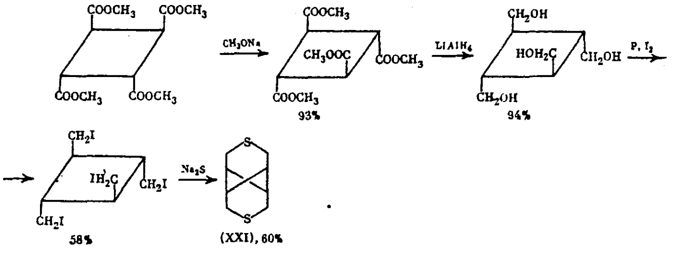


(XIX)



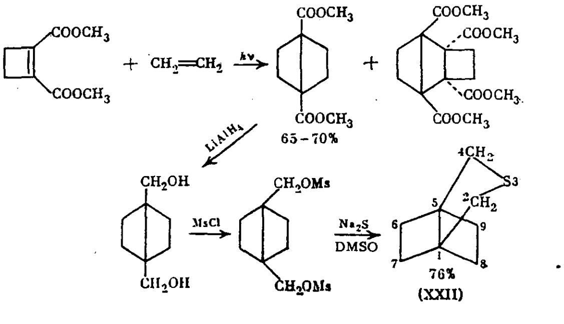
(XX)

4,9-Dithiatricyclo[4.4.0.$0^{2,7}$]decane (XXI) has been synthesised by a comparatively simple procedure.[110] The photodimerisation of dimethyl fumarate in the solid phase yielded tetramethoxycarbonylcyclobutane and from the latter *trans, trans, trans*,-1,2,3,4-tetra(iodomethyl)cyclobutane was obtained. Sodium sulphide is added into its solution in absolute ethanol with the aid of the Soxhlet apparatus and the sulphide (XXI) is obtained:

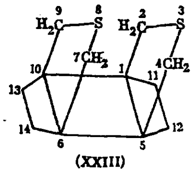


A characteristic feature of the structure of the sulphide (XXI) is the flattening of the six-membered ring. It is of interest that there is a maximum at 246 nm in its UV spectrum. The authors[110] explain this by the result of the interaction of the σ-orbitals of the four-membered ring and the *p* electrons of the sulphur atom.

3-Thiatricyclo[3.2.2.$0^{1,5}$]nonane or 3-thia[3.2.2]propellane (XXII) has been synthesised[111] by the photochemical cycloaddition of ethylene to 1,2-dimethoxycarbonylcyclobutene:

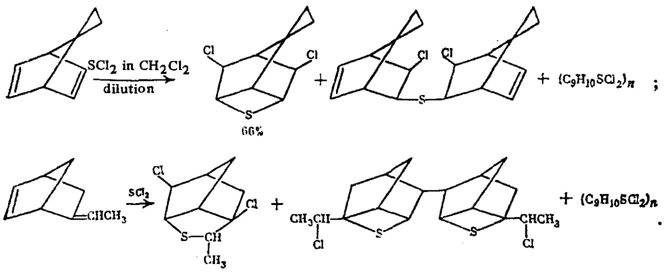


The pentacyclic sulphide (XXIII) was obtained[111] from the photodimer, formed in the first stage of the synthesis, via the same sequence of reactions; its yield in the last stage of the synthesis was 64%:



(XXIII)

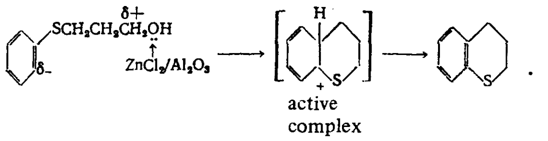
Adducts, consisting of chloro-derivatives of saturated tricyclic sulphides with a thiaskeletal structure have been obtained from bicyclic dienes and sulphur dichloride:[112]



3. Semiaromatic Sulphides

The advances in the synthesis of "semiaromatic" polycyclic sulphides (i.e. those where at least one CH_2 group adjoins the sulphur atom in the ring) have been associated in recent years with the study of the [3,3]sigmatropic ("thio-Claisen") rearrangement of alkenyl aryl sulphides and principally with the development of the syntheses of thiacyclophanes.

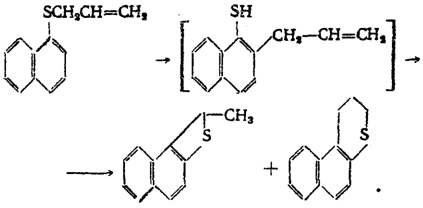
The reactions of alkenyl aryl sulphide and also certain thiophenols were carried out in the presence of acid catalysts.[113–116] This resulted in the formation of thiaindans and thiachromans. Thus, when 1-phenylthio-3-propanol is passed at 300 °C over alumina on which zinc chloride has been deposited, thiachroman is formed (31–35%):[113, 115]



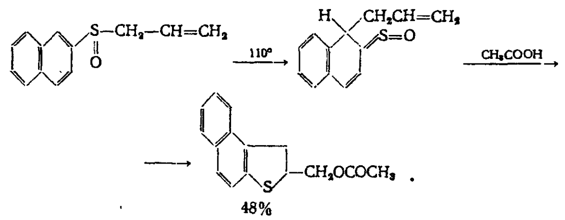
2-Methyl-1-thiaindan is formed in an insignificant yield from allyl phenyl sulphide over this catalyst, while over alumina, which is a less acid catalyst, the yield is better (33%).[114] Under these conditions, thiaindans are partly dehydrogenated to thiaindenes (in the presence of zeolite, the overall yield of 2-methyl-2-thiaindan and 2-methylthiaindene is 47%.[115]) The reaction of but-3-enyl phenyl sulphide in the presence of 20% $ZnCl_2/Al_2O_3$ at 30 °C takes place with formation of 33% of 4-methylthiochroman.[116] The formation of 15% of a tricyclic "semiaromatic" sulphide, namely cyclopentano-2,3-dihydrobenzothiophen, from cyclopentenyl phenyl sulphide has been noted:[116]

The catalytic synthesis of such semiaromatic sulphides from alkenyl phenyl sulphides is attractive by virtue of its simplicity but in the communications considered only the contents of the sulphide in the catalytic reaction mixture, determined by GLC analysis, are given, while the yields of the individual derivatives of thiaindans and thiachromans are not indicated.

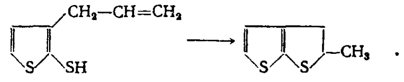
The "thio-Claisen" rearrangement has continued to be extended to new objects under traditional conditions—with heating in the absence of a solvent or in aprotic solvents. Heating of allyl 1-naphthyl sulphide at 190 °C in quinoline leads to the formation of a mixture of approximately equal amounts (59:41) of tricyclic derivatives of thiaindan and thiachroman:[117]



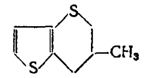
Japanese investigators[118] heated allyl 2-naphthyl sulphoxide in the presence of acetic acid and dimethylformamide and obtained a functional derivative of a tricyclic semiaromatic sulphide:



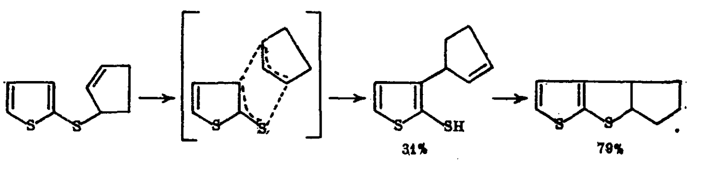
Semiaromatic sulphides have also been synthesised from thiophen derivatives.[119–121] In this case too mixtures of dihydrothiolen and dihydrothiopyran are usually formed. The synthesis where only one of the possible structural isomers is formed are of preparative interest. Thus, when 3-allylthiophen-2-thiol is heated in hexamethylphosphoramide, only 2-methyl-2,3-dihydrothieno[2,3b]thiophen is formed in 50% yield:[119]



The thermal rearrangement of β-methylallyl 3-thienyl sulphide leads to only 3-methylthieno[3,2*b*]dihydrothiopyran:[119]



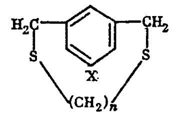
3-(Cyclopent-2-enyl)-thiophen-2-thiol cyclises at 120 °C in quinoline with formation of cyclopentano-2,3-dihydrothieno-[2,3*b*]thiophen; the initial thiol is obtained beforehand from cyclopent-2-enyl 2-thienyl sulphide:[120]



The corresponding thiol is obtained analogously in a low yield (12–14%) from cyclopent-2-enyl 2-benzothienyl sulphide and its cyclisation affords cyclopentano-2,3-dihydrobenzothieno[2,3*b*]thiophen:[121]

The synthesis of cyclophanes—cyclic compounds containing one or several benzene rings joined by polymethylene bridges in the *o*-, *m*-, or *p*-positions—has developed in recent years. These compounds serve as convenient objects for the study of a large number of problems in theoretical organic chemistry. Thiacyclophanes usually serve as precursors of cyclophanes, being converted into the latter, for example, with the aid of the Stevens rearrangement. The methods of synthesis of thiacyclophanes have been considered in detail in two reviews.[69,70]

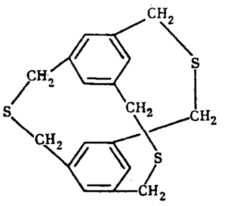
A general method of synthesis of thiacyclophanes involves the reaction of the corresponding dibromo-derivatives with dithiols. For example, more than 100 dithia-*meta*-cyclophanes have been synthesised and investigated in two studies,[69,122] for example, compounds of the type



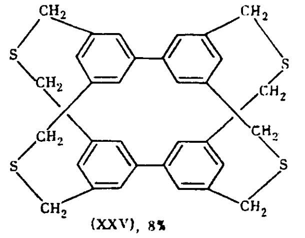
$n = 2-10$, X=H,F,Cl,Br,CH_3,CH_3O,CN

They were obtained by the reaction of equimolar amounts of αω-bismercaptans with the corresponding αα′-dibromo-*m*-xylenes in a basic medium (yields 3–90%). High dilution is used in the synthesis of thiacyclophanes of medium size.[123]

The precursors of two- and three-layer cyclophanes (also referred to as "cage compounds") are bridged polythiacyclophanes, for example, compounds (XXIV) and (XXV):

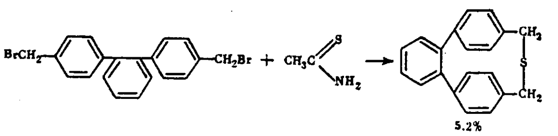


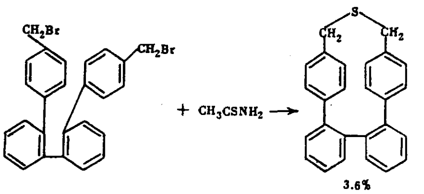
(XXIV), 12%

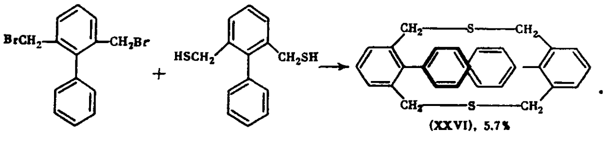


(XXV), 8%

Compound (XXIV) has been synthesised by Boekelheide and Hollings[124] and compound (XXV) by Vögtle et al.[125] Strained thiscyclophanes were synthesised subsequently[126] using the so called "caesium effect", which consists in the fact that the cyclocondensation of the dibromo-derivatives with thioacetamide or with 2,6-di-(mercaptomethyl)biphenyl takes place only in the presence of equimolecular amounts of caesium ions (in the form of Cs_2CO_3 in DMF); the yields of the required products are however low.



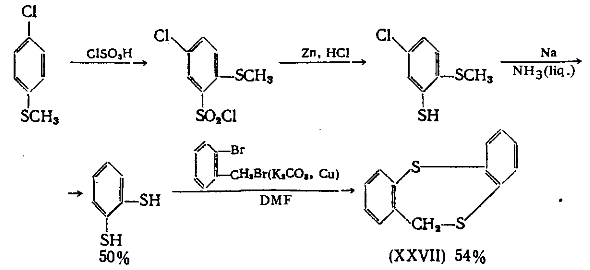




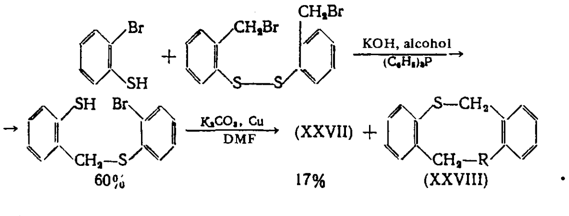
(XXVI), 5.7%

Compound (XXVI) is a mixture of the *syn*- and *anti*-stereo**isomers which are** separated by chromatography on silica gel.

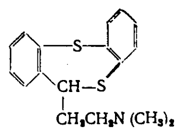
In order to obtain substances with psychotropic (antidepressant) activity, Czech investigators[127] synthesised derivatives of dithiacyclophanes—11*H*-debenzo[b,e]-1,4-dithiepin (XXVII); the starting compound was 4-chlorothioanisole:



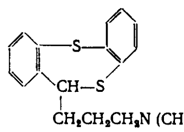
If the synthesis of compound (XXVII) was begun with 2-bromothiophenol, then another dithiacyclophane, namely 6*H*,12*H*-dibenzo[*b*,*f*]-1,5-dithiocin (XXVIII), was obtained together with compound XXVII):



By treating compound (XXVII) with butyl-lithium and 2-dimethylaminoethyl or 3-dimethylaminopropyl chloride, the dithiacyclophanes (XXIX) and (XXX) were obtained respectively (the pure compounds were obtained in the form of the oxalates); they were found to exhibit antireserpine activity:



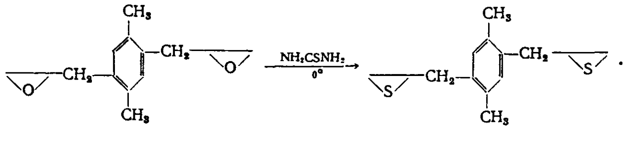
(XXIX), 97%



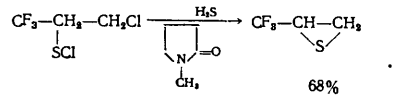
(XXX), 87%

The most important studies published during the preparation of the review for print are examined below.

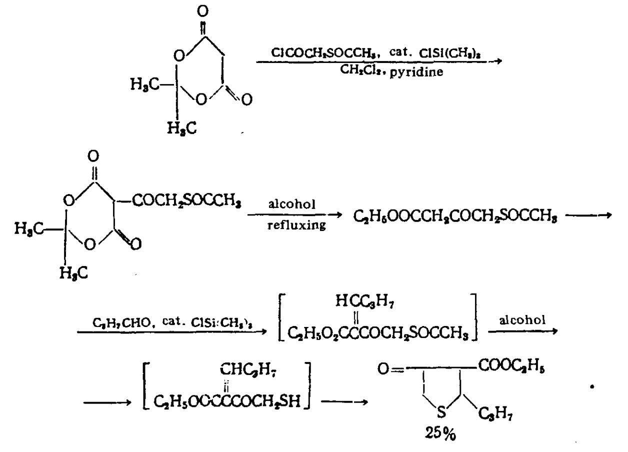
Unsubstituted acetylthiirans and 2- and 3-methylacetylthiirans have been obtained in 70–80% yields from acetyloxirans.[128] The latter are converted into diethylketals, which are treated with thiourea and then hydrolysed. The oxygen is readily replaced by sulphur in the symmetrical dioxiran:[129]



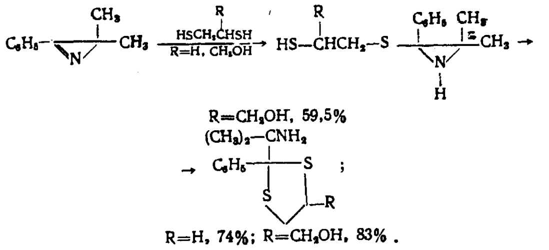
Trifluoromethylthiiran has been obtained[130] from chloropropane-2-sulphenyl chloride and hydrogen sulphide:



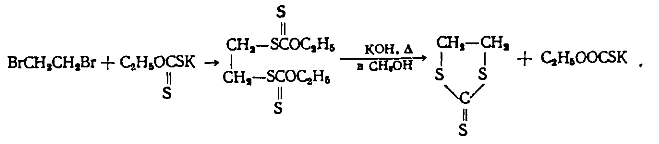
Polyfunctional derivatives of thiolan have been synthesised[131] using Meldrum's acid, for example:



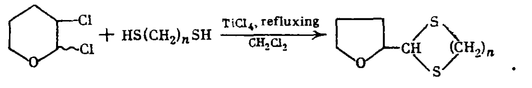
2-Aminoalkylated derivatives of 1,3-dithiolan have been synthesised from β-dithiols and 2*H*-azirines:[132]



A preparative method of synthesis of 1,3-dithiolan-2-thione and 4-phenyl-1,3-dithiolan-2-thione from dibromoethane and 1,2-dibromo-1-phenylethane and xanthate has been described:[133]

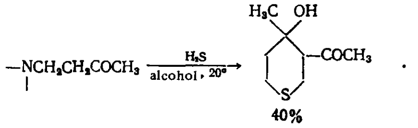


2-Tetrahydrofuryl-1,3-dithiolan and 2-tetrahydrofuryl-1,3-dithiane have been obtained[134] from dithiols and 2,3-dichlorotetrahydropyran:

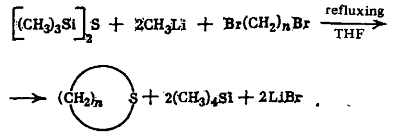


n=2–70%, n=3–73%

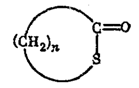
A polyfunctional thiane has been obtained by treating ketonic Mannich bases with hydrogen sulphide:[135]



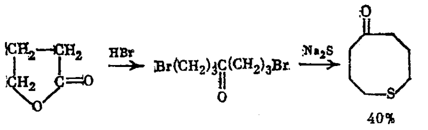
Sulphides containing more than six members in the ring have been synthesised[136] using the reactive form of Li_2S (at the instant of formation) in accordance with the scheme:



The yields in order of the number *n* were as follows (%): 6.61, 7.34, 8.22, 9.15, 10.20, and 12.31. The macrocyclic thiolactones

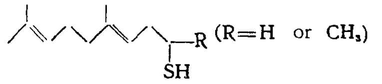


have also been obtained by reaction with $Br(CH_2)COCl$. The yields of the thiolactones in order of the number *n* were as follows (%): 5.73, 7.0, 11.47, and 15.64. 5-Cyclothiaoctanone has been synthesised[137] from γ-butyrolactone:[137]

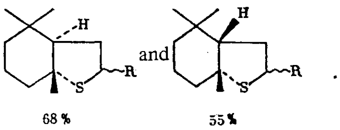


cis,cis-5,5,6,6-Tetracyano-2-thiabicyclo[2.2.0]hexane has been synthesised[138] in 55% yield by treating specially obtained 2-thieten with tetracyanoethylene.

Cyclisation of the stereoisomers of the homogeraniolthiols

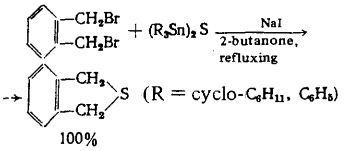


with the aid of boron trifluoride/etherate[139] the *trans*- and *cis*-*gem*-dimethyl- and the *trans*- and *cis*-trimethyl-thiahydrindans respectively; the method makes it possible to control only the stereochemistry of the ring junction:

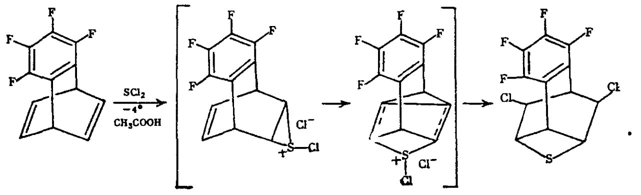


The thio-Claisen rearrangement has been extended[140] to alkenylthiotropones.

1,3-Dihydroisothionaphthene has been obtained[136] using organotin compounds:



exo-*exo* 6,9-Dichloro-3,4-tetrafluorobenzo-8-thiatricyclo-[3.3.1.0^{2,7}]nonene has been obtained[141] by means of the scheme



A thiocrown ether with a cycloheptatriene fragment has been synthesised from sodium cyclohepta-1,3,5-trienedithiolate:[142]

Phosphorylated Allenes. Methods of Synthesis and Properties

N.G.Khusainova and A.N.Pudovik

A systematic account is given of the literature data on the methods of synthesis of phosphorus-containing allenes. The unusual chemical behaviour of phosphorylallenes in their interaction with electrophilic addends is discussed and at the same time a new type of reaction, which leads to five-membered heterocycles containing a phosphorus atom directly in the ring, is considered. The review also deals with studies on nucleophilic addition to phosphorylallenes and
The bibliography includes 146 references.

I. INTRODUCTION

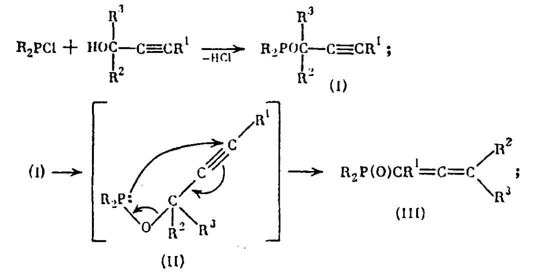
Considerable advances have been achieved in recent years in the synthesis and study of the chemical behaviour of phosphorylallenes. The enhanced reactivity of phosphorylallenes makes it possible to synthesise from them a wide variety of unsaturated organic open-chain and cyclic phosphorus compounds with functional-group substituents which are frequently difficult to obtain by other methods and which are likely to be useful as pesticides, medicinal drugs, monomers for the synthesis of plastics, etc. On the other hand, the characteristic features of the electronic structure of phosphorylallenes, in which the cumulene group with orthogonal π orbitals and different types of hybridisation of the carbon atoms (the sp^2 hybridisation of the extreme carbon atoms and the sp hybridisation of the middle carbon atoms) is combined with the electron-accepting phosphoryl group, is manifested in the physical and chemical properties of the compounds, which makes them convenient objects for the investigation of the interrelation between electronic structure, steric structure, and reactivity.

In a review of the chemistry of acetylenic and diene organophosphorus compounds (1967), mention was made of only seven allenylphosphonates;[1] since then, more than 200 phosphorus-containing allene derivatives have been synthesised. We thought it of interest and timely to survey the available information about the methods of synthesis of allene derivatives of tetracoordinate quinquevalent phosphorus. The present review also deals with certain physical characteristics of phosphorylallenes, their isomerisation, and their reactions with nucleophiles and electrophiles and derivatives of tervalent phosphorus. Studies on the 1,3-dipolar cycloaddition to phosphorylated allenes were considered earlier in other reviews.[2]

II. METHODS OF SYNTHESIS

1. The Acetylene–allene Rearrangement of Propargyl Phosphites and Phosphinites

The allene derivatives of tetracoordinate phosphorus have become available since the discovery of the acetylene–allene rearrangement of the propargyl esters of phosphorus and phosphinous acids, which are obtained from the chlorides of tervalent phosphorus acids and acetylenic alcohols in the presence of amines:[3-10]



$$R_2PCl + HOC(R^2)(R^3)-C\equiv CR^1 \xrightarrow[-HCl]{} R_2POC(R^2)(R^3)-C\equiv CR^1; \quad (I)$$

$$(I) \longrightarrow [(II)] \longrightarrow R_2P(O)CR^1=C=C(R^2)(R^3); \quad (III)$$

R=CH_3, C_6H_5, AlkO, $HC\equiv CCH_2O$, $HC\equiv CCH(C_3H_7)O$, $HC\equiv CC(CH_3)_2O$,

or $R_2 = -OCH_2CH(CH_3)O-$;

R^1=H, CH_3; R^2=R^3=H, CH_3; R^2=H, R^3=CH_3;

R^2=C_6H_5, R^3=CH_3; R^2+R^3=$(CH_2)_4$, $(CH_2)_5$.

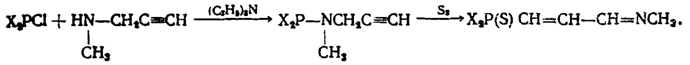
It has been suggested[3,10,11] that the rearrangement of the propargyl phosphite (phosphinite) (I) formed initially to the allenylphosphonate (III) takes place intramolecularly as an S_{ni} reaction via the five-centre cyclic transition state (II) as a result of the energy gain associated with the change in the coordination of the phosphorus atom P(III) → P(IV). The isomerisation of (I) to (II) is also regarded as a variety of the Arbuzov reaction occurring with participation of phosphorohalidites.[12]

The high stereospecificity of the acetylene–allene rearrangement, which has been confirmed experimentally in relation to the interaction of the optically pure *R*(+)-2,2,6,6-tetramethylhept-4-yn-3-ol with phosphorus trichloride, leading after hydrolysis to the optically pure *R*(−)-1,3-di-(t-butyl)-propa-1,2-dienylphosphonic acid, enabled Macomber to assume the possibility that these reactions have the mechanism involving a concerted [3,2]sigmatropic shift.[13,14]

The allenyl phosphonate (III) formed can subsequently isomerise to the corresponding acetylenic derivative (IV):[6,7]

$$\underset{(III)}{R_2P(O)CH=C=CH_2} \rightarrow \underset{(IV)}{R_2P(O)C\equiv C-CH_3}.$$

The final result of the reaction is determined by its conditions, the method of treatment of the reaction mixture, and the presence of substituents in the propargyl group.[8,10] The formation of propargyl phosphites (I) in the first stage has been confirmed by their isolation in a pure state.[8,10,15,16] It is noteworthy that, whereas propargyl phosphites and phosphorothioites[17,18] readily rearrange to allene derivatives of tetracoordinate phosphorus, their nitrogen analogues (V) are more stable:[19]

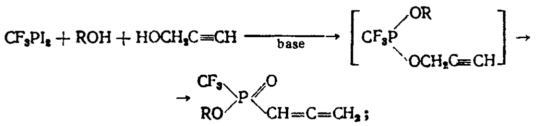


$$X_2PCl + \underset{\displaystyle CH_3}{HN}-CH_2C\equiv CH \xrightarrow{(C_2H_5)_3N} X_2P-\underset{\displaystyle CH_3}{N}CH_2C\equiv CH \xrightarrow{S_8} X_2P(S)CH=CH-CH=NCH_3.$$

(V) (VI)

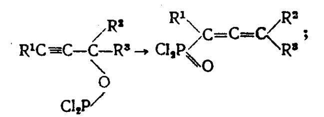
Only phosphines where X = C_2H_5 or C_6H_5 undergo the isomerisation (V) → (VI).

The rate of rearrangement of compound (I) to compound (III) depends to a large extent on the character of the substituents at the phosphorus atom and at the α-carbon atom in the propargyl group. Thus, the propargyl phosphinite (I), formed on interaction of chlorodiethylphosphine with propargyl alcohol, isomerises after several hours almost wholly with formation of an allenic phosphine oxide.[20] The propargyl esters of tervalent phosphorus acids, containing trifluoromethyl groups, also very readily isomerise to allene compounds:[21]



$R=C_2H_5$, $CH_2C\equiv CH$.

Like other phosphites containing the αα-disubstituted propargyl group, α-ethyl-α-methylpropargyl *o*-phenylene phosphite cannot be isolated in a pure state as a consequence of the rapid rearrangement of the corresponding phosphoryl allene.[22] The optimum condition for the rearrangement of propargyl phosphorodichloridite is ten day storage at room temperature.[16] Deuteriated propargyl phosphorodichloridite has been isomerised to the dichloride of α-deuterioallenylphosphonic acid by heating in benzene at 60–70° for 12 h.[23] Propargyl and α-methyl propargyl phosphorodichloridites isomerise to dichloroallenylphosphonates more slowly than αα-dimethylpropargyl phosphorodichloridite, whose acetylene–allene rearrangement to the chloride of 3-methylbuta-1,2-dienylphosphonic acid takes place especially readily.[12] The rate of rearrangement of acetylenic phosphorodichloridite to allenylphosphonate depends significantly on the substituents R^1, R^2, and R^3:



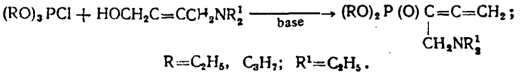
$R^1=H$, $R^2R^3=(CH_2)_4$ (a), $(CH_2)_5$ (b), $R^2=R^3=CH_3$ (c);
$R^1=(CH_3)_3C$, $R^2=R^3=CH_3$ (d), $R^2=H$, $R^3=(CH_3)_3C$ (e);
$R^1=R^2=R^3=H$ (f).

It varies in the sequence a > b > c > d > e > f.[13,14] The dichlorides of allenylphosphonic acids formed under these conditions are convenient starting materials for the synthesis of the corresponding esters,[12,14] acid difluorides,[16] and acids.[13,14,24] Dimethyl(3-methylbuta-1,2-dienyl)phosphine oxide has been obtained from the dichloride of 3-methylbuta-1,2-dienylphosphonic acid and methylmagnesium iodide.[25,26] It is noteworthy that the dichlorides of the allenylphosphonic acids

$$Cl_2P(O)CR^1=C\begin{matrix}R^2\\R^3\end{matrix}$$

can also be obtained from propargyl alcohols and phosphorus trichloride using a vigorous stream of nitrogen to remove the hydrogen chloride formed from the reaction mixture.[14] The dichlorides of allenylphosphonic acids can also be obtained by refluxing the corresponding acetylenic alcohols in an excess of phosphorus trichloride or by treating the amides of alkal-1,2-dienylphosphonic acids with hydrogen chloride.[27]

When the appropriate substituents are introduced into acetylenic alcohols, it is possible to obtain phosphorylated allenes with alkyl and aryl substituents[28–32] and also with various functional groups at the C(1) and C(3) carbon atoms of the cumulene. Thus halogenopropargyl alcohols react with halogeno-derivatives of tervalent phosphorus acids to form α-halogenoallenylphosphonates[33,34] and the corresponding phosphine oxides.[35,36] The products of the interaction of dialkyl phosphorochloridites with 4-*NN*-dialkylaminobut-2-yn-1-ols undergo thermal isomerisation with formation of dialkylaminomethyl-substituted propa-1,2-dienylphosphonates:[37]



$$(RO)_3PCl + HOCH_2C\equiv CCH_2NR^1_2 \xrightarrow[\text{base}]{} (RO)_2P(O)\underset{\displaystyle CH_2NR^1_2}{C}=C=CH_2;$$

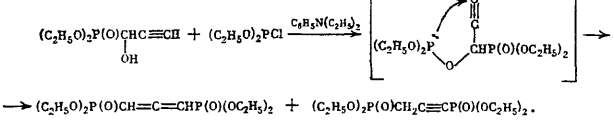
$R=C_2H_5$, C_3H_7; $R^1=C_2H_5$.

The dialkyl esters of 1-chlorobuta-2,3-dien-2-ylphosphonic acids[38] are unstable and have not been isolated in a pure state. Their formation has not been established either spectroscopically or from their chemical reactions. When sodium methoxide is introduced into the reaction mixture, chlorine is substituted by the alkoxy-group with formation of esters of 1-methoxybuta-2,3-dien-2-ylphosphonic acid:[39]

$$(RO)_2P(O)\underset{\displaystyle CH_2Cl}{C}=C=CH_2 + CH_3ONa \rightarrow (RO)_2P(O)\underset{\displaystyle CH_2OCH_3}{C}=C=CH_2.$$

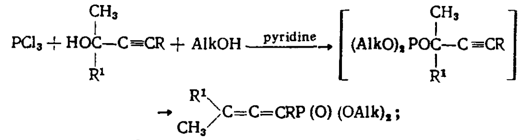
The latter have also been obtained by specific synthesis—the acetylene–allene rearrangement of the products of the interaction of 4-methoxybut-2-yn-1-ol with dialkyl phosphorochloridites.[35] The acetylene–allene isomerisation of the corresponding acetylenic phosphites, formed when the monomethyl ethers of acetylenic glycols are treated with phosphorus trichloride in the presence of pyridine, yielded the dichlorides of 1-methoxyalka-2,3-dien-2-ylphosphonic acids.[40] Dialkyl(1-methoxyalka-2,3-dien-2-yl)phosphine oxides have been synthesised by the reaction of the dichlorides of 1-methoxyalka-2,3-dien-2-ylphosphonic acids with alkylmagnesium halides.[40]

The interaction of 1-hydroxyprop-2-ynylphosphonic ester with diethyl phosphorochloridite afforded a mixture of allenic and acetylenic diphosphonates:[41]



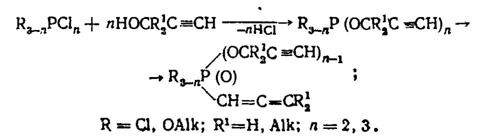
The esters of allenylphosphinothioic acids have been obtained by the isomerisation of the products of the interaction of dialkyl phosphorochloridites with acetylenethiols.[17,18]

The dialkyl esters of 1- and 3-vinylallenylphosphonic acids are formed when vinylacetylenic alcohols are treated with phosphorus trichloride and this is followed by the acetylene–allene isomerisation of the intermediate mixed phosphites;[32,33]



$R=CH=CH_2$, $R^1=CH_3$; $R=H$, $R^1=CH=CH_2$;
Alk$=CH_3$, C_2H_5, C_3H_7, iso-C_3H_7, C_4H_9.

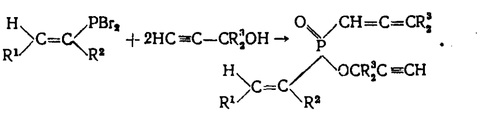
By substituting the halogen atoms in the corresponding halogeno-derivatives of tervalent phosphorus by acetylenic alcohol residues, it is possible to synthesise highly unsaturated phosphorylallenes:[3,4,42]



$$R_{3-n}PCl_n + nHOCR^1_2C\equiv CH \xrightarrow[-nHCl]{} R_{3-n}P(OCR^1_2C\equiv CH)_n \rightarrow R_{3-n}P(O)\begin{array}{l}(OCR^1_2C\equiv CH)_{n-1}\\ CH{=}C{=}CR^1_2\end{array};$$

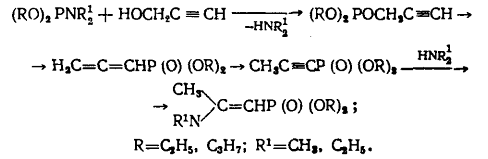
$$R = Cl,\ OAlk;\ R^1{=}H,\ Alk;\ n = 2, 3.$$

The reactions of the dibromides of alkenylphosphonous acids with acetylenic alcohols take place with rapid acetylene–allene isomerisation of the products, which leads to the monoalkynyl esters of alkenyl(allenyl)phosphinic acids:[43,44]



Alkyl allenylphosphonochloridates[44] and alkyl diethylamino-allenylphosphonates[45] have been obtained from propargyl alcohols and the corresponding tervalent phosphorus derivatives.

The alcoholysis of phosphoramidites by propargyl alcohol at 80–100 °C leads to the formation of propargyl phosphites, which immediately isomerise to allenylphosphonates and further to propynylphosphonates.[45] However, the reaction does not stop at this stage: the dialkylamine evolved adds to the triple bond of the propynylphosphonate:



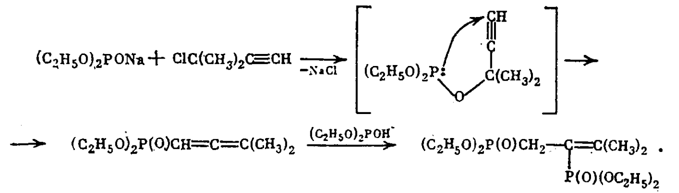
$$(RO)_2PNR^1_2 + HOCH_2C\equiv CH \xrightarrow[-HNR^1_2]{} (RO)_2POCH_2C\equiv CH \rightarrow$$

$$\rightarrow H_2C{=}C{=}CHP(O)(OR)_2 \rightarrow CH_3C\equiv CP(O)(OR)_2 \xrightarrow{HNR^1_2}$$

$$\rightarrow \begin{array}{l}CH_3\\ R^1N\end{array}\!\!>C{=}CHP(O)(OR)_2;$$

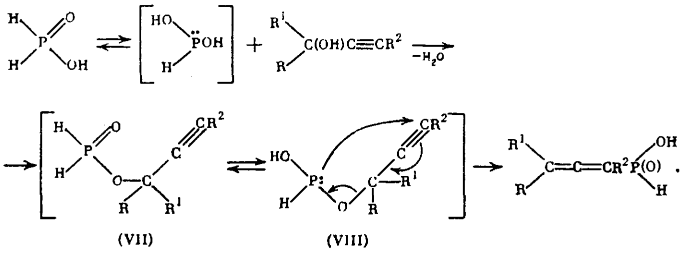
$$R{=}C_2H_5,\ C_3H_7;\ R^1{=}CH_3,\ C_2H_5.$$

The reaction of sodium diethyl phosphite with 2-chloro-2-methylbut-3-yne in ethereal solution yielded 1-diethylphosphono-3-methylbuta-1,2-diene and the product of the addition of diethylphosphorous acid to the latter:[46]



The allenylphosphonate, formed analogously in the reaction of sodium diethyl phosphite with propargyl bromide, isomerises to propynylphosphonate.[47]

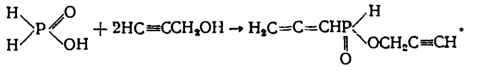
A large series of allenylphosphorous acids containing an active P–H bond have been synthesised by esterifying hypophosphorous acid with acetylenic alcohols:[48–57]



(VII) (VIII)

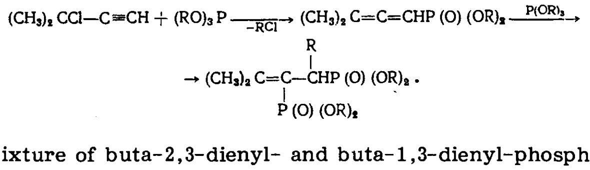
Despite the fact that the propargyl phosphite (VII) formed in the first stage contains a tetracoordinate phosphorus atom, the presence of two P–H bonds promotes the shift of the tautomeric equilibrium towards the tricoordinate form (VIII) to a larger extent than in the case of phosphite esters.[56] The high nucleophilicity of phosphorus in the intermediate (VIII) is responsible for the possibility of the acetylene–allene rearrangement.

By altering the reactant ratio, it is possible to obtain the propargyl esters of propa-1,2-dienylphosphonous acid:[52]



2. Other Methods of Synthesis of Phosphoryl Allenes

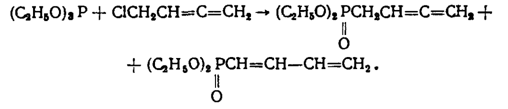
In a study of the Arbuzov reaction involving trialkyl phosphites and 2-chloro-2-methylbut-3-yne, the esters of 3-methylbuta-1,2-dienylphosphonic acid were obtained for the first time.[58] The reaction did not stop at this stage and a second molecule of the trialkyl phosphite added to the allenylphosphonate formed:



$$(CH_3)_2CCl{-}C\equiv CH + (RO)_3P \xrightarrow[-RCl]{} (CH_3)_2C{=}C{=}CHP(O)(OR)_2 \xrightarrow{P(OR)_3}$$

$$\rightarrow (CH_3)_2C{=}\underset{P(O)(OR)_2}{\underset{|}{C}}{-}\overset{R}{\overset{|}{C}}HP(O)(OR)_2.$$

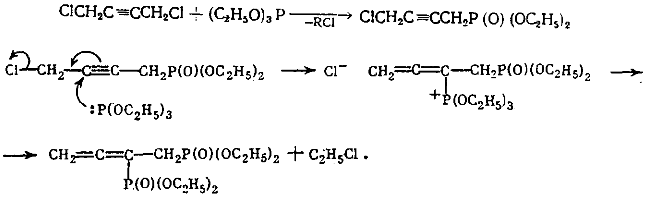
A mixture of buta-2,3-dienyl- and buta-1,3-dienyl-phosphonates is formed when triethyl phosphite reacts with 1-chlorobuta-2,3-diene:[59]



$$(C_2H_5O)_3P + ClCH_2CH{=}C{=}CH_2 \rightarrow (C_2H_5O)_2\underset{O}{\underset{\|}{P}}CH_2CH{=}C{=}CH_2 +$$

$$+ (C_2H_5O)_2\underset{O}{\underset{\|}{P}}CH{=}CH{-}CH{=}CH_2.$$

When 1,4-dichlorobut-2-yne is used, an asymmetric diphosphonate with an allene structure, namely the tetraethyl ester of buta-2,3-dien-1,2-ylenediphosphonic acid, is formed in addition to 4-chlorobut-2-ynylphosphonate:[60]



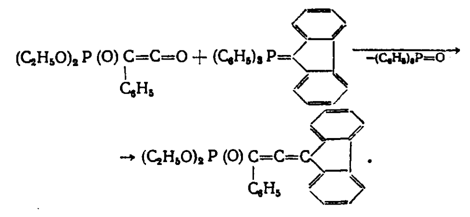
The formation of the allenediphosphonate is due to the reduced reactivity of the propargyl chloride group in 4-chlorobut-2-ynylphosphonate compared with the corresponding bromide in the Arbuzov reaction (in the latter case but-2-yn-1,4-ylenediphosphonate was obtained).

The reaction of propargyl bromide with trialkyl phosphite is of the type of Arbuzov rearrangement, being accompanied by the prototropic isomerisation of allenylphosphonate to propynylphosphonate.[61,62]

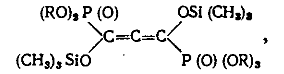
Diethyl allenylphosphonate has been obtained by the dehydrobromination of 2-bromo-1-diethylphosphonoprop-2-ene with the aid of a Grignard reagent.[63,64] The use of stronger bases (sodium alkoxide or hydride) in this reaction leads to the formation of propynylphosphonate.

C(1)- and C(3)-substituted *OO*-dimethylphosphonoallenes have been obtained in low yields in the photolysis of phosphorylvinylcarbenes.[65]

Trisubstituted phosphorylated allenes can be obtained from phosphorylketones and phosphorus ylides:[66]



A method of synthesis of 1,3-bis(dialkylphosphono)-1,3-bis-trimethylsiloxy)allenes



where R is ethyl or propyl, by the reaction of dialkyl trimethylsilyl phosphite with carbon suboxide at −30 to −70 °C,[67] has been proposed.

III. THE PROPERTIES OF PHOSPHORYLATED ALLENES

1. Structure and Physical Characteristics

Quantum-chemical calculations by the CNDO/2 method in terms of the *spd* basis set have shown that the electron density at the C(3) carbon atom increases significantly on passing from 3-alkyl-substituted to unsubstituted allenylphosphonates and -phosphonites on subsequent redistribution of the effective charges (Table 1).[68]

Table 1. Results of calculations for phosphorus-containing allenes $R^1R^2P(O)C^1H{=}C^2{=}C^3XY$ by the CNDO/2 method in terms of the *spd* basis set.[68]

R^1	R^2	X	Y	Atomic charges, a.u.

The ^{13}C chemical shift in the ^{13}C NMR spectra of phosphorylated allenes reflect the general characteristics of their structure. The signal of the *sp*-hybidised C(2) carbon atom is in the low field region (211–218 p.p.m.), while the C(1) and C(3) nuclei give rise to signals characteristic of the sp^2-hybidised atom (75–103 p.p.m.)[68] (Table 2).

The ^1H and ^{31}P NMR spectra of phosphorylated allenes have been described fairly fully in the literature[14,20,25,27,29,30,32,69,70], etc.). The chemical shift due to the phosphorus atom in the ^{31}P NMR spectra of allenylphosphonates is manifested by a signal in the range 15–20 p.p.m., shifting to the region 25–30 p.p.m. for allenylphosphine oxide and the dichlorides of allenylphosphonic acids.

Table 2. Parameters of the ^{13}C NMR spectra of allenic phosphonates and phosphinites $R^1R^2P(O)C^1R^3{=}C^2{=}C^3XY$.[68]

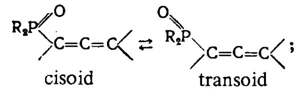
The band due to the antisymmetric vibrations of the C=C=C group in the region of 1950 cm^{-1} in the IR spectra of phosphorylallenes was found to be a doublet,[16,20,71] which can be explained by the conformational isomerism arising as a consequence of the rotation relative to the $P{-}C_{sp^2}$ bond.[71] Using the set of IR and Raman spectroscopic data, dipole moments, and Kerr effect data, it has been shown that, in the liquid state and in solutions of dimethyl(3-methylbuta-1,2-dienyl)phosphine oxide and the chlorides of 3-methylbuta-1,2-dienylphosphonic and propdienylphosphonic acids, there is a conformations equilibrium between the cisoid and transoid forms, somewhat displaced towards the latter:[26]



R=CH₃, Cl.

The study of the molecular geometry for a series of allenyldiphenylphosphine oxides by ^1H NMR[29,72–76] has shown that a diamagnetic anisotropy has arisen under the influence of the aromatic nuclei attached to the phosphorus atom. Conformational analysis of these systems relative to the σ-bond between the terminal C(3) carbon atom of the phosphorylated cumulene and the substituent at this atom indicates a structure with the $C_{sp^2}{-}C_{sp^3}$ bond eclipsed by the allene system. Whether or not this orientation is preferred depends on the substituents at the C_{sp^3} carbon atom and varies in the sequence $CH_3 \gg C_6H_5 > H$.

2. Isomerisation

The isolation of esters of the 3,3-unsubstituted allenylphosphonic acid frequently presents considerable difficulties owing to the ready isomerisation to methylacetylenic phosphonates.[8] The prototropic conversion of allenylphosphonate into propynylphosphonate by treatment with propargyl phosphite, which plays the role of a basic catalyst, or in the presence of amines, alkoxides, and phosphites is accompanied by an increase of temperature and takes place quantitatively. The isomerisation of allenyldiethylphosphine oxide to the corresponding acetylenic derivative is slower compared with allenylphosphonate, which is apparently associated with the weaker electron-accepting properties of the diethylphosphine oxide group.[20]

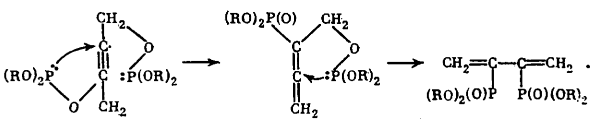
Allenylphosphonic acid dichloride and alkyl allenylphosphonochloridate do not undergo the prototropic transformation into acetylenic derivatives on heating for several hous at 100–150 °C.[34]

3-Monosubstituted allenylphosphonates are more resistant to prototropic isomerisation compared with propadienylphosphonates, which agrees with the charge distribution in phosphorylallenes[68] (Table 1). When diethylphosphonobuta-1,2-diene is heated in the presence of sodium ethoxide at 100 °C for 1.5 h, it isomerises to only a slight extent[77] and an equilibrium mixture is formed after 5 h at 160–180 °C:[78]

$$\underset{70\%}{CH_3C{\equiv}CCH_2P(O)(OC_2H_5)_2} \rightleftarrows \underset{20\%}{CH_3CH{=}C{=}CHP(O)(OC_2H_5)_2} \rightleftarrows \underset{10\%}{CH_3CH_2C{\equiv}CP(O)(OC_2H_5)_2}.$$

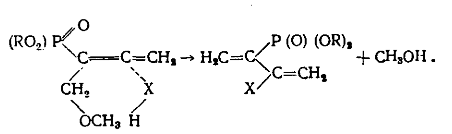
3,3-Disubstituted allenylphosphonates and allenylphosphine oxides are thermodynamically stable and do not isomerise to acetylenic derivatives.[8,78]

The allene–diene isomerisation is observed in the thermal rearrangement of diphosphites with a βγ-acetylenic bond in the common ester residue:[9]



Phosphonoprenes have been obtained by allene–diene isomerisation on distillation of relatively unstable esters of 1-chlorobuta-2,3-dien-2-ylphosphonic and 1-chloro-4-methylpenta-2,3-dien-2-ylphosphonic acids.[38,79]

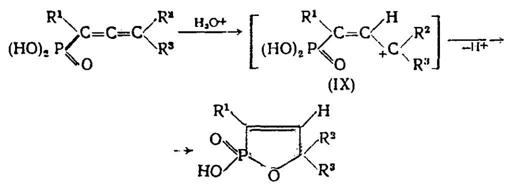
When dialkyl 1-alkoxybuta-2,3-dien-2-ylphosphonates are treated with hydrogen halides, the allene–diene isomerisation takes place with formation of esters of 3-halogenobuta-1,3-diene-2-ylphosphonic acid:[80,81]



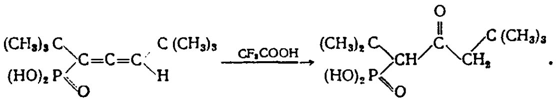
3. Electrophilic Addition

(a) Interaction of Phosphorylallenes with Proton-Donating Reagents

The reactions involving electrophilic addition to phosphorylallenes, in the course of the study of which a new reaction has been discovered, namely heterocyclisation, aroused most interest in recent years. In the study of the reactions of propargyl alcohols with phosphorus tribromide in 1971, it was observed that, when the HBr evolved is not bound by a base, then crystals of 2-bromo-3,5-di-t-butyl-2-oxo-1,2-oxa-3-phospholen are formed from 2,2,6,6-tetramethylhex-4-yn-3-ol.[82] Subsequent investigations demonstrated that the oxaphospholen is formed from phosphonoallene on treatment with proton donors.[13,14] The ease of the acid-catalysed cyclisation of allenylphosphonic acids depends to a large extent on R^2 and R^3 and to a lesser extent on R^1:



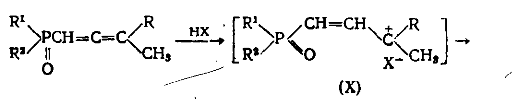
If $R^2 = R^3 = H$, then cyclisation is fully suppressed.[13] A necessary condition for cyclisation is the presence of alkyl substituents at the terminal carbon atom of phosphorylallene. The influence of substituents on the rate of cyclisation has been attributed[13] to the stability of the intermediate carbenium ion (IX), which arises in the stepwise protonation of the double bond; subsequent nucleophilic attack by the phosphoryl oxygen on the carbenium centre leads to the closure of the five-membered ring. Protophilic cyclisation proceeds as a rule regioselectively with attack by the proton on the central atom of the allene system. It might have been thought that not only Brønsted acids but also other electrophiles would promote the cyclisation of allenylphosphonic acids to the more stable oxaphospholen derivatives.[13] However, the attempt to cyclise 1,3-di-t-butylallenylphosphonic acid in trifluoroacetic acid leads to unexpected deviations,[83] which can be explained, according to the authors, by electophilic attack not on the central but on the terminal carbon atom of the allene system:



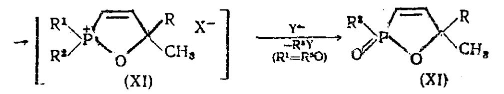
The cuases of the terminal attack by trifluoroacetic acid are not discussed in the above communication. They are most probably associated with the steric hindrance to the protonation of the central *sp*-hybridised carbon atom.

The interaction of allenylphosphonic acids with peracids leads to the formation of a mixture of products containing 4-oxo-1,2-oxaphospholan.[84]

The reactions of proton-donating electrophiles with allenylphosphonic acid esters have been fairly fully investigated.[85–89] The hydrochlorination of the dialkyl esters of 3-alkylalka-1,2-dienylphosphonic acids in polar solvents[85,86] entails cyclisation with formation of 1,2-oxaphospholens, as in the case of the allenylphosphonic acids themselves.[13,14] A general mechanism has been proposed for the cyclisation of 3,3-disubstituted allenylphosphonates in acid media, including the protonation of the central atom of the allene.[87] Subsequent attack by the internal nucleophile on the carbenium ion centre formed in the intermediate (X) leads to the cyclic quasi-phosphonium intermediate (XI) which in the case of alkoxy-substituents at the phosphorus atom is stabilised with elimination of an alkyl halide, analogously to the second stage of the Arbuzov reaction. The formation of the quasi-phosphonium intermediate (XI) in the protophilic cyclisation of phosphorylated allenes has been confirmed by the formation, in a pure state, of the crystalline quasiphosphonium salt (XI) on hydrochlorination of allenylphosphine oxide[88] for which the occurrence of a second stage of the Arbuzov reaction is impossible:



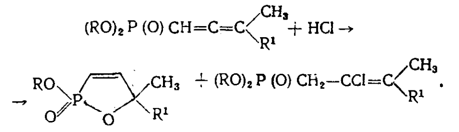
(X)



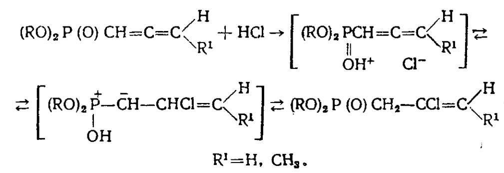
$R{=}R^1{=}R^2{=}CH_3$; $R{=}CH_3$, $R^1{=}CH_3O$, $R^2{=}C_6H_5$, CH_3O;
$R{=}CH_3$, $R^1{=}R^2{=}$iso-C_3H_7; $R{=}C_2H_5$, $R^1{=}R^2{=}CH_3O$;
$X{=}Cl^-$, HSO_4^-, CF_3COO^-;
$Y{=}Cl^-$, HSO_4^-, CF_3COO^-, HO^-, H_2O.

Kinetic study of the reactions of phosphorylallenes with aqueous solutions of sulphuric acid and anhydrous trifluoroacetic acid has shown that the protonation of the multiple bond is the slowest stage of the process considered.[87] The dependence of the rate of reaction on the acidity function of the medium and on the activation parameters indicates an appreciable degree of order in the transition state of the reaction. The acid-promoted cyclisation is an electrophilic addition reaction involving the proton and the substrate in the rate-determining stage. The protonation of the phosphoryl group slows down the reaction as a consequence of the destabilisation of the carbenium ion.

When non-polar solvents are used, products of the addition to the 1,2-double bond in allenylphosphonates are formed in the same amounts as the oxaphospholen derivatives. The yield of the 1,2-adducts reaches 80% when dimethyl sulphoxide is introduced into the reaction mixture as the aprotic ionising additive:[87]



The hydrochlorination of esters of unsubstituted allenylphosphonic acids or the acids monoalkyl-substituted at the terminal carbon atom leads to a complex mixture of open-structure compounds regardless of the polarity of the medium with the preferential formation of the products of addition to the 1,2-double bond of the allene system.[86] The authors postulate that the formation of 1,2-adducts is associated with the difficulty of stabilising the carbenium ion of type (X), which results in the competing reaction involving the nucleophilic addition of HCl:



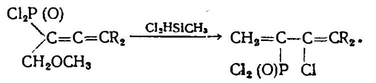
In the hydrochlorination of the dichloride of 3-methylbuta-1,2-dienylphosphonic acid, an oxaphospholen with a pentacoordinate phosphorus atom is formed slowly.[14] In the presence of aprotic ionising additives, the addition of hydrogen chloride to the dihalides of allenyl phosphonic acids leads to the formation of 1,2-adducts[89] and the introduction of alkyl substituents at the C(3) carbon atom of the cumulene system retards the reaction under these conditions. In the hydrochlorination of the dichloride of unsubstituted allenylphosphonic acid, a mixture of products of addition to the 1,2- and 2,3-double bond has been obtained:

$$Cl_2P(O)CH{=}C{=}CH_2 + HCl \rightarrow Cl_2P(O)CH_2CCl{=}CH_2 + Cl_2P(O)CH{=}CCl{-}CH_3.$$
Z and *E*

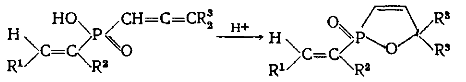
When dichloromethylsilane is used as the hydrochlorinating agent, hydrogen chloride adds to the 1,2- and 2,3-double bonds of the dichlorides of allenylphosphonic acids and a mixture of structural isomers is formed:[40]

$$Cl_2P(O)CH{=}C{=}CR_2 \xrightarrow{Cl_2HSiCH_3} Cl_2P(O)CH_2CCl{=}CR_2 + Cl_2P(O)CH{=}CCl{-}CHR_2.$$

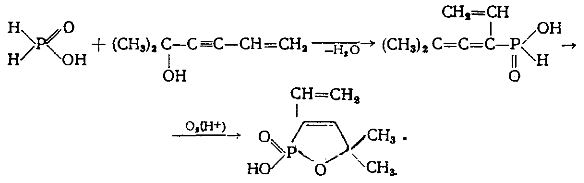
The dichlorides of 1-methoxyalka-2,3-dien-2-ylphosphonic acids react with dichloromethylsilane with the exclusive formation of the dichlorides of 3-chloroalka-1,3-dien-2-ylphosphonic acids:[40]



Highly unsaturated phosphorylallenes are converted into oxaphospholens under severe conditions (>100 °C) in the presence of inorganic acids:[44]

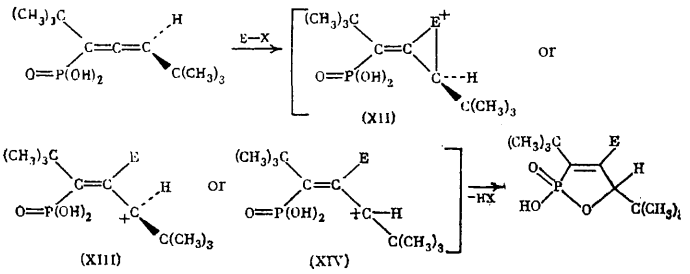


After prolonged heating of a mixture of hypophosphorous acid and Nazarov's carbinol, heterocyclisation takes place with oxidation of the P–H bond by atmospheric oxygen and the formation of 1,2-oxaphospholen:[54]



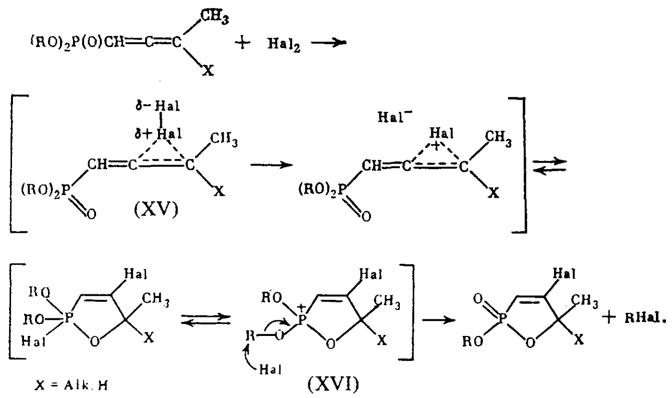
(b) The Interaction of Phosphorylated Allenes with Electrophiles Which Do not Contain a Proton

The hypothesis that phosphorylallenes are able to cyclise to 1,2-oxa-2-phospholens on treatment with not only acids but also other electrophiles[13] has been confirmed in the study of their reactions with bromine and mercury acetate. It was found that these electrophiles act more effectively than the proton-donating electrophiles. Thus 1,3-di-t-butylpropa-1,2-dienylphosphonic acid, which does not form oxaphospholens on treatment with Brønsted acids, readily cyclises on interaction with bromine or mercury acetate.[13] The stereospecificity of the interaction of electrophiles with optically active allenylphosphonic acids (81% for mercury acetate and 41% for bromine) is determined by the ability of the nucleophilic phosphoryl oxygen atom to stabilise the carbonium ion formed, which prevents racemisation. The regioselectivity of the reaction with attack by the electrophile on the central carbon atom can be accounted for by the same cause.



An intermediate in this reaction may be either the cyclic ion (XII) or the non-planar carbenium ion (XIII), which are responsible for the retention of configuration. The slight racemisation of the optically active compound may be caused by the formation of the intermediate planar allyl cation (XIV).

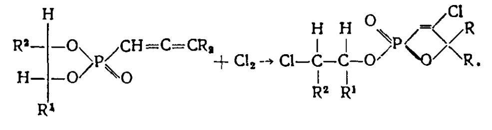
The formation of 1,2-oxa-3-phospholens is observed on interaction of bromine with allenylphosphonic acids.[90] Cyclisation takes place also when esters of 3-mono- and 3,3-di-substituted allenylphosphonic and allenylphosphinic acid are treated with halogens.[90–93] The authors[91] suggest that the π-complex or halogenium ion (XV) arising in the initial stage is converted into the cyclic quasi-phosphonium complex (XVI) as a result of the involvement of the phosphoryl oxygen:



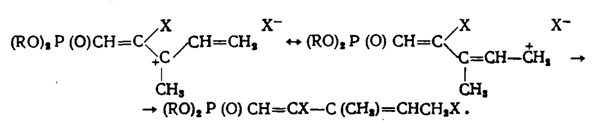
(XV) (XVI)

X = Alk, H

The authors assume that the pentacovalent structure is partly ionised and that the subsequent dissociation of the ion pair produced leads to equilibrium between tetracoordinate and pentacoordinate structures. In the case of alkoxy-groups with smaller moieties both structures are unstable and the system is stabilised by the concluding stage of the Arbuzov reaction—the elimination of the alkyl halide with formation of oxaphospholen. The rate of formation of oxaphospholens depends on the nature of the halogen and diminishes in the sequence ClI > BrI > I_2.[94] It is noteworthy that, in the interaction of allene derivatives of 1,2,3-dioxaphospholans with chlorine, the dioxaphospholan ring is cleaved and β-chloroalkoxy-1,2-oxa-3-phospholens are formed without the elimination of the alkyl chloride:[95]

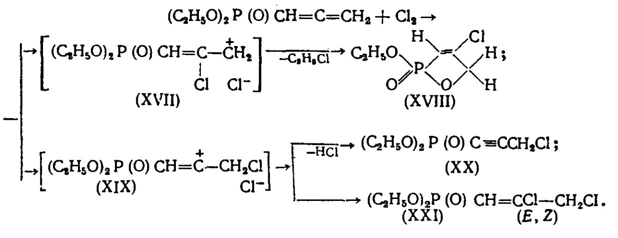


The introduction of the vinyl substituent in the 1- or 3-position in buta-1,2-dienylphosphonate does not alter the mode of interaction with halogens despite the appearance of a new reaction centre in the molecule: 3- or 5-vinyl-substituted 4-halogeno-1,2-oxa-3-phospholens are formed.[96,97] The esters of penta-1,2,4-trienylphosphonic acid afford on halogenation a small amount of 1,4-adducts together with oxaphospholens. This mode of addition has been explained by the authors by the possibility of the resonance stabilisation of the allyl cation:[97]



$(RO)_2P(O)CH{=}CX{-}C(CH_3){=}CHCH_2X$.

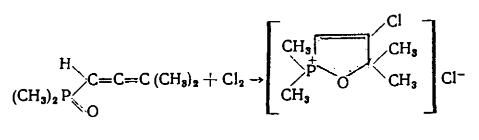
When the diethyl ester of propadienylphosphonic acid is chlorinated, a complex mixture of products is formed[92] in which it was possible to detect by NMR the oxaphospholen (XVIII), the ester of 3-chloroprop-1-ynylphosphonic acid (XX), and the ester of 2,3-dichloroprop-1-enylphosphonic acid (XXI) (the *E*- and *Z*-isomers) in the proportions (XVIII) : (XX) : (XXI) = 2 : 3 : 1. The mixture also contains a small amount of diethyl *E*-2-chloropropenylphosphonate. The formation of the ion (XIX) as an intermediate, together with the ion (XVII), leads to open-chain compounds:



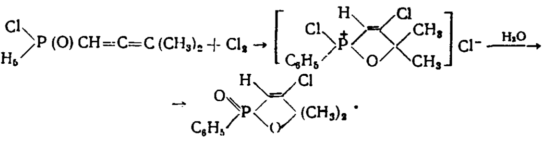
(XVII) (XVIII) (XIX) (XX) (XXI)

The introduction of electron-donating alkyl groups entails a significant difference between the energetic stabilities of the ions of the two types, which virtually rules out the formation of the intermediate (XIX).[91]

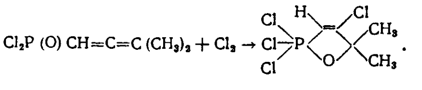
In the chlorination of buta-1,2-dienylphosphine oxides, the second stage of the Arbuzov reaction is impossible, as a result of which stable quasi-phosphonium salts are formed:[98]



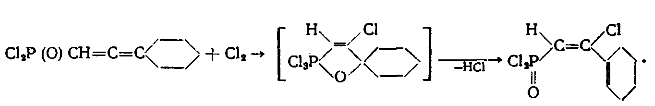
However, the chlorination of diphenylalka-1,2-dienylphosphine oxides, substituted and unsubstituted at the terminal carbon atom, leads to adducts with an open structure. The authors explained this mode of reaction by steric hindrance arising, owing the the presence of the bulky phenyl groups, in the overlap of the p-orbitals of the phosphoryl oxygen with the p orbital of the carbenium ion formed in the intermediate stage. The replacement of one phenyl group by the more electron-accepting chlorine atom leads to the formation of a ring:[98]



Cyclic phosphoranes—oxaphospholens with a pentacoordinate phosphorus atom—are formed when the chlorides of alka-1,2-dienylphosphonic acids are chlorinated:[99–102]

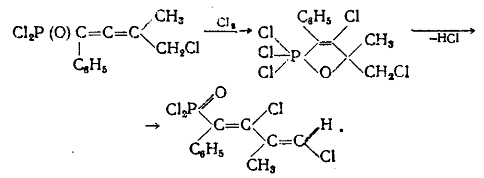


In the interaction of bromine the formation of a phosphorane cannot be observed possibly as a consequence of the more polar structure, compared with that of the phosphorane, of the bromo-derivatives of phosphorus.[100] On heating or storage, compounds of the phosphorane type split off HCl and are converted into 1,3-diene derivatives:[100–102]



The chlorination of the dichlorides of 1,3,3-trisubstituted allenylphosphonic acids also affords products with the

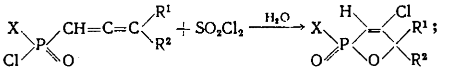
1,3-diene structure,[40,103–105] for example:



The chlorination of the dichloride of 1-t-butyl-4-chloro-3-methylbuta-1,2-dien-1-ylphosphonic acid leads to the formation of a stable quasi-phosphonium salt and the product of addition to the 2,3-double bond.[105] The stabilisation of the phosphonium salt is achieved as a consequence of the electronic and steric effects of the t-butyl group.

The interaction of chlorine with the dichloride of propyldienylphosphonic acid leads mainly to the formation of products of addition to the 2,3-double bond with an open structure.[92]

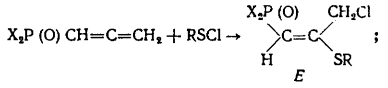
The interaction of the chlorides of 3-mono- and 3,3-disubstituted allenylphosphonic acids with sulphuryl chloride entails the formation of 1,2-oxaphospholens:[98,106]



X=Cl, C_6H_5.

A complex mixture of products of addition to one and two double bonds is formed in the chlorination of the dichloride of allenylphosphonic acid by sulphuryl chloride.[106]

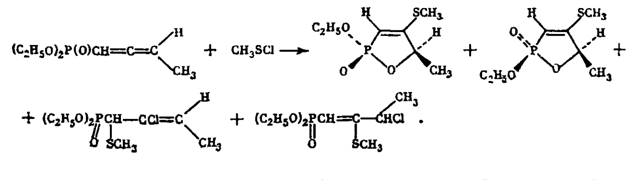
The addition of arene- and alkane-sulphenyl chlorides to the esters and dichloride of 3,3-unsubstituted allenylsulphonic acid and also to allenyldiphenylphosphine oxide takes place regioselectively and stereospecifically. Attack on the 2,3-double bonds of the cumulene takes place in the sterically more favourable *anti*-position relative to the bulky phosphoryl group located in the plane of the reacting double bond, with formation of mainly the *E*-isomer:[107–110]



X=AlkO, Cl, C_6H_5; R=C_6H_5, p-$CH_3C_6H_4$, Alk.

Similarly, selenyl chlorides form 2,3-adducts on interaction with allenylphosphonates but the *Z*-isomer predominates in the case of benzeneselenyl chloride.[111]

The introduction of alkyl substituents in the 3-position in phosphorylallene alters the mode of reaction. The ester of 3-monosubstituted allenylphosphonic acid reacts with arene- and methanesulphenyl chlorides to form diastereoisomeric oxaphospholens and also products of addition to the 1,2- and 2,3-double bonds of the cumulene in proportions of 4:1:1:1:[110]

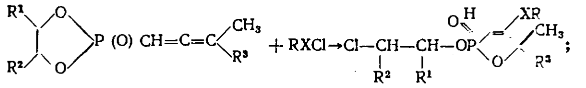


The orientation of the methylthio-group and of the chlorine atom in the 1,2-adduct has been confirmed by comparing the experimental chemical shifts of the proton at the olefinic carbon with the theoretical calculations. The diastereoisomeric oxaphospholens and products of addition to the 2,3-double bonds were not detected in the study of Angelov et al.[112] and a structure with the opposite positions of the alkylthio-group and the chlorine atom, compared with that found by Khusainova et al.,[110] was attributed to the product of addition to the 1,2-double bond.

Methaneselenyl chloride reacts with 3-monosubstituted allenylphosphonate to form an adduct at the 2,3-double bond and a small amount of a cyclic product (10%), while benzeneselenyl chloride affords exclusively the oxaphospholen.[111]

The esters of 3,3-disubstituted allenylphosphonic acids interact with alkane-, arene-,[107,113,114] and phosphonosulphenyl chlorides[110] and also with their selenium analogues[115,116] to form cyclic 4-organylthio(seleno)-1,2-oxa-3-phospholens with elimination of alkyl halides.

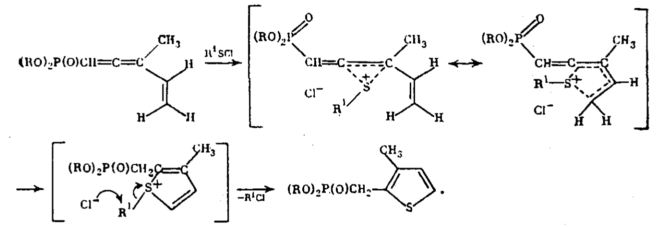
The reactions of sulphenyl and selenyl chlorides with 2-(alka-1,2-dienyl)-1,3,2-dioxaphospholan 2-oxides take place with cleavage of the dioxaphospholan ring and the formation of 1,2-oxaphospholens:[117]



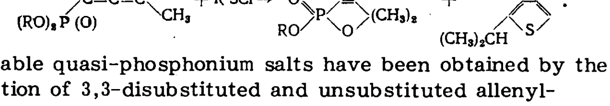
X = S or Se; R=CH_3, iso-C_3H_7; R^1, R^2, R^3=Alk.

Very small amounts of 1,2-adducts of methanesulphenyl chloride with 3-alkyl-3-methylallenylphosphonates have also been detected by column chromatography in the form of a mixture of *E*- and *Z*-isomers;[118] selenyl chloride interacts exclusively via the heterocyclisation mechanism.

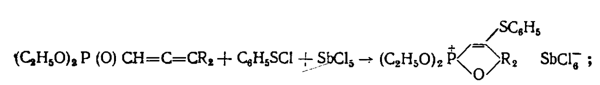
The introduction of the vinyl group into 3-methylpropa-1,2-dienylphosphonate at the C(3) carbon atom leads to the formation of phosphonylated thiophens in the reactions with alkanesulphenyl chlorides:[119]



1,3,3-Trisubstituted allenylphosphonates react with alkanesulphenyl chlorides to form 4-alkylthio-1,2-oxa-3-phospholens.[112] However, when the substituent at the C(1) carbon atom of the allene is a phenyl group, then linear products of the 2,3-addition of alkanesulphenyl chloride are formed together with oxaphospholens.[112] When the vinyl substituent is introduced into the geminal position relative to the phosphoryl group, the reaction of 1,3,3-trisubstituted phosphonoallene with alkanesulphenyl chlorides leads to the formation of a mixture of two heterocycles—thiophen and oxaphospholen:[120]

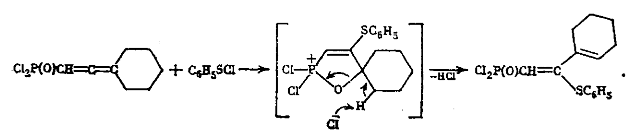


Stable quasi-phosphonium salts have been obtained by the reaction of 3,3-disubstituted and unsubstituted allenylphosphonates with benzenesulphenyl chloride in the presence of $SbCl_5$:[121]



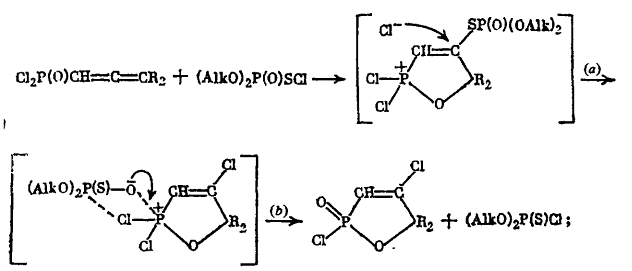
R = CH_3, H.

In contrast to esters, the dichlorides of 3,3-disubstituted allenylphosphonic acids form products with a diene structure on interaction with arenesulphenyl chlorides:[107,109]



Areneselenyl chlorides react with the dichloride of cyclohexylidenevinylphosphonic acid in the presence of SO_2 to form five-membered heterocycles.[116]

Phosphonosulphenyl chlorides react with the dichloride of 3,3-disubstituted allenylphosphonic acids to form 2,4-dichloro-oxaphospholen and the chlorides of the corresponding phosphorothioic acids, apparently via the following mechanism:[110]



$R{=}CH_3$, $R_2{=}(CH_2)_5$; Alk = CH_3, iso-C_3H_7.

Nucleophilic substitution of the "readily removed" thiophosphoryl group by the chloride anion takes place in stage (*a*). In stage (*b*) the ambident phosphorothioate anion attacks via its harder centre (the oxygen atom) the electrophilic phosphorus atom, which leads to the formation of dichloro-oxaphospholen and phosphorochloridothioate.

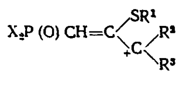
Together with the hypothesis of the formation of various open-chain and cyclic products in the reactions of phosphorylated allenes with sulphenyl chlorides, put forward as a possible explanation in a number of studies,[13,95,107] the following scheme has been discussed.[110] Four directions of attack on the allene system by the sulphenyl chloride molecule are possible in principle: at the 1,2- and 2,3-double bond in the *syn*- and *anti*-positions relative to the bulky substituent R^3 or P=O located correspondingly in the plane of the reacting double bond. Taking into account the electronic and steric factors, one can assume that there is a greater probability of attack by the sulphenyl chloride on the more nucleophilic 2,3-double bond of the phosphorylallene in the *anti*-position relative to the phosphoryl group [pathway (*a*) in the Scheme]. The nucleophilic cooperation of the phosphoryl oxygen in the attack by the sulphenyl chloride greatly facilitates the process and leads to the formation of the quasi-phosphonium intermediate (XXII). Subsequent attack by the chloride anion on the possible electrophilic centres of the quasi-phosphonium intermediate determines three main reaction pathways:

(1) If R^2, R^3 = H, then, regardless of the character of the substituents at the phosphorus atom, the attack by the chloride anion is directed to the carbon atom in the 5-position in the ring, which is the most electrophilic centre in the intermediate. This leads to intramolecular dealkylation with opening of the ring and the formation of the product of addition to the 2,3-double bond of the open-chain structure.

(2) When R^2, R^3 = Alk and X = AlkO, the attack by the chloride anion is directed to the carbon atom of the alkoxy-group and, in conformity with the second stage of the Arbuzov reaction, the quasi-phosphonium salt is dealkylated with elimination of the alkyl chloride and the formation of an oxaphospholen. When R^3 = H and X = OC_2H_5, the electrophilicities of the carbon atom of the alkoxy-group and of the C(5) atom of the intermediate are probably similar and for this reason the competing intramolecular and intermolecular dealkylation reactions take place and linear and cyclic products are formed.

(3) When R^2, R^3 = Alk and X = Cl, Alk, whereupon the second stage of the Arbuzov reaction is impossible, the attack by the chloride anion is directed to the hydrogen atom of one of the alkyl substituents in the 5-position in the ring. HCl is eliminated and products with a diene structure are formed.

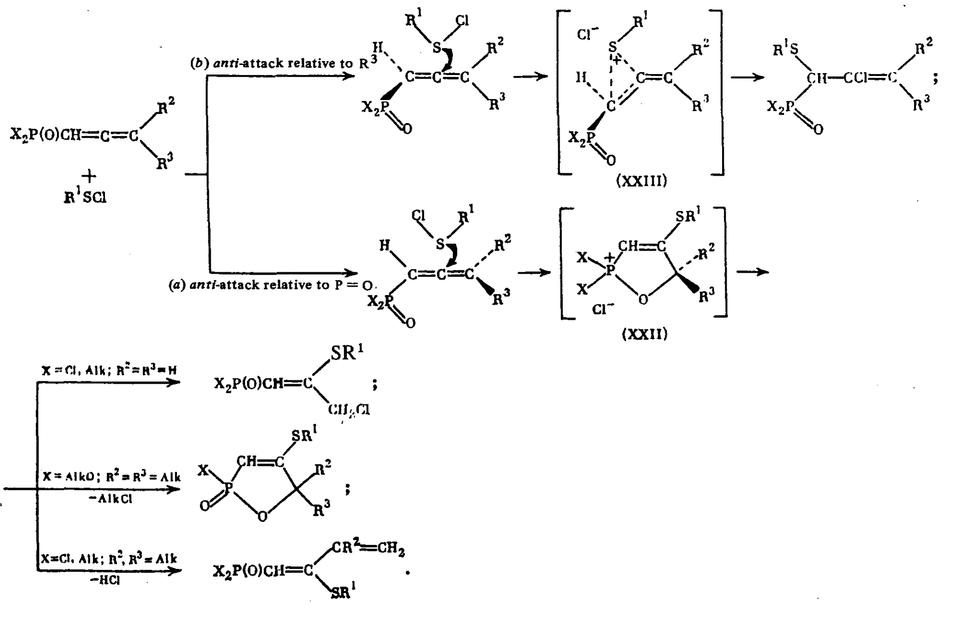
However, one cannot rule out the possibility that the formation of the 2,3-adduct and products with a diene structure is caused by the appearance of the carbenium ion



$$X_2P(O)CH{=}C(SR^1)\overset{+}{C}R^2R^3$$

and takes place by-passing the quasi-phosphonium salt (XXII) stage.[107,118]

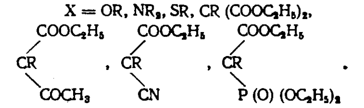
Scheme



The formation of 1,2-adducts can be accounted for solely by the attack by the sulphenyl chloride on the 1,2-double bond via pathway (*b*). According to generally accepted ideas,[122] the addition proceeds via the formation of a cyclic ion (XXIII) as an intermediate.[110,118] It may be that the addition takes place via a carbenium ion, which arises following the opening of the cyclic ion (XXIII).

4. Nucleophilic Addition to Phosphoryl Allenes

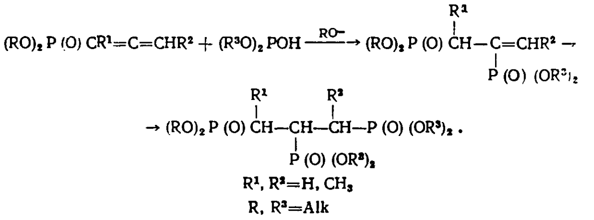
In the presence of alkali metal alkoxides, alcohols, dialkylphosphorous acids,[123,124] mercaptans,[125] and CH acids (acetoacetic and malonic esters and their homologues and cyanoacetic and phosphonoacetic esters)[125] readily add to the esters of 3,3-disubstituted allenylphosphonic acids at the 1,2-double bond activated by the electron-accepting phosphoryl group. Amines add in the absence of alkoxides also at the 1,2-double bond:[124]



$$(RO)_2P(O)CH{=}C{=}C(CH_3)_2 + XH \xrightarrow{RONa} (RO)_2P(O)CH_2{-}CX{=}C(CH_3)_2\,;$$

$$X = OR,\ NR_2,\ SR,\ CR(COOC_2H_5)_2,$$

The attack by the nucleophilic anion is directed to the central *sp*-hybridised carbon atom of the cumulene. The structure of the adducts has been demonstrated by their ozonisation, by oxidation with potassium permanganate, and by hydrolysis.[124] The degree of the addition reaction and the structure of the products formed are determined by the degree of substitution at the sp^2-hybridised carbon atoms of the allenylphosphonates. Thus only one dialkyl phosphite molecule adds to the 1,2-double bond of the esters of 3-methylbuta-1,3-dienylphosphonic acid with formation of the corresponding bisphosphonates.[124] In the case of buta-1,2-dienylphosphonic acid, small amounts of trisphosphonates are formed together with the bisphosphonates, the yield of the former increasing when esters of buta-2,3-dien-2-ylphosphonic acid are used[126]



$$(RO)_2P(O)CR^1{=}C{=}CHR^2 + (R^3O)_2POH \xrightarrow{RO^-} (RO)_2P(O)\overset{\displaystyle R^1}{\overset{|}{C}}H{-}\underset{\underset{\displaystyle P(O)(OR^3)_2}{|}}{C}{=}CHR^2 \rightarrow$$

$$\rightarrow (RO)_2P(O)\overset{\displaystyle R^1}{\overset{|}{C}}H{-}\underset{\underset{\displaystyle P(O)(OR^3)_2}{|}}{C}H{-}\overset{\displaystyle R^2}{\overset{|}{C}}H{-}P(O)(OR^3)_2\,.$$

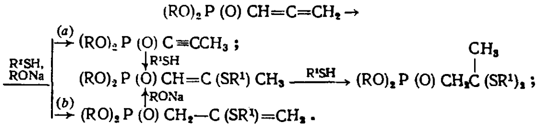
$$R^1, R^2{=}H, CH_3$$

$$R, R^3{=}Alk$$

These differences can be explained by the decrease of the steric hindrance in the sequence:[126]

The esters of 3,3-unsubstituted allenylphosphonic acid combine with dialkyl phosphites to form, together with trisphosphonates, mixtures of the isomeric bisphosphonates: 1,2-bis(dialkylphosphono)prop-2-ene and 1,2-bis(dialkylphosphono)prop-1-ene.[126] Evidently, the partial prototropic allene–acetylene isomerisation of propadienylphosphonate to propynylphosphonate with the subsequent addition of the dialkyl phosphite to the triple bond leads to the formation of 1,2-bis(dialkylphosphono)prop-1-enes. ^{1}H NMR data have shown that the addition of dialkyl phosphites to 3-monosubstituted allenylphosphonates is not accompanied by the migration of the 2,3-double bond: it is retained in the adduct and the *cis*-disposition of the proton and the phosphoryl group is observed.

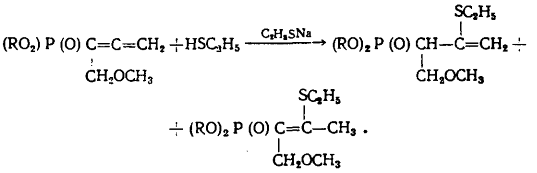
Isomerisation is likewise not observed in the addition of a mercaptan to diethyl buta-1,2-dienylphosphonates.[127] Propadienylphosphonates interact with mercaptans to form adducts with one and two addend molecules.[127] The formation of such adducts is possible also in the prototropic isomerisation of the products of addition to the 1,2-double bond of the cumulene, formed initially, to the thermodynamically more stable 1-dialkylphosphono-2-organylthioprop-1-ene [pathway (*b*)]:



$$(RO)_2P(O)CH{=}C{=}CH_2 \rightarrow$$

$$\xrightarrow[RONa]{R^1SH,}\left|\begin{array}{l} \xrightarrow{(a)} (RO)_2P(O)C{\equiv}CCH_3\,; \\ \qquad\qquad \downarrow R^1SH \\ \quad (RO)_2P(O)CH{=}C(SR^1)CH_3 \xrightarrow{R^1SH} (RO)_2P(O)CH_2\overset{\displaystyle CH_3}{\overset{|}{C}}(SR^1)_2\,; \\ \qquad\qquad \uparrow RONa \\ \xrightarrow{(b)} (RO)_2P(O)CH_2{-}C(SR^1){=}CH_2\,. \end{array}\right.$$

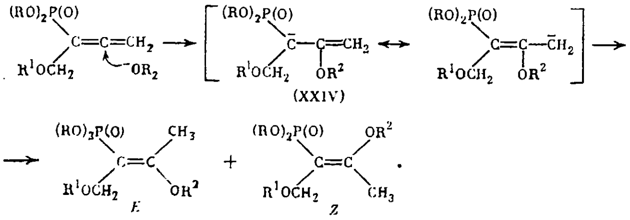
The interaction of dialkyl 1-methoxybuta-2,3-dien-2-ylphosphonates with ethanethiol in the presence of sodium mercaptide results in the formation of 3-ethylthio-1-methoxybut-3-en-2-ylphosphonates. The latter readily undergo prototropic transformations with migration of the double bond to the phosphonate group and the formation of 3-ethylthio-1-methoxybut-2-en-2-ylphosphonates:[128]



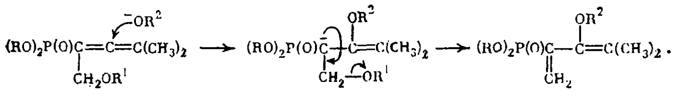
$$(RO_2)P(O)\underset{\underset{\displaystyle CH_2OCH_3}{|}}{C}{=}C{=}CH_2 + HSC_2H_5 \xrightarrow{C_2H_5SNa} (RO)_2P(O)\underset{\underset{\displaystyle CH_2OCH_3}{|}}{C}H{-}\overset{\displaystyle SC_2H_5}{\overset{|}{C}}{=}CH_2 +$$

$$+ (RO)_2P(O)\underset{\underset{\displaystyle CH_2OCH_3}{|}}{C}{=}\overset{\displaystyle SC_2H_5}{\overset{|}{C}}{-}CH_3\,.$$

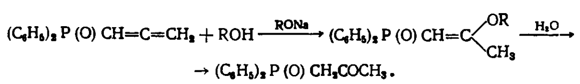
The addition of alcohols to 1-alkoxybuta-2,3-dien-2-ylphosphonates leads to the formation of the isomeric *E*- and *Z*-esters of 1,3-dialkoxybut-2-enylphosphonic acid (*E* : *Z* = 2 : 1).[39,129] Evidently, the composition of the product is determined by the thermodynamic control of the reaction with the intermediate formation of the carbanion (XXIV):



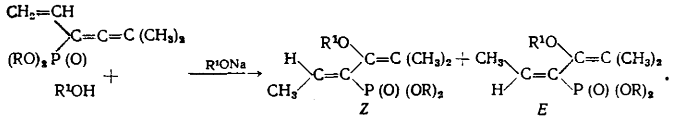
It is noteworthy that the interaction of alcohols with 1-alkoxy-4-methylpenta-2,3-dienylphosphonates results in the formation of 3-alkoxy-2-phosphonoalka-1,3-dienes:[129]



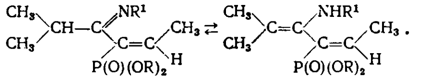
Unsubstituted phosphorylallenes combine with one alcohol molecule:[130]



3-Methyl-1-vinylbuta-1,2-dienylphosphonates readily interact with alcohols[131,132] to form 1,4-adducts, which are mixtures of the *E*- and *Z*-isomers:

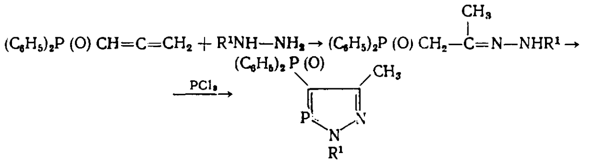


The interaction of secondary amines with 3-methyl-1-vinylbuta-1,2-dienylphosphonates also makes it possible to obtain diene phosphonates with the *trans*-disposition of the methyl and phosphoryl groups, whose formation is possible either as a result of addition to the 1,2-double bond of the allene and subsequent prototropic isomerisation or as a consequence of 1,4-addition. The use of primary amines in these reactions leads to the formation of a tautomeric mixture of imines and enamines:[133]

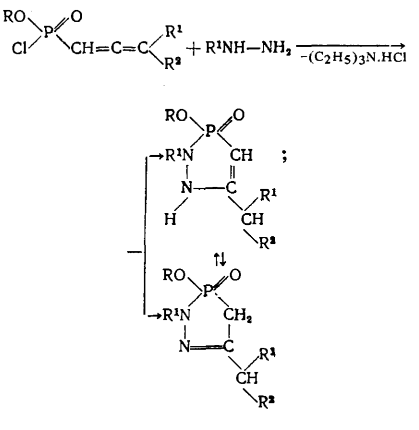


Dialkyl 1-methoxybuta-2,3-diene-2-ylphosphonates react with diethylamine to form 3-diethylaminobuta-1,3-dien-2-ylphosphonates.[134]

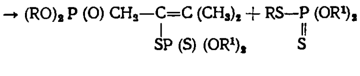
Interesting results have been obtained in the study of the interaction of phosphorylallenes with hydrazines:[130,135]



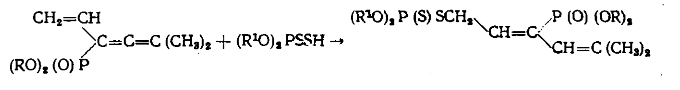
The use of the mono- and di-chlorides of allenylphosphonic acids in these reactions leads to intramolecular cyclisation:



OO-Dialkylphosphorodithioic acids interact with allenylphosphonates to form mixtures of products of addition to the 1,2-double bond of the cumulene and alkylation products—the full phosphorodithioate esters:[136]



In the reaction of 3-methyl-1-vinylbuta-1,2-dienylphosphonate the mode of addition of dialkylphosphorodithioic acids changes:[137]

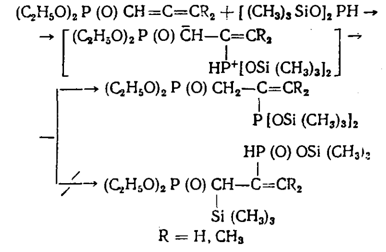


In a study of the interaction of vinylallenylphosphonates with acetylacetone, which is a CH acid, 1,2,4,5-disubstituted [tetrasubstituted? (Ed. of Translation)] benzenes were obtained unexpectedly in addition to the 1,4-adducts.

Alcohols, diethylamine,[139,140] and piperidine[141] add to the 1,2-double bond in quaternary 3-monosubstituted allenylphosphonium salts. The interaction of allylmercaptan with quaternary allenylphosphonium salts results in the formation of a mixture of products of addition to the 1,2- and 2,3-double bonds of the cumulene, which is associated with the partial prototropic isomerisation of the 1,2-adduct formed initially.[140]

5. Reactions With Derivatives of Tervalent Phosphorus

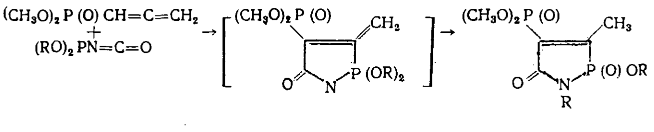
In the reaction of propa-dienyl- and 3-methylbuta-1,2-dienylphosphonates with bis(trimethylsilyl) hypophosphite the nucleophilic attack by the tricoordinate phosphorus is directed to the central carbon atom of the allene system. The intermediate dipolar ion is stabilised as a result of the migration of a proton:[142]



The prototropic isomerisation of propadienylphosphonate to propynylphosphonate is not observed under the reaction conditions.

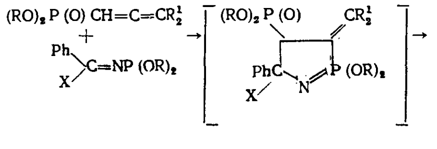
The reactions of allenylphosphonates with tervalent phosphorus derivatives containing an αβ-unsaturated fragment constitute a convenient method of synthesis of organophosphorus heterocycles.[2] The extensive experimental data which have accumulated hitherto on the reactions of these or "organophosphorus 1,3-dipoles" with alkenes and alkynes suggest that the interaction proceeds as a two-stage process and not as concerted [3 + 2]cycloaddition.

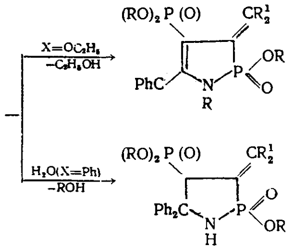
Dialkyl phosphoroisocyanatidite adds to the 1,2-double bond of allenylphosphonates:[143]



It is noteworthy that, under the cycloaddition conditions, the phosphoroisocyanatidite does not catalyse the isomerisation of allenylphosphonate to propynylphosphonate.

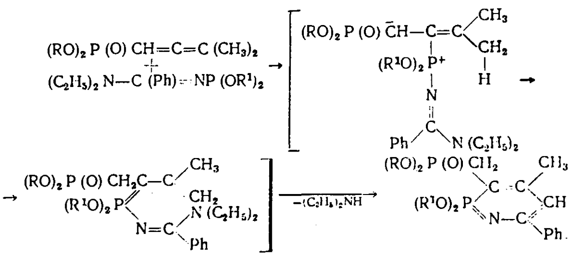
The reactions of *N*-diphenyl- and *N*-phenylethoxymethylenephosphoramidites with 3,3-disubstituted allenylphosphonates lead to the formation of the hydrolytically unstable five-membered azaphospholens with a P=N bond:[144]



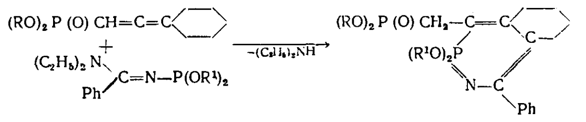


X=Ph, OC_2H_5;
$R^1=CH_3$, $R_2^1 = (CH_2)_5$

However, *N*-phenyl(diethylamino)methylenephosphoramidites give rise to stable six-membered azaphosphorines under the same conditions in accordance with the following scheme:[145]

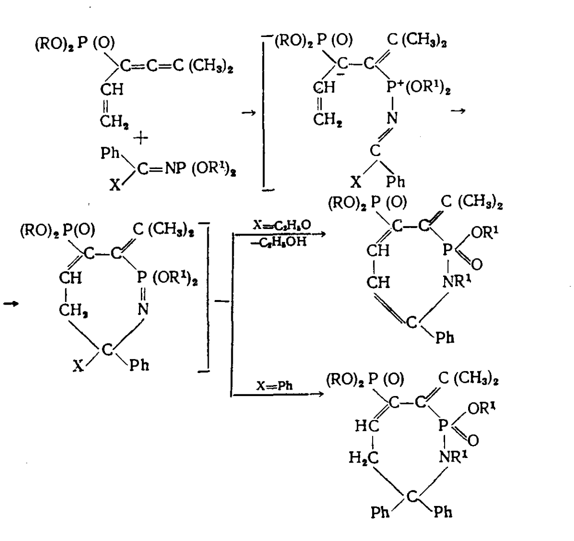


The reaction apparently begins with nucleophilic attack by the tervalent phosphorus atom on the central carbon atom of the allene system. The dipolar ion formed is stabilised by prototropic isomerisation and cyclisation with elimination of diethylamine. The interaction of cyclohexylidenevinylphosphonate with *N*-phenyl(diethylamino)methylenephosphoramidite results in the formation of a bicyclic adduct:

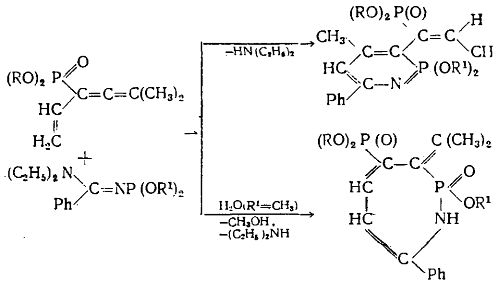


$R=CH_3$, C_2H_5, iso-C_3H_7; $R^1=CH_3$, C_2H_5

The introduction of a new reaction centre into the molecule of the 3,3-disubstituted allenylphosphonate (the vinyl group) results in the participation of the latter in the stabilisation of the intermediate dipolar ions formed in the reaction of 3-methyl-1-vinylbuta-1,2-dienylphosphonates with *N*-diphenyl- and *N*-phenyl(ethoxy)-methylenephosphoramidites:[146]



The structure of the seven-membered phosphepins was established by analysing their ^1H and ^{31}P NMR and mass-spectrometric data. 3-Methyl-1-vinylbuta-1,2-dienylphosphonates react with *N*-phenyl(diethylamino)methylenephosphoramidites to form six-membered azaphosphorines[146] similarly to 3-methylbuta-1,2-dienylphosphonates. However, this reaction pathway is not the only one: signals indicating the formation of azaphosphepines have been detected in the ^1H NMR spectrum of the reaction mixture. Crystalline azaphosphepine is the main product of the reaction of diethyl 3-methyl-1-vinylbuta-1,2-dienylphosphonate with dimethyl *N*-phenyl(diethylamino)methylenephosphoramidite:



Propadienylphosphonate does not react with *N*-methylenephosphoramidites, isomerising to propynylphosphonate in their presence.[145]

---o0o---

It follows from the data examined that phosphorylated allenes can be used successfully in the synthesis of a wide variety of organophosphorus compounds. By varying the degree of substitution and the character of the substituents at the sp^2-hybridised carbon atoms of phosphoryl allenes, it is possible to activate a particular unsaturated reaction centre in the molecule. As a result of the introduction of the electron-accepting phosphoryl group into the allene molecule, the initial step of the reaction with nucleophiles is attack by the anion on the central carbon atom of the cumulene with the subsequent addition of a proton to the C(1) carbon atom. The stability of the product formed depends to a large extent on the character of the substituents at the C(3) carbon atom of the allene and on the basicity of the reacting anion, which promotes to some extent the prototropic isomerisation. The addition of electrophiles proceeds mainly at the 2,3-double bond of phosphorylallenes, also with the initial attack on the central *sp*-hybridised carbon atom, and, depending on the character of the substituents at the C(1) and C(3) atoms, leads to the formation of either products having open-chain alkene or diene structures or to heterocycles with participation of the phosphoryl group.

Thermodynamic Compatibility of Polymers

A.A.Tager and V.S.Blinov

It is shown on the basis of an examination of studies carried out in recent years that, by a correct thermodynamically well-founded choice of polymers between which hydrogen bonds can be formed or which can give rise to electron donor-electron acceptor complexes, it is possible to create thermodynamically compatible systems; compatibility can also be improved by mixing homopolymers with copolymers. Various thermodynamic situations observed on blending polymers and the temperature dependence of their thermodynamic compatibility are discussed.

The bibliography includes 172 references.

I. INTRODUCTION

The main trend in the modern technology of the processing of polymeric materials involves their preparation from mixtures (blends) of polymers. The thermodynamic compatibility of polymers with one another, to which numerous studies surveyed in monographs, reviews, and text books have been devoted, plays a major role in this.[1-16] However, new aspects have recently arisen concerning the methods of determination of the thermodynamic compatibility of polymers, its causes, procedures for its enhancement, and its temperature dependence.

The term "compatibility", borrowed from technological practice, is usually understood as the miscibility of polymers. The authors of a monograph[2] believe that, in relation to polymer blends, the term is inept and they have suggested that it be replaced by the term "miscibility". They suggest that one can speak of miscibility only in the case of an ideal solution whose formation is possible solely following the interaction of low-molecular-weight substances. However, in essence, this is incorrect because the formation of an ideal solution is an extremely rare phenomenon and true real solutions of low-molecular-weight substances are non-ideal in the vast majority of cases.[17] Nevertheless, the concepts of "solubility" and "miscibility", which are identical, are applied to them. Evidently in the case of polymer compositions there is also no point is distinguishing these two concepts and the terms "mutual solubility" and "miscibility" should be regarded as synonymous. By thermodynamic compatibility we shall understand (a) the ability of the components to mix with one another spontaneously with formation of a true solution, i.e. their thermodynamic affinity relative to one another, and (b) a transition from possibility to reality, i.e. the realisation of the above affinity which leads to the miscibility of the components.

The thermodynamic compatibility of polymers is estimated by thermodynamic and non-thermodynamic methods. The latter include methods for the investigation of the phase structures of blends—electron microscopy and X-ray diffraction and also all the methods for the determination of the glass point of blends which yield information about the independent behaviour of the components in incompatible compositions. However, it is more correct to estimate thermodynamic compatibility by thermodynamic methods, i.e. to determine the thermodynamic affinity and phase diagrams for polymer–polymer systems.

II. THERMODYNAMIC AFFINITY BETWEEN POLYMERS

The thermodynamic affinity between a polymer and a solvent is estimated quantitatively in terms of changes in the chemical potential of the components $\Delta\mu_i$ or its excess value μ_i^e, the Gibbs free energy of mixing ΔG or its excess value G^e, the Flory–Huggins interaction parameter χ_1, and the second virial coefficient A_2.

The same parameters also characterise the thermodynamic affinity between polymers. They can be determined experimentally by studying the static and dynamic sorption of the vapour of a liquid on individual polymers and their blends, the dissolution of different polymers in a common solvent, the mutual diffusion coefficient of the polymers, etc.

The methods of the static sorption of the vapour of a common solvent was first used to estimate the thermodynamic affinity of two polymers by Kwei et al.,[18] who calculated the interaction parameter χ'_{23} from the sorption isotherm by Scott's equation:[19]

$$\ln a_1=\ln \varphi_1+(1-\varphi_1)+(\chi_{12}\varphi_2+\chi_{13}\varphi_3)(1-\varphi_1)-\chi'_{23}\varphi_2\varphi_3 \qquad (1)$$

where χ_{12} and χ_{13} are the parameters of the interaction of the polymer (2) and the polymer (3) with the common solvent (1) when the latter is sorbed on the polymer, a_1 is the activity coefficient of the solvent in the three-component polymer–polymer–solvent system, which is determined in the sorption of the vapour of the solvent on the polymer blends, and ϕ_1, ϕ_2, and ϕ_3 are the volume fractions of the solvent and the polymers (2) and (3) in the three-component composition.

It has been shown[19] that the critical value of χ'_{23} for the polymer–polymer system tends to zero. This means that any positive value of χ'_{23} characterises the incompatibility of the polymers.

Eqn.(1) has been used to estimate the compatibility of a series of systems on the basis of the sorption isotherms of the vapours of various substances.[20-22] The calculation for cellulose nitrate (CN)–poly(vinyl acetate) (PVAC) systems leads to negative values of χ'_{23}, which are consistent with data obtained by other methods and indicate the compatibility of these polymers.[21] However, negative values have also been obtained for incompatible systems. The authors suggest that Scott's equation (1), derived on the basis of the Flory–Huggins theory proposed for the model of a true solution of polymers, describes only compatible single-phase polymer systems, the theory being inapplicable to two-phase colloidal systems.

In this respect, the method involving the determination of the Gibbs free energy of mixing of polymers, proposed by Tager and co-workers,[23,24] has an undoubted advantage. The method requires no models and is based solely on the assumption that the Gibbs free energy is a function of state of the system and is independent of the path followed by the process. For this reason, the Gibbs free energy can be calculated from the thermodynamic equation

$$-\Delta g_x = \Delta G_{III} - (\omega_1 \Delta G_I + \omega_2 \Delta G_{II}), \qquad (2)$$

where Δg_x is the average Gibbs free energy of mixing of the polymers, ΔG_I, ΔG_{II}, ΔG_{III} are the Gibbs free energies of respectively 1 g of each polymer and their mixtures with the vapour of a common solvent (sorbate) having different compositions, and ω_1 and ω_2 are the weight fractions of the polymers in the polymer composition.

This method has been described in detail in original papers,[23,24] monographs, and textbooks.[2,3,16] It has been applied to polymer–oligomer[25] and polymer–polymer[26–29] systems, interpenetrating networks,[30,31] and graft[32] and block copolymers.[33–35] The physical significance of the quantities calculated by Eqn.(2) has been discussed.[35,36] For block copolymers, the quantity Δg_x reflects the work necessary to mix the blocks and is equal in magnitude but opposite in sign to the work of their separation, which has been calculated theoretically.[37,38] For polymer blends, Δg_x is an integral quantity, which depends on the chemical structure and the degree of dispersion of the system components. According to Gibbs,[39–42] any extensive thermodynamic property of a two-phase system can be regarded as the sum of three contributions: by the phase α, the phase β, and the interfacial region.

If the interface, which represents a conventional geometrical surface, is two-dimensional (has no volume), then the average Gibbs free energy of mixing, i.e. the energy per gram of the mixture, is defined by the expression

$$\Delta g_x = \Delta g_\alpha + \Delta g_\beta + \sigma S, \qquad (3)$$

where Δg_α and Δg_β are the average Gibbs free energies of mixing in each phase, σ is the surface tension, and S the specific area of the interface.

Since it is known that the interfacial tensions in polymer blends are very low,[43] the last term of Eqn.(3) does not contribute significantly to Δg_x, as shown by Kuleznev.[44]

However, for real two-phase systems the interface is not two-dimensional and has a definite thickness and volume. It is especially important to take this into account in relation to polymer systems where the thickness of the transition layer may be considerable.[3,45,46] In this case it is more correct to use Guggenheim's method,[40–42] which leads to the differential equation[36]

$$dg_x = dg_0 + \underbrace{[\sigma + (\mu_1 dc_1 + \mu_2 dc_2) h]}_{dg_s} S, \qquad (4)$$

where μ_1, μ_2, c_1, and c_2 are the chemical potentials and concentrations of the components in the transition layer, h is the thickness of the transition layer, and dg_0 the Gibbs free energy of mixing, which is independent of the degree of dispersion and is related solely to the chemical structure of the components and their affinity for one another. The second term of Eqn.(4) reflects the contribution of the structural factors, including the degree of dispersion and the volume of the transition layer. When there is a high affinity between the components and the latter are fully miscible, $S = 0$ and the second term is zero. Then $dg_x = dg_0$. In the complete absence of affinity (polymerophobic behaviour), $dg_0 = 0$ and dg_x is equal to the work of dispersion and depends on the degree of dispersion. In the intermediate cases, dg_x is given by the sum of both contributions: $dg_0 < 0$, $dg_s > 0$. The magnitude and sign of dg_x depend on the ratio of these quantities.

The method of dynamic sorption or reversed gas chromatography (RGC), which has been described in detail in books[47,48] and reviews,[49,50] is used widely to investigate the thermodynamic compatibility of polymers. In contrast to classical gas chromatography, the RGC method is used to solve the converse problem—the study of the behaviour of the stationary phase (SP) and its interaction with the mobile phase. The RGC method was applied to polymer systems for the first time by Smidsrød and Guillet.[51]

A theory of the method has been developed for ideal gas chromatography[52] on the assumption that, firstly, the Henry distribution isotherm for the sorbate between the carrier gas and the SP is linear, which is valid only for the infinitely dilute solution of the sorbate in the SP, and, secondly, that it is necessary to establish equilibrium in the sorption–desorption process, which is possible when certain conditions are maintained, but this is by no means always the case for polymeric SP. This applies particularly to polymers which exist in the vitreous state under the experimental conditions. For this reason, RGC experiments with polymeric SP are as a rule carried out at temperatures at least 50 °C above the glass point T_g of the polymer, where the latter exists in the highly elastic state.[53] However, in this case too the equilibration time may be very long as a consequence of the high viscosity of the polymer.

In the study of the compatibility of polymers, the stationary phases are polymer blends on which the vapour of a volatile liquid is sorbed. If the components of the mixed SP behave independently, then the specific retention volume is made up additively of its components;[54] if they interact with one another, then deviations are observed from the additivity of the chromatographic retention parameters.[54,55] In this case the excess Gibbs free energy G^e is calculated by the equation of Waksmundzki and Suprynowicz:

$$G^e = RT\left(\ln V_{\overline{M}} - \sum_i x_i \ln V_M\right), \qquad (5)$$

where x_i is the mole fraction of the ith component in the mixture and V_{M_i} and V_M are the molar volumes of the sorbate retained respectively by the individual components and the entire mixed phase. Eqn.(5) has been used to determine G^e for mixed liquid[55–57] and polymeric[58] SP. For mixed polymeric SP, the interaction parameter χ'_{23} and the contact energy parameter X_{23}, introduced in the new Flory–Prigogine–Patterson theory,[60–62] are also calculated from the retention volume data.[59]

The thermodynamic compatibility of many oligomer–oligomer, polymer–oligomer, and polymer–polymer pairs have been investigated by the RGC method. The results have been surveyed in a number of communications.[2,48–50,63]

The method involving the determination of the second virial coefficients A_{23}, proposed by Kratochvil and co-workers for the investigation of the compatibility of polymers,[64–66] is based on the study of the light scattering by dilute solutions of polymer blends in a common solvent with subsequent calculation of A_{23} by the equation obtained on the basis of the Stockmeyer theory. The values of A_{23} have been calculated for the polystyrene–poly(methyl methacrylate) (PS–PMMA) system and for blends of different polymethacrylates and styrene–methyl methacrylate copolymers.[64–66]

The second virial coefficients have been determined[67] for binary polymer–polymer systems with the aid of the method based on neutron scattering by dilute solutions of one polymer in another. For blends of deuteriated PMMA with statistical styrene—acrylonitrile copolymers containing 19.9 and 28.7% of acrylonitrile, $A_{23} > 0$ was obtained, which indicates the compatibility of the components. Later the same method was used to investigate blends of PS with poly(phenylene oxide) and its bromo-derivatives,[68,69] with poly(methyl vinyl ether),[70] and with polymethylstyrene[71] and also blends of PMMA with poly(vinyl chloride) (PVC) and blends of statistical copolymers of styrene and acrylonitrile.[72]

The advantage of the neutron scattering method compared with the scattering of visible light consists in the possibility of investigating components having similar refractive indices. However, the complexity of the experimental equipment and the need to use deuteriated polymers limit the wide-scale application of the method.

The mutual diffusion method[73] is based on the familiar relation between the mutual diffusion coefficient D_{mu} and the second derivative of the average Gibbs free energy or the first derivative of the chemical potential with respect to composition:

$$D_{\mathrm{mu}} = D_i^{*} \frac{\varphi_i}{RT} \frac{\mathrm{d}\mu_i}{\mathrm{d}\varphi_i} = D_i^{*} \frac{\partial^2 g}{\partial \varphi_i^2} , \tag{6}$$

where D_i^* is the self-diffusion coefficient of the ith component characterising the thermal mobility of the molecules of the component and ϕ_2 is its volume fraction. The application of this method has been described in detail in a number of communications.[74–78]

III. CAUSES OF THE COMPATIBILITY OF POLYMERS AND METHODS FOR ITS IMPROVEMENT

The data on the compatibility of polymers quoted in the literature show that polymers with similar chemical structures are not compatible. On the other hand, polymers differing in their chemical nature are compatible. The question of the causes of the compatibility of polymers and of the role of their chemical structure naturally arises. This question can be considered from the thermodynamic and molecular points of view.

A thermodynamic condition for spontaneous mixing is a negative Gibbs free energy of mixing, which represents the algebraic sum of two contributions—the enthalpy (ΔH) and entropy ($T\Delta S$) contributions:

$$\Delta G = \Delta H - T\Delta S . \tag{7}$$

The view that the change in entropy on mixing polymers plays no role predominated in the literature for a long time. It was based on calculations by Gee,[79] who took into account only the combinatorial entropy of mixing determined by the number of transpositions of unlike molecules; for a polymer—polymer system, it is indeed very low. However, there exists a non-combinatorial contribution to the entropy of mixing originating from the interaction between the components. Flory and co-workers demonstrated theoretically that this contribution can be fairly large.[80] This was confirmed experimentally for the first time by Tager and co-workers.[24,26,27]

For many compatible polymer—polymer pairs, negative values of ΔH and ΔS are observed and the thermodynamic requirements which are needed for the satisfactory compatibility of the polymers have been formulated on this basis.[11]

1. The entropy of mixing of polymers $\Delta S < 0$. This means that the macromolecules in the mixture are distributed in a more ordered manner than among similar macromolecules, i.e. jointly ordered polymer structures are formed.

2. The enthalpy of mixing of polymers $\Delta H < 0$, which is possible if the interaction energy between unlike molecules is greater than between like molecules.

3. The algebraic sum of the absolute values of ΔH and $T\Delta S$ must be negative, i.e. $|\Delta H| > |T\Delta S|$.

Patterson and Robard,[13] who demonstrated theoretically that the compatibility of polymers with high molecular weight is possible provided that $\Delta H < 0$, arrived at an analogous conclusion. They state that negative enthalpies of mixing are frequently accompanied by negative entropies of mixing and that the competition between these quantities determines the sign of ΔG, i.e. the compatibility of polymers.

Thermodynamic predictions have played a major role in the understanding of the mechanism of the compatibility of polymers and have laid the scientific foundation for the creation of new compatible compositions. Together with the thermodynamic aspect, the compatibility of polymers has been considered also from the standpoint of the interaction of the macromolecules. This has been reflected in a monograph[2] whose authors indicate two ways of improving compatibility, i.e. of creating compatible polymer—polymer systems. The first consists in joining macromolecules together via chemical bonds, which is achieved as a result of the synthesis of block copolymers and interpenetrating networks and by carrying out reactions leading to the cross-linking of the mixture components. The presence of chemical bonds prevents macrolayer formation in the mixtures even if the components are thermodynamically incompatible.

The second way of improving compatibility consists in altering the chemical structure of the blended polymers in a manner which leads to a negative Gibbs free energy of mixing, which is achieved by two procedures: (1) by mixing polymers having functional groups capable of strong interaction; (2) by modifying one of the blended polymers by altering the chemical structure of the monomer units or by copolymerisation.

1. The Mixing of Polymers Having Functional Groups

This method of improving compatibility is based on the idea that large negative values of ΔH, favouring negative values of ΔG, are possible in the presence of specific interactions between the polymers. In their monograph, Olabisi et al.[2] put forward the concept of "complementary dissimilarity", according to which the unlimited mixing of polymers is possible when the macromolecules of each contain different functional groups capable of interacting. This concept is close to the idea[81] according to which the best mutual dissolution or blending is observed in substances whose molecules contain groups with opposite functionalities and not in substances with similar structures. For example, the molecules of one component may contain only proton-donating groups and those of the other only proton-accepting groups; in the blends, hydrogen bonds arise between the components which promotes dissolution. Blending is also favoured by the situation where the molecules of one component are electron donors and those of the other contain atoms having unoccupied orbitals. In this case electron donor—electron acceptor bonds (EDA bonds) are produced. The influence of the chemical structure of polymers on their miscibility has been considered in recent years from the standpoint of this concept.

There has been a cycle of studies on the compatibility of PVC with certain polymers. The hydrogen atom in PVC, activated by the electronegative Cl atom joined to a neighbouring carbon atom, can participate in the formation of a hydrogen bond.[2,83] Consequently PVC tends to enter into donor—acceptor interactions with polymers whose molecules contain groups which function as electron donors with formation of hydrogen or EDA bonds. Poly(alkyl acrylates), poly(alkyl methacrylates), and polyesters belong to polymers of this kind. The compatibility of PVC with such polymers has been estimated from the T_g of the blends[84–90] and their transparency[84,86] and by IR spectroscopic[91–93] and DTA [differential thermal analysis] methods.[90]

It has been observed[84,94] that PVC is compatible with polyacrylates where the number of carbon atoms in the alkyl group is $n < 4$, and with polymethacrylates, where $n < 6$. The incompatibility of PVC with higher homologues has been explained by the decrease in the fraction of the $-C(O)-O$ groups in the macromolecules and by their shielding by long alkyl groups, which hinders the formation of hydrogen bonds between PVC and the ester groups of polyacrylates.

The studies considered above lead to the conclusion that PVC is compatible with PMMA, which disagrees with the data of other workers,[86,95,96] who demonstrated only their limited compatibility. The discrepancy between the results can be associated with the fact that Walsh and McKeown[84] estimated the compatibility from T_g and it is known that in the vicinity of T_g the components even in incompatible polymer systems have the same T_g.[4]

Table 1 presents data on the compatibility of PVC with polyesters. Despite the possibility of the formation of hydrogen bonds, not all the esters are compatible with PVC. The compatibility of PVC with aliphatic polyesters improves with increase in the number of CH_2 groups on passing from PBA to PCL and PHS (for the significance of the abbreviations, see Table 1), which is manifested by an increase of the negative values of the parameter χ'_{23}; when the content of CH_2 is even higher, the compatibility is impaired. It has been shown that the compatibility of aliphatic polyesters with PVC is observed in those cases where the ratio CH_x/COO ($x = 1, 2, 3$) is in the range 3 to 12.[90]

Many studies have been devoted to the compatibility of fluorine-containing polymers with other polymers. Fluorine is the most electronegative halogen and its atom therefore forms strong chemical bonds with other atoms.[97] The strength of these bonds is the reason why many low-molecular-weight compounds containing fluorine are much less miscible with other substances and with one another than are compounds containing other halogens.[98] Thus solutions of low-molecular-weight fluorine-containing compounds are characterised by very large positive deviations from ideality and on cooling as a rule separate into layers. Fluorine-containing polymers are also inert. For example, polytetraflouroethylene does not dissolve in any known solvents.

Table 2. The compatibility of PVDF [poly(vinylidene fluoride)] with oxygen-containing polymers.

Polymer	Designation	Structural formula	Compatibility	Refs.

Poly(vinylidene fluoride) (PVDF) and fluororubber are less inert, because their molecules contain hydrogen atoms capable of forming hydrogen bonds.[97] PVDF therefore dissolves in liquids with a high electron donating capacity—dimethylformamide, dimethylsulphoxide, etc.[99] Fluororubber dissolves in acetone. These features of fluorine-containing polymers affect also their compatibility with other polymers. Thus it has been established by the RGC method that fluororubber is incompatible with ethylene–propylene rubber over a wide temperature range,[100] since hydrogen and EDA bonds cannot be formed between their macromolecules. In contrast to this, PVDF can form hydrogen bonds with oxygen-containing polymers. Numerous studies have been devoted to these blends[101–111] and their results have been surveyed[112] and are presented in Table 2. The common solvent method,[102,108,109] the method based on the determination of T_g[101,102,105,106,108,109] and T_m (melting point) of PVDF,[103,104,112] the RGC[111] and NMR[107] methods, and also the study of phase diagrams of the mixtures[110] have been used to estimate the compatibilities.

It follows from Table 2 that PVDF is compatible with polymers containing the ester group and a small alkyl substituent (CH_3, C_2H_5) in the side chain. The increase in the size of the alkyl substituent on passing to PIPMA and PIPA leads to the incompatibility of these polymers with PVDF. When the methyl group is present in the side branches, structural isomerism does not play any role: PVDF is compatible with PVAC and PMA. It is believed[109] that the presence of the carbonyl group in the molecule of the oxygen-containing polymer is of decisive importance. This follows from the fact that PVDF is compatible with PVMK and incompatible with PVME. Analysis of the interaction parameters χ'_{23} showed that PVAC, in the macromolecules of which the carbonyl group is more remote from the main chain than in the other polymers investigated, shows the maximum affinity for PVDF. In terms of increasing impairment of compatibility with PVDF, oxygen-containing polymers can be arranged in the sequence PVAC > PMMA > PMA > PEMA > PVMK > PEA. The increase in the size of the alkyl substituent impairs the compatibility of the polymers with PVDF.

It is believed[112] that the compatibility of PVDF with oxygen-containing polymers is caused by the dipole–dipole interaction between unlike molecules. However, dipole–dipole interaction alone is insufficient. Hydrogen bonds in which the carbonyl group of the ester and the hydrogen atoms of PVDF participate may be formed in these systems. This hypothesis explains the role of the carbonyl group in ensuring the greater compatibility of poly(alkyl methacrylates) with PVDF compared with poly(alkyl acrylates): the electron-donating capacity of the carbonyl group in the former is higher than in the latter as a consequence of the inductive effect caused by the presence of the methyl substituent in the α-position.[113]

Studies of the compatibility of polycarbonates (PC) based on di(hydroxyphenyl)propane with polyesters are of considerable interest:[114–120] the compatibility has been estimated by the DTA and mechanical relaxation methods. It is seen from Table 3 that the majority of the linear aliphatic polyesters obtained are compatible with PC. With increase in the number of methylene groups per carbonyl group in the polyester molecule the compatibility with PC is impaired. Branched polyesters are incompatible with PC. The replacement of aliphatic dicarboxylic acid residues in the polyester molecules by aromatic residues (PETP, PEOP) leads to their incompatibility with PC.

It is believed[120] that the compatibility of PC with polyesters is caused by the strong energetic interactions between unlike molecules, which should entail negative enthalpies of mixing. To test this hypothesis, the authors used a model approach consisting in the determination of the heats of mixing of low-molecular-weight analogues of the polymers investigated. Diphenyl carbonate (DPC), propylene carbonate, and dimethyl carbonate were adopted as models. The models for the polyesters were different esters having analogous and similar structures. It was shown[120] that low-molecular-weight esters mix with aliphatic carbonates with absorption of heat and that the sign of the heat of mixing with DPC depends on the number n of carbon atoms in the ester molecules per carbonyl group: if $n < 6$, exothermic mixing is observed ($\Delta H < 0$) and, if $n > 7$, the mixing is endothermic ($\Delta H > 0$). The authors believe[120] that the magnitude and sign of ΔH for the mixing of esters with DPC are determined by the balance of two contributions, the exothermic contribution caused by the formation of donor–acceptor bonds between the C=O group of the ester and the aromatic ring of the carbonate molecule and the endothermic contribution arising as a result of the rupture of dispersion linkages. This explanation is similar to that proposed in a study[121] of the heats of solution and swelling of aromatic polymers in tetrachloroethane and DMF. The authors[120] suggested that the positive ΔH for the model systems should correspond to the incompatibility of the polymers, while negative values should correspond to their compatibility. However, they did not observe this correlation for all systems and they reached the correct conclusion that the use of low-molecular-weight analogues to infer the compatibility of polymers is illegitimate.

Table 3. The compatibility of polycarbonate with polyesters.

In this connection, it is appropriate to consider in a general form the relation between the thermodynamics of mixing of polymers and their liquid low-molecular-weight analogues. There is no doubt that the affinity between macromolecules of different chemical structure is related to the affinity of their monomer units. For example, CN is effectively compatible with PVA as a consequence of the high affinity of CN for vinyl acetate ($\chi_1 = 0.2$).[122] In the absence of affinity between monomer units, the polymers are undoubtedly incompatible. However, the unlimited mixing of low-molecular-weight analogues of the given polymers by no means implies that the polymers themselves are miscible.

Detailed analysis of the thermodynamic relations permits the formulation of the following rule: the higher the positive deviations from ideality in the mixtures of two liquids, i.e. the higher the excess Gibbs free energy, the less compatible the polymers whose units are analogous in structure to the molecules of these liquids. Here and henceforth the average Gibbs free energies (Δg), the enthalpies (Δh), and the entropies (Δs) of mixing of their excess values (g^e, h^e, and s^e) corresponding to the maximum in the curves relating these parameters to the composition will be used to characterise the mixing of the solution components. Thus the mixing of aromatic hydrocarbons with alkanes is accompanied by large positive deviations from ideality and the values of g^e reach 500–600 J per mole of the solution.[98] This is caused by strong $\pi-\pi'$ interaction of the aromatic rings, leading to association.[123] With increase in the size of the molecules of aromatic hydrocarbons and other aromatic compounds, the degree of association rises. For this reason, the latter do not dissolve in alkanes and are not compatible with polymeric aliphatic hydrocarbons.

Analogous behaviour has been observed in the mixing of polar liquids with non-polar liquids or of substances capable of forming hydrogen bonds with those which are not. These compounds differ sharply in the density of cohesion energy (solubility parameters) and their mixing at 298 K is accompanied by a large positive value of g^e of the order of 1000 J mol of the solution.[124] For this reason, polar polymers are incompatible with non-polar polymers over a wide temperature range.[16]

More complex rules are observed in the mixing of two polar substances or substances capable of forming hydrogen bonds. The difference between the chemical structures and not their similarity plays frequently a decisive role for these systems. We shall consider several situations.

1. The components have dissimilar chemical structures and contain only proton-accepting groups; for example, two esters. Hydrogen bonds, cannot be formed between them and their mixing is accompanied by positive values of g^e and h^e. Polymers containing ester groups as substituents are frequently altogether incompatible. The classical example is provided by the PMMA–PBMA system.[11] An improvement in compatibility can be achieved in this instance only by reducing the number of butyl substituents in the molecule of the second component, i.e. by blending PMMA with copolymers (see below).

2. The components have similar chemical structures and both contain proton-donating and proton-accepting groups: alcohol–alcohol, acid–acid, and alcohol–acid systems. In these cases, the formation of hydrogen bonds between like and unlike molecules is equally probable. For this reason, when alcohols are mixed with one another or alcohols are mixed with acids, one observes small positive values of h^e, which increase with increase in the size of the alkyl group in the molecules of alcohols or acids.[124] However, a large number of OH and COOH groups in the molecules of the mixed components promotes their blending and polymeric alcohols (PVA) are readily compatible with polyacids (PAA) with formation of polycomplexes.[125–127]

3. One component contains proton-donating and proton-accepting groups, while the other contains only proton-accepting groups. Low-molecular-weight alcohols and acids mix with esters in all proportions, but their mixing is accompanied by positive deviations from ideality. Polyacrylic acid (PAA) is infinitely miscible with poly(ethylene glycol).[127]

4. Mixing characterised by a negative value of g^e is the most favourable. It is observed in systems whose components have the opposite features: for example, one of them contains only proton-donating groups ($CHCl_3$, TCE), while the other contains only proton-accepting groups (ketones); or one is an electron donor, while the other is an electron acceptor (aromatic hydrocarbons and chloro-derivatives). Very strong hydrogen bonds or EDA complexes are formed between unlike molecules; this is accompanied by very large negative values of h^e, of the order of several thousands of J mol^{-1}, and negative deviations from ideality ($g^e > 0$). Polymers containing such groups are thermodynamically compatible for the appropriate ratios of the number of the groups and the number of hydrocarbon residues (see above).

2. Chemical Modification of the Components of a Polymer Blend

The essential feature of this method of improving compatibility consists in the alteration of the chemical structure of one of the components of the polymer composition, which leads to negative values of Δg. This is attained by replacing the units in the macromolecule of one polymer by those of the other polymer, i.e. by blending polymers with copolymers. Three cases are then observed.

In the first case, the polymer A is incompatible with the polymer B but is compatible with the polymer C. The replacement of some of the units in the macromolecule of the polymer B by those of the polymer C leads to the compatibility of the resulting copolymer with the polymer A. For example, poly(phenylene oxide) (PPO) is incompatible with poly-*p*-chlorostyrene (PPCS) but is compatible with polystyrene (PS). The compatibility of PPO with styrene–*p*-chlorostyrene copolymers of different composition has been investigated by the scanning calorimetric and mechanical relaxation methods.[128] It has been shown that the copolymers containing less than 65.3 mole % CS are compatible with PPO, while those containing more than 68% CS are incompatible. Using an improved calorimetric method, it has been shown[129] that the transition from compatibility to incompatibility occurs when the contest of CS units in the copolymer changes by less than 1% (from 67.1 to 67.8 mol %). The analogous "critical", as the authors put it, character of the compatability–incompatibility transition has been observed for mixtures of PPO with statistical styrene–*p*-fluorostyrene (PFS) copolymers:[130] PPO is compatible with copolymers containing less than 56 mol % of FS but is incompatible with copolymers with a higher FS content.

In the second case, the polymer A is incompatible with either the polymer B or the polymer C but is compatible with the copolymer BC. For example, PVC is incompatible with either polybutadiene[6] or polyacrylonitrile[131] but is compatible with their copolymer containing 40 mol % of polyacrylonitrile.[132–134] The ethylene–vinyl acetate copolymers form homogeneous mixtures with PVC, provided that their vinyl acetate content is in the range from 65 to 70 mole %.[135] An analogous "compatibility window" has been observed in the blending of PVC with butyl acrylate–acrylonitrile copolymers.[136] It has been established[137] that PMMA is compatible with the styrene–acrylonitrile copolymer containing between 9 and 27 mole % of acrylonitrile. According to other data,[138] PPO is incompatible with either PPCS or poly-*o*-chlorostyrene, but is compatible with their copolymer in the range of PS contents from 25 to 64 mole %.

Finally, an improvement of the compatibility of the polymer A with the polymer B can be achieved by replacing some of the monomer units in the macromolecule of the polymer B by those of the monomer A, i.e. by blending homopolymers with their copolymers or by blending statistical copolymers consisting of the same monomers but differing in composition. As in the previous two cases, the transition from compatibility to incompatibility occurs very sharply at a strictly defined ratio of the monomers. This has been shown in relation to the blending of statistical copolymers of different composition: styrene–acrylonitrile[139] and styrene–butadiene,[140] methyl methacrylate–butyl acrylate,[141] and butadiene–acrylonitrile.[142] It has been shown[143] that PMMA becomes incompatible with the copolymers of methyl methacrylate (MMA) with ethyl methacrylate (EMA) or butyl methacrylate (BMA) when the content of MMA in their macromolecules is less than 60%.[143]

Thermodynamic studies of the processes involving the blending of homopolymers with their copolymers[144,145] greatly expanded the existing ideas about the thermodynamics of the blending of polymers and demonstrated the possibility of the existence of several different thermodynamic situations, which are illustrated in Fig.1.

1. For strong interactions between the macromolecules of the blended polymers and for favourable steric configurations and conformations, ensuring the formation of strong ordered joint structures, negative enthalpies and entropies of mixing are observed and we have $|\Delta h| > |T\Delta s|$ and $\Delta g < 0$, i.e. the polymers are compatible over the entire composition

range. This is observed also in the blending of the polar polymers (CN–PMMA, CN–PVAC),[11,26] aromatic polymers whose macromolecules are capable of forming π-complexes,[146] and also in rubber–rubber systems.[100] In the latter case, the compatibility of the polymer is promoted by the dense joint packing of the flexible macromolecules, ensuring a strong dispersion interaction on which the π–π' interaction of the electrons of the double bonds is superimposed. The limiting case in this situation involves the formation of polycomplexes, for example the polycomplexes of polyacrylic acids with poly(vinyl alcohol) and PAA–PEO polycomplexes.[127]

Negative values of all the parameters of mixing are also observed for these systems and on the curves representing their concentration dependence there are singular points corresponding to a chemical compound with a stoichiometric component ratio (Fig.1*b*).

2. The blending of polymeric components is accompanied, as in the previous case, by a decrease of the enthalpy and entropy, but the values of $T\Delta s$ and Δh either cancel out, whereupon $\Delta g \cong 0$, or $|T\Delta s| > |\Delta h|$ and $\Delta g > 0$ (Figs.1c and 1*d*). This situation is characteristic of the blending of PVC with the copolymers of vinyl chloride (VC) and vinyl acetate (VAC),[145] containing 17.1 and 28.5 wt.% VAC, which is accompanied by the evolution of heat and a decrease of entropy as a consequence of the formation of hydrogen and EDA bonds between the macromolecules of PVC and the copolymers. However, the miscibility of PVC with these copolymers is limited and the positive Δg increase with increase of the content of VA units in the copolymer macromolecule.

3. All the thermodynamic parameters of mixing are positive (Fig.1*e*), i.e. the components are thermodynamically compatible over the entire composition range, since processes leading to the disruption of the structure, accompanied by an increase of entropy and enthalpy, predominate. A typical example of this situation is provided by the PMMA–PBMA system, for which $\partial^2 g/\partial \omega_2^2 < 0$ (ω_2 is the weight fraction of component 2), i.e. it is thermodynamically unstable.[26]

4. The compatibility of the components can be observed for positive values of Δh and Δs (Fig.1*f*). This has been noted in the blending of the oligomeric nitrile rubber SKN-40 with the ED-20 epoxy-resin.[77] The combinatorial entropy of mixing, which can be significant for oligomers, plays a role in this instance.

5. The polymeric components in one composition range are compatible ($\Delta g < 0$) while in another they are not ($\Delta g > 0$) (Fig.1*g*). Under these conditions, in the region of incompatibility ($\Delta g > 0$), the enthalpy and entropy of mixing are negative ($\Delta h < 0$ and $\Delta s < 0$), while in the region of compatibility ($\Delta g < 0$) these parameters are positive ($\Delta h > 0$ and $\Delta s > 0$). The antiparallel variation of the parameters, observed for example, for the system comprising PMMA and the copolymer of MMA and 26 wt.% BMA,[144] reflects the complexity of the processes occurring on blending the polymers, which is accompanied by the disruption of the structures of the components and the formation of new structures. The functional groups in PMMA and its copolymers are the same, but in BMA they are shielded by butyl groups. For this reason, PMMA molecules interact with one another more strongly than do the BMA units. If the copolymer macromolecules are inserted in the PMMA matrix, the energy expended on the disruption of the structure is greater than the energy gained in its interaction with PMMA. For this region, in the composition range enriched with PMMA, we have $\Delta h > 0$ and $\Delta s > 0$. Conversely, when PMMA molecules are inserted in the copolymer matrix, the energy gained is greater than the energy expended ($\Delta h < 0$ and $\Delta s < 0$). In the first case $T\Delta s > \Delta h$ and the components are compatible,

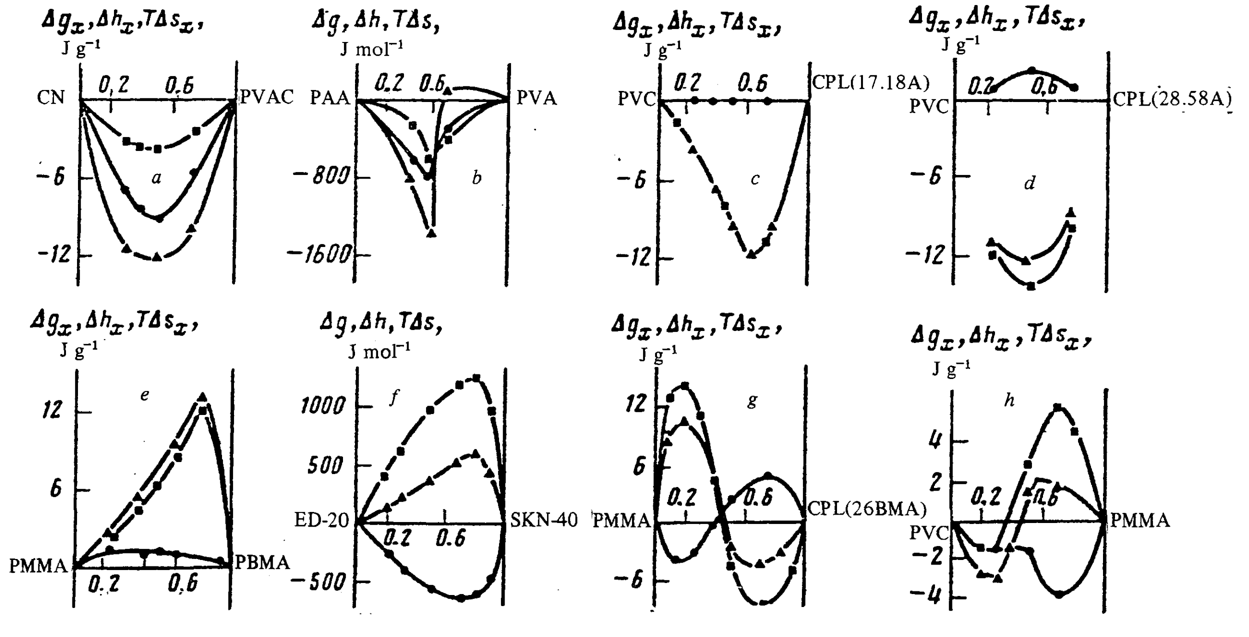

Figure 1. The possible cases of the dependence of the thermodynamic parameters of mixing on the composition of polymer blends (for the explanation, see text); the circles, triangles, and squares denote the values of Δg, Δh, and $T\Delta s$ respectively.

while in the second $|T\Delta s| > |\Delta h|$ and the blending of the components does not occur spontaneously.

It follows from Fig.1*g* that the change in the sign of Δg (transition from compatibility to incompatibility) always occurs for a component ratio which is rigorously defined for each system, i.e. a "critical" value of this ratio, since this entails a change in the ratio of Δh and $T\Delta s$. This accounts for the repeatedly observed "critical" compatibility–incompatibility transitions in homopolymer–copolymer systems.[129,139–142]

6. The enthalpy and entropy of mixing have different signs for different component ratios, as in the previous system, but the Gibbs free energy of mixing is negative over the entire composition range. On the curve for the concentration dependence of Δg_x, there is then a convex section for which $\partial^2 g/\partial\omega_2^2 < 0$ (Fig.1*h*). In this composition range, the system loses stability, but should separate into layers, which is usually observed for liquid–liquid systems.[17] However, as a consequence of the very high macroviscosity of polymer blends, layer formation does not occur and a colloidal two-phase system of this kind can exist indefinitely in a state of metastable equilibrium. This has been observed for the PVC–PMMA system[26,27] and for other similar systems.

IV. TEMPERATURE DEPENDENCE OF THE MISCIBILITY OF POLYMERS. PHASE DIAGRAMS

When the temperature is altered, single-phase binary liquid systems, including polymer solutions, undergo phase separation, which can be of the liquid–liquid type (amorphous separation) or liquid–crystal type (crystalline separation).[16,147] On the phase diagram, the boundary curve separating the homogeneous and heterogeneous regions is the binodal curve in the former case, while in the latter it is represented by the liquidus curve.

Depending on the nature of the components mixed, in amorphous phase separation binodal curves with upper and lower consolute temperatures (UCT and LCT), whose thermodynamic criteria are well known,[17] are observed. Thus for systems with UCT the excess enthalpies and entropies are positive ($h^e > 0$, $s^e > 0$) and the second derivatives of the average excess enthalpies and entropies with respect to composition are negative ($\partial^2 h/\partial\omega_2^2 < 0$, $\partial^2 s/\partial\omega_2^2 < 0$); $h^e < 0$ and $s^e < 0$ are characteristic of systems with LCT, whilst $\partial^2 h/\partial\omega_2^2 > 0$ and $\partial^2 s/\partial\omega_2^2 > 0$.

This applies fully to oligomer–oligomer and polymer–polymer systems. Consequently LCT are to be expected for systems characterised by the situations illustrated in Figs.1*a* and 1*b*, i.e. polymer blends which are compatible at the usual temperatures should separate into layers on heating. Conversely, blends characterised by endothermic mixing and positive entropies of mixing, should have UCT, i.e. the miscibility of the polymers should increase on heating. All this should be reflected in the phase diagrams, which have been obtained for many polymer compositions by various methods.

The first phase diagram for a polymer–polymer system was obtained by Allen et al.[148] by the turbidity point method or Alekseev's method.[149] Subsequently this method was used also for other polymer compositions.

The phase diagrams for oligomer–oligomer and polymer–oligomer systems have been published in a number of communications[10,12,77,78,150–157] and some of these are presented in Fig.2. They are characterised by binodal curves with UCT, limited mixing being observed even for oligomers with a very low molecular weight (MW). With increase in the MW of the components, the position of the UCT on the temperature scale changes in different ways. Thus the UCT increases steadily and the region of homogeneous mixing diminishes with increase in the MW of the components in the polydimethylsiloxane–polyisobutylene and polyethylene–polyisoprene systems (Figs.2*a* and 2*b*). The miscibility of oligomers containing end groups capable of forming hydrogen bonds (OH and others) with non-polar polymers in the region of low MW improves with increase in MW and the UCT is reduced (Figs.2*c* and 2*d*); this is associated with the decrease in the fraction of polar end groups, promoting the preferential interaction between like molecules. On further increase of MW, the end group no longer plays a decisive role and the UCT increases. In all cases at the usual temperatures, the components exhibit limited compatibility and their thermodynamic compatibility improves on heating. However, when polymers having very high molecular weights are blended, the region of homogeneous mixing is extremely small and the UCT lies in the unattainably high temperature range, i.e. does not occur in reality; this has been clearly demonstrated by Kuleznev.[3] The region of homogeneous mixing can be expanded and the UCT can be lowered by blending homopolymers with copolymers the macromolecules of which contain the residues of the same monomers. This is illustrated in Fig.3, which presents the phase diagram for poly(vinyl chloride) with vinyl chloride–vinyl acetate copolymers.[145] The figure shows that the miscibility of PVC with the vinyl chloride–vinyl acetate copolymer containing 28.5 mole % of VAC is limited. The system exhibits a wide range of heterogeneous mixing, which narrows appreciably with decrease in the number of VAC units in the copolymer macromolecule.

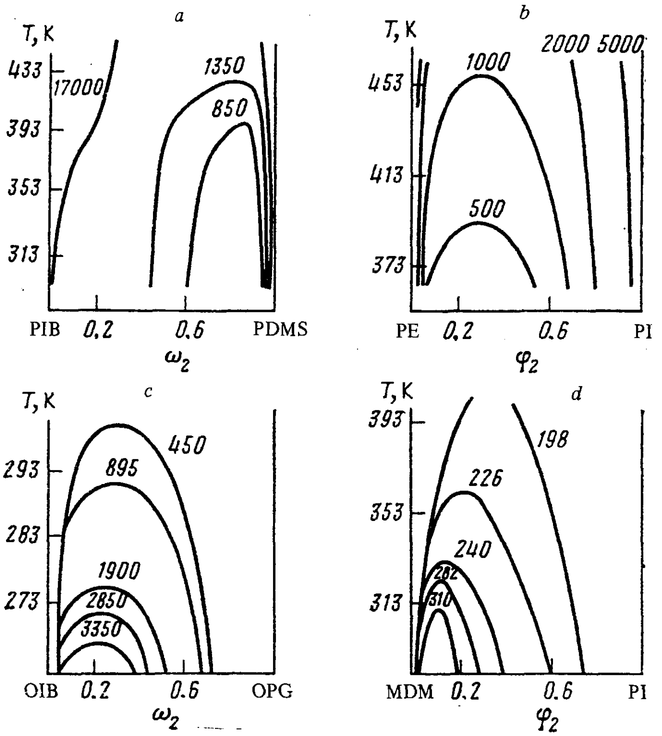

Figure 2. Phase diagrams for different systems: *a*) polyisobutylene (PIB, MW = 250)–polydimethylsiloxane (PDMS);[148] *b*) polyethylene (PE)–polyisoprene (PI, MW = 220 000);[154] *c*) oligoisobutylene (OIB, MW = 114)–oligo(propylene glycol) (OPG);[150] *d*) *p*-methylene dimethacrylate (MDM)–polyisoprene (MW = 220 000);[154] the numerals opposite the curves denote the molecular weight of the second component.

Polymers between the macromolecules where there is a possibility of specific interaction behave differently. At the usual temperatures they are miscible but their thermodynamic compatibility becomes impaired on heating and they are characterised by LCT. This was first predicted theoretically for polymer–polymer systems in two communications[8,13] and has been demonstrated experimentally for many polymer compositions (Table 4).

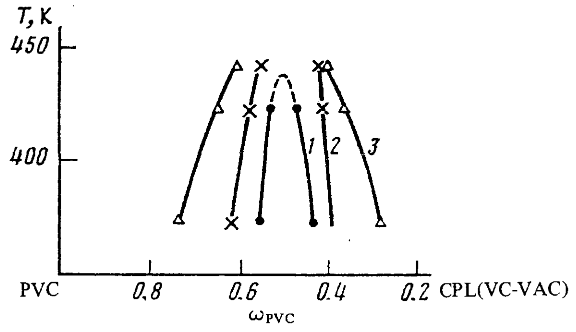

Figure 3. Phase diagram for blends of PVC with vinyl chloride–vinyl acetate copolymers containing different amounts of the latter (wt.%): *1*) 9.2; *2*) 17.1; *3*) 28.5.[145]

All that has been described above shows that the thermodynamic compatibility of polymers is promoted by the possibility of forming combined structures and by strong energetic interactions between their macromolecules. Amorphous oligomers and polymers whose macromolecules contain no functional group are incapable of specific interactions and for this reason their compatibility is as a rule limited over a wide temperature range. Their compatibility improves on heating. The compatibility of non-polar and weakly polar crystalline polymers with one another and with non-crystalline polymers is poor. Classical examples are provided by blends of polyethylene with polyisobutylene[4,134] and by blends of stereoregular rubbers—the polyisoprene and polybutadiene rubbers.[4] This can be explained by the impossibility of forming a common crystal lattice.

However, it is by no means permissible to draw from this the conclusion that the incompatibility of polymers is a rule, as has been assumed since the studies by Dobry and Boyer-Kamenoki.[172] By selecting polymers with functional groups having the opposite properties, between which there is a possibility of the formation of hydrogen bonds or electron-donor bonds, and also by reducing the size of the alkyl moieties shielding these groups, it is possible to create specifically thermodynamically stable polymer compositions, a procedure which should be followed by investigators and technologists in practice. Such compositions lose their thermodynamic stability on heating, i.e. they exhibit LCT and they must be obtained at temperatures below their LCT.

Table 4. Phase diagrams for polymer–polymer systems.

Stopped Flow and Reversed Flow Gas Chromatography

B.V.Stolyarov and L.A.Kartsova

The application of stopped flow and reversed flow gas chromatography to the study of the kinetics of slow chemical and physical processes in chromatographic column-reactors and also to the solution of a number of analytical problems is examined. It is shown that stopped flow and reversed flow gas chromatography should be regarded as a variety of headspace analysis in chromatographic column-reactors or in microreactors incorporated in a single chromatographic system.
The bibliography includes 77 references.

III. Reversed flow gas chromatography 599

I. INTRODUCTION

The advances achieved recently in the study of chemical reactions in chromatographic column-reactors have been determined to a large extent by the development of methodology and experimental technique. A number of communications and chapters in monographs published in recent years have been devoted to the application of chromatographic methods to the study of the kinetics and mechanisms of reactions on the surface of an adsorbent-catalyst or in solution in the stationary phase.[1-5] However, certain recently proposed methodological procedures are either discussed too briefly and incompletely in the above communications or are not considered at all.

This review deals with the application of stopped flow gas chromatography (SFGC) and reversed flow gas chromatography (RFGC) to the study of a number of slow chemical and physical processes and also to the solution of a number of analytical problems. From our point of view, SFGC and RFGC should be regarded as a variety of the headspace analytical method,[6-8] which combines many of the modern chromatographic methods based on the gas extraction of volatile compounds from condensed liquid or solid phases.[9] Two main groups of headspace analytical methods are known:[7,8] (1) the static methods where the gas and condensed phases in contact form a closed system; (2) the dynamic methods where the phases come into contact in an open system and the gas is blown through a layer or over a layer of liquid or a granulated solid phase. In the various analytical and physicochemical applications of headspace analysis, a combination of the static and dynamic versions is frequently employed and contact between the phases is usually achieved in autonomous vessels having a constant volume (flask, bottle) or a variable volume (syringe), which are not elements of a single gas circuit of the chromatograph. The specificity of the SFGC and RFGC methods consists in the fact that the gas extraction of volatile organic compounds from stationary solid or liquid phases takes place directly in the chromatographic column-reactors or in microreactors incorporated in a single chromatographic system.

II. STOPPED FLOW GAS CHROMATOGRAPHY

The gas-chromatographic method for the study of sorption processes and chemical reactions with periodic arrests of the carrier gas flow was proposed in 1967 by Phillips and co-workers.[10-12] A fairly rigorous theory of the method, dealing with the set of diffusion, sorption, and desorption phenomena and also with chemical reactions at the active centres of the adsorbent-catalyst and the distribution of the reactant and products between the stationary and mobile phases under equilibrium and non-equilibrium SFGC conditions, was developed by Katsanos and co-workers.[13-15] The method has been described briefly in a number of communications.[1-4]

Phillips and co-workers[10-12] gave the name stopped flow chromatography to the proposed method which has now been firmly established in the English language literature (the term "stop-flow chromatography" is sometimes encountered). It is in keeping with the term "stop-flow spectrophotometry", known in Russian as "metod ostanovlennoi strui".[16] However, the stopped flow method has been developed for spectrophotometric studies of very rapid chemical reactions and is based on completely different principles and it is thereform illegitimate to employ the phrase "gazokhromatogoraficheskii metod ostanovlennoi strui" as the Russian translation of the term "stopped-flow chromatography" (see the Russian resume in Lycourghiotis's paper[17]).†

In the early analytical gas chromatographic practice, arrests of the carrier gas flow were employed in connection with the application of combined separation and detection methods even before the introduction of SFGC but for quite different purposes. This concerns the "interrupted gas chromatographic" method in which provision is made for the arrest of the carrier gas flow every time when the compound eluted from the separating column enters the cell of an insufficiently rapidly responding detector or in the combustion tube for the measurement of the IR or mass spectra, the measurement of radioactivity, or elemental analysis.[18-23] We may note that many schemes proposed[18-23] for gas circuits can be used successfully also in SFGC. Certain versions of these schemes will be considered below.

1. Principles and Applications of the SFGC Method

The traditional eluent gas chromatography is based on the continuous extraction of the compounds to be determined by the carrier gas from the stationary liquid or solid phases. The method has been used successfully for the solution of numerous analytical problems and for the physicochemical

---

†The Russians use a phrase which can be translated as "gas chromatographic method with arrests of the carrier gas flow" (Ed. of Translation).

study of the processes occurring in the chromatographic column-reactors at sufficiently high rates. If a slow physical or chemical process with evolution of a volatile compound into the gas phase takes place in the column, then the chromatographic output curve for reaction systems characterised by strong retention of the reactants and weak retention of the reaction products, under the conditions of a traditional eluent gas chromatography, has the form illustrated in Fig. 1*a*. The asymmetry of the product peak is in this case due to the fact that the rate of the process investigated is lower than the rate of extraction:

$$k_r \ll k_e, \qquad (1)$$

where k_r is the reaction rate constant and k_e the extraction rate constant.

When the flow of carrier gas is stopped for a fixed time Δt, the dynamic gas extraction regime is transformed into a static regime. The volatile organic substances evolved from the stationary phase accumulate in a limited volume in the mobile phase in an amount sufficient for their detection in the form of narrow and symmetrical peaks (Fig. 1*b*) when the gas flow is subsequently restarted. The virtually identical degrees of spreading of the product bands after different arrests facilitates their identification in those cases where the impurities present in the reagent are eluted from the column. The procedure involving the repeated and consecutive stopping and restarting of the carrier gas flow for a rigorously fixed period (as a rule 1–2 min) makes it possible to measure the change in the concentration in substance B as a function of time. This distinguishes the present method from the majority of others in which the concentrations of the reactant or product thermselves are measured and not their changes.

An important advantage of the method consists in the possibility of using it to investigate reactions which lead to several products. If, for example, not one but two products are formed, traditional eluent chromatography can only indicate their formation (the break in the chromatographic output curve in Fig. 2*a*), while with the aid of SFGC it is possible to follow the changes in the ratio of the product concentrations as a function of time (Fig. 2*b*), to investigate the multistage process mechanism, and to obtain information about the comparative activities of the catalysts.

A distinctive feature of the SFGC method is the possibility of following in one experiment the course of the chemical reaction over a wide range of reactant conversions starting from very low and continuing up to very high (99.5%) degrees of conversion.[11]

At the present time many slow physical processes and chemical reactions in chromatographic column-reactors have become the objects of systematic study with the aid of SFGC: dehydration of alcohols,[11,12,17,24,25] dehydrohalogenation of alkyl halides,[10–12,26–29] deamination of aliphatic and alicyclic amines.[17,30–33] hydrocracking of paraffinic hydrocarbons,[34] hydrogenolysis of aliphatic aldehydes,[35] hydrogenation of aliphatic ketones,[36] deuterium exchange,[37] isomerisation of n-butenes,[38] adsorption and desorption of n-heptane in carrier gas–modified Al_2O_3 or porous glass systems,[39] and diffusion of ethylene, propene, and diethyl ether molecules in nitrogen.[40]

Together with the physicochemical applications, interesting possibilities of using SFGC for analytical purposes have been discovered (see below).

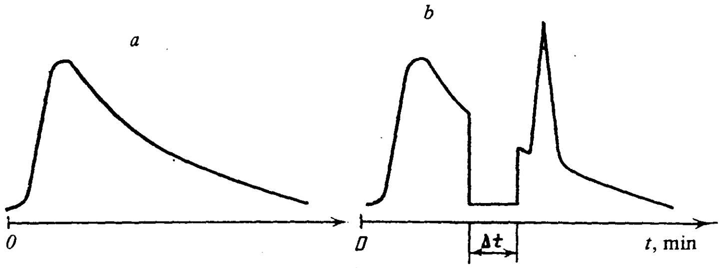

Figure 1. Approximate form of the chromatographic output curves for the reaction A → B in the column-reactor under the conditions of traditional eluent gas chromatography and gas chromatography with a single arrest of the carrier gas (for explanations, see text).

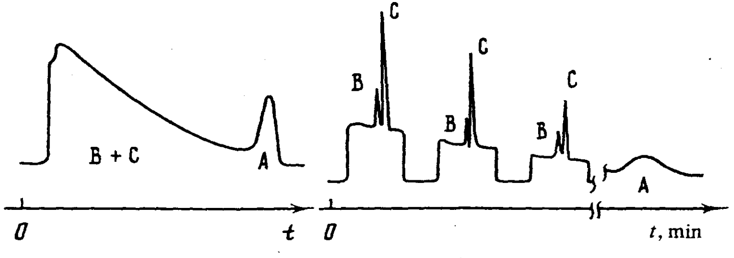

Figure 2. Chromatographic output curves for the reaction A → B + C in the column-reactor:[11] *a*) traditional eluent chromatography; *b*) SFGC.

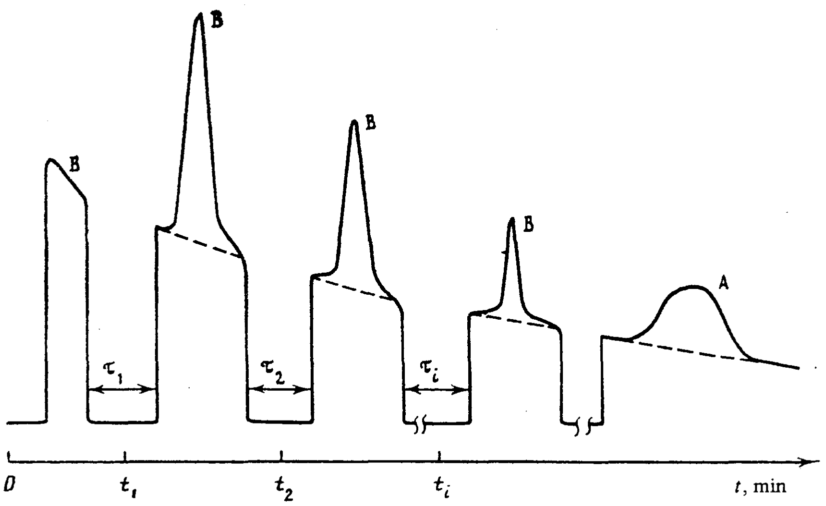

Figure 3. Typical chromatogram illustrating the possibilities of the SFGC method in the study of the kinetics of the first order chemical reaction A →B in the column-reactor (for explanation, see text).

2. Determination of the Rate Constants for Chemical and Physical First Order Processes

Phillips et al.[10] examined the possibility of investigating the kinetics of four types of first order chemical reactions by the SFGC method.

1. Isomerisation of A to B:

$$A \xrightarrow{k} B. \tag{2}$$

2. Decomposition of A with formation of one (B) or several products:

$$A \xrightarrow{k} B + C + \ldots \tag{3}$$

3. The formation from A of two (for example, B and C) or more products via independent parallel pathways:

$$A - \begin{cases} \xrightarrow{k_B} B \\ \xrightarrow{k_C} C \end{cases} \tag{4}$$

4. Consecutive conversion of A into B and then of B into C:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \tag{5}$$

The initial approach to the interpretation of the experimental results[10–12] was based on the model of linear and ideal chromatography, which was itself based on two important assumptions: the constancy of the partition coefficients of the compounds eluted in the course of the experiment and the instantaneous establishment of equilibrium between the phases in the column-reactor. It was also assumed that the surface of the adsorbent-catalyst contains centres with identical catalytic activities and that, when the carrier gas flow is interrupted, the chemical reaction proceeds under rigorously static conditions. In this case, when the flow of the carrier gas is restarted, one records the so called "stop-peak", whose area is rigorously proportional to the amount of product formed during the arrest.

It has been suggested that the rate constant for the reversible first order reaction (2) be found from the equation

$$k = [\ln(P_1\tau_i/P_i\tau_1)]/f(t_i - t_1) \tag{6}$$

where P_1 and P_i are quantitative parameters (the areas or heights) of the first and *i*th "stop-peaks" respectively, τ_1 and τ_i are the durations of the first and *i*th arrests respectively, t_1 and t_i are the instants corresponding to the centres of the first and *i*th arrests respectively, and f is the fraction of reactant molecules sorbed by the active centres on the surface.#

If the product $kf\tau$ is fairly large (exceeds 0.3, which is rarely observed in the experiment), the rate constant is found from the equation

$$k = \{\ln[P_1 \sinh)(kf\tau_i)]/P_i \sinh(kf\tau_1)]\}/f(t_i - t_1). \tag{7}$$

In order to increase the accuracy of the calculation, it has been recommended[10] that the areas (or heights) of the most remote "stop-peaks", referring to the beginning and end of the reaction (Fig.3), be compared and that the calculation from the intermediate parameters (for close values of T) be carried out only in order to estimate the stability of the operation of the column-reactor and to find the order of the reaction.

#The numerical values of f are determined by the ratio $[t'_{RA}/t_M) - 1]t_M/t'_{RA}$, where t'_{RA} is the corrected retention time of the reactant and t_M the dead time. In the majority of cases f is close to unity (0.985–0.987). When the direct experimental measurement of t'_{RA} is impossible, it can be found indirectly.[29]

We emphasise that, in the derivation of Eqns.(6) and (7), the duration of the arrest of the carrier gas is not stipulated[10] and that in principle it can vary (shorter at the beginning of the experiment and longer at the end). The only important factor is that the time during which the carrier gas flow is stopped should be significantly shorter than the half-life of the reactant. However, if one specifies the constancy of the duration of the arrests, then the numerical value of k can be found graphically with the aid of the relation:[29]

$$\lg P = \mathrm{const} - \frac{kf}{2.303}\cdot t \quad . \tag{8}$$

In order to calculate k for reaction (3) by Eqns.(6) and (7), the areas or heights of the "stop-peak" for any one, two, or all the compounds formed are measured. The last method is preferable if the chromatographic bands of the products are sufficiently separated.

For parallel reactions, for example, reaction (4), the ratio of the quantitative parameters of the peaks of compounds B and C after each arrest of the gas flow should be constant and the observed rate constant for the consumption of the reactant ($k_1 + k_2$) is calculated, as in the previous case, from the sum of the areas or heights of the "stop-peaks" B and C. The ratio of the areas of peaks B and C, adjusted to the same detection sensitivity and recorded after each arrest of the carrier gas, is equal to the ratio of the rate constants k_B/k_C.

Finally, when the consecutive reactions (5) take place, the ratio of the quantitative parameters of the "stop-peaks" of the products B and C does not remain constant. Furthermore, only the "stop-peaks" B will be symmetrical on the chromatograph. The superposition of the "tails" of the peak due to the reactant A and of the band of the intermediate compound B (formed continuously from A) hinders the differentiation of the band of the product C, which is formed during the arrest of the carrier gas flow (i.e. the "stop-peak" C). As a result, the accuracy of the determination of the rate constants for both the first stage (from the sum of the areas or heights of the "stop-peaks" of compounds B and C) and for the second stage (from the areas or heights of the "stop-peaks" C) is reduced. The accuracy of the determination of k_2 can be increased by measuring the rate constants for the second stage in independent experiments when the pure substance B is injected into the column-reactor.

In 1975–1978 Katsanos and co-workers developed a theory of the SFGC method on the basis of more complex models taking into account the non-ideality and non-equilibrium nature of slow diffusion and sorption processes in the column-reactor[13,14] and discussed the characteristic features of a first order chemical reaction in a dynamic regime under the conditions of ideal chromatography[15] taking into account the experimentally established fact that several (at least two) types of active centres exist on the surfaces of aluminosilicate catalysts.[41]

In the discussion of their model, the authors[13–15] rule out the spreading of the "plug" of the reactant or adsorbate vapour localised in the initial section of the space within the column-reactor and make the assumption that the isotherm of the distribution of the adsorbed species on all the centres is linear and that there is no longitudinal diffusion in the gas phase. For non-reaction systems, it is assumed that the establishment of interphase equilibrium in the column-reactor is inhibited solely by adsorption–desorption processes.[13,14] On the other hand, in describing the behaviour of the reaction system, the influence of sorption and diffusion processes is ruled out and the instantaneous distribution of reactants and products between the stationary and mobile phases is postulated.[15]

Having analysed the material balance established in the column-reactor throughout three artificially specified time intervals—before the first arrest, during the arrest, and after the flow has been restarted, Katsanos obtained a fairly cumbersome expression relating the area or height h of the "stop-peak", the duration of the arrest of the carrier gas flow t_S, and the rate of formation of the products R:[30–33]

$$R = \alpha\frac{h}{t_s} = \alpha m\left\{\sum_{i=1}^{n}\frac{k_2^{(i)}k_1^{(i)}g^{(i)}}{\bar{k}_1 - k_2^{(i)}}\cdot\exp[-k_2^{(i)}t] - \left[\sum_{i=1}^{n}\frac{k_2^{(i)}k_1^{(i)}g^{(i)}}{\bar{k}_1 - k_2^{(i)}}\right]\cdot\exp(-\bar{k}_1 t)\right\} \quad , \tag{9}$$

where α is a proportionality constant, m the mass of the injected reactant, and $g^{(i)}$ the fraction of reactant A absorbed on the ith active centre:

$$g^{(i)} = k_A^{(i)}\Big/\left(1 + \sum_{i=1}^{n}k_A^{(i)}\right) \quad ,$$

k_1 being the sum of the products $k_1^{(i)}g^{(i)}$:

$$\bar{k}_1 = \sum_{i=1}^{n}k_1^{(i)}g^{(i)} \quad .$$

For the simplest case of the irreversible first order reaction A → D on active centres of only one type without the formation of the intermediate B–S, i.e.

$$\mathrm{A} + \mathrm{S} \rightleftarrows \mathrm{A{-}S} \xrightarrow{k} \mathrm{D{-}S} \rightleftarrows \mathrm{D} + \mathrm{S} \quad .$$

Eqn.(9) reduces to Eqns.(6) and (8). The applicability of Eqn.(9) has been confirmed in an experimental study by the SFGC method of the deamination of a number of aliphatic and alicyclic amines on the surface of Al_2O_3 [30,31] and silica gel[32] and also in a study of the kinetics of the dehydration of cyclopentanol and cyclohexanol on the surface of Al_2O_3 irradiated with neutrons in a nuclear reactor.[25]

In analysing the Katsanos model,[15] it is logical to assume that only part of the reactant is consumed in the formation of volatile products on the ith active centres of the adsorbent-catalyst; an appreciable fraction of the reactant can be sorbed irreversibly on active centres of another type with formation of involatile compounds, which should be manifested by a reduced conversion Q of the initial alkyl halide, alcohol, or amine. For example, in relation to the deamination of cyclohexylamine on two types of active centres on the Al_2O_3 surface, the following inequality holds for Q:

$$Q = (k_1^{(1)}g^{(1)} + k_1^{(2)}g^{(2)})\Big/\sum_{i=1}^{n}k_1^{(i)}g^{(i)} < 1 \, . \tag{10}$$

The similarity of the numerical degrees of conversion of the initial cyclohexylamine into cyclohexene, calculated by Eqn.(10) and found by means of independent direct measurement, which has been discovered by Vattis et al.,[33] characterises the Katsanos model as fairly flexible. Nevertheless, we emphasise that the elimination of the influence of sorption and diffusion processes on the establishment of interphase equilibrium in the column-reactor during a chemical reaction, which has been adopted in this model,[15] is an artificial procedure which facilitates a formal description of the system within the limits of the conditions formulated. In fact the rate of accumulation of the product in the gas phase is an additive quantity determined by the set of the stages involving chemical reaction in the condensed phase and partition in the condensed phase–gas system. Only when condition (1) holds, is it possible to obtain information about the chemical process from the results of headspace analysis. If, on the other hand, $k_r \gg k_e$, then the slope of the resulting relation will characterise the rate of mass exchange (the rate of extraction).

Under real experimental conditions, particularly in the study by the SFGC method of chemical reactions in solution in the stationary phase, situations frequently arise where $k_r \cong k_e$. The linear relation (8) is then transformed into a non-linear relation, because two exponential functions are superimposed, which is formally analogous to the case of two consecutive-parallel first order processes.

Thus the optimisation of the conditions under which headspace analysis is employed, including the conditions in a version of the SFGC method, for the investigation of the kinetics of the chemical process in the condensed phase should consist in seeking a regime ensuring the validity of inequality (1). In many instances, this problem can be readily solved when chemical reactions are carried out at fairly high temperatures on the surface of adsorbent-catalysts such as Al_2O_3, molecular sieves, and coarsely porous glass. At high temperatures, conditions governing the desorption of the volatile products formed do not limit the rate of their accumulation in the gas phase and the experimental relation (8) obtained makes it possible to find the constant for the rate of the chemical process on the surface of the adsorbent-catalyst.

3. Apparatus

The possibility of constructing gas connector schemes for SFGC on the basis of the experience gained in the development of combined gas-chromatographic analytical methods (interrupted gas chromatography) has already been mentioned above. The simplest versions of these schemes have been designed for use in a column-reactor linked directly to the detector (as a rule a flame-ionisation detector). The taps switching the gas flow are located outside the thermostatted zone directly ahead of the chromatograph evaporator.[10] In order to smooth the pressure drops in the system when the gas flow is switched off and then switched on, Katsanos and co-workers[13,29] used two consecutive stopcocks separated by a buffer reservoir (0.5–1.0 litre). We may note that this complication of the gas circuit of the apparatus is not essential, since the change in pressure in the column during the alternation of the arrest and flow of the gas has itself little influence both on the effectiveness and degree of separation. Thus, according to Walker and Wolf's data,[22] three consecutive arrests of the carrier gas flow lasting 0.5 min each caused a change in the effectiveness of the operation of the column and in the degree of separation of model hydrocarbon mixtures just as insignificant as a single arrest lasting 1.5 min.

The duration of the arrest of the carrier gas flow has a much greater influence on the spreading of the band in the column working in the SFGC regime. By carrying out comparative tests of three versions of the gas circuit, the authors[22] established that, when any one of the versions with both packed and capillary columns is used, brief interruption of the carrier gas flow (for 1–2 min) causes an insignificant alteration in the effectiveness and the degree of separation, which are, however, significantly reduced when the duration of the arrest is increased to several minutes. an analogous conclusion concerning the inverse proportionality between the duration of the arrest and the effectiveness of the column was reached in another study.[23]

A gas circuit similar to those employed in the studies mentioned[20,22,23,33] exhibits an appreciable inertia. Thus, according to data of Liebman et al.,[20] the lag during the period from the instant of turning the tap to the complete arrest of the carrier gas was 20 s, while according to other data[33] the difference between the specified and actual durations of the arrest reached 40 s. In the vast majority of studies carried out using SFGC, arrests of the carrier gas of identical duration (1–10 min) were specified and for this reason the corrections to the results of experiments associated with the inertia of the gas circuits were not made.

However, changes in the duration of the arrests of the carrier gas flow constitute a useful procedure when secondary processes accompanying the chemical reactions investigated appear, for example, autocatalysis by the water evolved or polymerisation of the olefins formed on dehydration of alcohols.[24] In those cases where the reactant arrest time is short, it is possible to formulate a series of experiments with single arrests of the carrier gas flow, which, however, are of different duration.[34,42,43] It has been observed[44] that, when very short arrests of the carrier gas flow are specified (down to 30 s, 5 s, or even 1.5 s), each resumption of the gas flow is accompanied by the recording of a negative signal.

In the majority of the reaction systems investigated by the SFGC methods, the expected composition of the product formed was fairly simple and there were no difficulties with their identification. In doubtful cases the procedure involving the trapping of the eluate fraction at the outlet from the column-reactor with its subsequent chromatography on analytical higher performance columns under the conditions of traditional eluent chromatography was resorted to. With the outlet from the reactor column connected directly to the detector, it is possible to obtain kinetic data for the variation of the overall composition of the products. The combined schemes, tested successfully in our laboratory,[45,46] are useful for the investigation of the kinetics of the formation of individual compounds. They include a column-reactor and an anlytical column located in autonomous thermostats of gas chromatographs (for example, of the Tsvet-100 series).

4. The Principal Results of Kinetic Studies by the SFGC Method

There exists a possibility, in principle, of using SFGC for the investigation of both heterogeneous catalytic processes and homogeneous reactions carried out in solution in the stationary and liquid phase (see, for example, Refs.11, 12, and 47). However, in practice the gas-adsorption version of chromatography is usually employed. Column-reactors 3–4 mm in diameter and 30–150 cm long are filled with adsorbents (Al_2O_3, modified alkali metal halides, silica gel, or coarsely porous glass) ensuring the stable retention of the reactant (alcohols, alkyl halides, amines, carbonyl compounds) and the rapid elution of the products of the dehydration, dehydrohalogenation, deamination, and hydrocracking reactions.

Experimental conditions under which the retention time of the reactant amounted to tens of minutes, hours, or even days while the retention time of the product was 1–5 min were selected for each type of reaction system, which made it possible to record tens and sometimes even hundreds of "stop-peaks" in a single analytical cycle for the duration of arrests of the carrier gas flow between 30 and 120 s.[11,24] The treatment of the experimental data consisted in the plotting of kinetic curves corresponding to an equation of type (8). Among the systems investigated, the simplest

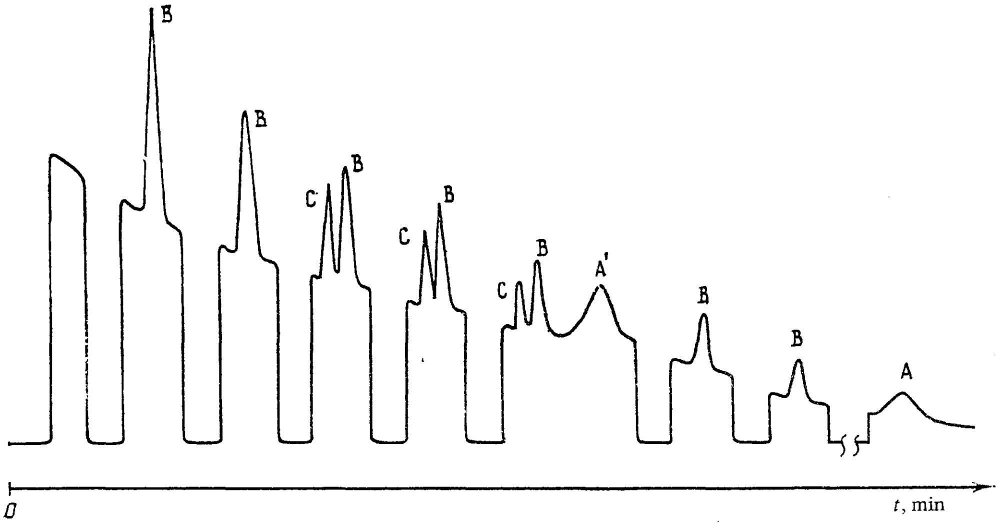

Figure 4. Chromatogram obtained in the study by the SFGC method of the dehydrobromination of isobutyl bromide on the surface of Al_2O_3 with 10 wt.% of LiCl:[27] A) isobutyl bromide; A') t-butyl bromide; B) isobutene (from isobutyl bromide); C) isobutene (from t-butyl bromide).

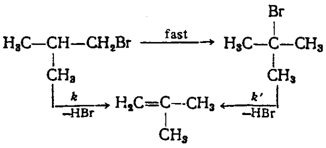
relations have been found for the dehydrohalogenation reaction. The reactants employed were cyclohexyl bromide, cyclohexyl chloride, cyclopentyl bromide[10] and also n-, s-, iso-, and t-butyl bromides.[33,34] The catalyst was γ-Al_2O_3 modified (10 wt.%) by the salts KCl, NaCl, CsCl, LiCl, KBr, NaBr, KI, and NaI. The reaction was carried out at different temperatures in the range from 50 °C to 150 °C. Depending on the specific reaction system and the experimental temperature, the numerical values of k varied from 20–30 s^{-1} to 30 min^{-1} and those of E_a from 50 to 130 kJ mol^{-1}. The simplicity and clarity of the experiment made it possible to recommend the investigation of the kinetics of the dehydrohalogenation of isobutyl bromide on an Al_2O_3 surface (with 10 wt.% of NaBr) by the SFGC method as a laboratory task in a University practical physical chemistry course.[29]§

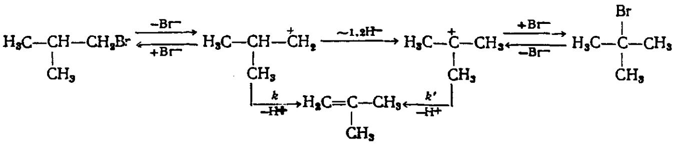
It has been possible to establish by the SFGC method[27] that the nature of the anion of the salt modifying agent has a major influence on the kinetics and mechanism of dehydrohalogenation. In particular, in experiments with isobutyl bromide and Al_2O_3, modified by alkali metal chlorides, after several single "stop-peaks" of the expected product (isobutene), two peaks began to be recorded on the chromatogram after each arrest of the carrier gas flow (Fig.4). The study of the kinetics for each series of "stop-peaks" showed that two parallel reactions take place in the column-reactor, one of which is described by a first order kinetic equation and the other by a zero or first order equation, but with a very low rate constant. On the basis of the evidence that both peaks observed are due to isobutene, the authors[27] suggested that the initial isobutyl bromide undergoes on the surface of the catalyst, together with the elimination of HBr, isomerisation to t-butyl bromide which subsequently also loses HBr with formation of isobutene:



The double "stop-peaks" continued to be recorded until the elution from the column of the broad band due to t-butyl bromide, after which (until the initial isobutyl bromide emerged from the column) single "stop-peaks" were recorded on the chromatogram as at the beginning of the experiment.

When Al_2O_3 modified by potassium iodide (10 wt.%) was used, double "stop-peaks" were also observed,[28] but, in contrast to experiments with Al_2O_3 treated with an alkali metal chloride, these continued to be recorded even after the initial reactant had emerged from the column. Hence it was concluded that in the given case the initial isobutyl bromide is converted, via the intermediate formation of carbenium ions, into an alcohol which is dehydrated very slowly at the selected temperatures (~80–100 °C) and which is very strongly retained by the active centres of the adsorbent.

However, if the multistage mechanism of the dehydrohalogenation of isobutyl bromide by Al_2O_3 modified using metal chlorides is represented by



taking into account the scheme examined by Katsanos and co-workers,[27,28] the problem arises how rigorous is the attribution of the markedly different numerical values of k and k' to the different reactivities of isobutyl and t-butyl

---

§ A similar task has been successfully carried out for several years by the students of Course IV in the Gas Chromatographic Laboratory of the Faculty of Chemistry at Leningrad University.

bromides respectively. It is most probably caused by the differences between the stabilities and reactivities of the intermediate isobutyl and t-butyl cations.

We may note that the dehydrohalogenation reaction on the surfaces of the catalysts specified above are the only ones, among those investigated by the SFGC method, for which the carbenium ion mechanism has been adopted. For the related heterophase dehydration and deamination reactions, a concerted mechanism of the processes (*trans*-elimination) has been reliably demonstrated.

Another important result of the application of the SFGC method to the study of the elimination reactions is the conclusion that each can be carried out simultaneously on several (two–three) types of active centres on aluminosilicate catalysts. Attention was first drawn to this fact by Phillips et al.[12] The experimental kinetic curves for the dehydration of primary, secondary, and tertiary C_2–C_8 alcohols[24] on the surface of γ-Al_2O_3 with 10% of KCl were very close to the kinetic curve for the simultaneous decomposition of two radioactive isotopes. The conclusion that there are two types of active centres on the catalyst surface, drawn from the finding, is supported by the available information[41] concerning the presence of two types of aluminium ions in γ-Al_2O_3 (in tetrahedral and octahedral coordination states). Phillips and co-workers[24] do not rule out the presence on the surface of unmodified γ-Al_2O_3 and also of catalytic centres of a third type distinguished by an increased activity and suggested that the role of the modifying agent employed (KCl) consists in passivating these centres.

Subsequently the hypothesis of the possibility of the simultaneous dehydration on all three types of active centres was confirmed experimentally[25] and similar relations were observed also in the study of the deamination reaction.[32]

The observation of identical kinetic relations for the deamination and dehydration reactions on the surfaces of aluminosilicate catalysts is noteworthy. The experimental kinetic curves for both processes using different Al_2O_3, porous glass, and silica gel specimens as catalysts at relatively low temperatures pass through a maximum and then fall steeply. An increase of temperature leads to the disappearance of the ascending section of the curve and to the approach of the remaining descending branch to the form of a simple exponential relation.

Mathematical analysis of the kinetic curves obtained showed that they can be adequately described by the following empirical equations:

$$R = a_1 \exp(-b_1 t) + a_2 \exp(-b_2 t) + a_3 \exp(-b_3 t) \,, \tag{11}$$

$$R = \sum_{i=1}^{3} [a_i \exp(-b_i t)] - a_4 \exp(-b_4 t) \,. \tag{12}$$

where R is the rate of formation of the product and a_i and b_i are positive constants which depend on the catalyst, the reaction investigated, and temperature. Eqn.(11) is valid for processes which proceed with participation of two types of active centres on the catalyst surface (deamination of amines on the Al_2O_3 surface[30,31]), while Eqn.(12) characterises reactions occurring on active centres of three types (deamination of amines on the surfaces of coarsely porous glass and silica gel,[32] dehydration of alcohols on the Al_2O_3 surface irradiated with neutrons[25]).

Both empirical equations, (11) and (12), agree fully with Eqn.(9) proposed previously.[15] The rate constants k_1, $k_2^{(1)}$, $k_2^{(2)}$, and $k_3^{(3)}$ were found from graphical relations of type (13) or using non-linear regression analysis with the aid of a computer.[25]

Since the absolute numerical values of k (like the absolute retention parameters in gas chromatography) are influenced by various experimental factors (the characteristic features of the preparation and conditioning of a particular column-reactor, its size, etc.), it was suggested as early as 1970[24] that the relative reactivities of the substrates be estimated by the method of competing reactions, injecting simultaneously into the column-reactor a mixture of two alcohols—the test alcohol and one selected as the standard. Unfortunately, this procedure was not developed in the subsequent practical employment of SFGC. Furthermore, the error in the measurement of the absolute values of k, obtained in experiments on different apparatus and columns, can reach 400%, while the reproducibility of the relative quantity k_1/k_2 is to within 10–15%.[24]

As a consequence of the very strong sorption of alcohols on the Al_2O_3 surface, the reactants hardly move in the column-reactor along the catalyst bed, which makes it possible to carry out a very large number (tens and hundreds) of measurements in each individual experiment in the study of dehydration kinetics by the SFGC method. Throughout such a long cycle, it is possible to carry out a stepwise variation of the temperature of the column-reactor and to obtain data necessary for the determination of the activation energy E_a without resorting to the additional injection of reactants. Phillips and co-workers[24] note correctly that the inadequate accuracy of the measurement of the numerical values of E_a (±1.5 kcal mol^{-1}) precludes any reliable conclusions about the character of the variation of E_a as a function of structure within the limits of an isotypical series (for example, in the series of normal primary or normal secondary alcohols), which, in their view, would have been possible if the error could be reduced to ±0.5 kcal mol^{-1}. Nevertheless, their results[24] reveal an appreciable difference between the activation energies for the dehydration of primary alcohols, on the one hand, and secondary and tertiary alcohols, on the other. One should note the proportional variation of the numerical values of E_a and $\ln A$ (the pre-exponential factor in the Arrhenius equation), which indicates the operation of the so-called compensation effect.

Most of the results obtained in the above study[24] refer to the kientics of the dehydration reaction on "slow" active centres of the modified Al_2O_3. Katsanos and co-workers[25,32] determined and compared the numerical values of E_a and $\ln A$ for each type of "slow" and "fast" active centres on the catalyst employed in the deamination and dehydration reactions. Having confirmed the operation of the compensation effect in all cases, they concluded that each type combines a group of centres characterised by the same values of $\ln A$ but different E_a.[25]

The application of the SFGC method to the study of the kinetics of the hydrocracking of hydrocarbons on the Ni–SiO_2 surface at temperatures in the range 160–220 °C established unusually high values of E_a (300–550 kJ mol^{-1}); the values of E_a depend so strongly on the structural features of the compounds of a particular homologous series (n-alkanes, isoalkanes, and cycloalkanes) that this can be used in group analysis.[34]

Subsequently the behaviour of aliphatic aldehydes[35] and ketones[36] on the Ni–SiO_2 surface at temperatures in the range 130–200 °C was investigated. It was established that, under the given conditions, the reactions involving the hydrogenolysis of aldehydes and the dehydrogenation of ketones respectively predominate. The hydrogenation of aldehydes and the hydrocracking of the resulting alkanes are concomitant processes whose role increases with increase of temperature. At a temperature of 300–350 °C, the only reaction products are methane and water, which agrees with the data obtained in our laboratory¶ using a nickel–aluminium catalyst prepared in accordance with the recommendations of Grumbuller et al.[48]

Scott et al.[35] suggest that the hydrogenolysis of aldehydes is limited by two kinetically independent consecutive stages: the RCH_2CHO molecules adsorbed initially on the surface are slowly cleaved to the alkane RCH_3, which is desorbed to the gas phase, and the CHO fragment, which remains in the adsorbed state and is in its turn slowly reduced to CH_4.

Ketones are hydrogenated in one stage and the similarity of the kinetics of the reduction of the intermediate HCO in the case of aldehydes and adsorbed molecules of the ketones RR'CO, established by Abdulah and Sulaiman,[36] is an important experimental fact.

5. Application of Discrete Gas Extraction in a Single Chromatographic System to the Solution of Analytical Problems

As already mentioned above, apart from the rigorously stoichiometric reaction in the chromatographic column-reactor in accordance with schemes (2)–(5), some of the reactant molecules can be sorbed irreversibly on the surface of the sorbent-catalyst with formation of involatile compounds and can also be converted into side products (mainly relatively involatile polymers); sometimes, and this is especially characteristic of reactions in solution in the stationary liquid phase, the "breakthrough" of the reactant through the reactor is observed. The knowledge of the amount (fraction) of the reactant which has reacted is important for the estimation of the degree of conversion via the relevant pathway.

In the quantitative reaction of the reactant via pathways (2)–(5), the determination of its initial content in samples analysed having a complex composition is an important task for analytical reaction gas chromatography. The method of determining the initial concentration of the reacting compound, based on the knowledge of the kinetic parameters of the reaction, was first proposed in a study[49] where a pulsed chromatographic method was used to measure the reaction rate constant k and the current concentration of the reactant c_i at time t_i, this being followed by the calculation of the initial concentration c_0 by the familiar equation

$$k=\frac{1}{t_i}\ln\frac{c_0}{c_i}\ .$$

The method was tested in relation to the interaction of butadiene with maleic anhydride. The chromatographic reactor was placed beyond the separating column. The time of contact between the reactants was determined by carrying out experiments at different carrier gas flow rates on the assumption that the contact time is inversely proportional to the gas flow rate. In order to determine c_i, a non-reacting compound (internal standard) was introduced into the initial specimen. The disadvantages of this method are the long time required, the necessity for several analytical cycles with the reactor disconnected or connected at different carrier gas flow rates, and the difficulties in the selection of a suitable standard compound.

A chromatokinetic method has been developed recently[46] for the determination of the initial content of the reactant, based on the discrete extraction of volatile products from the reaction zone of the chromatographic reactor by the carrier gas. The combination in a single analytical cycle of the stages involving the measurement of the reaction rate constant k and the determination of the amount of products m_i formed during a fixed period t_i must be regarded as advantages of this method. The constant k was measured by the SFGC method using Eqns.(6) and (8). The amount of products formed during a specified time was found by the method involving the absolute calibration of the chromatograph. The method was tested successfully in relation to the dehydration of cyclohexanol and also s- and t-butyl alcohols to the corresponding olefins in a chromatographic column-reactor on the surface of a diatomaceous carrier coated with a layer of phosphoric acid. The initial content of the alcohol m_0 was found from a rearranged first order kinetic equation:

$$m_0=m_i/(1-e^{-kt})\ . \qquad (13)$$

The relative error of the determination did not exceed 10% on average.

Equations analogous to Eqn.(13) can be used also to determine the content of the substance which has reacted in the quantitative headspace analysis of reaction systems in autonomous reactors outside the chromatograph.[50,51]

A discrete gas extraction procedure, analogous to the SFGC method in its experimental aspect, has been used[52,53] to investigate the dynamics of desorption and to determine the overall content of volatile impurities in polymeric materials. The finely dispersed polymeric material was placed in a glass insert in one of two parallel evaporators of the chromatograph connected to the analytical column via a T-junction. The carrier gas was passed periodically either through the empty evaporator or through the chamber with the specimen, all the volatile products evolved into the gas phase during the preceding period being directed to the column. Since the rate at which the volatile impurities are transferred from the solid polymer to the gas phase is proportional to their concentration and formally obeys a first order kinetic equation, the overall content of the volatile component can be found, according to Kolb and Pospisil,[52,53] from the results of only the first two extractions.

The problem of determining the overall content of the volatile impurities diffusing from polymeric materials has been solved in a more general form by Ioffe and co-workers, who suggested that the results of discrete gas extraction in open systems be subjected to a treatment involving the measurement and subsequent allowance for the so-called buffer coefficient B, which characterises the fraction of the non-extracted substance and is equal to the ratio of the areas S or the heights h of the peaks on the chromatograms of the vapour phase obtained in two successive extractions:[54]

$$B=\frac{m_{n+1}}{m_n}=\frac{c_{G(n+1)}}{c_{G(n)}}=\frac{S_{n+1}}{S_n}=\frac{h_{n+1}}{h_n}\ , \qquad (14)$$

where m is the mass of the extracted substance, c_G the concentration of the extracted substance in the gas phase, and n the number of the extraction.

In the general case, the quantity B can change during extraction, but for analytical purposes systems characterised by constant buffer coefficients are the most suitable. For B = const, the amounts of substance contained in the extract form a geometrical progression with B as the denominator and the total amount of substance extracted M_0 can therefore be determined without carrying out an exhaustive extraction:

$$M_0=\sum_{n=1}^{\infty}m_n=\frac{m_1}{1-B} \qquad (15)$$

The number of successive extractions necessary for the accurate estimation of the buffer coefficient by Eqn.(14) should be as small as possible owing to the risk of the distorting influence of the "memory" of the apparatus and the

---

¶ See B.V.Stolyarov and E.E.Galev "Tezisy Dokladov IX Vsesoyuznoi Konferentsii po Gazovoi Khromatografii" (Abstracts of Reports at the IXth All-Union Conference on Gas Chromatography), Kuibyshev, 1987 (in the press).

impairment of the phase equilibration conditions after many repetitions of the cycles involving flushing of the chamber with the specimen by the extractant gas.[55]

The authors of all the published studies on the practical employment of SFGC methods have failed to note the interfering influence of the above factors, although, according to the data of Ioffe et al.,[55] one cannot rule out the undesirable manifestation of the "memory" of the chromatographic system, especially after a large number of cycles involving the arrest and movement of the carrier gas. As a result of this, it is necessary to ensure fairly high concentrations of the compounds extracted in the gas phase and to confine oneself to the minimum necessary number of extractions for the solution of the given specific problem.

For a number of reaction systems resistant to high temperatures and characterised by low partition coefficients of the products formed, even a single arrest of the gas flow, sometimes combined with a sharp increase of the temperature of the column-reactor during the arrest, can ensure the quantitative conversion of A into B and the exhaustive extraction of the products from the condensed phase. The effective concentration of the impurities during their desorption from the surface of the sorbent in the absence of chemical reaction can be ensured in exactly the same way.[56]

The first example of the employment of the SFGC method for strictly analytical and not kinetic purposes has been the concentration, proposed by Phillips and co-workers,[11,12] of aliphatic alcohols as microimpurities from air or organic solvents on Al_2O_3 with their subsequent dehydration involving a single arrest of the flow (for 7 min) and with the simultaneous increase of temperature from 150° to 450 °C. The subsequent cooling of the column-reactor to the initial temperature and the restart of the carrier gas flow lead to the recording on the chromatogram of distinct olefin peaks, which are readily susceptible to integration.

A second example of the successful employment of a single arrest of the gas flow for analytical purposes is provided by a study carried out recently in our laboratory.† It was shown that a single arrest of the gas flow lasting 1 min is sufficient for the exhaustive hydrogenolysis of organic compounds of different classes on the surface of a nickel-aluminium catalyst in a hydrogen atomsphere at 350–400 °C. The new simple method for the determination of the total organic carbon in water and in aqueous solutions, developed in the above study, is based on the exhaustive conversion of carbon-containing compounds into methane, which is extracted in a single step by the mobile phase (hydrogen) from the surface of the catalyst. The relative error did not exceed 10% and the threshold sensitivity was 5 mg C $litre^{-1}$.

The disadvantages and limitations of headspace analysis in the SFGC version in the solution of both kinetic and analytical problems should be noted. In the first place, the method is applicable only to the investigation of processes whose kinetics are described by first order equations. The second disadvantage is the reduction of the accuracy of the measurement under the influence of diffusion of the extracted substance in the mobile phase during the arrest of its movement, which is aggrevated by the inertia of the gas circuit usually employed. An important limitation of the application of the SFGC method to the study of reaction systems is the necessity to ensure a greater retention of the reactant by the stationary phase compared with the retention of the products.

III. REVERSED FLOW GAS CHROMATOGRAPH

1. Principles, Apparatus, and Applications of RFGC

The gas chromatographic method with periodic change (reversal) of the carrier gas glow (RFGC), which is related to the SFGC method but is free from its main limitations, was proposed in 1980 by Katsanos.[57,58] The initial versions of the RFGC method were designed for the measurement of the kinetic parameters of chemical reactions on the surface of the adsorbent-catalyst in chromatographic column-reactors (a simple single stage first order reaction processes including two consecutive stages).[57,58] However, subsequently the applications of the method were greatly extended and RFGC was used to investigate the dynamics of adsorption and desorption, to measure the diffusion coefficients of volatile compounds in different gases, and to determine the activity coefficients of components of solutions.[59] The relative molar responses of the thermal conductivity detector and hence the molecular diameters and the critical volumes of different gases, the Lennard-Jones parameters, and the coefficients of the mass transfer of n-alkanes from the surface of Porapak P to a mobile gas phase (see below) have been measured recently by the RFGC method.

The fundamental possibilities of the RFGC method are illustrated in Fig.5. In contrast to SFGC, in the RFGC method the products concentrated in a limited volume of the mobile phase are sampled at fixed times by the repeated alteration of the direction of flow of the mobile phase and not by means of periodic arrests of the carrier gas flow. We shall consider one of the possible versions of the apparatus for the method. The reactor has the form of a T-piece, two arms of which (l and l') are alternately flushed with the carrier gas in opposite directions (F and R) by rotating the shell of the switching six-way tap ST (Figs.5*a* and 5*b*). The third arm L is at right angles to the first two and is used either for the evaporation of the reactant or for its pulsed injection directly into the adsorbent or catalyst bed. The catalyst or adsorbent are placed in sections l and l' in the stream of carrier gas. The gas circuit includes also the separating analytical column AC, which can be replaced by a permanent constriction. If after the injection of the reactant the position of the shell of the switching tap ST is altered periodically (at time intervals exceeding the retention time t_{RB} of the products in sections l and l' respectively), then one obtains a series of the so called F and R peaks associated with the movement of the gas in the forward (F) and reverse (R) directions. Each reversal of the gas flow then leads to the effective compression and symmetrisation of the band of the product continuously extracted from the reaction zone by the moving gas (Fig.5*c*).

The effectiveness of the concentration of the product in the gas plug directed to the detector can be increased by employing double flow reversal, which is entirely analogous to the replacement of single gas extraction by two consecutive extractions using the same volume of extractant gas. Having reversed at time $t_1 > t_{RB}$ the initial direction of the gas flow (F) to give the opposite flow (R) and without waiting for the recording of the peak of the extracted substance on the chromatogram, the tap is turned again, after a time interval Δt (several seconds) shorter than the retention time of the product t_{RB} in the l and l' sections of the reactor, returning the flow to the direction F. After recording the peaks of the products, the cycle is repeated, keeping constant the selected flow reversal time interval Δt. The form of the resulting chromatogram is illustrated in Fig.5*d*. If it is necessary to increase the extraction time during a

---

†See B.V.Stolyarov and E.E.Galev, "Khimiya i Tekhnologiya Vody" (The Chemistry and Technology of Water) (in the press).

single cycle, the number of passes of the carrier gas through the l and l' reactor sections in the forward and reverse directions can be increased an even number of times.

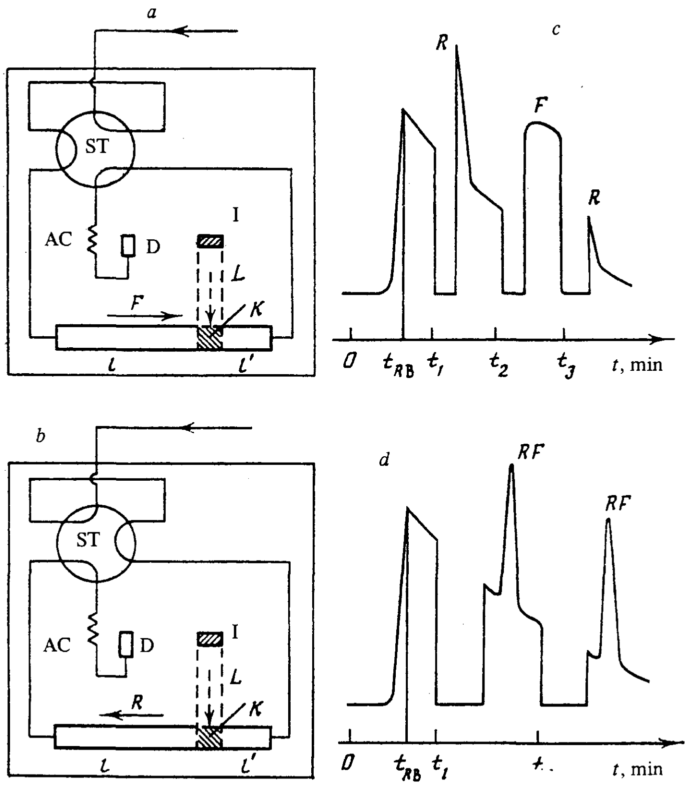


Figure 5. Schematic illustration of the apparatus for RFGC and specimen chromatograms (for explanation, see text).

For reaction systems with small and similar partition coefficients of the reactants and products between stationary and mobile phases and also in those cases where two gaseous reactants are used, none of which is the carrier gas, the catalyst bed is placed in the reactor branch L through which the carrier gas is not passed. The reactants (one or two) are introduced through the sample injection unit I; the end-face of the section is sometimes connected to a U-shaped tube containing 1–0.5 ml of the liquid reactant; a constant flow of the reactant vapour to the catalyst surface is thereby ensured.[59]

These procedures make it possible to investigate the kinetics of slow chemical reactions not only with respect to the reaction product but also with respect to the reactants provided that both are eluted from the catalyst bed together and are separated either in the sections l and l' of the reactor or in the analytical chromatographic column placed before the detector. In those cases where the volatile products and reactants pass from the reaction zone to the bulk of the carrier gas (i.e. to the reactor arms l and l') as a result of diffusional flow, this must be taken into account in interpreting the experimental results. The diffusion of the reactants and products in the carrier gas can be investigated in independent experiments using reactors unfilled with the sorbent.[60–63]

2. Determination of the Rate Constants for Chemical Reactions and Diffusion and Adsorption Coefficients

The analytical mathematical expressions permitting the determination of the equilibrium constant of a slow chemical or physical process from RFGC data depend on the process model adopted and on the chromatographic characteristics of the reactant and product.

We shall consider, for example, one of the simplest cases referring to first order reactions A → B, where the reactant A is rapidly adsorbed on the catalyst surface containing only isotypical active centres S. The compound A–S is then formed and is slowly converted into the adsorbed product B–S and the latter reaches equilibrium with the product B in the gas phase:

$$\mathrm{A}+\mathrm{B}\underset{K_\mathrm{A}}{\overset{\text{fast}}{\rightleftarrows}}\mathrm{A}-\mathrm{S}\xrightarrow{k}\mathrm{B}-\mathrm{S}\underset{K_\mathrm{B}}{\overset{\text{fast}}{\rightleftarrows}}\mathrm{B}+\mathrm{S}\ ,$$

where K_A and K_B are the partition coefficients of the reactant A and the product B respectively, with $K_A \gg 1$, and k is the reaction rate constant.

The kinetic experiment provides for the measurement of the amount of product accumulated in the gas phase volume of the reactor column during the time intervals between the successive changes in the direction of flow of the carrier gas, i.e. during the first R interval—from the instant t_1 (when the F direction changes to R) up to the instant t_2 (when the initial direction of the carrier gas flow is restored); the subsequent F interval extends from the instant t_2 to the corresponding instant t_3 when the direction of flow is switched (Fig.5c), etc. These time intervals should be shorter than the retention time of the reactant when the carrier gas moves in the forward and reverse directions.

Analysis of the material balance equation established for the system during the time intervals specified above makes it possible to relate the quantitative parameters of the F and R peaks (their areas or heights—P_F and P_R respectively) to the mass of the reactant m, the fraction of its molecules sorbed on the active surface centres f, the retention parameters of the product when it is eluted in the forward direction (t_R^F for the F peaks) or the reverse direction (t_R^R for the R peaks), and the total time (t_{tot}) elapsed from the instant of injection of the reactant to the subsequent reversal of the carrier gas flow:

$$P_R = mf\,[\exp(kt_R^F) - 1]\exp(-kt_{\text{tot}}); \qquad (16)$$

$$P_F = mf\,[\exp(kt_R^R) - 1]\exp(-kt_{\text{tot}}). \qquad (17)$$

In the case of a single stage first order chemical reaction of the type A → B under consideration, the graphical dependence of $\ln P_R$ and $\ln P_F$ on the time t_{tot} is represented by a straight line, from the slope of which the rate constant k can be found.

The physical significance of Eqns.(16) and (17) becomes more understandable when they are rewritten in the following form:

$$P_R = mf\exp[-k(t_{\text{общ}} - t_R^F)] - mf\cdot\exp(-kt_{\text{tot}}); \qquad (18)$$

$$P_F = mf\exp[-k(t_{\text{общ}} - t_R^R)] - mf\cdot\exp(-kt_{\text{tot}}). \qquad (19)$$

It is seen from Eqns.(18) and (19) that the peak areas are directly proportional to the retention times of the product with the carrier gas moving in the forward and reverse directions, so that all the experimental points should lie on a single straight line for rigorously identical lengths of the sections of the column-reactor ($l = l'$, Figs. 5*a* and 5*b*). When the lengths of the column-reactor sections are unequal, for example for $l' < l$, the *R* peaks should be smaller than the *F* peaks (and conversely). In this case the identical slopes of straight lines (18) and (19) can be regarded as proof of the absence of secondary effects (for example, the autocatalysis by the water evolved or the polymerisation of the olefins formed on dehydration of the alcohols) in the course of the conversion of the reactant A into the product B for different contact times with the active catalyst centres.

The non-linear character of the dependences of $\ln P_R$ and $\ln P_F$ on the time t_{tot} indicates a more complex process mechanism and the presence of not one but several rate-limiting stages. Some of them can be purely physical, for example, they can be determined by the slow diffusion of the reactant from the gas phase to the catalyst surface or the slow mass exchange of the products between the mobile and stationary phases.

In particular, in the study by the RFGC method of the deamination of aminocyclohexane on the γ-Al_2O_3 surface at 247 °C,[69] kinetic relations typical for two first order consecutive reactions were obtained. The application of RFGC to the study of processes with several consecutive-parallel first order stages has been examined by Katsanos and Kotinopoulos,[64] while Katsanos et al.[65] considered its application to the study of single stage reactions with a fractional order.

The case where the product and reactant are hardly sorbed on the catalyst surface and are eluted simultaneously is of special interest. This version has been considered in relation to the oxidation of CO to CO_2 by oxygen,[66] the hydrogenation of propene,[65] and the hydrodesulphurisation of thiophen to butane and butenes.[67] In solving problems of this kind, account must be taken of the complications associated with the diffusional flow of the reactant onto the catalyst surface. The concentration of the products or reactants at a fixed time is obtained by measuring the height of the corresponding chromatographic peaks. The concentration of the reactants depend on time, the diffusion coefficients, the catalyst mass, the volume flow rate of the carrier gas, and the rate of the chemical reaction. The concentration of the products depends in its turn on the rate of the chemical reaction, the mass of the catalyst, and the volume flow rate of the carrier gas. The expression for the reaction rate constant is as follows:[67]

$$k = \frac{v}{m_c}\ln\frac{1}{(1-x)},$$

where v is the volume flow rate of the carrier gas, m_c the mass of the catalyst, and x the fraction of the reactant converted into the product.

In particular, in the study of the reaction kinetics on the basis of the consumption of the reactant, we obtain the expression[67]

$$x = \frac{h_0^{(r)} - h^{(r)}}{h_0^{(r)}},$$

where $h_0^{(r)}$ is the height of the detector signal corresponding to the initial reactant concentration and $h^{(r)}$ the height of the detector signal corresponding to the concentration of the reactant which has passed through the catalyst bed.

3. The Principal Results of the Employment of the RFGC Method in Kinetic Studies

The reaction systems investigated by the RFGC method are of two types:

$$A \xrightarrow{\text{catalyst}} D + E + \ldots,$$

where A is the reactant strongly sorbed on the catalyst surface and undergoing slow decomposition and D and E are the volatile reactant decomposition products detected, and

$$A + Z \xrightarrow{\text{catalyst}} D + E + \ldots,$$

where A and Z are reactants weakly sorbed on the catalyst surface (one of them may be the carrier gas—for example, hydrogen) and D and E are the volatile reaction products detected.

The first group includes the dehydration of lower alcohols (propyl, isopropyl, and n-butyl[68]), the deamination of propyl-, isopropyl- and cyclohexyl-amines[68,69] on the surfaces of zeolite 13X and Al_2O_3, and also the catalytic cracking of cumene on the LaY and HY zeolites.[64] The second group combines the reactions involving the oxidation of CO by gaseous oxygen under the influence of Co_3O_4 deposited on Al_2O_3 modified with Ca^{2+},[66] the hydrogenation of propene on platinum (5% Pt on Al_2O_3),[65] and the hydrodesulphurisation of thiophen on the surfaces of catalysts with a complex composition, containing MoO_3 and Co_3O_4.[67]

The kinetics of the dehydration of alcohols have been investigated in the temperature range 179–385 °C, the first order of the reaction has been confirmed, and evidence for the absence of secondary processes on the catalyst surface has been presented.[68] The observed rate constants and activation energies agree fairly well with the literature data obtained by other methods, in particular by the SFGC method, using catalysts of similar composition.[24] Unfortunately, Katsanos and co-workers,[68] who previously employed actively the SFGC method for purposes including also the study of the kinetics of the dehydration of alcohols,[25] did not carry out direct experiments with the same reactants and catalysts for the purpose of the comparative assessment of the values of k and E_a obtained by the SFGC and RFGC methods. The only example of such a comparsion refers to the deamination reaction on Al_2O_3, the study of which by the SFGC and RFGC methods yielded results in satisfactory agreement.[33]

The reversal of the carrier gas flow made it possible to establish that the deamination reactions of propyl-, isopropyl-, and cyclohexyl-amines on the zeolite 13X in the temperature range 297–424 °C are described by a first order equation with a single rate-limiting stage, while on the active centres of γ-Al_2O_3 cyclohexylamine is deaminated via a mechanism including two consecutive first order reactions. With the aid of RFGC, it is possible to determine readily the numerical values of the rate constants for the rate-limiting stages, but the method does not enable one to discover to which particular stage each of the constants obtained refers.[69]

The most complex process investigated by the RFGC method is the cracking of cumene, catalysed by zeolites at 252 to 338 °C, to the study of the kinetics of which an extensive literature has been devoted.[64] It has been established that, depending on the nature of the catalyst, the kinetic process mechanism proposed previously[70] includes either one or two rate-limiting stages, but, as in the simpler cases considered before, the RFGC method does not enable one to find out which particular stages are rate-limiting.

It is noteworthy that compression of the product bands in the free volume of the reactor as a result of the reversal of the carrier gas flow leads to the loss of information about the number of types of active centres on the catalyst surface. In the interpretation of the RFGC data, this question is not even posed, while in studies on the theory[15] and the practical application[10,24,25,32] of the SFGC method much attention is devoted to precisely the determination of the role of the so-called "fast" and "slow" active centres of the catalyst.

On the other hand, the principle of the reversal of the carrier gas flow underlying RFGC made it possible to extend the application of the gas-chromatographic headspace analysis in kinetic studies and to include among such applications the study of reaction systems with reactants which are not retained on the adsorbent-catalyst bed, including systems with two gaseous reactants neither of which is the carrier gas. The study[66] of the kinetics of the oxidation of CO by molecular oxygen, catalysed by Co_3O_4 deposited on a zeolitic carrier modified with Ca^{2+}, is instructive in this respect.[66] The above study demonstrated experimentally the first order of the reaction with respect to CO, the reaction rate constants were determined in the temperature range 168–279 °C, and it was established that, with increase of the content of calcium ions in the catalyst (from ~0.4 to ~2.5 mmol g^{-1}), the activation energy for the oxidation of CO diminishes in proportion (from ~33 to ~14 kJ mol^{-1}) and then increases linearly (to ~44 kJ mol^{-1}). These observations clearly illustrate the possibilities in the employment of SFGC for the estimation of the comparative activities of catalysts of different composition.

The possibilities of the RFGC method are by no means restricted to the study of the kinetics of only first order processes. Thus a detailed investigation has been made[65] of the kinetics of the hydrogenation of propene by hydrogen and a catalyst comprising 5% of platinum on Al_2O_3 (carrier gas—nitrogen) at 136–166 °C. The fractional reaction order with respect to hydrogen, varying from 1.6 to 2.5 depending on the surface coverage of the catalyst by hydrogen, has been established by treating the experimental data using numerical methods.

Among the chemical reactions investigated by the RFGC method, the hydrodesulphurisation of thiophen to butane and butenes in a stream of hydrogen on aluminosilicate catalysts is of special interest.[67]

It is significant that the kinetic parameters of the diffusion and adsorption processes uncomplicated by accompanying chemical reactions can be investigated also in independent experiments using the RFGC method. Thus measurements have been made[60–62] of the diffusion coefficients in different carrier gases (H_2, He, N_2) for a series of lower gaseous alkanes and alkenes (both individual compounds and binary mixtures) and the temperature dependence of the diffusion coefficients has been found. A study has been devoted[63] to the application of the RFGC method to the measurement of the rate of evaporation of liquid C_5–C_8 n-alkanes and C_1–C_5 alcohols at 20–101 °C and to the simultaneous measurement of the diffusion coefficients of their vapours in helium. The adsorption of lower alkanes and alkenes on Al_2O_3 has been studied by Katsanos and co-workers,[71] while an investigation of the desorption of organic solvents (pentane, hexane, and acetone, and acetic acid) from the Al_2O_3 surface was described by the same workers in another communication.[72]

Slight changes in the experimental methods described above made it possible to determine, simultaneously with the measurement of the diffusion coefficients of air, oxygen, nitrogen, argon, CO_2 and lower gaseous alkanes and alkenes in the carrier gas (helium), also the relative molar sensitivities of the thermal conductivity detector with respect to the above substances and to characterise the critical volumes, molecular diameters,[73] and Lennar-Jones parameters.[74] The activity coefficients of methanol, ethanol, and 1-propanol in aqueous solutions at different concentrations have been measured by the SFGC method at 50°, 60°, and 65 °C respectively.[75] The application of RFGC to the determination of the mass transfer coefficients and also of the turbulent and longitudinal diffusion coefficients of hexane, heptane, and octane on columns filled with Porapak P (carrier gas—helium) has been discussed.[76]

We may note that the combination of the principles of RFGC and the circulation method proposed by Berezkin and Shiryaeva[77] may prove useful for the kinetic study of very rapid processes.

---o0o---

The data described in this review permit the conclusion that stopped flow and reversed flow gas chromatographic methods possess great possibilities, which have not yet been ultimately elucidated, for the investigation of the kinetics of chemical reactions and slow physical processes (diffusion, evaporation, sorption) in chromatographic column-reactors and are also promising for the solution of certain important analytical problems (determination of volatile impurities and of the overall content of chemical elements in different objects, determination of the initial content of the reactant).

For the further development and effective use of the SFGC and RFGC methods, it is essential to optimise them using the mathematical experimental design procedures. However, one can already say that both methods considered constitute a convenient instrument in the rapidly developing gas-chromatographic headspace analysis of reaction systems.[46,50,51]

Physical and Corrosion-electrochemical Properties of the Niobium–Hydrogen System

G.V.Khaldeev and V.K.Gogel'

Electrochemical and physical aspects of the dissolution of hydrogen in niobium with an ideal or a real structure are discussed. The interactions of hydrogen with various crystal lattice defects and the changes in physico-mechanical characteristics of niobium caused by hydrogenation are analysed. Data on the kinetics and mechanism of non-equilibrium cathodic and anodic processes on hydrogenated samples of monocrystalline or polycrystalline niobium are examined, and the changes in chemical stability towards corrosive media resulting from saturation with hydrogen are discussed.
The bibliography includes 122 references.

I. INTRODUCTION

Niobium is one of the most corrosion-resistant metals. In recent years it has been used not only as an additive in the production of special alloy steels but also as a construction material. The rapid increase in the production and application of niobium has stimulated extensive studies of its corrosion-electrochemical properties in aggressive media, because the main areas of applications of this metal are in the chemical industry, in nuclear and hydrogen energetics, and in various new technologies such as microelectronics, apparatus construction, photoelectrochemistry, etc.

Niobium can readily occlude gases (H_2, N_2, O_2). Their absorption is accompanied by structural and phase changes in the metal. The gas most actively sorbed by niobium is hydrogen, and extensive studies of the effect of hydrogenation on the physico-mechanical characteristics and on the corrosion-electrochemical behaviour of niobium in corrosive media have recently been reported. The importance of this information is obvious, because the wide-ranging applications of niobium and its alloys have not so far been guided by an adequate understanding of the nature of the passive state of niobium and niobium alloys in hydrogenating media.

Published information on the corrosion-electrochemical behaviour of niobium containing dissolved hydrogen is scattered throughout a variety of papers reflecting the physical aspects of the problem, or discussing the corrosion resistance of niobium in aggressive media. Electrochemists and materials scientists are mainly interested in the time-scale of the chemical stability of niobium and its alloys in corrosive media under conditions in which the metal is hydrogenated and its passivity may be impaired.

Both theoreticians and experimenters are interested in the formation of various phases in the Nb–H system, depending on the amount of hydrogen absorbed, and the very large volume of hydrogen which can be sorbed (up to a concentration corresponding to the composition NbH_3) suggests potential applications of niobium not only in nuclear energy but also as an occluder in hydrogen generators. This review examines the thermodynamic properties of the Nb–H system, problems associated with the dilatation of the niobium lattice caused by the penetration and diffusion of hydrogen, and the interaction of hydrogen with various defects of the metal lattice, as well as the final result of this interaction: the change in the physico-mechanical characteristics of niobium.

II. THERMODYNAMIC CHARACTERISTICS OF THE NIOBIUM–HYDROGEN SYSTEM

Niobium at room temperature absorbs a negligibly small amount of hydrogen from the gas phase.[1] The dissolution process begins only when the surface has been activated by high-temperature heat treatment (in the case of saturation from the gas phase) or by cathodic polarisation (if an electrochemical method of saturation is used). In the latter case the solubility of hydrogen in niobium at 293 K is sufficient to give an atomic ratio $\Phi_{H/Nb}$ as high as 0.68, the amount of hydrogen absorbed depending on the purity of the niobium.[2] In niobium of 98.5% purity the solubility (P_M) is 10 400 cm^3 H_2 per 100 g of metal (M), whereas in 94.8% Nb P_M = 5500 cm^3 per 100 g M, i.e. it is lower by about a factor of 2.

Structural characteristics of niobium hydrides.

Phase	Arrangement of metal atoms	Arrangement and coordination of hydrogen atoms	Stoichiometry and structure type	System, space group	Parameters of unit cell, Å	z	Refs.
α (>440 K)	b.c.c.	Disordered, tetrahedral	—	Cubic, *Im*3*m*	$3.43<a<3.45$	2	[11,13]
ζ (212—232 K) *	b.c.r.	Ordered, tetrahedral	Nb_2H	Orthorhombic, *C*222	$a\approx b=4.9$; $c=3.47$	2	[14]

ε	—	Ordered	Nb_4H_3	—	$a\approx b=9.8$; $c=3.47$	—	[15,17, 18]
δ	f.c.c.	Ordered, tetrahedral	NbH_2	Cubic, *Fm*3*m*	$a=4.55$	4	[19]

Symbols: b.c.c., body-centred cubic; b.c.r., body-centred rhombic; f.c.r., face-centred rhombic; f.c.c., face-centred cubic lattice; *z* is the number of atoms in the cell.

*For these phases the coordinates of the wave vector **k** are (½, ½, 0).

The early workers[3–5] could not detect hydride phases corresponding to a definite stoichiometric ratio in hydrogen-containing niobium. However, a detailed phase diagram of the Nb–H system has now been assembled (Fig.1) by the application of X-ray, neutron, and electron diffraction methods.[6,7] At room temperature an increase in the $\Phi_{H/Nb}$ ratio is accompanied by a gradual α → β transformation, followed by the formation of a (β + γ) phase. The phase diagram was constructed by using very pure niobium (99.99 at.%); the α and α′ phase are disordered solid solutions of hydrogen in a body-centred niobium cubic lattice, in which the hydrogen (5–6 at.%) in the α phase occupies tetrahedral positions. Increasing $\Phi_{H/Nb}$ results in the formation of a β phase which is an ordered interstitial solid solution of hydrogen in niobium. The α and β phases can coexist at 293 K up to $\Phi_{H/Nb}$ = 0.73.

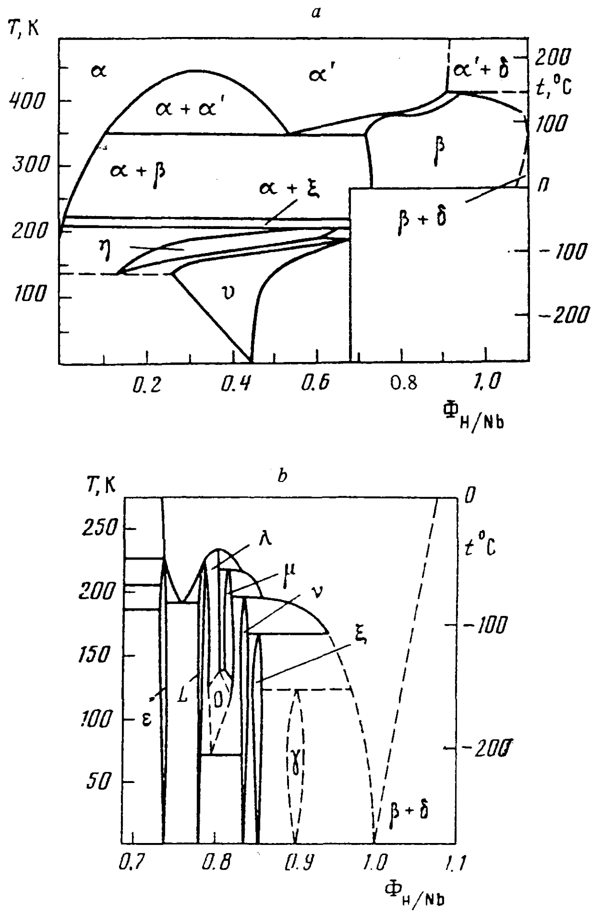

Figure 1. (*a*) Phase diagram of the Nb–H system; (*b*) low-temperature region of the phase diagram, for high concentrations of hydrogen in the niobium.[6,7,8–10] The broken lines define the regions for which no experimental data are available.

According to X-ray diffraction studies[11,12] the β phase has a face-centred rhombic lattice, and the α phase disappears at $\Phi_{H/Nb} > 0.73$. At $\Phi_{H/Nb} \leq 1.05$ only the β phase is observed (see Table), but at higher values of $\Phi_{H/Nb}$ a δ phase appears within the β phase, with a face-centred cubic lattice and corresponding to the compound NbH_2. The structural characteristics of the stoichiometric niobium hydrides are listed in the Table. Since a large proportion of the tetrahedral positions in the δ phase is occupied by hydrogen atoms, there is a high probability that the octahedral pores also may be occupied under suitable conditions, but so far we have no experimental proof of the existence of the compound NbH_3. However, we should not forget that the kinetics of the transformations in the H–M systems can be strongly affected by exposure to X-rays.[20]

Electron microscope studies, both morphological and in transmission, have shown that both the β phase in the α structure and the δ phase in the β matrix consists of long needle-like formations resembling the β phase in titanium and its alloys. Of course, phase transformations giving rise to precipitates having a volume greater than that of the matrix produce hydrogen "embrittlement" in the main structure, accompanied by rearrangements in the fine structure.

Various experimental methods can be used in the construction of phase diagrams, and the shape of the curves separating the existence regions of the phases depends on the chosen method. Details of various regions of the Nb–H diagrams have recently been determined, both at low ($\Phi_{H/Nb} \leqq 0.5$) and at high hydrogen contents ($\Phi_{H/Nb} = 1$). Thus, an unknown region of high hydrogen concentration between liquid helium temperatures and room temperature has recently been studied.[8] A combination of transmission electron microscopy and metallographic analysis has shown that a previously unreported[7] λ phase has an anisotropic cubic structure and can exist at $\Phi_{H/Nb} = 0.78$–0.81 and 207 K. At these very high hydrogen concentrations the precipitation of stoichiometric compounds of the Nb_4H_3 type (ε phase) is accompanied by the appearance of active H–H interactions and of lattice dilatation processes (discussed below). A detailed study of the phase diagram for $\Phi_{H/Nb} \leqq 0.5$ has shown[9] that the coexistence region of the α′ and the β phase is wider than suggested by X-ray measurements of lattice constant.[7] It has been reported[10] that regions of existence of η and θ phases can be identified at $\Phi_{H/Nb} < 0.7$ and temperatures below 200 K; the ν, *L*, *o*, μ, γ, and ξ phases also proposed have not yet been adequately investigated but will probably be confirmed by various experimental methods (as was done for the α, β, and δ phases).

As was stated above, Nb–H phase diagrams constructed from different experimental data can be markedly different. Thus, according to the Horner and Wagner theory,[21] which describes the H–H interaction as the result of the elastic anisotropic distortion of the lattice produced by the interstitial hydrogen atoms, the maximum in the curve separating the α′ and the (α + α′) phases is at 470 K and $\Phi_{H/Nb} = 0.36$, whereas according to measurements of lattice constants by X-ray diffraction this maximum lies at 443 K and $\Phi_{H/Nb} = 0.3$. These discrepancies probably arise because the samples (of different geometry) used in the various measurements contain a range of native structural defects, and the structure-sensitive methods used by different workers have different responses to the different types of defect produced by hydrogenation.

We should stress the need to allow for the geometric shape of the sample and for the extent of deformation in studies of phase transitions in the hydrogen–niobium system. Thus, a study[22] of the α–α′ transformation by X-ray structural analysis showed that in Nb–H alloys the lattice constant and the shape of the (440) line (from which the extent of the transformation was assessed) are strongly dependent on the extent of deformation and on the geometric shape of the sample (disk, foil, or wire). This effect should, of course, be correlated with differences in the concentration profiles in samples of different geometry.

Our understanding of phase transitions in the niobium lattice has been improved by studies of structures containing added hetero-atoms (O, N) by neutron-spectroscopy and resonance methods. The interaction of hydrogen with atoms of the matrix can be determined by both attractive and repulsive forces, depending on the type of deformation produced by the impurity atom. If the additive causes compression of the lattice the repulsion is predominant, but in the opposite case the predominant effect is attraction. The interaction of the hydrogen atoms with the lattice atoms is treated as the sum of contributions from electronic, elastic, and screening interactions with the ionic core of the lattice. For niobium (a typical 4d metal[23]) we can use the following empirical rule: impurity atoms from positions to the left of niobium in the Periodic Table act as hydrogen traps, whereas other atoms do not.

III. HYDROGEN IN THE IDEAL NIOBIUM LATTICE

It follows from the above discussion that hydrogen can exist in different states in the niobium lattice, and give phases corresponding to definite stoichiometric ratios, depending on the concentration of hydrogen absorbed by the metal. The hydrogen can be present both as dissolved atoms, occupying tetrahedral positions in the niobium lattice, and as H^- ions for high values of $\Phi_{H/Nb}$ (when niobium hydrides are formed).

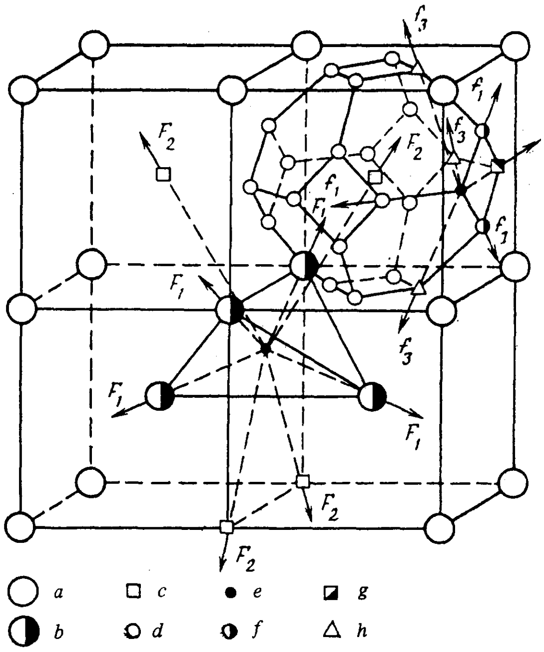

Figure 2. Radial Kanzaki forces (*F*) and H–H interaction forces (*f*) for stable positions of the hydrogen atoms in the tetrapores of the niobium lattice (the subscripts *1*–*3* denote the number of the coordination sphere).[28] In the diagram *a* are Nb atoms, *b* are Nb atoms of the first coordination sphere, *c* are Nb atoms of the second coordination sphere, *d* are tetrapores, *e* are H atoms, *f* are tetrapores of the first coordination sphere, *g* are tetrapores of the second coordination sphere, and *h* are tetrapores of the third coordination sphere.

Extensive experimental results obtained by neutron diffraction analysis and proton magnetic resonance methods show that tetrapores of three types (*x*, *y*, and *z* positions) are the stable sites for the introduction of hydrogen atoms. The radii of the hydrogen atom, of the tetrapores, and of the octapores are, respectively, $r_H = 0.0460$ nm, $r_T = 0.0426$ nm, and $r_0 = 0.0225$ nm. Hence $\Delta r = r_H - r_T \cong 0.003$ nm, and therefore the stabilisation of a hydrogen atom in an interstitial site should produce an anisotropic deformation of the lattice.[24,25] This results in the partial filling of the octapores, with an occupancy of the tetrapores of ~1/6.[26] The probability of hydrogen atoms with parallel spins being accommodated in adjacent interstitials of the first and the second coordination spheres is believed to be low. At high levels of hydrogenation ($\Phi_{H/Nb} \leqq 2$) the octahedral positions also can be partially filled with hydrogen atoms,[27] before the complete filling of the tetrapores.

According to Somenkov[26] when a tetrapore is filled with protium or deuterium (since the additional lattice distortion produced by the replacement of hydrogen by deuterium is small) the radial distribution of Kanzaki forces (the virtual forces acting on the neighbours of the inserted atom) takes the form shown in Fig.2. The Figure also shows the mutual disposition of the tetrapores in the Nb crystal lattice and the forces acting on the hydrogen atoms within these pores. A hydrogen atom of the centre of a tetrahedral pore produces an anisitropic deformation of the lattice. If another hydrogen atom is present in a neighbouring pore this deformation results in H–H interaction (or self-trapping), which is most marked under conditions of spin reorientation. If the hydrogen atom in adjacent interstitials have antiparallel spins the H–H interaction results in the formation of stable pairs. With a parallel arrangement of the spins the situation is less favourable to the formation of stable pairs. The stability of hydrogen in tetrapores has been experimentally demonstrated by neutron diffraction measurements.[26] The development of stable H–H interactions is accompanied by "swelling" of the hydrogenated crystal. Without allowing for anisotropic lattice deformation we can evaluate the relative change in volume $\Delta v/\Omega$ (where v is the volume of the unit cell and Ω is the atomic volume) per unit concentration of hydrogen, of deuterium, or of tritium (c) as $\Delta v/\Omega = 0.174 \pm 0.005$ for low c and $\Delta v/\Omega = 0.14 \pm 0.08$ for high c.

The filling of the d level by the 1s electrons of the hydrogen strengthens the M–M bond, and this should affect the mechanical characteristics of the niobium crystal in the hydrogenated state (plasticity, shock viscosity, strength, etc.). These characteristics are strongly dependent on the local dilatation of the Nb lattice, caused by the formation of hydride in limited volumes,[29] which stimulates the rearrangement of submicrostructures and thus affects the corrosion-electrochemical properties of niobium. The formation of clusters involving hydrogen is determined by the diffusional transport of the hydrogen in the lattice.

The diffusion problem can be discussed either in terms of the classical "jump" mechanism, according to which the diffusion act requires an amount of energy sufficient for a hydrogen atom in a tetrapore to surmount the diffusion barrier, or (in quantum-mechanical language) by identifying the interstitial atom with a small polaron, whose displacement is non-activated (tunnelling, or under-barrier transition).

According to Stoneham[30] there are two major differences between the quantum and the classical theory of diffusion of hydrogen in metals. The first is the quantisation of the energy levels, the second is the existence of a zero point relative to which the lattice distortions can be determined in the neighbourhood of a light impurity atom. In the jump mechanism for the displacement of hydrogen in the metal the probability of a jump is described by a simple equation of the Arrhenius type:

$$\Gamma \sim J^2 \cdot \exp\left(-E_a/k_B T\right) \tag{1}$$

where J is a tunnelling matrix element, given by

$$J = \frac{8\hbar^2}{2md^2}\left(\frac{2md^2}{h^2}\Delta\psi\right)^{3/4} \cdot \exp\left[-\frac{2}{\pi}\left(\frac{2md^2}{\hbar^2}\Delta\psi\right)^{1/2}\right] \tag{2}$$

and m is the number of the metal atom, d is the distance between the potential minima (the positions of the hydrogen atom in a stable state), and $\Delta\psi$ is the depth of the potential well.

Calculations[30] of the tunnelling matrix elements by formula (2) show that for niobium J is determined essentially by d and amounts to 1.45 MeV. The exponential factor in Eqn.(2) corresponds to a configuration in which the adjacent positions occupied by a proton before and after the diffusion act are equivalent.

The theory of small polarons treats a proton in a potential well before the diffusion act as having a lower energy than the adjacent interstitials. At the completion of the diffusion act the opposite situation exists. In the classical diffusion theory the quantity E_a corresponds to the relaxation energy at the instant when the proton is half-way to the second interstitial. Recent developments in the theory of small polarons have shown the need to allow for the dependence of J on the normal coordinates of the vectors for the displacement of the Nb atoms from their equilibrium positions. In this case, since in a b.c.c. metal lattice the hydrogen atoms are accommodated in tetrahedral interstitials, according to Flinn and Stoneham[30] the parameter Γ also depends on E_s (the energy needed to create a lattice configuration with normal coordinates large enough to give $J = J_{\lim} = \text{const}$):

$$\Gamma = \frac{J_{\lim}^2}{4\hbar\,(E_a E_s)^{1/2}} \cdot \exp\left[-(E_a + E_s)/k_B T\right] \tag{3}$$

Thus the localised proton moving through the lattice by a thermally activated process to a large extent "determines" the barrier which it must overcome. The diffusion problem is mor complicated when the adjacent interstitial is occupied by a proton or by some other light impurity element. In this case the H–H interaction results in a more substantial deformation of the neighbouring interstitial, and the diffusion process is facilitated for the pair of hydrogen atoms. Of course, in an ideal crystal the diffusional displacement of hydrogen is anisotropic and occurs preferentially along certain crystallographic directions. Surmounting saddle-points in the lattice must be discussed with allowance for the interaction between migrating particles even when the proton is identified with a small polaron. At low concentrations of hydrogen in niobium ($c_H \leqq 0.06$ at.%) the parameter E_a is linearly dependent on c_H. According to recent work,[31] and in contrast to earlier reports,[30] the average probability of a jump by a hydrogen atom in a niobium crystal for $c_H \leqq 0.06$ at.% is

$$\Gamma = \omega \cdot \exp\{-[(E^b - E^a)/4 + e_0]^2/e_0 k_B T - B^2/k_B T\}/B \tag{4}$$

where w is the vibration frequency of the hydrogen atom in the pore, and the quantities $(E^b - E^a)$, e_0, and B allow for the energy of the interaction between the diffusing hydrogen atoms.

It follows from (4) that the jump probability of a hydrogen atom in a niobium crystal, which depends on the activation energy for diffusion, is related to the vibration frequency of the hydrogen atoms in the pores, and therefore also to the mass of the hydrogen isotope. The strong dependence of the diffusion of hydrogen in metals on the mass of the isotope and on the type of crystal lattice was stressed in a recent interview.[32] It was pointed out that in a b.c.c. metal the diffusion parameter E_a is smaller for protium than for deuterium, whereas the opposite is true in metals with a f.c.c. lattice. The activation energy for the diffusion of protium in tantalum and in niobium suddently decreases at $T < 250$ K, but it remains constant for deuterium and tritium. This shows that the quantum effects are more substantial in b.c.c. than in f.c.c. metals. On lowering the temperature stronger effects are observed.

It was reported[28] that E_a for the diffusion of hydrogen isotopes in the b.c.c. niobium lattice at 133–373 K increases with the mass of the isotope, as also found by other workers.[32] However, it was also noted[28] that in the niobium samples the pre-exponential factor in the Arrhenius expression (1) is almost independent of the mass of the isotope. In that work[28] the diffusion process was discussed in terms of the Gorskii effect, for which the stress relaxation force Δ_E (allowing for the motion of the isotopes in a field of elastic stresses) is given by the Curie–Weiss expression

$$\Delta_E = A\frac{c_H P^2}{T - T_s} \quad , \tag{5}$$

where A is a constant depending on the elastic properties of the sample; T_S is the concentration-dependent spinodal temperature, which can be expressed as $T_S = uc_H/k_B$ for small concentrations of hydrogen in the metal (where u is the interaction energy); $3P$ is the dipole moment of the elastic deformation tensor (due to the presence of hydrogen), with $P_{ij} = \sum_m F_i^m x_i^m$ (F_i^m are the virtual Kanzaki forces acting on each atom m at a distance x_i^m from the defect site).

Therefore, as was stated above, it is essential to allow for the anisotropic dilatation of the lattice and for the change in lattice parameter a caused by the hydrogenation, which can be expressed as

$$\Delta a/a = (2c_H/a^3)P(S_{11} + 2S_{12}) \quad , \tag{6}$$

where S_{11} and S_{12} are the elastic coefficients.

An analysis of experimental data for the niobium–hydrogen system has shown[12] that $\Delta a/a$ can be found by assuming a linear dependence of a on the concentration c_H:

$$\Delta a/a = (4.72 \pm 0.25) \cdot 10^{-4}\, c_H \quad , \tag{7}$$

(where c_H is in at.%). By using (7), which is much simpler than (6) but does not allow for the anisotropic deformation of the lattice produced by hydrogenation, the concentration of hydrogen dissolved in the niobium can be determined with acceptable precision. From the results of various workers, reviewed in Ref.29, linear dependences of $\Delta a/a$ and $\Delta V/V$ (where V is the macroscopic volume of the sample) on the concentration of hydrogen in niobium are observed up to $\Phi_{H/Nb} = 1$. At attempt was made to explain these results in terms of the elastic interactions between hydrogen and niobium atoms by identifying the $\alpha \rightarrow \alpha'$ transition[33] with a gas → liquid transition.

It has also been reported[28] that at low concentrations of the hydrogen isotopes in niobium ($\Phi_{H/Nb} \cong 0.1$) the parameter E_a increases with the mass of the isotope (from hydrogen to tritium) from 0.068 to 0.133 eV, while the diffusion coefficient D_H is almost independent of the mass of the isotope.

IV. INTERACTION OF HYDROGEN WITH DEFECTS IN THE NIOBIUM CRYSTAL LATTICE

We have pointed out above the H–H pair interactions affect the diffusion of hydrogen. The hydrogen trapping phenomenon is found not only in interstitials but also in defects at higher dimensionality (vacancies and dislocations, single or in groups, grain boundaries, microscopic inclusions, and pores). The surface of the sample can also be treated as an energy trap. Let us examine the interaction of hydrogen and niobium with crystal lattice fectes of various dimensionalities.

1. Zero-dimensional Defects

The trapping of hydrogen by vacancies and vacancy clusters, by interstitial impurities (O, N), and by substitutional impurities (W, Mo, V, etc.) is of interest from the theoretical as well as from the practical standpoint. The latter impurities, being getter elements, have a substantial influence on the functional properties of Nb, especially those of technological importance (plasticity, shock viscosity, refractoriness, and corrosion resistance).

The hydrogen–vacancy interaction and the formation of vacancy–interstitial (hydrogen atom) pairs are usually treated as separate aspects in published papers. Hydrogen taken up by a single vacancy stabilises it and suffers a loss in diffusional mobility. However, it is possible for several hydrogen atoms to be adsorbed at a single vacancy, and this produces an anisotropic deformation of the lattice which results in an increase in the diffusional mobility of the vacancy–interstitial hydrogen atom pairs in some crystallographic directions. At high values of c_H the vacancy is transferred from one hydrogen atom to the next by a kind of "relay" mechanism.

Allowance for the change in mobility of the vacancy–interstitial hydrogen atom pair is essential at temperatures close to the melting point. "Anomalous superplasticity" has been observed experimentally in iron at high temperatures.[34] In the hydride-forming 4*d* metals, which include niobium, an increased concentration of hydrogen at the grain boundaries (i.e. at the sites where point defects are annihilated) may explain the change in mobility of these boundaries at relatively high temperatures. In materials previously deformed by large amounts (>90%) annealing after hydrogenation can yield larger-grained or even monocrystalline structures.

A study[35] of the low-temperature desorption of hydrogen from niobium has shown that at $T < 300$ K the formation of vacancy–hydrogen complexes is energetically favourable only for c_H values above the threshold of $\Phi_{H/Nb} > 2$. Further addition of hydrogen results in the merging of hydrogen–vacancy complexes into bubbles, detectable as low-temperature blistering (localised breakdown of the near-surface layer of metal).

Hydrogen can assist the combination of divacancies into vacancy clusters. The most stable clusters were found[31] to contain between three and six vacancies. Under these conditions we can expect the formation of gaseous hydrogen and pores of vacancies. However, because of the difficulty of producing vacnacies in b.c.c. metals very few experimental observations of this phenomenon have been reported, though one report[7] of the formation of screw dislocations near clusters of vacancies filled with hydrogen, detected by transmission electron microscopy, is noteworthy. The effects caused by the interaction of hydrogen in niobium with oxygen and nitrogen impurity atoms have been studied much more extensively.[37]

Nitrogen and oxygen atoms have relatively low mobilities in the niobium lattice at low temperatures, and therefore the capture of hydrogen atoms by nitrogen and oxygen atoms produces pairs with well defined configurations. Under conditions in which the interstitial oxygen atoms occupy octahedral positions the O–H pair can have a trigonal symmetry, i.e. be oriented in the <111> direction. The elastic interaction energy between an interstitial impurity accommodated in an octahedral position and a proton in an adjacent tetrapore has been calculated.[38] In this case the elastic energy is described by the expression

$$E = -F_0 Z F_T - \Delta E_s + \Delta E_0 \quad ,$$

where F_0 and F_T are the Kanzaki forces for interstial impurities in an octapore and a tetrapore respectively, Z is the harmonic lattice function in the near-surface layer of the pure metal, ΔE_S is the energy of the H–H bond, and ΔE_0 is the binding energy of the proton on the zeroth energy level.

Experimental studies,[39,40] mainly by elastic relaxation methods in the frequency range 30–170 MHz, have shown that the hydrogen atom can occupy tetrahedral positions when pairs with a <100> orientation are formed preferentially. This suggests that the hydrogen atoms are not localised in the tetrapores but are uniformly distributed in ring-like structures consisting of four tetrapores and four triangular sites (0, 3/8, 3/8) and surrounding an octapore not containing an oxygen atom. In this case the motion of hydrogen in the Nb lattice is accurately described by the Flinn–Stoneham theory [see Eqn.(3)]. It has been reported[32] that nitrogen atoms in niobium lower the diffusion coefficient of hydrogen, and at $T < 5$ K the local diffusion of hydrogen trapped by nitrogen atoms takes place by under-barrier crossing (tunnelling): under these conditions the hydrogen atom migrates through 16 adjacent tetrapores of the b.c.c. niobium lattice. The nitrogen atoms were shown[41] to be concentrated in the octahedral interstitials of the Nb crystal lattice by the proton channelling method, using the $^{15}N(p, \alpha\gamma)^{12}C$ nuclear reaction.

Thus the diffusional transport of hydrogen along the tetrapores takes place round an octapore occupied by a heteroatom (O or N). Trapping states created by the interstitial atoms must lower the mobility of hydrogen in Nb.

It has been shown[42] that the decrease in mobility of H (or D) in niobium containing up to 1 at.% of nigrogen is most marked at low temperatures (<200 K). The effective diffusion coefficient of hydrogen depends on the concentration of interstitial sites in Nb occupied by impurity atoms:

$$D_H^{\mathrm{eff}} = D_H(\partial c_H^f/\partial c_H) \quad , \tag{8}$$

where c_H^f is the concentration of free hydrogen in the niobium. According to results obtained by an electrochemical method[43] the D_H^{eff} value in interstial alloys with $c_H \geqq 0.03$ wt.% is $(1.80–3.90) \times 10^{-8}$ cm^2 s^{-1}.

It was recently confirmed[44,45] that at low temperatures (0.04–2 K) the trapping of interstial H and D atoms by oxygen impurities in niobium takes place by tunnelling. By measuring the temperature dependence of the specific heat experimental values of the tunnelling matrix elements were calculated by the Flinn–Stoneham theory, and no difference was detected between H and D interstitial atoms for oxygen concentrations ≤2 at.% in the niobium.

The situation in which oxygen is concentrated in the near-surface layer of niobium forming stoichiometric or non-stoichiometric Nb_xO_y compounds is of great practical interest. Extensive information is available on the structure and properties of these oxides. The substantial change in the concentration of hydrogen obtained by saturating niobium foils covered with niobium pentoxide Nb_2O_5 is due to the depletion of hydrogen in the surface layer.[46] These results were obtained by the $^1H(^{15}N, \alpha\gamma)^{12}C$ nuclear reaction, but a calculation of the thickness of the hydrogen-containing layers by an X-ray method gave almost the same result.

The effect of substitutional impurities (V, Ta, Mo) at low concentrations on the solubility of hydrogen in niobium has been studied.[46–50] Substitutional impurities are usually introduced in order to improve the mechanical properties and the inertness of niobium. Thus it was shown[49] that the solubility of hydrogen in Nb is raised by Ta, Mo, and (specially) V impurities. This effect is due to the energetically favourable interaction of H with the substitutional impurity atoms, which increases as the atomic radius of the alloying element is decreased with respect to the Nb lattice parameters (since the H atom decreases the lattice deformation produced by the alloying atom).

The bond energy of the hydrogen in tetrahedral positions round a V atom had been estimated[48] to be $E_{V-H} = 0.09 \pm 0.05$ eV, i.e. close to the bond energy in the complex between hydrogen and an interstitial impurity ($E_{H-O} = 0.09$ eV).[37] However, it was later shown[46] that the energy of the V–H bond has a much lower value (0.04 eV), and that trapping of hydrogen atoms on vanadium impurities in niobium is not normally observed between 2 and 293 K.[50] The probability of self-trapping of hydrogen and deuterium atoms and of μ^+ mesons in Nb crystals containing the substitutional impurities Ti, Cr, and V has been calculated.[51]

Recent experiments with Nb crystals containing substitutional Cr and Ti impurities[52,53] are inconsistent with the theoretical expectation of trapping of the hydrogen atoms mainly as a result of the deformation fields created by the impurities. A more general method, used in Ref.51, includes constructing the potential energy operator for the hydrogen in a suitably averaged crystal field, calculating the zero displacement of the hydrogen by an appropriate three-dimensional form of the Schrödinger equation, and finally evaluating the lattice distortions produced by the insertion of hydrogen (using a set of Green's functions as in calculations for static problems). This method was applied to the self-trapping of hydrogen, deuterium, and μ^+ mesons in Nb crystals containing Ti, Cr, and V substitutional impurities. Comparing the results with experimental data obtained by inelastic neutron scattering showed a generally good agreement: the few discrepancies were attributed to the simplifcations introduced in the calculation.

Of course, a much greater increase in the solubility of hydrogen can be expected in the presence of substitutional impurities from Groups V and VI, such as S, Se, Te, Bi, and Cr. In this case the increase in solubility results not only from the elastic distortions of the Nb lattice but also from the high energy of the bond between the hydrogen atoms and the elements of Groups V and VI.

2. Line Defects

The interaction between hydrogen and dislocations is very important in niobium, because it has a fundamental influence on the mechanical characteristics of the material. Extensive studies of the hydrogen–dislocation interactions have been reported: the most interesting result for b.c.c. metals is the non-conservative motion of the dislocations and the absence of a limited set of slip directions.

Phenomenological discussions of hydrogen–dislocation interactions are usually based on expression of the type of (1); the formation of a Cottrell atmosphere (the atmosphere of impurity hydrogen atoms surrounding the dislocation) can be described by the expression

$$c_H = c_H^0 \cdot \exp(\sigma_H V_H/RT) \quad , \tag{9}$$

where c_H^0 is the equilibrium concentration of hydrogen in the lattice, ν_H is the partial molar volume of hydrogen in the metal, and σ_H is the hydrostatic pressure of hydrogen. Attempts to allow for the dislocation core by the linear theory of elasticity[54] yielded a more complicated form of Eqn.(9):

$$c_H = \pi r_0^2 l c_H^0 \cdot \cosh(\sigma_H V_H/RT) \cdot \exp(\sigma_H' V_H/RT) \quad , \tag{10}$$

where σ_H' is the additional pressure on the dislocation core resulting from the chemical hydrogen–dislocation interaction, l is the length of the dislocation, and r_0 is the radius of the dislocation core (~0.18 nm).

For large c_H^0 Eqns.(9) and (10) should be replaced by Fermi–Diract distribution expressions.[55] In the quantum-mechanical approximation Eqn.(10) contains additional terms for the anisotropic nature of the hydrogen–dislocation interaction; Eqn.(10) should also contain terms allowing for the virtual forces (Kanzaki forces).

The hydrogen–dislocation interaction not only suppresses the mobility of the dislocations but it also affects their concentration, especially near the grain boundaries in a polycrystal. Thus it has been shown[56] that in the electrolytic hydrogenation of polycrystalline niobium the dislocation density ρ increases from 6×10^{11} to 1.3×10^{14} m^{-2} as c_H increases. This increase is attributed[56] to H–H interactions and to the precipitation of a hydride phase at the niobium grain boundaries, which activates a source of dislocations within the grain. A hydride phase can also be formed (at high P_H) directly within the grain, as a result of the inclusion of dissolved hydrogen atoms in clusters and local precipitation of hydride. Hydride formation takes place[57] as a cooperative rearrangement of the crystal lattice in small regions of supersaturated solutions of hydrogen in metals.

The most convincing evidence of hydrogen–dislocation interactions was obtained in studies of the relaxation properties of hydrogenated metals, in which the rearrangement of dislocation structures through reversible mechanical interactions is determined by impurities precipitated at dislocations. Thus a study of the stripping of dislocations from obstacles[58] in very pure polycrystalline niobium at 5–300 K by the internal friction method has shown that at $T < 70$ K the presence of hydrogen atoms leads to the pinning of dislocations. Similar results were obtained[59] at $T < 100$ K for high-purity niobium with a very low concentration of hydrogen ($<10^{-6}$ at.%). The stripping of the dislocations from the anchoring points produces internal friction peaks. The dependence of the vibration frequency of the sample (f) on E_a and on the applied load (σ) is given by the expression

$$f = \nu_0 \cdot \exp\left(-\frac{E_a - \sigma V_a}{k_B T}\right) , \tag{11}$$

where V_a is the activation volume, $\sigma = G\varepsilon_{max}$, G is the normal elastic modulus, ν_0 is the vibration frequency of the dislocations, and ε_{max} is the maximum deformation of the sample. It follows from (11) that decreasing V_a and G produces obstacles to the motion of the dislocations in a hydrogenated crystal. Obviously, this situation will be found in samples supersaturated with hydrogen.

The most detailed studies of the relaxation properties of hydrogenated niobium over a wide temperature range are described in Refs.60 and 61. Two peaks are found on the temperature dependence of the internal friction (Q^{-1}): the first (the α peak) at 123–143 K, and the second (the γ peak) at 263–268 K. In the absence of dissolved hydrogen the magnitude and position of these peaks depend on the extent of deformation of the niobium.[62] Increasing the vibration frequency of the hydrogenated niobium samples (f) from 0.49 to 3.4 Hz results in a degenerate γ peak, while the height of the α peak stays constant. On the other hand the height of the α peak is strongly influenced by the intensity of the preliminary deformation ε, and the signal is highest in the case of an annealed sample. The decrease in height of the peak with increase in f is attributed to hydrogen–dislocation interactions, and to the easier detachment of dislocations from their hydrogen atmosphere at higher frequencies. Allowance for the change in permeability of the dislocation stoppers as a result of hydrogenation is essential in the analysis of dislocation motions. Low-angle boundaries (consisting of dislocation walls) usually behave as strong barriers to the motion of dislocations. However, barriers such as grain boundaries, microscopic inclusions, etc. have an even greater effect.

3. Plane Defects

The changes in physical characteristics produced by the hydrogenation of niobium bicrystal samples are very fully characterised experimentally. It has been shown[63] that an iron bicrystal can be split into individual single crystals by hydrogenation under an applied stress. Large niobium bicrystals can be prepared by electron-beam zone melting,[64] with any required misorientation (δ); the dislocation density ρ in the bicrystal is higher than in a monocrystal grown under the same conditions (the ρ value was determined by measuring electrical resistance at room temperature and at liquid helium temperature).

When determining the rate of corrosion (K) along the boundary of a niobium bicrystal we must allow not only for δ but also for the crystallographic orientation $\{hkl\}$ of the contacting planes of the individual crystals, since the K value for a given plane depends on the $\langle hkl\rangle$ direction. Thus it has been shown[16] that for a $[011]/\langle 0\bar{1}1\rangle$ boundary with $\delta = 16°$ the parameter K along the grain boundary and the extent of corrosion (d_K) go through a maximum; however, the resulting concentration profile is asymmetric because of the difference between the K values for different crystal planes. The dependences of δ on d_K are linear only for $\delta \leq 20°$. Beyond this point non-linearity is observed, and a minimum appears on the plot of d_K against δ for $\delta = 28°$, probably due to a change in the structure of the grain boundary with increasing δ. Whereas the number of coincident sites decreases regularly with increasing δ for small misorientations, when $\delta \geq 20°$ this number can fall away steeply after an initial increase.

Point defects can easily interact with ground boundaries, and therefore very pure bicrystals must be used in studies of the effect of hydrogen. The accumulation of large atoms of the p and sp elements at the grain boundary can greatly distort the structure of the boundary and affect its adsorption properties towards hydrogen. The diffusional mobility of hydrogen moving in the bulk of the grain or along the grain boundary has been calculated.[66] The diffusion coefficient D_H determined electrochemically for grain-boundary diffusion is usually two orders of magnitude greater than for the bulk of the grain.

4. The Surface

The most important defect of a solid is its surface. We have already mentioned the influence of surface oxidation on the absorption of hydrogen by niobium samples. The surface acts as a kind of filter which transmits the adsorbed hydrogen atoms. Therefore even slight contamination of the surface by foreign atoms can seriously alter the energy balance of the adsorption and of the subsequent penetration of the hydrogen into the metal. The largest effects are produced by surface oxygen, or (in the case of electrochemical processes) by water molecules adsorbed by their oxygen atom. A study by electron-stimulated desorption[65] has shown that oxygen adsorbed on the (110) and (100) niobium surfaces can be desorbed by H^+ ions. The ability of H^+ to desorb oxygen by the electrochemical reaction $H^+ + MO + \bar{e} \rightarrow 2M + OH$ depends on the crystallographic indices of the plane: the rate of desorption is lower on the less densely packed (111) plane.

The most widely used method of protecting the surface of the metal to be hydrogenated from oxidation is to deposit a layer of a noble metal (for example, palladium). This is often done in studies of the hydrogen permeability of membranes. However, we must allow for the change in the electronic structure of both metals resulting from the formation of the Pd/Nb contact.[67] A large decrease in the density of *d* states of Nb at the Fermi level (E_F) after the adsorption of palladium was noted in a study of the (110) surface of the Pd/Nb contact. A decrease in the density of *d* states should lower the solubility of hydrogen in a transition metal, since the absorption of hydrogen is accompanied by interaction of the hydrogen *s* electron with the *d* band of the metal.

The hydrogen can exist in two types of bound state on the crystal surface (in other words, the energy level of the surface has two minima). In the case of one-centre adsorption on the first layer of atoms (*r*-type adsorption) the bond between H_{ads} and the surface is weaker. Hydrogen in the *r* form can diffuse along the surface, and it can form planar adsorbed structures with various periodicities on the billiard-ball packed (110) niobium surface. Hydrogen in the *s* state (in the second layer of surface atoms) is more strongly bound. In this case the less closely packed {111} surfaces can more readily form hydrogen structures in the *s* state. The rate at which an adsorbed hydrogen atom is transferred into the *s* state depends on the pressure of hydrogen on the metal surface. For monocrystalline samples the rate of crossing of the interfacial boundary by adsorbed hydrogen atoms is strongly dependent on (*hkl*), and the hydrogenation kinetics are determined by the combined processes at the surface and in the bulk of the niobium lattice. The contribution of the surface processes on the (110) niobium surface was found[68] to be predominant.

When the Nb surface is covered with oxygen the desorption of oxygen by hydrogenation should be easiest on the close-packed (110) surface and least effective on the (111) face. On the clean surfaces which can be produced by lengthy desorption treatment during hydrogenation the spin–spin interaction between the adsorbed hydrogen atoms cannot be ignored. The recombination and desorption of the hydrogen atoms from the surface take place most readily in the case of antiparallel spins.

V. CHANGES IN THE PHYSICO-MECHANICAL CHARACTERISTICS OF NIOBIUM CAUSED BY HYDROGENATION

The interaction of hydrogen with point and line defects and with grain boundaries and matrix atoms (hydride formation) produces a change in the physico-mechanical properties of the metal often accompanied by large-scale mechanical failure, even without externally applied loads. Thus it was reported[69,70] that the saturation of very pure rolled niobium with electrolytically generated hydrogen caused embrittlement of the sample. With Nb samples in wire form (0.3 mm diameter) containing $c_H \geqq 0.03$ wt.% of hydrogen the onset of hydrogen embrittlement (which depends on the extent of the previous deformation ε) was found to be associated with the formation of a hydride phase. The hydrogen embrittlement increases for $\varepsilon \leqq 5\%$, but as ε is further increased from 5 to 98% the embrittlement decreases. This has been attributed[70] to the formation of a cellular dislocation structure at high values of ε, whose rearrangement is hindered during hydrogenation.

Combined metallographic and X-ray diffraction studies[70] explained these changes in the mechanical properties of niobium as due to reversible distortions of the crystal lattice of the matrix during the first and the second hydrogenation stage, and to the formation of a hydride (Nb_xH_y) with a larger lattice constant during the third stage. Since its specific volume is greater than that of the matrix the hydride is concentrated along certain crystallographic directions <*hkl*> and produces large stresses (sufficient to cause spontaneous fracture of the metal when c_H is increased).

In some of the most detailed studies of hydrogen embrittlement[71,72] the effect in the Nb–H alloys was also associated with dislocation effects, resulting from the formation of hydride particles (precipitates) at the extremities of the resulting cracks. The hydrogen cracking is produced by the high internal stresses generated in the metal, and the hydride particles act as foci for the generation of breakdown, giving a high plasticity to the Nb–H alloys with a uniform distribution of particles. A study of the hydrogen embrittlement of niobium samples stretched within the column of the electron microscope showed that no embrittlement takes place at low c_H values, as also found in earlier investigations.[69]

A simple relationship between the increase in length of the hydrogen cracks $\Delta\tau_H$ and the characteristics of the hydrogen precipitates (hydride particles) has been reported:[73]

$$\Delta\tau_H = \frac{\pi r_B \gamma_0}{2bl_B}, \qquad (12)$$

where *b* is the Burgers vector of the dislocation, l_B is the distance between the hydrogen precipitates, r_B is their radius, and γ_0 is the surface energy of the hydrogen precipitate.

The hydrogen–dislocation interaction determines the growth of the crack during loads with an alternating sign, i.e. in the most hazardous conditions experienced in the practical application of niobium components operating in hydrogenating media. Experiments with foil samples of Nb at 293 K and a load cycling frequency of 4 Hz showed[74] that the liability to catastrophic breakdown increases with c_H.

In polycrystalline material the hydrogen embrittlement is strongly affected by impurities which can react chemically with hydrogen, as was stated above. Contamination of the niobium with oxygen or nitrogen (~0.1 at.%) raises the critical embrittlement temperature: the Porteven–Le Chatelier effect is clearly seen at 340–394 K in oxygen-containing samples[75]. It is due to the suppression of the motion of dislocations by the oxygen (Snoek) atmospheres. The interaction of oxygen with hydrogen should strongly influence this effect, partly because the hydrogen–dislocation interaction tends to retard the motion of dislocation in the hydrogen-saturated lattice, and partly because the increased mobility of the oxygen atoms in an anisotropically distorted hydrogenated lattice tends to oppose the effect.

The substitutional impurities V, Mo, and Ta (~3–5 at.%) have a dominant effect on the solubility of hydrogen (P_M) in niobium.[49] Vanadium impurities increase P_M most strongly, possibly because the interaction of hydrogen with substitutional impurities having a radius smaller than niobium is energetically favoured.[76] In this case the hydrogen decreases the deformation of the lattice. However, as was pointed out above, these systems (unlike those containing interstitial impurities) do not show direct M–H chemical interaction.

The effect of the distribution of impurities on the hydrogen embrittlement is stronger in polycrystalline than in monocrystalline samples.[76] For identical c_H values the differences in mechanical properties under tension between mono- and polycrystalline niobium samples are observable at 291–295 K, and the minima on the temperature dependences of the mechanical characteristics and of the internal friction are in similar positions. This is evidence that the hydrogen–dislocation interaction is responsible for the change in mechanical characteristics. The maxima in the temperature dependence of the mechanical characteristics near 300 K are also close to the maxima which characterise the γ peaks on the internal friction curves. Electron fractograms of the fracture surfaces of Nb mono- and polycrystals revealed fragmentation and cellular break,[7] typical of polycrystalline samples, at high c_H values. The formation of a "river pattern" on the fractogram in the presence of hydrogen embrittlement distinguished most of the tests at low temperatures (77 K).

Thus the change in mechanical characteristics of niobium is due to the rearrangement of the metal structure at a number of levels, initiated by the hydrogenation.

VI. ELECTROCHEMICAL ASPECTS OF THE PROBLEM

Let us now examine the corrosion-electrochemical behaviour of niobium in various electrolytes and the role in these processes of structural changes induced by hydrogenation.

1. Kinetics and Mechanism of the Corrosion-electrochemical Processes on a Niobium Surface in Acid Media

Electrochemical studies of niobium in acid media were begun only recently. Most of the published data refer to changes in the hydrogen overvoltage (η) on niobium in acid media. This is because niobium and its alloys are promising new materials for the electrolytic production of hydrogen by electrolysis of aqueous solutions. The dependence of the potential of an oxidised niobium electrode at 298 K on the pH of the solution can be expressed as

$$\varphi = \varphi^0_{Nb_2O_5/Nb} - 0.0591\,\mathrm{pH}\ , \tag{13}$$

which shows that this system can be used as an indicator electrode.[77] The equilibrium potential of the system in buffer media of pH ~ 2 is established in 15–20 min. It is reported[77] that after mechanical polishing or anodic surface treatment the niobium electrode can be used for potentiometric redox titrations in solutions of pH $\leq$ 10. The exact reversibility of the Nb–H binary system during hydrogenation cycles allows the Nb electrode to be used as an electrothermal resistor.[78]

The anodic characteristics of niobium (a valve metal whose oxide has semiconductor properties) and those of its alloys have been less extensively studied. The anodic oxide, as was stated above, plays a controlling role in metal–electrolyte exchange processes. Studies of Nb and Ni–Nb in the amorphous and the crystalline state have shown[79] that a defect-free oxide film having a high electronic conductivity is formed on the amorphous alloy. This allows the $Ni_{60}Nb_{40}$ alloy to exist in a stable passive state. In acid solutions niobium is easily passivated by anodic polarisation. According to Heusler[80] the stationary corrosion of Nb in the passive state is controlled by the structure of the oxide and depends on its rearrangement and erosion. The reforming of the oxide layer by electrochemical treatment is attributed[81] to the transport of ionic defects such as uncoordinated metal and oxygen atoms. These defects are formed on the metal–oxide and oxide–electrolyte interfaces, and their transport in the oxide layer takes place by the switching over of broken bonds on the metal and oxygen atoms.

In recent years Nb has been used in alloy making not only as a carbide-forming additive but also as a major component to assist austenitic grain growth and to give enhanced passivation.[82–86] As the Pourbaix diagram of the niobium–water system shows, oxide films on the niobium surface are unstable in alkaline solutions, and the niobium should corrode rapidly. Oxygen-covered Nb surfaces are strongly affected by anions (SO_4^{2-}, halides) and by surface-active species, which produce changes in the Nb–O bond energy. Thus, sulphur deposited on the niobium surface weakens the bond between adsorbed oxygen atoms and the surface very substantially. This can be explained[87] by assuming that the adsorption centres for oxygen and sulphur are the same.

Thus on the oxidised surface of a Nb electrode the adsorption of hydrogen is to a large extent reversible. The reversibility can be disrupted by the adsorption of anions from the electrolyte or of hydride-forming elements. Complete dissolution of the niobium oxide Nb_xO_y is possible only in a cathodic process far removed from equilibrium.

2. Electrochemical Characteristics of Niobium in the Cathodic Potential Region

Some of the earlier work[88–90] dealt with the hydrogen overvoltage on niobium and showed that the dependence of η on the cathodic current i_K and on the pH can be described by the slow discharge theory. For i_K = const we observe a strong time dependence of the potential ϕ: stabilisation occurs after 3 applications of cathodic polarisation lasting 1 h each. This is due mainly to the reduction of Nb_xO_y thin films during cathodic polarisation.

According to the polarisation measurements the nature of the alkali (NaOH, KOH, LiOH) has practically no effect on the overvoltage (unlike the concentration of the electrolyte).[90] Since the free energy of adsorption of atomic hydrogen on niobium is high, the hydrogen evolution reaction is rate-limited by the electrochemical desorption step:

$$H_2O + \bar{e}(M) \rightleftarrows H_{ads}M + OH^- \tag{14}$$

$$H_2O + \bar{e}(M) + H_{ads}M \rightarrow 2M + OH^- + H_2 \tag{15}$$

At surface coverages of the Nb by atomic hydrogen $\theta_H \cong 1$ the overvoltage equation is

$$\eta = k_{15} - \frac{1-\alpha}{\alpha} \cdot \frac{RT}{F} \ln a_{H_2O} - \frac{RT}{F} \ln a_{OH^-} + \frac{RT}{F} \ln i_K \tag{16}$$

where a_{H_2O} and a_{OH^-} are the activity of water and of the hydroxyl ion respectively, F is the Faraday, α is the transfer coefficient, k_{15} is the rate constant of reaction (15), and R is the gas constant.

This equation is accurately consistent with experimental data:[91] the dependence of η on $\ln [a_{H_2O}^{\frac{1-\alpha}{\alpha}} \cdot a_{OH^-}]$ is linear, with a slope (b_K) close to the theoretical value. A discontinuous change in hydrogen overvoltage on niobium resulting from previous cathodic treatment of the surface has also been reported,[88–90] and attributed to the discrete change in lattice constant caused by hydrogenation and hydride formation. After lengthy hydrogenation (30 h at i_K = 100 A m^{-2}) the lattice constant a becomes stable, resulting in a steady value of η; at higher values of i_K the changes in η are more rapidly suppressed.

A study of the electrochemical properties of the interface between niobium and a sulphuric acid electrolyte showed[89] that as a result of cathodic polarisation the double-layer capacitance (C_d) on Nb rapidly rises (in 0.5 h for i_K = 100 to 250 A m^{-2}) from 50–60 to 80 μF cm^{-2}. This increase is attributed[89] to the reduction of the thin oxide layers formed on the metal as a result of previous anodic treatment rather than to phase transitions in the near-surface layer of Nb. The micro-hardness *HV* of hydrogenated Nb layers gradually increased, reaching a stable value 10–15 h after the beginning of the cathodic polarisation, which is consistent with the X-ray analysis results. Sudden changes in current (oscillations) in alkaline solutions are well known in efficiently passivated 4*d* metals. In this case the kinetic equation for the hydrogen evolution reaction becomes

$$i_K = i_0 \cdot \exp\left[-\frac{(1-\alpha)F\eta}{RT}\right] \tag{17}$$

where i_0 is the exchange current. The oscillations of i_K often observed at high values of η are associated with ohmic changes in the near-electrode layer, i.e. with oscillations in the resistance of the electrolyte layer resulting from the alternate accumulation of molecular hydrogen and of Nb^{3+} ions.[92]

A calculation of the activation energy of the dissolution of hydrogen in Nb in H_2SO_4 solutions by Gorbachev's temperature-kinetic method gave values of 44.0 [88,89] and 47.3 kJ mole^{-1}.[93] In this case the hydrogen evolution corresponds to the Volmer process

$$H_3O^+ + \bar{e}(M) \rightleftarrows H_{ads}M + H_2O \qquad (18)$$

Thus the kinetics and mechanism of the hydrogen evolution reaction on a Nb electrode surface are very dependent on the formation of a hydride phase in the near-surface layer. The mechanism of the elementary act is complicated by the change in electronic structure of the surface on which the hydrogen is adsorbed. The overvoltage of the hydrogen evolution reaction on the hydride depends on the degree of saturation of the near-surface layer with hydrogen and on the intensity of the cathodic process.

A recent review[94] discusses three possible mechanisms of the hydrogen evolution reaction on niobium. The first includes the Volmer process (18), which determines the rate of evolution of hydrogen, followed by the fast step (Heyrovsky–Horiuti process)

$$H_{ads}M + H_3O^+ + \bar{e}(M) \rightleftarrows 2M + H_2 \qquad (19)$$

The second mechanism consists of the fast Volmer reaction (18) followed by the slow step (Tafel process)

$$H_{ads}M + H_{ads}M \rightleftarrows 2M + H_2 \qquad (20)$$

This mechanism is controlled by the recombination of H_{ads}, and therefore the rate of hydrogen evolution is independent of the electrode potential. The third mechanism postulates a fast Volmer reaction (18) followed by a slow Heyrovsky–Horiuti reaction (19). In this case the cathodic current is described by the expression

$$i_K = k_c a_{H_3O^+} \cdot \exp\left[-\frac{(1-\alpha)F\varphi}{RT}\right], \qquad (21)$$

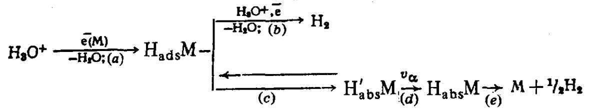
where k_c is the rate constant and $a_{H_3O^+}$ is the activity of H_3O^+. According to Eqn.(21) the slope of the polarisation curve is $(\partial\phi/\partial \lg i_K)_{pH,T} = 2.3RT/(1-\alpha)F$, and the order of the reaction with respect to OH^- ions is $(\partial \lg i_K/\partial\, pH)_{\phi,T} = 1$. These parameters apply to both polycrystalline and monocrystalline samples.

The adsorbed hydrogen can either be evolved from the metal surface or be transferred to an internally adsorbed state under the M electrode surface (*s* form), from which it can redistribute itself in the near-surface layer by diffusion:[95]

$$H_{ads}M \underset{k_{ads}}{\overset{k_{abs}}{\rightleftarrows}} H_sM \qquad (22)$$

Here k_{abs} and k_{ads} are the rate constants for the absorption of hydrogen by the metal and for its adsorption on the surface from the bulk of the metal.

In general the cathodic process leading to hydrogen evolution in acid media can be expressed as follows:[95]



$$H_3O^+ \xrightarrow[-H_2O;\,(a)]{\bar{e}(M)} H_{ads}M - \left| \begin{array}{l} \xrightarrow[-H_2O;\,(b)]{H_3O^+,\,\bar{e}} H_2 \\ \\ \xleftarrow{\hspace{3em}} \\ \xrightarrow[(c)]{\hspace{3em}} H'_{abs}M \xrightarrow[(d)]{v_\alpha} H_{abs}M \xrightarrow[(e)]{} M + {}^1/_2H_2 \end{array} \right. \qquad (23)$$

Here ν_α is the diffusional flow of hydrogen atoms into the bulk of the metal; $H'_{abs}M$ and $H_{abs}M$ denote an absorbed hydrogen atom on the metal surface and under it respectively. Some of the hydrogen forms molecules and emerges into the electrolyte, whereas the remainder penetrates into the metal where it can either form a solid solution or be bound in a hydride phase. It was suggested[69] that step (*c*) in Eqn.(23) is at equilibrium, i.e. that the hydrogen adsorbed in the *s* state is removed by electrochemical desorption according to Eqn.(19). In the case of the hydrogen absorbed by the metal two situations can arise: 1) the whole of the absorbed hydrogen is present in the bound (hydride) form, or 2) a chemical M–H bond is not formed, and supersaturation of the near-surface layer initiates the desorption process [step (*e*)], in which the hydrogen is returned to the metal–electrolyte interface where it undergoes electrochemical desorption by reaction (19).[96] Lastly, these two processes can occur simultaneously, producing a quasi-equilibrium state characterised by the slow breakdown of the hydride layer with evolution of hydrogen at the metal–electrolyte interface. We should stress that the hydrogen in solid solution is not desorbed from the entire surface of the metal but only from some specific active centres (usually, line or plane defects on the metal surface).

In the formal kinetic treatment of the scheme (23) the ratio of the rates of certain steps should affect the overall balance of hydrogen absorbed by the metal and hydrogen removed electrochemically. Experimental data for the hydride-containing metal agree well with mechanism of hydride layer formation followed by binding of the absorbed hydrogen in the hydride. In a hydrochloric acid solution the parameter b_K increases as a result of hydrogenation.[88,89] A study of the frequency dependence of the impedance[89] suggests that step (c) could be treated as a heterogeneous chemical reaction.

The general conclusion from this Section is that for low c_H in the near-surface layer (and correspondingly short cathodic polarisation times) the rate of the hydrogen evolution reaction is controlled by the slow discharge step (18). For longer cathodic processes (i.e. for high levels of hydrogenation) we must allow for the formation of Nb–H chemical bond, the decrease in the Fermi energy E_F, and the "ennoblement" of the metal resulting from the filling of the *d* band of the transition metal by the *s* electrons of the hydrogen. The decomposition of the supersaturated solid solution or the dissociation of the Nb_xH_y hydride influences the electrochemical process on the metal surface, causing an increase in the rate of formation of hydrogen molecules and possibly also in the rate of electrochemical desorption of the hydrogen.

3. Electrochemical Characteristics of the Niobium Electrode During Anodic Polarisation

Let us now examine the anodic process coupled with the hydrogen evolution reaction. The main process during anodic polarisation is the formation of an oxide layer on the anode. The initial stages of the reaction of oxygen with a clean monocrystalline niobium surface were studied[97] by a molecular beam method, which gave the changes in the sticking coefficient of the oxygen atoms (the ratio of the total number of sorbed oxygen atoms to the number of metal surface atoms on the (110) niobium face) as a function of θ_H and T. The adsorption of oxygen on the (110) face was shown to be a complex, multi-stage process, controlled by the diffusion of oxygen atoms into the bulk of the crystal. Thus on the most densely packed (110) face of niobium the adsorption of oxygen in the *s* state is possible only at high coverages of the surface by oxygen (θ_0), and its requires cooperative lateral displacements of the first layer of Nb atoms. At low θ_0 values a very thin ($l \cong 0.5$ nm) layer of oxide (Nb_xO_y, $x = 1$, $y \leq 1$) is first formed on a clean polycrystalline or monocrystalline Nb surface at 293–295 K, and this initial layer is converted into Nb_2O_5 when $l > 2$ nm.[98]

The growth of oxide films showing ionic conduction in electrolytes under anodic conditions is the result of a chemical diffusion process in an oxide of non-stoichiometric composition. Ionic transport in the growing oxide layer has been attributed[81] to the motion of positive or negative NbO_2^+ and NbO_2^- ions by the "switching over" of broken bonds on the oxygen and niobium atoms. The NbO_2^+ ions are formed at the metal–oxide interface, and the NbO_2^- ions at the oxide–solution interface. The kinetics of the formation of a layer of oxide on the anode are determined to a large extent by external conditions in the electrolyte (parameters of the anodic treatment, pH and concentration of the solution).

After a long cathodic treatment a layer of hydrides is formed on the niobium surface by the percolation mechanism. This process is hindered by non-uniform reduction of the oxide layer. An ellipsometric study[99] of changes in oxide films formed in air or by anodic oxidation of a niobium electrode, and of changes in the hydride layer previously formed by cathodic treatment over a wide range of electrode potentials, has been reported.

A study of the formation kinetics of anodic oxide on niobium by the capacitance method[100] in dilute solutions of salts, acids, and bases has shown that the formation potential of the oxide (ϕ_{ox}) is linearly time-dependent at 293–333 K. It was established[100] that under conditions of 100% current yield the thickness l of the oxide film increases according to the Young equation

$$l = k\varphi_{ox} \tag{24}$$

during the anodic oxidation, and that the rate constant of the formation $k = 2.6$ nm V^{-1} depends on the temperature and on the anodic current density i_a. Anodic polarisation of a Nb electrode covered with a layer of hydrides results in dissociation of the hydrides and formation of a new oxide layer. Cathodic polarisation of a Nb electrode bearing an anodic oxide layer does not immediately regenerate a layer of hydrides under the oxide layer. According to Auger spectral results a thin oxide layer may persist over the hydride layer even after lengthy cathodic treatment.[99] The rearrangement of the anodic oxide during hydrogenation has been interpreted[101] as an electron–proton reaction with a decrease in the valency of Nb:

$$Nb_2O_5 + H_3O^+ + \bar{e} \rightarrow Nb_2O_4OH + H_2O \tag{25}$$

The intermediate formed by reaction (25) is characteristic of the anodic treatment of Nb in alkaline solutions, since the discharge of hydrogen ions during the cathodic process increases the electronic conductivity of the Nb_2O_5 oxide: in these circumstances we must also allow for the electron-acceptor nature of the Nb^{4+} ions.

Anodic oxidation of a Nb electrode in alkaline KOH solutions leads to the formation of niobium dioxide NbO_2 as well as Nb_2O_5 on the surface.[102] Shatalov and co-workers[103] formed anodic oxides in 1 *N* solutions of HCl, HNO_3, H_3PO_4, and H_2SO_4, and they showed that the polarisation of the Nb electrode increases with time for a constant i_a. The most perfect anodic oxide layer was formed in a phosphoric acid solution, where the high electric fields needed to enhance the protective action of the Nb_xO_y are produced by changes in E_a rather than by the penetration of PO_4^{3-} into the oxide layer. However, the anionic composition of the solution during the anodic polarisation of niobium has a marked effect on the chemical composition of the anodic oxide layer. It has been reported[104] that the anodic layer produced in a 10 M H_3PO_4 solution at $i_a = 10^4$–10^6 A m^{-2} contains phosphorus impurities (up to 95 gm cm^{-2}). The partial inclusion of PO_4^{3-} ions in the anodic oxide layer is probably responsible for its high structural perfection. The anodic dissolution process is fastest in solutions containing F^- ions, since under these conditions the oxygen in the anodic layer is replaced by F^- (which has a higher affinity for Nb). The rate of dissolution of niobium fluorides is also high.

Some interesting aspects of the anodic behaviour of the $Nb_{25}Ni_{75}$ alloy in sulphuric acid solutions were observed in that work.[104] Separately, both nickel and niobium readily dissolve in sulphuric acid solutions containing halide ions (Hal^-) under anodic polarisation. However, their alloy is rapidly passivated in the same solutions. It is suggested[104] that the Nb atom is oxidised while still in the metal lattice, which lowers its activity (since NbO_2^+ has a low activity), so that the atom does not go into solution but is retained on the surface, forming a passivating oxide film. This film consists of a mixed oxide whose composition and properties are determined by the corrosion-kinetic characteristics of the components.

Alloying the niobium with noble-metal additives should make the passivating oxides chemically even more unreactive and should lower the rate of the anodic process.[105] Adding the Cl^- ion to the electrolyte increases i_a. Adding C_2H_5OH to an acid aqueous solution containing Hal^- ions lowers the number of activating anions which are adsorbed and incorporated into the anodic oxide film.[106] Accordingly, the addition of water to alcoholic bromide solutions increase the rate of the active dissolution of Nb, whereas the addition of C_2H_5OH to aqueous solutions suppresses it. A totally passive state of the Nb electrode can be obtained at some well defined ratios of alcohol to water.

The rate of anodic dissolution is very dependent on the pH. It was shown[107] that at pH > 11.3 the current i_a is almost independent of the concentration of ions ($c_{H_3O^+}$). The process is controlled by reactions (14) and (15), and its rate at $\theta_H \to 1$ can be calculated by Eqn.(21).

Thus during the formation of an anodic oxide layer the anions present in solution (especially Hal^- ions) can penetrate into the layer and affect the corrosion resistance of niobium and its alloys. The chemical affinity of the anion from the solution towards niobium is mainly responsible for determining the corrosion resistance of the metal in aggressive media: the chemical resistance of Nb can be increased not only by bulk doping but also by surface doping with cathodic additives. The near-surface layers of anodically treated Nb can be doped from acid solutions containing Mo, W, Cr, or Zn impurities, which enhance the protective action of the anodic oxide layer on Nb.[108]

4. Corrosion Behaviour of Niobium in Acid Media

Relatively few experimental results on the corrosion behaviour of niobium and its alloys in aggressive media have been published. In a study of the corrosion of Nb in aqueous hydrochloric acid solutions[109] the rate of corrosion *K* was found to decrease with time. When the temperature is raised from 305 to 373 K the parameter *K* initially increases about 20-fold, but 60 days after the beginning of the corrosion process *K* becomes almost independent of *T* (10 µm day^{-1}). In this temperature range Nb was classified as an absolutely stable metal in 1 *N* HCl solution.[109] The activation energy for dissolution in the HCl/Nb system is 50–90 kJ $mole^{-1}$. The changes in physico-mechanical and corrosion-electrochemical characteristics of Nb caused by hydrogenation without formation of hydride phases do not markedly affect the corrosion resistance of niobium in media of pH > 1, and they may even increase it slightly.[110]

The corrosion resistance of binary alloys based on niobium and of alloys doped with cathodic additives can be much higher than that of pure Nb. Thus a study[111] of the corrosion resistance of binary Nb–Ta alloys has shown that in H_2SO_4, HCl, and HNO_3 solutions these materials are in a passive state over a wide range of potentials and temperatures (373–523 K). This result was subsequently confirmed.[112] The corrosion stability of Nb–Ta alloys can be increased by high-temperature heat treatment, which produces a mixture of Nb and Ta pentoxides on the surface. The chemical inertness of β-Ta_2O_5 containing Nb is substantially higher than that of β-Nb_2O_5 containing Ta. Up to 50 at.% of niobium can be added without significantly impairing the corrosion resistance of tantalum.[112] By additionally doping these alloys with palladium or platinum we can produce constructions materials for the protection of systems operating in very corrosive media.

The corrosion resistance of niobium alloyed with ruthenium and molybdenum is discussed in Refs.113 and 114. Alloying with ruthenium lowers i_a and widens the region of potential in which the passive state is preserved. Measurements of the weight loss of these alloys in 1–10 *N* solutions of H_2SO_4 have shown that the rate of corrosion is extremely low: 10^{-4} mm $year^{-1}$ (~3×10^{-4} μm day^{-1}).[113] Thus the corrosion stability of niobium and its alloys in hydrochloric acid solutions is slightly worse than in sulphuric acid solutions. This is due to the effect of Hal^- ions on the structure and properties of the oxide films on niobium; the SO_4^{2-} ion has a very much lower surface activity.

The rate of corrosion of niobium can be decreased by alloying it with 5–10 wt.% of molybdenum or tungsten. In 4% H_2SO_4 $K = 2.2$ g m^{-2} h^{-1} for pure niobium, and 0.2–0.4 g m^{-2} h^{-1} for Nb–Mo and Nb–W alloys. However, these binary alloys have a low plasticity and require additional alloying. The addition of small quantities of zirconium (0.003–0.1 wt.%) worsens the plasticity but further improves the corrosion resistance by producing oxide layers with a more perfect structure.

The Zr + 2.5 at.% Nb alloys, whose corrosion resistance has been extensively studied,[116] is widely used in nuclear energetics and in various branches of technology. These concentrations of niobium produce a significant loss of corrosion resistance in the zirconium. Furthermore the ease of hydrogenation decreases in this alloy. Thus the Zr + 2.5 at.% Nb has some advantages over the Zircalloy-1 and Zircalloy-2 materials from the point of view of hydrogen embrittlement, but its chemical stability is inferior. This is because of the structural aspects of the oxide films discussed above. The search for effective corrosion inhibitors for this alloy is now an important problem.

5. Effect of Anions from the Solution on the Corrosion Behaviour of Niobium in Acid Media

The Hal^- ions have the strongest influence on the structure of the passivating niobium oxide layers. The passivating film is "infected" by the activating halogen ion,[116] and this lowers the active dissolution potential. Several studies of these processes have been reported, and the F^- ions are invariably found to be the most active depassivators of all the halide ions.

In the anodic dissolution of niobium in sulphuric acid electrolytes containing HF additions the following chemical and electrochemical processes on the anode have been suggested:[117–119]

$$Nb \xrightarrow{n\bar{e}, H_2O} Nb_2O_n \xrightarrow{HF} H_2NbO_xF_{(7-x)} \xrightarrow{HF, H_2SO_4} HNbF_6 , \quad (26)$$

with *x* decreasing from 7 to 0 with increasing distance from the metal surface. It follows from (26) that a film of niobium oxide fluoride is formed on the Nb electrode surface. Its formation is accompanied by oscillations of the current in the anodic polarisation curves. The parameter *n* varies between 4.65 and 4.95, i.e. non-stoichiometric niobium oxides (with poor dielectric properties) are formed. The formation of a layer of Nb_2O_5 depends on the rate of supply of oxygen to the electrode surface and requires currents higher than the limiting current. In media containing Hal^- the cathodically activated Nb electrode dissolves more rapidly. The previous cathodic polarisation increases the pH of the layer of solution adjacent to the cathode and thus helps the formation of an oxide structure more permeable to cations, resulting in a rapid decrease in *K*.[120]

In acid media Cl^- ions cause a loss of dielectric properties in the surface anodic oxides of niobium, obviously through the replacement of O by Hal^- in the film. The effectiveness of the discharge of Cl^- ions on the surface of the $Ni_{60}Nb_{40}$ alloy is increased by amorphisation of the alloy, which thus increases the chemical stability of the alloy in chloride solutions.[81] Anodic polarisation of niobium in a hydrochloric acid solution containing 0.05–10 mole $litre^{-1}$ of Cl^- lowers the effectiveness of the growth of the oxide film, the depassivating action of the adsorbed Cl^- ions being suggested[121] as an explanation.

The multi-step character of the dissolution of niobium is pointed out in many papers. The most obvious manifestations are the rearrangements in the anodic oxide layers on standing, caused by the desorption of electrolyte species. More complex electrochemical systems, containing various organic molecules in addition to solution anions, suppress the activation of niobium in Hal^- ions.[106,122] Thus, Br^- ions in aqueous solutions containing CH_3OH result in the formation of soluble $[Nb(OCH_3)_mBr_n]^{p+}$ complexes. The adsorption of organic molecules (for example, corrosion inhibitors) decreases the incorporation of active halide ions in the anodic oxide layer and thus it also lowers the constant *K*.

Thus halide ions can produce local depassivation of the Nb surface, which can take place on active centres with a low adsorption energy. The practical importance of this effect is obvious, since the great majority of assemblies, components, and apparatus used in the chemical industry are exposed to hydrogenating media containing halogen ions.

The decrease in the corrosion resistance of niobium and its alloys is strongly dependent on structural changes in the passivating oxide layer, which is itself determined by the distortion state, the concentration, and the topology of the defects in the near-surface layer, and by the crystallography of the corroding surface. Hydrogenation not only assists the dissolution of the oxide layers but also induces substantial disorder in the near-surface layer, resulting from the active interaction of the hydrogen with the defects in the metal. Further theoretical and experimental studies of the rearrangement of the surface as a result of hydrogenation and phase transitions in the near-surface layers are needed.

Modern Ideas About the Processes Involving the Formation and Growth of the Nuclei of a New Phase Under Potentiostatic Conditions

A.I.Danilov and Yu.M.Polukarov

The principal advances in the theory and practice concerning the initial stages of the electrocrystallisation of metals are considered. The thermodynamic and kinetic relations for the phase formation processes in electrochemical systems and the influence of the kinetics of the discharge of ions and of the adsorption of surfactants on the stationary rate of nucleation are analysed. The theories of the non-stationary nucleus formation and models taking into account the growth of the nuclei of a new phase are discussed.
The bibliography includes 196 references.

I. INTRODUCTION

The study of the mechanism of the formation and growth of the nuclei of a new phase in the electrodeposition of metals is of great theoretical and practical importance, because many properties of galvanic coatings are established precisely in the initial stages of the process. The development of modern technology requires the formation of thin non-porous current conducting, magnetic, and protecting layers and this is possible only on the basis of a careful study of the characteristics of the formation of a new phase.

A series of reviews and monographs have been published in recent years[1-10] in which the theories of homogeneous and heterogeneous nucleus formation have been analysed in detail. Phase formation under galvanostatic conditions has been studied.[11-28] The interpretation of the results obtained in the study of the electrocrystallisation of silver,[11,12,16] cadmium,[13] tin,[15] copper,[23-25,28] and zinc[26,27] under galvanostatic conditions is complicated by the fact that the systems enumerated, which determine the thermodynamics and kinetics of nucleation, vary in accordance with complex laws; the phase formation process is accompanied by a parallel process in which the electrical double layer is charged, part of the current is consumed on the growth of the nuclei already formed, and the ohmic potential drop can reach a considerable magnitude. The theory of galvanic nucleus formation proposed in a number of studies[13,14,17-22] involves, by virtue of the causes enumerated above, many assumptions, which complicate an adequate description of the real processes. In the present review we shall therefore consider mainly the latest theoretical and practical advances in the electrochemical nucleation of metals applicable to potentiostatic conditions.

II. THERMODYNAMICS OF THE FORMATION OF THE NUCLEI OF A NEW PHASE

The phase formation theory was initially developed for homogeneous systems, for example for the process involving the formation of a drop of liquid from a supersaturated vapour.[2,29-31] The change in the free energy of the system ΔG on formation of the nucleus of a new phase, which is equal to the work of nucleation, consists of the changes in the volume and surface energies:

$$\Delta G=-n\Delta\mu+\varphi(n)=-\frac{4\pi r^3\Delta\mu}{3V}+4\pi r^2\sigma ,$$

where n is the number of atoms or molecules in the nucleus, r the radius of the nucleus, $\phi(n)$ its surface energy, σ the specific surface energy at the vapour/liquid boundary, V the atomic or molecular volume, and $\Delta\mu$ the difference between the chemical potentials of the supersaturated and equilibrium vapours, i.e. the degree of supersaturation of the system.

The dependence of the work of formation of the drop on its radius is represented by a curve with a maximum,[2] which corresponds to the critical size of the nucleus, for the given degree of supersaturation, defined by the Gibbs–Thomson equation:

$$r_{cr}=2\sigma V/\Delta\mu \tag{1}$$

Drops with a radius $r < r_{cr}$ tend to dissolve spontaneously, while nuclei with a radius $r > r_{cr}$ tend to grow by virtue of favourable thermodynamic factors. With increase of the degree of such supersaturation in the system, the critical size of the nuclei and the work of their formation diminish and the $\Delta G(r)$ curve shifts to the origin of coordinates.

Using Eqn.(1), it is possible to formulate an expression for the rate of nucleation:[2]

$$\Delta G=\frac{16\pi\sigma^3V^2}{3\Delta\mu^2}=\frac{1}{2}n_{cr}\Delta\mu , \tag{2}$$

where the superscript "cr" corresponds to the critical state.

The critical nucleus can be defined in several ways. It is an aggregate of a new phase, which corresponds to one of the following conditions:

(1) It is in a state of metastable equilibrium with the supersaturated parent phase;

(2) its size is such that the probability of further growth is equal to the probability of dissolution;

(3) on fluctuation-induced formation, it requires the consumption of maximum work.

Within the framework of classical nucleation theory, which operates with continuous quantities, namely the size of the nucleus and the work of its formation, these three definitions are equivalent.[32]

Heterogeneous nucleus formation has been examined in a series of studies.[1,2,6,29,31,33] The formal theory presupposes that the nucleus of a liquid on the surface of a solid support has the form of a spherical segment and the change in the energy of the system ΔG^{het} following its formation is proportional to the work of homogeneous nucleation ΔG^{hom}:

$$\Delta G^{het} = \Phi \Delta G^{hom}, \tag{3}$$

where Φ is the shape factor which is equal to the ratio of the volumes of the spherical segment of the liquid phase on the surface of the support and the sphere of the same radius and depends on the wetting angle. A similar relation is valid also for the formation of crystalline nuclei.

It has been shown[34] that a force which tends to increase the radius of curvature acts along the perimeter of the drop wetting the surface of the support. When account is taken of this phenomenon, calculation of the work of formation of the critical nucleus and of its size yield values 1–2 orders of magnitude higher than those obtained when the changes in only volume and surface energy of the nucleus are considered. Whilst remaining within the framework of the macroscopic thermodynamic theory of the heterogeneous formation of a new phase, it is therefore necessary to take into account the linear tension. Neglect of the linear tension may be the reason why, for example, in the electrolytic formation of a new phase on an extraneous electrode, the calculated sizes of the nuclei are found to be of the order of several molecules or even fractions of a molecule. It is of interest to note that in these and other respects experiment agrees with the macroscopic theory.[34]

The satisfactory agreement between the classical ideas about the nucleation and experiment under the conditions of high supersaturation, which is frequently observed, it can be explained by the fact that there is an internal equilibrium in the nucleus (i.e. there is no chemical potential gradient). In this case the thermodynamic theory can be applied to the description of the nucleation of extremely small crystals. Here one must remember that the properties of such ultradisperse systems (including the surface energy) are no longer the same as those of the macrophases and the radius of curvature or the size of the cluster in the nucleation equations are obtained as a result of the replacement of the real system, consisting of two phases and the surface layer between them, by two bodies—the cluster and the parent medium with distinct interfaces.[35] The determination of the size of the crystals and of the surface energies from experimental nucleation data at high supersaturations therefore yields certain idealised values of the process parameters (we shall assume that the terms "nucleus" and "cluster" are equivalent; we have in mind an aggregate of a new phase consisting of a certain number of atoms or molecules).

On the other hand, numerous investigations of the properties of ultradisperse systems have shown[36,37] that for many metals a number of properties of the macrophase persist down to extremely small dimensions.

The main thermodynamic and kinetic characteristics of phase formation in electrochemical systems were first examined about 50 years ago.[38,39] The specific features of electrochemical nucleations have also been discussed in a number of studies.[1,2,6,40,41] The significant characteristics of electrochemical systems are as follows:[40]

(1) The presence of an electrical double layer (EDL) and an electric charge on the species (ions) arriving on the surface of the electrode and hence the need to take into acount the kinetics of charge transfer;

(2) the adsorption of water molecules, cations, anions, and organic substances on the electrode, which leads to a change in the work of formation of the nuclei and in the kinetics of the discharge of the ions;

(3) there is also a possibility of the presence of layers of partly or completely reduced atoms of the metal deposited (adatoms) formed at potentials more positive than the equilibrium value.[42,43]

We shall consider an ideal system which consists of an inert electrode immersed in the electrolyte (the term "inert" implies the absence of interaction between the deposited metal and the support). At equilibrium the electrode has a potential E_0 and the electrochemical potential of the system $\bar{\mu}_0$ is then defined by the expression[44]

$$\bar{\mu}_0 = \mu_p + zF\psi_0 \ ,$$

where μ is the chemical potential of the ion in solution, ψ_0 the Galvani potential at the metal–solution interface corresponding to E_0 (for simplicity, we shall assume that the external potential is zero), z the ionic charge, and F the Faraday.

When the electrode is polarised by an electric current, a potential E is established at the electrode and the Galvani potential and the electrochemical potential of the system change:

$$\bar{\mu} = \mu_p + zF\psi \ .$$

The quantity

$$\Delta\bar{\mu} = \bar{\mu} - \bar{\mu}_0 = zF(\psi - \psi_0) = zF(E - E_0) = zF\eta \tag{4}$$

characterises the deviation of the system from equilibrium, i.e. the degree of supersaturation in the system.[45] Eqn.(4) is valid if the chemical potential of the solution does not change when a current flows. Such conditions obtain for an insignificant change in the bulk-phase concentration of the electrolyte and are characteristic of the initial stages of the electrocrystallisation of metals.

The metal nucleus has a potential equal to the electrode potential E and its formation requires the performance of work proportional to the difference between the electrochemical potentials:[1,2,6,40,41,46]

$$\Delta G = \Phi \frac{16\pi\sigma^3V^2}{3(zF\eta)^2} = \frac{1}{2} n_{cr} zF\eta. \tag{5}$$

The Gibbs–Thomson equation can be written analogously for electrochemical systems:[46]

$$r_{cr} = \frac{2\sigma V}{zF\eta} \ . \tag{6}$$

However, there exist other points of view on the nature of the supersaturation in the electrocrystallisation of metals. For example, it has been assumed[11–13,23,24,47] that the energy relations of the nucleation process are determined by the excess number of the adatoms of the deposited metal on the electrode surface and not by the difference between the electrochemical potentials. It has been postulated[11–13] that the concentration of the adatoms depends only on the potential of the cathode:

$$c_{ad} = c_0 \cdot \exp\left(\frac{zF}{RT}\eta\right) , \tag{7}$$

where c_0 is the concentration of the adatoms at the equilibrium potential and in other studies the need to subtract from the overall overpotential η the overpotential of the transition η_t in order to differentiate the crystallisation overpotential η_c has been noted:[23,24,47]

$$\eta_c = \eta - \eta_t = \frac{RT}{zF} \ln \frac{c_{ad}}{c_0}$$

The work of formation of the nucleus is to be determined from the relation

$$\Delta G = \Phi \frac{16\pi\sigma^3V^2}{3(zF\eta_c)^2} \ .$$

This approach corresponds to the idea of the independence of the stages involving the discharge of ions with formation of adatoms and the actual process involving the formation of nuclei from the discharged atom present on the surface of the support, which in fact denies the possibility of the formation of its nucleus via the direct incorporation mechanism, which is believed by many workers[10,48] to be the most probable for electrochemical nucleation processes. Furthermore, it has been demonstrated[49] for the formation of copper nuclei on pyrographite from a sulphuric acid electrolyte that the concentration of the adatoms affects only the pre-exponential factor in the rate equation and the work of nucleation is determined by the overpotential of the cathode η.

In the atomistic theory[50,51] the supersaturation is also assumed to be $\Delta\bar{\mu} = zF\eta$ and the work of formation of the critical nucleus is calculated from the formula

$$\Delta G = n_{\text{cr}}\Delta\bar{\mu} + \varphi(n_{\text{cr}}),$$

where the function $\phi(n_{\text{cr}})$ characterises the difference between the energy of an n_{cr}-atomic complex and the overall energy of n_{cr} atoms forming part of an infinite crystal:

$$\varphi(n_{\text{cr}}) = n_{\text{cr}}\varphi_{1/2} - \sum_{n=1}^{n_{\text{cr}}} \varphi_n \ , \qquad (8)$$

where $\phi_{1/2}$ is the work required to separate an atom from the "half-crystal" position and ϕ_n is the work of separating an atom from an n-atomic cluster. In terms of its physical significance, $\phi(n_{\text{cr}})$ is equivalent to the surface energy of a complex consisting of n_{cr} atoms.

In contrast to the classical approach, in the given instance the work of formation of the nucleus is not a continuous function of n and the equivalence of the three definitions of the critical nucleus given before therefore breaks down. In the atomistic theory the nucleus is assumed to be critical if its formation requires the expenditure of maximum work. The specific size of the nucleus depends on the structure of the complexes and the interaction forces between the atoms and the support.

The relations between the work of formation of the nucleus, its critical size, and the rate of nucleation have been analysed.[52] Regardless of the approach to the phase formation processes employed, it is possible to formulate the following expressions:

$$\Delta G(n, \Delta\mu) = -n\,\Delta\mu + F(n, \Delta\mu) \ , \qquad (9)$$

$$J = A(\Delta\mu) \cdot \exp\left[-\frac{\Delta G(n_{\text{cr}}, \Delta\mu)}{RT}\right] , \qquad (10)$$

where the number of atoms in the nucleus n is a function of the degree of supersaturation, $F(n, \Delta\mu)$ is the change in the surface energy of the system on formation of an n-atomic complex, and $A(\Delta\mu)$ is the kinetic factor in the equation for the rate of nucleation J. It follows from Eqn.(9) that

$$\left[\frac{\mathrm{d}\,\Delta G}{\mathrm{d}\,\Delta\mu}\right]_{n=n_{\text{cr}}} = -n_{\text{cr}} + \left[\frac{\mathrm{d}\,F(n, \Delta\mu)}{\mathrm{d}\,\Delta\mu}\right]_{n=n_{\text{cr}}} .$$

After taking logarithms and differentiating Eqn.(10) with respect to $\Delta\mu$ at a constant temperature, the following expression was obtained:

$$n_{\text{cr}} = RT\frac{\mathrm{d}\ln J}{\mathrm{d}\,\Delta\mu} - RT\frac{\mathrm{d}\ln A}{\mathrm{d}\,\Delta\mu} + \left[\frac{\mathrm{d}\,F(n, \Delta\mu)}{\mathrm{d}\,\Delta\mu}\right]_{n=n_{\text{cr}}} .$$

When the nucleation processes are considered within narrow ranges of the degree of supersaturation, the changes in the surface energy and the kinetic factor can be neglected:

$$n_{\text{cr}} = RT\frac{\mathrm{d}\ln J}{\mathrm{d}\,\Delta\mu} . \qquad (11)$$

This equation makes it possible to determine the size of the critical nucleus from the experimental dependence of the rate of nucleation of the degree of supersaturation regardless of the nucleus formation model employed. According to the analysis[52] of the influence of the pre-exponential factor in Eqn.(10) and the surface energy $F(n, \Delta\mu)$ on the critical size of the nucleus, the error in the determination of n_{cr} by Eqn.(11) does not exceed 1–2 atoms.

Furthermore, the equations presented above permit the experimental estimation of the limits of applicability of the Gibbs–Thomson equation, since, having determined the rate of nucleation of the crystals for different degrees of supersaturation, it is easy to find the dependence of the critical size of the nucleus on $\Delta\mu$.

III. STATIONARY NUCLEATION KINETICS

The dependence of the stationary rate of nucleation J_0 on the work of formation of nuclei has been obtained in a fundamental investigation:[33]

$$J_0 = D_{\text{cr}} \cdot Z(1) \cdot \exp\left(-\frac{\Delta G}{RT}\right) = K_1 \cdot \exp\left(-\frac{K_2}{\eta^2}\right) , \qquad (12)$$

where D_{cr} is the flux of atoms becoming attached to the critical nucleus, $Z(1)$ the concentration of single atoms, and K_1 and K_2 are constants. As a result of fluctuations, a set of clusters of different size is formed in the system and their number obeys the Boltzmann distribution, so that the product

$$Z(1) \cdot \exp\left(-\frac{\Delta G}{RT}\right)$$

determines the number of critical nuclei.

The fluctuation theory was developed further in a number of studies.[6,30,41,53–58] Becker and Doring[53] used the kinetic approach to establish the relation between J_0 and ΔG. They examined the formation of kinetic nuclei as a chain of successive reactions involving addition to the cluster of or abstraction from the latter of single atoms and obtained the following equation for the rate of nucleation:

$$J_0 = K_1\left(\frac{\Delta G}{n_{\text{cr}}^2 RT}\right)^{1/2} \cdot \exp\left(-\frac{\Delta G}{RT}\right) , \qquad (13)$$

where ΔG is defined by Eqn.(2). The multiplier $(\Delta G/n_{\text{cr}}^2 RT)^{1/2}$, frequently called the Zel'dovich non-equilibrium factor,[6] characterises the deviation of the stationary size distribution of clusters from the equilibrium distribution. Analogous expressions have been obtained for J_0 in other studies.[41,54,57]

Several investigations,[6,53,55] also based on the approach of Becker and Doring, have been devoted to the kinetics of the formation of crystalline nuclei. The authors of these investigations expressed the frequencies of addition and abstraction in terms of the bonding energies between the nearest neighbours in the cluster and obtained equations for the rate of nucleation analogous to Eqn.(13).

The mathematical procedure for the solution of nucleation problems has been improved in a number of investigations.[30,56,59] The following equation has been obtained for the rate of nucleus formation:

$$J = -D(n_{\text{cr}}, t) \cdot Z_e(n_{\text{cr}}, t) \cdot \left[\frac{\partial}{\partial n}\left|\frac{Z(n, t)}{Z_e(n, t)}\right|\right]_{n=n_{\text{cr}}} , \qquad (14)$$

where $Z_e(n, t)$ is the equilibrium distribution function of the nuclei with respect to sizes and $Z(n, t)$ the number of n-atomic clusters at time t. In order to find the specific form of the function $Z(n, t)$, it is essential to solve the differential equation

$$\frac{\partial Z(n, t)}{\partial t} = \frac{\partial}{\partial n}\left[D(n, t) \cdot Z_e(n, t) \cdot \frac{\partial}{\partial n}\left|\frac{Z(n, t)}{Z_e(n, t)}\right|\right] , \qquad (15)$$

which is a complex mathematical task. However, in the stationary case, where the function $Z(n, t)$ can be assumed to be independent of time, the solution greatly simplifies. The expression for the stationary rate of nucleation, obtained by Frenkel'[30] and Zel'dovich,[56] resembles Eqn.(13), which makes it possible to describe fairly accurately the nucleus formation process in real systems.

However, for the analysis of experimental data obtained with narrow ranges of variation of the degree of supersaturation, the employment of the simpler expression (12) is frequently justified.

In examining the nucleation processes in heterogeneous systems, it is essential to take into account the change in the rate of nucleation as a result of the change in both the work of formation of the nucleus, in accordance with Eqn.(3), and in the frequencies of addition and abstraction of atoms.

The occurrence of heterogeneous nucleation via the mechanism involving the direct incorporation of atoms or molecules in the nucleus is unlikely in the gas phase,[31] so that the presence of adatoms on the support and their diffusion along the surface assume considerable importance. These factors have been examined in a review[2] and it has been shown that the rate of nucleation is higher the lower the activation energy for surface diffusion and the stronger the interaction of the adatoms on the support.

Numerous investigators dealt with the influence of the state of the support on the kinetics of nucleation from solutions.[2, 60-71] Ickert[60] considered the influence of chemical interactions during adsorption and the role of the real surface in processes involving the crystallisation of a new phase. The concept of nucleus formation on active centres, which are understood to be the sites on the surface of the support having an increased free energy, has been examined.[61-71] Nuclei are formed preferentially on these centres. Crystal lattice defects (dislocations, vacancies, and inclusions of extraneous atoms), mechanically damaged sites on the surface, or defects in the oxide layer, which are as a rule present on the surfaces of all the supports, can play the role of the active centres. The activity of the centres can vary within fairly wide limits on the same electrode, centres with the highest activity "working" initially, but, as the degree of supersaturation increases, the less active centres also begin to participate in the nucleation process. If the influence of shielding zones, arising around the growing nuclei,[72] can be neglected in a specific system, then the distribution function for the centres with respect to activities can be determined from the experimental dependence of the number of nuclei on the degree of supersaturation.[73]

The relations of the classical theory examined above can be applied also to nucleation processes in electrochemical systems if the degree of supersaturation is expressed in terms of the overpotential of the cathode in accordance with Eqn.(4). However, Eqn.(12) describes satisfactorily only experimental data obtained in systems with high exchange currents within fairly narrow ranges of overpotentials of the cathode, where it is possible to neglect the influence of the rate of discharge of the ions on the surface of the support. In this case the data on the rate of nucleation fit on the linear plots of $\ln J_0$ against $1/\eta^2$ or $\ln J_0$ against η, from the slopes of which it is possible to determine K_2 in Eqn.(12) or the number of atoms in the critical nucleus.

The description of nucleus formation within wide ranges of overpotentials in systems where the charge transfer stage is important requires allowance for the rate of discharge of the ions. A series of studies have been devoted to this problem.[23,24,46,50,51,74-79] It has been suggested[75] that the current density associated with the attachment of atoms to the critical nucleus, growing via the direct incorporation mechanism, be expressed in terms of the cathodic component of the current i_c:

$$i_c = i_0 \cdot \exp\left(\alpha \frac{zF}{RT} \eta\right)$$

and the following equation has been obtained for the stationery rate of nucleation:

$$J_0 = K_1 \cdot \exp\left(\alpha \frac{zF}{RT} \eta\right) \cdot \exp\left(-\frac{K_2}{\eta^2}\right),$$

where α is the electrochemical transfer coefficient and i_0 the exchange current density.

The discharge kinetics have been taken into account analogously in the derivation of equations for J_0 in the region of high overpotentials of the cathode in studies by Milchev and co-workers[50,51] and Chebotin et al.[76] However, this approach is not always justified. The nuclei of the new phase have a considerable surface curvature which affects the kinetics of the discharge of ions on their surface. Equations have been obtained[77] for slow discharge on a curved surface, but the Gibbs–Thomson effect[46] has been taken into account only for the anodic process. A more detailed examination of the kinetics of the discharge of ions on a curved surface has shown that the curvature influences the activation energies for the cathodic and anodic processes.[74,79,80]

The kinetics of the discharge of ions on the curved surfaces of clusters have been taken into account by Danilov and Polukarov.[79] The derivation of equations for the stationary rate of nucleation was based on the kinetic method of Becker and Doring.[53] In the derivation of the expression for the atom addition and abstraction flux densities, the cathodic and anodic components of the current density respectively were employed:

$$i_c = i_0 \cdot \exp\left(\alpha \frac{zF}{RT} \eta\right) \cdot \exp\left(-\alpha \frac{2\sigma V}{rRT}\right),$$

$$i_a = i_0 \cdot \exp\left[-(1-\alpha) \frac{zF}{RT} \eta\right] \cdot \exp\left[(1-\alpha) \frac{2\sigma V}{rRT}\right].$$

The following expressions have been obtained for the rate of nucleation via the mechanism involving the direct incorporation of atoms and nuclei:[79]

$$J_0 = K_1 \left(\frac{\Delta G}{n_{cr}^2 RT}\right)^{1/2} \cdot \exp\left[(1+\alpha) \frac{zF}{RT} \eta\right] \exp\left(-\frac{\Delta G}{RT}\right). \tag{16}$$

The work of formation of the nucleus can be expressed in different ways depending on which nucleation parameter has to be determined. For the estimation of the specific surface energy of the nucleus, ΔG is expressed in accordance with the first part of Eqn.(5) and Eqn.(16) is written in the form

$$J_0 = K_1 \eta^2 \cdot \exp\left[(1+\alpha) \frac{zF}{RT} \eta\right] \cdot \exp\left(-\frac{K_2}{\eta^2}\right). \tag{17}$$

The constant K_2 is determined from the slope of the experimental plot of the rate of nucleation against the overpotential in terms of the variables $\ln \{J_0 \eta^{-2} \exp[-(1+\alpha)zF/RT\eta]\}$ and $1/\eta^2$ and then σ is calculated.[79]

In order to calculate the number of atoms in the critical nucleus n_{cr}, it is necessary to use the second part of Eqn.(5). Eqn.(16) is then transformed into

$$J_0 = K_1 \eta^2 \cdot \exp\left[\left(1 + \alpha - \frac{n_{cr}}{2}\right) \frac{zF}{RT} \eta\right]$$

and n_{cr} can be determined from the formula

$$n_{cr} = \frac{RT}{zF} \left(\frac{d \ln J_0}{d \eta} - \frac{2}{\eta}\right) - 1 - \alpha.$$

Expressions have also been published[79] for the stationary rate of two-dimensional nucleation and nucleus formation via the surface diffusion mechanism.

Models not using macroscopic physical quantities have been proposed for the description of nucleation processes in the range of high degrees of supersaturation.[50,51,76,81–83] The atomistic theory of electrochemical nucleation has been developed by Milchev and co-workers.[50,51] The following expression has been obtained for the direct incorporation mechanism:

$$J_0 = K_1(n_{\mathrm{cr}})\cdot Z_0\cdot\exp[-\varphi(n_{\mathrm{cr}})/RT]\cdot\exp\left[(n_{\mathrm{cr}}+\alpha)\frac{zF}{RT}\eta\right],$$

where $K_1(n_{\mathrm{cr}})$ is a parameter which depends only slightly on the overpotential of the cathode, the function $\phi(n_{\mathrm{cr}})$ is defined by Eqn.(8), and Z_0 is the number of active centres on the support. To a first approximation, the dependence of the surface energy on η is neglected and the equation

$$J_0 = K_1Z_0\cdot\exp\left[(n_{\mathrm{cr}}+\alpha)\frac{zF}{RT}\eta\right] \tag{18}$$

is used.

The expression

$$J_0 = K_1Z_0^2\cdot\exp\left[(n_{\mathrm{cr}}+1)\frac{zF}{RT}\eta\right]$$

has been obtained for the formation of a nucleus via the mechanism involving the surface diffusion of adatoms.[50]

It has been shown[50,51] that the classical and atomistic models of nucleus formation are limiting cases of a single theory and are valid under the conditions of low and high supersaturations respectively. According to the atomistic theory, the number of atoms in the critical nucleus can be arbitrarily small and can even be zero. In this case the critical nucleus is an active centre of the support and addition of one atom to such a centre converts the complex into a stable formation capable of growing spontaneously under the conditions of the given supersaturation. Within the limits of a certain range of values of η, the number of atoms in the nucleus remains constant and then changes abruptly, so that the dependence of the logarithm of the rate of nucleation $\ln J_0$ on the overpotential η should be represented by broken lines. The slope of each section yields n_{cr} and the critical sizes of the nucleus in the neighbouring ranges need not necessarily differ by unity.[45,84]

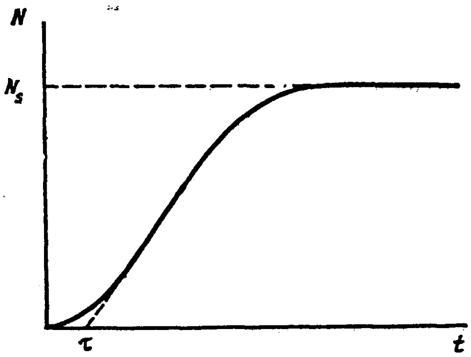
Nucleus formation in the presence on the support of centres with different activities has been examined.[76] Using the main principles of the atomistic theory, the authors obtained the following expression for the stationary rate of nucleation on active centres of the kth kind:

$$J_k = K_k\cdot\exp\left[(m_k+\alpha)\frac{zF}{RT}\eta\right]\cdot\left[1+a_k\exp\left(\frac{zF}{RT}\eta\right)\right]^{-1} \tag{19}$$

where K_k is a constant independent of η in the given range of overpotentials, $a_k = [Z_k(1)/Z_0, k)]_{\eta=0}$, and m_k is the number of atoms in the critical nucleus on the active centres of the kth kind. The numerator of Eqn.(19) yields a linear relation between $\ln J_k$ and η, analogous to that described by Milchev and co-workers,[50,51] while the denominator produces a deviation from it, which may be significant at high overpotentials and for a high adsorption capacity of the support when a_k is fairly large. In the general case, at a given overpotential, there is a set of values of m_k and the overall stationary rate of nucleus formation is determined by the sum of expressions of type (19) with respect to different kinds of active centres.[76]

Extensive experimental data have now accumulated and can be used to test the theoretical calculations for stationary nucleation in electrochemical systems. We shall not dwell on the results obtained within narrow ranges of overpotentials, because they have been examined in detail in a series of reviews.[1,2,4–6,8,9] We shall only mention that their analysis on the basis of the thermodynamic and atomistic models leads to practically identical conclusions and calculations yield similar values of the critical size and of the work of formation of the nuclei.

The determination of data for nucleation kinetics within wide ranges of overpotential is associated with considerable experimental difficulties. The main method of securing information about nucleus formation processes is the determination of the dependence of the number of nuclei of the metal deposited N on the duration of the potential static pulse t (see Figure). The use of the two-pulse method[6,85] enables the nuclei formed during the first pulse to grow further until the attainment of sizes visible under the microscope and makes it possible to count them. The stationary rate of nucleation is determined from the slope of the linear part of the $N(t)$ curve and the thermodynamic process parameters are then evaluated.



Schematic illustration of the dependence of the number of nuclei on the duration of the potentiostatic pulse (τ is the induction period and N_s the limiting number of nuclei).

Valuable results concerning the formation of silver nuclei on vitreous carbon have been obtained.[45,84] The plot of $\ln J_0$ against $1/\eta^2$ exhibits appreciable deviations from linearity, which indicates the inapplicability of Eqn.(12) to the description of the process. Treatment of the results in accordance with the atomistic model showed[45,84] that this theory describes the experiment satisfactorily and makes it possible to estimate the overpotential ranges in which the critical size of the nucleus remains constant: $n_{\mathrm{cr}} = 4$ for $\eta = 25–51$ mV, $n_{\mathrm{cr}} = 1$ for $\eta = 51–160$ mV, and $n_{\mathrm{cr}} = 0$ for $\eta > 160$ mV. However, the results[45,84] can be interpreted also on the basis of the thermodynamic theory.[79] In terms of the variables of Eqn.(17), the experimental data fit satisfactorily on a straight line, from the slope of which it is possible to calculate the constant K_2 and the critical size of the nucleus.

IV. NON-STATIONARY NUCLEUS FORMATION

The stationary course of nucleation can obtain only during a time interval before and after which nucleus formation proceeds under the conditions of a variable rate of nucleation. The increase in the rate of nucleation J in the initial stages of the process is usually attributed to the fact that supersaturation in the system is established not instantaneously but involves the slow formation of a stationary distribution of clusters with respect to size, the accumulation of the adatoms of the deposited metal, and the time variation of the activity of the extraneous electrode. The decrease in the rate of nucleation which follows the stationary section is due to the exhaustion of the active centres of the support, the overlap of the shielding zones, or the coalescence of the growing crystals, which leads to the termination of the nucleation process.

We shall consider the early stages of nucleus formation. Under the conditions of a constant supersaturation, the nucleation process can be described by the Frenkel'–Zel'dovich equations (14) and (15),[30,56] the most accurate solution of which has been obtained[86] on the assumption that the concentration of the adatoms instantaneously assumes the value corresponding to the given supersaturation [see Eqn.(7)]:

$$J(t)=J_0\left[1+2\sum_{m=1}^{\infty}(-1)^m\cdot\exp\left(-m^2\frac{t}{\tau}\right)\right], \tag{20}$$

where

$$J_0=D_{\rm cr}\left(\frac{K}{\pi}\right)^{1/2}Z(1)\cdot\exp\left(-\frac{\Delta G}{RT}\right), \tag{21}$$

$$\tau=4/\pi^2D_{\rm cr}K \tag{22}$$

Here m are positive integral numbers, τ is the induction period, and K is defined by the expression

$$K=-\frac{1}{2RT}\left[\frac{{\rm d}^2\Delta G(n)}{{\rm d}n^2}\right]_{n=n_{\rm cr}}.$$

According to this theory, the main reason for the non-stationary conditions in the early stages of the process is assumed to be the finite rate of establishment of the stationary size distribution of the clusters.

Solutions of Eqn.(15) have been obtained[87,88] taking into account the time-dependent concentration of adatoms using different mathematical approaches. The expression

$$J(t)=\frac{2J_0}{\tau}\sum_{m=1}^{\infty}(-1)^{m+1}m^2\int_0^t c(x)\cdot\exp\left[-\frac{m^2(t-x)}{\tau}\right]{\rm d}x, \tag{23}$$

where J_0 and τ are defined by Eqns.(21) and (22), c is the concentration of adatoms varying with time, and x an auxiliary variable, has been obtained.[88]

The equation for the rate of nucleation obtained by Roldugin et al.[87] is

$$J(t)=\frac{J_0}{c_\eta}\left\{c(t)-\exp\left(-\frac{t}{\tau_1}\right)\left[c_0+\int_0^t\frac{{\rm d}c(x)}{{\rm d}x}\cdot\exp\left(\frac{x}{\tau_1}\right){\rm d}x\right]\right\}, \tag{24}$$

where τ_1 is the induction period due to the redistribution of clusters with respect to size:

$$\tau_1=\frac{1}{4D_{\rm cr}K}=\frac{16RT\sigma}{i_0zF\eta^2}. \tag{25}$$

The second part of Eqn.(25) has been obtained taking into account the Gibbs–Thomson effect, according to which the flux of atoms adding to the critical nucleus in electrochemical systems is equal to the product of the surface area of the critical nucleus and the exchange current density and not the cathodic component of the current. This conclusion arises also from the second definition of the critical nucleus given above. Indeed, the probability of the growth of the nucleus is only equal to the probability of dissolution when the equality

$$i_{\rm c}=i_{\rm a}=i_0,$$

holds. Many investigators failed to take into account this fact in studying the kinetics of electrochemical nucleation.

The time variation of the concentration of adatoms in Eqn.(24) is defined by the expression[89]

$$c(t)=c_\eta-(c_\eta-c_0)\cdot\exp\left(-\frac{t}{\tau_2}\right),$$

where

$$\tau_2=\frac{zFc_0}{i_0^{\rm ad}}\cdot\exp\left[(1-\alpha)\frac{zF}{RT}\eta\right] \tag{26}$$

is the induction period due to the finite rate of accumulation of adatoms, c_η and c_0 are the limiting (for the given overpotential) and equilibrium concentrations of adatoms [see Eqn.(7)], and $i_0^{\rm ad}$ is the exchange current density of the adatoms. Evidently τ_1 diminishes and τ_2 increases with increase in the overpotential of the cathode.[87]

Estimation of the duration of the period of non-stationary conditions from Eqns.(25) and (26) yields times of the order of several milliseconds, which is close to the values determined experimentally, while neglect of the Gibbs–Thomson effect in the derivation of Eqn.(25) leads to values which are smaller by 3–5 orders of magnitude than those observed experimentally.

For $\tau_1=\tau_2=\tau$, Eqn.(24) reduces to

$$J(t)=J_0\left[1-\exp\left(-\frac{t}{\tau}\right)-\frac{c_\eta-c_0}{c_\eta}\cdot\frac{t}{\tau}\cdot\exp\left(-\frac{t}{\tau}\right)\right];$$

and if one of the components of the induction period is much greater than the other, we obtain[87]

$$J(t)=J_0\left[1-\exp\left(-\frac{t}{\tau}\right)\right]. \tag{27}$$

At low overpotentials, the effective induction period is determined by the redistribution of clusters with respect to size and decreases with increasing overpotentials in accordance with Eqn.(25); at $\eta\cong 200$ mV the minimum induction period should be observed and in the region of high supersaturations τ increases with increasing η in accordance with Eqn.(26) and the duration of the non-stationary section is determined by the rate of accumulation of adatoms on the surface of the support.[87] These theoretical estimates have been confirmed by experimental data[84] for the nucleation of silver on vitreous carbons: the relation $\tau(\eta)$ passes through a minimum at overpotentials of ~200 mV.

The influence of the time-dependent supersaturation $\Delta\mu(t)$ on the nucleation kinetics has been analysed by Kashchiev within the framework of the quasi-stationary approximation in two studies[90,91] and the following equations have been obtained:

$$\begin{aligned}J(t)&=J_0(t)\left[1-\frac{\pi^2}{6}n_{\rm cr}(t)\cdot\tau(t)\cdot\frac{{\rm d}\Delta\mu(t)}{{\rm d}t}\right],\\ J_0(t)&=D_{\rm cr}(t)\cdot[K(t)]^{1/2}Z_e[n_{\rm cr}(t),t],\\ \tau(t)&=4/\pi^2D_{\rm cr}(t)\cdot K(t),\\ K(t)&=-\frac{1}{2RT}\left[\frac{{\rm d}^2\Delta G(n,t)}{{\rm d}n^2}\right]_{n=n_{\rm cr}(t)}.\end{aligned} \tag{28}$$

These are valid subject to the condition

$$\frac{{\rm d}\Delta\mu}{{\rm d}t}<\frac{6}{\pi^2n_{\rm cr}(t)\tau(t)}.$$

Eqns.(20), (23), (24), and (28) were obtained for homogeneous nucleus formation but, by introducing the shape factor into the expression for the work of formation of the nucleus in accordance with Eqn.(3), it is possible to use them for the description of heterogeneous processes.[92]

Aleksandrov and Kedyarov[93] took into account the possibility of nucleation in which several energy barriers are overcome at a constant supersaturation and analysed the influence of the multistage course of the process on the nucleation kinetics. In particular, they showed that, in the presence of two energy barriers, the extrapolated induction period can be negative.

Milchev[94,95] developed a theory of non-stationary nucleation based on the assumption that the active centres of the support can arise during the operation of the initiating pulse at a rate which depends on the degree of supersaturation. Since the rate of nucleation is proportional to the number of centres active at the given instant, the stationary state is established only after an induction period during which all the active centres which can arise for the given degree of supersaturation are produced. For electrochemical systems, the active centres are, in particular, defects in the oxide layer on the metallic electrode, which exist before the application of the overpotential pulse or which arise during evaporation. The kinetics of the non-stationary nucleation are described by an equation identical in form to Eqn.(27), but the induction period τ should diminish with increase in the overpotential.

Theories of non-stationary nucleation have been tested thoroughly in a number of studies.[95-102] The integral form of Eqns.(20) and (27) in terms of their dimensionless variables $F = (J_0\tau)^{-1} \int\limits_0^\infty J(t)\mathrm{d}t$ and $y = t/\tau$ is more convenient for comparison with experimental data:

$$F(y) = y - \frac{\pi^2}{6} + 2\sum_{m=1}^{\infty} (-1)^m m^{-2} \cdot \exp(-m^2 y) \,, \qquad (29)$$

$$F(y) = y - 1 + \exp(-y) \,. \qquad (30)$$

It has been established that Eqn.(29) describes satisfactorily the non-stationary nucleation of mercury,[96-99] silver,[100] and cadmium[97,101] on platinum and of copper on pyrographite,[102] but systematic deviations of experimental data from the theoretical curve are observed in the region of low values of the ratio t/τ. Statistical analysis[95] of the experimental data for the nucleation of mercury on platinum showed that a more accurate description of this process is possible on the basis of the theory taking into account the variation of the number of active centres of the support[94] and the corresponding equation (30).

However, one should note that the same experimental data fit fairly well on the theoretical curves corresponding to Eqns.(29) and (30),[87] because the theoretical relations themselves differ insignificantly. The deviations from them are comparable to the experimental errors and the determination of the nature of the non-stationary conditions (the redistribution of the clusters with respect to size, slow accumulation of adatoms, the manifestation of active centres of the support, etc.) therefore requires additional information. It may be that, for each specific system, the non-stationary conditions in the initial stages of the nucleation process are due to specific causes: the state and nature of the support, the experimental conditions, etc.

In the late stages of nucleation, the rate of the process diminishes from J_0 (if it has been attained) to zero. The causes of this phenomenon have been analysed[72,103-106] on the basis of the concept that the aggregates of the new phase are initiated on the active centres of the support.

The phenomenon of such saturation in the formation of mercury nuclei on platinum has been explained[106] by the energetic homogeneity of the surface of the cathode. The possibility of explaining this finding from the standpoint of the concept of the development and overlap of shielding zones arising around the growing nuclei has been demonstrated.[72,103] These models have been generalised in a study[104] according to which the rate of nucleation is given by the relation

$$J(t) = \frac{\mathrm{d}N(t)}{\mathrm{d}t} = J_0\frac{Z_0(t)}{Z_0(0)} = J_0\frac{S(t)}{S(0)} \,,$$

where $Z_0(t)$ is the number of unoccupied active centres and $S(t)$ the surface area of the support not covered by shielding zones. At $t \to \infty$ we have $Z_0(t) \to 0$ and $S(t) \to 0$, which leads to the cessation of the nucleation process. Depending on the experimental conditions, either the exhaustion of the active centres or the overlap of the shielding zone play the decisive role.

The first case is described by the equation

$$N(t) = N_s\{1 - \exp[-J_0(t-\tau)/N_s]\} \,,$$

where $N_S = Z_0(0)$. When the shielding zones play the decisive role, the following expression has been obtained:

$$N(t) = N_s\gamma\left\{\Gamma\left(\frac{2q+2}{2q+1}\right)\frac{J_0(t-\tau)}{N_s}\right\} \,,$$

where Γ and γ are the complete and incomplete gamma-functions.

The quantities $N(t)$, N_S, J_0, and τ are determined directly from experimental plots of the number of nuclei against the duration of the pulse (see Figure) and the parameter q is found from the slope of the plot of $\ln N_S$ against $\ln J_0$.[104] In terms of the dimensionless variables $N(t)/N_S$ and $J_0(t-\tau)/N_S$, it is possible to determine the mechanism of the saturation process. For example, it has been established that, during the formation of mercury nuclei on platinum[105-107] and of copper nuclei on pyrographite,[102] the main role is played by the process involving the overlap of the shielding zones, while in the presence of surfactants the saturation during the nucleation of copper is caused by the exhaustion of the active centres of the support.[102]

V. STATISTICAL ANALYSIS OF NUCLEATION PROCESSES

One of the methods for the experimental study of nucleation kinetics involves the measurement of the time and probability of the appearance of the first nucleus. A random fluctuation process obeys the Poisson law and the probability of the appearance of at least one nucleus is given by[108]

$$P_{\geqslant 1} = 1 - \exp[-N(t)] \,,$$

where $N(t)$ is the average number of nuclei formed at a given overpotential during time t. If there is no induction period, then $N(t) = J_0 t$ and the average expectation time for the nucleus, which can be readily determined experimentally, is given by the formula

$$\bar{t}_1 = \int\limits_0^\infty t\,\mathrm{d}P_{\geqslant 1}(t) = \frac{1}{J_0} \,.$$

The stationary rate of nucleation J_0 can be determined analogously from the probability of the formation of m nuclei:

$$P_{\geqslant m+1} = 1 - \exp(-J_0 t) \cdot \sum_{k=0}^{m} (J_0 t)^k/m! \,,$$

$$\bar{t}_{m+1} = \int\limits_0^\infty t\,\mathrm{d}P_{\geqslant m+1}(t) = \frac{m+1}{J_0} \,.$$

However, in this case it is necessary to demonstrate that the process involving the appearance of m nuclei is random and obeys the Poisson law; this is not always true. For example it has been shown[45,65] that, in the nucleation of silver on vitreous carbon, deviations are observed from the Poisson law for the distribution of distances between nearest nuclei, due to the mutual influence of the growing crystallites.

If the stationary state is attained after an induction period τ, then the probability $P_{\geq 1}$ is given by the expression

$$P_{\geq 1} = 1 - \exp\left[-\int_0^t J(t)\,dt\right] .$$

Knowing the theoretical relation

$$J(t) = J_0 F(t, \tau) ,$$

where $F(t, \tau)$ is a function of time and τ, it is possible to estimate the stationary rates of nucleation and the induction period from the coordinates of the point of inflection P_i and t_i on the experimental plots of the probability of the appearance of the nucleus against time for a constant overpotential. The period τ is calculated from the relation

$$P_i = 1 - \exp\left\{-\left[\int_0^{t_i} F(t, \tau)\,dt\right] \cdot F^{-2}(t_i, \tau)\left[\frac{dF(t, \tau)}{dt}\right]_{t=t_i}\right\}$$

and then the stationary rate of nucleation is evaluated[108] from the formula

$$J_0 = -\ln(1 - P_i)/\int_0^{t_i} F(t, \tau)\,dt$$

A somewhat different mathematical procedure for the determination of J_0 and τ has been used by Milchev and Tsakova.[95] The product $J_0\tau$ is calculated from the formula

$$J_0\tau = \left[\frac{d^2F(y)}{dy^2}\right]_{y=y_i} \cdot \left[\frac{dF(y)}{dy}\right]^{-2}_{y=y_i} , \tag{31}$$

where $F(y) = N(t)/J_0\tau$ and $y = t/\tau$. The ordinate of the point of inflection in the $P_{\geq 1}(t)$ relation is given by the expression

$$P_i = 1 - \exp\left\{-\left[\frac{d^2F(y)}{dy^2}\right]_{y=y_i} \cdot \left[\frac{dF(y)}{dy}\right]^{-2}_{y=y_i} \cdot F(y_i)\right\} ,$$

on the basis of which the calibration curve $P_i(y)$ is plotted, provided that the theoretical relation $F(y)$ is known. Next the values of P_i and t_i are determined from the experimental relation between the probability of the formation of the nucleus and the duration of the potential static pulse and then $y_i = t_i/\tau$ is found with the aid of the calibration curve, the induction period τ is calculated, and the stationary rate of nucleation is evaluated from Eqn.(31).[95]

The theoretical relations (29) and (30) have been tested experimentally[95,101,108] for the nucleation of mercury and cadmium on platinum; satisfactory agreement has been found between the values of J_0 and τ determined from the experimental $N(t)$ relations and the values calculated from the results of statistical analysis.

Fairly numerous studies have been carried out recently on the statistical analysis of the processes involving the formation and growth of nuclei.[1,2,10,109–115] but their detailed examination would require too much space. We shall only note that the methods developed for the calculation of the spatial and temporal distribution of the nucleation steps permit a deeper understanding of the mechanism of nucleus formation and the analysis of the nature of the active centres of the support and of their influences on the kinetics and thermodynamics of nucleation.

VI. THE INFLUENCE OF SURFACTANTS ON THE FORMATION AND GROWTH OF NUCLEI

Surfactants have been used widely and for a long time in the cathodic deposition of metals and alloys to control the physicomechanical and structural properties of galvanic deposits. The theoretical and experimental studies of the influence of surfactants on various stages of electrochemical processes have been thoroughly described in a series of reviews and monographs,[116–119] but their action on phase formation processes has been studied to a much lesser extent.[2,24,73,107,120–125]

It has been shown[120,121] that the adsorption of surfactants in the system can alter the work of formation of nuclei and their critical size by altering the surface energy at the nucleus/electrolyte and nucleus/support interfaces (which is accompanied by a change in the wetting angle and the shape factor).

The influence of saponin on the nucleation of mercury on platinum has been studied[122] and it has been shown that, with increase in the concentration of the additive in solution, the stationary rate of nucleus formation and the number of nuclei N_s in the region of saturation on the $N-t$ curve decrease (see Figure), but the work of nucleation remains almost unchanged under these conditions. According to electrocapillary measurements, no appreciable adsorption of saponin on mercury was observed in the experimental range of potentials and concentrations of the additive, and the authors therefore explain the decrease of J_0 and N_s in terms of the blocking of the active centres of the support. It was suggested that the same centres are active in relation to both adsorption and phase formation processes. Other workers,[107] investigating the mechanism of the influence of poly(propylene glycol) on the nucleation of mercury on platinum, arrived at analogous conclusions.

The influence of acrylamide (AA) and acrylonitrile (AN) on the galvanostatic initiation of the zinc crystals on pyrographite has been investigated.[26,27] Calculation[27] showed that AN increases significantly ΔG as a consequence of its strong adsorption on the surface of the support and, after the introduction into the electrolyte of a combined additive comprising a mixture of AN and AA, the work of nucleation remains almost unchanged compared with the pure zinc sulphate solution. This finding was explained by the simultaneous adsorption of the surfactant on the nuclei and the support, which cancels out the changes in ΔG. However, these calculations, based on the separation of the crystallisation and transition overpotentials, are open to doubt because in the same study it is concluded that the size of the critical nucleus decreases after the adsorption of AN, which is inconsistent with the observed increase of ΔG.

The study of the influence of polyacrylamide (PAA) and acrylic acid (AAC) on the electrocrystallisation of copper under potentiostatic conditions[73,125] showed that PAA is adsorbed only on nuclei of specific size and is not adsorbed on the support, which leads to an increase of N_s, while the initial sections of the $N(t)$ curves in the presence of PAA coincide for the given overpotential. This effect has been explained by the decreased rate of growth of the shielding zone arising around the growing crystallites. In contrast to PAA, AAC is adsorbed on the pyrographite support and eliminates active centres, which decreases J_0 and N_s and also increases the period of non-stationary conditions.

Thus the majority of investigators have concluded that the influence of surfactants on the initial stages of electrocrystallisation is manifested mainly by the inversion of the ratio of the rates of formation and growth of the nuclei of the new phase as a result of the blocking of the active centres of the support and the inhibition of the discharge of ions on the surfaces of the growing crystallites.

VII. MODELS OF NUCLEATION TAKING INTO ACCOUNT THE GROWTH OF NUCLEI

The study of the character of the growth of nuclei can yield important information about the nucleation processes.[1,2] Analysis of the potentiostatic current–time relations (transients) has been recently used increasingly to determine the phase formation relations. The theory governing the growth of two-dimensional layers[10,127–139] and three-dimensional crystals has been confirmed by experimental studies of electrocrystallisation on dislocation-free phases of silver single crystals[10,140–146] and the formation of anodic films[147–154] and metallic nuclei,[155–159] and by mathematical modelling.[139,160–165] Investigators have devoted much attention to the role of processes involving mass transfer to the growing nuclei.[166–173]

In the present review we shall confine ourselves to the analysis of the most important studies of the three-dimensional nucleus formation and growth, which occur widely in processes involving the deposition of galvanic coatings on supports made of a different material. A general model taking into account the two-dimensional initiation and subsequent three-dimensional growth of crystals has been proposed.[174–177]

The relations governing the growth of nuclei were analysed for the first time by Sheludko and Bliznakov,[126] who derived the relation between the current associated with the growth of a single semispherical nucleus I_1 and time t for different rate-limiting stages. Under the conditions of slow discharge of ions, the current is proportional to t^2, while in processes subject to diffusional and ohmic control it is proportional to $t^{1/2}$, but the character of the dependence of the current on the potential differs significantly, which permits the experimental differentiation of the above growth mechanisms.

In the further development of the theory, the growth of an ensemble of nuclei was examined. For the diffusional growth regions, satisfactory results were provided by the model based on local semispherical diffusion;[178] corrections have been applied[17,80,179] for the initial radius of the nucleus and the Gibbs–Thomson effect. The experimental $I(t)$ relations were interpreted on the assumption of the independent increase of N for the crystallites, i.e. it was assumed that the overall current is equal to the sum of the individual currents associated with the growth of the nuclei. The following expression is then obtained for the instantaneous nucleation (the formation of N nuclei at a rate greatly exceeding the rate of their growth):

$$I_N(t) = NI_1(t),$$

while for progressive nucleation (when the rate of nucleus formation and growth are comparable)

$$I_N(t) = J_1Z_0I_1(t)\cdot t,$$

where J_1 is the specific (referred to one active centre) rate of nucleation and $I_1(t)$ the current associated with the growth of a single nucleus. An experimental test showed[17,80,178–184] that, despite the satisfactory agreement between experiment and theory in the description of the growth of single nuclei, we have $NI_1(t) > I_N(t)$ even in the initial stages of the process, which indicates a significant mutual influence of the growing nuclei.

Scharifker and Hills[185] took into account the overlap of the semispherical diffusion zones arising around the growing crystallites and obtained the following expression for the current associated with the growth of N nuclei formed simultaneously:

$$I_N(t) = zFc_v\left(\frac{D}{\pi t}\right)^{1/2}\cdot[1-\exp(\pi NkDt)], \tag{32}$$

where c_v is the volume concentration of the electrolyte, D the diffusion coefficient, and k the rate constant for the growth of the zone:

$$k = (8\pi c_v V)^{1/2}.$$

For progressive nucleation, the current is described by the expression

$$I_N(t) = zFc_v\left(\frac{D}{\pi t}\right)^{1/2}\cdot\left[1-\exp\left(-\frac{2}{3}\pi J_1Z_0kDt^2\right)\right]. \tag{33}$$

The plots of the growth current, corresponding to Eqns.(32) and (33), pass through a maximum, whose coordinate I_m and t_m can be readily found from the condition that the derivatives of the current with respect to time are zero. The product

$$I_m^2t_m = \delta D(zFc_v)^2,$$

where δ is a numerical multiplier equal to 0.1629 for instantaneous nucleation and 0.2598 for progressive nucleation, does not contain the quantities N and J_1Z_0 and is therefore a diagnostic criterion of the initial mechanism.[185] Furthermore, instantaneous and progressive nucleation can be distinguished on the basis of the experimental $I(t)$ relations plotted in terms of the variables $(I/I_m)^2$ and t/t_m and one can then calculate the quantities N and J_1Z_0. If the initiation ceases as a result of the overlap of the diffusion zones, then the limiting number of nuclei is given by the expression

$$N_s = \left(\frac{3J_1Z_0}{8kD}\right)^{1/2}.$$

Comparison of the relations obtained with the experimental data for the nucleation of lead on zinc oxide and of copper sulphide on copper[185] demonstrated a satisfactory agreement between theory and experiment.

The theory was developed further by Scharifker and Mostany.[186] In their study of diffusion-controlled nucleation on a limited number of active centres of the support, the authors of the above investigation were able to derive a system of transcendental equations, whose solution permits the independent calculation of J_1 and Z_0 from the experimental coordinates of the maximum on the current transient. Yet another advantage of this theory is the possibility of describing a diffusion-controlled potentiostatic initiation and growth process in a general form, where the instantaneous and progressive nucleation are limiting special cases.

Analysis of the current transients for the lead nucleation process on structureless carbon[187] demonstrated that the number of active centres on which the nuclei are formed increases with increasing overpotential but is almost independent of the electrolyte concentration. Furthermore, the concentration dependence of the rate of nucleation permits the conclusion that the atoms are directly incorporated in the nucleus without the intermediate deposition of adatoms. Treatment of the experimental data in accordance with the classical and atomistic nucleation theories leads to virtually identical critical sizes of the nucleus ($n_{cr} < 1$).

An interesting approach in the analysis of the formation and growth of nuclei was employed by Isaev and Baraboshkin.[188] Equations permitting the description of the nucleation processes under the conditions of diffusional and kinetic control of growth were derived on the basis of Kolmogorov's theory.
If the instantaneous nucleation takes place under the conditions of slow discharge of ions, then the current is defined by the expression

$$I = 2i_g x_1 \omega(x_1),$$

where

$$i_g = i_0 \cdot \exp\left(\alpha \frac{zF}{RT}\eta\right) - i_0 \cdot \exp\left[-(1-\alpha)\frac{zF}{RT}\eta\right]$$

and $\omega(x_1)$ is the tabulated Dawson integral:

$$\omega(x_1) = \exp(-x_1^2) \cdot \int_0^{x_1} \exp(x^2)\,dx ,$$

and the variable x_1 is defined by the expression

$$x_1 = i_g V (\pi N)^{1/2} t / zF .$$

The $I(x_1)$ relation has a maximum at $x_1 = 1.50$, which corresponds to the product $x_1\omega(x_1) = 0.64$ and the degree of surface coverage of the electrode by the growing deposit $\theta = 0.90$.

For diffusional control of growth, x_2 is described by the expression

$$x_2^2 = 2Dc_v V \cdot \pi N t \left[1 - \exp\left(-\frac{zF}{RT}\eta\right)\right]$$

and the following equation is valid for the current:

$$I = 2zFDc_v (\pi N)^{1/2} \cdot \omega(x_2) \left[1 - \exp\left(-\frac{zF}{RT}\eta\right)\right].$$

When $x_2 = 0.92$, a current maximum corresponding to $\omega(x_2) = 0.54$ and $\theta = 0.57$ is observed.

For progressive nucleus formation with kinetic control, the following equation has been obtained:

$$I = 3i_g \omega_2(x_3) ,$$

where

$$\omega_2(x_3) = \exp(-x_3^3) \cdot \int_0^{x_3} (x_3^2 - x^2) \cdot \exp(3x_3x^2 - 2x^3)\,dx ,$$

$$x_3^3 = \frac{i_g^2 V^2 \pi J_0}{3(zF)^2} t^3$$

Here the quantities $x_3 = 1.34$, $\omega_2(x_3) = 0.44$, and $\theta = 0.91$ correspond to the current maximum.

If the rate of the process is limited by bulk diffusion, then the following relation holds:

$$I = zF \left\{4Dc_v \left[1 - \exp\left(-\frac{zF}{RT}\eta\right)\right]^{3/4}\right\} \cdot \left(\frac{\pi J_0}{V}\right)^{1/4} \omega_4(x_4) ,$$

where

$$\omega_4(x_4) = \exp(-x_4^4) \cdot \int_0^{x_4} (x_4^2 - x^2) \cdot \exp(2x_4^2x^2 - x^4)\,dx ,$$

$$x_4^4 = Dc_v V \pi J_0 \left[1 - \exp\left(-\frac{zF}{RT}\eta\right)\right] \cdot t^2 .$$

In this case $x_4 = 1.08$, $\omega_4(x_4) = 0.36$, and $\theta = 0.4$ correspond to the current maximum.

The equations obtained make it possible to infer the mechanism of nucleation (instantaneous or progressive), to deduce the factor controlling the growth of nuclei (slow discharge of ions or volume diffusion), and to calculate the degree of coverage of the electrode by the deposit and the parameters of the initiation process.

The method of current transients has been used[189–193] to investigate the influence of the degree of surface coverage of the electrode by adatoms on the kinetics of three-dimensional nucleation. At potentials more positive than the equilibrium potential for the deposition of lead on the (111) and (100) faces of silver single crystals, a certain definite number of adatoms were deposited, an overpotential pulse was applied, and the time variation of the current was measured. The transients were treated on the assumption that the nucleation is progressive with diffusional control of the growth of semispherical nuclei in accordance with the theory developed in a number of investigations[180–183,194–196] and the rate of initiation of lead crystals was calculated. It was shown that, with increase in the degree of surface coverage by the adatoms, the rate of nucleation diminishes and does not increase as should have been expected.

This non-trivial fact was explained as follows: previously it had been established that the structures of the sorption layer of the adatoms and of the bulk phase of the metal differ appreciably from one another.[189,190,192] The formation of a three-dimensional nucleus therefore requires a rearrangement of the adsorption layer, whose rate depends on the density, symmetry, and ideality of the two-dimensional film. The dependence of the rate of nucleation on the potential at which the adsorption layer was formed on the surface can also be associated with the decrease of the number of active centres of the support as a result of the two-dimensional association of the adatoms or the adsorption of microimpurities.

According to the calculation based on the atomistic model of nucleation, the critical nucleus consists of 11 and 13 atoms for overpotentials in the range 10–20 mV on the (111) and (100) faces of silver single crystals respectively. Since the rate of initiation on the (100) face is much higher than on the (111) plane and the work of formation of nuclei is approximately the same, one may conclude that the preliminary maintenance of the electrode at potentials more positive than the equilibrium value influences mainly the kinetic factor in Eqn.(18) for the rate of nucleation.[193] It is therefore quite evident that, in the study of nucleus formation on supports made of a different material, it is necessary to take into account the possibility of the formation of adsorption layers or two-dimensional nuclei even in the anodic range of potentials.

---o0o---

The data considered in the review show that during recent years there has been a significant expansion of the range of studies on the initial stages in electrocrystallisation. New trends have arisen in research, in particular, a more logical allowance has been made for the specific features of the electrochemical reactions in the crystal initiation processes, a method has been developed for the analysis of the time variation of the current whereby one can estimate the number of nuclei generated and infer the mechanism of their growth, which splendidly supplements the classical two-pulse method. Interesting results have been obtained in the study of the dependence of the rate of initiation of crystal formation on the degree of coverage by adsorption layers made up of atoms of the metal deposited in the range of potentials more positive than the equilibrium potential of the phase. Systematic research has been begun on the influence of surfactants in the stage involving the initiation and growth of crystals.

The model ideas in the studies described are based on the assumption the absence of interaction between the nuclei formed. However, under the conditions of high supersaturation, which usually obtain in the electrodeposition of metals, the processes involving the coalescence of the nuclei with formation of aggregates are apparently entirely probable. There is no doubt that further study of the influence of surfactants and of the multistage occurrence of electrochemical reactions on nucleation processes will yield useful data both for the theory of electrochemical phase formation and for the practical deposition of galvanic coatings.

Spectral Sensitisation of Photoprocesses in Polymeric Donor-Acceptor Systems

A.V.Vannikov and A.D.Grishina

Processes are considered which involve the spectral sensitisation of polymeric electron donor-electron acceptor (EDA) systems as a result of which an electron is transferred and charged species are formed under the influence of visible light. Problems of the practical utilisation of the phenomenon in the development of light-sensitive recording layers, photovoltaic cells transforming light into electrical energy, and polymeric photoconductors are discussed.
The bibliography includes 148 references.

I. INTRODUCTION

The sensitisation of electron transfer reactions in EDA complexes to radiation at specific wavelengths, particularly in the visible spectral range, has been studied in detail as a fundamental problem of the effect of electromagnetic radiation on organic systems and also in connection with the possible practical applications of this phenomenon. This concerns the employment of organic complexes as photoconductors, as light-sensitive recording layers, and in photovoltaic cells transforming solar energy into electrical energy. The sensitisation is important also in the photochemical oxidation of organic compounds and in the utilisation of solar energy by photochemical methods.

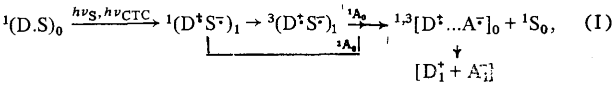
In the present review the concept of "polymeric electron donor—electron acceptor (EDA) complexes" includes not only complexes formed by polymeric components but also complexes which contain low-molecular-weight compounds distributed in a polymer matrix.

Questions concerning the spectral sensitisation of polymer compositions, incorporating donors (D), acceptors (A), and also weak charge-transfer complexes (CTC or D.A) are examined below. The sensitisation is achieved by introducing an additional component—the sensitiser (S), which exhibits optical absorption in the specified wavelength range. The present review does not discuss processes described in detail in existing publications[1-3] and based on the ionic dissociation reaction of polymer CTC ($D.A \xrightarrow{h\nu_{CTC}} D^{+\cdot} + A^{-\cdot}$) as a result of direct photoexcitation. We shall consider reactions involving sensitised electron transfer and reactions due to the sensitised formation of singlet oxygen.

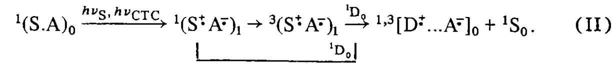
1. The Principal Types of Sensitised Charge-Transfer Reactions

(a) Reactions with Participation of the Sensitiser in Electron Transfer

The sensitiser forms CTC with the donor or acceptor component:



$$ {}^1(D.S)_0 \xrightarrow{h\nu_S,\,h\nu_{CTC}} {}^1(D^{+\cdot}S^{-\cdot})_1 \rightarrow {}^3(D^{+\cdot}S^{-\cdot})_1 \xrightarrow{{}^1A_0} \underset{\displaystyle \downarrow \atop \displaystyle [D_1^+ + A_1^-]}{{}^{1,3}[D^{+\cdot}\ldots A^{-\cdot}]_0} + {}^1S_0, \qquad (I)$$



$$ {}^1(S.A)_0 \xrightarrow{h\nu_S,\,h\nu_{CTC}} {}^1(S^{+\cdot}A^{-\cdot})_1 \rightarrow {}^3(S^{+\cdot}A^{-\cdot})_1 \xrightarrow{{}^1D_0} {}^{1,3}[D^{+\cdot}\ldots A^{-\cdot}]_0 + {}^1S_0. \qquad (II)$$

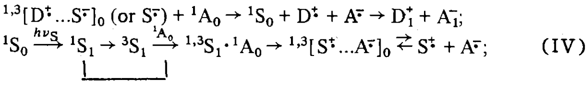
Here ${}^{1,3}(D^{+\cdot}S^{-\cdot})_0$ and ${}^{1,3}(S^{+\cdot}A^{-\cdot})_1$ are the singlet- or triplet-excited complexes and ${}^{1,3}[D^{+\cdot}\ldots A^{-\cdot}]_0$ is a geminal radical-ion pair in a singlet or triplet state.

The sensitiser forms a collision complex with the donor or acceptor component and also with the complex ${}^1(D.A)_0$:

$$ {}^1S_0 \xrightarrow{h\nu_S} {}^1S_1 \rightarrow {}^3S_1 \xrightarrow{{}^1D_0} {}^{1,3}S_1\cdot{}^1D_0 \rightarrow {}^{1,3}[D^{+\cdot}\ldots S^{-\cdot}]_0 \rightleftarrows D^{+\cdot} + S^{-\cdot}; \qquad (III)$$

secondary reaction:

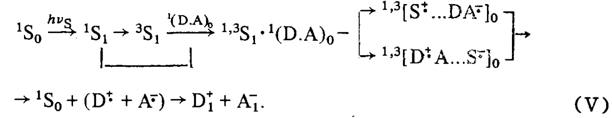
$$ {}^{1,3}[D^{+\cdot}\ldots S^{-\cdot}]_0 \,(\text{or } S^{-\cdot}) + {}^1A_0 \rightarrow {}^1S_0 + D^{+\cdot} + A^{-\cdot} \rightarrow D_1^+ + A_1^-;$$



$$ {}^1S_0 \xrightarrow{h\nu_S} {}^1S_1 \rightarrow {}^3S_1 \xrightarrow{{}^1A_0} {}^{1,3}S_1\cdot{}^1A_0 \rightarrow {}^{1,3}[S^{+\cdot}\ldots A^{-\cdot}]_0 \rightleftarrows S^{+\cdot} + A^{-\cdot}; \qquad (IV)$$

secondary reaction:

$$ {}^{1,3}[S^{+\cdot}\ldots A^{-\cdot}]_0 \,(\text{or } S^{+\cdot}) + {}^1D_0 \rightarrow {}^1S_0 + D^{+\cdot} + A^{-\cdot} \rightarrow D_1^+ + A_1^-;$$

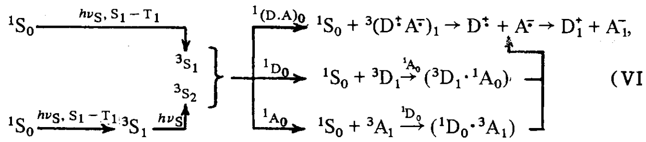


$$ {}^1S_0 \xrightarrow{h\nu_S} {}^1S_1 \rightarrow {}^3S_1 \xrightarrow{{}^1(D.A)_0} {}^{1,3}S_1\cdot{}^1(D.A)_0 - \left[\begin{array}{l} \rightarrow {}^{1,3}[S^{+\cdot}\ldots DA^{-\cdot}]_0 \\ \rightarrow {}^{1,3}[D^{+\cdot}A\ldots S^{-\cdot}]_0 \end{array}\right] \rightarrow$$

$$ \rightarrow {}^1S_0 + (D^{+\cdot} + A^{-\cdot}) \rightarrow D_1^+ + A_1^-. \qquad (V)$$

${}^{1,3}S_1.{}^1D_0$, ${}^{1,3}S_1.{}^1A_0$, and ${}^{1,3}S_1.{}^1(D.A)_0$ are collision complexes.

(b) The Sensitiser Subjected to One-Quantum or Two-Quantum Excitation is the Donor of Triplet Energy



(VI)

Processes (I)—(VI) have come to be referred to as autosensitisation when $S \equiv D_1^+$ or A_1^-.

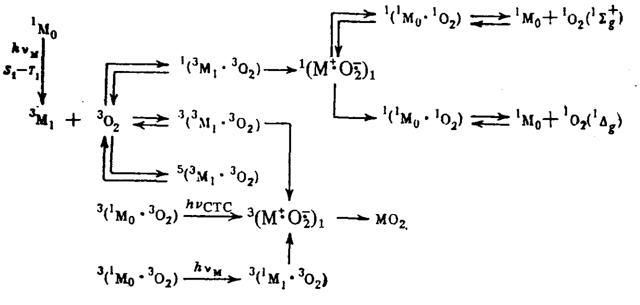
(c) Reactions with Participation of Singlet Oxygen

In the presence of O_2, singlet molecular oxygen is formed in the reaction with the triplet-excited organic molecule (${}^3M_1$) (${}^1O_2$ can be in the ${}^1\Sigma_g^+$ and ${}^1\Delta_g$ states). The reactions involving ${}^1O_2$ are used in information recording processes.

The quantum yield of $^1O_2$ is determined by the relative positions of the $E(^3M_1)$ level and the level of the excited charge-transfer state $E[^{1,3}(M^{\dot{+}}O_2^{\dot{-}})_1]$.

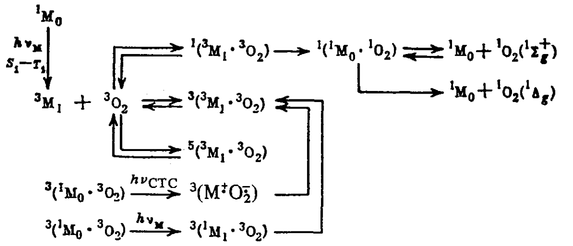
When the $E[^{1,3}(M^{\dot{+}}O_2^{\dot{-}})_1]$ level lies below $E(^3M_1)$, singlet oxygen is formed via the following reactions:

Scheme 1



When the $E[^{1,3}(M^{\dot{+}}O_2^{\dot{-}})_1]$ level lies above $E(^3M_1)$,[4,5] the direct involvement of the $^{1,3}(M^{\dot{+}}O_2^{\dot{-}})_1$ states in the process is ruled out:

Scheme 2



Comparison of the reactions via Schemes 1 and 2 shows that in the latter case only one pathway leads to the decomposition of the collision complex $^3M_1.^3O_2$ via the singlet state $^1(^3M_1.^3O_2)$ with formation of singlet oxygen, while in the former case, other conditions being equal, the reaction involving the decomposition via the state $^3(M^{\dot{+}}O_2^{\dot{-}})_1$, which does not lead to $^1O_2$, is included. Taking into account the ratios of the populations of levels with different multiplicities, one can postulate that the quantum yield in the formation of singlet oxygen via Scheme 2 will exceed by a factor of 4 the quantum yield in the formation reaction via Scheme 1.

II. PROBLEMS OF THE PRACTICAL UTILISATION OF SENSITISED ELECTRON PHOTOTRANSFER IN EDA COMPLEXES

In the development of recording polymeric donor–acceptor systems for photovoltaic cells sensitive to a given wavelength range, the sensitisers employed are dyes of different classes (cyanine, thiazine, xanthene, etc., dyes), variable valence ions, porphyrins, which are used in silver halide photography[6,7] and in the creation of liquid-phase photochemical systems transforming the energy of solar radiation into electrical or chemical energy.[8-11]

The reduction of acceptors [viologens (V^{2+})] sensitised by ruthenium complexes [including tris(2,2′-bipyridyl)ruthenium(II) or $Ru(bipy)_3^{2+}$], porphyrins, and dyes in the presence of donors of different nature has been successfully investigated in recent years in connection with the search for new systems for the storage of solar energy.[8-12] At the same time, in order to create non-silver (or low-silver) information recording systems, studies have been made of the reduction of acceptors (viologens) in the donor matrix of poly(vinyl alcohol) (PVA) under the conditions of the phoeoexcitation of additionally introduced sensitisers: riboflavin[13,14] and benzophenone.[15] For this purpose, we can also employ a system comprising V^{2+} and $Ru(bipy)_3^{2+}$ incorporated in a cellophane matrix.[12] A high sensitivity has been obtained in the composition deposited on a triacetate support and comprising PVA as the donor, *NN′*-bis(p-cyanophenyl)-4,4′-bipyridyl chloride as the acceptor, and riboflavin as the sensitiser. Excitation of riboflavin by light with $\lambda \cong 360-440$ nm in the PVA donor matrix ensures electron transfer from the matrix to the sensitiser with formation of the reduced form of riboflavin—a semiquinone radical, with a quantum yield of 0.09.[16] In the presence of V^{2+} the subsequent dark electron transfer from this radical to viologen ensures the formation of latent image centres—the radical-cations $V^{\dot{+}}$, for the visualisation and enhancement of which a physical development process is employed[14] with formation of a visible image made up of metallic silver:

$$B^{\dot{+}} + Ag^+ \rightarrow B^{2+} + Ag^0;\ Ag^0 + nAg^+ + nFe^{II} \rightarrow Ag^0Ag_n + nFe^{III}$$

The sensitivity $S_{0,1}$ to monochromatic light with $\nu_{inc} = 436$ nm was determined as the reciprocal of the exposure $H_{0,1}$ (in J cm^{-1}) for which the optical density on the exposed sections exceeds after development by 0.1 the optical density on the unexposed sections (the fog density):[14]

$$S_{0,1} = 1/H_{0,1} = 6.62\cdot 10^3\ \mathrm{cm^2\ J^{-1}}$$

Attempts have been made to create liquid-phase photogalvanic cells based on the photochemical reduction of thiazine dyes in the presence of iron(II).[17,18] Different versions of the recording of the effect of light, consisting in the photochemical reduction of thiazine dyes in the presence of donors of different nature and subsequent electron transfer from the reduced form of the dye to the metal cations in solid matrices, have been described by Oster.[19]

The products of the photochemical reduction of thiazine dyes—semiquinone radicals—initiate the polymerisation of vinyl and acrylic monomers.[19-22] A system based on the polymerisation of acrylic monomers initiated by the radical-cations $MbH^{\dot{+}}$ (Mb^+ is the dye Methylene Blue) has been used for the phase recording of holograms.[23] The effective photochemical reduction of Mb^+ was ensured by the presence in the reaction mixture of a donor—toluenesulphonic acid. The holograms were recorded by means of laser radiation with $\lambda = 632.8$ nm, which induces the photoexcitation of the dye Mb^+. It has been established[23] that two mechanisms are responsible for the phase recording: the first involves the formation of the relief and the second involves a change in the refractive index of the medium as a result of polymerisation. 4-Nitrophenylacetic acid was introduced into the reaction mixture to fix the light-sensitive layer. The dye Mb^+ decomposes irreversibly under the conditions of the photoexcitation of the acid by UV radiation. A light sensitivity of ~10^3 cm^2 J^{-1}, a resolution of 1500 mm^{-1}, and a diffraction efficiency of ~45% were attained: the contribution by the change of the refractive index is ~12% and the modulation of the thickness is ~33%.

Gelatine layers containing *N*-vinylcarbazole (VCA and CBr_4, distributed in the matrix in the form of particles whose size ranges from 0.5 to 20 μm, exhibit a high light sensitivity, approaching that of silver halide emulsions ($S_{0,2} = 3 \times 10^6$ cm^2 J^{-1} for the negative process and 3×10^4 cm^2 J^{-1} for the positive process).[24] Depending on the order in which photoexcitation and heat treatment are applied, a positive or negative process is achieved. Under the conditions of the photoexcitation of the sensitiser—the VCA.CBr_4 CTC, the latter undergoes ionic dissociation with formation of the active products $VC^{\dot{+}}$ and $Br^-...\dot{C}Br_3$, which initiate the polymerisation of VCA whose high concentration is due to its disperse state. A high quantum yield of the polymer is achieved by the subsequent intensification of the image by the alternate heat treatment of the entire layer and its exposure to intense illumination.

Sensitised donor–acceptor systems based on diazonium salts [p-aminobenzenediazonium sulphate and salts having the general formula $p\text{-X–C}_6\text{H}_4\text{–}\overset{+}{\text{N}}\equiv\text{N BF}_4^-$, where X = $(\text{C}_2\text{H}_5)_2\text{N}$, CH_3O, Br, CH_3COO, or NO_2] as acceptors[16,25–33] have been proposed for the recording of information. The donors employed are toluenesulphonic acid, sodium toluene-p-sulphonate, diphenylamine, 1,4-diazobicyclo[2.2.2]octane,[25–28] hypophosphorous acid, ascorbic acid, and the polymeric PVA matrix [combined with poly(ethylene glycol) as plasticiser].[16,29–33]

The sensitisers are dyes (thiazine, acridine, and xanthene dyes), riboflavin,[16,25–33] and variable-valence ions.[33] The essential components are also phenols and an acid stabiliser. In these systems the recording of information is due to the decomposition of the acceptors (diazonium salts) as a result of electron transfer, initially from the donor to the photoexcited sensitiser and then from the reduced sensitiser to the acceptor.

The image appears on treatment of the exposed layer with ammonia, which transforms the phenol $\text{RC}_6\text{H}_4\text{OH}$ into phenoxide ions ($\text{RC}_6\text{H}_4\text{O}^-$). The latter, which have more pronounced electron-donating properties than $\text{RC}_6\text{H}_4\text{OH}$, enter into the dark azo-coupling reaction with the acceptor preserved in the unexposed sections—the diazonium salts. This leads to the formation of the azo-dye and the colouring of the unexposed sections:

$$\text{ArN}_2^+ + \text{RC}_6\text{H}_4\text{O}^- \rightarrow \text{Ar—N=N—RC}_6\text{H}_3\text{OH}$$

The products of the photochemical decomposition of the diazonium salts do not react with phenoxide ions.

Depending on the polarity of the medium, the diazonium salts decompose via either ionic (heterolytic decomposition in polar matrices) or radical (homolytic decomposition in non-polar matrices) mechanisms:

$$p\text{-X—C}_6\text{H}_4\text{—N}_2^+ + \text{e} \rightarrow p\text{-X—C}_6\text{H}_4^{\cdot} + \text{N}_2$$

As a result of the interaction of the aryl radicals formed in the homolytic decomposition with H-donors (RH), new electron-donating free radicals R$^\bullet$, inducing the additional decomposition of the diazonium salt, are formed.[16,27] The formation of free radicals is used to initiate the polymerisation of the acrylamide introduced additionally into the layer.[28] The photoexcitation of Mb^+ by light with $\lambda = 665$ nm in a system containing p-aminobenzenediazonium sulphate as the acceptor, sodium toluene-p-sulphonate as the donor, Mb^+ as the sensitiser, and also acrylamide results in the formation of polyacrylamide (molecular weight $M = 7 \times 10^6$) with a quantum yield $\phi = 1.3 \times 10^4$. As noted above, the photosensitive dye Mb^+ initiates the polymerisation of monomeric acrylamide derivatives even in the absence of a diazonium salt. For example, the transformation of acrylamide into the polymer ($M = 9 \times 10^5$) has been found to occur[28] with a quantum yield of 1.7×10^3.

Layers based on polyvinylcarbazole (PVCA) and polyepoxypropylcarbazole (PEPC) as donors with acceptors of different nature, after the additional introduction of sensitising dyes, acquire a photosensitivity over a wide spectral range, including the absorption band of the dye. Rhodamine 6G, coumarin 6,[34] eosin,[35] as well as cyanine dyes with electron-accepting properties,[36] whose ground level lies below the upper limit of the valence band of PVCA are effective spectral sensitisers for PVCA. The effects of the sensitised photoconductivity in these systems have been discussed in detail.[1–3]

It is noteworthy that injection and chemical sensitisations are widely used for PVCA layers. Injection sensitisation at the PVCA/selenium boundary arises when aromatic molecules are introduced and is due to the formation on the interface of CTC between selenium and the aromatic molecule,[37] which equalise the "ceilings" of the valence bands of selenium and PVCA and ensure the transfer to PVCA of the holes† photogenerated in selenium.

Chemical sensitisation is ensured by the introduction of additives such as trichloroacetic acid[38] and diazonium salts[39–43] in a system consisting of a donor (PVCA) and a spectral sensitiser or acceptor (o-dinitrobenzene, trinitrofluorenone). The introduction of such additives increases the photoconductivity of the system almost by an order of magnitude and leads to the appearance of a "memory effect" consisting in an increase by 3–4 orders of magnitude (up to 24 h) of the time during which the photocurrent decreases after the illumination has been switched off. The effects are associated with the interaction of the radical-anions ($\text{A}^{\overline{\cdot}}$ or $\text{S}^{\overline{\cdot}}$), formed in the phototransfer of electrons, with the additive introduced (for example, $\text{A}^{\overline{\cdot}} + \text{H}^{\overset{+}{\cdot}} \rightarrow \text{HA}^{\overline{\cdot}}$), which lowers the rate constants for the bulk-phase recombination of the electron–hole pairs. The "memory effect" is used in the recording of information under electrophotographic conditions. A simplified scheme for the electrophotographic process on PVCA layers consists in the following steps: the layers are negatively charged uniformly with the aid of a corona discharge. After exposure, free holes, recombining with the surface negative charge, are generated in the section of the layer acted upon by light. This results in the formation of potential relief on the surface, which reproduces the distribution of illumination during exposure. The development is carried out with the aid of charged dye species.[1,44,Ch.2] The time required for this process, from exposure to development, is determined by the "retention" time of the charge on the surface, which generally speaking is short (not more than several minutes). The "memory effect" makes it possible to simplify significantly this process and to expose the uncharged surface of the film, i.e. to separate the charging and exposure stages in time and as regards apparatus. The retention of increased electroconductivity on the exposed section permits the visualisation of the image by charging the surface along time after exposure.

In photovoltaic cells and in information recording processes, it is possible to use systems which are a combination of thin metal layers and organic semiconductors. Layers of pure PVCA or PVCA containing disperse ZnO,[45] deposited on a metallic layer, are used for the electrophotographic process. In order to sensitise these systems with respect to visible light, a dye is introduced at the metal/organic layer interface. By employing dyes of different nature (sensitisers for either ZnO or PVCA), it has been established[45] that the primary stage is the photochemical oxidation of the sensitiser dye with electron transfer from the photoexcited dye to ZnO, while the secondary stage is the electron transfer from PVCA to the oxidiser sensitiser. As a result of this process, a pair of charged species is generated, which can recombine or move apart into space, contributing to the photoconductivity of the layer.

---

†Here and henceforth we shall speak of p-type (holes) and n-type (electrons) charge carriers in those cases where there is a possibility of the movement of electrons via the $\text{M}\ldots\text{M}^{\dot{+}}\ldots\text{M}$ and $\text{M}\ldots\text{M}^{\overline{\cdot}}\ldots\text{M}$ systems, where M is a neutral molecule and $\text{M}^{\dot{+}}$ and $\text{M}^{\overline{\cdot}}$ are radical-cation and radical-anion respectively.

The use of organic layers in photovoltaic cells for the transformation of solar energy into electrical energy is of special interest. The Schottky barrier, arising in the organic layer when it comes into contact with the metal, is usually employed for this purpose. Since the organic semiconductors usually exhibit p-type conductivity, a necessary condition for the formation of the Schottky barrier is $\Phi_m < \Phi_{sc}$ (Φ_m and Φ_{sc} are the electron work functions for the metal and semiconductor respectively). In this case, the organic metallic layers are charged positively and negatively respectively on contact, the height of the Schottky barrier does not exceed the difference $V_0 = \Phi_{sc} - \Phi_m$, and the electric field in the barrier region is $E_d = 2V_0/d$ (d is the width of the barrier).

The advantages of systems based on the Schottky barrier are the low cost of the necessary components and the ease of divising a technology for the preparation of the cells. Among the numerous studies devoted to this problem, we shall be interested in communications about the preparation of organic layers based on phthalocyanine without a metal (Phtc) dispersed in a polymer matrix.[46-48] Maximum efficiencies for organic systems (several per cent) have been attained on such layers sensitised by dyes. In principle, the mechanism of the generation of charge carriers in these systems is the same as in organic layers with a homogeneous distribution of the dye and semiconductor in the polymer. However, there are also specific features associated with the fact that the dye is distributed at the disperse Phtc/metal interface. In this case the redox processes in the solid-phase system proceed with electron transfer across the interface. Furthermore, for Phtc it is possible to employ the ideas of the band model of solids. Compared with the sputtered Phtc layers, polymer layers with dispersed Phtc particles make it possible to obtain cells with much higher efficiencies.[48] The main element of the photovoltaic cell is a thin (~1 μm) layer of the polymer (PVA, PVCA, polycarbonate) in which the particles of polycrystalline Phtc, with linear dimensions of several hundreds of ångstroms, are linearly distributed. This layer is deposited on a conducting support forming an ohmic contact with the latter (this requires the fulfillment of the condition $\Phi_{sup} > \Phi_{Phtc}$). A transparent layer of SnO_2 on glass or quartz and also metals (Au, Ag, Cu, Pt), are used as the conducting supports. A semitransparent layer of metal with a low electron work function is sputtered onto the free surface of the organic layer. The most stable characteristics of the cells have been obtained with indium ($\Phi_{In} = 4.0$ eV, $\Phi_{Phtc} = 5.1$ eV). When the cell is illuminated from the side of the metallic layer (for the maximum effectiveness, it is important that all the light is absorbed in the region of the barrier), electron–hole pairs are generated, are separated in the field E_d, the electron passes to the metal, and the positive charge passes into the bulk phase of the semiconductor. If the cell is in a closed electric circuit, then a short circuit current I_{sc} arises in the circuit on illumination. When the circuit is broken, a potential difference is generated in the metallic and SnO_2 layers—the open-circuit photo-e.m.f. (V_{oc}) which cannot exceed V_0. When a load resistance R is included in the external circuit, its value determines V and I generated when the cell is illuminated and the useful work is then VI.

The photo-e.m.f. and the photocurrent at which the useful work is a maximum are designated by V_{max} and I_{max}. In order to estimate the efficiency of the cell, the so called filling factor F is introduced:[34]

$$F = \frac{I_{max} V_{max}}{I_{sc} V_0}.$$

I_{sc}, V_0, and F can be calculated from the voltage–current characteristic of the cell on illumination.

The efficiency of the photovoltaic cell can be calculated relative to the intensity of the light incident on the cell L_0:

$$\eta = \frac{I_{sc} V_0 F}{L_0} \cdot 100\% \tag{1}$$

or relative to the intensity of the light which has passed through the metallic electrode L_T:

$$\eta' = \frac{I_{sc} V_0 F}{L_T} \cdot 100\% \tag{2}$$

The efficiency η characterises the efficiency of the cell as a whole and η' characterises the efficiency of the transformation of the energy at the barrier.

The quantum efficiency of the photogeneration of charge carriers can be obtained from I_{sc}:[34]

$$\varphi = 1.24 I_{sc}/L_T \lambda_{inc}, \tag{3}$$

where I_{sc} is expressed in A cm^{-2} and L_T in W cm^{-2}; λ_{inc} (nm) is the wavelength of the incident radiation.

The photocurrent spectrum is correlated with the absorption spectrum of Phtc, which indicates the independence of ϕ of λ_{inc} ($\phi = 0.27$ and $F = 0.33$). For monochromic radiation, $\lambda_{inc} = 670$ nm, $L_T = 6$ μW cm^{-2}, $I_{sc} = 1.4 \times 10^{-6}$ A cm^{-2}, $V_0 = 0.86$ V, $\eta' = 6.5\%$, and $\eta = 2\%$. However, for radiation having the same spectral composition as sunlight, $L_T = 1$ mW cm^{-2} (0.01 of the intensity of solar radiation) and $\eta' = 0.5\%$. With increase of L_T to 10 mW cm^{-2}, η' falls to 0.07%. The most readily understood pathways leading to an increase of η' are associated with the increase of I_{sc} owing to the increase of ϕ and the more effective absorption of sunlight, since the optical absorption by Phtc in the green part of the spectrum, where the maximum energy of solar radiation is concentrated, exhibits a break. The increase of ϕ on excitation by light corresponding to the absorption band Phtc can be achieved as a result of the chemical sensitisation of the system, for example, by introducing an acceptor which forms a CTC with Phtc. By selecting dyes having an absorption maximum in the green gap in the absorption by Phtc, it is possible to achieve the spectral sensitisation of the layer, which should ultimately also lead to an increase of ϕ and I_{sc}. The mechanisms of sensitisation have been discussed in two communications[34,35] and will be described in Section III.

Layers for the recording of information based on CTC between donors [aromatic amines (Am)] and acceptors (carbon tetrabromide (CBr_4) or bis(tribromomethyl) sulphone ($CBr_3SO_2CBr_3$)], which are sensitive to light in the wavelength range below 500 nm, have been sensitised with respect to visible light by the introduction of cyanine dyes;[3, Ch.5; 44, Ch.6; 49,50]. As in the silver halide process, the spectral sensitisation of these non-silver photographic systems is due to electron phototransfer reactions.

Non-silver photographic systems based on CTC between donors of different nature [the leuco-form of Crystal Violet,[51] PVCA,[52] 1,1-bis(*p*-dimethylaminophenyl)ethylene and *p*-diethylaminostyrylquinoline,[53] and benzyldiphenylamine and dibenzylaniline;[3, Ch.5; 44, Ch.6] and acceptors (CBr_4 and CHI_3) exhibit a high light sensitivity ($S_{02} \cong 10^5$ cm^2 J^{-1} [3,13, 51-58]) by virtue of the possibility of the optical intensification of the latent image, first established by Fotland.[51] The possibility of the optical intensification of the latent image is due to the fact that the coloured product formed as a result of the photodissociation of the CTC (in the final form[13,51-53, 55-57] or intermediate form[3, Ch.5; 44, Ch.6; 50,58]) is a sensitiser (autosensitiser) of a CTC-based composition for light in the region of the intrinsic absorption. The idea has been developed[51–53] that the mechanism of the optical intensification is due to the transfer of triplet energy from the photo-excited coloured product to the nearest CTC. A two-quantum mechanism of this process in the system based on the CTC between benzylamines and CBr_4 has been established.[58]

III. REACTIONS WITH PARTICIPATION OF THE SENSITISER IN ELECTRON TRANSFER

1. Energy Relations

In estimating the efficiency of electron transfer, the relative positions of the energy levels of the interacting components are compared. Together with energy characteristics such as the ionisation potential of the molecule I_M (I_D for the donor) or the electron affinity of the molecule E_M (E_A for the acceptor) in the condensed phase one uses the equilibrium oxidation-reduction potentials. The relation between these quantities is given by Eqns.(4) and (4a) for the ionisation potential and (5) and (5a) for the electron affinity

$$I_M^p = I_M^{liq} + (E_M^{\dot{+}} - P_M^{\dot{+}}), \qquad (4)$$

$$I_M^{liq} = I_M^{gas} - E_M^{\dot{+}} = E_0 + eE_{1/2}(M/M^{\dot{+}}), \qquad (4a)$$

$$E_M^p = E_M^{liq} - (E_M^{\dot{-}} - P_M^{\dot{-}}), \qquad (5)$$

$$E_M^{liq} = E_M^{gas} + E_M^{\dot{-}} = E_0 + eE_{1/2}(M^{\dot{-}}/M). \qquad (5a)$$

Here the superscripts p, liq, and gas denote the values of I_M and E_M in the polymer and in the liquids and gas phases respectively, $E_M^{\dot{+}}$ or $E_M^{\dot{-}} = (e^2/2r^{\pm})(1 - 1/\kappa)$ is the change in the real solvation energy in the liquid phase in the transition from the molecule to the radical-cation or radical-anion respectively, κ the dielectric constant of the liquid in which the potentials $E_{1/2}^{ox,\ red}$ have been measured,

$$P_M^{\dot{+}} \text{ or } P_M^{\dot{-}} = \frac{e^2}{2r^{\pm}}\left(1 - \frac{1}{\kappa_p}\right) \qquad (6)$$

the change in the polarisation energy of the polymer in the transition from the molecule to the radical-cation or radical-anion respectively, κ_p the dielectric constant of the polymer layer, $r^{\pm}$ the radius of the radical-cation or radical-anion respectively, $E_{1/2}^{ox} \equiv E_{1/2}(M/M^{\dot{+}})$ the equilibrium potential of the oxidation of the molecule via the redox reaction

$$M \rightleftarrows M^{\dot{+}} + e(S \rightleftarrows S^{\dot{+}} + e,\ D \rightleftarrows D^{\dot{+}} + e), \qquad (VII)$$

$E_{1/2}^{red} \equiv E_{1/2}(M^{\dot{-}}/M)$ the equilibrium potential of its reduction via the redox reaction

$$M^{\dot{-}} \rightleftarrows M + e(S^{\dot{-}} \rightleftarrows S + e,\ A^{\dot{-}} \rightleftarrows A + e), \qquad (VIII)$$

and E_0 the position of the level of the reference electrode relative to which the equilibrium oxidation-reduction potentials $E_{1/2}(M/M^{\dot{+}})$ and $E_{1/2}(M^{\dot{-}}/M)$ measured in the liquid phase are reckoned. According to Gurevich and co-workers,[59–61] $E_0 = \Phi + e\Delta\Phi$—reckoned from the vacuum energy of the electron in the Fermi level of the reference electrode at the equilibrium electrode potential—is determined as the electron work function (for the ejection of the electron into the gas phase) of the material of the reference electrode (Φ) with allowance for $\Delta\Phi$, where $\Delta\Phi$ is the surface potential jump due to the interaction of the reference electrode with the oriented solvent molecule; $\Delta\Phi$ depends on the nature of the reference electrode and the solvent.[59,60] Using $\Phi = 4.5$ eV and $e\Delta\Phi = -0.07$ eV for the platinum reference electrode in 1 *N* aqueous acid solution (normal hydrogen electrode: n.h.e), $E_0 = 4.43$ eV (n.h.e) was obtained.[60,61] This corresponds to $E_0 = 4.67$ eV (saturated calomel reference electrode: sat.c.e) and $E_0 = 4.62$ eV [silver chloride reference electrode in the 1 : 1 (vol.%) methanol: water mixture: Ag/AgCl].[62]

It has been noted[59] that the potential $\Delta\Phi$ is known only for some metal–solution combinations. Apparently for this reason E_0 is frequently identified with Φ. For example, E_0 has been estimated in a review,[8, p.199] as $\Phi = 4.5–4.7$ eV (n.h.e.).

It follows from the analysis of literature data that $\Delta\Phi' = 0.53$ V, i.e. the potential of the reaction at the reference electrode

$$e\ (\text{in Hg}) + HgCl_{surf} \rightleftarrows Hg^0 + Cl^-.$$

and not $E_0 = 5.07$ eV (sat.c.e.),[63,64] obtained on the basis of the idea that $E_0 = \Phi + e\Delta\Phi'$ in which $\Phi = 4.54$ eV was adopted, has been used in investigations in recent years.

The energy E_0 of the saturated calomel electrode has been calculated[65] from the measured redox potentials in aromatic hydrocarbons (AH). E_0 was obtained by adding together Eqns.(4a) and (5a) for the same molecule:

$$E_0 = \frac{I_{AH}^{gas} + E_{AH}^{gas}}{2} - \frac{e[E_{1/2}(AH/AH^{\dot{+}}) + E_{1/2}(AH^{\dot{-}}/AH)]}{2} + (E_{AH}^{\dot{-}} - E_{AH}^{\dot{+}}).$$

According to experimental data, we have

$$(I_{AH}^{gas} + E_{AH}^{gas})/2 = 4.34 \text{ eV};$$

$$\frac{e[E_{1/2}(AH/AH^{\dot{+}}) + E_{1/2}(AH^{\dot{-}}/AH)]}{2} = -0.31 \text{ eV (sat.c.e.)};$$

$$E_{AH}^{\dot{+}} = E_{AH}^{\dot{-}} = 1.94 \text{ eV}.$$

Thus $E_0 = 4.65$ eV (sat.c.e.). According to experimental estimates for aromatic hydrocarbons,[65, 66, 67] arylazonaphthols,[68] and cyanine dyes,[69] $E_M^{\dot{-}} \cong E_M^{\dot{+}} \cong 1.8–2.0$ eV in media with $\kappa > 10$ [when $(1 - 1/\kappa) \cong 1$].

Comparison of the values of I_M^{gas} measured by different methods and $E_{1/2}(M/M^{\dot{+}})$ yielded the relation

$$I_M^{gas} = E_0' + eE_{1/2}(M/M^{\dot{+}}) \qquad (4b)$$

in which $E_0' = E_0 + E_M^{\dot{+}} = 4.65 + 1.94 = 6.59$ eV (sat.c.e.),[65] $E_0' = 6.5$ eV (sat.c.e.),[70, 71] and $E_0' = 4.5 + 1.94 = 6.44$ eV (n.h.e.) [66] have been quoted for aromatic hydrocarbons in acetonitrile and $E_0' = 4.51 + 1.84 = 6.35$ eV (Ag/AgCl) for cyanine dyes in water (pH 10).[69, 72, 73]

Comparison of the values of E_A^{gas} measured by the magnetron method with the equilibrium potentials $E_{1/2}(A^{\dot{-}}/A)$ for strong acceptors (mainly those containing cyano-groups) yielded the relation[74]

$$E_A^{gas} = E_1'' + eE_{1/2}(A^{\dot{-}}/A), \text{ eV}, \qquad (5b)$$

in which $E_0'' = E_0 - E^{\dot{-}} = 2.7$ eV was obtained for solutions in acetonitrile. Similar values of E_0'' have been obtained for cyanine[69] and thiazine[75] dyes. It follows from the comparison of Eqns.(4b) and (5b) that $(E_M^{\dot{+}} + E_M^{\dot{-}}) = (E_0' - E_0'') = 3.89–3.8$ eV for the radical-ions derived from large molecules with conjugated bonds and that the real formation energy is $E_M^{\dot{+}} \cong E_M^{\dot{-}} \cong 1.95–1.9$ eV.

The polarisation energy in the solid medium P_M^{+} or P_M^{-} is determined by comparing I_M^{gas} with the threshold value for photoelectron emission.

The photoelectron emission from organic solids (including polymers) has been analysed in monographs.[76, 77] By comparing I_M^{gas} [78] with the threshold values of the photoelectron emission from compounds of different classes,[77] it is possible to estimate $P_M^{\dot{+}} \cong 1.5–1.9$ eV from Eqns.(4) and (4a). For molecules at an interface, $P_M^{\pm}$ differs from the value characteristic of the molecules within the solid phase.[47, 7] At the interface between phases having the dielectric constants κ_1 and κ_2, the energy $P^{\pm} = (e^2/2r^{\pm})(1 - 1/\kappa')$, where

$\kappa' = (\kappa_1 + \kappa_2)/2$; at the air–solid interface, $\kappa' = (1 + \kappa_{\mathrm{solid}})/2$.[36] For PVCA molecules, the polarisation energy of the radical-cation has been determined as the difference $P^{+\cdot} = I^{\mathrm{gas}}_{\mathrm{PVCA}} - I^{\mathrm{layer}}_{\mathrm{PVCA}} = 1.5$ eV [79] on the assumption that $I^{\mathrm{gas}}_{\mathrm{PVCA}} = I^{\mathrm{gas}}_{\mathrm{IPC}} = 7.6$ eV, where IPC = *N*-isopropylcarbazole. The value $I^{\mathrm{layer}}_{\mathrm{PVCA}} = 6.1$ eV has been obtained[79] by comparing the electron work function for metals *in vacuo* and the threshold energy of the light quanta ensuring the photoemission of holes from metals, sputtered onto a PVCA layer, into this polymer layer. The polarisation energies ~1.2 to 2.04 eV and 1.8 eV for aromatic hydrocarbons in polystyrene and poly(methyl methacrylate) respectively have been published in a monograph.[80] These values represent the differences between the threshold values for two-quantum ionisation of molecules in the gas phase and in the polymer matrix.

Taking into account the scatter of the values of E_0, $E^{\pm}_{\mathrm{M}}$, and $P^{\pm}_{\mathrm{M}}$ quoted in the above study, one can propose the following expressions relating the ionisation potentials of the molecule in the polymer matrix $I^{\mathrm{p}}_{\mathrm{M}}$ and the electron affinity $E^{\mathrm{p}}_{\mathrm{M}}$ to the equilibrium redox potentials.

$$I^{\mathrm{p}}_{\mathrm{M}} = E_0 + 1.9\left(\frac{1}{\kappa_{\mathrm{p}}} - \frac{1}{\varkappa}\right) + \mathrm{e}E_{1/2}(\mathrm{M}/\mathrm{M}^{+\cdot}),\ \mathrm{eV}, \tag{7}$$

$$E^{\mathrm{p}}_{\mathrm{M}} = E_0 - 1.9\left(\frac{1}{\kappa_{\mathrm{p}}} - \frac{1}{\varkappa}\right) + \mathrm{e}E_{1/2}(\mathrm{M}^{-\cdot}/\mathrm{M}),\ \mathrm{eV}, \tag{8}$$

where $E_0 = 4.6$ eV (sat.c.e.), 4.55 eV (Ag/AgCl in 1:1 (vol.%) $CH_3OH:H_2O$ mixture, and 4.36 (n.h.e.). The following notation has been adopted below:

$$\Delta G^{+}_{\mathrm{p}} = \Delta G^{-}_{\mathrm{p}} = 1.9\left(\frac{1}{\kappa_{\mathrm{p}}} - \frac{1}{\varkappa}\right)$$

$$eE'_{1/2}(\mathrm{M}/\mathrm{M}^{+\cdot}) = eE_{1/2}(\mathrm{M}/\mathrm{M}^{+\cdot}) + \Delta G^{+}_{\mathrm{p}},\ eE'_{1/2}(\mathrm{M}^{-\cdot}/\mathrm{M}) = eE_{1/2}(\mathrm{M}^{-\cdot}/\mathrm{M}) - \Delta G^{-\cdot}_{\mathrm{p}}. \tag{9}$$

2. Relative Positions of the Levels in the Electron Phototransfer Process

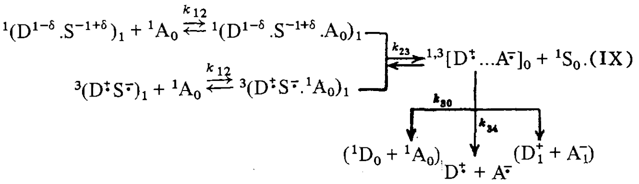
The quantum-mechanical theory of the elementary electron transfer step has been examined in detail in a monograph.[81,82] The relation between the rate constant for the quenching of the photoexcitation of molecules via electron transfer and the free energy of activation for this process in liquid media has been discussed.[83–89] In the present review attention is concentrated on the analysis of the energy characteristics of the components involved in the redox reactions and the relations between them as factors determining the direction and mechanism of the redox processes in these systems. In the development of photochemically active polymeric media on the basis of EDA complexes, the components D and A, forming either weak CTC or contact complexes corresponding to the complete electron transfer from D to A in the excited state, are employed. The use of CTC with a low-lying level and involving complete charge transfer would lead to the dark accumulation of electron transfer products.

We shall consider initially reactions with participation of the complexes D.S or S.A [compounds (I) and (II)]. Under the conditions of the formation of electron donor–electron acceptor complexes between S and D or A, there is a possibility of the processes illustrated in Fig.1. In the case of the CTC $^1(\mathrm{D.S})_0$, these processes can be represented by process (I) (Fig.1*a*):

$$\begin{tikzcd}
{}^1(\mathrm{D}^{+\delta}.\mathrm{S}^{-\delta})_0 \arrow[r, "h\nu_{\mathrm{S}}"] & ({}^1\mathrm{D}_0.{}^1\mathrm{S}_1); \arrow[d] \\
{}^1(\mathrm{D}^{+\delta}.\mathrm{S}^{-\delta})_0 \arrow[r, "h\nu_{\mathrm{CTC}}"] & {}^1(\mathrm{D}^{1-\delta}.\mathrm{S}^{-1+\delta})_1 - {}^3(\mathrm{D}^{+\cdot}\mathrm{S}^{-\cdot})_1.
\end{tikzcd}$$

Here δ is the degree of charge transfer in the ground state of the complex and $^1(\mathrm{D}^{1-\delta}.\mathrm{S}^{-1+\delta})_1$ the lowest excited singlet state of the CTC. For contact complexes, δ = 0 and $^1(\mathrm{D}^{1-\delta}.\mathrm{S}^{-1+\delta})_1 \equiv {}^1(\mathrm{D}^{+\cdot}\mathrm{S}^{-\cdot})_1$.

Next follows the formation of the collision complex with A (with the constant k_{12}) and electron transfer (k_{23}):



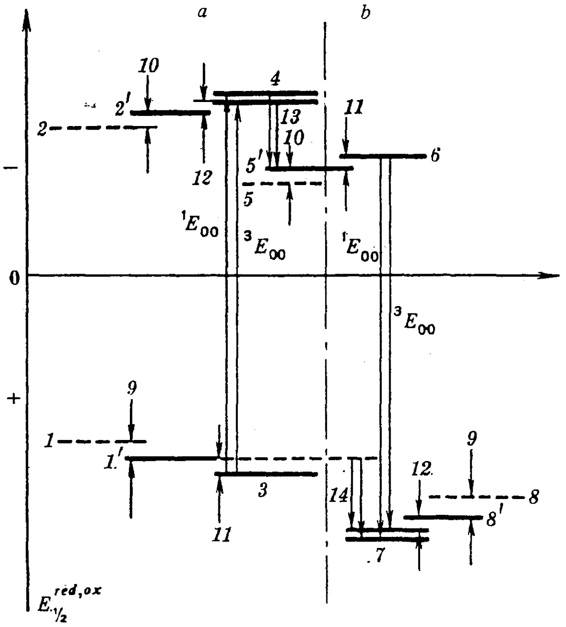


Figure 1. Schematic illustration of the relative positions of the oxidation-reduction potentials of the donor (D), the acceptor (A), and the complexes D.S (*a*) and S.A (*b*) in the ground and excited states; S = sensitiser; continuous line—polymer matrix; dashed line—liquid phase: *1*) and *1'*) $E_{1/2}({}^1\mathrm{D}_0/\mathrm{D}^{+\cdot})$, $E'_{1/2}({}^1\mathrm{D}_0/\mathrm{D}^{+\cdot})$; *2*) and *2'*) $E_{1/2}(\mathrm{S}^{-\cdot}/{}^1\mathrm{S}_0)$, $E'_{1/2}(\mathrm{S}^{-\cdot}/{}^1\mathrm{S}_0)$; *3*) $E_{1/2}[{}^1(\mathrm{D.S})_0/(\mathrm{D}^{+\cdot}\mathrm{S})]$; *4*) $E_{1/2}[{}^{1,3}(\mathrm{D}^{+\cdot}\mathrm{S}^{-\cdot})/.(\mathrm{D}^{+\cdot}\mathrm{S})$; *5*) and *5'*) $E_{1/2}(\mathrm{A}^{-\cdot}/{}^1\mathrm{A}_0)$, $E'_{1/2}(\mathrm{A}^{-\cdot}/{}^1\mathrm{A}_0)$; *6*) $E_{1/2}.[(\mathrm{SA}^{-\cdot})/{}^1(\mathrm{S.A})_0$; *7*) $E_{1/2}[(\mathrm{SA}^{-\cdot})^{1,3}(\mathrm{S}^{+\cdot}\mathrm{A}^{-\cdot})_1]$; *8*) and *8'*) $E_{1/2}.({}^1\mathrm{S}_0/\mathrm{S}^{+\cdot})$, $E'_{1/2}({}^1\mathrm{S}_0/\mathrm{S}^{+\cdot})$; *9*) $\Delta G^{+}_{\mathrm{p}}$; *10*) $\Delta G^{-}_{\mathrm{p}}$; *11*) *X*; *12*) $\Delta G^{\mathrm{p}}_{\mathrm{CTC}}$; *13*) ΔG_{23} (IX); *14*) ΔG_{23} (X).

The free energy ΔG_{23} (IX) of the electron transfer stage of reaction (IX) represents the difference between the redox potentials (Fig.1a):

$$\Delta G_{23}(\mathrm{IX}) = eE'_{1/2}[{}^{1.3}(\mathrm{D}^{+\cdot}\mathrm{S}^{-\cdot})_1/(\mathrm{D}^{+\cdot}\mathrm{S})] - eE'_{1/2}(\mathrm{A}^{-\cdot}/{}^1\mathrm{A}_0) \tag{10}$$

In this formula $E'_{1/2}[{}^{1/3}(\mathrm{D}^{+\cdot}\mathrm{S}^{-\cdot})_1/(\mathrm{D}^{+\cdot}\mathrm{S})]$ is the potential, adjusted to the polymer matrix, for the oxidation of the excited complex in the redox reaction

$$^{1,3}(\mathrm{D}^{+\cdot}\mathrm{S}^{-\cdot})_1 \rightleftarrows (\mathrm{D}^{+\cdot}\mathrm{S}) + \mathrm{e}$$

$$[\text{or } {}^1(\mathrm{D}^{1-\delta}.\mathrm{S}^{-1+\delta})_1 \rightleftarrows (\mathrm{D}^{+\cdot}\mathrm{S}) + \mathrm{e}],$$

which can be calculated from the relation

$$eE'_{1/2}[^{1,3}(D^{+\cdot}S^{-\cdot})_1/(D^{+\cdot}S)] = eE'_{1/2}[^1(D.S)_0/(D^{+\cdot}S)] - {}^{1,3}E_{00}, \qquad (11)$$

where $^{1,3}E_{00}$ is the distance from the ground to the excited singlet or triplet level of the complex:

$$eE'_{1/2}[^1(D.S)_0/(D^{+\cdot}S)] = eE_{1/2}(^1D_0/D^{+\cdot}) + X + \Delta G^+_p \qquad (11a)$$

—the equilibrium potential, adjusted to the polymer matrix, for the oxidation of the complex in the ground state by the reaction

$$^1(D.S)_0 \rightleftarrows (D^{+\cdot}S) + e.$$

In Eqn.(11a), X is the formation energy of the complex; for contact complexes, the term $X = 0$ and for CTC we have

$$X = \frac{\{W_{01} - eS_{01}[E'_{1/2}(^1D_0/D^{+\cdot}) + E_0]\}^2}{e[E'_{1/2}(^1D_0/D^{+\cdot}) - E'_{1/2}(S^{-\cdot}/^1S_0)] + (P^+_D + P^-_S) - (Q^{gas} + P)},$$

where $W_{01} = \int \phi_1(D,S)H\phi_2(\overset{+}{D^{\cdot}}S^{-\cdot})d\tau$ is the energy of the interaction of uncoupled states $[\phi_1(D,S)]$ and states corresponding to the total charge transfer between the components $[\phi_2(D^{+\cdot}S^{-\cdot})]$; $W_{01} = 0$ for contact complexes and $W_{01} \cong 0.05$ to 0.5 eV for CTC; $S_{01} = \int \phi_1(D,S)\phi_2(D^{+\cdot}S^{-\cdot})d\tau$ the overlap integral of the wavefunctions of these states; $S_{01} = 0$ for contact complexes and $S_{01} = 0.01$–0.1 for CTC. $Q^{gas} = e^2/2r$ is the energy of the Coulombic attraction of the radical-ions in the state $^{1,3}(D^{+\cdot}S^{-\cdot})_1$ in the gas phase.

$$P = 2\mu^2\left(\frac{\kappa_p - 1}{2\kappa_p + 1}\right)/a^3 \qquad (12)$$

P is the energy of the polarisation of the polymeric medium by the dipole $^{1,3}(D^{+\cdot}S^{-\cdot})_1$ including the rapid electronic and also the atomic and slow orientational components. $\mu = er_{D^{+\cdot}S^{-\cdot}} \cong 2er$ is the dipole moment, $a(\cong 2r)$ the radius of the cavity of the polarising dipole, and $r = r^+ = r^-$ the radius of the radical-cation or radical-anion. Hence

$$Q^{gas} + P = 1.9\left(\frac{4\kappa_p - 1}{2\kappa_p + 1}\right).$$

In reaction (IX) the lifetime of the polar states $^1(D^{1-\delta}.S^{-1+\delta}.A)_1$ is $>10^{-12}$ s when the formation of the collision complex between the excited complex and the molecule A is a result solely of the increase of the size of the complex on its photoexcitation. During this period, only the electronic polarisation of the medium is established (whence $\kappa_p = n^2$, n being the refractive index). At the same time, under the conditions of the segmental mobility of the polymer unit, collision with a molecule can occur after the relaxation of the excited complex to a state of equilibrium ($^{1,3}E_{00}$) corresponding to the polarisation energy P and hence corresponding to equilibrium in relation to the redox potential of the excited complex:

$$^{1,3}E_{00} = I^{gas}_D - E^{gas}_S + X - (Q^{gas} + P) + {}^{1,3}Q_e = e[E'_{1/2}(^1D_0/D^{+\cdot}) - E'_{1/2}(S^{-\cdot}/^1S_0)] + X + \Delta G^P_{CTC} + {}^{1,3}Q_e, \qquad (13)$$

$$\Delta G^P_{CTC} = (P^+_D + P^-_S) - (Q^{gas} + P), \qquad (14)$$

where $^1Q_e = X + {}^1Q'_e$, $^1Q'_e = J_{12} + K_{12}$, and $^3Q_e = J_{12} - K_{12}$ are the interelectron repulsion energies in the singlet-excited and triplet-excited complex. J_{12} and K_{12} are the Coulombic and exchange energies respectively.[90]

According to Eqns.(11), (11a), and (13),

$$eE'_{1/2}[^{1,3}(D^{+\cdot}S^{-\cdot})_1/(D^{+\cdot}S)] = eE_{1/2}(S^{-\cdot}/^1S_0) - \Delta G^P_{CTC} - \Delta G^-_P - {}^{1,3}Q_e. \qquad (15)$$

Thus we obtain from Eqns.(10) and (15) (Fig.1*a*):

$$\Delta G_{23}(IX) = e[E_{1/2}(S^{-\cdot}/^1S_0) - E_{1/2}(A^{-\cdot}/^1A_0)] - \Delta G^P_{CTC} - {}^{1,3}Q_e. \qquad (10a)$$

When a CTC of the type $^1(S.A)_0$ participates in the electron transfer, photoprocesses (X), analogous to (IX), proceed in accordance with Scheme (II) (with replacement of D by S and of S by A). The free energy of electron phototransfer is (Fig.1b)

$$\Delta G_{23}(X) = e\{E'_{1/2}(^1D_0/D^{+\cdot}) - E'_{1/2}[(SA^{-\cdot})/^{1,3}(S^{+\cdot}A^{-\cdot})_1]\}, \qquad (16)$$

where

$$E'_{1/2}[(SA^{-\cdot})/^{1,3}(S^{+\cdot}A^{-\cdot})_1] = eE'_{1/2}[(SA^{-\cdot})/^1(SA)_0] + {}^{1,3}E_{00};$$
$$eE'_{1/2}[(SA^{-\cdot})/^1S.A_0)] = eE'_{1/2}(A^{-\cdot}/^1A_0) - X;$$
$$^{1,3}E_{00} = e[E'_{1/2}(^1S_0/S^{+\cdot}) - E'_{1/2}(A^{-\cdot}/^1A_0)] + \Delta G^P_{CTC} + X + {}^{1,3}Q_e.$$

After substitutions, Eqn.(16) becomes

$$\Delta G_{23}(X) = e[E_{1/2}(^1D_0/D^{+\cdot}) - E_{1/2}(^1S_0/S^{+\cdot})] - \Delta G^P_{CTC} - {}^{1,3}Q_e.$$

We shall now proceed to the consideration of reactions (III) to (V) of the photoexcited sensitiser. The electron phototransfer reactions involving a sensitiser which does not form complexes with D or A components in the ground state are considered below. Spectral sensitisation is in this case caused by the formation of the collision complex between the photoexcited sensitiser and the D and A components of the system. It is shown below that the direction of the charge transfer process (the type of primary reaction) is determined by the relative positions of the levels of the photoexcited sensitiser and the equilibrium redox potential of the components of the EDA system.

We shall now examine the primary oxidation of the donor and the reduction of the excited sensitiser [reactions (III) to (V)]:

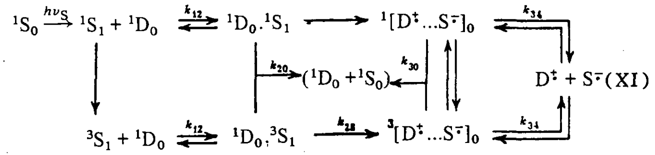

Fig.2*a* shows that reaction (XI) in stage 23 is determined by the shift of the reduction potential of the sensitiser in the excited state in the positive direction up to the value (in the polymer composition)

$$eE'_{1/2}(S^{-\cdot}/^{1,3}S_1) = eE_{1/2}(S^{-\cdot}/^1S_0) - \Delta G^-_p + {}^{1,3}E_{00}\ (\text{or } {}^{1,3}E). \qquad (17)$$

The potential defined by Eqn.(17) corresponds to equilibrium if the electron transfer reaction takes place after the transitions of $^{1,3}S_1$ to the lowest excited singlet or triplet level ($^{1,3}E_{00}$).

The free energy of electron transfer (stage 23) in reaction (XI) is

$$\Delta G_{23}(XI) = e[E_{1/2}(^1D_0/D^{+\cdot}) - E_{1/2}(S^{-\cdot}/^1S_0)] + 2\Delta G^+_p - \frac{e^2}{R\kappa} - {}^{1,3}E_{00}, \qquad (18)$$

where R is the distance between $D^{+\cdot}$ and $S^{-\cdot}$ in the geminal pair. It has been suggested that, in contrast to the excited CTC, for example $^{1,3}(D^{+\cdot}S^{-\cdot})_1$, polarising the medium as a single dipole [see Eqn.(12)], the geminal pair $^{1,3}[D^{+\cdot}...S^{-\cdot}]_0$ corresponds to the Coulombic attraction ($e^2/R\kappa$) of the radical-ions having their own solvation shells.

The free energy of the secondary reaction

$$S^{-\cdot} + {}^1A_0 \rightleftarrows {}^1S_0 + A^{-\cdot} \qquad (XII)$$

is defined as the difference between the following equilibrium redox potentials:

$$\Delta G_{sec}(XII) = e[E_{1/2}(S^{-\cdot}/^1S_0) - E_{1/2}(A^{-\cdot}/^1A_0)]. \qquad (19)$$

In the primary reduction of the acceptor as a result of the oxidation of the photoexcited sensitiser [reaction (IV)], processes (XIII) and (XIV) (Fig.2*b*), analogous to processes (XI and (XIX) (with the replacement of D by S and of S by A), take place.

The free energy of electron transfer via reaction (XIII) is (Fig. 2*b*)

$$\Delta G_{23}(\mathrm{XIII}) = e[E_{1/2}(^1\mathrm{S}_0/\mathrm{S}^{\cdot+}) - E_{1/2}(\mathrm{A}^{\cdot-}/^1\mathrm{A}_0)] + 2\Delta G_\mathrm{p}^{\pm} - \frac{e^2}{R\kappa} - {}^{1,3}E_{00}, \quad (20)$$

while that of electron transfer via reaction (XIV) is given by

$$\Delta G_\mathrm{sec}(\mathrm{XIV}) = e[E_{1/2}(^1\mathrm{D}_0/\mathrm{D}^{\cdot+}) - E_{1/2}(^1\mathrm{S}_0/\mathrm{S}^{+})]. \quad (21)$$

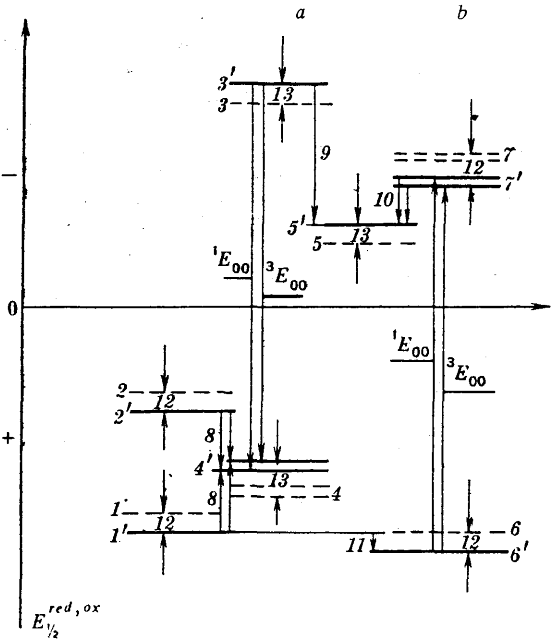

Figure 2. Schematic illustration of the relative positions of the oxidation-reduction potentials in the primary donor oxidation (*a*) and acceptor reduction (*b*) reactions; D and D′ = donors of different nature: *1*) and *1′*) $E_{1/2}(^1\mathrm{D}_0/\mathrm{D}^{\cdot+})$, $E'_{1/2}(^1\mathrm{D}_0/\mathrm{D}^{\cdot+})$; *2*) and *2′*) $E_{1/2}(^1\mathrm{D})'_0/(\mathrm{D}')^{\cdot+}$, $E'_{1/2}[^1(\mathrm{D}')_0/(\mathrm{D}')^{\cdot+}]$; *3*) and *3′*) $E_{1/2}(\mathrm{S}^{\cdot-}/^1\mathrm{S}_0)$, $E'_{1/2}(\mathrm{S}^{\cdot-}/^1\mathrm{S}_0)$; *4*) and *4′*) $E_{1/2}(\mathrm{S}^{\cdot-}/^{1,3}\mathrm{S}_1)$, $E'_{1/2}(\mathrm{S}^{\cdot-}/^{1,3}\mathrm{S}_1)$; *5*) and *5′*) $E_{1/2}(\mathrm{A}^{\cdot-}/^1\mathrm{A}_0)$, $E'_{1/2}(\mathrm{A}^{\cdot-}/^1\mathrm{A}_0)$; *6*) and *6′*) $E_{1/2}(^1\mathrm{S}_0/\mathrm{S}^{\cdot+})$, $E'_{1/2}(^1\mathrm{S}_0/\mathrm{S}^{\cdot+})$; *7*) and *7′*) $E_{1/2}(^{1,3}\mathrm{S}_1/\mathrm{S}^{\cdot+})$, $E'_{1/2}(^{1,3}\mathrm{S}_1/\mathrm{S}^{\cdot+})$; *8*) ΔG_{23} (XI); *9*) ΔG_sec (XII); *10*) ΔG_{23} (XIII); *11*) ΔG_sec (XIV); *12*) ΔG_p^{+}; *13*) ΔG_p^{-}.

The dominant direction of the primary reaction is determined by the difference between free energies $\Delta G_{23}(\mathrm{XI})$ to $\Delta G_{23}(\mathrm{XIII})$ and the ratio of the equilibrium concentrations is given by the expression

$$\frac{^{1,3}[\mathrm{D}^{\cdot+}\mathrm{S}^{\cdot-}]_1}{^{1,3}[\mathrm{S}^{\cdot+}\mathrm{A}^{\cdot-}]_1} = \exp\left[\frac{\Delta G_{23}(\mathrm{XI}) - \Delta G_{23}(\mathrm{XIII})}{kT}\right]$$

The collision of $^{1,3}\mathrm{S}_1$ (energy $^{1,3}E_{00}$) with the complex $^1(\mathrm{D.A})_0$ entails two possible reaction pathways (*a* or *b*):

$$\begin{tikzcd}
{^{1,3}\mathrm{S}_1 + {}^1(\mathrm{D.A})_0} \arrow[r] & {^{1,3}\mathrm{S}_1.{}^1(\mathrm{D.A})_0} \arrow[r, "d"] \arrow[d, "b"] & {^{1,3}[\mathrm{D}^{\cdot+}\mathrm{A}\ldots\mathrm{S}^{\cdot-}]_0,} \arrow[d] & {\mathrm{D}^{\cdot+} + \mathrm{A}^{\cdot-};} \\
 & {^{1,3}[\mathrm{S}^{\cdot+}\ldots\mathrm{DA}^{\cdot-}]_0} \arrow[r] & {^{1,3}[\mathrm{D}^{\cdot+}\ldots\mathrm{A}^{\cdot-}]_0} \arrow[r] \arrow[ur] \arrow[dr] & {\mathrm{D}_1^{+} + \mathrm{A}_1^{-},} \\
 & & & {^1(\mathrm{D.A})_0,}
\end{tikzcd}$$

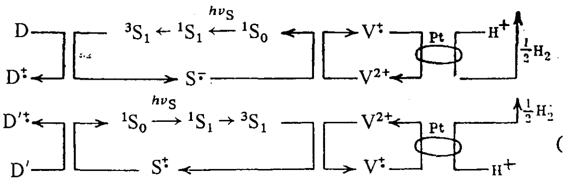
for which

$$\Delta G(a) = e[E_{1/2}(^1\mathrm{D}_0/\mathrm{D}^{\cdot+}) - E_{1/2}(\mathrm{S}^{\cdot-}/^1\mathrm{S}_0)] + 2\Delta G_\mathrm{p}^{\pm} + X + {}^{1,3}E_{00},$$
$$\Delta G(b) = e[E_{1/2}(^1\mathrm{S}_0/\mathrm{S}^{\cdot+}) - E_{1/2}(\mathrm{A}^{\cdot-}/^1\mathrm{A}_0)] + 2\Delta G_\mathrm{p}^{\pm} + X - {}^{1,3}E_{00}.$$

The dominant pathway is determined by the difference $\Delta G(a) - \Delta G(b)$:

$$\frac{^{1,3}[\mathrm{D}^{\cdot+}\mathrm{A}\ldots\mathrm{S}^{\cdot-}]_0}{^{1,3}[\mathrm{S}^{\cdot+}\ldots\mathrm{DA}^{\cdot-}]_0} = \exp\,[\Delta G(a) - \Delta G(b)]/kT.$$

Liquid-phase systems incorporating donors of different nature (D and D′), sensitisers comprising low-molecular-weight and high-molecular-weight derivatives $\mathrm{Ru(bipy)}_3^{2+}$, xanthene dyes, and porphyrins, and acceptors comprising the viologens (V^{2+}) in the presence of dispersed platinum have been investigated in detail[8-11,71,91-96] in connection with the development of converters of solar radiation into the chemical energy of the evolution of molecular hydrogen. The set of reactions can be represented by two schemes:



(XV)

(XVI)

In reactions (XV) and (XVI) the free energy of formation of H_2 is

$$\Delta G(\mathrm{H}_2) = e[E_{1/2}(\mathrm{V}^{\cdot+}/\mathrm{V}^{2+}) - E_{1/2}(0.5\mathrm{H}_2/\mathrm{H}^+)]$$

where $E_{1/2}(0.5\mathrm{H}_2/\mathrm{H}^+) = -0.059\mathrm{pH}$ V (n.h.e.) is the equilibrium potential of the reduction of H^+ to $0.5\mathrm{H}_2$ in the reaction $0.5\mathrm{H}_2 \rightleftharpoons \mathrm{H}^+ + e$ on the platinum surface.

A high quantum yield of H_2 [$\phi(0.5\mathrm{H}_2) = 0.25$] has been attained in a composition where S was a complex system comprising a mixture of three xanthene dyes with different regions of optical absorption which transmit the absorbed solar energy to the "aerial"— anthracene-9-carboxylic acid. The "aerial" in the excited triplet state participates in electron transfer from the donor [ethylenediaminetetraacetic acid (EDTA)] to the acceptor—methylviologen.[96]

Fig. 2 shows that the position of the ground energy level of the sensitiser, for example, the ruthenium complex $\mathrm{Ru(bipy)}_3^{2+}$, is characterised by two redox potentials:[71]

$$eE_{1/2}\{\mathrm{Ru(bipy)}_3^{1+}/^3[\mathrm{Ru(bipy)}_3^{2+}]_1\} =$$
$$= eE_{1/2}\{\mathrm{Ru(bipy)}_3^{1+}/^1[\mathrm{Ru(bipy)}_3^{2+}]_0\} + {}^3E_{00} = 0.84 \text{ eV} \quad (22)$$
$$({}^3E_{00} = 2.1 \text{ eV})$$
$$eE_{1/2}\{^1[\mathrm{Ru(bipy)}_3^{2+}]_0/\mathrm{Ru(bipy)}_3^{3+}\} = 1.27 \text{ eV (n.h.e.)}.$$

which determine the free energies of electron transfer in the interaction with the donor. The first value characterises the free energy, defined by Eqn. (18), of electron transfer from D to the lowest level of the triplet-excited sensitiser [reaction (XV)] and the second corresponds to the free energy, defined by Eqn. (21), of the secondary reaction (XVI) involving electron transfer from D′ to the oxidised sensitiser.

The position of the excited energy level of the sensitiser is characterised analogously by the redox potentials[71]

$$eE_{1/2}\{^3[\mathrm{Ru(bipy)}_3^{2+}]_1/\mathrm{Ru(bipy)}_3^{3+}\} =$$
$$= eE_{1/2}\{^1[\mathrm{Ru(bipy)}_3^{2+}]_0/\mathrm{Ru(bipy)}_3^{3+}\} - {}^3E_{00} = -0.83 \text{ eV};$$
$$eE_{1/2}\{\mathrm{Ru(bipy)}_3^{1+}/^1[\mathrm{Ru(bipy)}_3^{2+}]_0\} = -1.26 \text{ eV (n.h.e.)}.$$

which determines the free energies, defined by Eqns. (20) and (19), of electron transfer to the acceptor respectively from the excited ruthenium complex in the primary reaction (XVI) and from the reduced sensitiser in the secondary reaction tion (XV). Reaction (XV) predominates when donors with a low value of $E_{1/2}({}^1D_0/D^{\dot{+}})$ [0.16–0.64 V (n.h.e.)] are used, such as tetramethyl-p-phenylenediamine, diphenyl-p-phenylenediamine, tetramethylbenzidine, and tetrapyrenediamine, in combination with $Ru(bipy)_3^{2+}$ and methylviologen (MV^{2+}) as the acceptor: $E_{1/2}(MV^{\dot{+}}/MV^{2+}) = -0.44$ V (n.h.e). Reaction (XVI) proceeds in the presence of donors such as triethanolamine (TEOA) and EDTA, whose equilibrium oxidation potentials are $E_{1/2}[({}^1D')_0/(D')^{\dot{+}}] = 0.82$ and 0.9 V (n.h.e.) respectively and are almost identical with or more positive than the potential defined by Eqn.(22).

The positions of the energy levels of the sensitised dyes (azine, thiazine, and xanthene dyes) and donors (EDTA and TEOA) depend on the acid–base properties of the medium.[76, 97–100] For example, the thiazine dyes (Dy^+), thionine (TH^+) and Mb^+, widely used in non-silver information recording processes, have an equilibrium reduction potential in their protonated form which is more positive than in the non-protonated form by the amount

$$E_{1/2}(DyH^{\dot{+}}/{}^1(DyH^{2+})_0 - E_{1/2}(Dy^{\cdot}/{}^1(Dy^+)_0 =$$
$$2.303\,\frac{kT}{e}\,(pK_s - pK_a),\ (2.303\,\frac{kT}{e} = 0.059,\ V,\ at\ 293\ K),$$

where K_s and K_a are the equilibrium constants of the reactions

$$DyH^+ \overset{K_s}{\rightleftarrows} Dy + H^+ \text{ and } DyH^{2+} \overset{K_a}{\rightleftarrows} Dy^+ + H^+.$$

The quantities pK_s and pK_a are 10.4 and −0.4 for thionine and 9 and 0 respectively for Methylene Blue. The equilibrium potentials of the reduction of the triplet-excited dyes are more positive in the protonated form than in the non-protonated form by the amount

$$E_{1/2}(DyH^{\dot{+}}/{}^3(DyH^{2+})_1] - E_{1/2}[Dy^{\cdot}/{}^3(Dy^+)_1] = 0.059\,(pK_s - pK_t),$$

where K_t is the equilibrium constant of the reaction

$${}^3(DyH^{2+})_1 \overset{K_t}{\rightleftarrows} {}^3(Dy^+)_1 + H^+,$$

amounting to 7.0 and 7.2 respectively for TH^+ and Mb^+.

The decrease (shift in the positive direction) of the energy levels of the triplet-excited dyes on protonation increases the free energy (rate constant) for electron transfer from the donor to the photoexcited dye.

3. Methods of Limiting the Reverse Reactions

The suppression of the reverse reactions is one of the central problems for the practical realisation of electron transfer processes in systems incorporating CTC. In photoconducting systems, the suppression of the reverse reactions (recombination in geminal pairs) increases the quantum efficiency of the generation of free charge carriers. This can be achieved by applying strong electric fields or, for example, in the case of PVCA, by increasing the initial distance separating the charges in the geminal pair by increasing the energy of the excited quanta.[1,3]

In non-silver light-sensitive systems based on CTC, halogen-containing compounds (CBr_4, $CBr_3SO_2CBr_3$) are used as acceptors. The reverse reaction is quenched as a result of the dissociation of the acceptor on electron capture ($CBr_4 + e \rightarrow Br^- \ldots \dot{C}Br_3$; $CBr_3SO_2CBr_3 + e \rightarrow Br^- \ldots \dot{C}Br_2SO_2.CBr_3$, etc.). In sensitised systems based on viologens as acceptors one uses donors and conditions where the radical-cationic forms, formed as a result of the electron transfer reactions, are deprotonated [$DH^+ \rightarrow D^{\bullet} + H^+$ ($PVA^{\dot{+}}$,[3,101] $TEOA^{\dot{+}}$,[102,103] $EDTA^{\dot{+}}$ [104,105])]. In contrast to DH^+, the radicals $D^{\bullet}$ [$-CH-\dot{C}OH-$($PVA^{\bullet}$), $(CH_2OHCH_2)_2NCH_2\dot{C}HOH$ or $(CH_2.OHCH_2)_2N\dot{C}HCH_2OH$ ($TEOA^{\bullet}$), $R_2N-(CH_2)_2-(R)N-\dot{C}HCOO^-H^+$ with $R \equiv CH_2COO^-H^+$ ($EDTA^{\bullet}$)] are strong donors and effect additional electron transfer to the acceptor under dark conditions, accompanied by the irreversible formation of the carbonyl groups $-CH_2-\overset{\overset{\displaystyle O}{\|}}{C}-$ in PVA [3,101] and also of unstable imino-forms $\gt\overset{+}{N}=CH-CH_2OH$ or $-\underset{\underset{\displaystyle R}{|}}{\overset{+}{N}}=CHCOO^-H^+$ in TEOA [102] or EDTA,[105] which undergo subsequent irreversible decomposition. Thus in systems of this kind not only are the reverse reactions suppressed but the quantum yield of the reduced viologen is also doubled. In polymer systems the doubling of $\phi(V^{\dot{+}})$ is attained by the conversion of low-molecular-weight acceptors into polymeric forms with a high local concentration of viologen units, such as polypentamethyleneviologen, polydecamethyleneviologen, or poly-p-xylyleneviologen.[3,101,106]

According to Ohsako et al.[107], the polymer based on polystyrene with viologen substituents in the phenyl group [PV^{2+}: $E_{1/2}(PV^{\dot{+}}/PV^{2+}) = -0.135$ V (n.h.e.)] does not enter into a redox interaction either with the excited or the oxidised complex $Ru(bipy)_3^{2+}$ apparently due to steric hindrance. Electron phototransfer takes place after the additional introduction into the system of electron transferring agents (ET), for example, dipropyl-4,4'–dipyridylsulphonate [$E_{1/2}(ET^{\dot{-}}/ET) = -0.68$ V (n.h.e.)]. The charge transfer

$${}^3[Ru(bipy)_3^{2+}]_1 + ET \rightarrow Ru(bipy)_3^{3+} + ET^{\dot{-}},$$

which takes place after electron phototransfer via the reaction

$$ET^{\dot{-}} + PV^{2+} \rightarrow ET + PV^{\dot{+}},$$

effectively competes with the reverse reaction

$$ET^{\dot{-}} + Ru(bipy)_3^{3+} \rightarrow ET + Ru(bipy)_3^{2+},$$

ensuring a PV^+ lifetime of ~1.2 s and a ~50-fold increase of $\phi(PV^{\dot{+}})$ compared with $\phi(ET^{\dot{-}}) = 0.12 \times 10^{-2}$ in the absence of PV^{2+}.

In order to separate the reaction products in liquid media, use is made of micellar solutions, two-layer membranes,[9,10] and the components at the interface in the field of a negatively charged dispersed SiO_2.[108,109]

4. Oxidation-Reduction Potentials and Optical Transition Energies

The relation between the redox potentials, the electronic transition energies, and the positions of the highest occupied (ε_1) and lowest unoccupied (ε_2) orbitals, calculated by quantum-chemical methods (mainly the Hückel molecular orbital method: HMO) has been discussed in monographs[6,110,111] and in a large number of original and new communications in relation to polyenes and aromatic hydrocarbons,[110–113] heterocyclic compounds,[68,112,114] and dyes of different classes (palmitic, thiazine, oxazine, acridine, and xanthene dyes, aza-pigments, etc).[6,7,69,72,73,112,115,116] It has been demonstrated in monographs[110,111] in relation to a large number of polyenes and aromatic hydrocarbons that, for compounds of the same class, there is a linear relation between the experimental $E_{1/2}^{ox}$ (or I_M), $E_{1/2}^{red}$ (or E_M), and the values of m_1 and m_2, characterising the coefficients of the orbitals and calculated by the HMO method:

$$\varepsilon_1 = \alpha + \beta_0 m_1, \quad \varepsilon_2 = \alpha - \beta_0 m_2$$

where α and β_0 are the Coulombic and resonance integrals.

The following linear relations have been established:

$$E_{1/2}(\mathrm{M/M^{\ddagger}}) = \beta_1 m_1 + c$$

or [see Eqn.(4b)]

$$I_M = \beta_1 m_1 + c_1,$$

and also

$$E_{1/2}(\mathrm{M^{\mp}/M}) = -\beta_2 m_2 + c_2$$

or [see Eqn.(5b)]

$$E_M = -\beta_2 m_2 + c_3,$$

where $c - c_3$ are constants.

The following correlation has been derived:[6,7,72,73,115,116]

$$h\nu_{\max,\exp} = \beta_3(m_1 - m_2).$$

A linear relation has been proposed for aromatic hydrocarbons:[112]

$${}^3E_{00} = \beta_4(m_1 - m_2)$$

where $\beta_1 - \beta_4$ are correlation parameters relating the experimental and calculated quantities.

The relations between the positions of the energy levels and the calculated values for dyes have been subjected to a detailed analysis[68,69] on the basis of correlations:[114]

$${}^1E_{00} = \beta_5(m_1 - m_2) - J_{12} + 2K_{12} \tag{23}$$

$${}^3E_{00} = \beta_5(m_1 - m_2) - J_{12} \tag{24}$$

$$e[E_{1/2}({}^1\mathrm{M_0/M^{\ddagger}}) - E_{1/2}(\mathrm{M^{\mp}}/{}^1\mathrm{M_0})] = \beta_5(m_1 - m_2). \tag{25}$$

According to Eqns.(23)—(25), the difference between the redox potentials defined by Eqn. (25) can be regarded as the experimental distance between the half-filled orbitals ε_1 and ε_2 in the absence of electron-electron interaction. The occurrence of electronic interaction under the conditions of the photoexcitation of the molecule ($-J_{12} + 2K_{12}$ for the excited singlet state and $-J_{12}$ for the excited triplet state) should entail the appearance of the following relations:

$${}^1E_{00} = e[E_{1/2}({}^1\mathrm{M_0/M^{\ddagger}}) - E_{1/2}(\mathrm{M^{\mp}}/{}^1\mathrm{M_0})] - J_{12} + 2K_{12}, \tag{26}$$

$${}^3E_{00} = e[E_{1/2}({}^1\mathrm{M_0/M^{\ddagger}}) - E_{1/2}(\mathrm{M^{\mp}}/{}^1\mathrm{M_0})] - J_{12}. \tag{27}$$

In related series, such as those of aromatic compounds, mono-aza-compounds, and poly-*N*-heterocyclic compounds, an increase in molecular size leads simultaneously to a decrease of both J_{12} and of the polarisation energy $P^{\pm}$.[110] The experimental relations[68,112]

$$J_{12} = a + be[E_{1/2}(\mathrm{M/M^{\ddagger}}) - E_{1/2}(\mathrm{M^{\mp}/M})], \tag{28}$$

$${}^3E_{00} = (1 - b)e[E_{1/2}(\mathrm{M/M^{\ddagger}}) - E_{1/2}(\mathrm{M^{\mp}/M})] - a. \tag{29}$$

are linked to these changes. Table 1 presents the experimental constants $-J_{12} + 2K_{12}$, $1 - b$, and a in Eqns.(26) and (29) for a series of related compounds. Deviations from the common relations (26) and (29) are characteristic of molecules with either complex substituting groups or with variable conformations, which requires allowance for additional intramolecular interactions between non-neighbouring atoms.[110,111] It has been suggested[117] that the optical absorption energy of cyanine dyes be related to the redox-potentials by means of the formula [1 : 1 (vol.%) water—methanol mixture]:

$$h\nu_{\max} = 0.87e[E_{1/2}(\mathrm{S/S^{\ddagger}}) - E_{1/2}(\mathrm{S^{\mp}/S})],\ \mathrm{eV}.$$

The relation (in aqueous methanolic solutions)

$${}^1E_{00} = e[E_{1/2}({}^1\mathrm{S_0/S^{\ddagger}}) - E_{1/2}(\mathrm{S^{\mp}}/{}^1\mathrm{S_0})] + 0.37,\ \mathrm{eV}, \tag{30}$$

or

$${}^1E_{00} = I_S^{\mathrm{gas}} - E_S^{\mathrm{gas}} - 3.28,\ \mathrm{eV}, \tag{31}$$

has been obtained[69] for 100 sensitising dyes (mainly cyanine dyes—90 compounds, and also xanthene and thiazine dyes, and individual representatives of the groups of acridine, oxazine, and alloxazine dyes), which have been investigated in detail in connection with their use in the silver halide and non-silver photographic processes and in the development of photovoltaic cells. According to literature data, the splitting $S_1 - T_1$ is $2K_{12} \doteq 0.27$ eV for cyanine dyes,[90] ~0.32 eV, for acryidine dyes,[118] and ~0.31 eV for xanthene dyes.[118] We find from Eqns.(26) and (30) that the interelectron repulsion energy is small: $-J_{12} = +0.37 - 2K_{12} = 0.37 - (0.27\text{–}0.32) = +0.1\text{–}0.05$ eV. Thus, for sensitising dyes, we have

$${}^3E_{00} = e[E_{1/2}({}^1\mathrm{S_0/S^{\ddagger}}) - E_{1/2}(\mathrm{S^{\mp}}/{}^1\mathrm{S_0})] + (\leqslant 0.1),\ \mathrm{eV}; \tag{32}$$

for this series of compounds, we have the coefficients $b \cong 0$ and $a \cong -0.1$ eV in Eqn.(29) (Table 1).

Table 1. The coefficients $-J_{12} + 2K_{12}$, $1 - b$, and a in Eqns.(26) and (29) for a series of related compounds (aqueous and methanol solutions).[112]

5. The Mechanisms of the Spectral Sensitisation of the Photoelectric Sensitivity in Photovoltaic Cells

In the study of the processes in photovoltaic cells based on Phtc dispersed in a polymer matrix,[34,46-48] the positions of the levels of the additives adsorbed on the surfaces of the Phtc particles were estimated from electrochemical data, which, together with spectral and energy characteristics, are listed in Table 2. Polycarbonate was used as the polymer matrix in the photovoltaic cell. The quantity ϕ was determined from Eqn.(3) for $\lambda = 620$ nm and $L_T = 0.1$ mW cm^{-2}. The efficiency η' [see Eqn.(2)] was measured with exposure to sunlight; $L_T = 1$ mW cm^{-2}.

In a layer without additives, the charge carriers are generated at the Schottky barrier in accordance with the scheme in Fig.3*a*. The electron-hole pair formed in the region of the Schottky barrier dissociates in the barrier electric field, the electron passing to the metal and the hole drifting into the bulk of the Phtc. If the added substance S has an oxidation potential satisfying the condition $E_{1/2}\cdot$ $\cdot({}^1S_0/S^{\dot{+}}) < E_{1/2}({}^1Phtc_0/Phtc^{\dot{+}})$, then it captures a hole and functions as a densensitiser (Fig.3*b*):

$$S + Phtc^{\dot{+}}(hole) \rightarrow S^{\dot{+}} + Phtc.$$

The hole does not then escape into the bulk phase but is trapped by the additive molecule, which sharply increases the probability of its recombination with an electron and leads to a decrease of the photocurrent compared with the initial layer. Among the additives listed in Table 2, safranine and DPBF satisfy this condition. The densensitising effect of BPEA may be determined by the tendency of this substance to aggregate with formation of insulating layers on the Phtc grains, which diminish I_{SC}.

In a solid, the absorption of light by Phtc particles leads to the formation of the exciton state ${}^1Phtc_1$, which diffuses to the Phtc/S interface and forms an exciplex with a molecule of the additive, which can decompose into charged species, the process intensifying in an electric field (E_d):

$${}^1Phtc_1 + {}^1S_0 \rightarrow {}^1(Phtc.S)_1 \rightarrow {}^1(Phtc^{\dot{+}}S^{\dot{-}})_1 \xrightarrow{E_d} Phtc^{\dot{+}} + S^{\dot{-}}.$$

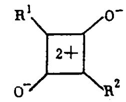
The free holes Phtc$^+$ escape into the bulk of the phthalocyanine particle and the reduced molecule of the additive gives up an electron to the metal (Fig.3*c*). This chemical sensitisation process constitutes an additional channel to the formation of free separated charge carriers and to the increase of J_{SC}.

In spectral sensitisation (Fig.3*d*), the additive molecule absorbs light. For effective spectral sensitisation, it is essential that the excited additive molecule should accept an electron from Phtc. The relation between the electrochemical and spectral parameters of the additive is given[34] by Eqn.(26) on the assumption that $-J_{12} + 2K_{12} \cong 0$, i.e. that the reduction potential of the excited additive molecule is equal to the oxidation potential of the molecule in the ground state. According to Table 2, almost all additives in their excited states, with the exception of DPBF and safranine, are capable of injecting holes into (of capturing electrons in) the bulk of the semiconductor Phtc and thus of effecting spectral sensitisation. In reality, spectral sensitisation was a maximum for coumarin 6 or rhodamine 6G and was weaker for rubrene and perylene, while DPBF, BPEA, and safranine did not influence the photosensitivity of Phtc. The agreement between experiment and the mechanism considered, involving charge transfer, does not rule out the contribution to the spectral sensitisation by processes involving the transfer of excitation energy from the additive to Phtc.

The study[119] of the photovoltaic effect in the cells

Al/the dye I dispersed in the polymer/SnO_2 – Sb

showed that I_{SC} is smaller by four orders of magnitude than in the cells based on sensitised Phtc. Here the dye I has the structure



R^1 and R^2 are radicals derived from anilines, indoles, azulenes, indolizines, and methines.

6. Spectral Sensitisation of Non-silver CTC-based Photographic Systems by Cyanine Dyes

Cyanine dyes, which have a large extinction coefficient, a small $S_1 - T_1$ splitting, and hence a short lifetime in the excited singlet state, enter into photochemical reactions in the excited triplet state.[85,87,90]

Table 3 presents the characteristics of cyanine dyes, which, as mentioned above (Section II), have been investigated as sensitisers of non-silver photographic polymeric layers based on the CTC of benzyldiphenylamine (Am) as the donor and acceptors (A = CBr_4 or $CBr_3SO_2CBr_3$). These polymeric layers are sensitive to light at wavelengths $\lambda \leq 500$ nm as a consequence of the optical absorption of A and Am in the region up to ~320 nm and of the CTC in the range 320–500 nm. The coloured product ($Am_1^{\dot{+}}$), which is assumed to have the structure

$$(C_6H_5)_2\overset{+}{N}{=}CH{-}C_6H_5 \qquad \text{(XVII)}$$

is formed under the influence of light.

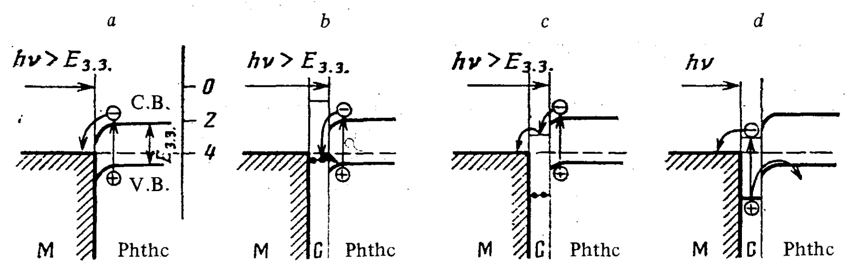


Figure 3. Schematic illustration of the generation of charge carriers (holes) at the Schottky barrier in the M/Phtc (dispersed in polycarbonate) photovoltaic cell; *a*) no additives; *b*) desensitisation by added safranine and DPBF; *c*) chemical sensitisation by added TNF and coumarin 6; *d*) spectral sensitisation by added rhodamine 6G, coumarin 6, etc.; M = metallic semitransparent layer; C.B. = conductivity band; V.B. = valence band; $E_{f.g.}$ = width of the forbidden gap of Phtc.[34]

When cyanine dyes are introduced, processes of three types take place:

(1) Dyes with $E_{1/2}(^1S_0/S^{+\cdot}) < 0.5$ V (sat.c.e.) are decolorised in the dark on contact with acceptors.

(2) Dyes having $E^{ox}_{1/2}$ in the range $0.5 < E^{ox}_{1/2} < 0.9$ V (sat.c.e) are decolorised as a result of photoexcitation on contact with A (Fig.4*a*), the efficiency of the process increasing with decrease of $E_{1/2}(^1S_0/S^{+\cdot})$. Such dyes are weak spectral sensitisers of compositions incorporating the complexes Am.A. It has been established[3, Ch.5; 49,50] that the quantum yield of the decolorisation of dyes increases linearly with acceptor concentration: $\phi_{dec} = a[A]$, where $A = CBr_4$ or $CBr_3SO_2CBr_3$.

Table 3. The structural formulae of the dyes, the potentials $E^{ox}_{1/2}$ and $E^{red}_{1/2}$ (sat.c.e.) measured in acetonitrile[49] and in the 1 : 1 (vol.%) $C_2H_5OH-H_2O$ mixture at pH 10–12,[72,73] and the values of λ_{max} in a CPVC film.[49]

19	 $CBr_3-\overset{\overset{\displaystyle O}{\Vert}}{\underset{\underset{\displaystyle O}{\Vert}}{S}}-CBr_3$	—	−0.6*	238** (shoulder at 265)	[50]

Remarks. *Calculated by Eqn.(5b) from $E_A(CBr_4) = 2.0$ eV and $E_A(CBr_3SO_2CBr_3) = 2.1$ eV.[50] **Measured in ethanol.

The type of decolorisation of group 1 and 2 dyes described justifies the conclusion[3, Ch.5; 49,50] that the decolorisation is determined by electron-donating properties.

(3) Dyes with $E_{1/2}(^1S_0/S^{+\cdot}) > 0.9$–$1.0$ V (sat.c.e.), i.e. with $E_{1/2}(^1S_0/S^{+\cdot}) > E_{1/2}(^1Am_0/Am^{+\cdot})$ (Table 3) are not decolorised on photoexcitation in the presence of A or simultaneously Am and A. These dyes are effective spectral sensitisers of the polymer composition based on Am.A.

The efficiency of the formation of Am_I^+ increases with decrease of the concentration of agents quenching the triplet excitation (for example, O_2), which confirms the idea that triplet-excited dye molecules participate in the sensitisation process.

The oxidation-reduction mechanism of spectral sensitisation has been established by EPR. The first step in the sensitisation process is electron transfer from the amine to the photoexcited sensitiser (Fig.2*a*):

$$^1Am_0 + {}^3S_1 \rightarrow Am^{+\cdot} + S^{-\cdot}. \qquad \text{(XVIII)}$$

The appearance of the EPR spectrum of the radical-cations $Am^{+\cdot}$ (a quartet with intensity ratios of 1 : 2 : 2 : 1) at the instant of the excitation S in the absence of the acceptor component from the layer corresponds to this stage.[120] Further reactions are as follows:

$$S^{-\cdot} + CBr_4 \rightarrow {}^1S_0 + Br^-...CBr_3, \qquad \text{(XIX)}$$

$$Am^{+\cdot} + Br^-...CBr_3 \rightarrow Am_I^+Br^- + CHBr_3. \qquad \text{(XX)}$$

The absence of the EPR spectrum under the conditions of the photoexcitation of S in the presence of only A in the layer and the simultaneous formation of $Am^{+\cdot}$ and radicals formed from $A^{-\cdot}$ as a result of the abstraction of the bromide ion on photoexcitation of S in the presence of Am and A correspond to these stages.[120]

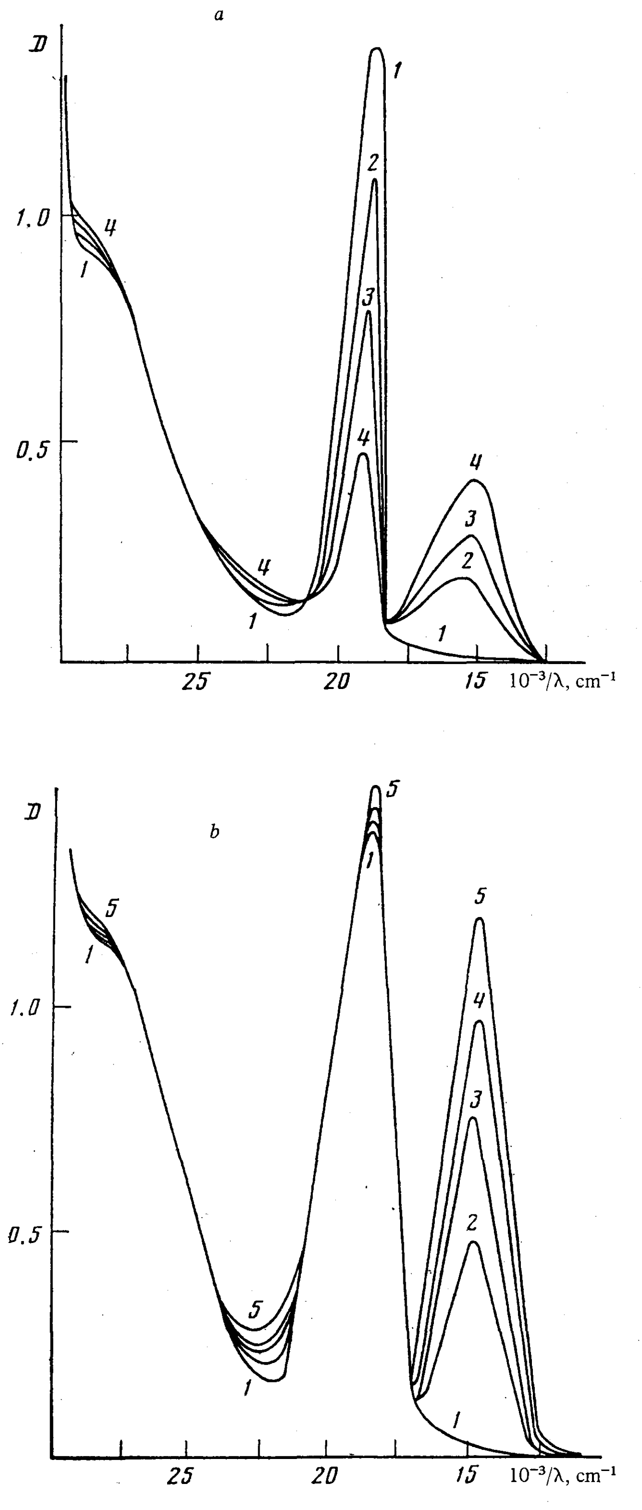

Figure 4. Variation of the optical spectra under the conditions of the photoexcitation of the dye (λ = 531–533 nm, $L_0 = 10^{-3}$ W cm^{-2}) in a composition containing benzyldiphenylamine (0.8 mol dm^{-3}) and CBr_4 (2.3 mol dm^{-3}); [S] = 0.03 ml dm^{-3}; *a*) dye No.7 (Table 3); illumination time (s): *1*) 0 (initial spectrum); *2*) 120; *3*) 240; *4*) 360; *b*) dye No.16 (Table 3); illumination time (s): *1*) 0 (initial spectrum); *2*) 15; *3*) 30; *4*) 45; *5*) 60.[49]

The quantum yield in the formation of the coloured product Am_1^+ via the reactions (XVIII)–(XX) initially increases with increasing concentrations of Am and A:

$$\varphi_{sens} = 0.12[Am][CBr_4]. \qquad (33)$$

Then, after the attainment of the values [Am] = 1 and [A] = 1 mol dm^{-3}, it assumes the constant value $\phi_{sens} = 0.12$.

In conformity with the above scheme (Fig. 2*a*), the cyanine dye participates in reaction (XVIII) at the oxidation-reduction potential $E'_{1/2}(S^{\bar{\cdot}}/{}^3S_1)$, defined by Eqn.(17), while in the secondary reaction (XIX) the reduced sensitiser interacts with the acceptor at the equilibrium potential $E'_{1/2}(S^{\bar{\cdot}}/{}^1S_0)$. The cyanine dyes listed in Table 3 belong to the group for which ${}^3E_{00}$ is related to $E_{1/2}^{ox,\ red}$ by Eqn.(32). Since the value of ${}^3E_{00}$ are unknown for many dyes (Table 3), Eqns.(17) and (32) were used to calculate $E'_{1/2}(S^{\bar{\cdot}}/{}^3S_1)$:

$$eE'_{1/2}(S^{\bar{\cdot}}/{}^3S_1) = eE'_{1/2}({}^1S_0/S^{\dot{+}}) + (\leqslant 0.1) + \Delta G_p^+.$$

The free energy of electron transfer from the Am molecule to ${}^3S_1$ via reaction (XVIII) is (Fig. 2*a*)

$$\Delta G(XVIII) = e[E'_{1/2}({}^1Am_0/Am^{\dot{+}}) - E'_{1/2}(S^{\bar{\cdot}}/{}^3S_1)] = e[E_{1/2}({}^1Am_0/Am^{\dot{+}}) - E_{1/2}({}^1S_0/S^{\dot{+}})] - (\leqslant 0.1), eV.$$

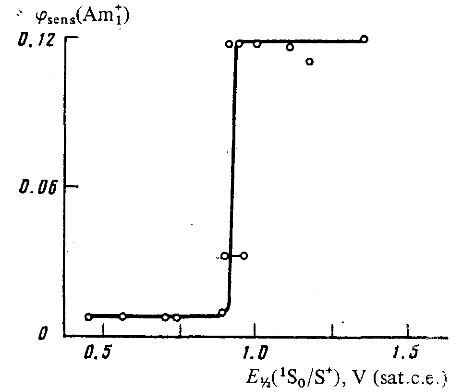

Figure 5. Dependence of the quantum yield ϕ_{sens} for the formation of Am_1^+ on $E_{1/2}({}^1S_0/S^{\dot{+}})$; concentrations of the components (in CPVC): [S] = 10^{-3}, [Am] = 0.8, [CBr_4] = 1.2 mol dm^{-3}.[3], Ch.5; [120]

Fig. 5 illustrates the dependence of ϕ_{sens} on $E_{1/2}({}^1S_0/S^+)$ (Table 3). With increase of $E_{1/2}({}^1S_0/S^{\dot{+}})$, there is a tenfold increase of ϕ_{sens} in the region of $E_{1/2}({}^1S_0/S^{\dot{+}}) = E_{1/2}.({}^1Am_0/Am^{\dot{+}})$ = 0.98 V (Table 3).

Thus the rate of the process is determined by reaction (XVIII) in the formation of Am_1^+ [reactions (XVIII)–(XX)] sensitised by cyanine dyes. The secondary reaction (XIX) does not influence appreciably the quantum yield in the formation of Am_1^+.

The coloured product Am_1^+ is unstable and, as a result of the interaction with CBr_4 and amine molecules, is transformed on heating, with an activation energy of 0.9 eV, into a dye resistant to light and heat[55] and is tentatively assigned to the triphenylmethane series. It has been established[55] that this dye is a sensitiser (autosensitiser) with respect to light active in the region of intrinsic absorption. The mechanism of the autosensitisation apparently consists in the involvement of the photoexcited dye in electron transfer from the donor to the acceptor [reactions (XVIII)–(XX)].[120]

IV. SENSITISATION VIA ENERGY TRANSFER

1. The Role of the CTC as the Triplet Energy Donor

The sensitisation via a mechanism of type (VI) (Section I) has been postulated in a polymer composition based on a CTC between benzylamines (benzyldiphenylamine, dibenzylaniline) and CBr_4.[3,54,57,121,122] According to the existing ideas about the formation of complexes by aromatic amines,[123] their interaction with CBr_4 entails the formation of complexes of at least two types: a complex of the n,σ-type between the nitrogen atom and the acceptor, responsible for the long-wavelength optical absorption (in the range 330–500 nm) of the polymer composition based on $Am.CBr_4$, and the complex of the π,σ-type, which is formed by the aromatic rings of the donor (possibly the excited donor) and the acceptor.

Under the conditions of the photoexcitation of the n,σ-type complex, the quantum yield $\phi(Am_1^+) = 0.12–0.16$ and is independent of [Am] and $[CBr_4]$ [for an optical density $D(Am_1^+) < 1$]. The introduction of a triplet energy acceptor (TEA), namely 1-naphthol, lowers $\phi(Am_1^+)$ and leads to the appearance of the relations[124]

$$\varphi(\mathrm{Am}_1^+) = b[\mathrm{Am}] \text{ and } 1/\varphi[\mathrm{Am}_1^+] = b_1 + b_2/[\mathrm{CBr}_4]. \qquad (34)$$

The appearance of such relations cannot be accounted for on the basis of the idea that a coloured product is formed as a result of the photodissociation of the n,σ-type complex itself, since in this case $\phi(Am_1^+)$ could not correspond to Eqn.(34) and should decrease with increase in the TEA concentration. The reactions leading to the cyclisation of amines, methylphenylamine and diphenylamine (the methylcarbazole and carbazole formation reactions), occurring as a result of triplet energy transfer to amines from triplet energy donors (propiophenone, acetophenone, benzaldehyde, etc.) photoexcited by light with $\lambda = 365$ nm, are well known.[125] It has been established that the effective triplet energy donors for these amines are compounds whose triplet level lies above the position of this level in the amines by 0.06 eV. In the diphenylamine (A), methyldiphenylamine (B), and benzyldiphenylamine series, the optical absorption maxima are at 282, 292, and 296 nm. The positions of the triplet levels in the liquid phase correspond to ${}^3E_{00} = 3.14$ and 3.05 eV for (A) and (B) respectively.[125] It is to be expected that the triplet level in the benzyldiphenylamine molecule is similar to that in compound (B) or is somewhat reduced relative to the latter.

In the light-sensitive system based on $Am.CBr_4$, the influence of TEA can be readily explained by the occurrence of competing reactions on the basis of the idea that, under the conditions of excitation by light with $\lambda = 365$ nm, the complex of the n,σ-type does not dissociate itself but serves as a triplet energy donor for benzyldiphenylamine molecules; the coloured product Am_1^+ is formed as a result of the dissociation of the complex of the π,σ-type:

$$\mathrm{A\cdot CBr_4}(n,\sigma) \xrightarrow{h\nu_{\mathrm{CTC}}\cdot \mathrm{S}_1-T_1} {}^3(\mathrm{Am.CBr_4})_1 - \left[\begin{array}{l} \xrightarrow{\mathrm{Am}} {}^3\mathrm{Am}_1 + \mathrm{Am.CBr_4} \\ \\ \xrightarrow{\mathrm{TEA}} \mathrm{Am.CBr_4} + {}^3\mathrm{TEA}_1 \rightarrow {}^1\mathrm{TEA}_0; \end{array}\right. \qquad \mathrm{(XXI)}$$

$${}^3\mathrm{Am}_1 + \mathrm{CBr_4} \rightarrow {}^3\mathrm{Am}_1.\mathrm{CBr_4}(\pi,\sigma) \rightarrow [\mathrm{Am}^{\dot{+}}\mathrm{Br}^-...\dot{\mathrm{C}}\mathrm{Br}_3] \rightarrow \mathrm{Am}_1^+\mathrm{Br}^- + \mathrm{CHBr_3}.$$

2. Desensitisation

On photoexcitation by light with $\lambda_{inc} = 742 \pm 3$ nm in a composition containing Am and CBr_4, the cyanine dye (Table 3, No.6) is decolorised in accordance with $\phi_{dec} = 0.0052[CBr_4]$ and also sensitises the given composition with respect to red light, ensuring the formation of Am_1^+ and with $\phi_{sens} = 0.0014$ for $[Am] = [CBr_4] = 1$ mol dm^{-3}.[122] The same dye is an effective quenching agent for the photoexcitation of the n,σ-complex $Am.CBr_4$. On photoexcitation of the complex $Am.CBr_4$ by light with $\lambda_{inc} = 365$ nm, this dye is decolorised with the quantum yield $\phi'_{dec} = 0.15$ for $[Am] = [CBr_4] = 1$ mol dm^{-3}.[122] There is no decolorisation under the influence of near UV radiation if the composition contains either no donor or no acceptor component (i.e. the CTC $Am.CBr_4$ is absent). The value of ϕ'_{dec} exceeds by a factor of ~30 that of ϕ_{dec} obtained under the conditions of the photoexcitation of the dye itself. This difference can be due to the fact that by accepting the triplet energy of the CTC, the dye can pass to a second triplet state in which the decolorisation is more effective than in the first.

An effective quenching agent for the excited state of the complex $Am.CBr_4$ is the coloured product Am_1^+. As Am_1^+ accumulates on photoexcitation of the CTC, in the quantum yield in the formation of the coloured product Am_1^+ is given by the following expression when its optical density $D(Am_1^+) \cong 1$ has been reached:

$$\varphi = \frac{0.12k[\mathrm{Am}]}{k[\mathrm{Am}] + k_1[\mathrm{Am}_1^+]} \cong \frac{0.12k[\mathrm{Am}]}{k_1[\mathrm{Am}_1^+]}.$$

This relation can be accounted for by the competition between Am and Am_1^+ [analogously to the behaviour of TEA in reaction (XXI)] for the capture of the energy of the complex ${}^3(Am.CBr_4)_1$ (of the n,σ-type). This desensitisation process determines the photographic characteristics of the light-sensitive polymer layers based on the CTC $Am.CBr_4$.[126]

3. The Sensitisation Effect Associated with the Polymeric State of the CTC

The polymer matrix exerts a sensitising influence in the region of visible light (400–600 nm) on the light-sensitive composition based on the complex $Am.CBr_4$. Indeed, it has been shown on the basis of the complex between benzyldiphenylamine and CBr_4 [127] that the optical spectrum of the complex $Am.CBr_4$ (of the n,σ-type) in the polymer matrix [chlorinated poly(vinyl chloride)—CP VC or polystyrene (PS)] and in the liquid (hexane) has the Gaussian form

$$D(\nu) = D(28{,}2)\exp[-(\Delta\nu_1)^2/\sigma^2] \qquad (35)$$

where $D(28.2)$ is the optical density at the absorption maximum at $\nu_{max} = 28.2 \times 10^3$ cm^{-1}, $\Delta\nu_1 = 28.2 - \nu_1$, and $\nu_1 = 10^{-3}\,\nu$ cm^{-1}.

The hexane $\sigma^2 = 7.0$; in polymer layers σ^2 is independent of the nature of the polymer and amounts to 13.5 in PS and 14.5 in CPVC. Thus, in the liquid phase, the optical spectrum of the complex $Am.CBr_4$ is approximately twice as narrow as in the polymer and does not extend outside the limit of the UV region (the long-wavelength edge corresponds to 400 nm). In the polymer matrix the optical spectrum of the complex extends to 500–600 nm. Apparently this effect occurs because, under the conditions of a limited free volume in the polymer, conformations of the amine in the CTC $Am.CBr_4$, of the type which do not obtain under equilibrium conditions in the liquid, are "frozen". Data have been published,[127] according to which the light sensitivity in the region of the absorption of the complex $Am.CBr_4$ has the following spectral in mind that $E_{1/2}(O_2^{-\cdot}/O_2) = -0.82$ V (sat.c.e.) in acetonitrile:[144]

$$E[^{1,3}(M^{+\cdot}O_2^{-\cdot})_1] = e[E_{1/2}(M/M^{+\cdot}) + 0.82] + \Delta G^{p}_{CTC} + {}^{1,3}Q_e.$$

According to generally accepted ideas concerning the nature of molecular complexes,[145] the wavefunction of the excited oxygen complex $^3(M.O_2)_1$ consists of the set of contributions of the following individual states:

$$\varphi^3(M\cdot O_2)_1 = \alpha_1\varphi_1^3(M^{+\cdot}O_2^{-\cdot})_1 + \alpha_2\varphi_2^3(^3M_1\cdot{}^3O_2) + \alpha_3\varphi_3^3(^1M_1\cdot{}^3O_2) \qquad (37)$$

The wavefunction of the singlet-excited complex $^1(M.O_2)_1$ is given by the set of the following contributions:

$$\varphi^1(M\cdot O_2)_1 = \alpha_1'\varphi_1^1(^1M_0\cdot{}^1O_2) + \alpha_2'\varphi_2^1(M^{+\cdot}O_2^{-\cdot})_1 + \alpha_3'\varphi_3^1(^3M_1\cdot{}^3O_2) \qquad (38)$$

We shall now consider Scheme 1 (Scheme I) when $E(^3M_1) > E[^3M^{+\cdot}O^{-\cdot})_1]$ (Fig. 6*a*). In this case the energetically lowest triplet state is the state with complete charge transfer $^3(M^{+\cdot}O_2^{-\cdot})_1$, which makes the main contribution to the configuration $^3(M.O_2)_1$ [it will be shown below that $\alpha_1 \cong 1$ in Eqn. (37)]. The contribution of other states, determined by the multipliers $(\alpha_2/\alpha_1)^2$ and $(\alpha_3/\alpha_1)^2$, is associated with the relative positions of the energy levels $\Delta E_1 = E(^3M_1) - E[^3(M^{+\cdot}O_2^{-\cdot})_1]$, because $\alpha_2/\alpha_1 = \beta/\Delta E_1$ and $\Delta E_2 = E(^1M_1) - E[^3(M^{+\cdot}O_2^{-\cdot})_1]$, since $\alpha_3/\alpha_1 = \beta/\Delta E_2$. Here

$$\beta = \int \varphi_2^3(^3M_1\cdot{}^3O_2)H\varphi_1^3(M^{+\cdot}O_2^{-\cdot})_1\,d\tau \simeq 0.01-0.1\ \text{eV}$$

is the potential energy of the transferred charge distributed in the electrostatic field of the radical-cation $M^{+\cdot}$.[145] The collision complex $^3(^3M_1.{}^3O_2)$ or the state $^3(^1M_1.{}^3O_2)$ is transformed into $^3(M.O_2)_1$ via the complex formation mechanism (37) with a rate constant $k = \beta/h \cong 2\times10^{12}-2\times10^{13}$ s^{-1} ($h = 4.2\times10^{-15}$ eV s). It is possible to estimate that the contribution to $\phi_3^3(M.O_2)_1$ by the states $^3(M^{+\cdot}O_2^{-\cdot})_1$ is $\geqslant$96% and that by the states $^3(^3M_1.{}^3O_2)$ and $^3(^1M_1.{}^3O_2)$ is $\leqslant$ 4% when $\Delta E_1 \geqq 0.5$ eV. Hence it follows that the formation of the triplet collision complex $^3(^3M_1.{}^3O_2)$ determines the primary electron transfer in the oxidation reaction of the organic compound.

The energetically lowest configuration among the states which contribute to $^1(M.O_2)_1$ [Eqn. (38)] is the collision complex $^1(^1M_0.{}^1O_2)$. The excited complex in the singlet state $^1(^3M_1.{}^3O_2)$, formed on collision of $^3M_1$ and $^3O_2$, is initially transformed, with a rate constant $\beta/h \cong 10^{13}$ s^{-1}, into the configuration with total charge transfer $^1(M^{+\cdot}O^{-\cdot})_1$, which is transformed in its turn into the state $^1(^1M_0.{}^1O_2)$ with a rate constant $\beta_1/h \cong 10^{11}$ s^{-1}, where

$$\beta_1 = \int \varphi_2^1(M^{+\cdot}O_2^{-\cdot})_1 H\varphi_1^1(^1M_0\cdot{}^1O_2)\,d\tau \simeq 10^{-2}\ \text{eV}$$

is the energy of the dipole $M^{+\cdot}O_2^{-\cdot}$ in the potential field of the neutral $^1O_2$ molecule. The dissociation of the states $^1(^1M_0.{}^1O_2:{}^1\Delta_g)$ and $^1(^1M_0.{}^1O_2:{}^1\Sigma_g^+)$ leads to the formation of $^1O_2$ in the forms $^1\Delta_g$ and $^1\Sigma_g^+$. Taking into account the statistical weights of the states with different multiplicities, formed on collision of $^3M_1$ and $^3O_2$ (see Section I), it is to be expected that in the case considered (Scheme 1) 75% of the total number of the triplet-excited molecules $^3M_1$, constituting the state $^3(M^{+\cdot}O_2^{-\cdot})_1$ [see Eqn. (37)], quench the energy in processes involving electron transfer from $^3M_1$ to $^3O_2$, while 25% of the $^3M_1$ participate in the formation of $^1(^3M_1.{}^3O_2)$ [see Eqn. (38)] and lead to the appearance of $^1O_2$. Hence it follows that the compounds satisfying the inequality $E(^3M_1) > E[^{1,3}(M^{+\cdot}O_2^{-\cdot})_1]$ are weak sensitisers of the formation of $^1O_2$ and may be oxidised via the mechanism involving electron transfer to oxygen.

We shall consider Scheme 2 (Section I) (see Fig. 2*b*) when $E(^3M_1) < E[^{1,3}(M^{+\cdot}O_2^{-\cdot})_1]$ and the main contribution to the overall configuration of the triplet-excited state [Eqn. (37)]

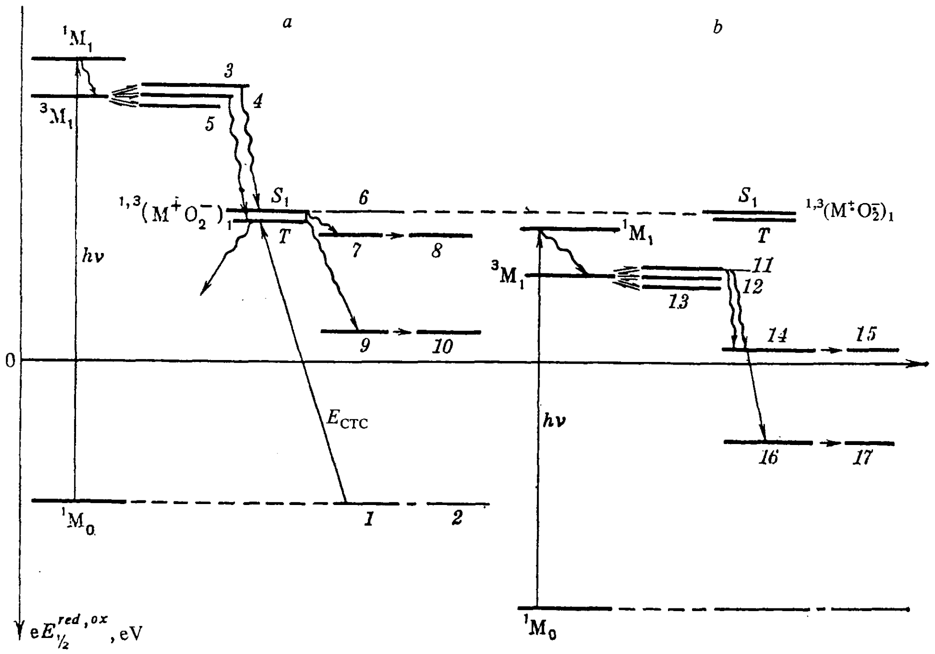

Figure 6. Schematic illustration of the photoprocess with participation of O_2: *a*) $E(^3M_1) > E[^{1,3}(M^{+\cdot}O_2^{-\cdot})_1]$; *b*) $E(^3M_1) < E[^{1,3}(M^{+\cdot}O_2^{-\cdot})_1]$; the molecules M are of different nature and the levels are reckoned from $E(^1M_0) = E_{1/2}(^1M_0/M^{+\cdot})$; the states corresponding to the positions of the levels: *1*) $^3(^1M_0.{}^3O_2)$; *2*) $^3\Sigma_g$; *3*) and *11*) $^1(^3M_1.{}^3O_2)$; *4*) and *12*) $^3(^3M_1.{}^3O_2)$; *5*) and *13*) $^5(^3M_1.{}^3O_2)$, S_1—$^1(M^{+\cdot}O_2^{-\cdot})$, T—$^3(M^{+\cdot}O_2^{-\cdot})$; *6*) $E_{1/2}(O_2^{-\cdot}/O_2)$; *7*), *9*), *14*), and *16*) $^1(^1M_0.{}^1O_2)$; *8*) and *15*) $^1\Sigma_g^+$; *10*) and *17*) $^1\Delta g$.[3], Ch.7.

comes from the state $^3(^3M_1.^3O_2)$. The contribution of the state $^3(M^{\dot{+}}O_2^{\dot{-}})_1$ in Eqn.(37) is determined by the ratio (α_1'/α_2'), where $\alpha_1'/\alpha_2' = \beta_2/\Delta E_3$, $\Delta E_3 = E[^3(M^{\dot{+}}O_2^{\dot{-}})_1] - E(^3M_1)$, and

$$\beta_2=\int \varphi_1^3(M^+O_2^-)_1\ H\varphi_2\cdot{}^3(^3M_1\cdot{}^3O_2)d\tau=10^{-2}\quad \text{eV}\ ^{145}$$

is the energy of the dipole $M^{\dot{+}}O_2^{\dot{-}}$ in the potential field of the neutral molecule $^3O_2$.[145] Hence $(\alpha_1'/\alpha_2')^2 < 2\%$ for $\Delta E_3 > 0.5$ eV and the charge transfer state $^3(M^{\dot{+}}O_2^{\dot{-}})_1$ does not participate directly in the photochemical oxidation process. In this case, which has been considered in detail,[146-148] the efficiency of the transformation of the energy of the triplet-excited molecules into the energy of singlet oxygen reaches 100%.

---o0o---

The above discussion of the charge transfer reactions with participation of CTC in polymer matrices confirms the validity of the initial postulate that the energy relations of the process are determined mainly by dielectric parameters of the polymer matrix, which functions as a binder for the photoactive components and it is immaterial whether the latter are monomeric or polymeric compounds. This should apparently be manifested in the kinetic characteristics of the process. However, kinetic studies of this kind have so far been clearly insufficient.

One can also conclude that the oxidation-reduction potentials measured in liquid solutions by electrochemical methods and adjusted with respect to the polymer matrix can be usefully employed for the analysis of charge transfer processes in polymers instead of the gas-phase values of the ionisation potential and the electron affinity. Firstly, this is consistent with the essential physicochemical nature of the processes considered and, secondly, it makes it possible to employ the numerous data on the oxidation-reduction potentials of a large number of organic compounds.

It also follows from the above analysis that measurements of the energies of the optical transitions of the donor–acceptor systems in the polymer matrices are necessary, since their comparison with the energies of the analogous transitions in liquid media, where oxidation-reduction potentials are measured, makes it possible to obtain directly the ionisation energies and electron affinities of the molecules in polymer matrices without using the polarisation energies in polymers and in solutions, which are difficult to fix.

The Surface-modified Carbon Materials for Electrocatalysis

M.R.Tarasevich and V.A.Bogdanovskaya

The principal trends and prospects in studies on the creation of carbon materials with a specified electrocatalytic activity and stability are examined and methods for the surface modification of disperse and compact carbon materials are surveyed. It is shown that charge transport in the electrocatalysis by surface-modified electrodes proceeds via both a mediator mechanism and via direct electron transfer. The electrocatalytic properties of electrodes modified by simple organic complexes, polymers, and biopolymers are discussed and the mechanisms of the acceleration of the electrochemical oxidation of organic substances, the evolution of hydrogen, and the electrochemical reduction of oxygen are analysed.

The bibliography includes 137 references.

I. INTRODUCTION

One of the main tasks in electrochemical science and technology is the creation of new types of electrode materials. For this purpose, vigorous studies have been carried out during the last decade on surface-modified electrodes whose electrochemical and electrocatalytic properties can be altered specifically by varying the surface composition. The "construction" of the surface composition of electrodes is achieved virtually at the molecular level and is therefore extremely promising.

The possibilities in the employment of surface-modified electrodes are wide. They can be used in electrocatalysis, photoelectrocatalysis, and electroanalysis.[1,2] The attachment to the surface of specific electrochemically active compounds makes it possible to create selective electrode materials. The attachment to semiconductors of compounds with a known molecular structure ensures the formation of a surface having the necessary energy level and photosensitive in the specified part of the spectrum.[3] Modification of the surface, especially by polymers, can ensure an increase in the corrosion stability of electrodes and photoelectrodes.[4]

The study of electrodes modified by organometallic complexes makes it possible to obtain information about the influence of molecular conformation on their catalytic and oxidation-reduction properties.

Surface-modified electrodes constitute a convenient system for the elucidation of the mechanism of electron transfer. Studies on electrodes coated by polymers can significantly supplement the available information about the physical chemistry of polymers and biopolymers. Electrodes modified by enzymes are of special interest. The study of enzymes in electrochemical systems opens up a way to the creation of synthetic complexes with a high electrocatalytic activity and selectivity.

Metals, oxides with semiconducting properties, and carbon materials of various types can be used as a basis for the creation of modified electrodes. In the present review attention will be concentrated on electrodes based on carbon materials. According to the authors, this type of surface-modified materials is of greatest interest for practical use.

II. WAYS OF CREATING SURFACE-MODIFIED CARBON MATERIALS

Various methods based on the unique properties of carbon substances are used at the present time to prepare modified carbon materials. Depending on the method of preparation, carbon materials can have compact or disperse forms with the necessary texture of the inner surface. The possibility of the existence of surface carbon atoms in different valence states is responsible for the great variety of the surface oxygen-containing groups. The above properties of carbon materials make it possible to use for the modification of their surfaces of virtually all the known methods for the heterogenisation of catalytically active compounds. They can be divided into three main groups: (1) adsorption methods based on the retention of the modifying agents by physical adsorption forces; (2) chemical attachment with fixation of the catalyst via different groups, including groups specially obtained on the carbon material; (3) deposition of a polymer film with incorporation in the latter of metal ions or an organometallic complex.

1. Crystal-Chemical Properties of Carbon Materials

The physicochemical properties of carbon materials have been fairly completely reviewed in a monograph[5] from the standpoint of their employment in electrochemical systems. We shall deal only with those features of carbon materials which must be taken into account for the successful modification of their surfaces.

(a) *Relation between the electronic structure and the physicochemical properties of carbon materials.* A characteristic feature of carbon materials is the variation of their physicochemical properties as a function of structure for a constant composition. In its turn, the possibility of the formation of a large number of structures is determined by the ability of the carbon atom to exist in different valence states and to form bonds of different types. Depending on the mixing of the *s* and *p* orbitals, the quadrivalent carbon atom can exist in three different hybrid states, a particular structure being characteristic of each. Thus a three-dimensional polymer with tetrahedral bonds between the carbon atoms (sp^3-hybridisation) corresponds to the diamond structure. Graphite, which is a parquet type polymer with sp^2-hybridised carbon atoms, is most often used in electrochemistry. sp-Hybridisation is characteristic of a linear polymer carbon chain. The peripheral carbon atoms in graphite can also exist in the sp-hybrid state. A carbon material with the graphite structure exhibits a marked anisotropy of its physicochemical properties. Thus the electrical conductivities of single crystals in two directions at right angles can differ by three orders of magnitude.

A series of carbon materials having a crystal structure are known: they include graphite and its synthetic analogue (pyrographite), which are characterised by a pronounced anisotropy of their electrical conductivity and other properties. In electrochemistry, crystalline carbon materials are used as a rule to create model electrodes with a small specific surface.

Among the transitional forms of carbon, vitreous carbon, carbon black, and activated carbon are most often used in electrochemical research. Vitreous carbon is characterised by the highest corrosion stability. In terms of their structure, carbon blacks occupy an intermediate position between crystalline graphite and amorphous carbon. Activated charcoals are obtained in the carbonisation and subsequent activation of a wide variety of carbon-containing materials. The texture of the activated charcoal depends on the method of its activation and is characterised by a large set of pores.

The carbon materials used in electrochemical systems must possess a high electrical conductivity, which increases on heat treatment and graphitisation of the transitional forms as a result of the expansion of the graphite-like regions.[6]

(b) *Surface groups in carbon materials.* The bulk-phase and surface properties of carbon materials have been compared.[7] The composition of the surface can be changed during heat treatment in atmospheres of different gases: nitrogen, oxygen, the halogens, ammonia, etc. As a result of such treatment, functional groups capable in many instances of increasing the catalytic activity of the initial material without additional modification are formed on the surface.

Fig.1 presents the most important surface-modifying oxygen-containing groups. They are formed on the surfaces of carbon materials both during synthesis and as a result of the adsorption of oxygen. Among acid oxides, quinonoid, carboxy- and phenolic groups have been detected on carbon blacks and charcoals.[8] Basic oxides are formed under much milder conditions compared with acid oxides. The oxygen is weakly bound to the surface and the identification of basic oxides is difficult.[5] One should also note the possibility of the existence on the surfaces of carbon materials of free radicals, which arise on dissociation of a carbon–carbon bond. An unpaired electron is then liberated and passes to the cyclic carbon system.[9] The adsorption of oxygen entails either a reversible or irreversible decrease of the number of free radicals.

The hydrophobic-hydrophilic properties of carbon materials are closely related to the chemistry of their surfaces. Since the carbon material is apolar, the degree of its oxidation does not affect the adsorption of non-polar compounds. On the other hand, the wettability by water is greater the greater the number on the surface of oxygen-containing groups, which are the primary centres for the adsorption of water.[10] Detailed studies[11,12] established a relation between the nature of the surface oxides and the hydrophilic-hydrophobic properties: surfaces containing basic oxides are more hydrophobic; for low degrees of activation, only macropores and partly mesopores are hydrophobic.

The possibility of the variation within wide limits of the porous structure of carbon materials should also be noted. This is especially important for modification by macromolecules such as enzymes and polymers, because the micropores and some of the mesopores are inaccessible for their adsorption.

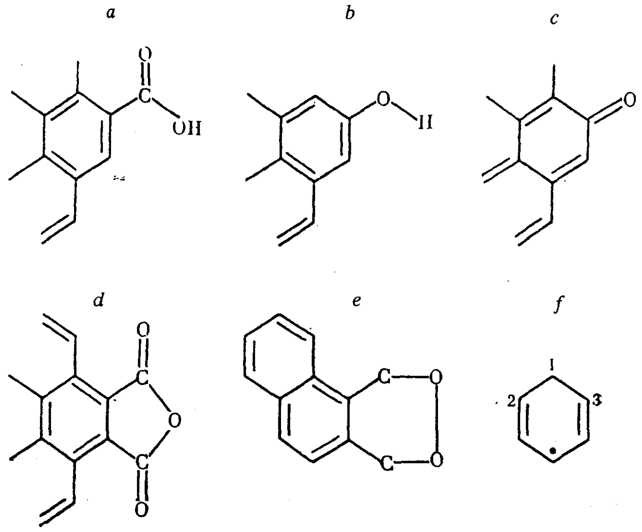

Figure 1. The surface groups of carbon materials: *a*) carboxy-group; *b*) phenolic group; *c*) carbonyl group of the quinone type; *d*) acid carboxy-group; *e*) cyclic peroxy-group; *f*) free σ-radical.

Thus the extensive use of carbon materials for the creation of surface-modified electrodes can be accounted for by the combination of a series of properties such as the presence on their surfaces of a wide variety of groups and free radicals, their high electrical conductivity, and the wide limits within which their porous structures and hydrophobic-hydrophilic properties vary.

2. Attachment by Adsorption

The method of adsorption modification of the surface is best known and simplest. Its principal disadvantage is the gradual desorption of the substance from the surface. The specificity of the adsorption interaction is determined by the type of carbon material and the chemical nature of the substance adsorbed.

Organic materials functioning as ligands for the formation of complexes[13] or metal complexes[14] are immobilised on carbon materials by the adsorption method. The degree of adsorption of organic compounds of this type increases with increase of the number of aromatic rings in the structure. The stronger and irreversible adsorption of N_4-complexes takes place both on polycrystalline pyrographite and on single crystals.[15] According to Zagal et al.[15], the N_4-complexes of iron are adsorbed on the electrode surface in a planar fashion, while tetrasulphonated phthalocyanine complexes of cobalt and iron are disposed on the surface edgewise.

The ability of graphite electrodes to adsorb strongly aromatic molecules has been used[16] to attach the complex $[Ru(NH_3)_5L]^{2+}$, where L is a large aromatic ligand, for example 4-aminomethylpyridine or *N*-(4-picolinyl)benzamide. The complex $[Ru(bipy)_2]_2L^{2+}2(PF_6^-)$, where L is the dianion of 1,5-dihydroxyanthraquinone, has been adsorbed on vitreous carbon.[17] The adsorption of simpler phenanthroline and bipyridyl complexes and also the Salen and corrin complexes of cobalt has been investigated.[18] The strength of their adsorption is low. Macroheterocyclic complexes of cobalt have been adsorbed on carbon materials from their solutions in butanol by evaporating the organic solvent.[19] The complexes are retained on the electrode surface over a wide range of potentials.

The adsorption method for the modification of the surfaces of carbon materials by proteins and enzymes is most widely used in electrochemical measurements. The first studies on the immobilisation of hydrogenase, cytochrome *c*, and laccase on carbon materials already showed that they are strongly adsorbed and that the amount of adsorbed protein is greater the higher the degree of oxidation of the carbon material.[20–22] Peroxidase has been immobilised on carbon black;[23] glucose oxidase and cytochrome b_2 have been adsorbed on vitreous carbon.[24,25] Cytochrome *c* was adsorbed on carbon fibres after the preliminary anodic-cathodic treatment of the surface in the potential range +2.5 to −2.5 V.† This made it possible to observe oxidation-reduction reactions of cytochrome *c*.[26]

In all cases proteins were strongly held on the surface and retained a high catalytic activity. The activity of the enzyme depends on the type of carrier and its specific surface. For example, in the case of laccase immobilised on pyrographite,[2,27] the stationary potential established in an oxygen atmosphere does not exceed 0.9 V; on the other hand, the equilibrium oxygen potential is observed when laccase is adsorbed on carbon black.

An attempt has been made[28,29] to investigate the influence of the nature of carbon sorbents on their capacity with respect to the protein and on the catalytic activity of laccase. The activity of immobilised laccase is influenced by the degree of coverage of the surface by the enzyme, which depends in its turn on the degree of oxidation of the surface of the carbon black or on the porous structure when charcoals are used. The dependence of the activity of the immobilised laccase on the degree of surface coverage in both phenol oxidase and electrochemical reactions passes through a maximum. The greatest capacity with respect to the protein has been noted for charcoals with a large surface area of the mesopores, such as BM-4 and T-39. On the basis of adsorption measurements and porometric data, it has been suggested that macropores and partly mesopores are accessible to the adsorption of protein macromolecules.

However, one should note that, despite the high capacity with respect to the protein, activated charcoals proved to be less convenient electrode materials for the immobilisation of laccase, because in its presence a high anodic potential, inducing the electrochemical corrosion of the charcoal, is established. Carbon blacks exhibit a higher corrosion stability and are more promising for reactions at high anodic potentials with participation of enzymes such as laccase, tyrosinase, and peroxidase.

The favourable and strong adsorption of proteins on carbon materials is determined by the crystal-chemical structure of their surfaces. One of the factors responsible for strong adsorption may be the formation of bonds between the surface groups of the carbon material and the aminoacid residues on the surface of the protein globule. Our studies have shown that the adsorption of many aminoacids and peptides is strong.# Thus glycine and valine cannot be desorbed from the surfaces of carbon materials in the range of their electrochemical stability potentials. Hydrophilic–hydrophobic interactions probably contribute appreciably to the adsorption interaction of the protein with the carbon surface. Their influence on the retention of the nativity of the immobilised proteins has been noted.[30]

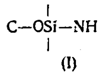
The relation between the isoelectric point of the protein, which determines the surface charge of the protein globule, and the structure of the electrical double layer at the carbon material–electrolyte interface is also noteworthy.

Thus, by virtue of the exceptional properties of carbon materials, strong attachment of the modifying substances, with retention of their high catalytic activity, may be achieved even by adsorption immobilisation.

3. Chemical Modification

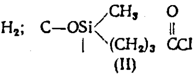
The chemical methods for the modification of the surfaces of carbon materials are based on various organic synthetic reactions.

The most general method for the chemical attachment of modifying agents to the surface involves its preliminary silanisation.[31] Organosilanes, such as the alkylamines (I), the chloroacids (II), and the pyridine derivatives (III) can be used to modify the carbon surface:



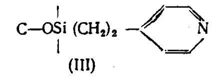
$$\mathrm{C{-}O\overset{|}{\underset{|}{Si}}{-}NH_2};$$

(I)



$$\mathrm{C{-}O\underset{|}{Si}\langle^{CH_3}_{(CH_2)_3\overset{O}{\overset{\|}{C}}Cl}};$$

(II)



(III)

The active centres obtained as a result of silanisation are used for the subsequent "grafting" of various electrocatalytically active groups of complexes.[32,33] The ion exchange method,[34] which consists in the formation, for example, of an insoluble compound by reaction between the surface atoms and a ligand, can also be applied to carbon materials.

A very general procedure used for the modification of carbon materials involves reaction with thionyl chloride[34] or acetyl chloride[35] with the intermediate formation of chloride–oxygen compounds:

In order to increase the concentration of the oxygen-containing groups, the carbon material is subjected to preliminary oxidation in air or is treated with an oxygen plasma. The active groups are introduced by the action of amines or alcohols. This method has been used to prepare various modified materials with pyridine and porphyrin ligands.[36–38] The immobilised ligand may then be metallated with formation of electrocatalytically active complexes.

---

†Here and henceforth, unless otherwise stipulated, the potentials are quoted relative to the hydrogen electrode in the same solution.

#L.R.Aleksandrova, V.N.Andreev, V.A.Bogdanovskaya, and A.Yu.Safronov, Elektrokhimiya, 1987 (in the press).

Amines have been attached[39] to the oxygen-containing groups on carbon materials. This leads to the possibility, in principle, of the subsequent grafting of any functional group.

The intermediate chloride–oxygen compounds on the surfaces of carbon materials can be used for the introduction of various heteroatoms,[40] for example:

$$-C\overset{O}{\underset{Cl}{\lt}} + H_2S \rightarrow -C\overset{O}{\underset{SH}{\lt}} + HCl\ .$$

Another way of creating surface-modified carbon materials involves the use of a surface free from oxides, which can be obtained by the mechanical cleaning of vitreous carbon in an atmosphere of nitrogen or by its treatment with argon plasma.[41] In the presence of vinylpyridine or vinylferrocene, such a surface is modified.

The possibility of attaching the butyl cation or CO_2 to graphite by cathodic treatment in dimethylformamide has been demonstrated.[42]

4. Deposited Films

A special and particularly rapidly developing field concerned with the creation of new electrode materials involves modification by polymers. Here one uses the adsorption, chemical, electrochemical, and radiation attachment methods. The thickness of the polymer films can vary from several to hundreds of nanometers. Depending on the type of reacting or coordinating groups in the polymer film, there is a possibility of its additional modification by metal ions or complexes.

The formation of the polyvinylpyridine complex of copper on various carbon materials by depositing a polymer film from its solution in methanol has been studied in detail.[43] The degree of dispersion of the carbon material influences the activity of the complex, which can be accounted for by the deposition of the polymer in different conformations. The deposition of the polymer film has also been used for the preparation of a surface modified by polystyrene with various functional groups.[44]

The preparation of polyacrylonitrile films on platinum, vitreous carbon, and stainless steel and of polyvinylpyridine films on platinum in a glow discharge at 250 °C has been described.[45–47]

The γ-radiation-induced cross-linking of alkylphenol films is used on metallic electrodes;[48] such cross-linking is also employed for other polymers, which are adsorbed in the monomeric state and are then polymerised.

The methods involving the electrochemical deposition of polymer films, which have many advantages compared with the traditional procedures because they make it possible to eliminate a number of intermedate stages such as the formation of the polymer, its dissolution, etc., have been developing vigorously. In the electrochemical deposition of films, it is possible to regulate the thickness and chemical composition of the resulting coating. On the other hand, electrochemical polymerisation permits the cross-linking of a film already deposited on the electrode.[49]

Polyacrylamide films have been obtained under the conditions of cathodic initiation.[50] Polymer deposits can be obtained electrochemically from solutions containing unsaturated carboxylic acids, certain aldehydes, and alcohols.[51] As a rule, polymer films are deposited electrochemically on metallic electrodes. The uses of polymer electrodes for various purposes, including electrocatalysis and photoprocesses, have been described in a review.[51]

III. ELECTROCHEMICAL PROPERTIES OF THE MODIFIED SURFACES

The study of the properties of surface layers on modified electrodes includes the study of the nature of the bonds between the modifying agents and the surface, the orientation of the modifiers, the degree of surface coverage, the thickness of the layer, the redox reactions of the groups attached to the surface, and the interactions of the species on the surface.

Among the non-electrochemical methods for the investigation of the surface groups of modified electrodes, spectroscopy with optically transparent electrodes,[52] mirror reflection spectroscopy,[53] and also IR and X-ray photoelectron spectroscopy[54,55] should be mentioned. The first two methods are used for the investigation of redox reactions of the attached groups and the last two provide proof that particular stages of the addition reactions have been effected.

The difficulty of measuring the spectra of the modified surfaces *in situ* arises from the necessity to obtain the spectral characteristics of molecules whose number does not exceed that corresponding to a monolayer. Anomalous extinction coefficients have been observed in a series of studies[57–59] on the adsorption of complexes with a conjugated system of π electrons. They all involve the intensification effect due to the roughness of the surface. In the measurement of Raman spectra, this phenomenon has been frequently observed and its possible causes have been considered.[56] In electronic spectroscopy the phenomenon of the anomalous increase of the extinction coefficients was observed for the first time in the adsorption of chlorophyll on an amalgamated gold electrode.[57] Later an analogous phenomenon was noted in the adsorption of tetrasulphonated complexes of cobalt and iron on platinum and pyrographite[58] and of the bipyridyl complexes of ruthenium on SnO_2.[59]

This apparently indicates an extremely strong chemisorption linkage between the modifying group and the electrode surface.

1. Oxidation-Reduction Reactions of the Modifying Complexes

Potentiodynamic and differential pulsed measurements make it possible to investigate the redox reactions of active groups on the surface-modified electrodes and to compare them with the oxidation-reduction properties of the complexes in solution. The possibility of redox reaction of covalently bound groups depends on their orientation on the carbon surface.[60,61] Of the two isomeric 1- and 2-aminoanthraquinones, only the former underwent pronounced redox reactions. It can be oriented parallel to the surface, which ensures the maximum degree of electronic interaction and facilitates electron transfer. Methylaminopropylviologen, attached to the surface via cyanuric chloride, is electrochemically active and stable for a long time.[54] The redox potentials of various ferrocene derivatives attached to graphite differ little from the corresponding values for derivatives in solution in acetonitrile.[40]

Much attention has been devoted to the study of electrodes modified by ruthenium complexes attached to polymers or directly to the carbon surface. In many instances,[13,16] the redox potentials of the adsorbed or chemically attached ruthenium complexes are close to the normal potential of the complex in solution. On formation of metal complexes with polymer films, redox transitions have been observed,[60] whose number depended on whether the metal was coordinated to one or two pyridine rings.

The potentiodynamic curves obtained in the presence of adsorbed phenanthroline complexes of copper[18] show maxima which may be attributed to the Cu^{2+}/Cu^{+} transition on the electrode surface, since the redox potential of the Cu^{2+}/Cu^{+} pair in the corresponding ligand environment is close to the potentials of the redox reactions in solution. As the electrode surface is covered by the complex, a steady increase of the amount of electricity corresponding to the given redox process is observed. The change in the orientation of the complex on the surface is manifested in its adsorption from solutions at different concentrations. A greater order of the adsorption layer, expressed by the fact that the entire complex is reduced and oxidised at similar potentials, is observed in adsorption from dilute solutions. The results of potentiodynamic measurements have shown that redox processes with participation of cobalt and copper complexes proceed under nearly reversible conditions. For complexes of the phenanthroline series, limiting surface coverage approaches the monolayer coverage.

Under the conditions of weak adsorption of the modifying agents,[61] the redox potentials of copper, cobalt, and iron complexes on the pyrographite surface also agree with the corresponding values in solution according to the results of potentiodynamic measurements.

Analysis of all the available data on the oxidation-reduction potentials of various groups attached to carbon carriers leads to the conclusion that their properties in the immobilised state and in solution are similar. This indicates a very high rate of electron transfer from the electrode to the modifying complex.

2. The Influence of the Polymer Coating on the Electrochemical Behaviour of the Carbon Material

The oxidation-reduction reactions of polymer layers on various electrode materials have been described.[62-64] The main results can be summarised as follows. At scanning rates <1 V s^{-1}, the cyclic curves are close to those observed for typical surface reactions. The curves are symmetrical and the current at the maximum is proportional to the rate of application of the potential. These data indicate the absence of transport-dependent limitations. However, at high rates of application of the potential,[65] particularly in the case of relatively thick films,[41,66] a discrepancy between the potentials of the anodic and cathodic maxima is observed. Similar phenomena have been noted on reducing the temperature and on increasing the size of the electrolyte ions.[64]

As a rule, in the case of symmetrical maxima, their parameters differ from those corresponding to equilibrium electronic transitions. Thus the width of the maximum at the level of half the height of the current peak was 0.09 V, which corresponds to a reversible one-electron transition, only in a few cases.[60] Usually this value ranged from 0.15 to 0.54 V. The broadening of the maxima is attributed to repulsive interactions[64] or to a distribution of the given species with respect to the potentials of the redox reaction caused by the existence of electrochemically non-equivalent sites in the polymer film.[3] The asymmetric character of the potentiodynamic $I-E$ curves for polymer coatings can be caused by the slow rearrangement (conformational changes) occurring in the oxidation or reduction of the polymer complex.[66-68] The swelling of the polymers is also possible. Thus significant differences in the behaviour of polymerised vinylferrocene in acetonitrile and water have been noted.[68]

The electrochemical behaviour of polyvinylpyridine (PVP), polycaproamide, and copper polyvinylpyridinate on carbon materials has been studied in detail.[69,70] Fig.2 presents the potentiodynamic curves obtained on a pyrographite electrode with a deposited PVP film. The $I-E$ curves have an analogous form in the presence of a polycaproamide film. It has been noted that the cationic composition of the electrolyte has a significant influence on its polarisation capacity. The relative increase of the polarisation capacity then rises in the sequence Na < K < Ba in the presence of a PVP film and falls in the sequence K > Cs > Ba in the presence of polycaproamide.

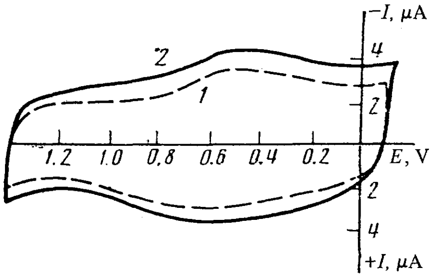


Figure 2. Potentiodynamic $I-E$ curves obtained at a pyrographite electrode (curve *1*) and a pyrographite electrode with a deposited PVP film (curve *2*) for $\nu = 0.05$ V s^{-1} at pH 7.0.[69,70]

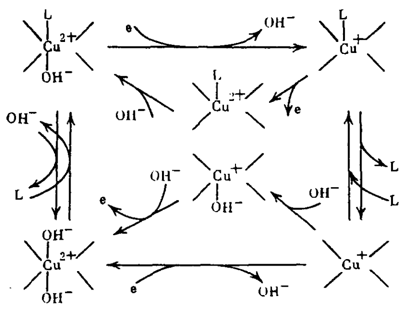
When copper ions from an alcoholic solution are introduced into a PVP film, a stable complex is formed, namely Cu-poly-4-vinylpyridine (Cu-P-4VP), which is indicated by the possibility of measuring quasi-stationary potentiodynamic curves in the potential range 1.2–0.0 V.§ The potentiodynamic curves reveal the occurrence of the Cu^{2+}/Cu^{+} redox transition. The successive changes in these curves during the cyclic process suggested the possible conformational rearrangement of the complex in the course of the redox reactions and as a function of time. The stability of the polymer coating is fairly high and is independent of the degree of oxidation of the copper ion. In contrast to this, cobalt complexes decompose on transition of the metal to the bivalent state. The stability of the polymeric copper complex can apparently be explained by the formation of cross-linked structures,[71] as for the ruthenium complexes.[60]

Analysis of the potentiondynamic curves at different rates of application of the potential and with a variable scanning amplitude suggests the presence of at least two types of coordination of copper as a function of the distance between the copper ion and the electrode surface.[43] One of these corresponds to the redox processes at the electrode–polymeric complex interface (type I copper) and the other to the processes occurring in the bulk of the polymer film (type II copper). The redox reactions of type I copper can be described by the following scheme on the basis of the data obtained:

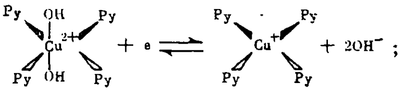
---

§S.B.Orlov, M.R.Tarasevich, V.A.Bogdanovskaya, and V.S.Pshezhetskii, Elektrokhimiya, 1986, 22, 768.



The surface groups of pyrographite or H_2O can serve as the ligand L. A significant feature of this scheme is the importance of the protonation–deprotonation reaction.

The maximum current for the redox reactions of type II copper is not a linear function of the rate of application of the potential. The following reaction most probably corresponds to this process:



$$\mathrm{Py_4Cu^{2+}(OH)_2} + e \rightleftharpoons \mathrm{Py_4Cu^{+}} + 2OH^- ;$$

Py = pyridine.

It is of interest to note that anodic polarisation at $E = 1.2$ V reduces the height of the anodic and cathodic maxima. The mechanism of this phenomenon can be formulated on the basis of the idea that there are different electrostatic repulsions between neighbouring copper ions in the oxidised and reduced forms, which leads to the contraction and expansion of the ion-containing polymer film in the course of redox reactions and the rate-limiting stage is the relaxation of the polymer chain.

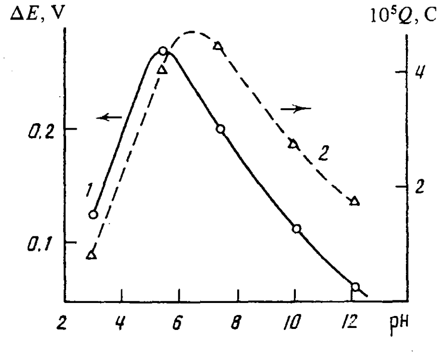


Figure 3. The pH dependence of the shift of the polarisation curve for the electrochemical reduction of oxygen relative to the background curve at $I = 0.03$ mA (curve *1*) and of the overall amount of electricity Q under the I–E curve obtained on pyrographite modified with Cu-P-4VP in the range of potentials 1.2–0.0 V (curve *2*).[43]

Whereas in the absence of copper ions in the polymer coating, the character of the I–E curves is influenced by the electrolyte cations, in the case of the copper-containing PVP the form of the potentiodynamic curves depends on the anionic composition of the electrolyte. Thus the replacement of the PO_4^{3-} ions by Cl^- yields more symmetrical potentiodynamic curves. In conformity with the ideas developed by Shigehara et al.[72], the observed phenomenon can be explained by the facilitation of charge transfer for the polymer layer as a result of migration whose rate is determined by the size of the diffusing counterion (in the given case Cl^-, OH^-, or PO_4^{3-}).

The dependence of the total amount of electricity under the I–E curve on the pH, reflecting the stability of the polymer complex, is illustrated in Fig. 3 (curve *2*). Comparison of this relation with literature data[73,74] shows that tetrapyridinate complexes formed at pH 5–6 are electrochemically active, while the dipyridinate complexes (pH 3–4) are electrochemically inactive. The decrease of the amount of electricity in alkaline solutions (pH > 7) is associated with the formation of copper hydroxide.

The complex character of the kinetic parameters obtained for the electrochemical behaviour of polymer electrodes indicates the necessity to resort to other physicochemical methods for the development of detailed ideas about the mechanism of the redox reactions. One can only note that the redox potentials of a whole series of polymer complexes in solution and in the immobilised state[75,76] change little in the irreversible interaction with the electrode, which indicates the absence of strong ion pairs[77] and shows that the environment of the copper ion on the electrode is close to its environment in aqueous solution.[78,79]

3. The Capacity of Protein Macromolecules for Oxidation-Reduction Reactions in the Immobilised State

The necessity to investigate the electrochemical behaviour of protein macromolecules arises from the prospect of the use of proteins and enzymes in electrocatalysis. The first studies on redox reactions of proteins and enzymes were carried out on mercury electrodes.[2,80,81] However, the interaction of a protein with mercury leads to the partial or complete uncoiling of the protein globule and either the denatured protein or the protein adsorbed on the second layer undergoes the oxidation-reduction reactions.[2] Furthermore, in their interaction with mercury, sulphur-containing proteins form compounds of the type $(HgS)_2$ and the potentiodynamic curves reflect their redox reactions.[81] It has been established that the potential of the oxidation-reduction reactions of these compounds is identical with the redox potential of the transition $HgS \rightleftharpoons Hg^{2+} + S^{2-}$ observed for a sulphur-containing aminoacid—cysteine.

In this respect, carbon materials are superior to mercury. In the first place, it has been shown[2,14,27] that proteins and enzymes retain their catalytic activity after adsorption on the carbon carrier and are therefore not denatured. Some decrease of activity may be explained by the restriction of mobility on formation of bonds between the surface groups of the protein globule and the corresponding groups of the sorbent.

The redox reactions of cytochrome *c* on carbon fibres have been described[26,82] and it has been shown that cytochrome *c* is oxidised and reduced almost reversibly. Our investigations¶ on a pyrographite electrode subjected to preliminary anodic-cathodic activation in the potential range 2.0 to −2.0 V showed that cytochrome *c* is oxidised and reduced at potentials close to the oxidation-reduction potential of the

---

¶V.A.Bogdanovskaya, A.M.Kuznetsov, M.R.Tarasevich, E.D.German, and E.F.Gavrilova, Elektrokhimiya, 1987 (in the press).

protein. The rate of reduction of the protein in the temperature range 5–20 °C is independent of temperature. Calculation carried out on the assumption that one electron is consumed on the reduction of the active centre of cytochrome *c* showed that the surface coverage of pyrographite by the protein does not exceed a monolayer.

It has been noted[83] that, in electrochemical systems with electrodes made of carbon materials, the redox reactions of the active centre may be accompanied by the oxidation of certain aminoacids, for example, tyrosine. However, this hypothesis is unlikely, because the oxidation of aminoacids at a potential of +0.66 V relative to the silver, silver chloride electrode is hardly feasible; it is contradicted by data on the electrochemical oxidation of aminoacids.[84–86]

The electrochemical reactions of enzymes on carbon materials have been investigated[81,87,88] and it has been shown[81] that peroxidase does not undergo redox reactions in the experimental potential range. On the other hand, when peroxidase is denatured, the haem liberated gives rise to almost reversible maxima. It has been stated that laccase is reduced on carbon black at a potential of 0.75 V.[87] The possibility of the oxidation-reduction of glucose oxidase has been noted,[88] but systematic studies of the oxidation-reduction properties of enzymes have not so far been carried out. One of the causes of this may be the high redox potentials of enzymes, which require the use of special electrode materials stable at these potentials. Mercury electrodes dissolve at fairly low potentials and carbon materials are corroded at potentials more positive than 1.0 V.

IV. CHARGE AND MATERIAL TRANSFER IN THE SURFACE LAYER

An adequate description of the mechanism of charge and material transfer in the surface layer at the interface between the conducting support and the bulk of the electrolyte is the main fundamental task in the problem of modified electrodes. Only on the basis of data for the mechanism and kinetics of transport stages can one estimate the possible limits of the acceleration of electrochemical reactions and optimise the electrocatalytic effect.

The main trends in the study of transport processes are the calculation of the rate of transfer of charged species, the search for phenomenological models for the representation of experimental data, and direct experimental investigation of the electron (charge) transfer stage.

In the case of monolayer coverage, the transport stages as such are absent and the mechanism of the electron transfer between the metal and the substrate is determined by the character of the electronic interaction of the metal, the catalytically active group, and the substrate. For a distributed catalytically active layer, the redox reaction of the substrate can occur throughout its bulk and electron transport is achieved via jump or mediator mechanisms, with the simultaneous diffusion of counterions. Depending on the morphology of the active film, account must be taken also of the diffusion of the substrate in the pores or through the film (Fig. 4).

As shown above, the redox potentials of compounds immobilised on electrodes differ little from the corresponding values in solution, which indicates rapid electron transfer in those cases where a direct electronic interaction of the active group and the support is established as a result of the overlap of the corresponding electron orbitals. In a series of studies,[3,67,89] the potentiodynamic I–E curves for surface-modified electrodes were examined quantitatively taking into account the interaction of neutral and charged surface groups, the heterogeneous properties of the surface, and the effect associated with the rearrangement of the surface layer as a function of time. The dependences of the potential of the maximum and of the current at the maximum on the rate of scanning of the potential are described by fairly complex equations. By means of numerical computer calculations, it is possible to "adjust" the shape of the calculated I–E curve to agree fairly well with the experimental curve. However, in view of the large number of initial assumptions, this can hardly serve as proof of their validity.

The general relations governing electron jumps via the tunnel mechanism† have been examined in a number of studies.[90–93] The influence of the degree of interaction of the adsorbate with the surface on the tunnel electron transfer in the electrode/adsorbate/redox pair system has been analysed. For a very strong interaction, a volcano-like dependence of the exchange current on the electron work function of the metal has been predicted.[92] The height of the potential barrier on the residence time of the electron in the intermediate state determines whether electron transfer is of the two-channel type or the multichannel type.

Tunnel electron transfer takes place in the redox reaction of immobilised ferrocene[94] at a distance of 8 Å from the surface of the electrode. The temperature variation of the rate of reaction obeys the Arrhenius equation. The change in the rate of reaction by two orders of magnitude on passing

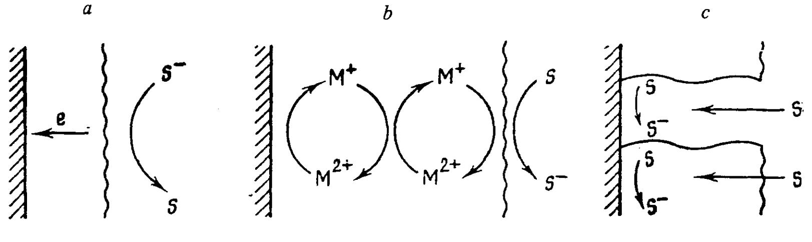

Figure 4. Methods of carrying out the redox reactions of the substrate S on surface-modified electrodes: *a*) injection of charge into the film; *b*) mediator transport (M = mediator); *c*) diffusion through the film or in the pores.[5]

---

† Since the number of studies devoted to tunnel transport is small, we shall employ the available data regardless of the type of conducting support.

from sulpholan to acetonitrile is associated with the change of the activation energy from 44 to 34 kJ mol^{-1}. Using the elastic tunnelling model, the authors[94] begin with the fact that the overall activation energy for the electronic transition in the given system is made up of the energies of the reorganisation of the solvent and of the change in the bond lengths. However, this assumption is arbitrary, since the first process is adiabatic and the other is not.

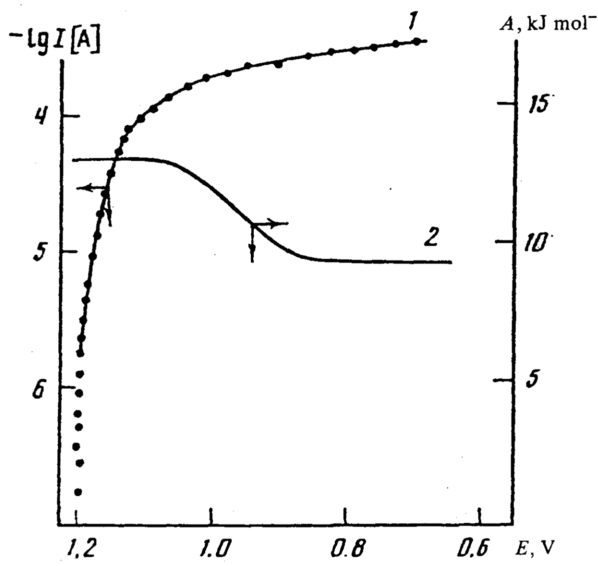

Figure 5. Dependence of the rate of electrochemical reduction of oxygen (curve *1*) and the activation energy for this reaction (curve *2*) on the potential of a carbon black electrode with immobilised laccase.[97]

Tunnel electron transfer has been examined as the transport stage for carbon electrodes modified by enzymes.[95–97] The dependence of the rate of the cathodic reduction of oxygen on a carbon black containing laccase on the thickness of the lipid layer between the protein globule and the support has been investigated.[95] For a thickness of the lipid layer in excess of 20 Å, the rate of reaction falls sharply, which is caused, according to the authors, by the decrease of the effective tunnel electron transfer. The estimates of the possible distance over which tunnel electron transfer takes place[95,97] were based on the hypothesis of rapid electron transfer between the electrode and the active centre and that the rate of the process is limited by the rate of the enzyme reaction.

Detailed studies of the kinetic characteristics and of the temperature variation of the rate of reaction[97] deepened the existing ideas about the mechanism of the bioelectrocatalytic oxygen reduction reaction. In the region of relatively low polarisations, the rate of the electrochemical reduction of oxygen is limited by the rate of the electron transfer stage and is described by the Tafel relation between the current and the potential (Fig.5). In the region of the limiting current, the process is controlled by the stage characteristic of enzyme catalysis.

In the region of low polarisations, the activation energy A is low and the acceleration of the reaction is to a large extent caused by the change in the pre-exponential factor ν in the equation

$$i=\nu\exp(-A/kT) \ .$$

Application of modern quantum theory[98] permitted the conclusion that a collectivised state of the adsorbent–adsorbate system arises in the immobilised laccase–carbon electrode system. The electron density is not localised on the active centre of the enzyme, because its interaction with the solvent is weak. The oxygen electrochemical reduction current is

$$i\cong\int d\varepsilon\rho_a(\varepsilon)f(\varepsilon)W(\varepsilon)\sim\rho_a(\varepsilon^*)f(\varepsilon^*)W(\varepsilon^*) \ ,$$

where $f(\varepsilon)$ is the Fermi function of the distribution of the energy of the electrons, $W(\varepsilon)$ the probability of electron transfer from the level ε on the active centre to the substrate molecule, $\rho_a(\varepsilon)$ the density of electronic states associated with the active centre, and ε^* the energy for which the contribution to the total current is a maximum. Since the active centre of the enzyme is at a distance of ~10 Å from the electrode their potentials are different. The dependence of the pre-exponential factor on the potential is then determined by the influence of the latter on the energy of the electronic level of the active centre of laccase.

In the study of charge transfer# in multilayer (including polymer) electrodes containing active centres, three possible mechanisms are taken into account: electron jumps, exchange of electrons between the active centres, and the diffusion of counterions. It is usually assumed that the electron transfer process through the polymer is analogous to diffusion:[99]

$$D_{\text{exp}}=D_0+\pi k\delta^2c/4 \ , \qquad (1)$$

where D_0 characterises the actual contribution of diffusion, k is the rate constant for electron exchange between the redox centres in the polymer layer, c the concentration of the species reduced at the electrode, and δ the distance over which the electron is transferred.

In order to elucidate the mechanism of electron transfer, one investigates the influence on the latter of temperature, the type of solvent, the nature of the electrolyte, the degree of cross-linking of the polymer, and the concentration of charges. The determination of the apparent diffusion coefficient D_{exp} for a polymer of the nafion type on a pyrographite electrode[101] showed that the charge transfer mechanism depends on the type of cation incorporated. Fig.6 illustrates schematically the dependence of D_{exp} on the concentration of active groups for polymers of two types differing in the strength of attachment of the active centres. An example of the system of type (*a*) is provided by a copolymer containing ruthenium and osmium ions;[102] the system (*b*) obtains for a polymer containing the Ru(bipy)$_3^{3+/2+}$ ions.[101] Section *2* is described in both cases by Eqn.(1) presented above. In region *3*, the rate of transfer is determined by the mobility of the polymer lattice or polymer chains. In region *1* (*a*), ions are separated by a distance greater than the characteristic diffusion distance and the rate of transfer diminishes. Region 1 (*b*) corresponds to simple diffusion of ions. Comparison of the diffusion coefficient and of the rate of quenching of the luminescence of Ru(bipy)$_3^{2+}$ [103] leads to the conclusion that the slow stage is the movement of counterions. The diffusion mechanism is

---

#The electronic properties of the polymers themselves, including those which have been doped electrochemically, have been examined in a review[100] and a monograph.[101]

most important for thick films and when there is a significant difference between the potentials of the substrate and the attached mediator.

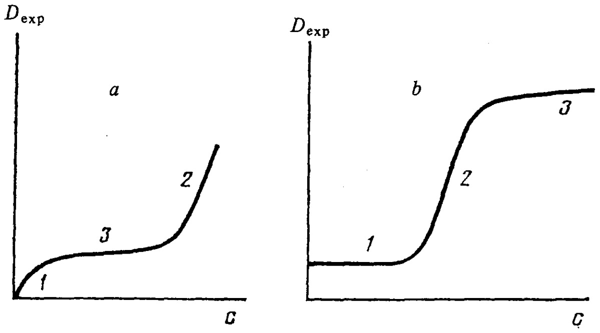

Figure 6. Schematic illustration of the dependence of D_{exp} on the concentration of active groups for polymers with chemically attached (*a*) and electrostatically bound (*b*) ions; for the characteristics of sections *1–3*, see text.[101]

A series of experimental facts outside the framework of the ideas formulated above have been described in the literature. Thus it has been observed[104] that, when copper ions are incorporated in polyphenol oxidase films at Cu^{2+} concentrations above the critical value, there is an avalanche-like increase of the rate of electron transfer. A phenomenon, previously unknown, involving an increase in the polarisation capacity in the pyrographite–polymer–electrolyte system has been described.[69,70] The magnitude of the effect depends on the nature of the cation and decreases with decrease of the radius of the hydrated cation. It has been suggested that this is associated with the shielding by the cationic charge of the free electrons of the support, entering the polymer layer, and not with the doping of the polymer by electrolyte cations.

The ideas about the mechanism of charge transport are used to solve two main problems: the analysis and quantitative description of the redox reactions in the surface layer and the estimation of electrocatalytic effects which can be attained using electrodes of the type considered. In the interpretation of the form of the *I–E* curves, one begins with the idea of slow heterogeneous electron transfer and data on the kinetics of the reorganisation of the film and the interaction within the film.[67,105]

An attempt has been made to estimate the efficiency of electrocatalysis on the surfaces of modified electrodes compared with homogeneous catalysis. It has been shown[89] that, for the same activation energy, homogeneous catalysis is more effective than electrocatalysis under conditions where the concentration of the active centres corresponds to monolayer coverage. Bearing in mind the influence of binary and ternary collisions and also the electrostatic work of the double layer and the reflection layer, large effects cannot be expected in the case of an outer-sphere mechanism of electrocatalysis. This is confirmed by calculations for a surface-modified disc electrode.[89]

In estimating the electrocatalysis effect for electrodes with a distributed active layer, one must take into account the rate of transfer of both electrons and of the substrate to the active centre. Various instances of electrocatalysis on polymer electrodes with redox centres have been investigated theoretically and experimentally.[106,107] If the electron transfer stage is rapid (on the electrochemical scale), then polymer or multilayer coatings are useful when the transport stage is relatively slow and the films are readily permeable. However, this conclusion is hardly valid if the polymer exhibits electronic conductivity[108] or when a conducting filler, for example, carbon particles, has been introduced into the film.

The stationary diffusion equations for a disc electrode coated by an electrochemically active polymer film have been examined.[89,109] In this case the thickness of the diffusion layer δ is replaced by the quantity $\delta' = l + (D_f/D_s)_\delta$, where D_f and D_s are the diffusion coefficients in the film and in the free solution. If the rate of diffusion in solution is much smaller than in the film ($D_s/\delta \ll D_f/\delta$), then the usual voltage–current curves are obtained. For the opposite relation, the system becomes more reversible than on the "clean" electrode. However, this is manifested by the approach of the half-wave potential to the reversible value and not by the increase of the overall current.

V. NON-ELECTROCATALYTIC REACTIONS ON MODIFIED ELECTRODES

In simple oxidation-reduction reactions unaccompanied by a redistribution of the bonds or strong coordination of the molecules, the modifying groups serve as mediators in electron transfer processes. The rates of reaction of this type are independent of the nature of the electrode material after the application of corrections for changes in the structure of the double layer, but data for their kinetics yield much information necessary for the understanding of the mechanisms of electrocatalytic reactions.

Three types of non-catalytic reactions on surface-modified electrodes are possible. If the substance is oxidised more readily than the mediator modifying the surface and the film of the modifying agent is poorly permeable to the reacting substance, the process proceeds on the outer boundary at the redox potential of the mediator. If the redox potentials of the mediator and the reactant are equal, the reaction proceeds in the same way as on an unmodified surface. The third case, where the mediator is oxidised more readily than the substrate and its transfer becomes dominant, is of greater interest. This mechanism has in fact been observed.[110] The complex $K_4Mo(CN)_8$, introduced into a PVP film on pyrographite, can act both as an oxidant and as a reductant. The processes occurring in the system are illustrated schematically in Fig.7. The redox potential of the $Mo(CN)_8^{4-}/Mo(CN)_8^{3-}$ transition for the complex incorporated in the film is +0.52 V, while for the Fe^{2+}/Fe^{3+} system it is +0.49 V. The closeness of these redox potentials makes it possible to accelerate both the oxidation of Fe^{2+} and the reduction of Fe^{3+}. The above hypotheses are confirmed by the curves (Fig.7) obtained for electrodes of three types: unmodified, modified with PVP, and modified with PVP containing the complex $K_4Mo(CN)_8$.

The second cause of the interest in non-catalytic reactions on modified electrodes is the possibility of investigating the redox reactions of proteins on such electrodes. Studies of the electrochemical reactions of their active centres are of special interest. In such systems, the modifying agents play the role of mediators and at the same time serve as enzyme substrates, which makes it possible to achieve the redox transformations of the active centres. As a rule the redox reactions of proteins are investigated on modified metallic electrodes. Thus the immobilisation of methyl- or benzyl-viologen on gold makes it possible to carry out the oxidation-reduction reactions of myoglobin,[111] while the immobilisation of polyvinylviologen permits the reduction of cytochrome *c*.[112] Cytochrome *c* can be oxidised and reduced electrochemically on gold and platinum electrodes with adsorbed 4,4'-bipyridyl.[113]

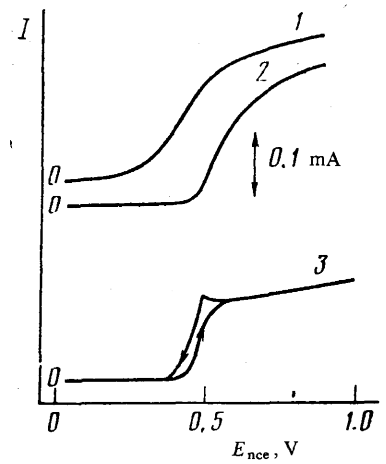

Figure 7. Polarisation curves for the oxidation of Fe^{2+} (at a concentration of 4 mM) at pH 1.5 and $v = 0.0075$ V s^{-1} at a rotating pyrographite electrode (curve *1*) and a pyrographite electrode modified with PVP (curve *2*) and the $PVP-Mo(CN)_8^{4-}$ complex (curve *3*).[110]

On a carbon surface, the redox reactions of proteins have been observed both after the modification of the electrode and after the preliminary electrochemical treatment of the surface. Cytochrome *c* is reduced on pyrographite modified by polymeric methylviologen[114] and peroxidase, glucose oxidase, and xanthine oxidase, as well as certain other enzymes are reduced on vitreous carbon.[115,116] The electrochemical reactions of laccase occur in the presence of a whole series of modifying agents and the positions of the potential maxima depend on their nature. On modification of 2,9-dimethylphenanthroline, the maximum is at 0.64 V, while on modification with 4,4'-bipyridyl it is at +0.74 V (n.h.e.).[115,117]

The anodic-cathodic treatment of the surface can result in the appearance of a large number of oxygen-containing groups which function as modifying agents. The redox reactions of cytochrome *c* have been observed on electrochemically treated carbon materials.[26] It is most likely that oxygen-containing groups, including quinone-hydroquinone groups, effect the oxidation-reduction reactions of the active centres of the proteins via the mediator mechanism.

VI. THE MECHANISMS OF ELECTROCATALYTIC REACTIONS

By virtue of the possibility of the specific creation of an active layer, surface-modified electrodes have been finding increasing application in a whole series of electrocatalytic reactions, because they exhibit an increased selectivity and a high catalytic activity.

1. The Activation of Organic Molecules

The oxidation reactions of organic molecules proceed as a rule at high anodic potentials on platinum group metal electrodes. The use of surface-modified electrodes permits in many cases the elimination of noble metals or it is even possible to achieve reactions which cannot occur on other electrodes.

Using modified pyrographite, sulphoxide has been synthesised[118] and anisole and toluene have been chlorinated.[119] The yield of the target products, namely carbinol and pinacol, on a graphite electrode modified with amine depended on the nature of the surface oxides.[119] In the presence of basic oxides, pinacol was synthesised preferentially, while on a surface coated with acid groups, carbinol was the main product. Presumably the strength of the bond between the modifying amine and the electrode surface plays an important role.

Data have been published[55] on the acceleration of the oxidation of ascorbic acid on pyrographite electrodes with chemically bound benzidine. It is noteworthy that preliminary treatment with plasma leads to an increase of the true surface area of the pyrographite electrode and the true acceleration effect is therefore not unduly great. Graphite electrodes modified with vinylferrocene are the most effective in this reaction.[120] The electrocatalytic current is limited by the rate of diffusion of ascorbic acid in the polymer film. The graphite electrode modified with quinone[54] accelerates the electrochemical oxidation of NADH to NAD^+. The oxidation of NADH is accelerated to an even greater extent in the presence of polymer films of dopamine (DP), phenazine methanesulphonate (PPMS), and phenazine ethanesulphonate (PPES).[121] [The latter two films are not mentioned in Ref.121 (Ed.of Translation)]. Data concerning the acceleration of the reaction in the presence of the above compounds are compared in the Table. It is noteworthy that the half-wave potentials ($E_{1/2}$) and current maxima (E^*) for the oxidation of NADH (see Table) are remote from the redox potential of the $NADH/NAD^+$ pair, which is −0.56 V (s.c.e.).

The half-wave potentials ($E_{1/2}$) and the potentials at the maximum (E^*) for the oxidation of NADH on electrodes modified by different compounds at pH 7.0.[121]

Type of modifying agent	Quinone	PD	PPMS	PPES
$E_{1/2}$, V	+0.16	+0.12	−0.16	−0.21
E^*, V	+0.26	+0.21	−0.05	−0.10

The high catalytic activity of pyrographite modified with tetrasulphonated water-soluble phthalocyanine complexes of iron and cobalt in the oxidation of certain organic molecules has been noted.[1,2] The phthalocyanine complex of cobalt accelerates the oxidation of cysteine to cystine. In both acid and alkaline solutions, the slope of the Tafel curve is close to $2 \times 2.3RT/F$. In the region pH < 8.5, we have $\partial \lg i / \partial \text{pH} \cong 1$, whereas at higher pH the corresponding function is close to zero. These kinetic parameters correspond to the following possible reaction mechanisms:

$$R{-}SH \rightleftharpoons RS^- + H^+ ,$$
$$RS^- \rightarrow RS^{\cdot} + e ,$$
$$2RS^{\cdot} \rightarrow R{-}S{-}S{-}R .$$

The use of carbon electrodes modified by enzymes for the oxidation of various organic substrates has been examined fairly fully.[96] Enzymes of the oxidase class—cytochrome b_2, peroxidase, glucose oxidase, xanthine oxidase, and galactose oxidase—effect the reaction of their substrates in the immobilised state on the electrode. Two reactions take place consecutively on two-enzyme electrodes based on glucose oxidase and peroxidase:

$$\text{glucose} + O_2 \xrightarrow{\text{glucose oxidase}} \delta\text{-gluconolactone} + H_2O_2;$$

$$H_2O_2 + 2Fe(CN)_6^{4-} + 2H^+ \xrightarrow{\text{peroxidase}} 2Fe(CN)_6^{3-} + 2H_2O.$$

Xanthine oxidase or uricase may be used in two-enzyme electrodes. Analysis of the experimental data shows that the rate-limiting stage in the overall process is the first reaction,[123] i.e. the oxidation of glucose, hypoxanthine, or uric acid. The efficiency of such electrodes is extremely low and the creation of electrochemical sensors for the detection of various substrates is a more realistic application of such devices.

Immobilised enzymes belonging to the class of dehydrogenases can be used for the oxidation of organic substrates. As a rule, the regeneration of coenzymes, which can be achieved with the aid of enzymes, is essential for their functioning. NAD was regenerated in the presence of alcohol dehydrogenase and lactate dehydrogenase.[124] However, such a system is unduly complex and its employment is hardly promising.

Enzyme electrodes based on hydrolases immobilised on a graphite paste electrode or vitreous carbon have been examined.[96] The enzymes are retained in the vicinity of the electrode surface with the aid of membranes. The operation of such electrodes is based on the fact that the hydrolase, for example, cholinesterase, effects the reaction which is typical for such enzymes, involving the cleavage of a covalent bond in the substrate, while the product of the enzyme reaction participates in the electrochemical reaction. Catechol mono-orthophosphate, indoxyl acetate, and other substrates have been oxidised in this way.[96]

The mechanisms of the electrochemical oxidation reactions on electrodes whose surfaces have been modified by enzymes have been studied little. As a rule, the authors confine themselves to comparing the enzyme and electrocatalytic activities and to the calculation of the Michaelis constant. On the basis of these data, it is concluded that the nature of the rate-limiting stage is kinetic or diffusional.[96] Systems in which the electrochemical and enzyme reactions are coupled with the aid of mediators have been studied in greater detail. In essence, such systems do not belong to the class of surface-modified electrodes, because the enzyme immobilised on the electrode effects the enzyme reaction and the acceleration of the electrode reaction is due to the overall effect of all the processing occurring in the system.

Our studies on the oxidation of model compounds derived from lignin (hydroquinone, guaiacol, syringol, and veratrole) on a carbon black electrode modified with laccase demonstrated the possibility, in principle, of the oxidation of these compounds.§ According to the results of chromatographic analysis, the products of electrochemical oxidation on the unmodified and laccase-modified carbon black electrodes are different.

2. Acceleration of the Hydrogen Evolution Reaction

Carbon materials modified by titanium compounds, namely $C{-}OTiCl(OC_2H_5)_2$ or $C{-}OTiCl(OH)_2$, have been used to activate the hydrogen reaction.[39] The potentiodynamic curves obtained for such electrodes show an anodic maximum in the potential range between −0.3 and −0.4 V after cathodic polarisation to $E = -0.6$ V. After prolonged cycling, the shape of the curves does not change, which indicates fairly strong binding of the titanium compounds. With increase of the amount of attached compound, the rate of hydrogen evolution also increases. The reaction on the unmodified carbon material may be represented as follows:

$$2Ti^{IV} \xrightarrow{2e} 2Ti^{III} \xrightarrow{2H^+} 2Ti^{IV} + H_2.$$

The reverse reaction involving the anodic oxidation of molecular hydrogen is not accelerated in the given system, which agrees with the results of a study[125] where it was shown that carbon modified by titanium compounds does not catalyse the hydrogenation of aromatic compounds by molecular hydrogen.

Carbon materials with an immobilised hydrogenase have been used[2,126] to accelerate the electrochemical oxidation of hydrogen. Methylviologen (MV) was used as the mediator in this system. The redox potential of the MV^{2+}/MV^+ pair is +0.011 V, i.e. is extremely close to the equilibrium hydrogen potential. The overall result of the set of reactions is the oxidation of molecular hydrogen:

$$E + H_2 \rightleftharpoons EH_2,$$

$$EH_2 \rightleftharpoons EH^- + H^+,$$

$$EH^- + MV^{2+} \rightleftharpoons MV^{\dot{+}} + E + H^+ + e,$$

$$MV^{\dot{+}} \rightarrow MV^{2+} + e,$$

$$E = \text{enzyme}.$$

The activity of the immobilised hydrogenase and the rate of reaction are higher the greater the amount of enzyme adsorbed on the carbon black, which may be due to the fact that at low coverages there is a strong interaction of the enzyme with the carrier leading to partial denaturation of the protein. With increase of the surface coverage, the interaction of the enzyme with the support weakens, the molecules are oriented in the most favourable manner, and the activity of the enzyme approaches that of the native form.

Kinetic studies have been made of the hydrogen reaction under the conditions of the direct electron transfer from the active centre of the enzyme to the electrode.[127] However, analysis of the electrochemical data refers to the range of potentials where the process is concentration dependent and the observed stoichiometric number yields no information about the mechanism of the kinetic stage.

The use of electrodes modified by polymers and complexes based on them for the activation of the hydrogen reaction has not as yet been described.

3. The Oxygen Reaction

The majority of studies of the use of surface-modified electrodes in electrocatalysis are associated with the reduction of molecular oxygen. At the present time several ways of making modified electrodes for this purpose have been developed: the binding of quinones and phenanthroline and bipyridyl complexes and N_4-complexes, the "assembly" on the electrode surface of polymer systems of various types, and finally the modification of the electrode surfaces by enzymes.

Fig.8 presents the group of quinones which have been used to accelerate the reduction of oxygen in neutral electrolytes.[39] When the quinones R^3 and R^4 with asymmetric substituents are adsorbed, steric hindrance obtains, and they exhibit only

---

§ V.A.Bogdanovskaya, M.R.Tarasevich, and V.G.Vorob'ev, in "Novosti Elektrokhimii Organicheskikh Soedinenii" (New Aspects of the Electrochemistry of Organic Compounds), Moscow—Lvov, 1986, p.65.

a weak catalytic activity. On the other hand, the molecules of R^2 and R^5, which each contain two NH_2 groups, apparently assume a planar disposition on the surface and in their presence the highest stationary potential $E = 1.02$–1.05 V is established on the charcoal. At a current of 0.25 mA g^{-1}, the shift of the electrochemical reduction potential of oxygen in the positive direction is more than 0.3 V.

A large group of relatively simple copper, cobalt, manganese, and iron complexes of *NN'*-disalicylidene-ethylenediamine, adsorbed on a pyrographite electrode, have been investigated. αα'-Bipyridyl and *o*-phenanthroline are known as ligands with a polyfunctional activity which can participate in the resonance transfer of electrons via systems of conjugated bonds. Furthermore, they are effective catalysts of the oxidation of various substrates by molecular oxygen in homogeneous systems.[128,129] Fig.9 illustrates the polarisation curves obtained at disc and ring electrodes for an approximately monolayer coverage of the disc electrode surface by the complex investigated. In the presence of cobalt complexes (curves *2*, *2'*, *3*, and *3'*) the half-wave potential shifts in the positive direction, but oxygen is reduced solely via the formation of hydrogen peroxide. When copper complexes are deposited (curves *4* and *4'*), the reaction proceeds both via the intermediate formation of hydrogen peroxide and with direct reduction to water, the ratio of the constants $K_1/K_2 = 0.23$ for $[Cu(5NO_2phen)]Cl_2$. The activity of the copper complexes depends on the degree of surface coverage by the latter and on the type of substituents. The activity is a maximum for a low coverage and falls when the coverage increases. This type of dependence can be explained if it is assumed, by analogy with homogeneous catalysis,[129] that the substrate (O_2) and the electrode surface are in the *cis*-conformation relative to the central ion of the adsorbed complex. The synchronous transfer of two electrons to the oxygen molecule is possible under these conditions. With increase of the degree of surface coverage, the possibility that such a conformation occurs diminishes, and the activity falls. Thus, in the case of phenanthroline complexes of copper, the role of the support (the carbon material) is manifested directly. The study of Vol'pin et al.[18] is the first in which it was possible to achieve the electrocatalysis of the oxygen reaction by organic copper complexes.

The tetrasulphonated phthalocyanine complexes of cobalt,[15,130] haemin and the chlorin e_6 complex of iron,[21] and the porphyrin complexes of iron and cobalt[131] exhibit a notable electrocatalytic activity in the cathodic reduction of oxygen.

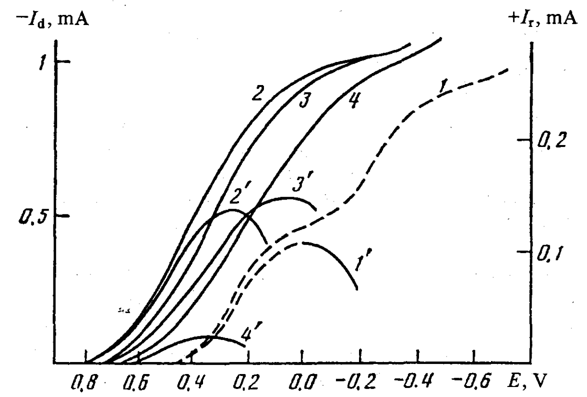

Figure 9. Polarisation curves for the electrochemical reduction of oxygen on a platinum disc electrode (curves *1*–*4*) and for the oxidation of hydrogen peroxide on a platinum ring electrode (curves *1'*–*4'*) in the absence (curve *1*) and presence of the complex adsorbed on the disc electrode:
2) cobalt–salen; *3*) cobalt–decamethyloctadehydrocorrin;
4) $[Cu(5NO_2phen)]Cl_2$.[18]

The mechanism of the reduction of oxygen by these substances differs little from that which obtains on carbon materials coated by a thick layer of the N_4-complexes.[130] The adsorbed phthalocyaninecobalt complex accelerates only the two-electron reaction and the phthalocyanineiron complex promotes the occurrence of the direct reduction to water.[130]

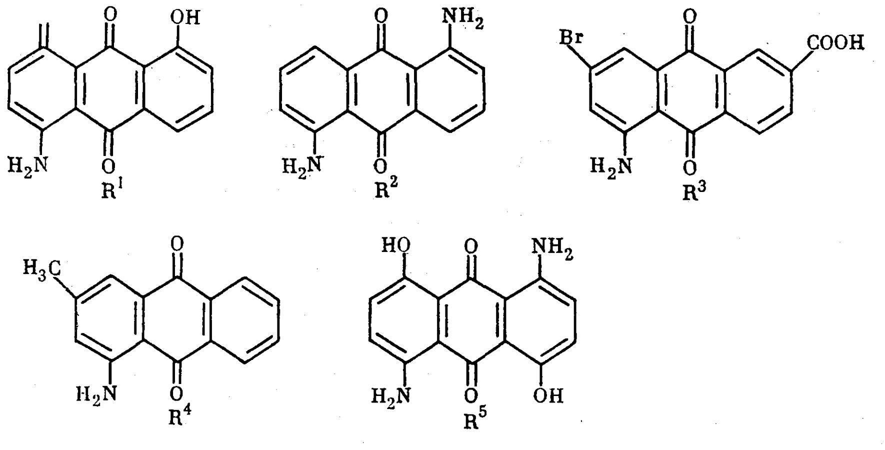

Figure 8. Different types of quinones used for the surface modification of carbon materials.[39]

In the region of high polarisation the slope of the $-\lg I-E$ plots is close to $2 \times 2.3\ RT/F$, which corresponds to slow addition of the first electron. For low polarisations, $\partial E/\partial \lg I$ ranges from $2.3\ RT/2F$ to $2.3\ RT/F$. According to the authors,[130,131] this is due to the approach to the O_2/HO_2^- equilibrium in alkaline electrolytes at low polarisations. According to Zagal et al.[130], such slow slopes can be accounted for also by the operation of different versions of the redox mechanism:

$$M^{III}OH + e \rightleftharpoons M^{II} + OH^- ,$$
$$M^{II} + O_2 \rightleftharpoons M^{III}{-}O_2^- ,$$
$$M^{III}{-}O_2^- + H_2O + e \rightarrow M^{III}{-}H_2O_2 + OH^- .$$

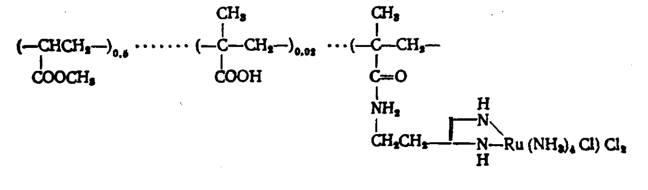
Unfortunately, lack of data for the surface coverage of the electrode by N_4-complexes hinders the quantitative comparison of the electrocatalytic properties of the complexes at a molecular level and the elucidation of the role of the carbon support.

Dinuclear complexes—covalently bound ("face to face") porphyrins—have been used recently[132] to modify the carbon surface. The activation of oxygen by these complexes can be represented schematically as follows:

$$LCo^{III}{-}Co^{III}L + 2e \rightarrow LCo^{II}{-}Co^{II}L ,$$
$$LCo^{II}{-}Co^{II}L + O_2 \rightarrow LCo^{II}{-}O{-}O{-}Co^{II}L ,$$
$$LCo^{II}{-}O{-}O{-}Co^{II}L + H^+ \rightarrow [LCo^{II}{-}OH{-}O{-}Co^{II}L]^+ ,$$
$$[LCo^{II}{-}OH{-}O{-}Co^{II}L]^+ + 2e + 3H^+ \rightarrow LCo^{III}{-}Co^{III}L + 2H_2O .$$

The 4-atom connecting chain between the ligands apparently corresponds to the optimum conditions for the coordination of the oxygen molecule between two cobalt atoms. When the monomer and the dinuclear cobalt dimer with the connecting fixed atom chain are adsorbed on pyrographite, the oxygen reduction reaction in an acid medium (0.5 M $HClO_4$ or $CF_3.COOH$) is accelerated compared with pure pyrographite, but proceeds via the intermediate formation of hydrogen peroxide. The quantity $\partial E/\partial \lg I \cong 2.3 \times 2RT/F$ agrees with the concept of the slow transition of the first electron.

The use in electrocatalysis of carbon electrodes modified by polymers constitutes an exceptionally promising trend. Polyfunctional electrocatalysts ensuring the simultaneous transfer of more than one electron in the slow stage, the optimum hydrophobic–hydrophilic environment in the active centres, and the reversibility of the protonation reaction can be created on their basis. However, despite the fact that an enormous number of studies on the electrochemical properties of polymer electrodes have been carried out, at the present time there have been only isolated studies devoted to electrocatalysis on such electrodes. The properties of polymeric acrylonitrile films on vitreous carbon and platinum have been investigated in the oxygen reaction.[133] Some acceleration of the electrochemical reduction of oxygen has been observed on the pyrographite electrode in the presence of a polymer coating made up of polyxylylviologen with a molecular weight of 11 000: .[134] The possibility of constructing more complex systems by attaching two active groups fulfilling different functions was reported in the same communication. The ruthenium(III) complex of the polymer is a highly active catalyst of the electrochemical reduction of hydrogen peroxide:



The complex is soluble in water but becomes insoluble at an electrolyte concentration in excess of 0.1 M. This makes it possible to obtain a stable polymer coating on the pyrographite surface. The complex $[Cu(o\text{-}phen)_2(ClO_4)_2]$, which is a highly effective catalyst of the two-electron reaction, is added to the immobilised polymer. Thus the simultaneous attachment to the pyrographite electrode of two active groups permits the creation of an electrocatalyst of the reduction of oxygen to water.

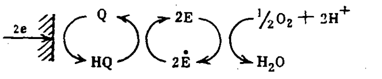
The PVP complex of copper shows a high catalytic activity in the cathodic reduction of oxygen.[43] However, its activity falls rapidly. Thus in the absence of current a potential of 1.15 V was recorded in the initial instance. The potential then shifts in the cathodic direction and is stabilised near 0.9 V. The stationary potential, established for charcoals modified by the complex, is higher than for pyrographite electrodes and reaches 1.2 V.

There is a correlation between the degree of saturation of the polymer by copper ions and the electrocatalytic activity, whose measure is the shift of the polarisation curve relative to the background curve. The extremum in the relation between the activity of the modified electrode and the pH (Fig.3, curve *1*) can be explained by taking into account data on the stability of the polymer complex. It has been shown[73,74] that copper mono- and di-pyridinate complexes are formed at pH 3–4 and are converted into the tetrapyridinate complexes at pH 5–6. One may therefore conclude that copper tetrapyridinate complexes exhibit catalytic activity. The pH dependence of the total amount of electricity corresponding to the redox transitions for the modified electrode (Fig.3, curve *2*) also passes through an extremum, which confirms the hypothesis that copper tetrapyridinate complexes are electrochemically active. The decrease of the amount of the active complex with alkaline pH can be explained by the decomposition of the catalytic complex with formation of copper hydroxide.

As the particle size of the highly disperse carbon materials increases, the catalytic activity of the complex also rises for low polarisations.[43] Having compared this result with data showing that the high-molecular-weight polymer (molecular weight 160000) is 2.5–4 times less active than the polymer having a lower molecular weight (50000), one may suppose that, depending on the ratio of the sizes of the polymer globule and the carrier particles, the character of the adsorption varies.[43] The difference between catalytic activities can be caused by the different macrokinetic characteristics of the highly disperse carbon catalysts and the polymers with different molecular weights deposited on them.

The most stable equilibrium oxygen potentials have been obtained using enzymes as modifying agents for the carbon surface.[2,22,23,27–29,135]

The mediator mechanism of the acceleration of the electrochemical reduction of oxygen, i.e.



has been achieved using a whole series of enzymes immobilised on carbon materials: peroxidase,[136] cytochrome c oxidase,[137] tyrosinase,[135] and laccase.[26]

In the case of the electron-transport protein cytochrome *c* [21] and also the enzymes tyrosinase [135] and laccase,[22,26] it has been possible to achieve a non-mediator mechanism of acceleration of this process in neutral solutions. The most reproducible data have been obtained with laccase. The adsorption of the enzyme on carbon black electrodes is almost irreversible. The parameters $\partial E/\partial pH$ and $\partial E/\partial \lg p_{O_2}$ for this electrode correspond to the coefficients of the Nernst equation for the O_2/H_2O pair. The small deviation from the theoretical equilibrium potential is apparently caused by the local increase of the pH in the layer of the adsorbed protein relative to the pH in the bulk of the solution.

The mechanism of the electrocatalytic reduction of molecular oxygen by immobilised laccase has been studied in detail.[97] The observed variation of the rate of reaction with the pH, the oxygen pressure (Fig.10), the concentration of laccase inhibitors (Fig.11), and temperature suggested the following mechanism of the activation of molecular oxygen in the electrode/laccase/oxygen system:

$$\begin{aligned}
&E + O_2 \rightarrow EO_2 && (\Delta E = 0.2 - 0.6\,V),\\
&EO_2 + e \rightleftharpoons EO_2^- ,\\
&EO_2^- + H^+ \rightarrow EO_2H && (\Delta E = 1.15 - 1.10\ V),\\
&EO_2H + 2e + H^+ \rightarrow EO^- + H_2O && (\Delta E = 1.20 - 1.15\ V),\\
&EO^- + e + H^+ \rightarrow EOH^-,\\
&EOH^- + H^+ \rightarrow E + H_2O\ .
\end{aligned}$$

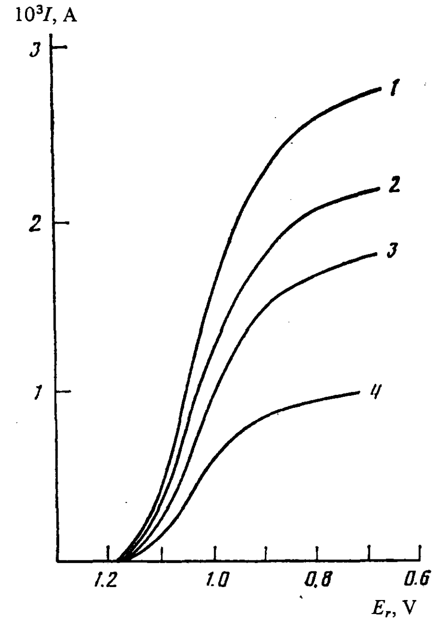


Figure 10. Polarisation curves for the electrochemical reduction of oxygen on an electrode with immobilised laccase at pH 4.5 and different oxygen partial pressures (atm): *1*) 1; *2*) 0.3; *3*) 0.25; *4*) 0.12.[97]

On the basis of the entire set of data, one may regard as entirely justified the claim that, in the region of low polarisations, the rate of electrochemical reduction of oxygen is limited by the rate of electron transfer stage, while in the region of the limiting current it is limited by the stage characteristic of enzyme catalysis. In the latter case, the dependences of the rate of the electrochemical reaction on the pH, the oxygen pressure, and the concentration of the inhibitors should be analogous to the experimentally observed dependences for the enzyme reaction[97] (Figs.10 and 11). In the region of low polarisations, the Tafel relation between the rate of reaction and the potential is observed, which shows that the electron transfer stage is slow.

The temperature variation is important for the elucidation of the mechanism of the cathodic reduction of oxygen on the enzyme electrode. In the first place, one should note that, over the entire potential range, the Arrhenius relation between the rate of reaction and temperature holds. The activation energy in the experimental potential range varies from 14.0 to 9.0 kJ mol^{-1} as the potential shifts in the cathodic direction (Fig.5).[97] Within the framework of the proposed mechanism of the electrocatalysis of the reduction of oxygen on the electrode with immobilised laccase, the rate-determining stage in the region of high polarisations is that characteristic of the enzyme reaction—this may be the binding (adsorption) of molecular oxygen to the active centre of laccase. The activation energy found in this range of potentials is virtually identical with the activation energy for the phenol oxidase reaction of the solubilised enzyme (10 kJ mol^{-1}). The activation energy for the solubilised enzyme was determined from the rate of oxidation of hydroquinone by atmospheric oxygen in the same temperature range as in the electrochemical reaction. Thus the conclusion that the slow stages in the enzyme reaction and in the biocatalytic reduction of oxygen are the same in the range of potentials more negative than 0.8 V has been confirmed.

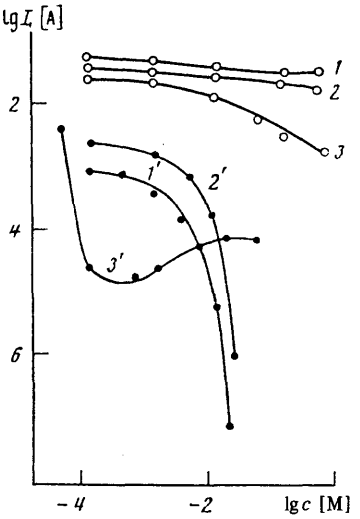

Figure 11. The influence of the concentration of inhibitors on the electrocatalytic activity of the electrode with immobilised laccase in the reduction of oxygen at pH 4.5; curves *1*–*3* were obtained for E = 0.8 V and curves *1'*–*3'* for E = 1.15 V in the presence of different ions: *1*) and *1'*) iodide; *2*) and *2'*) chloride; *3*) and *3'*) fluoride.[97]

In the region of low polarisations, the activation energy is likewise low. As shown above (Section IV), the rate-limiting stage is electron transfer from the active centre of the enzyme to the oxygen molecule.

Other examples of electrocatalysis on carbon electrodes modified by enzymes have also been described. In the presence of peroxidase adsorbed on pyrographite or carbon black,[23] a stationary potential ranging from 1.05 to 1.24 V is established in a hydrogen peroxide solution. Since the active centre of peroxidase (haemin) accelerates the reaction of H_2O_2 to an insignificant extent, peroxidase functions as the electrocatalyst, retaining its integrity and catalytic activity on immobilisation.

Comparison of data for the application of chemically modified carbon electrodes in electrocatalysis shows that the most important results have been achieved for enzyme electrodes. In the immediate future, one can probably expect the creation of active surface-modified electrodes on the basis of synthetic polymer systems. However, the lack of methods for the creation of such electrodes with an adequate chemical and electrochemical stability and activity in the anodic oxygen evolution reaction and other anodic reactions of electrochemical synthesis at high anodic potentials constitutes a serious gap. This problem is one of the most urgent in electrochemistry.

Analysis of the available data shows that the creation of electrodes on the basis of polymer systems closest to macromolecular biological systems is likely to be most useful.

The Role of Peroxide Derivatives of the Elements in the Selective Catalytic Oxidation of Organic Substances

I.V.Spirina, V.P.Maslennikov, and Yu.A.Aleksandrov

Various mechanisms of the selective action of catalysts in the liquid-phase oxidation of organic substances are discussed. It is shown that the high selectivity of the autoxidation of organic substances catalysed by compounds of transition and non-transition elements is due to the interaction of the substrate being oxidised with the peroxide derivative of the element formed via the reaction between oxygen or the hydroperoxide product and the catalyst.
The bibliography includes 120 references.

IV. Conclusion 678

I. INTRODUCTION

The oxidation of hydrocarbons and other organic substances by molecular oxygen is one of the principal ways of synthesising oxygen-containing chain compounds: aliphatic acids and alcohols, phenols, ketones, epoxides, etc. According to the ideas which have developed, this process is assigned to the class of degenerate-branched chain reactions; it leads to the formation of a large number of intermediates and final products.[1-3] The development of methods for the selective conversion of the petroleum raw material into oxygen-containing compounds under mild conditions is at present one of the most important tasks in chemical science.[4] As a rule, in order to increase the selectivity, the oxidation process is carried out in the presence of catalysts such as the salts of constant- and variable-valence elements, metal complexes, Lewis acids, etc. The study of the detailed mechanisms and kinetics of the above catalytic processes is therefore especially important for the solution of the problem of increasing selectivity.

The autoxidation of hydrocarbons in the presence of various catalysts has been the subject of numerous investigations and has been discussed in detail in a series of reviews and monographs.[2,3,5-11] Various mechanisms have been proposed in the literature for the action of catalysts in the liquid-phase oxidation of hydrocarbons. The increase of process selectivity in the presence of the catalyst is usually explained either by the milder reaction conditions, which is caused by the formation of a complex between oxygen or the hydroperoxide and the catalytic additive, and the subsequent decomposition of this complex with generation of free radicals, or by the appearance of new non-radical stages in the reaction of oxygen or the hydroperoxide activated in a complex with the catalyst.[5-11]

One of the mechanisms of the catalysis of oxidation reactions of organic compounds by derivatives of various elements, which ensures a high selectivity, involves the interaction of the substrate being oxidised with the peroxide derivative of the element formed via the reaction between oxygen or the hydroperoxide product and the catalyst.[12,13]

II. CATALYSIS OF FREE-RADICAL CHAIN OXIDATION REACTIONS OF HYDROCARBONS

The catalytic action of variable-valence metal compounds in chain oxidation reactions of hydrocarbons has been investigated in detail and is widely used.[2,3,5-10] The most important details of the mechanism of these reactions have been reliably demonstrated. Thus it is generally recognised that metal compounds can participate in any stage of a degenerate-branched chain oxidation reaction of a hydrocarbon: initiation, chain propagation, or chain branching.[2,3,6,7,11]

The principal radical formation reaction in the oxidation chain initiation stage in the presence of a catalyst is the activation of oxygen and the interaction of the resulting oxygen-containing metal (M) complex with the hydrocarbon:[3,6,7,11]

$$M^{n+} + O_2 \rightleftharpoons M^{(n+1)+}O_2^{\dot{-}} \; ;$$
$$M^{(n+1)+}O_2^{\dot{-}} + RH \rightarrow M^{n+} + HO_2^{\cdot} + R^{\cdot} \; .$$

The free-radical chain oxidation of hydrocarbons is catalysed via this mechanism by low-valence complexes of iridium, rhodium, ruthenium, osmium, platinum, etc.[14-16]. The occurrence of this type of initiation has been demonstrated using inhibitors in relation to the oxidation of ethylbenzene in the presence of nickel bis(acetylacetonate)[17] and has been confirmed in a study of the oxidation of cumene catalysed by *o*-phenanthroline complexes of copper.[18]

The commonest method for chain branching in oxidation by compounds of various elements presupposes catalysis of the homolytic decomposition of the primary hydrocarbon oxidation products, namely hydroperoxides.[2]

The catalysis by variable-valence metals is based on one-electron oxidation-reduction reactions between metals ions and the hydroperoxide:[2,3,6,11]

$$ROOH + M^{n+} \rightarrow RO^{\cdot} + M^{(n+1)+} + HO^{-} \; ;$$
$$ROOH + M^{(n+1)+} \rightarrow RO_2^{\cdot} + M^{n+} + H^{+} \; .$$

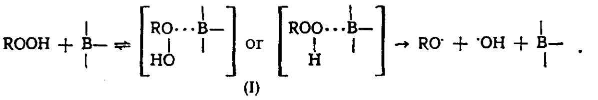
It has been shown[10, 19-22] that Lewis acids and compounds of alkali and alkaline earth metals can also induce the radical decomposition of hydroperoxides. The mechanism of the catalytic action of Lewis acids and constant-valence metal salts in the autoxidation reactions of hydrocarbons has been inadequately investigated. The existence of two alternative pathways has been postulated: the homolysis of the hydroperoxide bound in a complex with the catalyst and the bimolecular interaction of this adduct with a second hydroperoxide molecule:[10,19-22]

$$ROOH \cdot Ct \rightarrow RO^{\cdot} + HOCt;$$
$$ROOH \cdot Ct + ROOH \rightarrow RO^{\cdot} + H_2O \cdot Ct + RO_2^{\cdot} \; .$$

where Ct is a Lewis acid or a constant valence metal ion. Furthermore, radicals may be generated in the interaction of the complex with the substitute being oxidised, for example styrene:[19]

$$ROOH \cdot Ct + H_2C{=}CHC_6H_5 \rightarrow ROCH_2\dot{C}HC_6H_5 + HOCt^{\cdot} \; .$$

The ability of boron compounds to increase the yield of secondary alcohols in the liquid-phase autoxidation of paraffins has been known for a long time.[23] However, the mechanism of this process has not been treated unambiguously. According to some investigators,[24–26], the complex formation reaction between the catalyst and the hydroperoxide accelerates the reaction of ROOH with formation of free radicals initiating new chains:

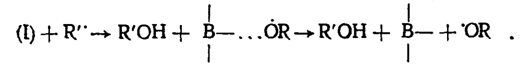


$$\mathrm{ROOH} + \underset{|}{\overset{|}{\mathrm{B}}}{-} \rightleftharpoons \left[\begin{array}{c}\mathrm{RO}\cdots\underset{|}{\overset{|}{\mathrm{B}}}{-}\\ |\\ \mathrm{HO}\end{array}\right] \text{ or } \left[\begin{array}{c}\mathrm{ROO}\cdots\underset{|}{\overset{|}{\mathrm{B}}}{-}\\ |\\ \mathrm{H}\end{array}\right] \rightarrow \mathrm{RO}^{\cdot} + {}^{\cdot}\mathrm{OH} + \underset{|}{\overset{|}{\mathrm{B}}}{-}\ .$$

(I)

The preferential formation of alcohols in the oxidation of alkanes catalysed by boron compounds takes place, according to Wolf et al.,[27] as a result of the decomposition of the hydroperoxide coordinated to the catalyst induced by solvent radicals:

$$\mathrm{RO^{\cdot}(HO^{\cdot}) + R'H \rightarrow ROH(H_2O) + R'^{\cdot}}\ ;$$



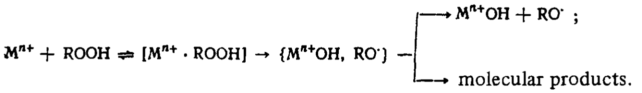
$$(\mathrm{I}) + \mathrm{R'^{\cdot}} \rightarrow \mathrm{R'OH} + \underset{|}{\overset{|}{\mathrm{B}}}{-}\ldots\dot{\mathrm{O}}\mathrm{R} \rightarrow \mathrm{R'OH} + \underset{|}{\overset{|}{\mathrm{B}}}{-} + {}^{\cdot}\mathrm{OR}\ .$$

Thus the primary step in the catalytic initiation and branching of oxidation chains is complex formation between the catalyst and oxygen or the hydroperoxide product, which leads to the activation of the oxidant. The catalyst makes it possible to carry out the oxidation at high rates under milder conditions. However, there is no significant increase in the selectivity of the process as a result of its being achieved via a free-radical mechanism.[3] The mixture of oxidised products contains in this case various oxygen-containing substances.

III. MOLECULAR SELECTIVE CATALYTIC OXIDATION REACTIONS OF HYDROCARBONS

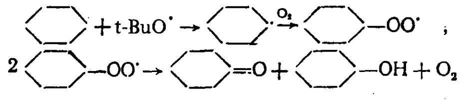
1. The Mechanisms of the Selective Catalytic Oxidation of Hydrocarbons with Participation of the Catalyst–Hydroperoxide Complex

In the autoxidation reactions of hydrocarbons, catalysts not only influence the rate of oxidation but also change the ratios of the products formed in the reaction, increasing the process selectivity. Thus the catalytic acceleration of the decomposition of organic hydroperoxides by copper, cobalt, nickel, chromium, molybdenum, and vanadium compounds increases the content of ketones in the reaction mixture.[28–34] In this case the radical decomposition is accompanied also by the molecular decomposition of the hydroperoxides, whose contribution can reach 90%. Both pathways in the catalytic decomposition of hydroperoxides involve the formation of the same catalyst–hydroperoxide complex.[29,32–34] The molecular decomposition is an example of the manifestation of the "cage effect": some of the radicals formed in the solvent cage interact with the metal ions affording molecular products, while others are released into the surrounding space:[3,11,34]



$$\mathrm{M^{n+} + ROOH \rightleftharpoons [M^{n+}\cdot ROOH] \rightarrow \{M^{n+}OH,\ RO^{\cdot}\}} \rightarrow \begin{cases}\mathrm{M^{n+}OH + RO^{\cdot}}\ ;\\ \text{molecular products.}\end{cases}$$

In the study of the decomposition of organic hydroperoxides catalysed by cobalt, chromium, vanadium, boron, molybdenum, titanium, etc. compounds the oxidation of the hydrocarbon used as the solvent has been observed, which leads to an increased content of alcohols or ketones in the reaction mixture.[35–41] According to Sheldon and Van Doorn,[35] up to 50% of cyclohexanol and cyclohexanone in the products of the decomposition of t-butyl hydroperoxide in cyclohexane in the presence of variable valence metal stearates and acetylacetonates is formed as a result of radical processes:

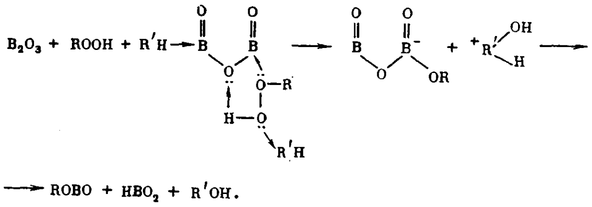


However, it has been shown[36] that the oxidation of nonane and cyclohexane by t-butyl hydroperoxide, catalysed by transition metal compounds and involving the formation of ketones and cyclohexanol, proceeds without the participation of free t-butoxy-radicals.

According to Pek Lak Von et al.,[39] only a small proportion of the radicals (10–15%) formed in the decomposition of the hydroperoxide bound in a complex with borate are released into the surrounding space and ensure the initiation of the oxidation process. The preferential accumulation of alcohols in this instance takes place as a result of the non-radical decomposition of the complex of the hydroperoxide with the catalyst in its bimolecular interaction with the paraffin:

$$-\underset{|}{\overset{|}{\mathrm{B}}}\cdot\mathrm{ROOH} + \mathrm{R'H} \rightarrow \mathrm{ROH} + \mathrm{R'OH} + \underset{|}{\overset{|}{\mathrm{B}}}{-}\ . \qquad (1)$$

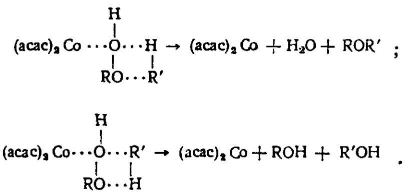
It has been suggested[40] that the catalysis of the oxidation of hydrocarbons by boron trioxide proceeds via an electrophilic substitution mechanism:



(2)

According to Eqns.(1) and (2), the increased yield of alcohols is caused by the formation of two alkanol molecules—one from the hydroperoxide and the other directly from the paraffin.

The participation of hydrocarbons with a labile C–H bond in the decomposition of cumenyl hydroperoxide catalysed by cobalt acetylacetonate has been described.[41] A mechanism has been proposed according to which the hydroperoxide forms a coordinate bond with the catalyst and there is simultaneous activation of the hydrocarbon forming part of the composition of the solvate shell of the adduct. The ternary complexes formed decompose via a non-radical mechanism:



$$\mathrm{(acac)_2Co\cdots\underset{\displaystyle\underset{|}{RO}}{\overset{\displaystyle\overset{H}{|}}{O}}\cdots\underset{\displaystyle\underset{|}{\cdots R'}}{H}} \rightarrow \mathrm{(acac)_2Co + H_2O + ROR'}\ ;$$

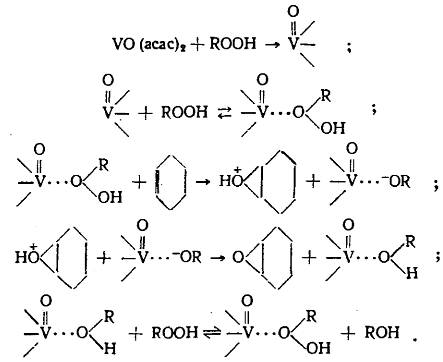
$$\mathrm{(acac)_2Co\cdots\underset{\displaystyle\underset{|}{RO}}{\overset{\displaystyle\overset{H}{|}}{O}}\cdots\underset{\displaystyle\underset{|}{\cdots H}}{R'}} \rightarrow \mathrm{(acac)_2Co + ROH + R'OH}\ . \qquad (3)$$

The contribution of molecular decomposition to the overall reaction of the hydroperoxide depends on the nature of the solvent and increases with decrease of the strength of the C–H bonds in the hydrocarbon. Thus cumenyl hydroperoxide reacts to the extent of 40% via the molecular pathway in ethylbenzene.[41] Since methylphenylmethanol was not detected among the reaction products, the authors[41] believe that the process proceeds via the mechanism (3).

Thus the significant increase of the selectivity of the autoxidation of hydrocarbons occurs when, together with the homolytic decomposition of the hydroperoxide bound in a complex with the catalyst, there is a possibility of its reaction via the molecular mechanism. The molecular pathway in many instances is an example of the "cage effect". Certain catalysts are capable of involving the hydroperoxide in an oxidation reaction via the C–H bonds of the hydrocarbon, which leads to an increased yield of oxygen-containing products. It has been suggested[41] that this process represents molecular interaction of the catalyst–hydroperoxide complex with the solvent.

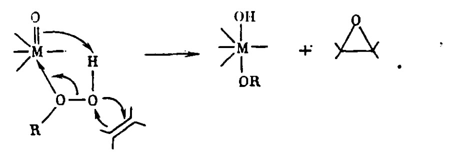
The high selectivity of the catalytic epoxidation of olefins by hydroperoxides is also caused by the molecular character of the process. This is indicated by the lack of influence by oxygen on the rate of epoxidation, the passivity in this reaction of catalysts reacting with hydroperoxides to form free radicals, and the stereospecificity of the catalytic epoxidation. The absence of a single point of view on the mechanism of this process is noteworthy; only the involvement in it of the metal in the highest oxidation state is not open to doubt.[9,42,43,46]

According to some investigators,[9,35,42–48] the catalytically active species in these processes is the complex of the catalyst with a hydroperoxide molecule, with the aid of which oxygen is transferred to the olefin. Thus a mechanism has been proposed for the epoxidation of cyclohexene by t-butyl hydroperoxide in the presence of vanadyl acetylacetonate,[44] according to which the first stage involves the rapid activation of the metal by the hydroperoxide, i.e. the transition of the metal to the highest valence state. This is then followed by the rapid and reversible formation of an active complex of the catalyst with a hydroperoxide molecule. The complex formation reaction induces the heterolysis of the O–O bond with transfer of the hydronium cation to the substrate. The elimination of a proton and its transfer to the alkoxide anion, bound to the complex, lead to the formation of the olefin oxide and the catalyst–alcohol complex. The interaction of this complex with the hydroperoxide entails ligand exchange and the regeneration of the active species:[44]

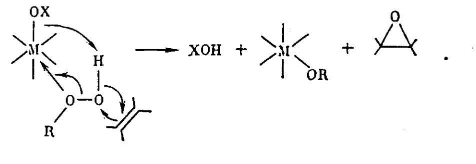


An analogous mechanism has been proposed[35] for the epoxidation of cyclohexene by t-butyl hydroperoxide catalysed by $Mo(CO)_6$. According to Sheldon,[43] catalysts based on tungsten(VI), vanadium(V), and titanium(IV), act in the same way.

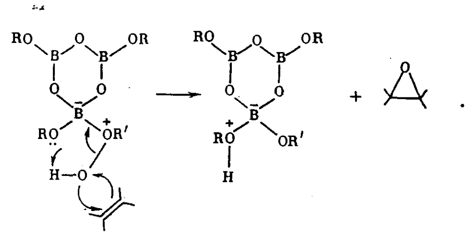
From the parallel variation of the electron-accepting properties of the catalytic additive and the rate constants for the epoxidation reaction, it has been suggested[27,35,47,48] that the function of the catalyst is to withdraw electron density from the oxygen atoms of the peroxide bridge, i.e. the catalyst acts in this instance as a Lewis acid. Two probable mechanisms have been proposed for the reaction of the catalyst–hydroperoxide complex with the olefin.[35] For compounds containing the M=O fragment, the process proceeds via a cyclic transition state:



The second mechanism has been proposed for compounds containing the M–OX (X = H, R) group, which acts as a proton acceptor:[35]



The epoxidation of olefins by alkyl hydroperoxides in the presence of metaborates has been explained analogously:[27,47–49]



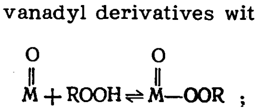
Consequently the molecular conversion of the hydroperoxide coordinated to the catalyst in the reaction with the saturated or unsaturated compound to form oxygen-containing products can be the cause of the high selectivity of the catalytic autoxidation of hydrocarbons and the epoxidation of olefins. The formation of complexes of the hydroperoxide with the compounds of transition and non-transition elements used as catalytic additives has been demonstrated by kinetic and physicochemical methods.[3,11,22,26,32] However, the numerous experimental data obtained do not conflict with the hypothesis that peroxide derivatives of the elements participate in selective catalytic processes.

2. The Involvement of Peroxide Derivatives of the Elements in Selective Catalytic Processes

(a) *The formation of intermediate alkyl peroxide derivatives of the elements in the liquid-phase catalytic oxidation of hydrocarbons.*

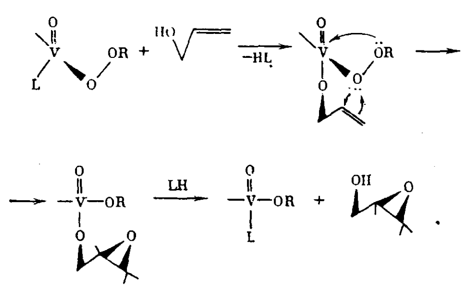
According to Mimoun[12] and Spirina et al.,[13] organoelemental peroxides play an active role in the hydroperoxide epoxidation of olefins and their conversion into ketones, catalysed by added compounds of non-transition and transition elements.

Thus in the middle 1970s, it was suggested[50,51] that, in the epoxidation of olefins in the presence of molybdenum and vanadium compounds, the accumulation of the peroxides of these elements may be a result of the reactions of the corresponding molybdenyl and vanadyl derivatives with the alkyl hydroperoxide:



$$\overset{O}{\overset{\|}{M}} + ROOH \rightleftharpoons \overset{O}{\overset{\|}{M}}{-}OOR\ ;\quad M{=}Mo,\ V\ .$$

The higher reactivity of allyl alcohols compared with olefins and their high *syn*-selectivity indicate the participation of the peroxides of transition elements in the catalytic epoxidation of unsaturated compounds.[42,52–55] In this case one of the ligands in the organo-metallic peroxides is substituted by the allyloxy-fragment and the epoxidation takes place intramolecularly, the disposition of the reacting fragments favouring the formation of the *syn*-epoxyalcohol:



(4)

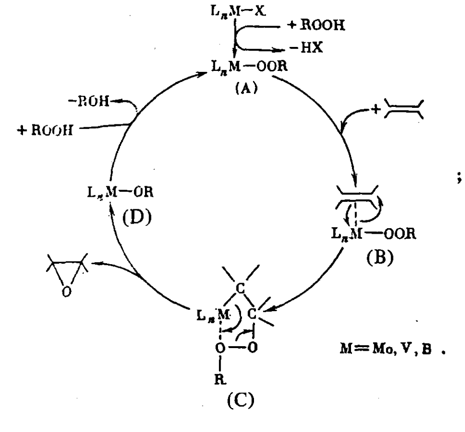
The high stereoselectivity of the epoxidation of aryl-alcohols by t-butyl hydroperoxide in the presence of tri(t-butoxy)aluminium is caused also by the participation of organo-elemental peroxides in this process, whose mechanism is assumed to be analogous to Scheme (4).[56]

From the results obtained in a number of studies,[57–60] the catalytic cycle illustrated in Scheme I has been proposed to explain the epoxidation of olefins and allyl alcohols by hydroperoxides, catalysed by molybdenum, vanadium, and boron compounds.[12] It is suggested that the active species in the reaction are the organometallic peroxides (A). The process involves the formation of a complex of the unsaturated compound with the peroxide of the given element (B), which is accompanied by the peroxymetallation of the substrate. This reaction proceeds via the formation of a five-membered peroxometallocyclic intermediate (C), which decomposes to the epoxy-compound and the alkoxy-derivative of the metal (D). The interaction of the alkyl hydroperoxide with compound (D) leads to the regeneration of the initial organoelemental peroxide (A).

However, the occurrence of the stage involving the formation of compound (B) in catalysis by boron compounds is in our view extremely unlikely, since, according to Nesmeyanov and Sokolik,[61] the addition of an alkene to an organoboron compound is possible only at the boron–carbon bond at temperatures in excess of 100 °C. The olefin is not inserted in the boron–oxygen bond.

The possibility of the formation of intermediate peroxide derivatives of vanadium and cobalt in catalytic liquid-phase oxidation reactions of hydrocarbons has been postulated[62,63] from kinetic data obtained in the study of the reactions of t-butyl and cumenyl hydroperoxides in the presence of cobalt and vanadium acetylacetonates.

Scheme I



According to Makin et al.,[64] the interaction of borates with hydroperoxides leads to the establishment of the equilibrium

$$\mathrm{ROOH+B(OR')_3 \rightleftharpoons B(OOR)(OR')_2+R'OH} \qquad (5)$$

Direct proof of the formation of alkyl peroxide derivatives of boron, vanadium, molybdenum, and tungsten in the reactions of alkyl peroxides with the derivatives of these elements and their participation in selective oxidation reactions has been obtained.[65–72]

The study of the interaction of a mixture of t-butyl hydroperoxide with the organoborane $R_mB(OR')_{3-m}$, where $m = 0 - 2$, $R = C_3H_7$, C_5H_{11}, or C_6H_5, and $R' = C_4H_9$ [65–88] or with derivatives of quadrivalent or quinquevalent vanadium [$V(OC_4H_9)_4$ and $VO(OC_4H_9\text{-t})_3$][69,70] by IR and ^{1}H NMR spectroscopy demonstrated that the alkoxy-group is exchanged for the alkylperoxy-fragment in the system. It is preceded by complex formation between the reactants. Depending on the nature of the organo-elemental compound, the process takes place during a fraction of a second or over a period of several minutes. The yield of the alkyl peroxide derivative of the element for the equimolar reactant ratio at 20 °C is between 10 and 90%.[65–70] Organoelemental peroxide derivatives of boron, aluminium, silicon, vanadium(V), and cobalt(III) have been obtained by a reaction analogous to reaction (5).[13,69,73–75]

The study of the oxidation of alkanes by t-butyl hydroperoxide catalysed by boron, aluminium, silicon, titanium, vanadium, and palladium compounds[13,69,76–80] demonstrated that at 50–160 °C paraffins are converted into oxygen-containing products—aliphatic alcohols and ketones, in nearly quantitative yields (Table 1).

Table 1. The yields of the products of the oxidation of paraffins by the system t-butyl hydroperoxide—derivative of the element (in moles per mole of the peroxide which has reacted).

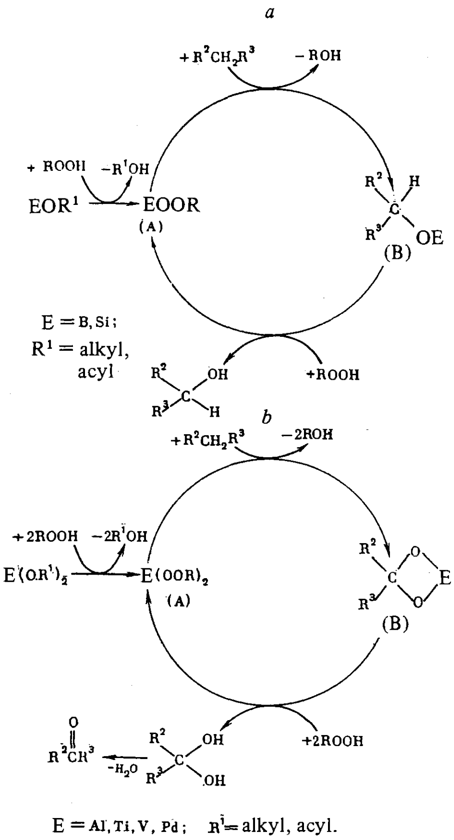
Paraffin	c_{hp}, M	Element-containing additive	c_a, M	t, °C	Yield: alkanols	Yield: alkanones	Refs.
Dodecane	0.10	$(C_4H_9O)_3B$	0.10	150	0.48	—	[76]
Octane	0.10	$(C_3H_3F_4O)_3B$	0.10	130	0.98	—	[80]
Pentane	0.10	$(t\text{-}C_4H_9O)_3Al$	0.01	50	—	0.49	[77]
Nonane	0.10	$(C_4H_9O)_4Si$	0.10	160	0.84	—	[80]
Nonane	0.10	$(C_4H_9O)_4Si$	0.05	140	0.42	0.11	[80]
Octane	0.10	$(C_4H_9O)_4Ti$	0.005	60	0.02	0.29	[79]
Octane	0.12	$(t\text{-}C_4H_9O)_3VO$	0.02	50	—	0.30	[69, 78]
Octane	0.10	$(CF_3COO)_2Pd$	0.01	60	—	0.40	[79]

Notation: c_{hp} is the concentration of t-butyl hydroperoxide and c_a the concentration of the additive.

The oxidation of hydrocarbons by alkyl hydroperoxides in the presence of catalysts—alkoxy— or acyloxy-derivatives of the elements—can be achieved in the catalytic cycles illustrated in Scheme II. The boron and silicon compounds in cycle *a* catalyse mainly the conversion of paraffins into secondary alcohols. Cycle *b* operates in the catalysis of the oxidation of hydrocarbons by derivatives of aluminium, titanium, vanadium, and palladium, which leads to aliphatic ketones. The oxidising agents in this process are the organoelemental peroxide (A), which interacts with the C–H bonds of the substrate to form organoelemental compounds containing a fragment of the hydrocarbon oxidised (B), and the alcohol corresponding to the hydroperoxide. The element-containing derivative (B) gives rise to the oxidation product (the alcohol or ketone) under the influence of the excess hydroperoxide and the initial organoelemental peroxide is regenerated. The operation of Scheme II has been confirmed also by the fact that the products of the oxidation of paraffins by the alkyl hydroperoxides–organoelemental compound system (with the equimolar reactant ratio) contain no free alcohols or ketones, with the hydrocarbon skeleton corresponding to the initial alkane.[79,80]

These compounds are formed either when an excess of the hydroperoxide is used or as a result of the hydrolysis of the reaction mixture.

Scheme II



In order to confirm the participation of organoelemental peroxides in catalytic oxidation processes, a detailed study has been made[13,69,76–80] of one of the stages in the catalytic autoxidation of hydrocarbons—the thermal decomposition of a series of alkyl peroxide derivatives of boron, aluminium, silicon, vanadium, and palladium in solutions in paraffin. It was found that the peroxides of these elements interact with hydrocarbons to produce in the hydrolysed reaction mixture high yields of the oxidation products identical with the oxygen-containing compounds obtained in the hydroperoxide oxidation of alkanes catalysed by non-peroxide derivatives of the elements (Tables 1 and 2).

The character and structure of the peroxide derivative and also its state in solution determine the composition of the hydrocarbon reaction products. Thus boron and silicon monoperoxides oxidise paraffins with a high selectivity to organoelemental compounds, which affords secondary aliphatic alcohols after hydrolysis.[80,81] The introduction into the molecule of the peroxide of the given element of one or two additional alkylperoxy-groups leads to the accumulation of aliphatic ketones together with alcohols in the hydrolysed reaction mixture.[76,79–81] The oxidation of alkanes by aluminium, vanadium, or palladium peroxide leads to the preferential formation, under mild conditions, of element-oxyderivatives, which hydrolyse to the isomeric ketone.[77–80]

Table 2. The yields of the products of the oxidation of paraffins by element peroxides (in moles per mole of the peroxide which has reacted, after the hydrolysis of the reaction mass).

The peroxides of elements are capable of more than the oxidation of saturated hydrocarbons at the C–H bond. They interact with alkenes to form olefin oxides and methyl ketones,[12,71,72,82–87] they oxidise ethers to acetals[88] and alcohols to aldehydes and ketones;[56,75] they hydroxylate aromatic and unsaturated compounds[80,89,90] and they lead to the ring expansion in cyclic acetals, converting them into diol monoethers[91] (Table 3).

Table 3. The yields of the products of the oxidation of organic substances by element peroxides (in moles per mole of the peroxide which has reacted, after the hydrolysis of the reaction mass).

Peroxide*	Substrate oxidised	t, °C	Product	Yield	Refs.
$(C_4H_9O)_2BOOR$	Dibutyl ether	90	Acetals of butyraldehyde	0.56	[88]

*R = t-C_4H_9.

The data described above make it possible to explain fairly reliably the decrease of the rate of reaction observed in the autoxidation of alkanes in the presence of boron-containing additives, with simultaneous increase of the yield of secondary alcohols.[23] The alkyl hydroperoxide accumulated in the autoxidation of the paraffin reacts with the catalyst to form an organoboron peroxide. The probability of chain branching in the oxidation process then diminishes, because the homolytic decomposition of the boron peroxide proceeds at higher temperatures than the decomposition of the corresponding alkyl hydroperoxide. The molecular reaction of the organoboron peroxide with the initial alkane is accompanied by the formation of secondary alcohols, which increases the selectivity of the oxidation reaction.

(b) *The mechanisms of the oxidation of organic compounds at the C–H bond by alkyl peroxides and peroxo-complexes of the elements.*

In the study of the interaction of organoelemental peroxides (Table 2) with organic compounds it has been observed that the oxidation of the substrate is accompanied by the disappearance of peroxide oxygen.[13,69,76–81] Analysis of the composition of the products of the decomposition of the element peroxides in various organic solvents and also the character of their accumulation show that the element peroxides react via two parallel pathways in solutions in organic compounds:

1) via the oxidation of the solvent:

$$EOOR + HR' \rightarrow EOR' + ROH;$$

2) homolytically with dissociation of the peroxide bond:

$$EOOR \rightarrow EO^{\bullet} + \dot{O}R.$$

The interaction of an organoelemental peroxide with the hydrocarbon used as the solvent was observed for the first time in the thermal decomposition of t-butylperoxytriethylstannane in n-dodecane.[92]

The kinetic parameters of the oxidation of organic substances by organoelemental peroxides and of the homolytic decomposition of peroxide compounds have been determined.[80–82,88,90] The activation energy for the homolytic cleavage of the peroxide bond is significantly higher (by 10 to 20 kcal mol^{-1}) than the activation energy for the interaction of element-containing peroxides with organic compounds. The decrease of the yield of the oxidation products with increase of the process temperature is consistent with this finding.[13]

It has been demonstrated by a thermochemical method that the reaction of organoelemental peroxides in solutions in ethers and in unsaturated and aromatic compounds proceeds via the preliminary formation of a complex of the peroxide with a solvent molecule. The constants for the complex formation reactions of t-butylperoxydi(butoxy)borane with organic substances, calculated by the method of Becker et al.,[93] range from 0.16 to 0.35 litre mol^{-1} (at 20 °C).[80,94] The 1 : 1 complex formed then decomposes as a result of the oxidation of the organic substrate or homolytically, generating two hydroxy-radicals.[13,80,88,90]

As stated above, organoelemental peroxides interact with the organic substances being oxidised to form element alkoxide derivatives of the substrate. When the reactions proceed via a free-radical mechanism, these compounds can accumulate only on decomposition of the organoelemental peroxide compound induced by solvent radicals R'$^{\bullet}$:

$$EOOR + R'^{\bullet} \rightarrow EOR' + RO^{\bullet}.$$

However, the reaction rate constant is independent of the initial peroxide concentration and remains unchanged when inhibitors of free-radical reactions (galvinoxyl, ionol) are introduced into the system.[80,82,88,90] Furthermore, as the process temperature is reduced, the yield of oxidation products increases. Consequently, hydroxy-derivatives of the elements, containing the substrate radical, appear in reactions involving the oxidation of organic compounds by organoelemental peroxides in the absence of the induced decomposition of alkyl peroxide derivatives of the elements. They are formed via the molecular mechanism (6) or the cryptoradical mechanism (7):

$$EOOR + HR' \rightarrow \left[\begin{array}{c} EO—OR \\ \vdots \qquad \vdots \\ R'—H \end{array}\right] \rightarrow EOR' + ROH \quad ; \qquad (6)$$

$$EOOR + HR' \rightarrow \{EO^{\bullet} + R'^{\bullet} + ROH\} \begin{cases} \rightarrow EOR' + ROH \; ; \\ \rightarrow EO^{\bullet} + R'^{\bullet} + ROH \; . \end{cases} \qquad (7)$$

The rate of release of radicals from the solvent cage is then correlated with the variation of the viscosity of the medium.[10] The study of the influence of the viscosity of the medium on the interaction of t-butylperoxydi(butoxy)borane with a series of hydrocarbons ranging from hexane to hexadecane at 150 °C[80] revealed that a change in solvent viscosity from 0.168 to 0.532 cP does not affect the kinetic parameters and the yield of the products of this reaction (Table 4). The data in Table 4 support the molecular mechanism, but they can also arise from a cryptoradical process when the cage effect is manifested in this reaction to an inadequate extent.

Table 4. The influence of the viscosity of the medium η on the oxidation of alkanes by t-butylperoxydi(butoxy)borane at 150 °C and an initial peroxide concentration of 0.10 M.[80]

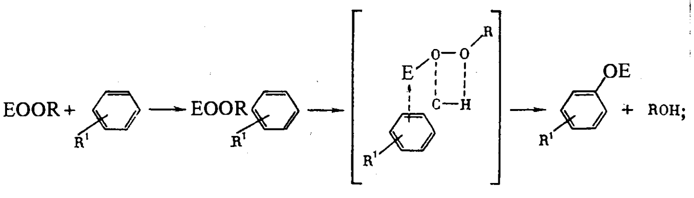
Hydrocarbon	η_{150}, cP	$10^5 k_{\mathrm{eff}}$, s^{-1}	W, mol mol^{-1}	$10^7 k_{\mathrm{ox}}$, litre mol^{-1}s^{-1}
Octane	1.168	3.0	0.48	3.0
Decane	0.249	3.1	0.46	3.3
Dodecane	0.339	3.2	0.48	3.1
Tridecane	0.380	3.1	0.45	3.3
Hexadecane	0.532	3.3	0.47	3.2

Notation: W is the yield of s-alkyl alcohols, k_{eff} the effective rate constant for the disappearance of the peroxide oxygen, and k_{ox} the rate constant for the oxidation of alkanes.

In the study of the oxidation of mesitylene by t-butylperoxydi-(1,1,3-trihydrotetrafluoropropoxy)borane in magnetic fields with an induction of 0.05–0.4 T, it was observed that the yield of mesitol diminishes by 5–15% compared with the yield in the Earth's magnetic field.[95] This effect can be explained as follows. The peroxide investigated reacts via two parallel pathways in solutions in organic substances: via the oxidation of the substrate and homolytically with formation of two hydroxy-radicals. The magnetic field acts on the liquid-phase radical reactions at the stage involving the recombination of two radicals in the cage. The rate of transition of the radical pairs from the singlet to the triplet state and the fraction of these states and ultimately also the yield of the product of the recombination within the cage depend on the induction of the magnetic field. In the oxidation of mesitylene by an organoboron peroxide, which proceeds via a cryptoradical or molecular mechanism, the yield of mesitol is independent of the induction of the magnetic field. On the other hand, the rate of the parallel process in which radicals are released from the cage (via the triplet state) varies with the induction, which leads to the observed magnetic effect.

Thus the results obtained in the study of the influence of the viscosity of the medium and of the magnetic field on the oxidation of organic substances by element peroxides indicate the molecular character of the interaction of organoelemental peroxides with organic substrates.

The molecular mechanism of this process has also been confirmed by data for the oxidation of aromatic compounds by element peroxides. In the study of the hydroxylation of toluene and mesitylene by organoelemental peroxides at 90 °C [80,90,95] no products of the interaction of the radicals $EO^{\cdot}$ and $RO^{\cdot}$ with the CH_3 groups of the aromatic compounds were detected in the reaction mixtures. The mechanism of the action of element-containing peroxides in the reaction with aromatic derivatives is analogous to the mechanism of the hydroxylation of the latter by organic hydroperoxide (or hydrogen peroxide)—Lewis acid systems, i.e. an electrophilic substitution reaction obtains in the given instance:[13,90,95]



E = B, Si; R = t-C_4H_9 ; R'=CH_3, OCH_3, OC_4H_9.

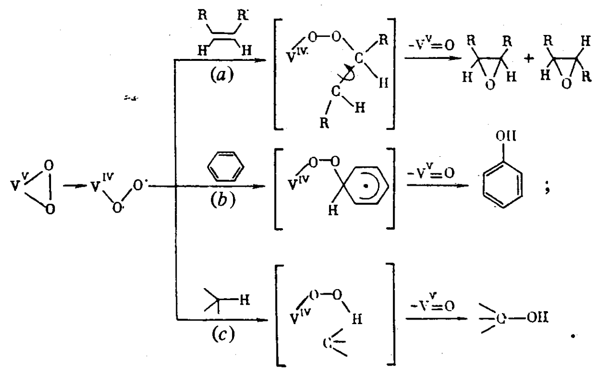
Consequently, in many cases the active oxidising agents in the catalytic autoxidation of organic substances are organoelemental peroxides formed as a result of exchange between the intermediate in the oxidation of hydrocarbons (a hydroperoxide) and the catalytic additive. Alkyl peroxide derivatives of the elements oxidise organic compounds with formation of products whose composition is identical to that obtained using peroxide forms of these elements as the catalyst.[13,76–82,90] The high selectivity of the catalytic oxidation is caused by the interaction of the element peroxides with organic compounds via a molecular mechanism.

The compounds of certain transition elements, used as catalysts of the autoxidation of hydrocarbons, are capable of binding molecular oxygen with formation of peroxo-complexes of the metals.[5,12,96] The peroxide character of the oxygen coordinated to the metal is indicated by IR spectroscopic data for these compounds[5,96] and also by the finding that the peroxo-complexes can be obtained both by the reaction of hydrogen peroxide with derivatives of elements containing the M=O bond[12,97–99] and as a result of the direct interaction of molecular O_2 with the metal complex.[5,12] Furthermore, hydrogen peroxide was evolved in the hydrolysis by strong acids of the adducts of molecular oxygen and palladium and platinum complexes.[12]

Like the alkyl peroxide derivatives of the elements, the peroxo-complexes of metals participate in the catalytic oxidation of saturated hydrocarbons[5,6,11,16–18,99–101] and arenes.[4,99,101] The mechanism of the interaction of the oxygen complex of the metal with the hydrocarbon depends on the nature of the metal complex and the substrate being oxidised; it can be of the free-radical, cryptoradical, or molecular type. The involvement of the peroxo-complexes of metals in the radical-chain oxidation of hydrocarbons, described above (Section II), does not lead to a significant increase of the process selectivity.

The covalent and anionic oxoperoxo-complexes of vanadium(V) of the type $VO(O_2)(O{-}N)L_IL_2$ or $[VO(O_2)(Pic)_2]^-A^+L$ (where O - N = pyridine-2-carboxylate, Pic = picoline-2-carboxylate, L_1, L_2 = H_2O, MeOH, or hexamethylphosphoramide, and A^+ = H^+ or PPh_4^+) in aprotic media under mild conditions, epoxidise olefins and hydroxylate aromatic hydrocarbons to form phenols and hydroxylate alkanes to form alcohols and ketones in yields up to 50, 60, and 25% respectively.[99] The peroxo-complexes of vanadium(V) differ sharply in their reactivities from the analogous molybdenum(VI) compounds.[57,58,86] The vanadium complexes are active only in aprotic solvents, epoxidise olefins non-stereospecifically, and behave as hydroxylating agents. From experimental data, the authors[99] suggested that peroxovanadium(V) complexes are homolytically converted into the reactive V^{IV}–O–$O^{\cdot}$ species in aprotic media. This distinguishes them from the peroxo-complexes of rhodium and molybdenum, investigated elsewhere,[57–60] which interact with olefins via the 1,3-dipolar addition of the fragment M^+–O–O^-.

A cryptoradical mechanism has been suggested[99] for the reaction of peroxovanadium(V) complexes with hydrocarbons:



(8)

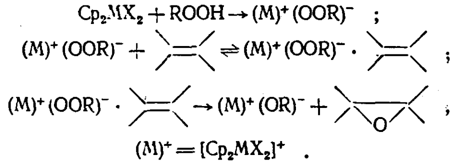
The peroxochromium complex $Ph_3POCrO(O_2)_2$ in the mixed alkane—methylene chloride—t-butyl alcohol solvent oxidises saturated hydrocarbons to alcohols and carbonyl compounds at room temperature. It has been suggested that the mechanism of this reaction is described by an equation analogous to that for pathway (*c*) in Scheme (8).[101] A characteristic feature of the mechanism proposed[99,101] is the combination of the stages involving the reduction of the metal in the peroxo-complex to $M^{(n-1)+}OO^{\cdot}$ and the formation of a new radical species as a result of the interaction of this radical with the olefin or arene [see formula (8), pathways (*a*) and (*b*). In its interaction with the paraffin, $M^{(n-1)+}OO^{\cdot}$ is converted into the metal hydroperoxide $M^{(n-1)+}OOH$ and an alkyl radical [see formula (8), pathway (*c*)]. These intermediate compounds are then oxidised to vanadium(V) or chromium(VI) derivatives and oxygen-containing organic products.

The one-electron oxidation-reduction reactions with participation of the transition metal ion and the hydroperoxide in the catalytic oxidation of hydrocarbons are well known. Furthermore, it has been shown[70] that derivatives of quadrivalent vanadium and t-butyl hydroperoxide, taken in 1 : 1 proportions, react with one another at room temperature to form vanadium(V) compounds. The re-reduction of the latter to vanadium(IV) derivatives under these conditions takes place to an extent not greater than 5%. Consequently, in the oxidation of organic substances by peroxo-complexes of vanadium and chromium, the occurrence of oxidation-reduction reactions of the type $M^{n+} \rightarrow M^{(n-1)+} \rightarrow M^{n+}$ is unlikely.

In our view the oxidation of hydrocarbons by peroxo-complexes of vanadium and chromium with formation of olefin oxides as well as alcohols and phenols probably proceeds without the participation of radicals.

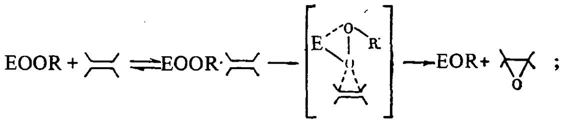
Thus the high selectivity of the catalytic liquid-phase oxidation of organic substances is due to the interaction via a molecular mechanism of the peroxide derivatives of the elements with the C—H bonds of the substrate being oxidised.

(c) *The mechanisms of the interaction of peroxide derivatives of the elements with olefins.* According to Aleksandrov et al.,[71,72] t-butyl hydroperoxide epoxidises olefins at a high rate and with a quantitative yield in the presence of compounds of the type Cp_2MX_2 (where Cp = cyclopentadiene, M = Mo or W, and X = Cl, Br, or I). The epoxidising agent in this process is the metal peroxide formed on oxidation of the initial molybdenum or tungsten compound. The process is described by the scheme:



Alkyl peroxide derivatives of molybdenum of the type $[Cp_2.MoX_2]^+(OOR)^-.ROOH$ have been synthesised by the reaction of biscylopentadienylmolybdenum halides with t-butyl hydroperoxide and their high reactivity in the epoxidation of cyclohexene has been demonstrated.[71]

As stated above (Table 3), the alkyl peroxide derivatives of boron, silicon, and gallium interact with alkenes to form olefin oxides. The alkyl peroxide derivative of the element reacts with the olefin bimolecularly and the epoxidation takes place as a result of the interaction of the electrohpilic peroxide oxygen atom with the π electrons of the double bond in the alkene.[13] The reaction is preceded by the formation of a complex between the reactants:[80,94]

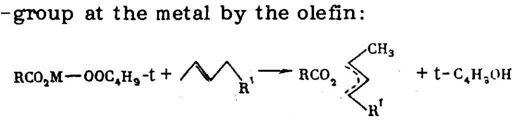


E = B, Si, Ga, Mo, W .

The possibility of the formation of transition states of this type has been confirmed by quantum-chemical calculations.[102,103]

The reactivity of the peroxides of different elements in the epoxidation reaction is determined by the electrophilic character of the peroxide oxygen atoms, which is in its turn related to the acid properties of the heteroatom of the organoelemental compound. The heteroatom, which has an occupied *p* or *d* orbital, interacts with the unshared electron pairs of the peroxide oxygen atoms, which renders the latter more electrophilic and hence more reactive in relation to olefins. There is no information about the electrophilicity of organoelemental peroxides in the literature, but one can postulate that it is correlated with the variation of the acidity of the full oxides of these elements. According to Sheldon and Van Doorn[35] and Tanabe,[104] the properties of the oxides of the elements as Lewis acids weaken in the sequence $MoO_3 \gg Ga_2O_3 > V_2O_5 > B_2O_3 > SnO_2 \gg SiO_2$. The above data for the reactivities of molybdenum, gallium, and boron peroxides in the epoxidation of olefins are consistent with this series. Among the oxides of the elements enumerated, the weakest Lewis acid is SiO_2. Consequently silicon peroxide should not epoxidise olefins effectively. Indeed, on interaction with oct-1-ene, t-butylperoxytributoxysilane forms not more than 0.1 of a mole of octene α-oxide per mole of the peroxide which has reacted, while t-butyl-peroxydibutoxyborane epoxidises oct-1-ene quantitatively under analogous conditions (Table 3).[80]

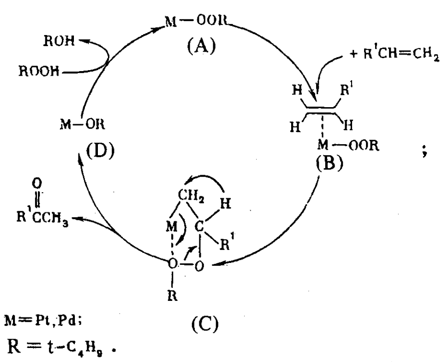
The peroxide derivatives of Group VIIIB elements, whose electrophilic character is weak, convert α-olefins into methyl ketones (Table 3). Thus palladium(II) and platinum(II) t-butylperoxycarboxylates oxidise α-olefins to the corresponding methyl ketones at 20 °C in dry benzene over a period shorter than 10 min (the olefin : peroxide ratio is 50) in 90% yield.[84-86] Aldehydes or other ketones are not formed. β-Olefins are oxidised very slowly or not at all, forming a stable π-allyl complex on substitution of the t-butylperoxy-group at the metal by the olefin:



Platinum(II) t-butyl peroxides of the type *trans*-$(PR_3)Pt(R^1)-OOC_4H_9$-t (where $R_1 = CH_3$, CF_3, or an arene) are also effective in the oxidation of oct-1-ene to 2-octanone (80 °C, 16 h, yield of ketone 80%).[87]

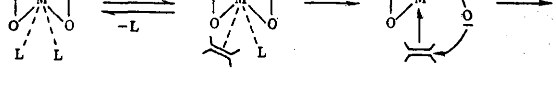
The mechanism of the conversion of α-olefins into ketones by organic peroxide derivatives of palladium and platinum can be represented, according to the authors,[84-87] by a cycle analogous to the catalytic cycle in the hydroperoxide epoxidation of unsaturated compounds in the presence of molybdenum and vanadium derivatives[12] (Scheme III).

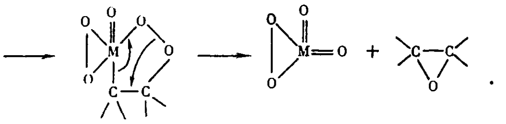
Scheme III



The key stage in this mechanism is the peroxymetallation process, which is preceded by the coordination of the olefin to the metal (B). The intermediate five-membered adduct (C) formed decomposes with cleavage of the O–O bond, which is followed by the β-hydride transfer with formation of methyl ketone and the t-butoxy-derivative of the metal (D). In the presence of an excess of the hydroperoxide, the t-butoxy group is substituted by the t-butylperoxy-group and the initial metal peroxide is regenerated.

The peroxymetallation process in the epoxidation of olefins and their conversion into ketones by metal peroxo-complexes has been justified in detail.[12,58-60,105-108] The peroxo-complexes of molybdenum and tungsten of the type $L_2MoO(O_2)_3$ (where L are organic ligands with very pronounced electron-donating properties) epoxidise olefins in organic solvents with a high selectivity (the yield of the epoxide can reach 50–90% relative to active oxygen).[58] The reaction takes place in two stages: the reversible coordination of the olefin to the metal is followed by the irreversible transfer of oxygen to the olefin. It is assumed[12] that the oxygen transfer takes place via a cyclic mechanism involving the 1,3-dipolar addition of the peroxo-complex to the olefin with formation of a five-membered metallocyclic compound, which is converted into the epoxide and the dioxo-complex of the metal:

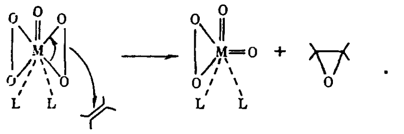




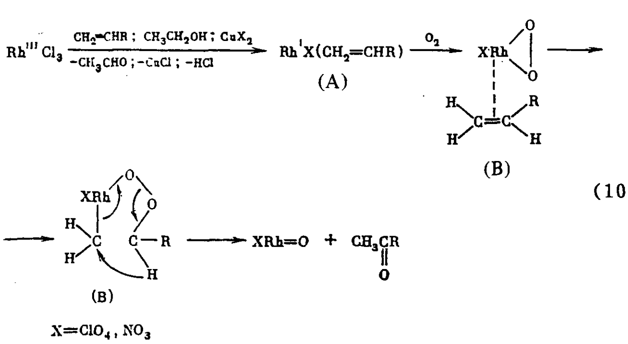
(9)

The exchange of the ligand for the olefin in complexes of this type has been confirmed by analysis of the NMR spectra.[107] Kinetic measurements[105] have shown that the rate of the process is determined by the stage in which the olefin is coordinated to the metal. The results of experiments using the [^{18}O]-labelled peroxomolybdenum complex have shown[106] that exclusively peroxo-oxygen, and not oxo-oxygen atoms as suggested previously,[43] are transferred to the olefin.

A mechanism of the epoxidation of olefins by peroxo-complexes of metals, involving a three-membered transition state, has been proposed[106] as an alternative to Scheme (9):



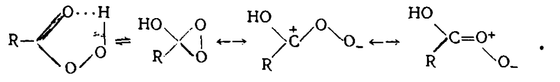
It has been observed[59] that, in the presence of copper perchlorate or nitrate, rhodium complexes in alcoholic solutions at room temperature catalyse the selective conversion of olefins containing the double bond at the end of the carbon chain into methyl ketones on treatment with molecular oxygen. The active species in the reaction, whose mechanism is illustrated in Scheme (10), are olefinic cationic complexes of rhodium (A), capable of activating molecular oxygen with formation of the peroxide complex (B). This compound is converted into the peroxometallocycle (C), which decomposes to the ketone and a rhodium compound containing the Rh=O bond after the migration of the proton to the neighbouring carbon atom:



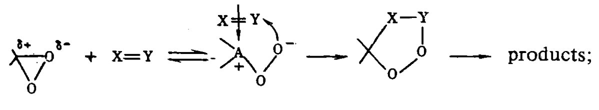
To demonstrate the validity of this mechanism, Igersheim and Mimoun[60] synthesised the peroxorhodium complexes [Rh(As.Ph$_3$)$_4$O$_2$]$^+$A$^-$, where A$^-$ = ClO$_4^-$ or PF$_6^-$, and investigated their interaction with unsaturated compounds. It was found that these complexes react with α-olefins at room temperature in methylene chloride in an atmosphere of argon with formation of methyl ketone, whose yield reached 85%. When the [^{18}O]-labelled peroxorhodium complex is used, methyl ketones containing the labelled oxygen atom in the carbonyl group are formed.[60]

The mechanism represented by Eqns.(9) and (10) requires the coordination of the substrate and an oxygen molecule to one metallic centre. The necessity for the coordination of the olefin is confirmed by the fact that the peroxorhodium complex {RhO$_2$[Ph$_2$P(CH$_2$)$_2$PPh$_2$]$_2$}ClO$_4$, containing two phosphine ligands and not having a free coordination site, is inactive in the reactions with α-olefins.[107] It has been shown[109,110] that the rhodium complex RhCl(C$_8$H$_{14}$)$_2$ with two unsaturated ligands absorbs one mole of oxygen with formation of the peroxo-complex. The coordinated oxygen of the latter oxidises quantitatively the coordinated cyclo-octa-1,5-diene to a ketone at 150 °C in cyclohexene. Furthermore, it has been observed[108,111,112] that oxygen adducts of the type (Ph$_3$P)$_2$ MO$_2$, where M = Ni, Pd, or Pt, in solutions in methylene chloride readily combine with electrophilic olefins. This results in the formation of stable peroxometallocycles in a high yield. It has been demonstrated by NMR and IR spectroscopy that these products are analogous to those formed in accordance with Scheme (10).[61,105,107]

It has been suggested that dioxirans are reactive intermediates in the oxidative reactions of olefins on treatment with oxygen, ozone, and hydroperoxides with participation of catalysts (compounds of different elements and also peroxyacids).[112] The formation of dioxiran, present in the form of a stable zwitterion in the case of peroxyacids, has been confirmed by indirect data:[112]



The transfer of oxygen to organic substrates takes place in two stages. A charge-transfer complex between the nucleophilic substrate (for example, the olefin) and the electrophilic carbon atom of the dioxiran or the metal of the peroxo-complex is formed initially in the slow reversible stage. In the second stage, the coordinated substrate adds to the nucleophilic terminal oxygen atom and a cyclic peroxide is formed and then decomposes to the corresponding products:



A = carbon, metal.

Thus the catalytic reactions involving the oxidation of unsaturated compounds by oxygen and hydroperoxides take place via a non-radical mechanism and with a high selectivity. The peroxide derivatives of the elements—alkyl peroxides and peroxo-complexes—play an active role in these reactions. The interaction of the peroxide derivative of the element with the olefin takes place via intermolecular nucleophilic attack by the peroxide oxygen atom, coordinated to the organoelemental compound of the alkene. There is no unanimous view concerning the structures of the transition states in this process. The nature and yield of the products of the oxidation of the unsaturated compound and also the activity of the peroxide derivative of the element in its reaction with the olefin are determined by the electron-accepting properties of the heteroatom in the organoelemental compound.

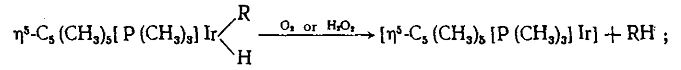
IV. CONCLUSION

An increase in the selectivity of the liquid-phase oxidation of organic compounds by molecular oxygen can be achieved by employing compounds of different elements as catalysts. The multiplicity of the catalytic system is responsible for the absence of a single mechanism of the catalytic oxidation of hydrocarbons. However, it has been established firmly that the selectivity of the oxidation of organic compounds increases when the process proceeds without the participation of free radicals and the obligatory activation of the oxidant. The oxidant is in many cases activated as a result of the formation of peroxides of different types, which accumulate in the reaction mixture as a consequence of the addition of oxygen to the metal complex or the exchange between the primary oxidation product (hydroperoxide) and the ligands of the catalytic additive. The peroxo-complex or the alkyl peroxide derivative of the element interact with the organic substance by a molecular mechanism, effecting with a high selectivity the direct transfer of oxygen to the hydrocarbon.

The activation of the substrate as a consequence of its coordination to the catalyst in selective catalytic oxidation reactions of organic substances has been reliably demonstrated for unsaturated and aromatic hydrocarbons. However, the necessity for the activation of the C–H bonds of alkanes in their selective oxidation needs experimental confirmation. According to Shilov and Shteinman,[113,114] in homogeneous systems alkanes can be activated by their oxidative addition to a transition metal complex.

Since the discovery of the activation of alkanes in aqueous solutions of platinum(II) complexes by Shilov and co-workers,[115] numerous examples of the activation of the C–H bonds of paraffins by iridium, rhodium, ruthenium, and rhenium compounds[116–119] and also by complexes of the type of the Ziegler–Natta catalyst[120] have been discovered. However, hitherto such activation has not been observed in autoxidation processes. On the contrary, there exist data which permit the claim that the activation of the alkane via its oxidative addition to the transition metal complex is not an essential condition for the selective conversion of the substrate into an oxygen-containing product.

Thus it is known that iridium compounds of the type IrX.(CO)PPh$_3$, where X = Cl or Br, activate the O_2 molecule with formation of the peroxocomplex and catalyse the autoxidation of ethylbenzene to acetophenone and of *p*-xylene to *p*-toluic aldehyde.[4] It has been shown recently that the iridium complex η^5-$C_5(CH_3)_5[P(CH_3)_3]Ir(H_2)$ activates alkanes and arenes with formation of hydridoaryl and hydridoalkyl derivatives of iridium.[119] However, treatment of the compounds obtained with oxygen or hydrogen peroxide leads only to the reductive elimination of the unchanged hydrocarbon molecule:



$$\eta^5\text{-}C_5(CH_3)_5[P(CH_3)_3]Ir\begin{matrix}R\\H\end{matrix} \xrightarrow{O_2 \text{ or } H_2O_2} [\eta^5\text{-}C_5(CH_3)_5[P(CH_3)_3]Ir] + RH\,;$$

$$R{=}CH_3,\ CH_2C(CH_3)_3,\ C_6H_{11},\ C_6H_5\ .$$

Furthermore, in the selective oxidation of hydrocarbons by the alkyl peroxide derivatives of non-transition elements (boron, aluminium, silicon, etc.), it is difficult to imagine that the alkanes are activated as a result of oxidative addition.

Consequently, the decisive factor in this process is the activation of the oxidant. The high selectivity of the oxidation of organic substances with participation of peroxide derivatives of the elements is caused, from our point of view, by the special state of the peroxide bond in the alkyl peroxide or peroxo-complex molecule "activated" by the heteroelement. Thus the activation of the O–O bond can lead to the formation of the oxiran ring, which facilitates the electrophilic attack by the peroxide oxygen on the nucleophilic organic substrate[112] or promotes the molecular interaction of the peroxide with the C–H bonds of the substance oxidised, which proceeds in a cyclic activated state.[113]

Arenechromium Tricarbonyls in Organic Synthesis

V.N.Kalinin

The characteristic features of the chemical properties of arenechromium tricarbonyls, caused by the change in the reactivity of the aromatic groups and the organic substituents linked to them on passing from ArH to $ArHCr(CO)_3$, are examined and data concerning the application of arenechromium tricarbonyls in organic synthesis are surveyed.
The bibliography includes 167 references.

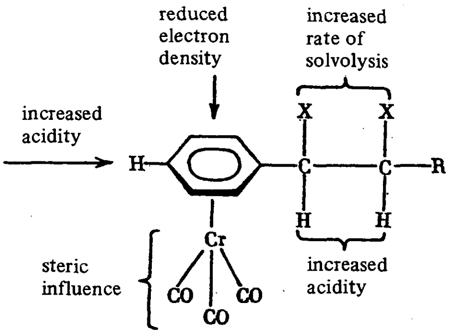
I. INTRODUCTION

The present stage in the development of organic synthesis is characterised by the wide-scale application of organoelemental and organometallic reagents in order to effect chemoselective, regioselective, and stereoselective processes, which are frequently impossible within the framework of the usual "organic" scheme. During the last 15–20 years, transition metal complexes (TMC) have been vigorously employed in organic synthesis together with traditional derivatives of non-transition metals (Grignard reagents, lithium alkyls), etc.). It is possible to differentiate two main aspects of the application of TMC in synthesis—catalytic reactions and reactions in stoichiometric proportions. The latter presuppose the existence of three stages: (a) the formation of a complex between the organic substrate and the transition metal (TM); (b) the use of the characteristic features introduced by the TM for the chemical modification of the organic residue; (c) decomposition of the complex and isolation of the altered organic molecule. For the effective employment of TMC in synthesis, these stages must proceed with high yields and the complex itself must be cheap and readily available. These requirements are to a large extent satisfied by derivatives of benzenechromiumtricarbonyl (benchrotrene),[†] which are readily obtained from organic derivatives and $Cr(CO)_6$ or $L_3Cr(CO)_3$ (L = Py, MeCN, or NH_3).

The synthesis of BCT has been examined in detail in various chapters of existing monographs.[1-3] The preparative method has been described specifically in two communications.[4,5] The physicochemical properties of BCT, the nature of the bonding in these compounds, and the principal factors influencing the orientation of the ChTC relative to the arene ligand have been discussed in a review.[6] The reactivity of BCT and their applications in organic synthesis in individual stages have been described in monographs,[7,8] and in greater detail in reviews.[9-14] Striking examples of the employment of BCT in synthesis have been published recently.

The present review deals both with studies having a bearing on specific applications in organic synthesis and studies of the reactivity of BCT which may find applications in the future. The ligand exchange reactions of BCT and the metallotropic rearrangements in a series of condensed systems containing ChTC will not be discussed. Earlier studies included in previous reviews[6,12] are quoted whenever necessary and in a more concise form.



The influence of the formation of a complex with ChTC on the reactivity of the arene ligand.[10]

The formation of a complex between the arene ligand and ChTC imposes characteristic features on the reactivity of the ligand. The changes in the properties of the ligand and the groups linked to it are illustrated in the Figure.[10] The introduction of ChTC leads to strong withdrawal of electron density from the arene ligand (the electron-accepting effect of ChTC is comparable to the influence of the nitro-group),

---

[†] The following notation has been adopted in the text of this review: BCT = benchrotrene $(PhH)Cr(CO_3)$ and its ring-substituted derivatives $(Arene)Cr(CO)_3$ also the benchrotrenyl residues $(CO)_3Cr(Ph^-)$; ChTC or [Cr] = $Cr(CO)_3$ group.

which is manifested by the high acidity of the ChTC derivatives of benzoic acids,[15,16] phenols,[17] and anilinium ions[18] compared with the corresponding benzene compounds.

The ability of the aromatic system to transmit the electronic effect of the substituent is significantly reduced in BCT.[16] The correlation of the thermodynamic dissociation constants of 38 substituted ChTC-benzoic acids in 50% aqueous ethanol at 25 °C within the framework of the Yukawa–Tsuno equation showed that the reaction constant ($\rho = 0.8$) is significantly lower than for benzoic acids ($\rho = 1.4$).

The complex formation reaction between the arene and ChTC promotes the stabilisation of α-carbenium ions and to some extent also β-carbenium ions, increases the acidity of the C–H bonds in the arene ligand and in the α-position in an alkyl substituent, and facilitates nucleophilic addition and substitution reactions. ChTC exerts an appreciable steric influence on the reactions of BCT. These effects are used in synthesis.

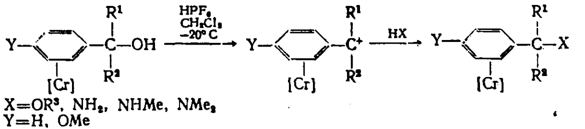
Arenes are usually isolated from BCT by oxidation with iodine[15] or cerium(IV) salts,[19] exposure to light,[20] or displacement with *n*-donor ligands: amines[21] and phosphines.[22]

II. REACTIONS PROCEEDING VIA α-CARBENIUM IONS

A characteristic feature of the BCT substituent, and in general of metallocenyl substituents,[23] is its great ability to stabilise the carbenium centres in the α-position relative to the aromatic ligand. This is indicated by the high rates of solvolysis of $(PhCH_2Cl)ChTC$ and $(Ph_2CHCl)ChTC$ in 80% aqueous acetone, amounting to 2.2×10^{-4} s^{-1} and 7.0×10^{-2} s^{-1}, which is respectively 10^5 and 10^3 times higher than the rate of solvolysis of benzyl chloride and diphenylmethyl chloride.[24] These kinetic results are in good agreement with the thermodynamic stability constants of the carbenium ions:[25] $pK_{R^+} = -11.8$ for $(\pi\text{-}PhCH_2^+)ChTC$, $pK_{R^+} < -17.3$ for $PhCl_2^+$, and $pK_{R^+} = -13.4$ for Ph_2CH^+.

The formation of complexes with ChTC appreciably increases the rate of isomerisation of benzyl thiocyanate to benzyl isothiocyanate $[(PhCH_2SCN)ChTC \rightarrow (PhCH_2NCS)ChTC]$;[26] the rate-determining stage of the process is ionisation.

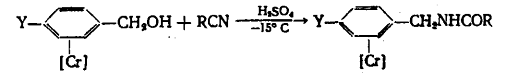
The formation of complexes by benzyl alcohols with ChTC and the subsequent generation of carbenium ions lead to extensive possibilities for the synthesis of *N*- and *O*-benzyl derivatives. The reactions of ChTC-containing carbenium ions with NH_3, amines, and alcohols provide convenient methods of synthesis of the corresponding derivatives:[27]



$X = OR^3, NH_2, NHMe, NMe_2$
$Y = H, OMe$
$R^1, R^2 = H, Me, Ph$
$R^3 = Me, Et$

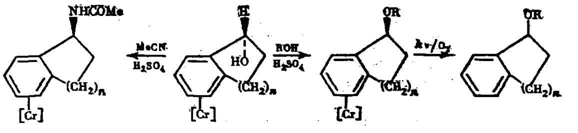
This approach greatly expanded the range of alcohols used in the Ritter reaction. Tertiary alcohols usually afford satisfactory yields of amides in this reaction, while the use of primary and secondary alcohols leads to unsatisfactory results.

The primary BCT-carbinols react smoothly with various nitriles, forming *N*-benzylamide complexes:[28,29]



$Y = H, OMe$
$R = Me, Pr, Ph, o\text{-}MeC_6H_4, PhCH_2, ClCH_2, CH_2{=}CH$

The formation of complexes with ChTC imparts characteristic features to the stereochemical course of the reactions of the intermediate carbenium ions. This is clearly illustrated by the total stereospecificity of the reactions of the carbenium ions generated from (*endo*-1-indanol)ChTC (I) and (*endo*-1-tetralinol)ChTC (II): the reactions with H_2O, MeOH, and RCN are accompanied by the complete inversion of configuration and the formation of *exo*-products:[29–31]

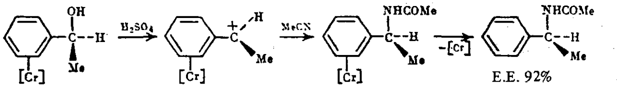


(I), (II)

R = H, Me; *n* = 1 (I), 2 (II)

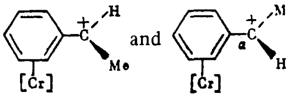
The racemisation of optically active complexes is not observed in these reactions and the photochemical decomposition of the complexes also proceeds with almost 100% retention of configuration.

Even in the acyclic series the reaction of BCT-carbinols via carbenium ions proceeds with an appreciably stereoselectivity.[29,32] The high degree of retention of optical purity in the products formed has been demonstrated in relation to the reactions of optically active *S*-(+)-(α-hydroxyethylbenzene)-ChTC, for example:



E.E. = enantiomeric excess.

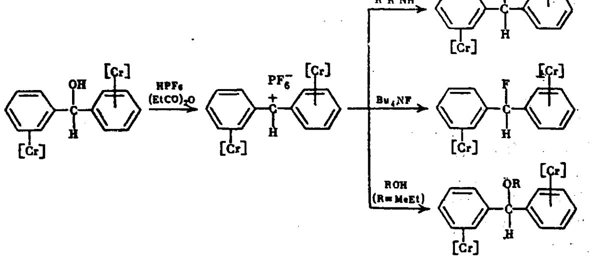
The retention of configuration in acyclic systems can be explained by *exo*-attack in the formation of the carbenium ion and in its subsequent reactions, i.e. of the two potentially feasible carbenium ions (A) and (B), namely



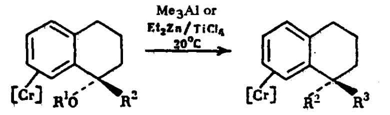
(A) (B)

the ion (A) is formed and the interconversions (A) ⇌ (B) are hindered by the high energy barrier to the rotation about the C(1)–C(α) bond.[33]

The stable α-carbenium ions with two ChTC, isolated in the solid crystalline state, are of special interest.[34,35] They are formed in the reaction of doubly complexed diphenylmethanol in propionic anhydride with 55% HPF_6. On treatment with alcohols, these complexes give rise to esters, while their reactions with primary and secondary amines afford secondary and tertiary amines respectively. Reactive aromatic substrates, namely dimethylaniline, pyrrole, and *N*-methylpyrrole are alkylated by carbenium ions but anisole and less nucleophilic aromatic derivatives do not react with them.[34,45] The reaction with tetrabutylammonium fluoride yielded the corresponding π-complex of diphenylmethyl fluoride:[27]

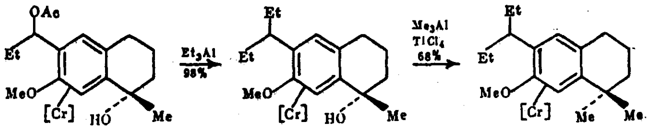


The ChTC-derivatives of *endo*-benzyl alcohols and their acetates are convenient sources of alkyl derivatives, which are obtained by reaction with Me_3Al or Et_2Zn in the presence of $TiCl_4$:[36]

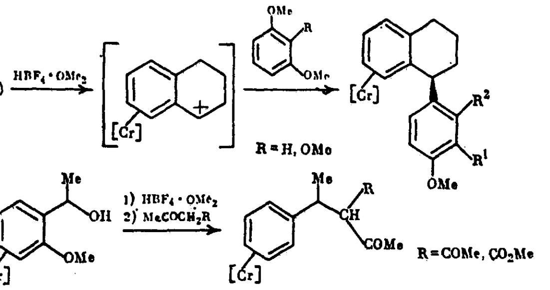


$R^1=H$, Ac; $R^2=H$, Me; $R^3=Me$, Et

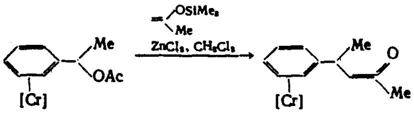
Depending on the conditions, when the substrate contains two types of benzyl hydroxy-groups, it is possible to introduce stepwise different alkyl groups:



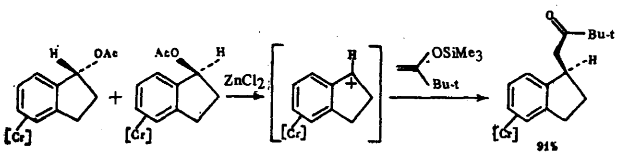
The BCT-carbenium ion, formed *in situ*, reacts rapidly with aromatic derivatives containing electron-donating groups and with β-dicarbonyl compounds, forming *exo*-substituted complexes:[37]



The acetates of α-BCT-carbinols are active alkylating agents and produce ketones smoothly in reactions with silyl enol ethers,[38] for example:



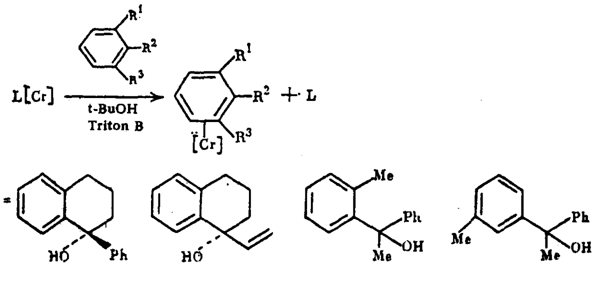
The reaction of a distereoisomeric mixture of indanyl acetates, bound in a complex, with 1-t-butyl-1-trimethylsiloxyethylene leads to a single *exo*-substituted complex via an intermediate carbonium ion with planar chirality:



The alkylation of enol ethers by the acetates of α-BCT-carbinols provides a convenient preparative method for the stereospecific formation of a C–C bond.

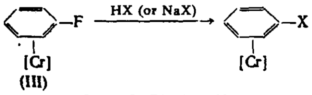
It is noteworthy that it has been suggested that BCT with t-hydroxy-groups in the ligand, which exhibit an increased tendency towards the formation of carbenium ions, be employed for the transfer of ChTC to other arenes.[39,40]

The reaction is used for the synthesis of BCT with functional-group substituents:



III. NUCLEOPHILIC SUBSTITUTION AND ADDITION

The strong electron-accepting effect of ChTC facilitates reactions involving nucleophilic substitution in (η^6-halogenoarene)ChTC. The fluorine and chlorine atoms in BCT are readily substituted by *O*-, *S*-, and *N*-nucleophiles, the fluorobenzene complex (III) exhibiting the highest reactivity:[41–44,75]:



(III)

X=RO, RS, RNH, R_2N

The relative ease of substitution of the halogen by the MeO group in halogenobenzenes activated by complex formation increases in the following sequence for different π-linked organometallic residues:[45,46]

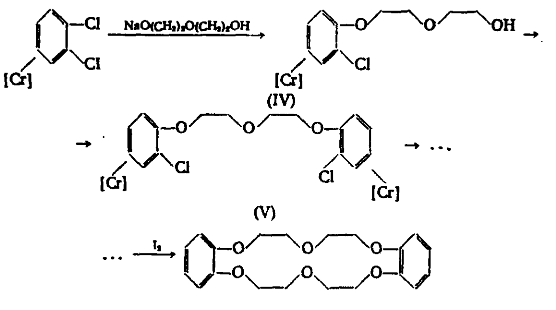
$$(OC)_3Cr < (OC)_3Mo < (\eta^5\text{-}C_5H_5)Fe^+ < (OC)_3Mn^+$$

Difluoro-BCT readily exchanges both fluorine atoms for methoxy-groups.[47]

The halogen in (halogenbenzene)ChTC is readily exchanged for the mercapto-group under the condition of phase-transfer catalysis.[48]

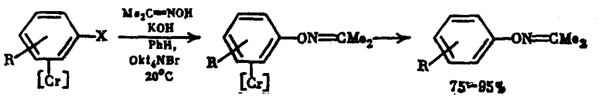
In (dichlorobenzene)ChTC, the substitution of the halogens can be carried out consecutively.[49,50]

The possibility of the stepwise substitution of chlorine atoms in (1,2-dichlorobenzene)ChTC permitted its use in the synthesis of dibenzo-18-crown-6 ether by reaction with the sodium salt of diethylene glycol via the complexes (IV) and (V):[51]



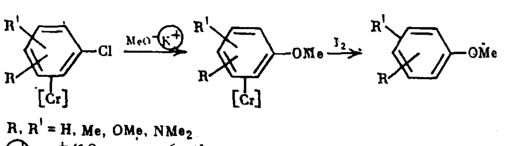
The yield of the crown ether is 27%.

Under the conditions of phase-transfer catalysis, BCT reacts smoothly with acetone oxime, forming *O*-aryloximes:[52]



R = H, *o*-Me, *m*-Me, *p*-Me; X = Cl, F.

when (chloroarene)ChTC is heated with non-solvated MeOK in benzene or acetonitrile in the presence of 18-crown-6 ether, (methoxyarene)TC is formed in high yields:[53]



R, R' = H, Me, OMe, NMe$_2$
K⁺ = K$^+$/18-crown-6 ether

Intramolecular nucleophilic substitution in the series of BCT is an effective method of synthesis of benzocyclic systems, for example, chromans:[54,55]

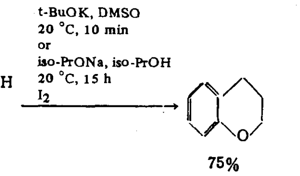


Table 1. The coupling of carbanions to BCT [Eqn.(1a)].[10,56]

Carbanion	Product	Yield, %
LiCMe$_2$CN	PhCMe$_2$CN	94
LiCH$_2$CN	PhCH$_2$CN	68
		93
	PhCO(CH$_2$)$_2$Me	90*
	PhCOPr-iso	88*
LiCH(SPh)$_2$	PhCH(SPh)$_2$	84
LiBu-t	PhBu-t	97
		71
LiCH$_2$CO$_2$Bu-t	PhCH$_2$CO$_2$Bu-t	87
LiCHMeCO$_2$Bu-t	PhCHMeCO$_2$Bu-t	88
LiCMe$_2$CO$_2$Bu-t	PhCMe$_2$CO$_2$Bu-t	88

*R = CHMeOEt; the products were isolated by successive acid and base hydrolysis.

A notable property of *C*-nucleophiles is their ability to add to BCT with formation of η^5-cyclohexadienyl complexes, which are formal analogues of Meisenheimer complexes.[56] The reaction takes place rapidly at 0 °C. It has been shown from the products of the addition of the lithiodithiane complex to BCT that the entering substituent occupies the *exo*-position in the structure, where one of the ring carbon atoms is deflected in the opposite direction relative to ChTC.[57] Anionic complexes are capable of two types of reactions:

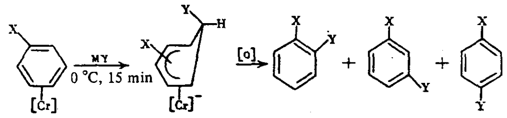
 (1)

(VI)

The oxidation of the complex leads to the formal substitution of the hydride ion by the carbanion (pathway *a*) and the formation of a substituted benzene. The process has come to be called "addition/oxidation".[56,58] The protonation of the complex by strong acid liberates alkylcyclohexa-1,3-diene ("addition/protonation", pathway *b*).[56,59,60] "Addition/oxidation" has potentially many applications in organic synthesis for the phenylation of organic compounds (Table 1).[10,56]

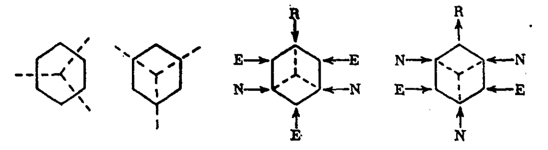
Reactive organolithium compounds are effectively phenylated by BCT under mild conditions in tetrahydrofuran (THF).

Table 2. The mode of addition of carbanions to BCT.[61,62]

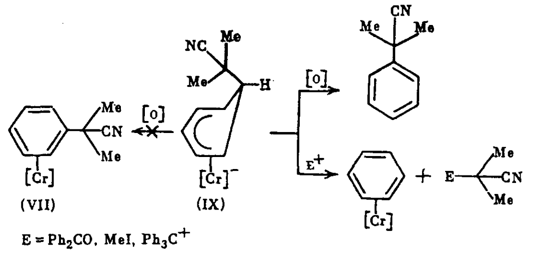


X	MY	Product ratios *o*:*m*:*p*
Me	LiCH$_2$CO$_2$Bu-t	28:72:0
Me	LiCMe$_2$CO$_2$Bu-t	3:97:0
Me	LiCMe$_2$CN	1:97:2
Me		51:47:2
OMe	LiCH$_2$CO$_2$Bu-t	4:96:0
Cl	LiCH$_2$CO$_2$Bu-t	54:45:1
Cl	LiCHMeCO$_2$Bu-t	53:46:1
Cl	LiCMe$_2$CO$_2$Bu-t	5:95:1
Cl	LiCH$_2$COBu-t	76:24:0
Cl	LiCMe$_2$CN	10:89:1
Cl		46:53:1
SiMe$_3$	LiCMe$_2$CN	0:2:98
CF$_3$	LiC(CN)(OR)Me	0:30:70
NMe$_2$	LiCMe$_2$CN	1:99:0
Et	LiC(CN)(OR)Me	0:94:6
iso-Pr	LiC(CN)(OR)Me	0:80:20
t-Bu	LiC(CN)(OR)Me	0:35:65
CH(Bu-t)$_2$	LiC(CN)(OR)Me	0:0:100

In substituted BCT the nature of the substituent has a decisive influence on the regioselectivity of the addition of nucleophiles (Table 2).[61,62] To a lesser extent the ratio of the isomers is influenced by the nature of the nucleophiles. The direction of attack by the reactants on BCT is qualitatively correlated with the coefficients of the lowest unoccupied molecular orbital of the free arene, which is associated with the distribution of charge density, and attack by the nucleophiles Nu is directed preferentially to the carbon atom eclipsed by the CO group, while that of the electrophile E is directed to neighbouring atoms.[63–66] Despite the low energy barrier between the hindered (C) and eclipsed (D) conformations (~0.3 kcal mol^{-1}), BCT's with an electron-donating substituent exist preferentially in the *syn*-eclipsed conformation (E), while those with an electron-accepting substituent exist in the *anti*-eclipsed conformation (F):

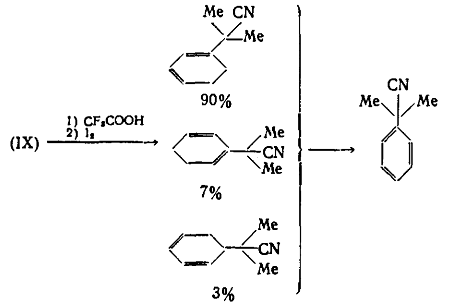


Nucleophilic substitution takes place in the *m*-position in complexes with R = OMe or NMe$_2$ and in the *p*-position in those with R = CF$_3$ or SiMe$_3$. Alkyl-BCT are an exception.[67] With increase of the bulk of the alkyl group, *p*-attack become preferred to *m*-attack. The attempts to obtain the complex (VII) by the selective oxidation of the adduct (IX), obtained by the reaction of the BCT with 2-lithio-2-methylpropionitrile (VIII) on treatment with I_2, $FeCl_3$, benzoquinone, $CuCl_2$/DMF,# and cerium(IV), led only to the formation of 2-methyl-2-phenylpropionitrile. When electrophiles are used as hydride ion acceptors, the initial arene complex is regenerated as a consequence of the abstraction of the carbanion:[56,57]

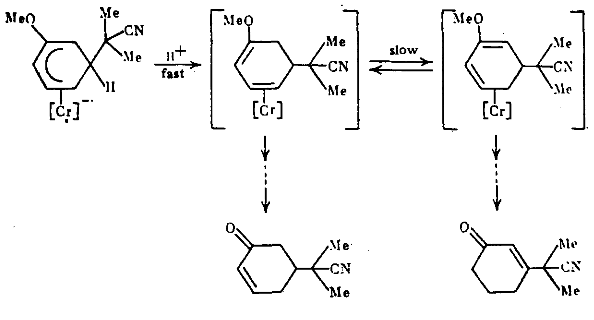


E = Ph_2CO, MeI, Ph_3C^+

The intermediate (IX) reacts rapidly with proton donors (H_2O, AcOH, CF_3CH_2OH) to regenerate the initial BCT in 70—90% yield, while on treatment with CF_3COOH (5 equiv.) and subsequent oxidation a mixture of isomeric cyclohexadienes is formed and can be readily aromatised:[57]

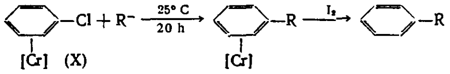


In the case of the adduct of (η^6-anisole)ChTC and compound (VIII), proton transfer results in the formation of dienol ethers, whose hydrolysis affords 3- and 5-substituted cyclohexenones; the ratio of the latter depends on the duration of stirring with acid:



If the adducts of nucleophiles with BCT are treated with CF_3COOH in an atmosphere of CO, then $Cr(CO)_6$ is readily regenerated together with dienes or arenes.[68]

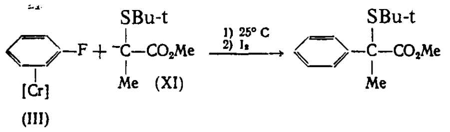
The reaction involving nucleophilic substitution of chlorine in (η^6-chlorobenzene)ChTC by stabilised carbanions, which can be regarded as a preparative phenylation method, has been discovered:[69,70]



R=CMe_2CN, CMe_2CO_2Et, $CMe_2CO_2^-$, $CH(CO_2Et)_2$, C(Ph)(CN)(OCHMeOEt)

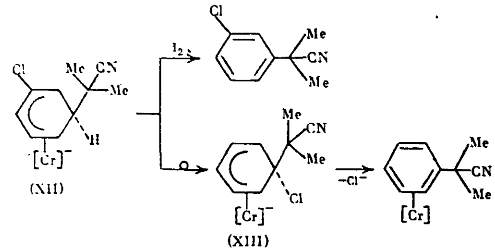
The lithio-derivatives of 1,3-dithiane, 2-methyl-1,3-dithiane, t-butyl acetate, acetophenone, 5,6-dihydro-2,4,4,6-tetramethyl-4*H*-1,3-oxazine, and acetonitrile are not phenylated under these conditions. Primary and secondary carbanions are apparently relatively ineffective in this reaction owing to the presence of an active hydrogen atom. The diethylmalonate anion, which reacts slowly with the complex (X), is an exception.

It has been shown that the fluorine-containing complex (III) reacts rapidly with the carbanion (XI), giving rise to methyl α-(t-butylthio)-α-phenylpropionate in 94% yield after the decomposition of the complex:

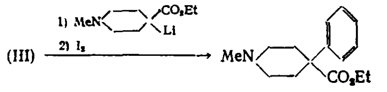


The rate of nucleophilic substitution of the halogen in (η^6-halogenobenzene)ChTC depends on the character of the leaving group and diminishes in the sequence F > Cl > I.[70]

The mechanism of the nucleophilic substitution of the halogen in halogeno-BCT is complex. For example, when (chlorobenzene)ChTC (X) is treated with 2-lithio-2-methylproprionitrile (VIII) at −78 °C and is then oxidised, a 1,3-disubstituted benzene is formed. However, at 20 °C the intermediate (XII) slowly isomerises to the complex (XIII), which loses Cl^- and gives rise to an *unco*-substitution product:[56]



Nucleophilic substitution and addition reactions have found applications in fine organic synthesis. Thus substitution of the fluorine atom in (PhF)ChTC (III) by the carbanion derived from 4-ethoxycarbonyl-1-methylpiperidine leads to the analgesic demirol in 85% yield:[56]



The regioselectivity of the nucleophilic attack has been used in the synthesis of polysubstituted benzenes. The role of the MeO and Me_3Si groups as *m*- and *p*-directing groups respectively is a decisive factor in the synthesis of 1,2,3- and 1,2,4-trisubstituted benzenes:[62]
