The electrochemistry of short-lived intermediate species

V A Benderskii, A G Krivenko
Institute for Energy Problems of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The results of the study of the electrode reactions of hydrogen atoms, simple organic radicals, and ions with anomalous valence by pulse radiolysis and laser photoelectron emission from the metal into the solution have been reviewed.

The bibliography contains 119 references.

I. Introduction

Most electrochemical processes are many-electron processes consisting of a sequence of one-electron stages in which intermediate species (IS) are formed and undergo further transformations. Since these species usually have a higher free energy than the reagents and products, their formation determines the energy barrier of the process as a whole, characterised by the magnitude of the overvoltage. Thus the electrochemistry of IS is a necessary part of modern electrochemistry, just as the study of the chemical transformations of IS forms part of chemical kinetics in general. Since IS take part in electrode reactions and are present in the adsorbed state on the electrode or diffuse to it from the layer of the solution next to the electrode, in the electrochemistry of short-lived IS, methods making it possible to determine the concentration or the current of the electrode reactions of the IS immediately after their generation are used. Extensive use is made of non-stationary electrochemical methods in which the IS are generated by an initial current pulse, and their subsequent transformations are recorded from the changes in the current and the electrode potential. These methods have been used to study a large number of reactions of free radicals and ions with anomalous valence (see in particular the published review[1]) with characteristic transformation times greater than $10^{-3}-10^{-4}$ s. The study of more rapid processes involving IS is restricted by the electrical double layer charging currents with change in potential. This restriction has stimulated the development of the methods of pulse electrochemical radiolysis (PECR) and laser photoelectron emission from the metal into the electrolyte solution (LPE), in which the IS are generated at a constant electrode potential. The present review examines the principles of these new methods and summarises the main results of their application. Particular attention is paid to the LPE method, since PECR data have already been reviewed.[2,3]

The sequence of processes taking place in a solution after pulse photoelectron emission from a metal has now been studied in sufficient detail.[4,5] The emitted electrons, which usually have energies in the range 0.5–2 eV, are thermalised and hydrated in aqueous solution, and the hydrated electrons (e^-_{aq}) are situated at a distance $l \simeq 3$ nm from the electrode surface. These electrons either diffuse to the electrode and are returned to the metal or are captured by an acceptor added to the solution, forming IS in a layer with approximately the same dimensions next to the electrode. As a result of these rapid processes, which with nanosecond duration bring about the photo-emission of laser pulses, a source of IS is formed close to the electrode; these IS diffuse to the electrode and take part in electrode reactions, accompanied by a change in the current or potential. The kinetics of this change are determined directly by the rate constants of the electrode reactions, so that it is possible to measure their absolute values up to 10^8 s^{-1}. The absence in the LPE method of the diffusion restrictions characteristic of electrochemical measurements is due to the small size of the IS source, noted above. Another characteristic of the method is that the rate constants are measured at a small degree of coverage, independent of potential, of the surface by the IS, the quantity of which is controlled by the intensity of the laser pulses and usually does not exceed 10^{11} cm^{-2}. Despite the small magnitude of the emitted charge, the pulse currents in LPE are fairly high ($\gtrsim 10^{-1}$ A cm^{-2}), so that the influence of contaminants is less significant than in ordinary electrochemical measurements at low overvoltages.

While the rates of the generation of the IS are similar in the LPE and PECR methods, the first of these has two important advantages: the absence of interfering reactions of primary radiolysis products (primarily hydrogen peroxide) and diffusion restrictions. In PECR, as a result of the uniform generation of IS in the bulk of the solution, their currents are restricted by diffusion and bulk recombination, so that it is possible to measure the rate constants only in a comparatively narrow range from 10^3 s^{-1} to 10^5 s^{-1}. In the LPE method, as shown below, it is possible to measure constants in the range 10^0-10^7 s^{-1}.

The idea of using pulse photo-emission measurements to study the fast electrode reactions of IS was put forward as early as 1971,[6,7] but it was only several years later[8,9] that apparatus was developed for quantitative measurements.

II. Generation of short-lived intermediate species

By using radiation-chemical data[10,11] to select an acceptor, it is possible to obtain most IS of many-electron electrode processes, so that the PECR and LPE methods are universal. Table 1 gives the rate constants k_a of the reactions yielding the IS whose electrochemistry has been studied by LPE. When it is difficult to select an acceptor of e^-_{aq} to obtain a required species, as for example in the case of hydroxyalkyl radicals, use is made of the reactions of OH radicals and H atoms previously generated in the solution by the reaction of e^-_{aq} with nitrous oxide and hydrogen ions respectively. The reactions listed in Table 1 have been studied by pulse radiolysis with identification of the IS from the absorption spectra. Most IS have also been identified from the EPR spectra of irradiated frozen solutions of the corresponding acceptors.

Table 1. Rate constants for the reactions of IS formation, studied by LPE methods.[10]

a) Reactions involving e^-_{aq} acceptors

IS	Acceptor	$10^{-9}\,k_a$, $mol^{-1}\,s^{-1}$	IS	Acceptor	$10^{-9}\,k_a$, $mol^{-1}\,s^{-1}$
H	H_3O^+	8	$CFCl_2$	$CFCl_3$	16
OH	N_2O	6	CF_3	CF_3Cl	7
CH_3	CH_3Cl	1.1	CCl_3	CCl_4	30
C_2H_5	C_2H_5Cl	0.8	C_2H_4Cl	$C_2H_4Cl_2$	9
n-C_3H_7	**n-C_3H_7Cl**	0.7	HCO	H_2CO_2	0.2
n-C_4H_9	**n-C_4H_9Cl**	0.4	$(CH_3)_2COH$	$(CH_3)_2CO$	6
C_6H_5	C_6H_5Br	4	CO_2^-	CO_2	8
CH_2Cl	CH_2Cl_2	6	NO_3^{2-}	NO_3^-	11
$CHFCl$	$CHFCl_2$	3	NO_2^{2-}	NO_2^-	4
CHF_2	CHF_2Cl	3	NO^-	NO	30
$CHCl_2$	$CHCl_3$	30	NH_2	NH_2OH	0.9
CF_2Cl	CF_2Cl_2	14	BrO_2	BrO_3^-	3

b) Reactions involving OH acceptors

IS	Acceptor	$10^{-9}\,k_a$, $mol^{-1}\,s^{-1}$	IS	Acceptor	$10^{-9}\,k_a$, $mol^{-1}\,s^{-1}$
CH_2OH	CH_3OH	0.6	$CH_2CH(OH)Cl$	C_2H_3Cl	7
CH_2CH_2OH	C_2H_4	3	CO_2^-	HCO_2^-	3
CH_3CHOH	C_2H_5OH	2	NH_2O	NH_2OH	9

III. Kinetics of the change in the current of electrode reactions

The changes with time in the current or emitted charge in LPE are calculated by solving the non-stationary equations for the diffusion of e^-_{aq} and the IS. A detailed analysis has been published.[5,12,13] The concentration of e^-_{aq} is given by the equation

$$\partial n/\partial t = D_e\partial^2 n/\partial x^2 - k_a N_a n + \frac{I_0}{l}\exp(-x/l)\,f(t), \qquad (1)$$

where D_e is the diffusion coefficient of e^-_{aq}; k_a the rate constant of the capture of e^-_{aq} by the acceptor added to the solution to give a concentration N_a; I_0 the photo-emission current generated by the laser pulse, whose form is described by the time function $f(t)$; and l the characteristic dimension of the source of e^-_{aq}. Because of the high rate of the electrode reaction of e^-_{aq}, the quantity $n(0, t) = 0$. For the concentration of IS stable† in solution $n_1(x, t)$, the following equation is applicable:

$$\partial n_1/\partial t = D\partial^2 n_1/\partial x^2 + k_a N_a n. \qquad (2)$$

As a result of their diffusion, a flux of IS into the adsorption plane $x = 0$, equal to $\kappa_a n_1(0, t)$, is created, where κ_a is the rate constant of the adsorption, with dimensions cm s^{-1}. The adsorbed species are desorbed with a rate constant W_d and take part in the electrode reactions with an overall rate constant $W = W_2 + W_3$ (W_2 and W_3 are the rate constants of the oxidation and reduction of the IS respectively). The surface concentration of IS (Γ) obeys the equation

$$d\Gamma/dt = \kappa_a n_1(0, t) - (W_d + W)\Gamma. \qquad (3)$$

As a consequence of the continuity of the flux at $x = 0$ there arises the boundary condition

$$D(\partial n_1/\partial x)_{x=0} = \kappa_a n_1(0, t) - W_d\Gamma. \qquad (4)$$

This adsorption–desorption scheme for the electrochemically active IS is applicable if the degree of coverage is small, that is κ_a and W_d are independent of Γ. If the rate constant W is smaller than the rate of the processes involving e^-_{aq} and the reciprocal of the laser pulse duration t_0^{-1}, that is

$$W < D_e/l^2,\ k_a N_a,\ t_0^{-1}, \qquad (5)$$

the equation for the change in the current with time is independent of the duration of the laser pulse, the characteristic length of the source l, and the rate of capture of e^-_{aq}. From the solution of Eqns. (1) and (2) it follows[13] that the form of the kinetic curves of the charge emitted into the solution $Q(t)$ is determined by the parameter

$$\xi = 4\kappa_a W/W_d^2 D \qquad (6)$$

and, depending on its value, is described by one of the following relationships ($t > t_0$):

$$Q/Q_m = \begin{cases} 1 + \dfrac{W_3 - W_2}{W_3 + W_2}(1 - \exp(-Wt)), & \xi \gg 1; \\ 1 + \dfrac{W_3 - W_2}{W_3 + W_2}\left(1 - \dfrac{1}{\varkappa}\sqrt{\dfrac{D}{\pi t}}\right), & \xi \ll 1,\ \varkappa\sqrt{t/D} > 1, \end{cases} \qquad (7)$$

where Q_m is the number of e^-_{aq} captured by the acceptor, and κ the effective rate constant of the electrode reaction, determined by the quasi-stationary current

$$\varkappa = \kappa_a \frac{W}{W + W_d}. \qquad (8)$$

The rate constants for the adsorption and desorption are related by the detailed equilibrium condition

$$\frac{\kappa_a}{W_d} = \frac{\Gamma_0}{N_0}\exp\left(-\frac{\Delta G_a^0}{RT}\right), \qquad (9)$$

where ΔG_a^0 is the free energy of adsorption, corresponding to the selected standard bulk (N_0) and surface (Γ_0) concentrations. With allowance for Eqn. (9), the condition $\xi \gg 1$ means that the kinetic

† The case in which the IS is transformed in the bulk has been examined.[7] The stability of the IS means that the time of their homogeneous transformation is greater than the time of their movement to the electrode.

curves $Q(t)$ have an exponential form in the following range of values of W:

$$\frac{\varkappa_a^2}{D} > W > \frac{D}{4}\left(\frac{N_0}{\Gamma_0}\right)^2 \exp\left(\frac{2\Delta G_a^0}{RT}\right) = W_{\min}. \quad (10)$$

The upper boundary of the range is determined by the condition that W be small compared with the rate of adsorption. The opposite inequality corresponds to diffusion-controlled reactions, whose rate is limited by the transport of the reagent to the surface. The values of W in this case are greater than 10^8 s^{-1}, and cannot be measured by the LPE method, since the conditions (5) do not apply. The lower boundary depends on ΔG_a^0, and for $\Delta G_a^0 < -25$ kJ mol^{-1} does not exceed 1 s^{-1} for the following typical values of the other parameters: $N_0 = 64 \times 10^{20}$ cm^{-3} (standard 1 M solution), $\Gamma_0 = 10^{14}$ cm^{-2}, $D = 10^{-5}$ cm^2 s^{-1}, $T = 300$ K. Estimation of $W_{\min}$ shows that even for comparatively weakly adsorbed IS, the range of values of W satisfying relationship (10) is greater than $10^7 - 10^8$. When condition (10) is satisfied, there is no adsorption equilibrium, and the IS are not desorbed and take part in electrode reactions. Otherwise, when $\xi \ll 1$, adsorption equilibrium is established, the form of the kinetic curves changes, and $Q(t)$ is characterised by the effective rate constant κ, as in ordinary electrochemical measurements, under the conditions of a quasi-stationary current: $j_c = \kappa n_1(0)$. The range of values of κ that can be measured is restricted by the condition

$$\varkappa < \sqrt{W_{\min} D},\ \sqrt{k_a N_a D},\ \sqrt{D/t_0},\ D/l \quad (11)$$

from which it follows that the LPE method can be used to measure the rate constants of the electrode reactions of non-adsorbed IS ($\Delta G_a^0 \geqslant 0$) up to 30–50 cm s^{-1}.

It follows from conditions (7) that the kinetic curves $Q(t)$ are determined by the existence of two signals: the initial rapid signal corresponding to the photo-emission and return to the electrode of the e_{aq}^- not captured by the acceptor, and the subsequent slower signal due to the electrode reactions of the IS. The ratio of the amplitudes of these signals equal to $Q(t)/Q_m - 1$ as $t \to \infty$ corresponds to the number of electrons transferred from the metal to the solution, calculated for one electron captured by the acceptor, that is for one IS, so that $Q(\infty)/Q_m - 1$ is the order (n) of the electrode reaction

$$X + n e^- \rightarrow X^{n-} \quad (12)$$

with respect to electrons. The values of n, unlike W, can also be determined by measuring the relative values of the photo-current for stationary photo-emission into the solution being studied and into a solution for which n is known.[4,5] The latter are usually N_2O solutions, in which the capture of e_{aq}^- gives OH radicals, produced throughout the working range of the mercury electrode, so that $n = 1$.

$Q(t)$ is measured using the laser electrochemical relaxometer[5,9,14,15] (Fig. 1). The nitrogen laser with a wavelength of 337 nm, the fourth harmonic of the neodymium laser (265 nm), and excimer lasers (220 nm and 248 nm) [15] are used as light sources. To avoid the superposition of effects due to pulse heating to the electrode, the production of capillary waves (in the case of liquid metal electrodes), and decrease in the concentration of the acceptor in the layer next to the electrode, the light intensity is restricted to 700 kW cm^{-2} for a pulse duration of $\sim 10^{-8}$ s. The range 20–200 kW cm^{-2} is most convenient for the measurements. The restriction of the light intensity and the low quantum yield of the photo-emission ($\sim 10^{-4}$ A W^{-1}) make it necessary to record the weak signals in a broad frequency band. It is most convenient to use a stroboscopic recording scheme, employing laser pulses with a repetition frequency of 6–25 Hz and a signal measured at a given moment of time (relative to the laser pulse) and a given electrode potential. The signal recording time is 30–40 s, so that it is possible to average over a large number ($\sim 10^3$) of pulses. With time scanning, the relaxometer can be used to obtain the kinetic curves $Q(t)$, and when the potential E is scanned, it gives the $Q(E)$ relationship at the selected moment of time. A design feature of the cell with the mercury electrode, ensuring suppression of capillary waves, is the use of a photocathode with a flat mercury surface which is kept in an amalgamated platinum capillary and is replaced after each scanning cycle.

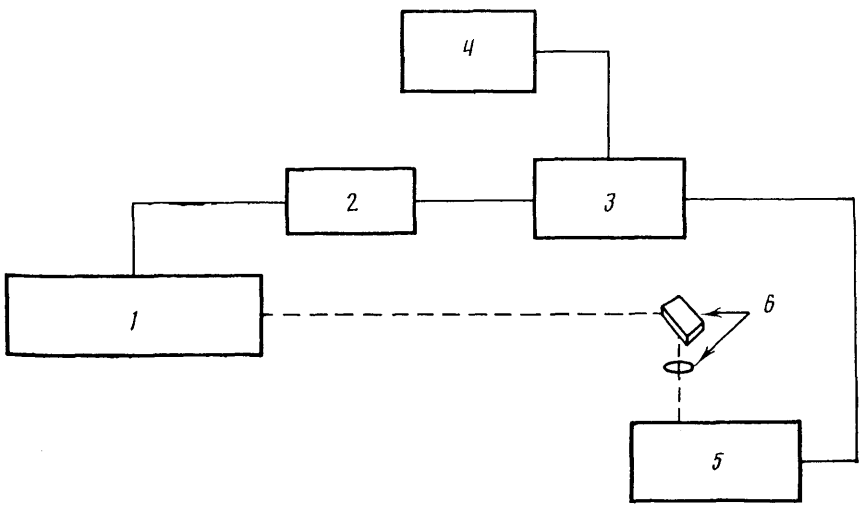

Figure 1. Block diagram of the laser electrochemical relaxometer: *1*, photon generator; *2*, synchronisation system; *3*, stroboscopic oscillograph; *4*, recorder; *5*, measuring cell with amplifier and polarisation scheme; *6*, laser beam focussing system.

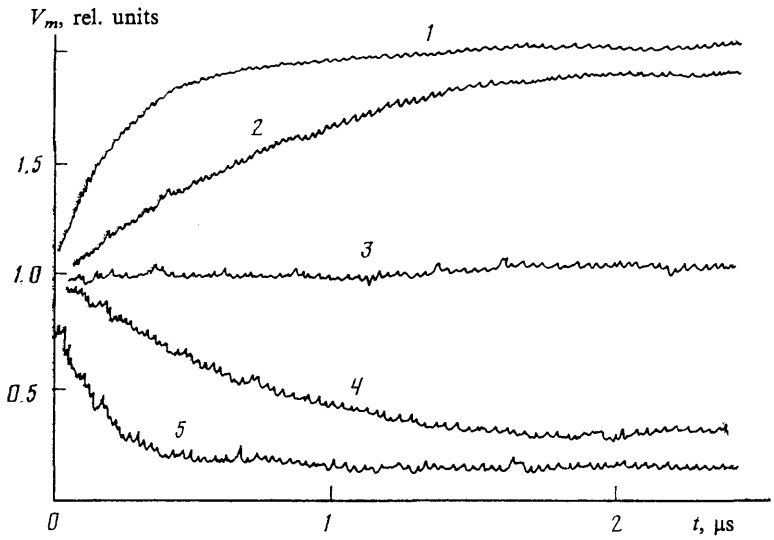

Figure 2. Kinetic curves for the electrochemical reduction and oxidation of H atoms in 1 M aqueous KCl solution with the addition of 0.1 M HCl at different values of the potential of the mercury electrode, V: *1*, −0.9; *2*, −0.7; *3*, −0.55; *4*, −0.5; *5*, −0.4.

The recorded signal $V(t)$ is equal to the variation in the electrode potential brought about by the change in its charge, and is given by the relationship[5]

$$V(t) = \frac{1}{C}\int_0^t \frac{dQ(t')}{dt'} \exp\left(-\frac{t-t'}{\tau_0}\right) dt', \qquad (13)$$

where C is the capacity of the electrical double layer; $\tau_0 = RC$ the time constant of the electrochemical cell and the input circuit; and R their total ohmic resistance. From Eqns. (7) (for $\xi \gg 1$) and (13) it follows that

$$\frac{V}{V_m} = \frac{2W_3\tau_0 - 1}{W\tau_0 - 1} \exp(-t/\tau_0) - \frac{(W_3 - W_2)\tau_0}{W\tau_0 - 1} \exp(-Wt), \; t \gg t_0, \qquad (14)$$

where $V_m = Q_m/C$. For $W\tau_0 \gg 1$, $V(t) = Q(t)/C$. These charge measurement conditions are used for values of W from 10^7 s^{-1} to 10^4 s^{-1}, since τ_0 is usually equal to $10^{-3}-10^{-4}$ s. The rate constants of slower reactions are measured using current conditions in which $W\tau_0 \ll 1$ and

$$V/V_m = \exp(t/\tau_0) + (W_3 - W_2)\tau_0 \exp(-Wt). \qquad (15)$$

To extend the range of measurement of the constants under current conditions, τ_0 is decreased, and t_0 is increased. The use of current–voltage transformers with an input resistance close to zero decreases to τ_0 to 3–5 μs, so that the highest values of W that can be measured under current conditions are 10^5 s^{-1}.[16] $W \leqslant 10^3$ s^{-1} are measured using the pulses of a continuous helium–cadmium laser (λ = 325 nm) produced by a mechanical modulator; periodic illumination methods are also used.[17] The combination of the two measurement conditions (charge and current) makes it possible to cover the range of values of W from 1 s^{-1} to 10^7 s^{-1}, satisfying the inequalities (10).

The kinetic curves are treated using relationships (14) and (15). The accuracy of the determination of W is restricted by the scatter in the amplitude of the laser pulses, and is generally 10–15%. Eqns. (7) show that the form of the kinetic curves deviates from the exponential for $\xi \simeq 1$. For electrode reactions whose characteristic time is less than 10^{-4} s, $\xi \leqslant 1$ at rates of desorption greater than 10^5 s^{-1}, that is in the case where there is practically no adsorption of the species ($\Delta G_a^0 > -10$ kJ mol^{-1}). Analysis of the $V(t)$ curves makes it possible not only to determine the absolute values of W or κ but also to establish the state (adsorbed or not) in which electron transfer takes place.

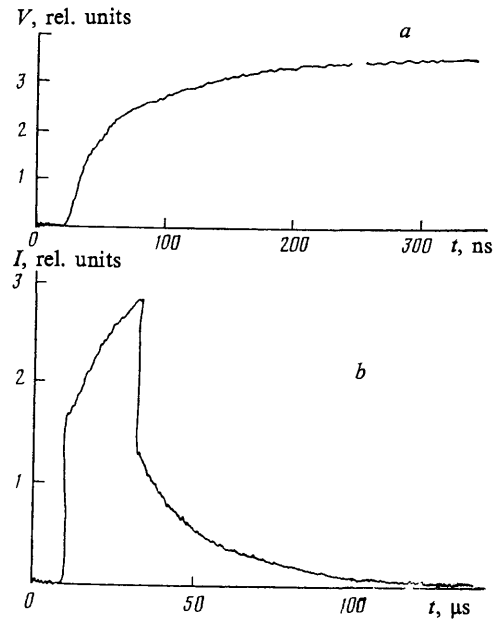

Figure 3. Form of the kinetic curves for the reduction of the Ch_2Cl radical adsorbed on a mercury electrode: *a*, under charge measurement conditions (E = −1.67 V, $W_3 = 1.4 \times 10^7$ s^{-1}), *b*, under current measurement conditions (E = −0.89 V, W_3 = 30 s^{-1}, laser pulse duration 20 ms).[16]

Typical $V(t)$ curves are given in Figs. 2 and 3. The changes in the form and characteristic times of these curves are due to the

changes in W_2 and W_3 with change in the electrode potential.‡ The rate of the rapid reactions of adsorbed hydrogen atoms are measured under charge conditions. In the cathodic potential range, in which the reduction of H atoms predominates, the $V(t)$ curves consist of a short initial section and a section corresponding to the slower doubling of the emitted (captured by the acceptor) charge ($W_3 \gg W_2$, $n = 1$). The characteristic rise time, that is W_3^{-1}, decreases with increase in $-E$. For anodic displacement of E, the rise time increases, and the amplitude in the "slow" section decreases. At the characteristic potential E^*, when the rate constants of the reduction and oxidation become equal:

$$W_2(E^*) = W_3(E^*) = W^*, \tag{16}$$

the "slow" section disappears, since when oxidation and reduction are equally probable (and when the values of n are identical), the transformations of the IS do not change the charge of the electrode. For $E > E^*$, the magnitude of $V(t)$ decreases from the initial value V_m to $V_m W_3/(W_2 + W_3)$, since the main channel for the transformation becomes the ionisation of H atoms, leading to the return to the electrode of the emitted electrons and the electrons captured by the acceptor ($n = -1$). The decay time of $V(t)$ decreases with increase in E as a result of the increase in W_2. Fig. 3 gives the $V(t)$ curves corresponding to the reduction of the CH_2Cl radical, for which the $W_3(E)$ relationship can be measured over a range of change in $W_3(E)$ of almost 10^7.

IV. Polarograms of the species generated by a variable photoelectron emission current

Varying illumination with a frequency of Ω creates an IS flux in phase with it, with a characteristic source length $l_1 \simeq \sqrt{D/k_a N_a} \simeq 10^{-5}-10^{-6}$ cm, so that at the low frequencies usually employed $l_1 \ll \sqrt{D/\Omega}$ and the resulting photo-emission current, as in the case where the inequalities (5) are satisfied, is independent of the conditions under which the IS are formed. Without forgetting that photoemission gives IS and not stable reagents, the obvious similarity in the methods used to observe the polarograms and the photocurrent should be emphasised. In polarography, a stationary flux of the reagent to the electrode is maintained by its constant concentration at the outer boundary of the Nernst layer (see for example the works by Bond[1] and Damaskin and Petrii[18]), and in the version of the LPE method being considered it is maintained by the constant amplitude of the current of the emitted electrons, which, like the diffusion polarographic current, determines the height of the polarographic wave. Although the reasons for the production of the limiting current are different in the two cases being considered, the polarisation dependence of the photocurrent coincides with the polarographic wave. The range of Ω suitable for observing the polarograms of IS is restricted by the conditions of small interfering charging currents and convective mixing of the layer with a thickness $\sqrt{D/\Omega}$:

$$\tau_0^{-1} > \Omega > D/\delta^2, \tag{17}$$

where $\delta \simeq 10^{-2}$ cm is the thickness of the Nernst layer in the absence of forced mixing. The range of electrode reaction rate constants ($\kappa \simeq \sqrt{D\Omega}$) that can be measured in this range of Ω ($0.1-3 \times 10^3$ Hz) is $10^{-3}-1$ cm s^{-1}.

The form of the polarographic waves for a periodic photoemission current has been analysed.[17,19-22] The solution of Eqns. (1) and (2) under the conditions in which a periodic source is used shows that the amplitude and phase of the first harmonic of the photocurrent in the irreversible n-electron reduction of a non-adsorbed product of the capture of e_{aq}^- are given by the relationship

$$j = \frac{I}{I_0} = \left| 1 + n\frac{v_1}{v_1 + \sqrt{2i}} \right|, \quad \operatorname{tg}\Phi = -\frac{nv_1}{((1+n)v_1 + 1)(v_1+1)+1}, \tag{18}$$

where I is the measured photocurrent, I_0 the current for the formation of the IS, equal to the difference between the currents of the photoemission and the return to the electrode of the e_{aq}^- not captured by the acceptor, and $v_1 = \kappa_1\sqrt{2/D\Omega}$. When the rate constant of the reduction κ_1 obeys the equation of retarded discharge

$$\kappa_1 = \kappa_{10}\exp(\alpha\eta), \quad \eta = \frac{e}{kT}(E^0 - E), \tag{19}$$

(E^0 is the standard potential, and α the transfer coefficient), the $j(E)$ relationship has the form of a polarographic wave in which j increases from 1 to $1 + n$. The half-wave potential of the one-electron reduction, for which $j = 3/2$, is

$$E_{1/2} = E^0 - \frac{1}{2\alpha}\ln\left(0.91\frac{D\Omega}{\kappa_{10}^2}\right). \tag{20}$$

With increase in Ω, the potential $E_{1/2}$ increases in logarithmic proportion while the form of the wave is preserved. The slope of the wave in the region of $E_{1/2}$, equal to $(dj/dE)_{E=E_{1/2}}$, is independent of Ω and equal to $0.29\alpha kT/e$. The wave for the irreversible reduction of adsorbed IS is described by the relationships

$$j = \left| 1 + n\frac{W_3}{W_3 + i\Omega} \right|, \quad \operatorname{tg}\Phi = -\frac{n\Omega W_3}{(1+n)W_3^2 + \Omega^2} \tag{21}$$

and its slope in this case is approximately twice that for non-adsorbed species. The phase shift is greatest close to $E_{1/2}$, and is several times greater for adsorbed species than for non-adsorbed species. The wave for the reversible reduction of non-adsorbed IS ($X + ne^- \leftrightharpoons X^{n-}$) is described by the equation

$$j = \left| 1 + n\frac{v_1}{v_1 + v_2 + \sqrt{2i}} \right|. \tag{22}$$

Here, $v_2 = k_2\sqrt{2/D\Omega}$, where κ_2 is the rate constant of the back reaction of X^{n-} oxidation. The potential of the reversible half-wave is equal to the standard redox potential X^{n-}/X, and its slope is $nkT/4e$, like the slope of the usual reversible polarographic wave under stationary diffusion conditions.[18] The wave remains reversible, and $E_{1/2} = E^0$, when $\Omega \ll 2\kappa_{10}^2/D$. At higher values of Ω, the wave becomes irreversible, it is displaced along the E axis, its slope decreases, and a phase shift is produced. The characteristics of the E-waves for the one-electron reduction and oxidation of IS are summarised in Table 2.

The wave for the n-electron irreversible reduction with previous irreversible transformation of the primary IS ($X \rightarrow Y \rightarrow Y^{n-}$) is described by the relationship

$$j = \left| 1 + n\frac{v_1}{v_1 + \sqrt{2i}}\frac{\sqrt{\beta_1 + 2i} - \sqrt{2i}}{\sqrt{\beta_1 + 2i}} \right|. \tag{23}$$

Here, $\beta_1 = 2k_1/\Omega$, where k_1 is the rate constant of the homogeneous

‡ All the values of E except the standard values are given relative to the saturated calomel electrode.

reaction X → Y. As in the case of ordinary polarographic *CE*-waves, a limiting current determined by the rate of the chemical stage is produced. With increase in Ω, the height of the wave (the amplitude of the limiting current) decreases, and the wave is displaced to more negative potentials. When the chemical stage is reversible and the rate constant of the back reaction k_2 is appreciably greater than the rate constant of the homogeneous reaction k_1, the limiting current j_∞ is determined by the equilibrium constant of this stage:

$$j_\infty = \left| 1 + n \frac{p}{p + \sqrt{2i}} \right|, \text{ where } p = \frac{k_1}{k_2} \sqrt{\frac{k_1 + k_2}{\Omega}}. \quad (24)$$

As an example of a *CE*-wave, Fig. 4 gives the $j(E)$ relationships for the three-electron reduction of NO to NH_2OH. The reversible chemical stage preceding the electrode reaction is the protonation of NO in the presence ot NH_4^+ ions.[23]

Table 2. Characteristics of the *E*-waves of the one-electron reduction (oxidation) of the intermediate species generated by a periodic photoelectron emission current.[22]

Mechanism of reduction (oxidation)	Relationships		
	$\eta_{1/2}$ (Ω)	$(dj/d\eta)_{\eta=\eta'_{1/2}}$	$\operatorname{tg} \varphi_m^*$
$A \underset{(\varkappa_2)}{\overset{\varkappa_1}{\rightarrow}} B$	$a \ln\left(bD\Omega/\varkappa_0^2\right)$, where $a = \frac{1}{2}\alpha(\frac{1}{2}\beta)$, $b = 0.91$ (1.35)	0.294 α (0.282 β)	−0.143 (0.451)
$A_{ads} \underset{(W_3)}{\overset{W_3}{\rightarrow}} B$	$a \ln\left(b\Omega/W_0\right)$, where $a = 1/\alpha$ (1/β), $b = 0.84$ (1.73)	0.486 α (0.375 β)	−0.354 (1.73)
$A \underset{\varkappa_2(\varkappa_1)}{\overset{\varkappa_1(\varkappa_2)}{\rightleftarrows}} B$	0 (0)	0.25 (0.25)	$-0.17\sqrt{D\Omega/\varkappa_0^2}$ $\left(0.35\sqrt{D\Omega/\varkappa_0^2}\right)$
$A_{ads} \underset{W_3(W_3)}{\overset{W_3(W_3)}{\rightleftarrows}} B_{ads}$	0 (0)	0.25 (0.25)	$-0.17\,\Omega/W_0$ $(0.5\,\Omega/W_0)$
$A_{ads} \underset{\varkappa_2(\varkappa_1)}{\overset{W_3(W_3)}{\rightleftarrows}} B$	$a \ln\left(b\varkappa_0^2\Omega/W_0^2D\right)$, where $a = \frac{1}{2}(-\frac{1}{2})$, $b = 0.91$ (1.35)	0.291 (0.272)	−0.143 (0.451)
$A \underset{W_3(W_3)}{\overset{\varkappa_1(\varkappa_2)}{\rightleftarrows}} B_{ads}$	$a \ln\left(b\varkappa_0^2\Omega/W_0^2D\right)$, where $a = -\frac{1}{2}(\frac{1}{2})$, $b = 1.10$ (0.91)	0.291 (0.272)	0.143 (0.451)

* In oxidation reactions the phase shift reaches π/2. Here the values of tan ϕ for $E = E_{1/2}$ are given.

Since most IS are capable of undergoing both reduction and oxidation, the $j(E)$ relationships usually have the form of cathodic–anodic waves. For one-electron irreversible processes ($n = \pm 1$) involving non-adsorbed and adsorbed IS, their form is determined by the relationships:

$$j = \left| 1 + \frac{v_1 - v_2}{v_1 + v_2 + \sqrt{2i}} \right|, \quad \operatorname{tg} \Phi = -\frac{v_1 - v_2}{(2v_1 + 1)(v_1 + v_2 + 1) + 1}$$

or

$$j = \left| 1 + \frac{W_3 - W_2}{W_2 + W_3 + i\Omega} \right|, \quad \operatorname{tg} \Phi = -\frac{(W_3 - W_2)\,\Omega}{2W_3(W_2 + W_3) + \Omega^2} \quad (25)$$

The potential at which $j = 1$ is equal to E^*. The slope of the cathodic–anodic wave at $E = E^*$ is determined by the sum of the transfer coefficients

$$\left(\frac{dj}{dE}\right)_{E=E^*} = \frac{v^*(1 + 2v^*)}{(1 + 2v^*)^2 + 1}(\alpha + \beta)\frac{kT}{e} \text{ or}$$
$$\left(\frac{dj}{dE}\right)_{E=E^*} = \frac{2W^{*2}}{\Omega^2 + 4W^{*2}}(\alpha + \beta)\frac{kT}{e}. \quad (26)$$

Here, $v^* = \kappa^*\sqrt{2/D\Omega}$, where κ^* is the value of the constants for $E = E^*$, when the rates of oxidation and reduction are equal. According to Eqns. (26), as $\Omega \to 0$ the slope of the cathodic–anodic wave is equal to $(\alpha + \beta)kT/2e$ and decreases with increase in Ω. The wave is then split into separate cathodic and anodic components, and the difference in the half-wave potentials increases logarithmically. Splitting of the cathodic–anodic wave with increase in Ω has been observed for alkyl and hydroxyalkyl radicals.[24] The determination of the rate constants and transfer coefficients becomes possible in the split wave.

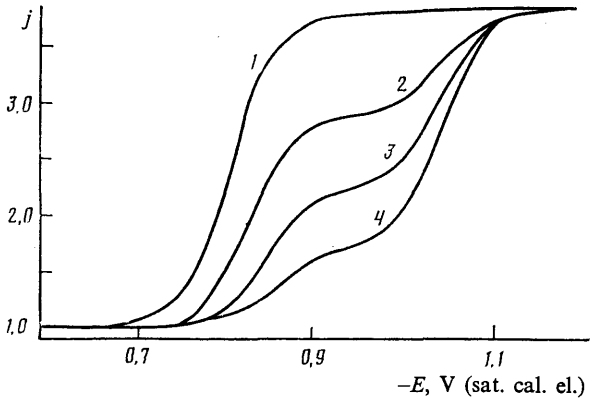

Figure 4. Polarograms for the three-electron reduction of NO, generated by a photoelectron emission current with a frequency of 1, 6.4, 29, and 87 Hz (curves *1*–*4* respectively) in aqueous 0.5 M Na_2SO_4 + 0.5 M $(NH_4)_2SO_4$ + 10^{-3} M $NaNO_2$.[23]

The analysis of the form and phase of the polarograms over a wide frequency range makes it possible to study fairly complex IS transformations.[22]

V- Time-resolved polarograms of intermediate species

The $Q(E)$ relationship at a fixed moment of time *t* for the one-electron reduction and oxidation of adsorbed IS has the form:[25]

$$q(\varphi, \tau) = \frac{Q(\varphi, \tau)}{Q_m} = 1 + (1 - \exp(-\tau(e^{\alpha\varphi} + e^{-\beta\varphi})))\operatorname{th}\frac{\alpha + \beta}{2}\varphi, \quad (27)$$

where

$$\varphi = \frac{e}{kT}(E^* - E), \quad \tau = W^*t,$$

and the rate constants of the oxidation and reduction are described by the equations for retarded discharge

$$W_2 = W^* \exp(-\beta\varphi), \quad W_3 = W^* \exp(\alpha\varphi). \tag{28}$$

Eqn. (27) describes a time-resolved cathodic–anodic wave. The quantity $q(\tau)$ is the number of electrons transferred to the solution, calculated for one IS at the moment of time t after its formation. If the species is not adsorbed, the $q(\varphi, \tau)$ relationship is described by the expression

$$q(\varphi, \tau) = 1 + (1 - w(a_1 (e^{\alpha\varphi} + e^{-\beta\varphi}))) \operatorname{th} \frac{\alpha+\beta}{2}\varphi, \tag{29}$$

where

$$w(z) = e^{z^2} \operatorname{erfc} z, \quad a_1 = \varkappa_a \frac{W^*}{W^* + W_d} \sqrt{\frac{t}{D}}. \tag{30}$$

It follows from Eqns. (27) and (29) that the splitting of the cathodic–anodic wave takes place in a narrow range $t^{-1} \sim W^*$. For $W^*t < 1$, two waves are observed with a section $q = 1$ close to E^*, which becomes narrower with increase in t. When $W^*t > 1$, one wave is produced

$$q_{in}(\varphi) = 1 + \operatorname{tn}\left(\frac{\alpha+\beta}{2}\varphi\right).$$

Fig. 5 gives the time-resolved polarograms for the CH_2OH radical. The asymmetry of the cathodic and anodic waves is due to the difference in the transfer coefficients for W_2 and W_3. If the electrode reactions are accompanied by the destruction of IS not associated with electron transfer, then the section $q = 1$ does not disappear even when $W^*t > 1$. This has been observed for CH_3 radicals,[24] whose recombination is more rapid than the electrode reactions in the region of E^*. As an example of the time-allowed polarogram of a many-electron reduction, Fig. 6 gives the $q(\varphi, \tau)$ relationships for the BrO_2 radical.[25] For $t = 0.25$ μs and 0.5 μs and $E \geqslant -0.9$ V, the radical is unable to undergo complete reduction to BrO_2^-, which is formed quantitatively at $E < -0.9$ V ($n = 1$). The bromite ion is reduced at $E < -1.15$ V. The extent of the reduction increases with increase in t and $-E$. At $t > 50$ μs, the waves for the reduction of BrO_2 and BrO_2^- are not resolved, and the overall five-electron wave for the formation of Br^- is observed.

The time-resolved polarograms obtained under charge measurement conditions can be used to study more rapid processes than when a periodic photoemission current is used.

Examples of polarograms obtained by the PECR method have been published.[2,3,26] Unlike the polarograms obtained by the LPE method, they show a broad range of E values in which $j = 0$, due to the more rapid recombination of the IS, compared with the electrode reactions.

VI. Electrode reactions of hydrogen atoms

The adsorbed hydrogen atom is an IS in the electrochemical liberation of hydrogen (ELH), which in the case of metals with a high overvoltage includes a stage involving the discharge of hydrogen ions

$$H^+(aq) + e^- \xrightarrow{\varkappa_1} H_{ads}, \tag{31}$$

the reverse ionisation stage

$$H_{ads} \xrightarrow{W_2} H^+(aq) + e^- \tag{32}$$

and electrochemical desorption, in which the proton donors (PD) are water molecules and hydrogen ions[18,27–29]

$$H_{ads} + H_2O + e^- \xrightarrow{W_{30}} H_2 + OH^- \tag{33}$$

$$H_{ads} + H^+(aq) + e^- \xrightarrow{W_{31}} H_2. \tag{34}$$

The detailed study of the polarisation relationships observed when low-frequency photocurrents ($W \gg \Omega$) are used in solutions of acids[4,5,30–33] has established that the value of E^* depends on the pH of the solution, since a linear relationship exists between the overall rate constant of the electrochemical desorption and the concentration of hydrogen ions (N_{H^+}):

$$W_3 = W_{30} + W_{31} N_{H^+}. \tag{35}$$

The sum of the transfer coefficients of reactions (32) and (34) at a mercury electrode was found to be close to 0.5. Since the transfer coefficient for the discharge of hydrogen ions (α_1) at high overvoltages is equal to 0.5 and is related to β by the detailed balance condition ($\alpha_1 + \beta = 1$), it follows from the photo-emission data that the value of α in electrochemical desorption reactions is small, that is these exothermic reactions are almost activationless.

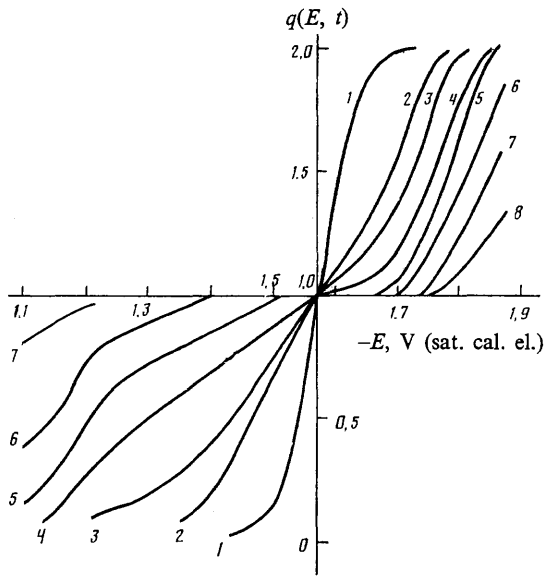

Figure 5. Time-resolved polarograms of the hydroxymethylradical adsorbed on a mercury electrode; photo-emission in 0.5 M KCl + 0.2 M CH_3OH + 2×10^{-2} M N_2O;[25] the curves correspond to the following instants of time, s: *1*, stationary; *2*, 10^{-4}; *3*, 5×10^{-5}; *4*, 2×10^{-5}; *5*, 10^{-5}; *6*, 5×10^{-6}; *7*, 2×10^{-6}; *8*, 10^{-6}.

The first measurements of the absolute values of the rate constants of electrochemical desorption[8] showed that W_3 is about 10^6 s^{-1}. Quantitative measurements have been carried out.[31,34–36] The kinetic curves $Q(t)$ are exponential, that is the hydrogen atoms take part in the electrode reactions after adsorption. The overall rate constant is described by Eqn. (35). The values of W_{30} and W_{31} are given in Table 3. It has been found[33,34] that the rate constant of reaction (34) on mercury and bismuth shows an exponential

dependence on the electrode potential, but is independent of temperature (Fig. 7). This relationship, which differs from that expected from the theory of retarded discharge, has been attributed[29,34,35] to the tunnel transfer of an electron from the metal to the reaction complex $H_{ads}-H_3O^+$. Since the change in the height of the barrier for electron tunnelling is equal to the change in the electrode potential, the rate constant of the tunnel electrode reaction shows an exponential dependence on E, but is independent of T. The electron transfer is accompanied by a simultaneous quantum displacement of the proton along the reaction coordinate, and this is the reason for the observed isotopic H/D effect. The model[34,35] predicts a decrease in W_{31} and an increase in the isotope effect with increase in both the energy of the M–H bond and the energy of reorganisation along the coordinate of the proton. The increase in the isotope effect on going from Hg to Bi and Ga (Table 3), when the energy of the bond between the H atom and the metal surface increases by 30–34 kJ mol,[37] is apparently due to the first of these factors, and the fact that the isotope effect is greater for Ga than for Bi indicates that reaction (34) involves a greater quantum displacement of the proton on the gallium electrode. This suggestion agrees with the high values of the isotope separation factors for hydrogen and tritium, characteristic of ELH reactions on Ga.[28] The measured values of W_{31} correspond to an electron tunnelling length of 4–5 Å for a height of the parabolic barrier of about 1.5 eV. The $W_{31}(E)$ relationship is described by the expression

$$W_{31}(E) = W_{31}(E^0)\exp\left(\frac{e(E^0-E)}{\gamma}\right), \qquad (36)$$

in which the value of γ is related to the tunnelling parameters of the electron and the proton. The values of γ for Hg, Bi, and Ga are 0.12, 0.18, and 0.17 eV respectively.

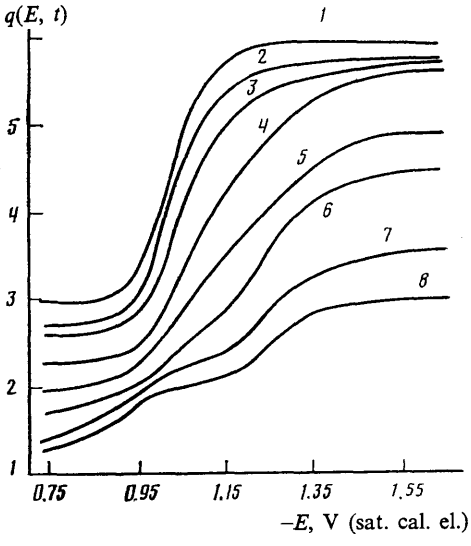

Figure 6. Time-resolved polarograms of the five-electron reduction of the BrO_2 radical in 0.5 M KCl + 10^{-2} M $KBrO_3$ solution;[25] the curves correspond to the following instants of time, s: *1*, stationary; *2*, 10^{-4}; *3*, 5×10^{-5}; *4*, 10^{-5}; *5*, 3×10^{6}; *6*, 10^{-6}; *7*, 0.25×10^{-6}.

The rate constant of reaction (33) depends little on E (Table 3), and its temperature dependence is characterised by an activation energy of ~15 kJ mol^{-1}, which remains unchanged in the electrode potential. The mechanism of this reaction has not been satisfactorily explained. From the value given for the activation energy, typical of dipole relaxation in water, and the times of this relaxation in the double layer ($10^{-8}-10^{-7}$ s),[38] it has been suggested[36] that the rate of reaction (33) is limited by the rate of the orientational rearrangement of the water molecules in the reaction complex. The values of W_{30} correspond to the bimolecular rate constants of reaction (33), which are ~10^{-3} times smaller than those for reaction (34).

Table 3. Rate constants of the electrochemical desorption of hydrogen and deuterium.[35,36]

Constant	Electrode	Value* of the constant at −E, V					
		0.9	1.0	1.1	1.2	1.3	1.4
$10^{-6}W_{30}$, s^{-1}	Ga **	—	1.9	2.1	2.8	3.6	4.3
			1.0	1.0	1.6	1.8	2.1
	Hg	1.0	1.6	3.1	5.7	9.0	—
		0.9	1.5	3.0	4.0	7.8	—
	Bi	—	0.03	0.09	0.13	0.16	0.18
			0.02	0.05	0.05	0.08	0.09

	Bi	—	0.06	0.11	0.16	0.30	0.54
			0.03	0.05	0.07	0.15	0.27

* The upper row refers to H atoms, and the lower row to D atoms [$D^+(aq)$ ions in D_2O].
** Liquid electrode at 38 °C.

Ammonium ions are stronger PD than water molecules. The rate constants of electrochemical desorption involving them

$$H_{ads} + NH_4^+ + e^- \rightarrow H_2 + NH_3 \qquad (37)$$

on mercury are ~50 times greater than those for reaction (33) for identical values of $\gamma \simeq 0.18$ eV.

The ratio W_{31}/W_{30} increases with increase in $-E$ (Table 3), so that at low overvoltages, reaction (33) becomes the main reaction.

The electron transfer coefficient in electrochemical desorption from a polycrystalline gold electrode at $E \geqslant -0.1$ V increases to ~0.5,[32] that is there is a change from the activationless reaction to the normal reaction described by Eqn. (19), in accordance with the general ideas of the theory of electrode reactions.[28]

By comparing the values of W_3 measured by the LPE method with the ELH current

$$j_0 = 2ex_1N_{H^+}W_3/(W_2 + W_3), \qquad (38)$$

it is possible to find the surface concentration of H_{ads}:

$$\Gamma_H = j_0/2eW_3. \qquad (39)$$

Eqn. (39) follows directly from the quasi-stationary character of the ELH current, and is not based on any model considerations. The calculated $\Gamma_H(E)$ relationships are given in Fig. 8. The values

of Γ_H depend little on N_{H^+}, since W_3, like j_0, is proportional to N_{H^+}, when $W_{31}N_{H^+} > W_{30}$. The increase in Γ_H on going from Hg to Ga and Bi is due to the increase in κ_1, and the fact that the values of Γ_H are higher on Bi than on Ga is due to the decrease in W_3. The value of Γ_H does not exceed 3×10^{12} cm^{-2} on all three metals, and is small for measurements by the usual electrochemical methods.

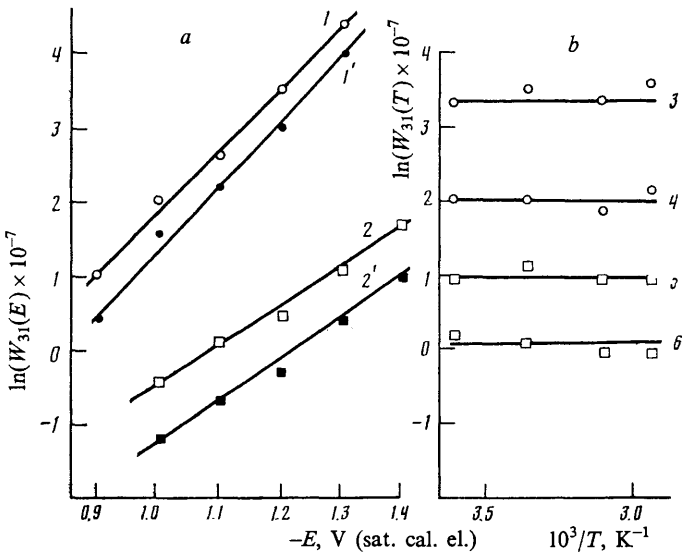

Figure 7. Dependence of the rate constant of the electrochemical desorption of hydrogen according to reaction (34) on the electrode potential (*a*) in H_2O (straight lines *1* and *2*) and D_2O (*1'*, *2'*) and on temperature (*b*) (straight lines *3*–*6*) on mercury (*1*, *1'*, *3*, *4*) and bismuth (*2*, *2'*, *5*, *6*) electrodes; the $W_{31}(E)$ relationships were measured at 22 °C, and $W_{31}(T)$ at $-E$ = 1.2, 1.0, 1.3, and 1.1 V (straight lines *3*–*6* respectively).[34]

The rate constants for the ionisation of H_{ads} on Hg were first measured by Benderskii and co-workers.[39,40] The $W_2(E)$ relationship is given in Fig. 9. In the range of E values from −0.6 V to −0.2 V, W_2 increases from 10^5 s^{-1} to 2×10^7 s^{-1} (β = 0.4–0.5), and in the range from −0.2 V to −0.1 V the transfer coefficient β decreases to 0.05–0.1. The decrease in β means that close to the equilibrium potential of ELH, the transfer coefficient for the direct reaction of hydrogen ion discharge (31) increases, tending to $\alpha_1 \simeq 1.0$, that is the Tafel law ($\alpha_1 = 0.50 \pm 0.05$), applicable for ELF at high overvoltages,[29,41] breaks down, and reaction (31) becomes barrierless. The suggestion that there is no barrier to the discharge of hydrogen ions at low overvoltages was previously put forward[42] (see also the book by Krishtalik[28]) on the basis of the fact that the overvoltage is independent of the composition of concentrated solutions of the anions adsorbed, although the data obtained,[42] like those in subsequent studies,[30,31] did not exclude a change not to barrier-free discharge but to quasi-equilibrium ($W_2 \gg W_3$) discharge, when it follows from Eqn. (38) that the effective transfer coefficient also becomes equal to 1. The results obtained by Babenko and co-workers[40] provide direct experimental confirmation of the existence of the barrier-free electrode processes assumed by Krishtalik.[42]

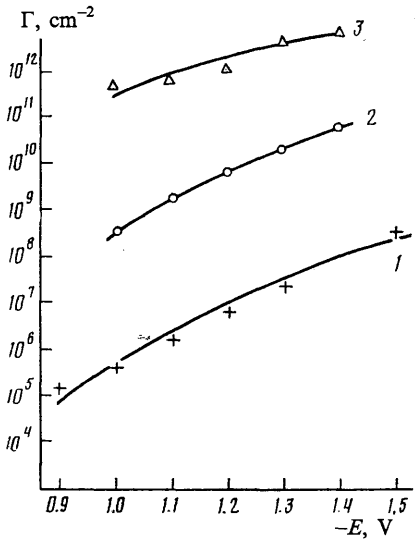

Figure 8. Surface concentration of hydrogen atoms adsorbed on mercury (*1*), liquid gallium (*2*), and bismuth (*3*).[36]

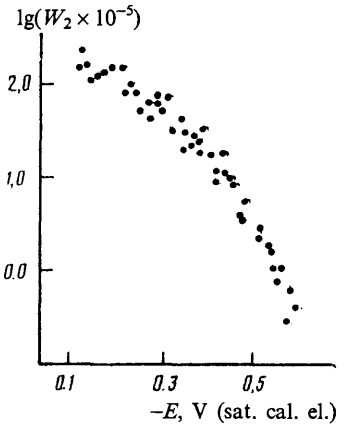

Figure 9. Dependene of the rate constant of the ionisation of hydrogen, adsorbed on mercury, on the electrode potential (0.3 M aqueous NaF solution with the addition of 0.01–0.03 M HF).[40]

As a result of the change in the transfer coefficients, the ELH exchange current on mercury is ~150 times smaller than that calculated by extrapolating the Tafel law to zero overvoltage (3×10^{-15} A cm^{-2} instead of 4×10^{-13} A cm^{-2}). A decrease in β analogous to that observed[40] for the mercury electrode was also observed on Au.[32] According to the detailed equilibrium principle,

the rate constants of reactions (31) and (32) are related by the thermodynamic expression

$$\frac{\kappa_1(E)}{W_2(E)} = \frac{\Gamma_H^0}{N_{H^+}^0} \exp\left(\frac{\Delta G(E)}{RT}\right), \quad (40)$$

where ΔG is the free energy of the discharge of $H^+(aq)$, and the values of Γ_H^0 and $N_{H^+}^0$ relate to the standard states. Eqn. (40) and the measured values of W_2 and j_0 can be used to find ΔG. When $\Gamma_H^0 = 10^{15}$ cm^{-2} (degree of coverage 1/2) is taken as standard state, the standard free energy ΔG^0 is 99.4 ± 3 kJ mol^{-1} (1.03 ± 0.03 eV). This agrees with the value found[42] from the temperature dependence of the barrier-free discharge current. The free energy of the adsorption of H atoms on mercury, equal to $\Delta G_H^0 - \Delta G$, is −104.1 ± 3 kJ mol^{-1}. The entropy of H_{ads}, according to an estimate[39] from the frequencies of the vibrations of the H atoms on the surface, does not exceed 8 J mol^{-1} K^{-1}, so that the energy of the Hg−H bond in the adsorbed state ($E_H = -\Delta G_a - T\Delta S_a$) is 136 ± 6 kJ mol^{-1}, confirming Frumkin's estimate of this quantity.[43]

Table 4. Values of E^0 and E^* for the two-electron stages of the electrochemical carbon cycle.[50]

Stage	pH	E^0, V (NHE)	E^*, V (NHE)
I. $CO_2+2e^-+2H^+ \rightarrow H_2CO_2$	0	−0.19	−0.73*
	3	−0.36	−1.04
	4.7	−0.43	−1.23
	7.0	−0.47	−1.23
II. $H_2CO_2+2e^-+2H^+ \rightarrow H_2CO+H_2O$	0	−0.01	−0.99*
	2.5	−0.15	−1.16
	3.5	−0.21	−1.23
	7.0	−0.58	−1.27
III. $H_2CO+2e^-+2H^+ \rightarrow CH_3OH$	0	0.24	−0.97*
	3.5	0.04	−1.06
	5.0	−0.06	−1.11
	7.0	−0.17	−1.17
IV. $CH_3OH+2e^-+2H^+ \rightarrow CH_4+H_2O$	0	0.58	−0.87*
	7.0	0.17	−0.87

*Obtained by extrapolating the E^* (pH) relationships.

The facts that α_1 is constant over a large range of change in κ_1, which for ELH reactions on mercury reaches 10^{12}, and that α_1 increases from 0.5 to 1.0 at low overvoltages, have been explained quantitatively using a theoretical model developed by Benderskii and co-workers.[29,44–46] In this model, the view that there is a reorganisation of the polar medium on electron transfer is supplemented by taking account of the simultaneous quantum displacement of the proton.[47,48] Allowance for the inter-related movement of the proton and the medium leads to the following expression for the rate constant of hydrogen ion discharge:

$$\kappa_1 = \kappa_1^0 N_{H^+} \exp\left(-\frac{(E_s + E_p + \Delta G^0 - e(E_H^0 - E))^2}{4E_s kT + F^2\delta^2}\right), \quad (41)$$

where E_s and E_p are the energies of reorganisation along the coordinates of the medium and the proton respectively; δ the amplitude of the zero-point vibrations of the proton in the initial state; F the curvature of the proton term of the final state M−H; E_H^0 the potential of the normal hydrogen electrode (NHE); and κ_1^0 a pre-exponential term determined by the rate of tunnel electron transfer. According to Eqn. (41), the Tafel law applies for

$$e(E_H^0 - E) < E_s + E_p + \Delta G^0, \quad (42)$$

that is the reason for its applicability over a wide range of E is the high total energy (~3.3 eV, as shown below) of the reorganisation (the intramolecular reorganisation and that of the environment of the reaction complex).

The discharge becomes barrier-free when[46]

$$\Delta G^0 > E_s\left(1 - \frac{4kT}{\hbar\omega}\right) + e(E_H^0 - E), \quad (43)$$

where ω is the frequency of the vibrations of the proton in the initial state. The theoretical model describes the change in $\kappa_1(E)$ in the range of both normal and barrier-free discharge, where the value of κ may change by a factor of more than 10^{18}. The values of E_s and E_p are 1.75 eV and 1.55 eV respectively. Thus the LPE method, which makes it possible for the first time to measure the absolute values of the rate constants of rapid ELH reactions, has led to the development of existing ideas on the mechanism of one of the most fundamental electrochemical processes.

VII. Intermediate species of the electrochemical carbon cycle

The electrochemical reduction of carbon dioxide to methane (the electrochemical carbon cycle) is an eight-electron process in which stable products: formic acid, formaldehyde, methanol, and methane, are formed at each of the successive two-electron stages. The redox potentials of these stages are given in Table 4. In acidic and neutral solutions in the absence of overvoltage, all the stages of the carbon cycle should have an appreciable rate even in the region of E_H^0. The overvoltage of stages (I) and (III), however, is greater than 1 V, and the reduction of H_2CO_2 and CH_3OH in aqueous solutions requires even higher overvoltages.[49] As in ELH reactions, the overvoltage is due to the formation of high-energy IS. An important role in the study of their electrochemistry was played by work[2,3,50–52] carried out by the PECR method, which established that for the radicals of the carbon cycle CHO, CH_2OH, and CH_3 there exists a fairly wide range of potentials in which the rate constants of the oxidation and reduction are lower than 10^3 s^{-1}. The relative electrochemical stability of the radicals and the weak pH dependence of the potentials of the polarographic waves of CH_3 and CH_2OH indicated that the products of the electrode reactions of the radicals are the high-energy organic ions CHO^-, CH_2OH^-, and CH_3^-, which then undergo homogeneous transformations into stable products (CH_2O, CH_3OH, and CH_4 respectively), whereas the exothermic electron−proton transfer reactions

$$R + e^- + H^+(aq) \rightarrow RH \quad (44)$$

take place at very low rates. The formation of CH_3^-, and not CH_4, in the reduction of CH_3 has been confirmed.[53] Calculation of the free energy of reactions (44) [2,54] also shows that the formation of HCO and CH_3 radicals cannot be responsible for the high overvoltage of stages (II) and (IV), that is the mechanism of the reactions of the carbon cycle is much more complex than a simple sequence of one-electron stages involving the formation and reduction of radicals. Low rates of reactions (44) have also been observed for many homogeneous processes associated with the formation of a CH bond with proton transfer.[55]

Each of the two-electron stages of the carbon cycle can be represented by the scheme

$$A \underset{W_2}{\overset{W_1}{\rightleftharpoons}} R \underset{W_4}{\overset{W_3}{\rightleftharpoons}} B, \tag{45}$$

which leads directly to the relationship between E^* and the standard potential B/A:

$$E^* = E^0 - \frac{kT}{e(\alpha+\beta)} \ln \frac{W_2^0}{W_3^0}, \tag{46}$$

where the rate constants of the electrode reactions of the radical W_2^0 and W_3^0 refer to the potential E^0 at which the two channels for the transformation of R have the same free energy. Since the rates of the transformation of the same species by two channels of equal energy under identical conditions cannot differ greatly, E^* and E^0 should be approximately equal. Thus by comparing the values of E^* and E^0 for the stages of the carbon cycle it is possible to establish whether the stable species listed in Table 4 are the products of the electrode reactions of the radicals.

The rate constants of the electrode reactions of the radical ion CO_2^- have been measured by the LPE method.[56,57] The $W_2(E)$ and $W_3(E)$ relationships are given in Fig. 10. The fact that the kinetic curves $Q(t)$ are exponential indicates that the electrode reactions involve adsorbed IS. Oxidation is observed at $E > -1.4$ V, W_2 is independent of pH and is equal to 3.5×10^6 s^{-1} at -1.35 V, and $\beta = 0.55-0.65$. Reduction takes place at $E < -1.5$ V, and $\alpha = 0.25-0.30$. The value of W_3 is linearly dependent on N_{H^+}. The participation of hydrogen ions in the reduction is confirmed by the marked isotope effect; the value of W_3 in H_2O solutions is three times that in D_2O. There is no isotope effect in the oxidation. The pH dependence of E^* is described by Eqns. (35) and (46);

for $W_{31}N_{H^+} \gg W_{30}$, the derivatives of $\frac{dE^*}{d\,pH} = -\frac{2.3}{\alpha+\beta}\frac{kT}{e}$,

and for $W_{31}N_{H^+} < W_{30}$ (pH $\geqslant$ 4.5), the potential E^* is constant. The polarograms obtained[53,56,57] for the CO_2^- ion generated by a low-frequency photo-emission current ($\Omega \ll W_2 + W_3$) give the sum of the transfer coefficients, which correspond to the values found by the pulse method.

According to Buxton and Sellers,[58] pK for the carboxyl radical HCO_2 is 1.4, so that in the solutions with pH $\geqslant$ 2.5 in which the LPE was measured, the IS are present as the radical ion CO_2^-. On adsorption on a negatively charged metal surface, the IS is apparently converted into the protonated form. The electrode reactions take place according to the equations:

$$HCO_2 \xrightarrow{W_2} CO_2 + H^+ + e^-,$$

$$HCO_2 + e^- + H^+ \xrightarrow{W_3} H_2CO_2. \tag{47}$$

At pH $\geqslant$ 4.5, water molecules become the main proton donors. From the numerical values of the constants found by the LPE method, it follows that in the region of E^* there is a change from the quasi-equilibrium reduction of CO_2 ($E > E^*$, $W_2 > W_3$) to ordinary reduction, and this change, in accordance with Eqn. (38), is in fact accompanied by a decrease in the effective transfer coefficient from $1 + \alpha$ to $1 - \beta$.[59] The measured[59] polarisation dependence of the current of the two-electron reduction of CO_2 coincides with the curves calculated from the LPE data using Eqn. (38). This means that the oxidation product of HCO_2 is CO_2. Comparison of the reduction current of CO_2, that is the values of κ_1, with W_2 made it possible, using Eqn. (40), to find the standard free energy of the reaction

$$CO_2 + e^- + H^+(aq) \rightarrow HCO_{2\,ads}, \tag{48}$$

equal to $\sim$154 kJ mol^{-1}. The coverage of the mercury surface by the radical does not exceed 10^8 particles cm^{-2}.

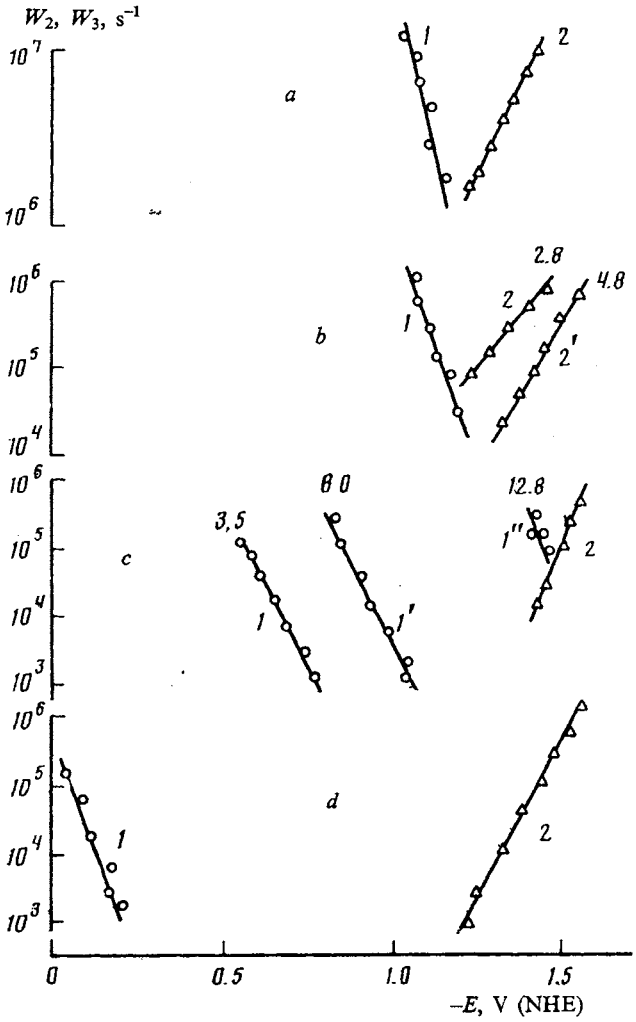

Figure 10. Tafel relationships for the rate constants of the oxidation (*1*, *1'*, *1''*) and reduction (*2*, *2'*) of the radicals CO_2^- (*a*), HCO (*b*), CH_2OH (*c*), and CH_3 (*d*) of the electrochemical carbon cycle at a mercury electrode; the pH values are given at the straight lines; for the other reactions, W_2 and W_3 are independent of pH.[54]

The electrode reactions of formyl radicals adsorbed on mercury have been studied.[60] As in the case of HCO_2, the rate constant for the oxidation of HCO [or its hydrated form $HC(OH)_2$] is independent of pH, and W_3 increases with decrease in pH, indicating that the reduction of the radical involves one hydrogen ion.

The values of W_2 and W_3 (Fig. 10) change from 10^4 s^{-1} (at $-E$ = 1.3–1.5 V) to 10^6 s^{-1} (at $-E$ = 1.5×1.8 V) (β = 0.45, α = 0.27). E^* changes in accordance with the pH dependence of W_3 (Table 4). At pH ⩾ 4, the reduction involves water molecules, leading to a change in the transfer coefficient (α' = 0.35).

The difference $E^0 - E^*$ for the carboxyl and formyl radicals (Table 4) is such that it corresponds to a difference in W_2^0 and W_3^0 in Eqn. (46) by $10^{10}-10^{15}$. The unrealistic value of this difference indicates that the reduction of these radicals involves the formation of products with much higher energies than formic acid and formaldehyde. The fact that the reduction involves one electron and one proton shows that these species with higher energy must be isomers of these stable compounds. A high-energy isomer of formaldehyde is hydroxymethylene HCOH, formed, in particular, by the recombination of HCO and H after the photodissociation of H_2CO.[61] According to published data,[61,62] the energy of the ground state of HCOH is ~2.2 eV greater than that for H_2CO, so that the value of E^0 for the reaction

$$H_2CO_2 + 2H^+ + 2e^- \rightarrow HCOH + H_2O \qquad (49)$$

is close to –1.1 V and corresponds to the measured values of E^*. By analogy with the formyl radical, the product of the one-electron reduction of HCO_2 is apparently dihydroxymethylene $C(OH)_2$ [or its anion $C(OH)O^-$ in the reduction of CO_2^-]. These carbene derivatives subsequently undergo homogeneous isomerisation to H_2CO and H_2CO_2. Judging from a quantum-chemical calculation,[61] the barrier to the intramolecular rearrangement of *cis*-hydroxymethylene into H_2CO is ~50 kJ mol^{-1}, and the lifetime of HCOH in the gas phase is 4 μs.[63] The formation of carbene derivatives in electron–proton transfer reactions is consistent with the existing view that the hydrogen atom adds on to oxygen much more readily than to carbon.[55]

The methanol radical[64–66] is electrochemically much less active than HCO_2 and HCO; the constants W_2 and W_3 are 10^2-10^5 s^{-1} (Fig. 10). The rate constant for the reduction of CH_2OH adsorbed on mercury is independent of pH in the range 3–13, and remains unchanged when 1 M NH_4^+ ions as PD are added to the solution. The transfer coefficient for W_3 is 0.68. Unlike W_3, the rate of oxidation increases sharply with increase in pH, and change in pH also leads to a change in the transfer coefficient. In the pH range 3.5–7, β = 0.63, and the displacement of E with change in pH at constant W_2 (dE/dpH) is ~0.06 V. In the pH range 8–12, β = 0.3, and dE/dpH ≃ 0.16, corresponding to a first order reaction with respect to OH^- ions. At pH ⩾ 12.5, at which the radical is present in the ionic form (pK = 10.6[3]), W_2 is independent of pH, and β = 0.5. The dependence of W_2 and W_3 on pH and E corresponds to the reactions

$$CH_2OH + OH^- \rightarrow CH_2O + H_2O + e^-,$$
$$CH_2OH + e^- \rightarrow CH_2OH^-. \qquad (50)$$

At pH ⩽ 8, water molecules act as hydrogen acceptors in the oxidation of the radical. Because of the relatively low values of W_2 and W_3, the surface concentration of the radical increases to such an extent that its electrode reactions can be detected by ordinary electrochemical methods, in particular by the cyclic voltammetric study of formaldehyde solutions. The $\Gamma(E)$ relationships calculated using Eqn. (39) from the polarisation curves for the reduction of H_2CO[49] are given in Fig. 11. They agree with published data;[49,67,68] appreciable accumulation of the radical is observed in the pH range 6.8–9.0, and is not recorded in more alkaline solutions. The position and height of the maxima of the anodic current on the voltammetric curves[67,68] coincide with those calculated from the measured[66] constants W_2 and W_3. The published[66] comparison of the LPE and cyclic voltammetric data shows that the IS generated in photo-emission and in the reduction of CH_2O are identical. In both cases the IS is CH_2OH. The fact that W_3 is independent of pH, indicating that hydrogen ions do not take part in the reaction, the high transfer coefficient, characteristic of endothermic reactions, and the large difference in the potentials E^* and E^0 for the formation of CH_3OH from CH_2O (Table 4) show that the reduction product of formaldehyde is the carbanion CH_2OH^-, and not methanol. The calculated[69] energy of the tautomerisation of the methoxide ion CH_3O^- into CH_2OH^- is ~93 kJ mol^{-1}. The potential E^0 for the reaction

$$CH_2O + 2e^- + H^+ \rightarrow CH_2OH^-(aq), \qquad (51)$$

calculated from this value and pK for CH_3OH, agrees with the measured value of E^*. The free energy of the adsorption of CH_2OH on mercury is –40 kJ mol^{-1},[66] and for HCO_2, ΔG_a = –44 kJ mol^{-1}.[56]

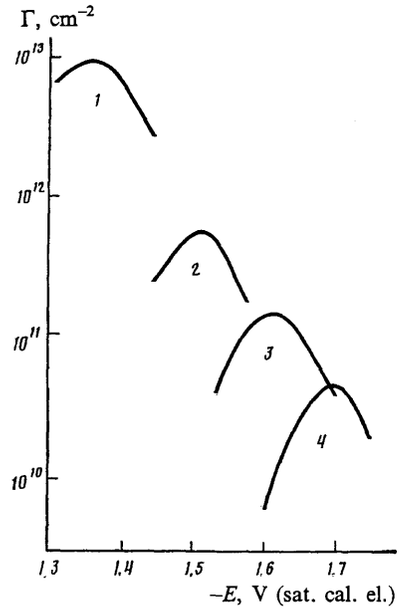

Figure 11. Surface concentration of the CH_2OH radical in the reduction of formaldehyde at a mercury electrode at different pH values: *1*, 6.8; *2*, 9.0; *3*, 11.1; *4*, 13.0.[66]

The reduction of CH_3 also takes place without the participation of PD, and leads to the formation of the CH_3^- anion, whose free energy has been calculated.[3]

The diagram of the free energies of the successive one-electron reactions of the electrochemical carbon cycle, based on the values of E^* given in Table 4 for stages (I)–(III) and the thermodynamic characteristics of the free radicals,[70] is given in Fig. 12. In a neutral

solution, the free energy of the overall process

$$CO_2 + 8\,H_2O + 8\,e^- \rightarrow CH_4 + 8\,OH^- \qquad (52)$$

is 204 kJ mol^{-1}. The additional energy losses at each of the two-electron stages are due to the transformation of the reduction products of the radicals $C(OH)_2$, HCOH, CH_2OH^-, and CH_3^- into H_2CO_2, H_2CO, CH_3OH, and CH_4 respectively, and amount to 755 kJ mol^{-1}. From this it follows that the energetic efficiency of the electrochemical carbon cycle does not exceed 21%. Since the energy losses are due to the formation of the carbanions CH_2OH^- and CH_3^-, which are not adsorbed on the negatively charged electrode surface, the efficiency of the corresponding stages is the same for different metals. Thus even the energy efficiency (without allowance for current losses) of the sequence of one-electron reactions being considered is extremely low, so that it is important to find catalytic electrochemical systems in which either two-electron transfer without the intermediate formation of radicals or simultaneous electron transfer and proton addition with the formation of a CH bond are possible.

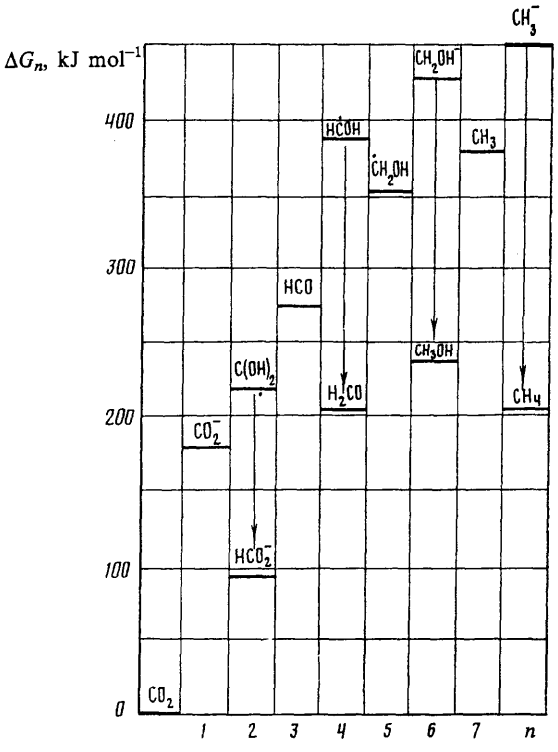

Figure 12. Free energies of the reactions of the electrochemical carbon cycle at pH 7.

VIII. Electrochemistry of alkyl and hydroxyalkyl radicals

Alkyl radicals are IS in the two-electron reduction of alkyl halides;[71] they are also formed in the one-electron reduction of alkylmercury compounds.[72,73] The PECR method gave the polarograms of CH_3 at a mercury electrode 10^{-5} s after a radiolysis pulse, and detected a wide range of potentials in which the CH_3 radical is electrochemically inactive.[2] It has been suggested that the reduction product of CH_3 is the carbanion CH_3^-, and not methane.[2,53,72,73] The rate constants of the electrode reactions of alkyl radicals could not be measured by electrochemical methods, since their recombination is a multi-stage process. It has been suggested[72,74] that the formation of HgR_2 is preceded by the rapid formation of the organic calomel Hg_2R_2, capable of dissociation, and that the radicals are present on the mercury surface as HgR. The rate constants of the heterogeneous reactions of these radicals have been measured by the LPE method.[24] In the working range of the mercury electrode ($E < -0.1$ V), only the oxidation of CH_3 is observed. The Tafel straight lines $\ln W_3(E)$ are displaced to more negative values of E in the series CH_3, C_2H_5, n-C_3H_7, n-C_4H_9. There exists a wide range of E (for CH_3, for example, from -0.6 V to -1.3 V) in which there are no IS electrode reaction currents, that is the rates of these reactions are lower than the rate of surface recombination. An analysis of the polarograms recorded at different Ω gave the rate constants of the last process, which takes place according to the scheme

$$\begin{array}{ccccc} CH_3Hg^+ & \overset{W_2}{\leftarrow} & CH_3Hg & \overset{W_3}{\rightarrow} & CH_3^- + Hg^+ \\ & \gamma\downarrow & \uparrow k_2 & & \\ & & (CH_3)_2Hg_2 & \overset{k_3}{\rightarrow} & (CH_3)_2Hg \end{array} \qquad (53)$$

with $\gamma = 5 \times 10^{-9}$ cm^2 s^{-1}, $k_2 = 3 \times 10^2$ s^{-1}, $k_3 \simeq 20$ s^{-1}. The values of the constants correspond to the cyclic voltammetric curves for the radical.[73] The surface concentrations of the radical (Γ_R) and the dimer (Γ_d) in the kinetic scheme (53) are:

$$\Gamma_R = \frac{W}{2m\gamma}\left(\sqrt{1+\frac{4mj_R}{W^2}}-1\right), \quad \Gamma_d = \frac{m\gamma}{k_3}\Gamma_R^2, \quad m = \frac{k_3}{k_2+k_3}, \qquad (54)$$

where j_R is the current of the electrochemical or photo-emission formation of CH_3. In the range in which the radical is electrochemically stable ($W < \gamma\Gamma_R$), the adsorbate exists chiefly as the dimer ($\Gamma_d \gg \Gamma_R$). When the rate of the electrode reactions increases to such an extent that $W > \gamma\Gamma_R$, the concentrations Γ_R and Γ_d decrease, and $\Gamma_R > \Gamma_d$. During the cyclic scanning of the potential in the range corresponding to the reduction of RHg^+, the dimer accumulates, and the limiting stage of the reduction at $E \leqslant -1.3$ V becomes its decomposition to radicals with rate constant k_2.

According to PECR data,[50,75] the α-ethanol radical CH_3CHOH, which is an IS in the reduction of acetaldehyde, is oxidised with a rate constant W_2 which decreases from 10^5 s^{-1} to 10^4 s^{-1} in the range of E values from -1.0 V to -1.3 V. The $W_2(E)$ and $W_3(E)$ relationships for this radical, measured by the LPE method,[21,76] are similar to the corresponding relationships for the CH_2OH radical (see Fig. 10). The reduction rate constant W_3 is independent of pH. The $W_3(E)$ relationships measured in the range $10-10^3$ s^{-1} and 10^4-10^5 s^{-1},[75,76] lie on the same Tafel straight line, and in this case the transfer coefficient α is 0.5. The constant W_2 increases with pH at pH > 8, in agreement with the fact that the oxidation is first order with respect to OH^- ions [see Eqn. (50)]. At pH < 7, the constant W_2 is independent of the acidity, that is the radical is oxidised to the aldehyde with the formation of a hydrogen ion.

The $W_2(E)$ and $W_3(E)$ relationships for the isopropyl alcohol radical at different pH values (Fig. 13) show that the oxidation and reduction of this radical take place by the same mechanism as the transformations of CH_2OH and CH_3CHOH. Studies of the electrochemical reduction of acetone[77,78] have shown that the adsorbed radical $(CH_3)_2COH$ is the IS in this process.

At $E > -1.3$ V, the formation of the radical in acidic solutions takes place in quasi-equilibrium fashion ($W_2 > W_3$), so that under the conditions of a cyclic increase in E, the IS is oxidised almost quantitatively to acetone. The absolute values of W_2, measured by the potential jump method,[77] increase from 10^4 s^{-1} to 4×10^4 s^{-1} with increase in E from –1.3 V to –1.23 V ($\beta = 0.5$). The formation of the radical in the reduction of acetone is a first-order reaction with respect to hydrogen ions. The order of magnitude of the values of W_2 measured by the LPE method agrees with that of published data;[77] the β values also coincide. A quantitative comparison of the results obtained by these two methods is difficult, because of the difference in the pH and acetone concentrations at which the measurements were carried out (pH < 1 and $N_a \simeq 4$ M in the study of Brown and Lister,[77] and pH $\geqslant$ 4 and $N_a \leqslant 0.5$ M in the LPE measurements). Since acetone and the radical are adsorbed on mercury, the values of W_2 correspond to different degrees of coverage of the surface. The values of W_3 measured by LPE and low-frequency photoemission methods[21,64] at pH $\geqslant$ 4 are smaller by factors of 10^3-10^4 than those corresponding to the current for the reduction of acetone to isopropyl alcohol at pH $\leqslant$ 1.[77] This difference indicates that in strongly acidic solutions, the reduction of the radicals involves hydrogen ions:

$$(CH_3)_2COH + e^- + H^+ \rightarrow (CH_3)_2CHOH, \quad (55)$$

whereas at pH $\geqslant$ 4, as in the case of CH_2OH and CH_3CHOH, the reduction product is the carbanion $(CH_3)_2COH^-$. With two parallel channels for the quasi-equilibrium formation of the radical, the reduction current of acetone is given by the relationship

$$j_0 = 2e\Gamma_0 \frac{W_1}{W_2} N_{H^+}(W_{30} + W_{31}N_{H^+}), \quad (56)$$

where Γ_0 is the surface concentration of acetone, and W_1 the rate constant for its reduction to the radical, equal to 3×10^2 s^{-1} at $E = -1.28$ V in 0.5 M H_2SO_4 solution ($\alpha_1 = 0.5$).[77] It follows from Eqn. (56) that $j_0 \sim N_{H^+}^2$ when $W_{31}N_{H^+} > W_{30}$, in agreement with published data.[78] Comparison of the values of W_{30} and W_{31} measured by the LPE and potential jump methods shows that at pH 3, $W_{31}N_{H^+} \simeq W_{30}$. In alkaline solutions, the main reduction product of acetone is pinacone, which, as suggested as early as 1927,[79] is formed either by the bimolecular recombinations of the radicals or by the reaction of acetone with the carbanion. With increase in pH, the rate constant W_2 increases, and the reduction of acetone takes place at more negative potentials, at which, as a result of the increase in W_3, the concentration of the radical decreases [see Eqn. (39)], as in the case of the methanol radical (see Fig. 10). The decrease in Γ with increase in pH does not agree with the first of these mechanisms, whereas with increase in W_3, which indicates an increase in the rate of formation of the carbanions, it is possible to explain the increase in the yield of pinacone in alkaline solutions.

According to PECR [2,3] and LPE data, the reduction of the β-ethanol radical CH_2CH_2OH involves one hydrogen ion:

$$CH_2CH_2OH + e^- + H^+ \rightarrow C_2H_4 + H_2O. \quad (57)$$

The values of W_3 change from 10 s^{-1} to 10^5 s^{-1} in the range of E values from –0.65 V to –1.34 V at pH 5.5 ($\alpha \simeq 0.4$). The marked displacement of the reduction potential of the radical into the cathodic range compared with the expected potential for the production of ethylene according to Eqn. (57), for which the free energy is –131 kJ mol^{-1}, indicates that the reaction product is the adsorbed biradical CH_2-CH_2. This is consistent with the high overvoltage observed in the electrochemical synthesis of cycloalkanes from their dihalogeno-derivatives,[71] taking place at $E \leqslant -2.0$ V.

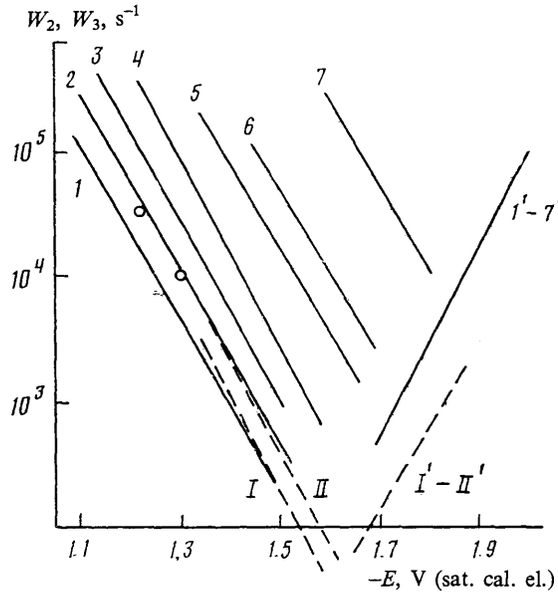

Figure 13. Tafel relationships for the rate constants of the oxidation (*1*–*7*) and reduction (*1'*–*7'*) of the isopropyl alcohol radical adsorbed on a mercury electrode at different pH values: *1*, *1'*, pH 4.25; *2*, *2'*, pH 6.8; *3*, *3'*, pH 7.35; *4*, *4'*, pH 8.1; *5*, *5'*, pH 9.15; *6*, *6'*, pH 10.0; *7*, *7'*, pH 10.8; the points give the values measured by Brown and Lister,[77] and the broken lines the data of Rotenberg and Rufman;[64] the straight lines *I* and *I'* were obtained at pH 4.6, and *II* and *II'* at pH 7.0.

Mairanovskii[80] has suggested that there is no protonation with the formation of a CH bond in the electrode reactions of organic compounds. The opposite view was put forward by Elving,[81] who considered that the reduction of organic compounds is analogous to the electrochemical desorption of hydrogen.

The above data obtained by the LPE method, which has made it possible for the first time to measure systematically the rate constants of the electrode reactions of simple alkyl and hydroxyalkyl radicals, provide clear evidence in support of the first suggestion. Even in the reduction of the $(CH_3)_2COH$ radical in acidic solutions, where it was possible to observe the electron–proton transfer reaction (55), its rate constant was 10^6 times smaller than the rate constant for electrochemical desorption (Table 3). For other radicals, W_{31} is even smaller. The diagram in Fig. 12 makes it possible to estimate quantitatively the difficulty of protonation with the formation of a CH bond. For example, the exothermic formation of methane from the methyl radical takes place at a lower rate than the endothermic formation of the CH_3^- ion, although ~180 kJ mol^{-1} is liberated in the first reaction, whereas 75 kJ mol^{-1} is used up in the second. The CH_2OH^- and CH_3CHOH^- anions are formed instead of methane and ethanol, despite the fact that the free

energies of formation of these carbanions from the radicals are ~170 kJ mol^{-1} greater than those for the alcohols. Thus the barrier associated with the reorganisation of the the complex in the transfer of a proton with the formation of a CH bond for simple organic radicals is greater than 150–200 kJ mol^{-1}. Since the rates of protonation with the formation of an OH bond are much higher, carbene derivatives are formed in the reduction of carboxyl radicals.

Tafel relationships for the rate constants of the reduction of simple organic radicals to carbanions:[82] *1*, CCl_3; *2*, CCl_2F; 3, $CClF_2$; *4*, CF_3; *5*, $CHCl_2$; *6*, CHFCl; *7*, CHF_2; *8*, C_6Cl_5; 9, CH_2Cl; *10*, C_6H_5; *11*, CH_3; *12*, CH_2OH; *13*, C_2H_5; 14, C_2H_4OH; *15*, $(CH_3)_2COH$; *16*, n-C_3H_7; *17*, n-C_4H_9.

IX. The p*K* scale for weak CH-acids

The rate constants for the one-electron reduction of a number of simple organic radicals to carbanions have been measured by the LPE method.[82] The $W_3(E)$ relationships for all the radicals studied have similar values of the transfer coefficient $\alpha = 0.45 \pm 0.05$ (Fig. 14). An empirical rule was proposed[82] for relating the potentials of the Tafel straight lines $\ln W_3(E)$ to the energy characteristics of the carbanions: the displacement of the standard redox potential E^0 of the reaction

$$R + e^- \rightarrow R^- \qquad (58)$$

for a series of organic radicals is equal to the displacement of the potential corresponding to identical values of W_3. The equation for the retarded discharge can be written as:

$$\ln W_3 = \ln W_3^0 - \frac{E_a^0}{RT} - \alpha\frac{\Delta G_a^0}{RT} + \alpha\frac{E}{RT}(E^0 - E), \qquad (59)$$

where E_a^0 and W_3^0 are respectively the activation energy and the pre-exponential term for $E = E^0$. In Eqn. (59), allowance has been made for the fact that the radical is present in the adsorbed state. It follows from Eqn. (59) that the relative displacement of the Tafel straight lines along the E scale for equal values of W_3 and α is related to the difference in E^0 by the expression

$$\Delta E_{12} = \Delta E_{12}^0 - \frac{RT}{\alpha F}\ln\frac{W_{31}^0}{W_{32}^0} - \frac{1}{\alpha F}(E_{a_1}^0 - E_{a2}^0) - \frac{1}{F}(\Delta G_{a1}^0 - \Delta G_{a2}^0). \qquad (60)$$

According to Eqn. (60), the rule formulated above ($\Delta E_{12} = \Delta E_{12}^0$) applies if the transfer coefficients of the radicals, the pre-exponential terms, the activation energies E_a^0, and the free energies of adsorption coincide. It has been established experimentally that α is constant. The fact that E_a^0 and W_3^0 coincide is a direct consequence of the model of electron transfer in a polar medium;[47,48] according to this model, W_3 characterises the probability of electron transfer from the metal to the reaction complex, and $E_a^0 = E_s/4$ (E_s is the energy of reorganisation of the medium in this transfer). The requirement that ΔG_a^0 be constant, which means the preservation of the energy of the M–C bond in the series of radicals, is the least rigid of the above conditions, since this quantity is comparatively small ($\leqslant 50$ kJ mol^{-1}).

From the empirical rule and the measured values of $W_3(E)$, it is possible to compile a scale of relative values of E^0. To change to the absolute scale, the standard potentials of the following reactions were calculated[82]

$CH_3(gas) + e^- \rightarrow CH_3^-(aq)$ and
$CH_2OH(gas) + e^- \rightarrow CH_2OH^-(aq)$:

$$E^0 = \frac{F}{RT}(\Delta G_{R^-}^0 - \Delta G_R^0) = \frac{F}{RT}(\Delta G_h^0 - EA - \Delta G_{H^+}^0 - RT\ln 24{,}5), \qquad (61)$$

where ΔG_h^0 is the hydration energy of R^-, EA the electron affinity of the radical in the gas phase, and $\Delta G_{H^+}^0 = -430$ kJ mol^{-1} the standard free energy of hydration of the proton, used to change from the energy scale in a vacuum to the energy scale in aqueous solution. The last term in Eqn. (61) takes account of the difference between the standard states of the ion in the gas and in solution. The value $\Delta G_h^0 = -322$ kJ mol^{-1} for CH_3^-, taken as equal to the hydration energy of the hydride ion,[2] is close to the values of ΔG_h^0 for the NH_4^+ and K^+ ions (−314 kJ mol^{-1} and −330 kJ mol^{-1} respectively), which have approximately the same dimensions. The electron affinity of the methyl radical is 7.7 ± 2.9 kJ mol^{-1},[83] so that the free energy of the CH_3^- ion in water is 230 ± 16 kJ mol^{-1} and $E^0 = -0.77 \pm 0.16$ V. The calculated energy of the ground state of the CH_2OH^- ion is 93 kJ mol^{-1} greater than the energy of CH_3O^-.[84] Using the value of pK (CH_3OH) and assuming that the solvation energies of the two ions are equal, it is found that for $CH_2OH^-(aq)$, $\Delta G^0 \simeq 60$ kJ mol^{-1}, and $E^0 = -0.85$ V. The difference in E^0 for these two reactions corresponds to the displacement of the Tafel curves. The free energies of the other carbanions are given by the expression

$$\Delta G_{R^-}^0 = \Delta G_{R_0^-}^R + \delta(\Delta G_{CH}^0) + \frac{RT}{F}\Delta E^0, \qquad (62)$$

where $\Delta G_{R_0^-}^0$ is the free energy of the "standard" carbanion CH_3^-, and $\delta(\Delta G_{CH}^0)$ the difference between the free energies of the rupture of the CH bond in R_0H and RH. In Eqn. (62), the difference in the hydration energies of R and RH is not taken into account. The free energies of different carbanions are given in Table 5, which also gives the values of E^0 and pK for the CH-acids conjugate with R^-:

$$pK = \frac{1}{2{,}3RT}(\Delta G_{R^-}^0 - \Delta G_{RH}^0), \text{ where } \Delta G_{RH}^0 \text{ is the free energy of RH.}$$

The pK scale defines the relative reactivity of organic substances in nucleophilic substitution reactions.[85] Several methods have been proposed for constructing it from indirect data, in particular from the rate constants of proton exchange.[86] Attempts have been made to determine the pK values by semi-empirical quantum-chemical calculations.[87] The most universal is the polarographic pK scale, constructed using the half-wave potentials for the two-electron

reduction of the symmetrical organomercury compounds HgR_2 to the carbanions in non-aqueous solvents.[88] It was assumed[88] that the reduction of HgR_2 takes place under conditions close to equilibrium, and that the change in $E_{1/2}$ corresponds to the displacement of pK. Because of the complexity of the two-electron process, indicated, for example, by the above data on the reduction of CH_3Hg^+ to CH_3^-, this approximation is less obvious than that used by Benderskii and co-workers.[82] The values of pK found by different methods sometimes differ by factors of $10^{10}-10^{12}$.[88] For comparison, it may be noted that even a difference by factors of 10^3-10^4 in the pre-exponential terms in Eqn. (60) leads to a scatter in the relative values of pK of 5–7 units. The pK values for the haloforms CHF_3 and $CHCl_3$ found by the published methods[88,82] coincide.

Table 5. Free energies of organic radicals (ΔG^0_R) and carbanions ($\Delta G^0_{R^-}$, aq), standard redox potentials E^0 of the formation of the carbanions from the radicals, and the pK values of CH-acids RH.[82]

The pK values for CH-acids in the gas phase have been found by measuring the electron affinity of the radicals by the ion-cyclotron resonance method.[89,90] Although these data are extremely convenient for determining the influence of different substituents on pK, they cannot be used to construct the pK scale for solutions, since the differences in the solvation energies of the carbanions mask the changes in acidity associated with the introduction of the substituents. For example, the pK values for the CH-acids CH_4 and CHF_3 differ by 29 units in the gas phase,[89] and by 17 units in aqueous solution, that is the difference ΔG^0_h is 69 kJ mol^{-1}.

The pK scale in solutions is not universal, since the change to another medium changes $\Delta G^0_{R^-}$ by an amount equal to the free energy of the transfer of the carbanion between the solvents ΔG^0_t. For inorganic ions, the value of ΔG^0_t lies in the range 10 to 25 kJ mol^{-1}.[91] In the method of Benderskii and co-workers,[82] change in the solvent leads to additional errors due to the relative changes in the energy of reorganisation. Measurements of $W_3(E)$ for CH_2Cl and $CHCl_2$ radicals in acetonitrile and water–dioxan mixtures showed that the displacement of the Tafel curve does not exceed 0.15 V, that is the difference in the relative values of pK in these solvents and in water is less than 5 units. It should be emphasised that the method[82] is universal, and does not lose its accuracy with increase in pK, and the range in which measurements can be made corresponds to the working range of potentials of the mercury electrode, and is greater than 30 pK units.

The range of change in W_3 in which the $W_3(E)$ relationships were measured for the CH_2Cl and $CHCl_2$ radicals[16] is greater than 10^6 (Fig. 14). The deviations from the Tafel law predicted by the theory of electron transfer in a polar medium[47,48] were not detected in this range. According to Marcus' model, the transfer coefficient for outer-sphere reactions in the range of normal discharge is a linear function of the overvoltage:

$$\alpha = \frac{1}{2} - \frac{e}{2E_s}(E^0 - E), \quad |e(E^0 - E)| < E_s. \tag{63}$$

Eqn. (63) shows that at $E_s \leqslant 200$ kJ mol^{-1}, corresponding to ELH reactions (see section IV), α should decrease from 0.5 to 0.30–0.25 in the measured range of E, but this does not agree with experiment. It was previously concluded from an analysis of the polarisation relationships in simple electrode reactions[92,93] that Eqn. (63) does not agree with experiment. The data of Benderskii and co-workers[16] confirm this conclusion; for the fulfilment of the Tafel law to agree with Eqn. (63), it is necessary to assume that $E_s \gtrsim 300$ kJ mol^{-1}, which is comparable with the solvation energy of the carbanions. This is contrary to the concept of a linearly polarised medium[94] on which the theory is based.[47,48] Benderskii and co-workers[16] suggested that the electron transfer is associated not only with reorganisation of the medium but also with reorganisation of the reaction complex itself. In the initial state, the adsorbed radical is in the compact part of the electrical double layer, where the water molecules are oriented by a strong electric field and cannot solvate the carbanion formed by electron transfer. Thus the solvation of the reaction product involves a displacement of the reagent along the adsorption coordinate in the direction of the Helmholtz plane. The existence of this reaction coordinate, associated with the desorption of the radical, which is necessary for solvation in the transition state, leads to the appearance of an additional energy of reorganisation. The combination of these two movements (of the radical and the medium) is similar to that examined[45] for ELH reactions, and leads to the relationship

$$\ln\frac{W_3}{W_3^0} = -\frac{(E_s + E_1 - e(E^0 - E))^2}{4E_s kT + rF^2\delta^2}, \tag{64}$$

where E_1 is the energy of reorganisation of the adsorbed radical, F the curvature of the carbanion term, $r^{-1} = 2\tanh(\hbar\omega/2kT) - 1$, and δ and ω are respectively the amplitude and frequency of the vibrations in the initial state. Eqn. (68) agrees with experiment for $E_1 \simeq E_s$. The value $E_s \simeq 150$ kJ mol^{-1} corresponds to the energy of reorganisation of the medium in the one-electron reduction of NO to NO^- (see section X), and explains why pK changes little with change in the solvent.

X. Intermediate species of the electrochemical nitrogen cycle

The electrochemical reduction of NO_3^- ions to NH_3 (the electrochemical nitrogen cycle) is an eight-electron process including the electronic stages of the formation of NO_2^- from NO_3^- ($n = 2$), NO from NO_2^- ($n = 1$), NH_2OH from NO ($n = 3$), and NH_3 from NH_2OH ($n = 2$). Each of these stages is associated with the transformation of short-lived IS: NO_3^{2-}, NO_2^{2-}, NO^-, H_2NO, and NH_2. Although the existence of these IS in aqueous solutions was

established by pulse radiolysis and EPR methods, their role in the nitrogen cycle was revealed only recently, by the LPE method.[95–98] The results are summarised in Fig. 15, and the rate constants of the homogeneous and electrode reactions of the IS are given in Tables 6 and 7.

$H_2NO+e^++NH_4^+ \rightarrow NH_2OH+NH_3$	>1.0	>1	—

The product of the capture of e^-_{aq} by the nitrate ion is oxidised on mercury with a rate constant which increases from 0.1 cm s^{-1} to 10 cm s^{-1} with change in E from −1.2 V to −0.9 V (β = 0.25).[9] The oxidation competes with the homogeneous decompostion of the IS, for which the characteristic time is 1.3×10^{-5} s and 3×10^{-6} s for NO_3^{2-} and HNO_3^- respectively.[100] The decomposition product in the one-electron process is reduced. The charge of the IS oxidised was established[95] from the kinetic ψ_1-effect. At $\psi_1 < 0$, the electric field of the diffuse double layer retards the movement of the negatively charged IS towards the electrode. Since they have a finite lifetime in solution, this retardation increases the proportion of IS decomposing, compared with the proportion oxidised at the electrode, leading to an increase in the current and potential of the anodic half-wave of the IS. Analysis of the equations for the diffusion in the field of the ψ_1 potential of e^-_{aq} and the IS being oxidised leads to the relationship

$$j_1 = 2\frac{j-j_{\min}}{2-j_{\min}} = \left(1+\varkappa\sqrt{\frac{\tau}{D}}e^{-\Phi}+\frac{\varkappa x_0}{D\Phi}\right)^{-1}, \qquad (65)$$

where $j_{\min}$ is the minimum value of the current, corresponding to $\kappa \rightarrow \infty$, κ the rate of oxidation of the IS, τ the decomposition time of the IS, x_0 the characteristic dimension of the diffuse double layer, and $\Phi = \frac{eZ}{kT}\psi_1$, where Z is the charge of the IS. The second term in the denominator of Eqn. (65) characterises the ratio of the rates of the electrode reaction to the diffusion of the IS to the electrode under the condition of Boltzmann equilibrium, and leads to the Frumkin relationship[27]

$$\Delta E_{1/2} = (1+Z/\beta)\,\Delta\psi_1 \qquad (66)$$

which gives the dependence of the displacement of the half-wave potential of the species stable in solution on the ψ_1-potential. The third term, equal to the ratio of κ on the rate of the drift of the IS from the electrode into the solution, takes account of the deviation from equilibrium in strong fields, when the ψ_1-effect is due to the above-mentioned retardation of the IS. Eqn. (66) is applicable when $|\Phi| < \Phi^*$, where Φ^* is the solution of the equation $\Phi^*\exp(-\Phi^*) = x_0/\sqrt{D\tau}$, so that the applicability of the Frumkin equation depends on the lifetime of the IS in solution. The measured[95] displacement of the anodic wave in solutions with different ionic strengths, in which the ψ_1-potential changed from 0 to 0.09 V, corresponds to $Z = -2$, that is the primary IS is the NO_3^{2-} ion. It follows from the kinetic LPE curves that the characteristic time of the reduction of the product of the transformation of NO_3^{2-} does not exceed 2×10^{-7} s. The absence of an arrest corresponding

to the lifetime of HNO_3^- means that the decomposition of this ion (to give NO_2) does not precede the reduction, that is the species being reduced is HNO_3^-, and not NO_2. This conclusion[96] is confirmed by the fact that, judging from the rapid increase in the LPE signal, the rate of reduction is greater than 10 cm s^{-1} ($\kappa > \sqrt{D/\tau}$), whereas the reduction of NO_2 is a much slower process. The addition of different PD to the solution increases the rate of protonation of NO_3^{2-} (the rate constants are given in Table 6), and suppresses the oxidation wave. The published data[95,96] indicate that the electrochemical reduction of NO_3^- to NO_2^-, which is associated with a high overvoltage and is observed at $-E > 1.6$ V, involves the intermediate formation of the high-energy NO_3^{2-} ion, and, as a result of its rapid oxidation, is a quasi-equilibrium process. The decrease in the overvoltage in the presence of PD, which is also characteristic of various other anions,[101] is due to the increase in the rate of protonation, as a result of which NO_3^{2-} is converted into the HNO_3^- ion being reduced.

The wave for the one-electron reduction of the product of the capture of e_{aq}^- by the NO_2^- ion in neutral solution coincides with the polarographic reduction wave for NO. The characteristic reduction time found by the LPE method is greatest close to the half-wave potential and remains the same ($\sim 4 \times 10^{-7}$ s), independent of the NO_2^- concentration , at more negative potentials.[97] These data show that the species being reduced is NO, and the time for its formation in the decomposition of NO_2^{2-} is 2×10^{-7} s. The reduction of NO is reversible, since it is only if this is the case that the characteristic time, determined by the sum of the rates of the forward and back reactions, can be greatest when these rates are equal. The dependence of $E_{1/2}$ and the form of the wave on the frequency of the periodic photo-emission current Ω corresponds to the reversible reduction (see section IV) only at $\Omega > 10^2$ s^{-1}. At lower frequencies there is observed a component of the current due to subsequent irreversible transformations of NO^- with a characteristic time of $\sim 10^{-2}$ s, which depends on the bulk concentration of NO, proportional to the photo-emission current. These data correspond to the conversion of NO^- into $N_2O_2^-$ by reaction (8), whose rate constant has been measured.[101] In the one-electron reduction of $N_2O_2^-$, as in the bimolecular recombination of NO^-, the hyponitrite ion $N_2O_2^{2-}$ is formed, and its decomposition leads to the appearance of the final reduction product N_2O.

In the presence of PD, the extent of the reduction of NO increases from 1 to 3. The formation of NH_2OH in quantities corresponding to the photo-emission current and $n = 3$ was confirmed by chemical analysis.[98] In addition to the main wave, whose form and position are independent of n, a preliminary wave appears (see Fig. 4), whose height increases with increase in the PD concentration (N_p), reaching 3. Like the main wave, the preliminary wave is reversible. The fact that the values of n are the same for the preliminary wave and the main wave indicates that the reduction of NO to NH_2OH takes place by two parallel channels. The fact that the main wave is independent of N_p indicates that the process taking place by one of the channels, as in the one-electron reduction, includes the formation of NO^- and its protonation (the formation of NOH) and subsequent two-electron reduction. Since the preliminary wave lies in the range of E in which NO is reduced, the existence of the second channel is due to the formation of a new electrochemically active species in the reaction of NO with the PD. According to published suggestions,[102] this species is NOH^+. The height of the preliminary wave increases with decrease in Ω (see Fig. 4), so that the rate of protonation is of the order of Ω and the protonation is the limiting stage of the reduction. The $j(E, \Omega)$ relationship in the preliminary wave is described by the expression

$$j = \left| 1 + \frac{3}{1 + \sqrt{k_5 \Omega / 2 k_4^2}\,(1 + e^{-\eta}\sqrt{k_5/k_{10}})\sqrt{2i}} \right|. \quad (67)$$

Here, $\eta = \ln(\kappa_6/\kappa_5) = e/kT(E^0 - E)$, where E^0 is the standard NOH/NOH^+ potential, and the significance of the constants in Eqn. (67) can be seen from Fig. 15. Comparison of Eqn. (67) with the experimental data makes it possible to determine the ratio k_4^2/k_5, which was found to be equal to 10^2 s^{-1}. The $j(E)$ relationship, which corresponds to an effective transfer coefficient of 1, indicates that the reduction of NOH^+ is reversible. It follows from the kinetic LPE curves that the characteristic time of the two-electron reduction of NOH is $\sim 2 \times 10^{-6}$ s. The existence of an equilibrium between NO and NOH^+ means that $k_5 \gg k_{10}$ and the decomposition time of NOH^+ does not exceed 10^{-6}s, while $k_4 > 10^4$ mol^{-1} s^{-1}. The decrease in the height of the preliminary wave with increase in the NO_2^- concentration (N_a) indicates that NO^- and NOH react with NO_2^- according to Eqn. (9). The hyponitrate ion $N_2O_3^{2-}$ formed subsequently decomposes to give N_2O,[103] decreasing the extent of the reduction. The dependence of the limiting low-frequency current of the main wave on N_p and N_a, with allowance for the competition of the protonation of NO^- and reaction (9), has the form

$$j_n = 2(1 + (1 + k_7 k_9 N_a / k_8^2 N_p^2)^{-1}), \quad (68)$$

that is j_m depends on N_p^2/N_a, and $k_7 k_9 / k_8^2 \simeq 80$ mol. The nitroxyl radical H_2NO undergoes one-electron reduction at $-E > 0.2$ V (characteristic time less than 10^{-6} s).

Thus at high PD concentrations, NO is reduced quantitatively to hydroxylamine if the concentrations of NO_2^- and NO are so low that reactions (8), (9), and (11) which compete with the protonation do not interfere with the formation of NOH and the reduction of H_2NO. The scheme of transformations of the IS given in Fig. 15 provides a basis for the quantitative description of the concentration dependence, obtained from electrochemical measurements,[104] of the relative yield of the main products of the reduction of N_2O and NH_2OH. It follows from the scheme that only the protonated forms of the IS can be reduced, and that protonation precedes the electrode reaction. The protonation is apparently accompanied by the isomerisation of the IS. Since an O–H bond is formed in NOH^+, the reduction product is NOH. This species should be converted into the more stable form HNO,[105] and its subsequent reduction should also be associated with the formation of an O–H bond, and not N–H. The resulting IS HNOH (zerovalent nitrogen) undergoes isomerisation to H_2NO. It is this more stable radical that is observed in the gas phase[106] and in solution,[107] although in the oxidation of NH_2OH by the OH radical, HNOH is formed initially.[108] The suggestion that the IS undergoes isomerisation is consistent with the observed high rates of the electrode reactions (Table 7), since they are associated with the formation of O–H bonds, as in the rapid reduction of the radicals HCO_2 and HCO (see section VII).

The magnitude of the energy of rupture of the O–H bond in NH_2OH [106] shows that the standard H_2NO/NOH potential is greater than the NO^-/NO potential and that the quantitative transformation of NO into NH_2OH is determined by the latter; the reduction of HNO and H_2NO at $E < E^0$ for the NO^-/NO couple is isothermal. The quantitative transformation of NO into NH_2OH requires the expenditure of free energy (more than 234 kJ mol^{-1}). The standard NOH/NO potential, corresponding to $pK(NOH) = 4.7$,[101] is -0.54 V, so that the energy required for the reduction of NO to

NH_2OH in a standard solution with pH = 0 is greater than 155 kJ mol^{-1}, despite the fact that the process as a whole is exothermic (the standard NH_2OH/NO potential is +0.38 V).

The values of the ψ_1-potential appearing in Eqns. (65) and (66) coincide with the total decrease in the potential in the diffuse layer ψ_{10} only for dilute solutions ($\leqslant 10^{-2}$ M), where $x_0 \geqslant 2$ nm.[95] In more concentrated solutions, $|\psi_1| < |\psi_{10}|$. The difference between ψ_1 and ψ_{10} indicates that the NO_3^{2-} anion is discharged at a distance of 0.5–0.7 nm from the plane of maximum approach. The distance of electron transfer, which is several times greater than the geometric dimensions of the ion, is typical of tunnel reactions.[109] The probability of tunnel electron transfer from the reaction complex to the metal, W_0, is related to the rate constant of the oxidation by the simple expression $\kappa = W_0/a$, where a characterises the decrease in the electron density with increase in the distance. The values found[95] for κ correspond, in particular, to electron transfer through a parabolic barrier with a height of ~2 eV. As in ELH reactions (see section VI), the $\kappa(E)$ relationship is determined by the change in the height of the barrier with change in the potential.

The energy of reorganisation of the medium in the reduction of NO to NO^-, not associated with intramolecular rearrangement, can be estimated from the value of κ at $E = E^0$ using Marcus' equation[47] with a reasonable value of the pre-exponential term ($\leqslant 10^{14}$ s^{-1}). According to Benderskii and co-workers,[97] $E_s \simeq 135$ kJ mol^{-1}, which agrees with estimates of E_s in ELH reactions and in the reduction of organic radicals (section IX).

XI. Reduction of ions with anomalous valence

The homogeneous reactions of cations with anomalous valence have been studied in detail under pulse radiolysis conditions. Since the rate constants for the reduction of NO_3^-, NO_2^-, and hydroxyalkyl radicals by Zn^+, Ni^+, and Cd^+ ions are close to the diffusion values,[110] these reactions are exothermic, and the redox potentials for the formation of these ions from the divalent ions should be smaller than −1.5 V. According to published estimates,[111,112] $-E^0$ for the Ni^+/Ni^{2+} couple is greater than 1.8 V, and that for the Pb^+/Pb^{2+}- couple lies in the range 1.1–1.5 V. Comparison of E^0 with the half-wave potentials $E_{1/2}$ for the reduction of the corresponding divalent ions to the metal shows that the intermediate formation of the monovalent cations in this two-electron process is unlikely. According to LPE data the oxidation of the Cd^+, Zn^+, and Ni^+ ions on mercury in the range $E > E_{1/2}$ takes place in less than 10^{-7} s.

The many-electron reduction of anions has been studied by LPE for NO_3^-, NO_2^- (see section X) and BrO_3^-.[113–115] The product of the capture e_{aq}^- by the bromate ion is the BrO_2 radical, whose time-resolved polarograms (see Fig. 6) correspond to its five-electron reduction to Br^- with $E_{1/2} = -1.0$ V. An unexpected result is the value $j = 3$ in the range $E > E_{1/2}$, which formally corresponds to the one-electron reduction of the bromite ion BrO_2^-, although its half-wave potential is −0.88 V,[116] whereas $j = 3$ as far as $E = -0.3$ V, where the BrO_2^- ion is known to be electrochemically stable. The disproportionation of BrO_2^- to give BrO_3^- and BrO^- is also too slow to explain its reduction in 10^{-4} s. The observed increase in j is due to the ion–radical reaction

$$BrO_2 + BrO_2^- \rightarrow BrO + BrO_3^-, \qquad (69)$$

analogous to the transfer of O^- between the reagents, whose rate constants for exothermic reactions are close to the diffusion values.[117] Reaction (69) gives the BrO radical, which is reduced to Br^-, since the product of its one-electron reduction, that is the BrO^- anion, is electrochemically active at $E \leqslant 0$.[116] In reaction (69) with the subsequent three-electron reduction of BrO, only half of the BrO_2 radicals are converted into Br^-, that is $j = 3$. The scheme for the reduction of BrO_3^- at $E > E_{1/2}$ has the form:

$$BrO_3^- \xrightarrow{e^-} BrO_2 \xrightarrow{e^-} BrO_2^- \quad BrO \xrightarrow{e^-} BrO^- \xrightarrow{2e^-} Br^-. \qquad (70)$$

The kinetic LPE curves divide into sections, well separated in time, corresponding to the successive reduction of BrO_2 to BrO_2^- ($n = 1$, the characteristic time decreases from 3×10^{-6} s to 5×10^{-7} s in the range of E values from −0.70 V to −0.95 V) and of BrO^- to Br^- ($n = 2$, τ decreases from 4×10^{-3} s to 6×10^{-5} s in the range of E values from −0.4 V to −0.9 V). For $E < E_{1/2}$, the rate of the reduction of BrO_2^- is greater than the rate of reaction (69), so that $j = 6$. The kinetic LPE curves are described by the relationship

$$Q/Q_m = 6 - 4w(\varkappa_2 \sqrt{t/D}), \qquad (71)$$

where $\varkappa_2$ is the rate constant of the reduction of BrO_2^- to BrO, which is the limiting stage of the overall process.

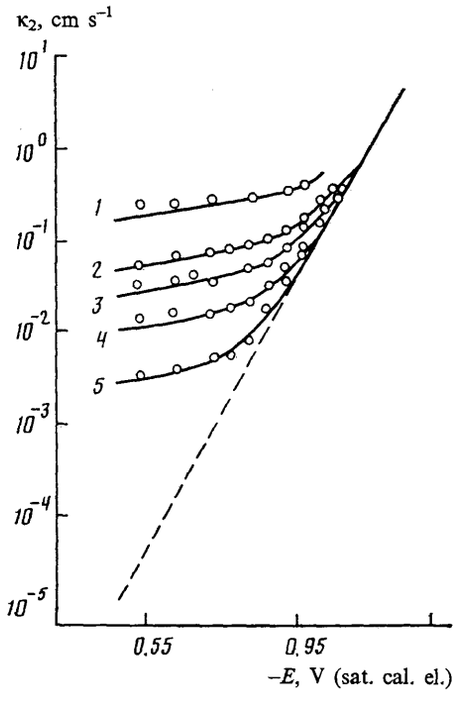

Figure 16. Dependence of the rate constant of the reduction of the BrO_2 radical on the electrode potential at NH_4^+ concentrations, M: *1*, 3.8×10^{-2}; *2*, 1.1×10^{-2}; *3*, 6×10^{-3}; *4*, 3×10^{-3}; and *5*, 1.5×10^{-3}; the broken straight lines corresponds to $N_p = 0$.[115]

Adding NH_4^+ ions to the solution leads to qualitative changes in the polarograms and the kinetic LPE curves. Increase in N_p is accompanied by an increase in $E_{1/2}$ and j for $E > E_{1/2}$ (for

$N_p > 7 \times 10^{-2}$ M, $j = 6$ throughout the working range of E), and the characteristic reduction time decreases rapidly. These changes are due to the increase in κ_2 as a result of the participation of PD in the electrode reaction

$$BrO_2^- + e^- + NH_4^+ \rightarrow BrO + OH^- + NH_3. \quad (72)$$

The $\kappa_2(E)$ relationships for different N_p are given in Fig. 16, and confirm the published conclusion[100,118] that PD take direct part in the reduction of the anions. The rate constant of reaction (72) depends little on E and is close to the diffusion value (~ 5 cm s^{-1}).

XII. Summary

The examination of the electrochemistry of IS opens up new possibilities in the study of both complex many-electron transformations at an interface and the elementary stage of electrode reactions. The significant role of intramolecular reorganisation on electron transfer means that Marcus' model, which takes account of only the reorganisation of the polar medium and for this reason claims to be universal, should be supplemented by an examination of the rearrangement of the reaction complex itself and its solvate layer. In the present state of quantum chemistry, these calculations are becoming possible. Allowance for these last processes may lead to fundamental changes in existing ideas, since reorganisation of this kind (like reorganisation of the medium) not only creates a dynamic barrier to transfer but also leads to the production of a nuclear configuration favourable for reaction. This last feature, in particular, is the factor responsible for rapid low-temperature solid-phase transformations,[119] and possibly plays an equally important role in electrode reactions. The formation of high-energy IS (derivatives of carbene, carbanions, biradicals, etc.), detected by PECR and LPE methods in many electrode reactions, also requires further experimental and theoretical study. The development of these new methods should lead in turn to the development of more selective polarographic analysis, compared with the polarography of stable species.

The parameters of the ^{13}C NMR spectra of substituted acetylenes: relation with electronic structure and reactivity

A G Proidakov, G A Kalabin, S F Vasilevskii
Irkutsk State University
Institute of Chemical Kinetics and Combustion, Siberian Division of the USSR Academy of Sciences

ABSTRACT. Questions concerning the electronic structure of the ethynyl fragment and the effectiveness of its interaction with various heteroatomic and unsaturated substituents are examined on the basis of the analysis of an extensive set of parameters of the ^{13}C NMR spectra of mono- and di-substituted acetylenes. The additive influence of the two substituents in disubstituted acetylenes on the shielding of the *sp*-carbon atoms, due to the counterpolarisation of the orthogonal π-systems of the triple bond, is demonstrated. The question of the possible use of the ^{13}C NMR spectral parameters for the estimation of the reactivity of the triple bond is discussed.

The bibliography includes 140 references.

I. Introduction

The unique reactivity of acetylenic compounds is responsible for their extensive use in thermographic synthesis—both in laboratory practice and in industry. However, the development of theoretical aspects of the behaviour of acetylenic compounds in reactions lags significantly behind practical advances. The extensive employment (in careful analysis and survey of results of studies on acetylenes themselves and on the reactions with their participation) of instrumental physical methods combined with theoretical quantum-chemical methods should help to overcome this discrepancy.

The ^{13}C NMR spectroscopy with its modern apparatus (Fourier transformation, the application of multipulse sequences, ultra-high magnetic fields) is one of the most universal methods for the study of the electronic and geometrical structures of organic and organo-element molecules and it has the highest information content. Its possibilities as regards acetylenic compounds are simple unique. Indeed, of the six parameters of NMR spectra with the aid of which it is possible to characterise the terminal ethynyl fragment of monosubstituted acetylenes [the chemical shift δ and the spin–spin coupling constants (SSCC or *J*): one ^{1}H chemical shift, two ^{13}C chemical shifts, two $^{13}C-^{1}H$ SSCC, and one $^{13}C-^{13}C$ SSCC], five can be obtained from the ^{13}C NMR spectrum and in the case of disubstituted acetylenes the entire spectroscopic information about the triple bond and about the carbon atoms involved in it is contained in the ^{13}C NMR spectrum. Since the chemical shifts of the acetylenic proton in monosubstituted acetylenes are exceptionally sensitive not only to intramolecular effects but also to solvation effects, they will not be considered in this review. The constants for the spin–spin coupling of this proton with the ^{13}C nuclei are more characteristic and permit an unambiguous assignment of the ethynyl carbon atoms in the ^{13}C NMR spectrum and they are therefore discussed in this review together with the $^{13}C-^{13}C$ SSCC. Here and henceforth the relaxation times of the nuclei and isotope substitution effects will not be considered.

II. Chemical shifts of the ethynyl ^{13}C atoms

1. General features and formulation of the problems

Whereas the number of known values of δC for the carbon atoms in certain unsaturated hydrocarbon fragments, for example in the benzene ring or in the double bond, reaches several thousands, the number of δC for acetylenic compounds is smaller by an order of magnitude. Most of the data refer to alkynes, alkynols, and compounds having the general formula $R_3EC{\equiv}CH$, where E = Si, Ge, or Sn.

The signals of the ethynyl carbon atoms in the ^{13}C NMR spectra are manifested in the range 65–95 p.p.m. [relative to the signal of the carbon atom in tetramethylsilane (TMS)], which is intermediate between the regions characteristic of the ^{13}C nuclei of the sp^3- and sp^2-carbon atoms. The alkyl groups attached to the triple bond shield the C_β atoms and deshield the C_α atoms, inducing changes in the shift of approximately 4–6 and 10–20 p.p.m. relative to δC for acetylene (72.0 p.p.m.).[1] Calculation of the distribution of charges in 1-alkynes by the CNDO/2 method has shown[2] that mainly the polarisation of the triple bond takes place under the influence of the alkyl substituent. In disubstituted acetylenes, the influence of two alkyl groups on δC is additive and quantitative estimates of the contributions of the groups having normal[3,4] and branched[5] structures are available. A topological scheme has been developed for highly accurate calculations (±0.6 p.p.m.) of δC_{sp} for alkynes and alkynols from data for 86 compounds.[5,6] A characteristic feature of the influence of the Alk_3E (E = Si, Ge, Sn) groups on the chemical shifts of the C_{sp} atoms is the deshielding of both carbon atoms (an average shift of 20 p.p.m.), which is explained by the appreciable π-acceptor effect of the Alk_3E groups ($p_\pi-d_\pi$ or $p_\pi-\sigma^*$ conjugation).[7–12] The acceptor properties of the silicon atom in relation to the triple bond have been confirmed by calculations of

the charge distribution.[12,13] The influences of the X and Me_3E groups on δC_{sp} are independent within series of compounds with identical E and can be described to a first approximation by the Hammett–Taft equation.[7] This conflicts with the results of studies of substituted hexynes $Bu^nC\equiv CX$, for which the absence of a relation between δC and the induction and resonance characteristics of the groups X has been noted.[14] In a number of cases a relation has been observed between the kinetic parameters of the reactions involving addition to acetylenic compounds and the σ-constants of the substituents (see, for example, Refs. 15–19). It is noteworthy that, whereas the AlkO groups of ethynyl ethers shield anomalously strongly the β-carbon atom, the AlkE groups, where E = S, Se, or Te, actually deshield it, which is explained by the reduced capacity of these chalcogens for p_π-interaction and the dominant influence of the d_π-acceptor properties.[7,20–22] The above features require refinement, because all chalcogens exhibit π-donor properties in relation to vinyl and phenyl fragments.[23]

Limited information is available about the chemical shifts of the ^{13}C atoms in acetylenic compounds containing boron,[24,25] phosphorus,[7,20,21,26] and the halogens.[7,14] The R_2P and R_2PO groups deshield the C_β atom to virtually equal extents (a 20 to 25 p.p.m. shift), whereas their effects on C_α are different: shifts of 10–15 and 2–8 p.p.m. respectively are observed. This has been explained by the π-acceptor effect of the phosphorus-containing substituents on the triple bond.[20,21,26] The R_2P group acts similarly on the triple bond. In the series of halogen-substituted acetylenes, the changes in δC are very great: on passing from Cl- to I-substituted compounds, the shielding of C_α increases by 60 p.p.m., while that of C_β diminishes by 30 p.p.m.; the values of δC_β for iodoacetylene derivatives exceed 100 p.p.m., while the values of δC_α are close to 0 p.p.m.[7,14] The explanation of changes in δC of this kind by the effect of anisotropy[27] or intermolecular dispersion interactions[28] is hardly acceptable.

The available information about δC for acetylenic compounds containing other substituents, including unsaturated ones, is even more scanty and is less susceptible to unambiguous interpretation. Analysis of the ^{13}C NMR spectra of several substituents in the ring of phenylacetylenes permitted the hypothesis that the π-electron systems of the triple bond and the aromatic ring do not interact at all,[29] although in another study[30] the field, resonance, and π-induction effects of the substituents were accepted as determining the charge distribution on the triple bond carbon atoms. The hypothesis that the lower sensitivity of the shielding of C_{sp} compared with C_{sp^2} to changes in charge density may be the counter-polarisation of the triple bond has been put forward.[30] This was first suggested when the changes in δC_{sp} and δC_{sp^2} for arylpropynes and arylpropenes were compared.[31] The possibility of the counterpolarisation of the π-electron systems of the triple bond follows from the results of the non-empirical calculation for the hypothetical aminoacetylene molecule.[32] All these features agree with the results of the analysis of the integral intensities of the triple bond bands in the IR spectra as a measure of their resonance interaction in monosubstituted[33,34] and disubstituted[35] acetylenes, indicating a lower sensitivity of the triple bond, compared with the double bond, to the resonance effect, although the resonance interactions in acetylenic compounds involve both π-systems of the triple bond.

The question of the transmission of the π-electronic perturbations through the triple bond remains obscure. Comparison of the reactivities of the group Y in the $p\text{-}XC_6H_4-M-C_6H_4Y\text{-}p$ bridged systems has shown[36] that similar coefficients for the transmission of the π-electronic perturbations are characteristic of molecules with M = $-CH=CH-$ and $-C\equiv C-$ bridges (0.89 and 0.82 respectively). On the other hand, there is evidence that the effects of the Alk_3E (E = Si, Ge, and Sn) groups are transmitted to an extremely slight extent across the triple bond to the neighbouring $C=C$[10] and $C=O$[11] double bonds.

Among general features, we may note the hypothesis of Rosenberg and co-workers,[20,21] according to which the sum of the values of δC_{sp} characterises the overall charge on the triple bond and their difference characterises its polarisation. Doubts were subsequently cast on the legitimacy of this conclusion.[22]

Thus analysis of the literature data permits the formulation of the following key questions concerning δC_{sp} for acetylenic compounds:

(1) how independent of one another are the effects of two substituents on the shielding of ethynyl carbon atoms;

(2) what is the relation between the charge distribution and the chemical shifts of the carbon atoms in the triple bond;

(3) what are the mechanisms of the interaction of various heteroatomic and functional groups with the triple bond;

(4) to what extent is the model of the counterpolarisation of the triple bond justified;

(5) to what extent are the electronic effects of the substituents transmitted through the triple bond;

(6) is there a relation between the parameters of the ^{13}C NMR spectra and the reactivity of the triple bond.

In the analysis of experimental results, we used three main approaches: (a) comparison of NMR data with the results of quantum-chemical calculations for the molecules; (b) correlation analysis based on the principles of the linearity of free energies (LFE) and polylinearity (PPL) as a quantitative theory of organic chemistry; (c) comparison of the values of δC for the corresponding derivatives of ethane, ethylene, and acetylene.

2. Analysis of the joint effect of substituents on the chemical shifts of ^{13}C atoms in disubstituted acetylenes

The independent effects of the substituents on δC for the triple bond is a characteristic feature of certain series of disubstituted acetylenes—alkynes,[5,6,37] phosphorus derivatives,[26] and silicon, germanium, and tin derivatives.[7] This made it possible to determine the additive contributions of the individual substituents in the calculation of δC_{sp}.[38,39] A survey of all the available δC data (1184 values) showed[40,41] that the nature of the groups R^1 and R^2 in the compounds $R^1C\equiv CR^2$ influences δC and induces changes in it in the range of approximately 100 p.p.m. General relations taking into account the simultaneous changes in the structures of R^1 and R^2 within the framework of the polylinearity principle have been found.

According to the polylinearity principle, δC† can be formulated as follows:[40]

$$\delta C(R^1C\equiv CR^2) = a_0 + a_1X_1 + a_2X_2 + a_{12}X_1X_2, \quad (1)$$

where X_1 and X_2 are quantitative characteristics of the structures of R^1 and R^2 respectively, a_0, a_1, a_2, and a_{12} are coefficients, and $a_{12} \neq 0$ only when the effects of R^1 and R^2 are non-additive. It has been shown,[40] that the applicability of Eqn. (1) is determined by the applicability of the LFE principle to δC_{sp}. The absence of a cross term in Eqn. (1) requires that the following simple relation should

† Here and henceforth we have in mind δC_{sp} for the detector atom—the carbon atom at the substituent R^1.

hold between the values of δC for disubstituted acetylenes and the corresponding monosubstituted acetylenes:

$$\delta C(R^1C{\equiv}CR^2) = a_0 + a_1[\delta C(R^1C{\equiv}CH) + \delta C(HC{\equiv}CR^2)], \quad (2)$$

where a_0 = δC(HC−CH) and a_1 = 1.00.

Fig. 1 presents the theoretical relation (continuous line) corresponding to Eqn. (2) on which the experimental data for 369 acetylenic compounds have been plotted (of these, 366 refer to disubstituted acetylenes). A satisfactory agreement is observed between the theoretical straight line and the experimental data, which is indicated by the high statistical parameters of the equations:

$$\delta C(R^1C{\equiv}CR^2) = -75.60\,(1.13) + 1.02\,(0.007)\,[\delta C(R^1C{\equiv}CH) + \delta C(HC{\equiv}CR^2)],$$
$$r = 0.992,\ s = 1.98,\ n = 369. \quad (2a)$$

For points whose deviations from the theoretical straight line are ⩽ ⩽43.0 p.p.m., we have

$$\delta C(R^1C{\equiv}CR^2) = -74.60\,(0.91) + 1.01\,(0.006)\,[\delta C(R^1C{\equiv}CH) + \delta C(HC{\equiv}CR^2)],$$
$$r = 0.995,\ s = 1.43,\ n = 334, \quad (2b)$$

where r is the correlation coefficient, s the standard deviation, and n the number of points included in the correlation. The coefficients a_0 and a_1 in these equations have values close to theoretical ones. A further improvement of the quality of the description is pointless, since the accuracy with which the LFE principle is maintained for $\delta C(R_1C{\equiv}CR^2)$ does not exceed ±1.3 p.p.m.[40] For 24 of the most common substituents R^1 and R^2, a resultant matrix has been set up and their additive contributions Δ to the shielding of the C_α and C_β atoms attached to the triple bond have been calculated. The regression equation obtained

$$\delta C(R^1C{\equiv}CR^2) = 72.0 + \Delta\delta C_\alpha(R^1) + \Delta\delta C_\beta(R^2) \quad (3)$$

permits the calculation of δC_{sp} for 576 of the corresponding acetylenic compounds with an accuracy not less than to within 2.0 p.p.m.[42] The additive contributions are listed in Table 1. The application of the additive scheme permits a significant simplification of the assignments of the ^{13}C signals in disubstituted acetylenes and is extremely useful for the theoretical calculation of the δC for the ethynyl carbon atoms.

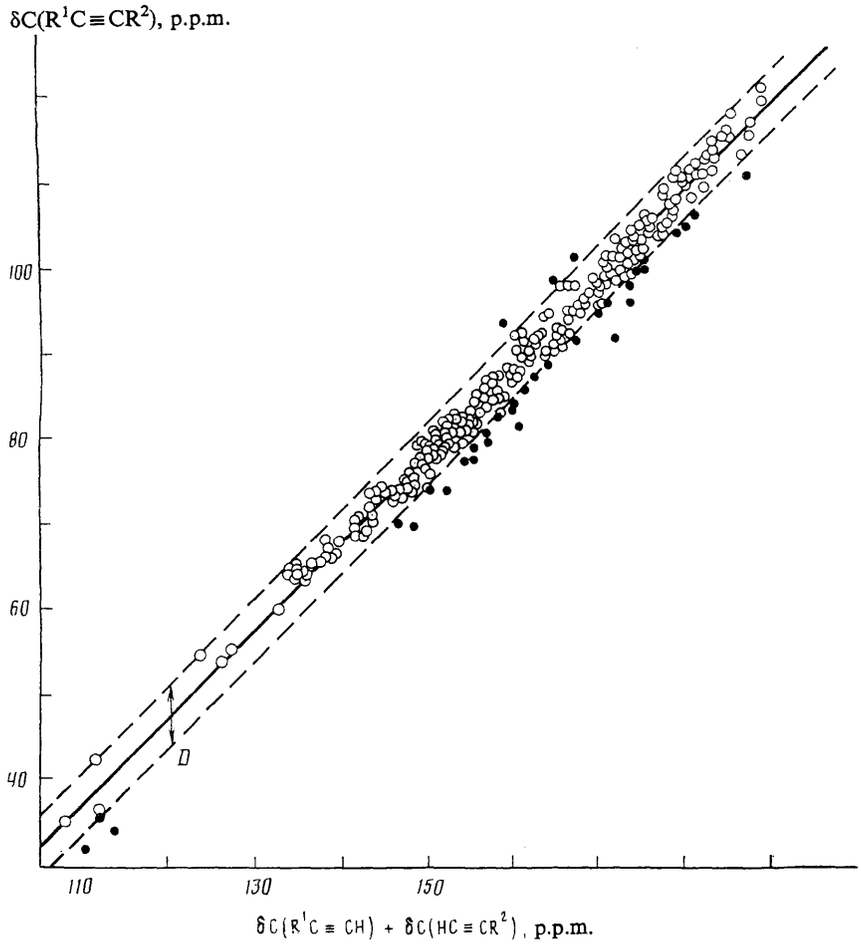

Figure 1. Dependence of the experimental shifts $\delta C(R^1C{\equiv}CR^2)$ on the theoretically calculated sums $\delta C(R^1C{\equiv}CH) + \delta C(HC{\equiv}Cr^2)$ (according to the results of Kalabin and co-workers[40,41]): *D* is a ±3 p.p.m. "corridor" around a theoretical straight line; ●—points whose deviations exceed 3.0 p.p.m.; ○—points corresponding to experimental data whose deviations from the theoretical straight line do not exceed 3.0 p.p.m.

The reliable establishment of the fact that the substituents have additive effects on the δC for acetylenic compounds is extremely useful for utilitarian purposes, but it is somewhat unexpected, since it presupposes the absence of interactions between the substituents R^1 and R^2. Together with disubstituted acetylenes, model *trans*-1,2-disubstituted ethylenes and 1,4-disubstituted benzenes were also examined. These are the simplest unsaturated compounds where there is no steric interaction between the substituents but there is an effective interaction via the mechanism involving direct polar conjugation.[29,42–47]

In order to discover how the interaction of the substituents is manifested in such substituted benzenes and acetylenes, the values of δC for these series of compounds were subjected to a statistical treatment within the framework of the corresponding mathematical model.[41,48] In *trans*-1,2-disubstituted ethylenes and 1,4-disubstituted benzenes, the influence of the substituents R^1 and R^2 is significantly non-additive. In the compounds $R^1C{\equiv}CR^2$, the substituents R^1 and R^2 influence the chemical shift δC_{sp} independently of one another, and their effects are described satisfactorily within the framework of the polylinearity principle. The additivity of the effects of the substituents on the δC for ethynyl carbon atoms in disubstituted acetylenes presupposes the absence of direct interaction between the substituents through the triple bond. The possibility of the constancy of the contribution of such interaction appears unlikely.

Table 1. The additive contributions of the substituents to the shielding of the $^{13}C_{sp}$ nuclei in disubstituted acetylenes.[42]

R^1	$\Delta\delta\ C_\alpha$	$\Delta\delta\ C_\beta$	R^1	$\Delta\delta\ C_\alpha$	$\Delta\delta\ C_\beta$
H	0.0	0.0	Me_3Si	17.6	23.1
Me	7.8	—4.4	Et_3Si	15.6	23.8
Et	13.4	—4.1	Me_3Ge	17.5	21.4
Bu	13.0	—3.3	Et_3Ge	14.9	23.2
Bu^t	20.6	—5.6	Me_3Sn	15.7	26.8
Ph	12.0	6.0	Et_3Sn	14.2	26.8
p-$MeOC_6H_4$	11.9	4.9	$P(O)(OEt)_2$	1.6	17.0
p-MeC_6H_4	11.9	5.5	C≡N	—15.9	3.2
p-ClC_6H_4	10.6	7.0	COMe	10.8	6.7
$CH_2{=}CH$	9.9	6.7	COPh	9.0	9.3
$Me_2C(OH)$	17.5	0.2	OEt	16.2	—52.3
CH≡C	—3.3	—7.2	SEt	0.5	11.2

Note. The error of the determination of the contributions does not exceed ±2.0 p.p.m.

The non-additivity of the effects of substituents on δC_{sp^2} for *trans*-1,2-disubstituted ethylene derivatives is very considerable. The maximum deviations of δC from values calculated on the assumption of additivity reach 30 p.p.m. Although the deviations from additivity are much smaller for disubstituted acetylenes, (the number of compounds for which experimental δC deviate by more than 3.0 p.p.m. from the theoretical values is 27 and 3% of the total number for *trans*-disubstituted ethylenes and disubstituted acetylenes respectively[41]), analysis of these deviations can throw light on the nature of this phenomenon. Table 2 presents compounds for which the values of δC_{sp} for R^1 differ by more than 3.0 p.p.m. from the values calculated theoretically by Eqn. (2). If one excludes from consideration compounds 5 and 6 (data obtained in H_2O[49]), it is found that out of 31 compounds, 28 compounds (>90%) have substituents $ER^1R^2R^3$, where E = Si, Ge, Sn, or P, which is undoubtedly not fortuitous. We shall consider in greater detail the cause of the observed phenomenon.

3. The counterpolarisation of the π-systems of triple bonds

The π-electron systems of the triple bond in acetylene are energetically degenerate, i.e. the π-charge is distributed along the axial position relative to the molecular axis. Depending on the symmetry, the substituents remove this degeneracy to a greater or lesser extent. The degeneracy is apparently removed to the least extent by alkyl substituents and halogen atoms, in the presence of which the molecular symmetry is close to C_{3v} and the barrier to rotation is low. The non-equivalence of the π-orbitals of the triple bond increases with increase in this barrier, reaching a maximum for substituents having a symmetry plane (the COR, Ph, $CH{=}CH_2$, etc. groups). Such substituents are capable of interacting only with one of the π-systems of the triple bond, polarising it or becoming conjugated with it (an appreciable π-charge transfer takes place). The polarisation of the second, orthogonal π-system can partly compensate for the redistribution of the π-charge in the first system, i.e. the counterpolarisation of the orthogonal π-systems of the triple bond takes place. The possibility of this phenomenon has been stated in a number of studies[29–31] (see above).

Table 2. The deviations (*D*, p.p.m.) of the experimental shifts δC for the compounds $R^1{-}C{\equiv}C{-}R^2$ from the calculated values.[41]

If each substituent in disubstituted acetylenes interacts with only one π-electron system of the triple bond, then the effectiveness of the interaction between the substituents themselves can be minimal and their effects on the triple bond can be entirely independent. The observed additivity of the effects of substituents confirms these ideas. The substituents in disubstituted ethylenes and benzenes interact with one π-system and their effects cannot be independent. The non-additivity of the effects of substituents on δC_{sp^2} in these systems can therefore be also understood.

The general features of the influence of substituents on the shielding of ethynyl carbon atoms can be formulated on the basis of the counterpolarisation idea in the following manner.

1. If the substituent interacts with one only π-system of the triple bond, then, as a result of the counterpolarisation, its effect on δC_{sp} is equal to or smaller than its effect on a double bond.

2. If the substituent interacts simultaneously with both π-systems of the triple bond, then counterpolarisaiton is difficult and its effect on δC_{sp} is equal to or greater than its effect on a double bond.

3. The greatest deviations from additivity are characteristic of disubstituted acetylenes in which one of the substituents is capable of interacting with both π-systems, while the other, regardless of symmetry, exerts a complementary or competitive π-electronic effect.

The latter is confirmed by the data in Table 2: the electron-accepting properties of Si, Ge, Sn, and P in relation to the π-system depend little on the angles of rotation of the corresponding substituent relative to the multiple bond.[50] For this reason, one should expect appreciable deviations for ethynyl ethers, in which the oxygen atom has a π-donor capacity in relation to both orthogonal π-systems.[33] Finally, the orthogonal orbitals of neighbouring triple bonds also interact with one another in the same way.

Table 3. The influence of various substituents (ΔδC) on the shielding of the α- and β-carbon atoms of the double and triple bonds in monosubstituted derivatives of ethylene and acetylene.

R	R–CH=CH₂		R–C≡CH		Presence of counter-polarisation (+, –)	σ_R^0	$(\sigma_R^0)_{tw}$

Note. Effects relative to saturated compounds are indicated, i.e. $\Delta\delta C_{sp^2(sp)} = (\delta C_{sp^2(sp)} - \delta C^0_{sp^2(sp)}) - (\delta C_{sp^3} - \delta C^0_{sp^3})$. The values $\delta C^0_{sp}(HC\equiv CH) = 72.0$, $\delta C^0_{sp^2}(CH_2=CH_2) = 122.8$, and $\delta C^0_{sp^3}(CH_3CH_3) = 5.7$ were used.

* The estimate was made for 1,2-trans-disubstituted ethylenes and disubstituted acetylenes.

The first two postulates have been confirmed by the analysis of the relative effects of different substituents on the shielding of α- and β-carbon atoms of the multiple bond in vinyl and ethynyl compounds (Table 3). The Table also indicates the resonance constants of the substituents α_R^0 and $(\sigma_R^0)_{tw}$,[33] which correspond to the interaction of the substituents with the two orthogonal π-systems of the triple bond. The signs of these constants are always the same but the constants $(\sigma_R^0)_{tw}$ are equal to or smaller than σ_R^0. The numerical values of the constants indicate a non-equivalence, in certain cases, of the π-systems of triple bonds and the possibility of their counterpolarisation. Table 3 does not include data for compounds with R = $GeEt_3$ and $SnEt_3$, since they are identical with data for R = $SiEt_3$. All the results, with the exception of those which correspond to compounds with the EtS and N≡C groups, are fully consistent with the model of the counterpolarisation of the triple bond π-orbitals developed here.

The fact that the concept of the counterpolarisation of the triple bond is well founded has been confirmed by the calculation of the distribution of π-electron densities in a series of model acetylenic compounds, which have been performed by non-empirical methods using the OST-4GF basis set (Table 3). The countertransfer of the π-charge via the orthogonal π-systems of the acetylenic fragments has been noted for aminoacetylene, formylacetylene, and phosphinoacetylene molecules‡, i.e. in the presence of substituents (π-donor and π-acceptor) capable of direct interaction with only one π-system of the triple bond.

The fluorine atom interacts effectively with both triple bond π-systems. This gives rise to the maximum transfer in the given instance of the negative π-charge to the terminal carbon atom of the triple bond and also agrees with experiment.

The presence of two hybrid orbitals with different symmetries, which include the unshared electron pairs of the oxygen atom in hydroxyacetylene, is responsible for the effective interaction of one of the unshared electron pairs in the case of a planar molecular conformation, whereas the contribution of a second electron pair to the corresponding π-MO is much smaller and compensates for the possible countertransfer of the charge (Table 4).

Table 4. The distribution of charge density ($10^3 q_\pi$) in the acetylenic fragment of the compounds $H-C_\beta\equiv C_\alpha-X$.[41]

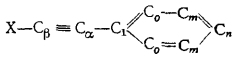
X	q_{C_α}			q_{C_β}		
	π_y	π_z	Σπ	π_y	π_z	Σπ
H	0	0	0	0	0	0
$CH=CH_2$	1	16	17	–6	–20	–26
CHO	–16	16	0	36	–15	21
COOH	–19	1	–18	36	4	40
NH_2 (planar molecule)	–48	58	10	44	–134	–90
NH_2 (non-planar molecule)	–31	38	7	21	–93	–72
PH_2	31	–51	–20	–25	26	1
OH	19	–30	–11	–79	1	–78
F	–28	–28	–56	–48	–48	–96

The results presented in Tables 3 and 4 make it possible to estimate the sensitivity of the chemical shifts of the *sp*-carbon atoms to π-electronic effects (it amounts to 600 p.p.m. per charge unit, which is approximately three times greater than the analogous characteristic of the sp^2-carbon atoms of substituted ethylenes).

Overall, the results of quantum-chemical calculations for monosubstituted acetylenes, the analysis of the chemical shift δC_{sp} for mono- and di-substituted acetylenes, and their comparison with the analogous results for disubstituted ethylenes indicates the occurrence of the counterpolarisation of the orthogonal π-systems of the triple bond.

‡ The calculation for the phosphinoacetylene molecule was performed in terms of the *sp*-basis set (without taking into account the *d* orbitals) and the phosphorus atom therefore behaves as a π-donor as a result of the presence of its unshared electron pair.

4. The ability of the triple bond to transmit the effects of substituents



We shall consider the character and degree of the transition of the electronic effects of the groups X through the triple bond in relation to the compound X−C≡C−R, where R = Ph, $CH=CH_2$, or C≡CH. In vinylacetylenes $X-C_\alpha\equiv C_\beta-C^1H=C^2H_2$,[51–53] there is no explicit relation between the changes in δC_β and δC^2. One may note that the effect of X on the triple bond is specific, since the substituent X induces a displacement of δC_β by more than 40 p.p.m., whereas δC^2 is displaced by only 4 p.p.m. and δC^1 by only 2 p.p.m. The effect of X on the terminal vinyl group is mainly manifested by the polarisation of π-electrons by the dipole of the X−C bond (the changes in δC^1 and ΔC^2 take place in the opposite directions and agree with the direction of the dipole). This can be seen from a comparison of the δC for the two compounds $Et_2NCH_2C_\alpha\equiv C_\beta-C^1H=C^2H-SEt$ (A) and $[Et_2MeNCH_2-C_\alpha\equiv C_\beta-C^1H=C_2H-SEt]I$ (B):[54]

	C_α	C_β	C^1	C^2
δC(A), p.p.m.	92.4	81.6	104.9	139.6
δC(B), p.p.m.	87.2	84.1	101.9	144.8
Δδ C	−5.2	2.5	−3.0	5.2

The results presented as well as the available data for diacetylenic compounds[53,55–57] agree fully with the model involving a significant polarisation of the triple bond.

The ability of the triple bond to transmit electronic effects to the benzene ring can be characterised and the degree of interaction of the ethynyl and phenyl groups can be elucidated most correctly by analysing the data for β-substituted phenylacetylenes X−C≡CPh. This series of compounds is attractive because the values of δC for the compounds X−Ph are known for virtually any groups X and the $Ph-C_\alpha\equiv C_\beta-X$ fragment has a rigid conformation, while the presence of four indicator centres in the benzene ring facilitates the classification of the effects of the group X.

The values of δC for 39 β-substituted phenylacetylenes

have been published.[41] As for other series of compounds, not even a qualitative relation is observed in this instance between the δC_{sp} and any of the sets of the σ constants of the group X. We shall consider the characteristics of the variation of the degree of shielding of the aromatic carbon atom. The changes in the latter amount to 9.2, 10.0, 4.0, and 18.0 p.p.m. for C_1, C_o, C_m, and C_p respectively. The effect of the substituent X on the shielding of the C_{sp^2} atoms in the compounds X−C≡C−Ph is formally of the same type,[41] which follows from the equation

$$\delta C_m = 0.183(0.006)\delta C_p + 104.9(0.8),\quad r = 0.985,\ s = 0.14;$$
$$\delta C_o = 0.545(0.018)\delta C_p + 61.5(2.3),\quad r = 0.981,\ s = 0.41;$$
$$\delta C_1 = -1.27(0.07)\delta C_p + 286.5(8.4),\quad r = 0.97,\ s = 0.46. \qquad (4)$$

The principal causes of the influence of X on the benzene ring are the field and resonance effects,[41] which have been described most fully for various substituted benzenes in terms of resonance (R) and field (F) constants.[58] The difference between the values of δC for the *para*- and *meta*-positions in the ring of X−Ph is usually determined by the pure resonance effect of the group X.[59] In our case, the corresponding equation is

$$\delta C_p - \delta C_m = 0.22(0.09) + 4.7(0.3)F + 4.9(0.5)R,\quad r = 0.987,\ s = 0.2,\ n = 14. \qquad (5)$$

Consequently the field effect is the principal factor governing the influence of the groups X on the aromatic fragment through the triple bond. Examination of the shielding of the proton at the β-carbon atom of the triple bond in the *para*-substituted phenylactylenes $X-C_6H_4-C_\alpha\equiv C_\beta-H$, carried out by Klasine et al.,[29] leads to a similar conclusion.

The ability of the −C≡C− bridging group to transmit the influence of substituents can be estimated by comparing the values of δC_p for the compounds Ph−X, Ph−CH=CHX (*trans*-isomer), and Ph−C≡CX. The regression equations are presented below (the values of δC_p are quoted relative to the corresponding unsubstituted compounds with X = H). For monosubstituted benzenes, the values of δC_p were taken from Ewing[60] and those for *trans*-styrenes were taken from Glukhikh et al.[61]

$$\delta C_p(PhC\equiv CX) = 0.55(0.02)\delta C_p(PhX) + 0.75(0.18),\quad r = 0.98,\ s = 0.8,\ n = 29; \qquad (6a)$$
$$\delta C_p(PhCH=CHX) = 0.88(0.04)\delta C_p(PhC\equiv CX) - 0.19(0.09),\quad r = 0.99,\ s = 0.2,\ n = 11. \qquad (6b)$$

The transmission coefficient in Eqn. (6a) is identical with the value determined as a result of the investigation of the reactivities of dinuclear bridged systems (see, for example, Litvinenko, et al.[62]). It follows from Eqn. (6b) that the coefficient of the transmission of substituent effects to the benzene ring through the triple bond is close to the corresponding value for the double bond. The high confidence level of Eqn. (6b) can serve as evidence for the similarity of the formal mechanisms of the transmission of the substituent effect through the double and triple carbon−carbon bonds.

5. Characteristic features of the influence of substituents on the shielding of C_{sp}

Group IVA elements. The nature of the influence of substituents on the shielding of *sp*-carbon atoms in acetylenic compounds can be usefully examined by comparing the experimental values of δC_{sp} for acetylene itself and for its monosubstituted derivatives or by analysing the additive contributions found (Table 1). The characteristic features of the effects of alkyl groups on δC_{sp} can be seen from the comparison of the corresponding data for substituted acetylenes, ethanes,[63] ethylenes,[64,65] and benzenes[60,66] (the values of δC for the carbon atoms in these compounds are presented in Table 5).

A good relation is observed between the values of δC in the series of alkylacetylenes and alkylethylenes, the shielding of C_α in the series of alkyl-acetylenes being less sensitive (approximately by 30%) to the nature of the alkyl substituent than in the series of alkylethylenes.[67] The values of δC_{sp} for the β-carbon atoms in alkyl acetylenes remain virtually constant within the series. This is also characteristic of the C_p atoms of the benzene ring and reflects the independence of the π-polarisation of the unsaturated fragment of the size of the alkyl group. The increase in the shielding of the C_β atoms in ethynyl and vinyl derivatives and of the C_o atoms in phenyl derivatives is a consequence of the enhancement of the steric interaction of these atoms with the alkyl group as the bulk of the latter increases.

Substituents containing other Group IVA atoms influence the ethynyl fragment of the substituent quite differently. Since the effects of the $EAlk_3$ groups depend little on the character of E (Si, Ge, Sn) and of the alkyl (Alk), we shall examine them in relation to only the $SiEt_3$ group. The values of δC for hydrocarbon fragments

containing the $SiEt_3$ substituent (data taken from Proidakov[74]) are presented in Table 5. The deshielding effect of the $EAlk_3$ group on the C_β atom of the triple bond is stronger than for a single bond (by a factor of 20) and a double bond (by a factor of 2.5), while the shielding of the C_α atom in all the unsaturated fragments is the same.[52] The enhanced π-acceptor properties of the Si, Ge, and Sn atoms in relation to the triple bond have been explained by their ability to participate in the interaction with both its π-systems.[68] The fact that $EAlk_3$ groups deshield the C_β (C_o) atoms of the unsaturated fragments and hardly affect C_p in the benzene ring makes it possible to exclude from consideration the mechanism in which the effect is exerted through π-polarisation and through $p_\pi - d_\pi$ conjugation. Since the $EAlk_3$ groups act predominantly on the two nearest unsaturated carbon atoms, one can assume that the atomic orbitals of the two nearest sp^2- and sp-carbon atoms participate in the formation of the molecular orbitals (MO) responsible for the charge transfer from the π-system of the substituent to the atom E, which agrees with the model postulating the participation of the unoccupied σ* orbitals of the E–C bonds in the donor–acceptor interaction.[68]

Table 5. The ^{13}C chemical shifts (p.p.m. relative to TMS) of substituted ethanes, ethylenes, acetylenes, and benzenes.

R	$R-C_\alpha H_2-C_\beta H_3$		$R-C_\alpha H=C_\beta H_2$		$R-C_\alpha \equiv C_\beta H$	
	C_α	C_β	C_α	C_β	C_α	C_β

Pr^i	148.7	126.6	128.6	126.1
Bu^t	149.1	125.4	128.4	125.9
Et_3Si	140.4	133.6	128.6	128.7

Group VIA and VIIA elements. Alkoxy- and aryloxy-groups significantly shield the C_β atom at the triple bond, displacing its signal by 20–30 p.p.m. relative to that of the TMS carbon atom,[20,21,69] which is explained by the effective conjugation of the lone electron pairs (LEP) of the oxygen atom with the π-electron system of the triple bond, i.e. with the appreciable contribution of the canonical structure of the type $R-\overset{\oplus}{O}=C=\overset{\ominus}{C}H$. The extent of such interaction has been examined in relation to ethynyl ethers.[69] The shielding of the C_β atom in the ether $PhOC_\alpha \equiv C_\beta H$ is less pronounced than in the ether $EtOC_\alpha \equiv C_\beta H$ (the difference between the displacements is 10 p.p.m.) in view of the competing interaction of two π-electron substituents with the ether oxygen as the electron donor. This is confirmed by the comparison of the values of δC of the phenyl group (p.p.m. relative to δC_{TMS}) for isoelectronic ethers R–O–Ph:

R	C_1	C_o	C_m	C_p
CH_3-CH_2	159.26	114.53	129.38	120.57
$CH_2=CH$	156.25	117.03	129.24	122.67
$CH \equiv C$	155.54	114.81	129.36	124.23

Comparison of the degrees of shielding of C_p in these compounds shows that the delocalisation of the charge of the oxygen LEP over the benzene ring diminishes by a factor of 1.4 on passing from the vinyl to the ethynyl ether and by a factor of 2 on passing from the ethyl to the ethynyl ether§, i.e. the degree of charge transfer from the oxygen atom to the triple bond is appreciably greater than the charge transfer to the double bond. This follows from a comparison of the excess shielding of the C_β atom in the ethynyl group (the displacement of the shift is by 38.4 p.p.m. relative to acetylene) and in the vinyl group (the displacement is by 28.2 p.p.m. relative to ethylene).[69] Bearing in mind the different sensitivities of the shielding of the C_{sp} and C_{sp^2} atoms to changes in their charge density,[29] one may conclude that the excess charge on the C_β atom in the ethynyl ether is greater by a factor of 1.6 than in the vinyl ether. The similarity of the excess charge follows from the results in the literature[33,50] subject to the condition that in acetylenic ethers both orthogonal π orbitals of the triple bond participate in the p_π interaction with oxygen. These results agree with the results of the calculation of the charge distribution in the hypothetical $HC \equiv COH$ and $H_2C \equiv CHOH$ molecules by the OST-3G method.[70]

The sensitivities of the chemical shifts of the C_p atom of the benzene ring and of the C_β atom of the multiple bond of the group R to the effects of the substituent X in the compounds

have been compared for *para*-substituted ethynyl phenyl,[69] phenyl vinyl,[23] and phenyl propargyl[71] ethers, substituted styrenes,[72] and phenylacetylenes.[29] It is seen from the data in Table 6 that the ΔC_p for these series of compounds are fairly close, in contrast to ΔC_β. The ratio $\Delta C_\beta / \Delta C_p$ is appreciably lower for ethynyl and especially propargyl ethers. The numbers presented in the last two columns of Table 6 indicate a decrease of the resonance effect in the case of substituted acetylenes, while the field effect, i.e. the π-induction effect, remains unchanged. As was to be expected, it becomes dominant in propargyl ethers. This is also confirmed by the relation between δC for *para*-substituted propargyl ethers $CH \equiv CCH_2O-C_6H_4X$ and the dipole moments[73] of the corresponding monosubstituted benzene derivatives Ph–X:

$$\delta C_\beta = 0.34\,(0.04)\,\mu_{PhX}, \quad r = 0.975,\ s = 0.14,\ n = 7. \qquad (7)$$

§ The charge transfer from the ether oxygen atom to the benzene ring can be most correctly estimated from the change in δC_p (this value is proportional to the change in the charge on the atom):

	δC_p, p.p.m.	$\Delta\delta C_p$, p.p.m. (relative to benzene)
C_6H_6	128.5	0
$C_2H_5OC_6H_5$	120.4	−8.1
$CH_2=CHOC_6H_5$	122.7	−5.8
$CH \equiv COC_6H_5$	124.2	−4.3

i.e. the charge transfer to the benzene ring on passing from the ethyl to the vinyl ether diminishes by a factor of (−8.1/−5.8) ≃ 1.4 whilst on passing from the ethyl to the ethynyl ether the decrease is by a factor of (−8.1/−4.3) ≃ 2.

Thus the influence of substituents capable of conjugation on the shielding of the carbon atoms of the triple bond through the saturated fragment is exerted via its π-polarisation.

Table 6. The displacements of the chemical shifts of the C_p atom of the benzene ring and the C_β atom of the multiple bond (in p.p.m.) and their sensitivity to the effects of the substituent X in the compounds

R	ΔC_n	ΔC_β	$\Delta C_\beta/\Delta C_n$	$\lambda(C_n)$	$\lambda(C_\beta)$	$\rho_R(C_\beta)/\rho_R(C_n)$	$\rho_F(C_\beta)/\rho_F(C_n)$
CH_2=CH	13.1	7.0	0.54	6.8	2.6	0.45	1.03
CH≡C	13.8	6.1	0.44	6.4	1.8	0.28	0.98
CH_2=CHO	10.6	5.5	0.52	6.9	1.9	0.32	1.17
CH≡CO	10.0	2.9	0.29	8.8	1.7	0.20	1.00
CH≡CCH_2O	11.2	1.6	0.14	6.1	1.0	0.08	0.45

Note. ΔC is the range of variation of δC when X is varied in the series from the NO_2 acceptor to the OMe donor; $\lambda = \rho_R/\rho_F$ is the ratio of the sensitivities of δC to the resonance and field effects obtained from statistically reliable correlations ($r \geqslant 0.99$).

Table 7. The influence of the heteroatomic groups Alk_nE on the shielding of α- and β-carbon atoms of substituted acetylene, benzene, and ethane derivatives (displacements of the chemical shifts, p.p.m.).[78]

Note. The displacements of the chemical shifts are quoted relative to the corresponding unsubstituted compounds.

* The electronegativities of the heteroatoms taken from Batsanov[77] are quoted.

** The differences between the corresponding values obtained on passing from elements of the 3rd Period to those of the 5th Period are quoted.

The results presented characterise the ability of bridging groups to transmit the electronic effects and show that the employment of "transmission factors" for individual bridging groups as stable characteristics is erroneous.[62] Comparison of the values of $\Delta C_\beta/\Delta C_p$ for the first four compounds demonstrates that the ability of the ether oxygen to transmit perturbations is significantly different even in fairly close structural series and depends on the conformational structure of the molecules, the character of the detector group, and, finally, on the property or parameter of the group chosen for the comparison. The ether oxygen atom has an enhanced π-donor capacity in relation to the triple bond because it can interact simultaneously with two orthogonal π orbitals. This is reflected in the non-universality of the existing scales of the resonance constants σ_R (with the possible exception of Katritzky's scale[33,50] mentioned above), which is due to the unequal effectiveness of the interaction of the group R with different (as regards the character of the symmetry of the π-system) unsaturated fragments. In the compounds $AlkEC_\alpha\equiv C_\beta R$, where E = S, Se, or Te, an increased shielding is characteristic of the C_α atoms (regardless of the character of R); the chemical shift is displaced by 9—11 p.p.m. on passing from the sulphides to the selenides and by 33—36 p.p.m. on passing from the sulphides to the tellurides. On the other hand, the C atom is deshielded and the corresponding displacements are 5—6 and 17—18 p.p.m.[53] Evidently chalcogens exhibit π-acceptor properties in relation to the triple bond, because the EtS and $EtCH_2$ groups, having similar induction constants, exhibit significantly different effects on the vinyl and ethynyl fragments, while the effects on the ethyl groups are similar (the values of δC are listed below in p.p.m.):[74]

	$R-C_\alpha H_2-C_\beta H_3$		$R-C_\alpha H=C_\beta H_2$		$R-C_\alpha\equiv C_\beta H$	
	C_α	C_β	C_α	C_β	C_α	C_β
δC(R=EtS)	26.5	15.8	132.7	109.7	74.0	82.2
δC(R=$EtCH_2$)	22.6	13.7	137.6	113.5	83.6	68.2
Δδ C	3.9	2.1	—4.9	—3.8	—9.6	14.0

Whereas the π-electronic effect of the ethylthio-group on the C_β atom of the double bond is shielding, in the case of the triple bond it has the opposite sign and is three times greater. It may be that in the latter case this effect has the character of $d_\pi-p_\pi$ conjugation. Such conjugation is promoted by the increase in the electronegativity of the substituent at the sulphide sulphur atom.[68,75] This is confirmed by the X-ray fluorescence spectra of the compounds $AlkEt\equiv CH$, which indicate an appreciable contribution of the charge on the 3*d* orbitals of the sulphur atom.[76] A non-empirical calculation for the $HSC\equiv CH$ molecule in terms of the contracted STO-3G basis set[70] indicates nevertheless the existence of an appreciable negative charge (−0.19) on the ethynyl fragment. On the basis of the concept of the π-acceptor nature of the deshielding of the C_β atom, one may conclude that, since it increases significantly from sulphur to tellurium, the $5d-2p$ π-interaction is energetically most favourable. In view of the unexpected nature of this conclusion, we shall consider the characteristic features of the influence of Group VIA elements on the δC of the closest carbon atoms of the group R in the series of isologous compounds of Group IVA, VIA, and VIIA elements (Table 7). With increase in the number of the Period, the shielding of the C_{sp^2} atom, in the α-position relative to the Group VIA element, leads to an increase in the chemical shift by 50—70 p.p.m., while δC_β hardly changes. In the series of halogenoalkanes, the character of the changes in δC is analogous, although their range is wider by 20—30%.[79,80] In the isologous series of compounds of Group IVA elements (Alk_3ER), the changes in δC for the alkyl group are not regular and their range is much narrower.[81]

The shielding effect of the chalcogens on C_α in the case of sp^2-carbon atoms increases with increase in the number of the Period, as for sp^3-carbon atoms, although the range of variation of

δC in the latter case is somewhat wider. The values of δC_β for the C_{sp^2} atoms increase with increase in the atomic number of E and for the vinyl fragment this increase is more appreciable than for the phenyl fragment (Table 7). This is apparently induced by the redistribution of the π-charge of the heteroatom in the case of the phenyl substituent between two positions (*ortho*- and *para*-positions).[78]

The shift δC_{sp} changes under the influence of the heteroatom E (E = O, S, Se, Te) approximately in the same way as in halogenoacetylenes, but the change is different from that observed in Group IVA elements (Table 7).

In the isologous series of compounds of Group IVA, VIA, and VIIA elements (Table 7), the "heavy atom effect" apparently makes a considerable contribution to the change in the shielding of the C_α and C_β atoms of the triple bond in the chalcogenides and halides. The occurrence of this effect for the halogens has been noted in a number of studies.[80,82,83] Although the electronegativity of Group IVA elements also changes appreciably, this effect is not manifested in this instance. The following qualitative model of the observed phenomenon can be proposed. The effect of the elements of different Groups in the Periodic System on neighbouring hydrocarbon fragments is determined by the presence in these elements of different numbers of LEP (O for C, Si, Ge, Sn, and Pb, 2 for O, S, Se, and Te, and 3 for F, Cl, Br, and I), which are capable of interacting with substituents at a distance more strongly the greater the increase of the diffuseness of the corresponding *p* orbitals within the Group. The size of the substituent, the presence in the latter of a π-system, and the polarisability of the system determine the extent of the influence of the heteroatom on the substituent, i.e. the extent of the changes in δC. The absence of the "heavy atom effect" in Group IVA elements is a consequence of the absence of the LEP from them.

Since a rigorous test of this concept by a reliable quantum-chemical calculation of the shielding of the ^{13}C nuclei for the set of compounds examined has not been carried out, the results are mainly of applied interest—they assist in the correct assignment of the ^{13}C signals.

III. The constants for the spin–spin coupling in the acetylenic fragment

For all acetylenes without exception, it is possible to measure only one spin–spin coupling constant $^1J_{CC}$. In addition, for monosubstituted acetylenes it is possible to measure the SSCC between the terminal proton and the acetylenic carbon atoms across one and two bonds: $^1J_{CH}$ and $^2J_{CH}$ respectively.

1. The spin–spin coupling constants $^1J_{CH}$ and $^2J_{CH}$

The values of the SSCC $^1J_{CH}$ and $^2J_{CH}$ for acetylene (these constants have been measured most accurately by Mohantry[84]) are +248.97 and +49.62 Hz respectively. The SSCC for more than 60 monosubstituted acetylenes are presented in Table 8. The range of variation of $^1J_{CH}$ is about 50 Hz and that of $^2J_{CH}$ is about 25 Hz. For the series of compounds HC≡CX, a relation has been obtained from which it follows that the electronegativity X exerts a decisive influence on $^1J_{CH}$:[88]

$$^1J_{CH} = 208.4\,(4,7) + 17.4\,(1.8)\,E_X,\ r = 0,95,\ n = 13. \quad (8)$$

The following relation has also been put forward:[89]

$$^1J_{CH} = 5,7\,(\%s) - 18,4, \quad (9)$$

It has been used to estimate the amount of *s* character of the carbon atom in discussing the mechanisms of the interaction of various heteroatomic substituents with the triple bond.[20,21] The appreciable decrease of these SSCC for compounds containing Si, Ge, or Sn atoms as substituents at the triple bond has been explained in a number of publications[3,7,8,90] by the decrease in the amount of *s* character of the hybrid orbital of the terminal carbon atom, participating in the formation of the C–H bond, as a result of the π=acceptor effect of E: $R_3\overset{\ominus}{E}=C=\overset{\oplus}{C}-H$. This model is relatively unconvincing because $d_\pi - p_\pi$ interaction is also characteristic of the substituents R_2SO_2 (this follows from the appreciable population of the *d* orbitals of the sulphur atom according to X-ray fluorescence data), although for these compounds $^1J_{CH}$ is greater by 13 Hz than for alkynes (Table 8). Furthermore, the decrease in the amount of *s* character of the terminal carbon orbital in ethynyl ethers can be induced by the π-donor properties of oxygen:

$$RO-C\equiv C-H \longleftrightarrow \overset{\oplus}{RO}=C=\overset{\ominus}{C}-H.$$

However, in this case too there is an appreciable increase in $^1J_{CH}$ and the influence of the nature of R on $^1J_{CH}$ is insignificant (Table 8).

Table 8. The spin–spin coupling constants $^1J_{CH}$ and $^2J_{CH}$ (in Hz) for monosubstituted acetylene derivatives R–C≡CH.

A reliable relation between $^1J_{CH}$ for monosubstituted acetylenes and characteristics of the substituents (σ_I, σ_R, *F*, *R*) other than E_X could not be observed, although the correlation between the constants $^1J_{CH}$ and $^2J_{CH}$ is reliable:[41]

$$^1J_{CH} = 1,73\,(0,07)\,^2J_{CH} + 164\,(3.5),$$
$$r = 0.975,\ s = 2.0,\ n = 35. \quad (10)$$

The latter shows that both these SSCC are controlled by the same factors.

2. The spin–spin coupling constants $^1J_{CC}$

The values of $^1J_{CC}$ increase sharply with increase in the *s* bond order: in the calculation by the method involving summation with respect to states in terms of the "average excitation energy" approximation, the Fermi-contact contribution is proportional to the product of the amounts of *s* character of the hybrid orbitals of the interacting carbon atoms forming the C–C bond.[91] In acetylenic compounds, the *s* order has the maximum possible value (50%), which is the reason for the very high values of $^1J_{CC}$ and the wide range of their variation.

For acetylenic compounds, the constants $^1J_{CC}$ increase linearly, like the constant $^1J_{CH}$, with increase in the electronegativity of the substituent,[86,92,93] which is induced by the increase in the Fermi-contact contribution.[94] A specific feature of the $^1J_{CC}$ for acetylenic compounds is a significant contribution of non-contact interactions transmitted predominantly via the π-electron system.[95]

The range of the experimental values of $^1J_{CC}$ (for 100 acetylenic compounds[96]) is unusually large: from 56.8 to 230.4 Hz, i.e. more than 170 Hz. According to theoretical estimates,[97] the limiting values may be 31.8 Hz (LiC≡CLi) and 356.0 Hz (FC≡CF). If the group electronegativity parameter of the substituent σ^2, calculated from the atomic charge density of hydrogen in the H–X molecules by the *ab initio* method in terms of the 6-31GF basis set[98] disregarding π-interactions, is used as a characteristic of the substituent in monosubstituted acetylenes, it is possible to obtain the relation

$$^1J_{CC} = 317.6\,(11.9)\,\sigma_\chi^2 + 164.9\,(0,8),$$
$$r = 0.983,\ s = 4.0,\ n = 27. \qquad (11)$$

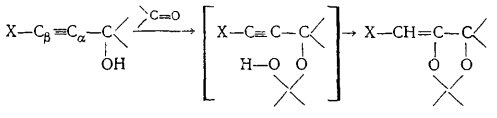
Equations of a similar type have also been found for disubstituted acetylenes with a single fixed substituent, although this approach does not take into account the mutual influence of the substituents, which leads to non-additivity. A general relation for all acetylenic compounds of the type XC≡CY assumes the form[96]

$$^1J_{CC} = 270.8\,(7.3)\,(\sigma_\chi^2 X + \sigma_\chi^2 Y) + 720.4\,(151.8)\,\sigma_\chi^2 X \sigma_\chi^2 Y + 162.4\,(0.7),$$
$$r = 0.982,\ s = 5.4,\ n = 59. \qquad (12)$$

The cross-term in Eqn. (12), which is statistically significant, reflects the non-additivity of the influence of the substituents. It is greatest when the α-atom of one of the substituents is Si, Ge, Sn, Br, I, or Hg, which influences significantly the π-system of the acetylenic compound.

There is a reliable relation between the constant $^1J_{CC}$, on the one hand, and $^1J_{CH}$ and $^2J_{CH}$ for monosubstituted acetylenes:[96]

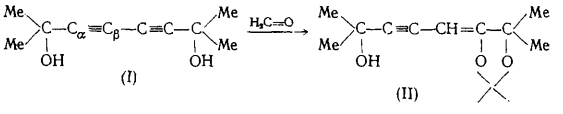
$$^1J_{CC} = 2.87\,(0.15)\,^1J_{CH} - 545.6\,(37.1),$$
$$r = 0.981,\ s = 4.37,\ n = 16; \qquad (13a)$$
$$^1J_{CC} = 5.67\,(0.25)\,^2J_{CH} - 109.6\,(12.0),$$
$$r = 0.986,\ s = 3.70,\ n = 17. \qquad (13b)$$



The statistically significant (r = 0.995) relation between the constants $^1J_{CC}$ for disubstituted acetylenes and the force constants of the triple bonds in these compounds must be regarded as the most reliable relation for practical purposes.[99]

IV. Relation between the reactivity of substituted acetylenes and the chemical shifts of the ethynyl carbon atoms

The reactivity of acetylenic compounds and the stereospecificity of the addition of various reactants to them depend on the nature of the substituents, which determine the energy of the transition state, the steric accessibility of the triple bond to the attack by reactants, and the distribution of electron density in the molecule.



Since, according to literature data,[20,21] the values of δC_{sp} on the ^{13}C NMR spectra reflect the distribution of electron density in the acetylenic fragment, the difference between them ($\Delta\delta C$) characterises the polarisation of the triple bond. Presumably, these parameters can have a definite importance for the explanation and prediction of the regiospecificities and stereospecificities of reactions involving addition to the triple bond and in general as regards the possibility of their occurrence. The search for such relations is the aspect of the application of NMR to acetylene chemistry of greatest current interest.

The reaction involving the addition of carbonyl compounds to α-ethynyl alcohols containing a wide range of functional groups, both directly at the triple bond and separated from them by the methylene bridge, has been studied:[49,100–107]

Heterocyclisation proceeds readily in the series of α-ethynyl alcohols with X = Br, CN, COOR, COR, or C≡CR, but does not occur when X = H, CH=CH$_2$, PhO, ROCH$_2$, or R$_2$NCH$_2$. This difference in the chemical behaviour agrees well with the parameters of the ^{13}C NMR spectra of the corresponding acetylenic compounds.[49,100] Thus, whereas $\Delta\delta C_{\alpha,\beta}$ for the terminal alcohols (X = H) is 8–19 p.p.m., for the bromo-derivatives (X = Br) this quantity reaches 32–42 p.p.m., i.e. in the halogenoalcohols the degree of polarisation of the triple bond is greater, which favours nucleophilic addition. The direction of polarisation is determined mainly by the σ-acceptor effect of the bromine atom.

It is of interest to note that formaldehyde interacts with only one hydroxyethynyl group of the diacetylenic glycol (I):

Analysis of the values of δC for the dyne (I) and the enyne dioxolan (II) permits the conclusion that in the former case polarisation promotes the nucleophilic addition of the hydroxy-group with formation of the dioxolan ring, while in the latter case polarisation has the opposite direction and hinders the heterocyclisation ($\Delta\delta C_{\alpha,\beta}$ = 19.2 and –20.6 p.p.m. respectively[49]). In the isotypical compounds XCH$_2$C$_\beta$≡C$_\alpha$CH$_2$OH, in which the substituent X is separated from the triple bond by the methylene bridge, the changes in δC are determined mainly by its polar influence:[49]

$$\delta C_\alpha = 78.4\,(1.4) + 12.0\,(1.4)\,\sigma^*(XCH_2),\quad r = 0.977 \qquad (14)$$

The qualitative relation between $\Delta\delta C$ and the reactivity of substituted propargyl alcohols suggested an increase in the reactivity of substrates on passing from bases (aminoalcohols) to their quaternary

salts, for which the values of $\Delta\delta C$ are higher:[49]

$R_2NCH_2C_\beta{\equiv}C_\alpha C(OH)R^1R^2$ $\quad$ $I^{\ominus}MeR_2\overset{\oplus}{N}CH_2C_\beta{\equiv}C_\alpha C(OH)R^1R^2$

$\Delta\delta C_{\alpha,\beta}=4-7$ p.p.m. $\quad$ $\Delta\delta C_{\alpha,\beta}=17-22$ p.p.m.

The heterocyclisation of aminoalcohols on heating with paraformaldehyde in the presence of bases (potassium carbonate, potassium hydroxide, tetraethylammonium hydroxide) in boiling methanol for 8 h does not take place although the corresponding methiodides readily cyclise even at room temperature, affording high yields (75–90%) of the methiodides or 4-(2-dialkylaminoethylidene)-1,3-dioxolans. The latter were also obtained from the methiodides (IIIa–c) and the reactivity of these salts also agrees with the differences in δC_{sp}:[101]

$$I^{\ominus}MeR_2\overset{\oplus}{N}CH_2C{\equiv}CH \xrightarrow[KOH-EtOH]{H_2C=O} \overset{\ominus}{I}MeR_2\overset{\oplus}{N}CH_2CH{=}C(CH_2)(O)(O)(CH_2)$$

(IIIa–c) $\quad$ (IVa–c)

R = Me (a), Et (b), C_5H_{10} (c).

Comparison of the parameters of the ^{13}C NMR spectra of propargylamines $R_2NCH_2C_\beta{\equiv}C_\alpha H$ ($\Delta\delta C_{\alpha,\beta}$ = –5–6 p.p.m.) and their salts ($\Delta\delta C_{\alpha,\beta}$ = 8–12 p.p.m.)[101] permits the assumption that the triple bond in the molecules of the salts is polarised by the σ-acceptor effect of the ammonium group, which increases the acidity of the acetylenic proton and facilitates the interaction with paraformaldehyde under the conditions of the Favorskii reaction. This hypothesis has been confirmed by experimental data: on interaction with paraformaldehyde in alcoholic potassium hydroxide solution (60 °C, 1 h), the methiodides readily form substituted 1,3-dioxolans (IVa–c) in 90–91% yield.[101]

Terminal α-ethynyl alcohols react with phenyl isocyanate to form the corresponding *N*-phenylcarbamates, which isomerise to 4-alkylidene-2-oxazolidinones in the presence of bases:[108–110]

$$H{-}C{\equiv}C{-}CR_2(OH) \xrightarrow{PhNCO} H{-}C{\equiv}C{-}CR_2(NH{-}Ph)(C{=}O) \rightarrow CH_2{=}C(CR_2)(N(Ph)(C{=}O))(C{=}O)$$

Substituted 4-dialkylaminobut-2-yn-1-ols (V) also react with phenyl isocyanate to form the corresponding *N*-phenylcarbamates (VI), but their cyclisation in the presence of bases to the corresponding 2-oxazolidines does not occur:[111]

$$R_2NCH_2C_\beta{\equiv}C_\alpha{-}CR'_2(OH) \xrightarrow{PhNCO} R_2NCH_2C{\equiv}C{-}CR'_2(O)(C(=O)NHPh) \longrightarrow$$

(V) $\quad$ (VI)

$$\rightarrow \overset{\ominus}{I}MeR_2\overset{\oplus}{N}CH_2C{\equiv}CCR'_2(O)(C(=O)NHPh) \rightarrow \overset{\ominus}{I}MeR_2\overset{\oplus}{N}CH_2CH{=}C(CR'_2)(N(Ph)(C{=}O))(O)$$

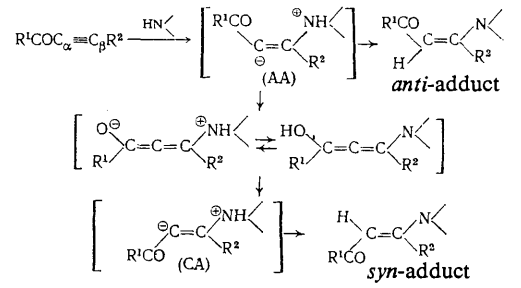
(VII) $\quad$ (VIII)

R, R′ = Alk

This difference between the reactivities of the carbamates of terminal ethynyl alcohols[108–110] and their aminomethyl analogues can be explained on the basis of ^{13}C NMR spectroscopic data. The polarisation of the triple bond is essential for the nucleophilic attack by the nitrogen atom on the ethynyl carbon atom. The electron-donating substituents R_2NCH_2 give rise to an unfavourable polarisation: $\Delta\delta C_{\alpha,\beta}$ = 0–7 p.p.m. For the methiodides (VII), $\Delta\delta C_{\alpha,\beta}$ = 10–15 p.p.m., i.e. a deficiency of electron density arises on the C_α atom, creating favourable conditions for nucleophilic attack. Indeed, in the presence of sodium methoxide at room temperature, the methiodides (VII) cyclise to the oxazolidines (VIII) in high yields.[111]

The set of data obtained for aminoalkyl- and bromo-ethynyl alcohols in the heterocyclisation reaction justifies the hypothesis that the polar and not the steric influence of the substituents at the ethynyl carbon atom is the decisive factor for its occurrence.

Thus, according to the available data, for the reaction involving addition to the ethynyl alcohols there is a qualitative correspondence between the reactivity and the ^{13}C chemical shifts of the initial acetylenic compounds, although the values of δC_{sp} themselves cannot serve as an adequate criterion of the charge distribution on the triple bond.



The results of a kinetic study of the hydroboration reaction of 1-halogenoalk-1-ynes, which is important for synthesis, have shown[112] that the rate of reaction and its regioselectivity agree with the parameters of the ^{13}C NMR spectra.

The addition of nucleophiles to α-ethynyl ketones is an important and widely occurring reaction. The conjugation of the triple bond with the carbonyl group ($-C^4{=}C^3{-}C^2{=}O^1$) permits 1,2-, 3,4-, and 1,4-addition. Thus alcohols and amines add to the 3,4-positions, while hydrazines and semicarbazides add to the 1,2-positions. Hydroxylamines, which occupy an intermediate position as regards nucleophilicity between strong (hydrazines) and weak (amines, alcohols) nucleophiles, react with both electrophilic centres simultaneously.[113] However, there is no rigorous correlation between the basicity of the amines and the reactivity of acetylenic ketones.[114,115] The relation between the reactivity of acetylenic ketones and other parameters—the Hammett constants[114] and entropy characteristics,[116] including parameters of the ^{13}C NMR spectra[117,118]—have been investigated. NMR parameters serve as an extremely useful source of information, provided that δC_{sp} does indeed characterise the electron density on these compounds and the difference between them characterises the polarisation of the triple bond,[20,21] which determines the reactivity of acetylenes in nucleophilic addition reactions.

One of the first attempts on these lines involved the study of the reactivity α-ethynyl ketones in reactions with amines and the search for a relation between the reactivity of substrates and the characteristics of the ^{13}C NMR spectra.[117] If the variable substituents R^1 and R^2 are located directly at the ynone fragment ($R^1COC_\alpha{\equiv}C_\beta R_2$), when their anisotropic and steric effects on δC_{sp} are considerable, the changes in δC_{sp} do not reflect the true changes in electron density on the C_α and C_β atoms, and the values of $\Delta\delta C_{\alpha,\beta}$ are not related to the corresponding kinetic parameters.[117,118] If the R^1 and R^2 substituents are remote from the triple bond in space (for example, in $R^1C_6H_4COC_\alpha{\equiv}C_\beta C_6H_4R^2$), then a relation between δC_{sp} and the electronic properties of the substituents is manifested. However, in this case too there is no linear relation between the rate constants for the addition of morpholine to these substances and $\Delta\delta C$.[41,74,118] The electron-donating substituents R^1 in the *para*-position in the benzene ring reduce both the reaction rate and $\Delta\delta C$, while electron-donating substituents R^2 reduce the reaction rate but increase $\Delta\delta C$ (Fig. 2). On the other hand, a satisfactory relation is observed between the reaction rate and the ratio of the products formed (Fig. 3).

Both the reaction rate and the yield of the *syn*-adduct increase with the enhancement of the electron-accepting character of the substituents. This is apparently associated with the fact that, in

conformity with the reaction mechanism established,[74] the probability of the isomerisation of the *anti*-anion, formed initially, to the *syn*-anion (SA) and hence also the fraction of the *syn*-adduct should increase as a result of the stabilisation of the intermediate by the electron-accepting substituents:

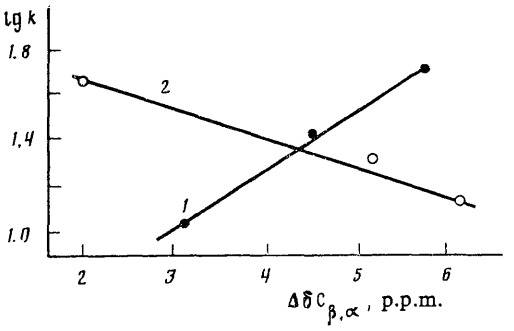


Figure 2. Dependence of the rate constants for the reactions between $R^1C_6H_4COC{\equiv}CC_6H_4R^2$ and

on $\Delta\delta C_{\beta,\alpha}$:[74] (1) variation of the substituents R^1; (2) variation of the substituents R^2.

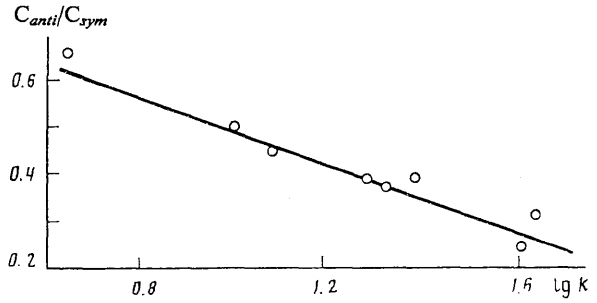

Figure 3. Dependence of the isomer ratio (determined from ^1H NMR spectra) on the reaction rate constant (lg *k*).[74]

It is also possible that the reaction rate and the ratio of the isomers are determined by the rate of protonation of the oxygen of the carbonyl group in the intermediate, which depends on the charge on the oxygen atom.[118]

A qualitative relation between the reactivity of acetylenes and the parameters of their ^{13}C NMR spectra has been noted in a number of studies. Thus the reactivity of thiacycloalkynes increases with increase in δC_{sp} (the polarisation of the triple bond).[119]

The site where nucleophiles are inserted into the acetylenic fragment of halogenoacetylenes cannot be predicted unambiguously, because it is known[120] that they contain three centres susceptible to nucleophilic attack: the halogen atom and the C_α and C_β carbon atoms of the triple bond. Under the conditions of the Arbuzov rearrangement, halogenoacetylenes react with trialkyl phosphites to form the products resulting from the substitution of the halogen (attack on C_α):[121,122]

$$RC_\beta{\equiv}C_\alpha X + P(OAlk)_3 \rightarrow [RC{\equiv}CP(OAlk)_3]^{\oplus}X^{\ominus} \rightarrow RC{\equiv}CP(O)(OAlk)_2 + AlkX.$$

Both the values of δC_{sp} (Table 9) and the distribution of the effective charges in model compounds calculated in terms of the CNDO/2 approximation agree with the experimental composition of the products.[122,126] The value of δC_α is lowest for the ynamine probably because of the strong π-donor effect of the dimethylamino-group in the "push-pull" system (a system with concerted effects of two substituents).

Table 9. The ^{13}C chemical shifts of the *sp* carbon atoms (in p.p.m. relative to TMS) and the differences between them ($\Delta\delta C$, p.p.m.) for certain heteroatomic substituted acetylenes $R^1C_\alpha{\equiv}C_\beta R^2$.

The preferential attack by the nucleophile on the carbon atom joined to the halogen atom occurs in the reaction of alkyl(aryl) chloroethynyl sulphides with triphenylphosphine and trialkyl phosphites. In the latter case, the only reaction products are the normal products of the Arbuzov rearrangement:[123]

$$(RSC{\equiv}\overset{\oplus}{C}PPh_3)Cl^{\ominus} \xleftarrow{PPh_3} RSC{\equiv}CCl \xrightarrow{P(OEt)_3} RSC{\equiv}CP(O)(OEt)_2.$$
(A) (B)

The signals of the C_α and C_β atoms in the ^{13}C NMR spectra of the reaction products (A) and (B) are deshielded relative to chloroacetylenes (Table 8) and the greatest degree of polarisation is observed in the ionic compound.

Organoelement compounds of the acetylenic series frequently exhibit a specific reactivity. An attempt has been made[11] to estimate the reactivity of silyl- and germyl-acetylenic carbonyl compounds from ^{13}C NMR data. Table 1 shows that the effects of the Si- and Ge-groups as well as carbonyl-containing groups are deshielding. Reactions of a silylacetylenic ketone with methyl- and dimethylamines proceed anomalously:

$$R_3SiC{\equiv}CC(O)Me + HNR^1R^2 \rightarrow R_3SiNR^1R^2 + R^2R^1N{-}CH{=}CHC(O)Me.$$

This unusual result has been explained[11] by the fact that the R_3E and C=O groups, which behave as acceptors in relation to the triple bond, diminish the electron density on both C_α and C_β atoms, which should reduce the reactivity of the triple bond in nucleophilic addition reactions. It is hardly possible to agree with this explanation. Electron-accepting groups are known to increase and not to decrease the reactivity of the triple bond in relation to nucleophiles. Thus it has been stated[113] that acetylenic compounds containing two electron-accepting substituents [the compounds PhC(O)C≡CC(O)Ph, PhC(O)C≡CC(O)Me, etc.] readily combine with amines at the triple bond. On the other hand, the result obtained by Arshavshkya et al.[11] is apparently associated with the fact that trialkylsilylacetylenes are very readily desilylated even at room temperature in the presence of a base,[127] whose role in the given reaction is probably assumed by the amine.

Alkynylamines and the related alkynyl ethers exhibit an unusual chemical reactivity, the reactivity of alkynyl ethers in ionic reactions being lower.[125,128]

The mode of addition of electrophiles and nucleophiles to alkenylamines[125] corresponds to their electronic structure, established by the CNDO/2 method, and the characteristics of their ^{13}C NMR spectra

$$\underset{-0.014}{cis\text{-}CH_3}-\underset{0.034}{CH}=\underset{-0.120}{CH}-\underset{0.061}{C_\alpha}\equiv C_\beta-\underset{-0.176}{N(C_2H_5)_2}$$

The excess electron density on the C_α atom agrees with the manifestation of the π-donor effects of nitrogen in the ^{13}C NMR spectra (Table 8). Although the values of δC_α for diethylamino- and dipropylamino-pent-3-en-1-ynes (62.65 and 62.08 p.p.m. respectively) as well as the values of δC_β for these compounds (99.45 and 99.02 p.p.m.) agree with the calculated charges, the upfield shift of the C_α signal and the value of $\Delta\delta C_{\alpha,\beta}$ for the alkynylamines are significantly smaller than might have been expected from data for the alkynyl ethers.[21] This indicates a more effective interaction of the ether oxygen with the π-systems of the triple bond,[41] but conflicts with experimental data according to which alkynylamines are much more reactive than alkynyl ethers in electrophilic addition reactions (attack on the C_α atom).[125] It has been suggested[125] that this is associated with the dynamic shift of the *p* electrons of the nitrogen atom towards the triple bond at the instant of reaction.

The regiospecificity of the addition of organocopper compounds to various heterosubstituted acetylenes is determined by the influence of the heteroatoms:[129]

$$\underset{\text{E=N, O, S.}}{\underset{\text{(IX)}}{RCu + R^1C{\equiv}CEAlk_n}} \xrightarrow[H_2O]{THF} \underset{\text{(X)}}{\overset{H}{\underset{R^1}{>}}C{=}C\overset{R}{<}EAlk_n} + \underset{\text{(XI)}}{\overset{R}{\underset{R^1}{>}}C{=}C\overset{H}{<}EAlk_n};$$

Under these conditions, compounds with E = S form exclusively the isomer (XI), while compounds with E = N or O give rise preferentially to the isomer (X). Thus in the given instance the mode of addition of RCu to compound (IX) agrees with the changes in δC_{sp} as a result of the effect of E on the triple bond (Tables 3 and 9).

Electrophiles add to the triple bond in the compounds $RC{\equiv}CER^1$ (E = S, Se, Te) and in the analogous ethers in the same manner, but the mode of addition differs from that in hydrocarbons.[130,131] The addition of hydrogen chloride and bromide to alkylthio- and alkylseleno-vinylacetylenes always takes place at the triple bond and the halogen atom adds to the C_α atom:

$$CH_2{=}CH-C_\beta{\equiv}C_\alpha ER^1 \xrightarrow[X_2]{HX} CH_2{=}CH-CH{=}CXER^1;$$

E=S, Se; X=Cl, Br.

Comparison of the experimental data with the distribution of electron density in the molecules of 1-methylthio- and 1-methylseleno-but-3-en-1-ynes (without taking into account the *d* orbitals of the heteroatom) shows that the maximum electronic charge is concentrated on the β-carbon atom of the triple bond, which is consistent with the order and orientation of the electrophilic addition:[131,132]

$$\underset{-0.051}{CH_2}=\underset{-0.008}{CH}-\underset{-0.104}{C_\beta}\equiv\underset{0.014}{C_\alpha}-\underset{0.160}{S}-\underset{0.008}{Me}$$

$$\underset{-0.036}{CH_2}=\underset{-0.005}{CH}-\underset{-0.073}{C_\beta}\equiv\underset{0.003}{C_\alpha}-\underset{0.006}{Se}-\underset{0.006}{Me}$$

The ^{13}C NMR spectra of these compounds contain valuable information about the degree of conjugation of the heteroatoms (S, Se, Te) and the triple and double bonds.[22] The character of the polarisation of the triple bond (Table 8), indicating an enhancement of the electron-accepting properties on passing from alkylthio- to alkyltelluro-vinylacetylenes, conflicts with the data on the reactivities of these compounds.[22]

The data presented demonstrate yet again that the experimental values of δC_{sp} and the differences between them do not permit, despite the hypotheses expressed in the literature,[20,21] the prediction of not only the reactivity but also of the mode of addition of the reactants even in an isologous series of compounds. One of the causes of this is the "heavy atom effect" mentioned above, whose influence on the shielding of the C_{sp} atom in selenium-, bromine-, and especially tellurium-substituted acetylenic compounds cannot so far be estimated quantitatively.

The high reactivity of monosubstituted acetylenes in many reactions (acetylene condensation, Favorskii, Mannich, oxidative coupling, etc. reactions) is usually explained by the CH acidity, although little information is available about the equilibrium CH acidity. This is associated both with the difficulty of measuring the p*K* (which requires special apparatus and the use of dry media) and with the fact that certain derivatives (nitro-, alkoxycarbonyl, and other compounds) undergo side reactions under the conditions of the measurement (a highly basic medium). The acidity of monosubstituted acetylenes should be higher the lower the charge on the C_β atom. There are correlations between the energies of the heterolytic dissociation of the ≡C−H bonds and the charge on the ethynyl group[133] and also between the values of δC_β and the charge density on the same atom in *para*-substituted phenylacetylenes.[29] It therefore appeared useful to compare the values of δC_β with the p*K* for the monoacetylenic compounds. A linear relation has been observed between the p*K* for ethynylpyrazoles, the heterolytic dissociation energies of the ≡C−H bonds (the thermodynamic CH acidity of these compounds was measured in dimethyl sulphoxide by the transmetallation method[134,135]), and the charges on the ethynyl groups (calculated by the CNDO/2 method[133]).[136] These results agree with the fact that the relative rate of the Mannich reaction (piperidine, 35 °C) in the series of isomeric 3-, 4-, and 5-ethynyl-1-methyl pyrazoles is four times higher for the 5-C≡CH isomer than

for the 4-C≡CH isomer and 1.6 times higher than for the 3-C≡CH isomer.[137] However, a linear relation has not been observed between the pK or the charge $q\,C_\beta$ and the values of δC_β for these compounds. Presumably in the given series the shift δC_{sp} does not reflect the charge density.

The parallel variation of the acidities of *para*-substituted phenylacetylenes with δC_β and $\Delta\delta C_{\beta,\alpha}$ (Fig. 4) justifies the assumption that in the given series the shift $\delta C_{\beta(\alpha)}$ reflects the charge density on the atoms indicated.[29]

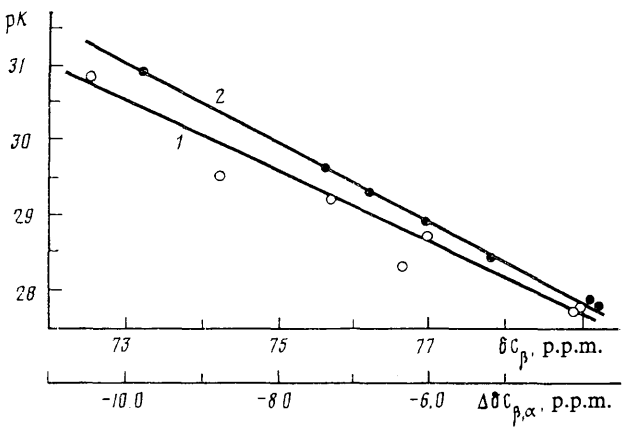

Figure 4. Dependence of pK on δC_β (line *1*) and $\Delta\delta C_{\beta,\alpha}$ (line *2*) in the series of ***para*-substituted phenylacetylenes (the values of δC_{sp} were taken from Klasine et al.[29]).**

A linear relation has also been observed reliably between the regiospecificity and stereospecificity of the nucleophilic addition of *p*-fluorophenol to *para*-substituted phenylacetylenes[138] and the values of δC_{sp}.[116]

On the whole, comparison of the calculated charge densities on the ethynyl carbon atoms[41,74] with the measured shifts δC_{sp} both for the simplest monosubstituted acetylenes[139] and for acetylenes containing heteroatomic substituents at the triple bond[140] does not exhibit a rigorous relation between these characteristics. This is associated primarily with the fact that substituents located close to the triple bond exert an appreciable steric and anisotropic influence on δC_{sp}.

Thus the relation between the reactivities of acetylenic compounds and the parameters of their ^{13}C NMR spectra is mainly qualitative. One of the main reasons for this is apparently the different distributions of electron density in the molecule, especially on the triple bond, in the stationary and dynamic states. Another possible explanation is the multifunctionality of the dependence of $\delta^{13}C$ on the structural parameters of the test compounds, which is not susceptible to a quantum-chemical description.

There is in general no justification for relating the degree of polarisation of the triple bond to the difference between the chemical shifts of the *sp*-carbon atoms or the overall charge on the triple bond to the sum of the shifts. This approach is valid only for chemical compounds in which the substituent is fairly reliably separated from the triple bond by a conformationally rigid fragment, for example, the benzene ring.

The state of the NMR theory at the present time is such that one can explain the available experimental facts rather than make predictions. There is no doubt about the usefulness of further studies on these lines, particularly if they are directed towards individual classes of reactions with participation of structurally similar acetylenic compounds.

Periodicity of the change in properties in the series of *d*- and *f*-elements

G V Ionova
Institute of Physical Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. Many physicochemical properties in series of *d*- and *f*-elements change periodically with change in the number of *d*- or *f*-electrons in the d^q- or f^q-electron configurations. In the lanthanide and actinide series for a fixed electron configuration, the f^q-periodicity of the change in properties is called the tetrad or double–double relationship.

A number of properties of *d*-elements, lanthanides, and actinides depend on the initial d^q-, f^q- and final d^{q-1}-, f^{q-1}-electron configurations. These properties include the ionisation potentials of the free atoms and ions, electron affinity, redox potentials, excitation energies, and enthalpies of the decomposition and disproportionation of the halides, oxides, chalcogenides, and pnictides of the lanthanides and actinides, the oxidation state in compounds with variable oxidation states, etc. The present review analyses the regularity of the change in these properties in the lanthanide and actinide series, demonstrates the nature of the change in these properties, formulates a simple rule making it possible to predict unknown properties, and carried out an extensive comparison with the properties of *d*- and *p*-elements and their compounds. The properties of the trans-actinide *g*- and *h*-elements are predicted.

The bibliography contains 37 references.

I. Introduction

With increase in the atomic number in the series of *f*-elements, the *f*-levels are gradually filled, leading to a similarity between the lanthanides and actinides. The similarity in many properties of their trivalent states is a long established fact. At the same time, the lanthanides and actinides exist in higher oxidation states: $Ln^{III,IV}$ and $An^{III-VII}$. In this way they show a similarity to the *d*-elements. Thus the actinides, showing a qualitatively new increase in the complexity of the electronic structure, resemble the lanthanides, but in their high and highest oxidation states they show a definite analogy with the *d*-elements. There is thus an overall regularity in the properties of the actinides, lanthanides, *d*-elements, and their compounds.

A number of recent papers have compared all these elements. Everyone who has studied, on the one hand, solid state physics, and on the other hand the chemistry of the simple and coordination compounds inevitably draws attention to the differences in the focus of the theoretical approaches in these branches of science. Qualitatively, however, both approaches lead to the conclusion that the light actinides are the analogues of the 3*d*-elements, rather than the 4*f*-elements. In each series, the behaviour of the electrons changes from delocalised bonding behaviour to localised non-bonding behaviour. At the same time, a group of elements show intermediate behaviour of the electrons: Ce, Pr, U, Np, Pu, Mn, and Fe. Subsequent analysis of experimental and theoretical data[1–3] has shown that there is a definite periodicity in the change in the physicochemical properties with change in the atomic number of the element in the *d*- and *f*-series. This periodicity covers a wide range of properties of both the free atoms and ions and their compounds, is general in character, and extends to the super-heavy compounds in the *g*- and *h*-series which have not yet been obtained.

II. Systematics of the properties of the free atoms and ions

Many physicochemical properties P of the lanthanides Ln and actinides An change periodically with change in the atomic number of the element or in the number of electrons q in a fixed f^q-electron configuration in accordance with the periodic change in the orbital quantum numbers L_q of the normal terms. Many examples of the existence of this periodicity can be given:[4] the change in the standard energy of extraction of the trivalent lanthanides, the ionic radii of the *d*- and *f*-elements in different charged states, the critical temperature of the appearance of superconductivity of the metals of the *d*-series, etc. In the final analysis, the periodic change in these properties is determined by the characteristic dependence of the quantum numbers L_q on q (Fig. 1) in the corresponding l^q-electron configurations (l = *d*-, *f*-, *g*-, and *h*-elements). Fig. 1 shows that in each series there is a characteristic double–double effect in the change in the properties P: d^0-d^5-d^{10}, f^0-f^7-f^{14}, g^0-g^9-g^{18}, h^0-h^{11}-h^{22}. Moreover, as a consequence of the two-fold symmetry with respect to the central pair in each half of the series d^2-d^3, d^7-d^8, f^3-f^4, f^{10}-f^{11}, g^5-g^6, g^{14}-g^{15}, h^7-h^8, h^{18}-h^{19} for the quantum numbers L there are respectively pairs of triads, tetrads, pentads, and hexads in the *d*-, *f*-, *g*-, and *h*-series.

Thus in the series of *s*-, *p*-, *d*-, *f*-, *g*-, and *h*-elements it is possible to construct definite sequences of electron configurations depending on the number of electrons and the quantum numbers L_q: s^0-s^1, s^1-s^2; p^0-p^1, p^2-p^3; d^0-d^2, d^3-d^5; f^0-f^3, f^3-f^7; g^0-g^4, g^5-g^9; h^0-h^5,

h^6-h^{11}. Similar sequences can be constructed in the second halves of the series, with a displacement by a number of electrons equal to the number of electrons in the half-filled levels.

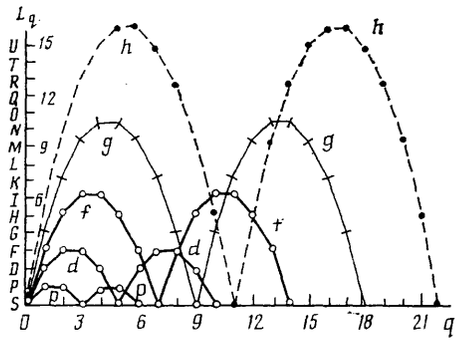

Figure 1. Plot of the quantum numbers L_q against the number of electrons q in the series of *s*-, *p*-, *d*-, *f*-, *g*-, and *h*-elements.[12]

1. Redox processes

If the electron configurations of the atoms or ions change in a reaction, the periodicity of the change in properties depends on the quantum numbers L_q and L_{q-1} in the initial and final electron configurations f^q and f^{q-1} or d^q and d^{q-1}. The ionisation equilibrium $f^q \rightleftharpoons f^{q-1} + e$ and $d^q \rightleftharpoons d^{q-1} + e$ ($L_q \rightleftharpoons L_{q-1}$), corresponding to a redox reaction, can be examined. It will be assumed that there exists a temperature range in which there are only two kinds of ion containing q and $q-1$ electrons; for example doubly- and triply-ionised, or triply- and quadruply-ionised ions, etc. The condition for chemical equilibrium can then be written as

$$E_0/kT = \ln(\zeta_q n_q/\zeta_{q-1} n_{q-1}), \quad (1)$$

where E_0 is the absolute magnitude of the difference in the energies of the non-split normal terms of the l^q- and l^{q-1}-electron configurations, n_q and n_{q-1} the numbers of ions in these configurations, and ξ_q and ξ_{q-1} the values of the corresponding distribution functions or the multiplicities of the degeneracy of the normal terms with respect to the quantum numbers M_L for fixed spin quantum numbers S. The parameter α giving the probability that an ion has the oxidised electron configuration d^{q-1} or f^{q-1} can be introduced. In the high-temperature limit $kT \gg E_0$,

$$\alpha = \frac{n_{q-1}}{n_q + n_{q-1}} = \left[\left(1 + \frac{\zeta_q}{\zeta_{q-1}}\right)\exp(-E_0/kT)\right]^{-1} = \frac{2L_{q-1}+1}{2L_q + 2L_{q-1} + 2}, \quad (2)$$

which corresponds to ionisation equilibrium. The dependence of α on q for *p*-, *d*-, *f*-, *g*-, and *h*-elements is shown in Fig. 2*a*, which demonstrates the periodicity in the change in the redox properties in each half of the series with increase in the atomic number or the number of electrons q. This periodicity is revealed in the sharp–retarded–sharp change in properties in each half of the series. The sharpest change in properties is observed on going from the first to the second half of the series. For the elements of the *f*-series, with allowance for the equalities

$$L_q = q(7-q)/2, \; q \leqslant 7; \; L_q = (14-q)(q-7)/2, \; q > 7 \quad (3)$$

it is possible to rewrite Eqn. (2) as follows

$$\alpha = \frac{9q - q^2 - 7}{16q - 2q^2 - 6}, \; q \leqslant 7; \; \alpha = \frac{23q - q^2 - 119}{44q - 2q^2 - 216}, \; q > 7. \quad (4)$$

This dependence of α on q covers a wide range of properties: ionisation potentials, electron affinity, redox potentials, excitation energies, etc. The section of the plateau corresponding to the retarded change in properties is not observed for the *p*-elements; for two-electron reactions $d^q - d^{q-2} + 2e$ the section of the plateau becomes indistinct, and the dependence of α on q is close to linear.

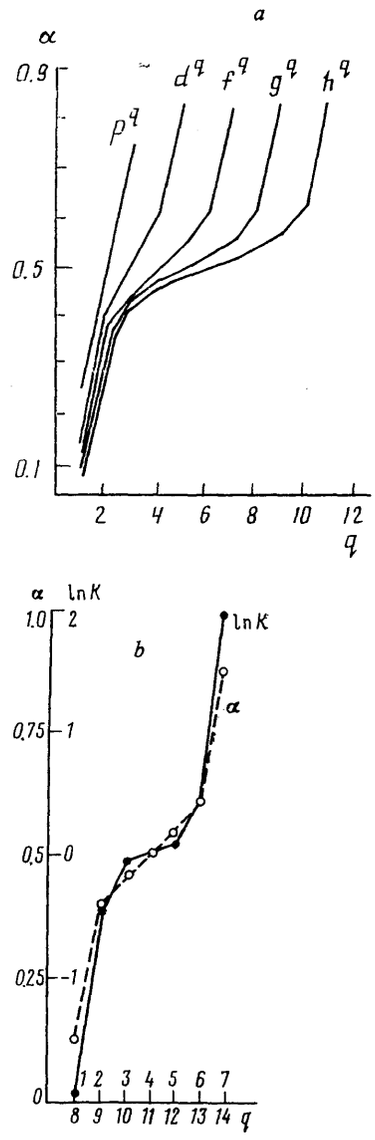

Figure 2. Dependence of the parameter α on the number of electrons for various elements[4] (*a*) and the dependence of the parameters α and $\ln K$ on the number of electrons (*b*) in the series of *f*-elements.

Similar conclusions are reached for the constants K of the ionisation equilibrium $f^q \overset{K}{\rightleftharpoons} f^{q-1} + e$ for a monatomic gas consisting of f-ions. The free energy for this reaction, $F = -RT \ln K$, depends on the number of electrons q and $q-1$, the quantum numbers L_q and L_{q-1}, and the ionisation energy I_q (Fig. 2*b*). At $T \simeq I_q$ the periodicity of $\ln K$ with change in q is determined by the difference $\Delta L = L_{q-1} - L_q$

$$\ln K \approx 2\,(L_{q-1} - L_q)\,(L_{q-1} + L_q + 1)^{-1}. \qquad (5)$$

The section of the plateau corresponding to elements for whose oxidised and reduced forms the values of ΔL are low, are shown in Fig. 2*b*.

2. The rule of intervals in redox processes

In the LS-coupling approximation, the d-, f-, g-, and h-levels have internal symmetry, according to which, for the normal terms of the ions with the electron configurations l^q, where $l \equiv d, f, g, h$, the quantum numbers L_q and S_q are given by the equations

$$\text{for } q<7\text{: } L_q = q(2l+1-q)/2,\ S_q = q/2;$$
$$\text{for } q>7\text{: } L_q = (4l+2-q)(q-2l-1)/2,\ S_q = (4l+2-q)/2. \qquad (6)$$

Eqns. (2) and (6) lead to the simple rule of intervals in the change in the properties P_q with change in q in the d- and f-series of elements.

For the f-elements:

$$\text{for } q \leqslant 7,\ c=0\text{: } (P_{1+c}+P_{7+c}):P_{4+c} = (P_{2+c}+P_{6+c}):P_{4+c} = (P_{3+c}+P_{5+c}):P_{4+c} = 2;$$
$$\text{for } q>7,\ c=7\text{: } (P_{1+c}+P_{7+c}):(P_{2+c}+P_{6+c}) = (P_{2+c}+P_{6+c}):(P_{3+c}+P_{5+c}) = 1;$$

For the d-elements:

$$\text{for } q \leqslant 5,\ e=0\text{: } (P_{1+e}+P_{5+e}):P_{3+e} = (P_{2+e}+P_{4+e}):P_{3+e} = 2;$$
$$\text{for } q>5,\ e=5\text{: } (P_{1+e}+P_{5+e}):(P_{2+e}+P_{4+e}) = 1.$$

It is important to emphasise that these expressions relate the properties of different elements of the same series. For example, in the first half of a series, the ratio $(P_{1+c} + P_{7+c}):P_{4+c}$ is determined by the properties of the ions with the electron configurations $f^1(^2F)$, $f^7(^8S)$, and $f^4(^5I)$: the triply-charged ions of thorium, curium, and neptunium, or the quadruply-charged ions of protactinium, berkelium, plutonium, etc. These relationships are particularly useful for those elements whose properties are difficult to measure because they are available in only small quantities or are highly radioactive, etc.

For redox reactions in each half of a series, inversion of the normal term takes place relative to the element for which it does not change:

$$d^1 \to d^0 + e\text{: } D \to S;\quad d^5 \to d^4 + e\text{: } S \to D;$$
$$d^2 \to d^1 + e\text{: } F \to D;\quad d^4 \to d^3 + e\text{: } D \to F;$$
$$d^3 \to d^2 + e\text{: } F \to F.$$

For the elements of the d-, f-, g-, and h-series, these reactions are:

$$d^3 \to d^2 + e;\quad f^4 \to f^3;\quad g^5 \to g^4;\quad h^6 \to h^5$$
$$F \to F \qquad I \to I \qquad N \to N \qquad U \to U\ .$$

III. Experimental confirmation of the periodicity of the change in the properties of the free atoms and ions with change in the number of electrons

1. Excitation energies

For neutral atoms, the periodic character of the change in the excitation energies with change in the number of electrons $f^{q-1}ds^2 \to f^q ds$, $f^q ps$, $f^q s^2$, $f^q d^2$ has been noted in a number of studies.[2,4,9] The presence of the electrons in the dsp-atomic orbitals and the similarity in the energies of several electron configurations for the elements of the start of the actinide series, however, lead to slight departures from the predictions of periodicity theory. For lanthanide and actinide atoms in f^q-electron configurations, when the one-configuration approximation is sufficiently correct, the dependence of the excitation energies on q is close to the theoretical. This leads to the rule of intervals for the excitation energies (Table 1). For a comparison of the p-, d-, and f-elements, Fig. 3 gives various excitation energies calculated from spectral data.[5–8] They confirm the periodicity in the change in excitation energies, the existence of the plateau section for the d- and f-elements, and its absence for the p-elements. In addition, the experimental values of the excitation energies E for the doubly-charged ions of the $3d$-series,[5] $3d^q \to 3d^{q-1}4s$, satisfy the relationships

$$[E\,(\text{Ti}) + E\,(\text{Gr})]/E\,(\text{V}) = 1.99;\quad [E\,(\text{Fe}) + E\,(\text{Zn})]/E\,(\text{Ni}) = 2.00;$$
$$[E\,(\text{Co}) + E\,(\text{Cu})]/E\,(\text{Ni}) = 1.99,$$

confirming the applicability of the rule of intervals for these ions.

The excitation energies of the free atoms and ions correlate with many properties of their compounds:[10–13] redox potentials, energy of cohesion of the metals, and thermodynamic stability; these properties determine the semiconducting, superconducting, and magnetic properties, etc. In the chemistry of the lanthanides and actinides, the solution of the problem of the localisation or delocalisation of electrons is related primarily to the question of the excitation of the electrons and their transfer to an unoccupied d-level. This range of problems makes it important to study the regularities of the change in the excitation energies with change in the atomic number of the elements.

2. Ionisation potentials

Jørgensen[11] expressed the ionisation energy of f-electrons in terms of the parameter V defining the reference point, the energy of stabilisation of the f-electrons from one element to another $E - A$, the spin–orbit splitting energy ζ, and the parameter D, defined as a linear combination of Slater–Condon integrals:†

$$q=1\text{: } I_1 = V + 2\zeta;\quad q=2\text{: } I_2 = V + (E-A) + (^8/_{13})D + 9E^3 + \zeta;$$
$$q=3\text{: } I_3 = V + 2(E-A) + (^{16}/_{13})D + 12E^3 + {}^1/_2\zeta;$$
$$q=4\text{: } I_4 = V + 3(E-A) + (^{24}/_{13})D;$$
$$q=5\text{: } I_5 = V + 4(E-A) + (^{32}/_{13})D - 12E^3 - {}^1/_2\zeta;$$
$$q=6\text{: } I_6 = V + 5(E-A) + (^{40}/_{13})D - 9E^3 - \zeta;$$
$$q=7\text{: } I_7 = V + 6(E-A) + (^{48}/_{13})D - 2E^3 - 2\zeta;$$
$$q=8\text{: } I_8 = V + 7(E-A) + (^{48}/_{13})D + {}^3/_2\zeta,$$
$$q=9\text{: } I_9 = V + 8(E-A) + (^{40}/_{13})D + 9E^3;$$
$$q=10\text{: } I_{10} = V + 9(E-A) + (^{32}/_{13})D + 12E^3 + {}^1/_2\zeta;$$
$$q=11\text{: } I_{11} = V + 10(E-A) + (^{24}/_{13})D;$$
$$q=12\text{: } I_{12} = V + 11(E-A) + (^{16}/_{13})D + 21E^3 - {}^1/_2\zeta.$$

† Jørgensen[11] gives estimates of the parameters used for the Ln^{3+} ions: $E - A \simeq 3000$ cm^{-1}, $D \simeq 6500$ cm^{-1}; the values of ξ change from 650 cm^{-1} to 2950 cm^{-1} on going from Ce^{3+} to Yb^{3+}. In the examination of the relative change in the ionisation potentials in the f-series, the values of the one-electron energies V are excluded.

Table 1. Change in the excitation energies[7,8] illustrating the rule of intervals.[1,2,13]

No.*	$(f^x+f^y):f^{(x+y/2)}$	An^{2+}			An^{3+}			Ln^{3+}			Ln^{3+}

1	$(f^1+f^7):f^4$			1.88	2.03	1.92	1.96	1.98	1.92	1 93	1.98	1.97	1.96
2	$(f^2+f^6):f^4$			1.96	1.95	1.97	1.98	1.93	1.98	1.98	1.99	1.99	1 99
3	$(f^3+f^5):f^4$			1.98	1.98	1.99	2.00	1.98	2.00	2.00	2.00	2.00	2.00
4	$(f^8+f^{14}):f^{11}$	1.90	1.84	1.95	1.95	1.96	1.97	1.84	1.97	1 90	1.97	1.99	1.97
5	$(f^9+f^{13}):f^{11}$	1.95	1.92	1.98	1.98	1.98	1.99	1.89	1.98	1.97	1.98	1.99	1.99
6	$(f^{10}+f^{12}):f^{11}$	1.99	1.98	2.01	1.99	1.99	2.00	1.98	1.99	1.98	1.99	1.99	2.00
7	$(f^1+f^7):(f^2+f^6)$			1.04	1.00	0.97	1.01	1.01	1.02	0.98	1.00	0.99	1.00
8	$(f^2+f^6):(f^3+f^5)$			1.02	0.98	1.01	1.01	1.02	1.02	1.04	1.01	1.00	1.00
9	$(f^8+f^{14}):(f^9+f^{13})$	0.97	1.04	1.01	0.99	0.99	0.95	0.97	0.99	0.96	1.01	0.99	1.00
10	$(f^9+f^{13}):(f^{10}+f^{12})$	1.00	1.03	0.98	1.01	1.01	1.00	1.02	1.00	1.01	1.01	1.00	1.00

* The theoretical values are 2.00 for ratios 1–6, and 1.0 for ratios 7–10.

From these expressions it follows that

$(I_1 + I_7) : I_4 = (I_2 + I_6) : I_4 = (I_3 + I_5) : I_4 = (I_8 + I_{14}) : I_{11} = (I_9 + I_{13}) : I_{11} = (I_{10} + I_{12}) : I_{11} = 2.00$.

Table 2 gives the corresponding relationships for the doubly- and triply-charged lanthanides and actinides.

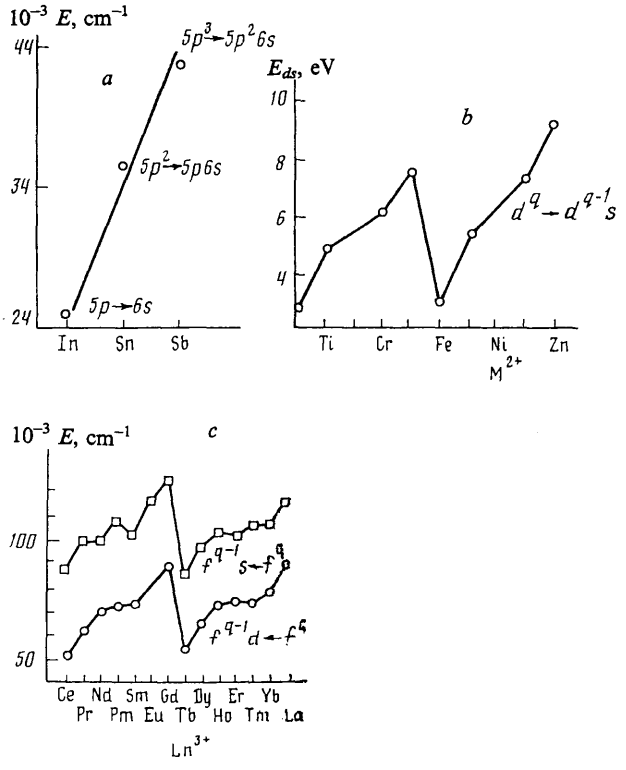

Figure 3. Excitation energies for elements of the *p*- (*a*), *d*- (*b*), and *f*-series (*c*): $p^q \rightarrow p^{q-1}s$; $d^q \rightarrow d^{q-1}s$; $f^q \rightarrow f^{q-1}s$.

3. Redox potentials

Fig. 4 illustrates the periodicity of the change in the oxidation potentials for $E^0(An^{2+}/An^{3+})$, $E^0(Ln^{3+}/Ln^{4+})$, and $E^0(An^{4+}/An^{5+})$, which have been measured or calculated. The general trends in the change in the potentials $E^0(An^{+}/An^{2+})$, $E^0(An^{2+}/An^{3+})$... for the actinides are shown in Fig. 5, from which it can be seen that the numbers of the atoms corresponding to the so-called plateau section are displaced with change in the oxidation state. For example, for the actinides:

E^0(II/III) — Pa, U, Np;
E^0(III/IV) — U, Np, Pu;
E^0(IV/V) — Np, Pu, Am.

This displacement is characteristic of the ranges corresponding to the sharp and sharpest changes in the properties in both series, lanthanides and actinides.

Table 2. Change in the ionisation potentials of the lanthanides[12] and actinides[13] illustrating the rule of intervals.[1,2,13]

IV. Thermodynamic properties of compounds of the *f*-elements

1. Hydrated ions

The chemistry of aqueous solutions, and allowance for the influence of hydration on the physical and chemical properties of ions, represent an extensive and varied problem. Water is a strongly polar solvent, in which both cations and anions are solvated, and in which even the hydrated electron may be formed. The effects of lanthanide and actinide ion hydration have been studied by a number of authors.[15–17] In particular, the solubility, conductivity, relative viscosity, free energies of hydration, and equilibrium constants of aqueous solutions of lanthanide salts, etc. have been measured.

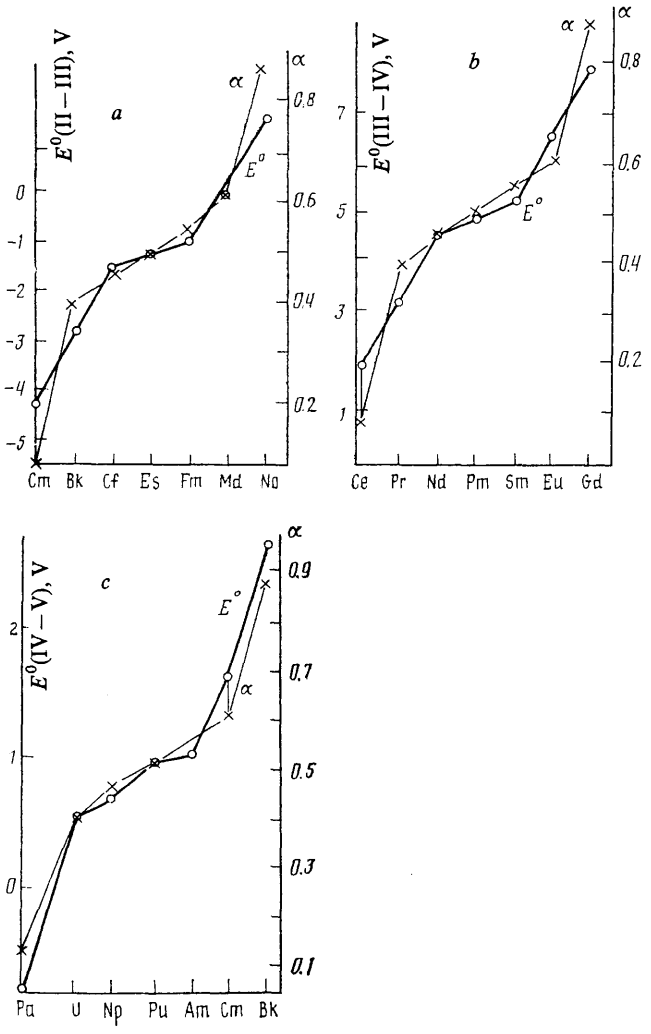

Figure 4. Periodicity of the change in the redox potentials in the lanthanide and actinide series.

The behaviour of lanthanide and actinide ions in solution is characterised by a number of specific features. Thus in aqueous solutions the dependence of the thermodynamic and transport properties on the number of electrons is regular for the light ions from La to Nd and the heavy ions from Tb to Lu, whereas the properties change in the opposite sense for the ions from Pm to Gd. This unusual behaviour for the *f*-series is due to the nature of the interaction of the *f*-ions with water molecules and the change in the coordination number of the lanthanides with change in the number of electrons of the ion. Similar studies were later carried out for actinide ions.[16] The electronic structures of the hydrated ions have been calculated.[18] All these experimental and theoretical studies show that the chemical bonds in the hydrated ions are partly covalent, as revealed by a variety of physicochemical properties. The important role of the second coordination sphere in hydration in different solutions has been revealed. Although the problem of the aqueous solutions of the lanthanides and actinides is complex and varied, a number of general semi-empirical and empirical relationships in the structures of the hydrated ions and the thermodynamic properties are firmly established (Fig. 6).

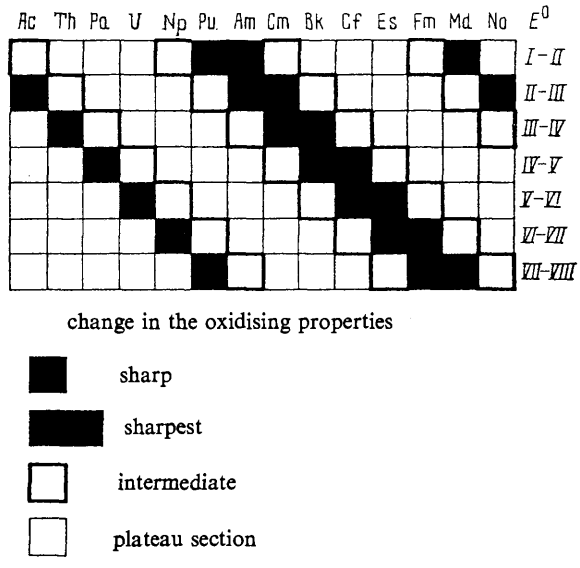

Figure 5. Diagram of the change in the oxidising properties of the actinides.

With increase in the number of electrons q in the f^q-electron configurations, the partial molar volumes $\overline{V}^0_m$ decrease for the light lanthanides (f^0–f^4), increase for the elements of the middle of the series (f^5–f^8), and decrease again for the heavy lanthanides (f^9–f^{14}) (Fig. 6*a*); that is, there are three clearly defined regions of change in $\overline{V}^0_m$.

The total number of water molecules h surrounding the ion, and the number of water molecules n_m in the first hydration shell, change in the opposite sense with increase in the number of electrons q for both series (Ln and An). The curves giving the dependence of h and

n_m on q show two plateaux for the light and heavy elements. A crossed analogy is observed for the lanthanides and actinides: a short plateau section for the light lanthanides and heavy actinides, and a long plateau section for the heavy lanthanides and the light actinides (Figs. 6*b* and 6*c*).

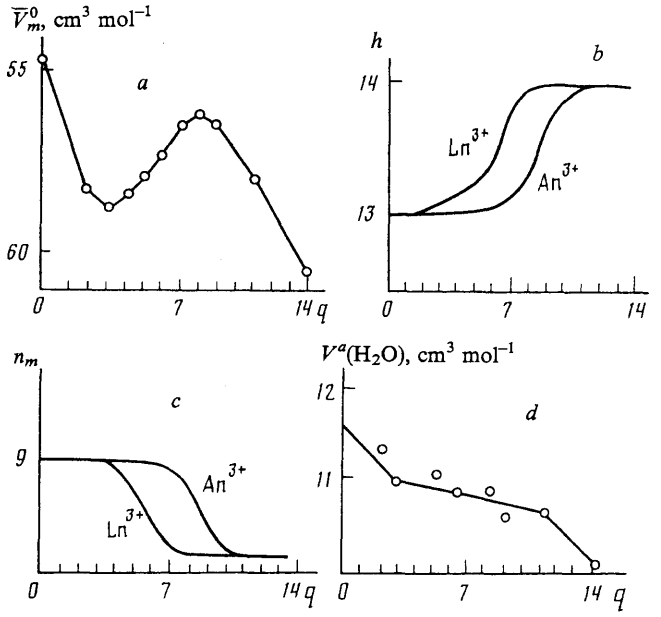

Figure 6. The three types of dependence of the properties of the triply-charged lanthanide and actinide ions in solution on the number of electrons: *a*, partial molar volumes; *b*, number of water molecules in the first and second hydrate layers; *c*, number of water molecules in the first hydrate layer; *d*, average volume of a bound water molecule in the hydrate layer.

The sections of intermediate change in h and n_m in the lanthanides and actinides are displaced: for the lanthanides this section lies in the first half of the series (Pr, Sm, Eu, and Gd), and for the actinides it lies in the second half (Cm, Bk, Cf) (Figs. 6*b* and 6*c*).

The average volume of the water molecules in the hydration shell (Fig. 6*d*) decreases with increase in the number of electrons q; a sharp decrease in volume is observed at the beginning and end of the series, and a plateau in the middle.

The thermodynamic properties of the aquo-ions have been analysed.[19] The enthalpy of hydration H_h for Ln^{3+} and An^{3+} changes regularly and almost linearly along the series, except for the elements in the middle of the series. The components of H_h, however, that is the enthalpy of formation of the aquo-ions $H(Ln^{3+}_{aq})$ and the cations $H[Ln^{3+}(gas)]$ change irregularly and in opposite directions, due to the existence of the compensation effect. As a result, the dependence of H_h on q for Ln^{3+} and An^{3+} is close to linear. This makes it possible to calculate the quantity $H_h(An^{3+})$ using approximate equations, for example:[20]

$$H_h = \frac{7.32Z^2(An^{3+})}{R+0.85},$$

where R is the radius of the ion with charge Z, and the constant 0.85 characterises the change in the radius of the ion in solution.

2. Halogen compounds of divalent and trivalent lanthanides and actinides

Since the halogen compounds of the lanthanides and actinides have important practical applications, their properties, in particular their thermodynamic properties, have been studied by many authors, by both experimental[21–24] and theoretical[25,26] methods. The enthalpies of formation of $LnHal_3$ have been determined by mass spectrometry, solution calorimetry, etc., and also calculated from the equation

$$H_0[MX(crystalline)] = H_0[M^{Z+}(gas)] + \frac{A}{R_{M^{Z+}} + R_X} + B,$$

$$H_0[M^{Z+}(gas)] = H_{sub}(M) + \sum_{i=1}^{3} I_i + {}^5/_2 ZRT,$$

where $R_{M^{Z+}}$ is the ionic radius of the metal, R_X the radius of the anion, A and B are constants, $H_{sub}(M)$ the standard enthalpy of sublimation, and $\sum_{i=1}^{3} I_i$ the sum of the ionisation energies; the last term represents the change in enthalpy as a function of temperature for an ideal gas.

According to published data,[25,26] the enthalpy of formation of $LnHal_3$ shows an irregular dependence on the number of f-electrons. In addition to the features of the structure of the f-levels characteristic of Ln^{3+}, revealed by the change in the values of H_{sub} and $\sum_{i=1}^{3} I_i$, the irregular change in $H_0(LnHal_3)$ with change in the number of f-electrons is also related to a change in the type of crystal structure. Thus in the trifluorides, the tetragonal LaF_3 structure is replaced in the second half of the series by the hexagonal–trigonal α-YF_3 structure. At the same time there is a change in the coordination number of the metal: with increase in the number of electrons q for the $Ln^{3+}(f^q)$ ion, the ninth fluorine atom is, as it were, displaced from the first coordination sphere, so that, for example, for HoF_3 and YbF_3 the internuclear distance Ln–F for one of the nine fluorine atoms is greater by 0.20 Å and 0.34 Å respectively[27] than the average Ln–F distance for the other eight fluorine atoms. This effect is similar to that observed for the aquo-ions, where the number of water molecules in the first coordination sphere changes from nine to eight on going from the ions of the light elements to the ions of the heavy elements.

At all stages of the development of the theory of the compounds of the trivalent f-elements, new examples of chemical regularities have been discovered. These regularities show a common feature, however, namely a regular change in properties for the light and heavy elements, and an anomalous change for the intermediate elements. The section of the anomalous relationship may include a larger or smaller number of elements, depending on the type of ligand, but for these elements there is always a change in the coordination number, internuclear distances, structure, etc.

The existence of three regions of change in the crystal-chemical properties is reflected in the melting points T_f and the enthalpies of solution. Thus the compounds LnF_3 can be divided into three groups, depending on the values of T_f: the heavy Dy–Lu, the light La–Nd, and the intermediate Nd–Dy.[28]

The difference between the lattice enthalpy of a crystalline compound H_c and the enthalpy of hydration of the ionic components determines the enthalpy of solution H_s. For $LnHal_3$,[21] the change in structure, for example for $EuF_3 \rightarrow GdF_3$ or $GdCl_3 \rightarrow TbCl_3$, is due to the anomalous change in H_s.

The experimental values of H_c are known for the chlorides of the actinides of the middle of the series:[21] for UF_3, H_c = −1502 kJ mol^{-1}, and for PuF_3, H_c = −1586 kJ mol^{-1}; for the chlorides of uranium, plutonium, americium, and curium, the corresponding values are −866, −960, −978, and −974 kJ mol^{-1}; for the bromides of uranium, neptunium, and plutonium, H_c = −699, −730, and −793 kJ mol^{-1}; and for the iodides of these metals, H_c = −467, −513, and −580 kJ mol^{-1} respectively. Solution calorimetry has been used to measure the standard enthalpies of formation of $CsSmCl_3$, $CsTmCl_3$, and $CsYbCl_3$.[29] The last two compounds have the ideal perovskite structure, and $CsSmCl_3$ and $CsEuCl_3$ have a distorted perovskite structure. The experimental values of H_0 for the synthesised compounds $CsLnCl_3$ and the calculated values for $CsNdCl_3$ and $CsDyCl_3$ correlate with the corresponding values for $LnCl_3$:

Ln in $CsLnCl_3$	Nd	Sm	Dy	Tm	Yb
H_0, kJ mol^{-1}	−1124	−1230	−1165	−1194	−1285

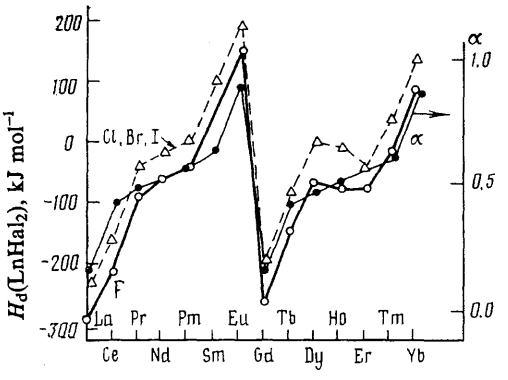

Figure 7. Dependence of the parameter α and the free enthalpies of decomposition (H_d) according to the scheme $LnHal_2 \rightarrow {}^1/_3Ln + {}^2/_3LnHal_3$ on the atomic number of the element.

The standard enthalpies of formation of the corresponding compounds $LnHal_2$ and $LnHal_3$, and also $AnHal_2$ and $AnHal_3$, can be used to calculate the standard enthalpies of the disproportionation

$$MHal_2 \rightarrow {}^1/_3M + {}^2/_3MHal_3$$

where M = Ln or An. The principal quantity determining the nature of the change in the enthalpies of decomposition with change in atomic number is not the sum of the ionisation potentials, as in the case of the enthalpies of formation, but the difference in the sums of the ionisation potentials, that is the third ionisation potential. This leads to a periodic change in the values of the enthalpies of decomposition in accordance with the periodic change in the ionisation potentials and the parameter α. This leads to the characteristic dependence of the enthalpies of decomposition on the number of electrons (Figs. 7 and 8).

3. Halogen compounds of tetravalent lanthanides and actinides

Experimental studies of the thermodynamic characteristics of the tetrafluorides are limited to the mass-spectral analysis of TbF_4 and CeF_4, tensimetric measurements for CeF_4, PrF_4, and TbF_4, and calorimetric measurements for CeF_4 and TbF_4 in an HCl + H_3BO_3 mixture.[24] The experimental values of $H_0(LnF_4)$ show a large scatter.

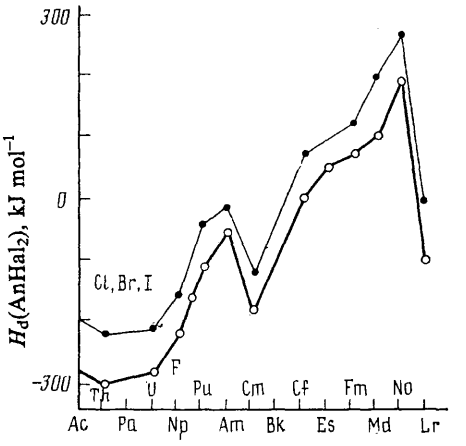

Figure 8. Dependence of the standard enthalpies of decomposition (H_d) according to the scheme $AnHal_2 \rightarrow {}^1/_3An + {}^2/_3AnHal_3$ on the atomic number of the element.

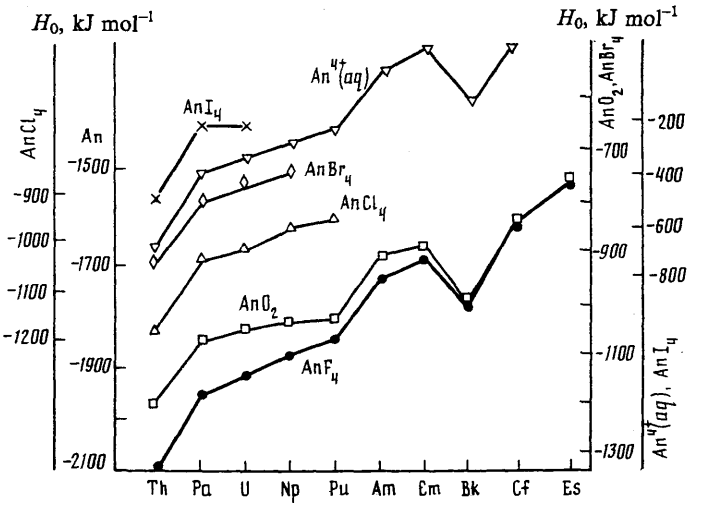

Figure 9. Dependence of the standard enthalpies of formation on the atomic number of the element.

The thermodynamic properties of the actinide tetrahalides ThF_4, PaF_4, UF_4, NpF_4, PuF_4, and AmF_4 have been studied experimentally.[21] Even for thorium tetrafluoride, however, the standard enthalpies of formation measured in fourteen studies show a scatter in the values of about 36 kJ mol^{-1}. Fig. 9 gives the dependence of the measured and calculated enthalpies of formation of the actinide tetrahalides in solution on the number of *f*-electrons. The data for

AnO_2 and $An^{4+}(aq)$ [21] are given for comparison. A noteworthy feature is the clearly defined plateau for Pa(f^1), U(f^2), Np(f^3), and Pu(f^4) and the sharp change in the enthalpies of formation on going from Th(f^0) to Pa(f^1) and from Pu(f^4) to Am(f^5) in the first half of the series. The same characteristics are observed for the compounds of the lanthanides.

The values of the enthalpy of decomposition of the tetrahalides

$$MHal_4 \rightarrow Hal + MHal_3$$

are determined by the difference

$$\sum_{i=1}^{4} I_i - \sum_{i=1}^{3} I_i.$$

Thus the rule of intervals formulated above is also applicable in this case.

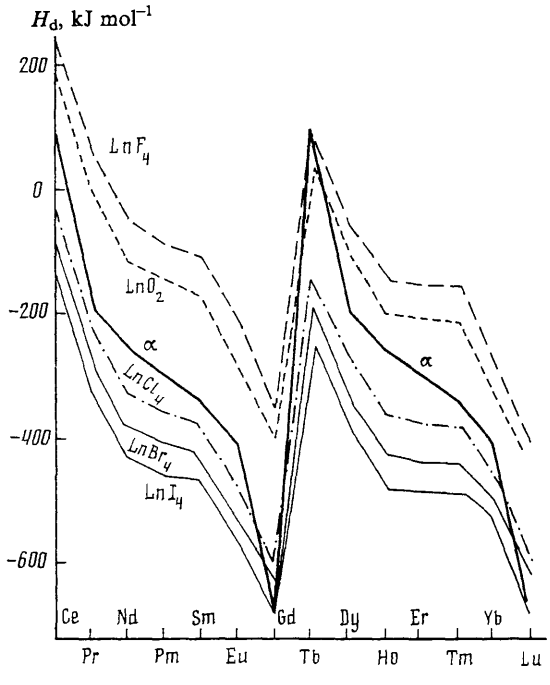

Figure 10. Dependence of the standard enthalpies of decomposition according to the scheme $LnX_4 \rightarrow X + LnX_3$ on the atomic number of Ln.

4. Oxides and chalcogenides

Of the lanthanide monoxides, EuO and impurity YbO have been characterised; in the monoxides LaO, CeO, PrO, NdO, and SmO, two valence electrons from the lanthanide atom are used for chemical bond formation, and the third for the formation of the conductivity band. Monoxides of Th, U, Np, Pu, and Am, formed on the surface of the metals, are known. The monoxide PuO is also obtained by reducing the dioxide PuO_2 using Pu and C; AmO is formed by the reaction of Am with HgO or in the gas phase. The standard enthalpies of formation of LnO and AnO have been calculated.[25,26]

For various lanthanides existing in the divalent state, for example La, Ce, Gd, and Lu, the one-configuration approximation is inadequate, and it is necessary to take account of several electron configurations involving *d*- or *s*-orbitals: $f^q + f^{q-1}d + f^{q-1}s \ldots$ In this case the rule of intervals for the disproportionation $MO \rightarrow {}^1/_3M + {}^2/_3MO_{1.5}$ should not apply. If however the electron configuration of the lanthanide f^q in the divalent state is stable, the rule of intervals applies.

In Fig. 10 the standard enthalpies of the decomposition $LnO_2 \rightarrow {}^1/_2O + LnO_{1.5}$ are compared with the corresponding values for $LnHal_4$. The characteristic periodicity of the change in these values with change in the number of electrons is again observed. Irrespective of the ligands, for all compounds of the tetravalent lanthanides and actinides, the standard enthalpies of decomposition change in accordance with the theoretical dependence of α on *q*. This periodicity should also be observed for higher oxidation states, for example for An_2O_5 (An = Pa, U, Np, Pu, ...), where the series includes hypothetical compounds.

For the sulphides and pnictides of the lanthanides and actinides, according to calculations of the standard enthalpies of formation of MS, $MS_{1.5}$, MS_2, and MAs, where M = Ln or An,[25,26] the same trends are observed in the change in these quantities with increase in the atomic number as in the case of the corresponding oxides, that is for the systems MO and MS, $MO_{1.5}$ and $MS_{1.5}$, and MO_2 and MS_2. An analogy is also observed in the dependence of the standard enthalpies of decomposition to the metal and the corresponding sulphide on the number of electrons.

V. Metals of the *d*- and *f*-series and intermetallic compounds

1. Crystal structures and electron configurations

Fundamental studies of the metallic lanthanides and actinides have been carried out in recent years, and the results reviewed.[30–35] In these studies, the role of the 4*f*- and 5*f*-electrons in the formation of the metallic bond was extensively discussed. Many problems have been resolved, but there is still no answer to the main question, namely the actual electron configurations of the atoms in the metals and the oxidation states of various actinides in the metals.

In accordance with the main purpose of the present review, which is to follow the regularity in the change in various properties of the lanthanides, actinides, and their compounds and to compare them with other series of elements, this task will also be carried out for the *d*- and *f*-metals.

In the lanthanide series, all the metals are trivalent, except Eu and Yb, and in the actinide series the heavy elements are divalent in the metallic state, the light actinides include tetravalent metals, and the intermediate elements are trivalent. In the actinide series, anomalous effects associated with a change in oxidation state will be superimposed on the periodicity in the change in properties due to the structure of the 5*f*-level.

The light metallic actinides (as far as plutonium) have crystal structures with a low symmetry; for plutonium, six different phases exist in the temperature range from 298 K to 913 K. Distorted and complex structures are generally formed if the 5*f*-electrons are involved in the production of the metallic band. The crystal structures of the heavy metals resemble the structures of the metallic lanthanides. The crystal structures are different for the light and

heavy actinides. The largest number of phases is observed for the metals in the middle of the series.

The crystal structure depends on the energy of excitation from the electron configurations of the ground state into low-lying excited states. Thus in the lanthanide series, where the 4*f*-electrons remain practically non-bonding, the crystal structure is determined by the valence *d*- and *s*-electrons, that is by the electron configurations: $f^q ds^2$, $f^q d^2 s$, $f^q dsp$, $f^{q+1} s^2$, $f^{q+1} ds$, $f^{q+1} sp$. If the neutral atom has the electron configuration $f^q ds^2$, then in the metal with the double hexagonal structure its electron configuration changes from $f^q d^{1.3} sp^{0.7}$ to $f^q d^{0.9} sp^{1.1}$.[33] If in the free state the atom has the electron configuration $f^{q+1} s^2$, then in the metal with the double hexagonal structure it changes from $f^{q+1} d^{0.3} sp^{0.7}$ to $f^{q+1} sp$.

2. Melting points of the metallic actinides

The change in the melting point T_f in the series of metallic actinides reflects their complex electronic structure. On going from metallic thorium to einsteinium, T_f changes from 2023 K to 1133 K. Even for metals having delocalised 5*f*-electrons, such as Pa, U, Np, and Pu, the melting point changes from 1840 K to 913 K. The dependence of T_f on the atomic number of the element is shown in Fig. 11. At high temperatures close to the corresponding melting points, the heavy metals (from Am to Es) have a face-centred cubic structure, and the light actinides (from Th to Np) a body-centred cubic structure.

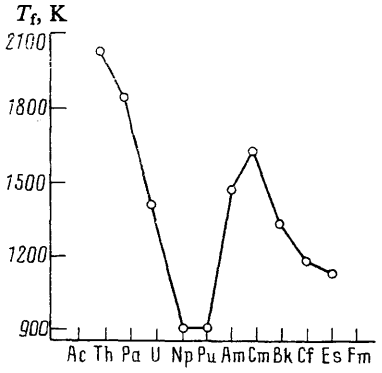

Figure 11. Dependence of the melting points of the metallic actinides on the atomic number.

The melting point T_f of the metal depends on the atomic number of the element. It decreases on going from Th to Np and Pu, increases from Pu to Am, and then decreases regularly from Cm to Fm. There is a correlation between the T_f values and the orbital quantum numbers L_q of the normal terms of the actinide ions: Th(f^0), Np(f^3), Pu(f^4), Am (f^6), Cm(f^7), Bk(f^8) (Fig. 12). These electron configurations correspond to the tetravalent states for the light actinides (from Th to Pu), the trivalent states for the elements of the middle of the series (from Bk to Am), and to divalent states for the heavy actinides (from Es to No).

The populations of the valence orbitals in the metals are fractional. The values for the 5*f*-orbitals are apparently greater than those indicated above. Fig. 12 shows clearly that the electron configurations Th(f^0), Np(f^3), Pu(f^4), Am(f^6), Cm(f^7), and Bk(f^8) have a significant influence on the production of the electronic structure of the atoms in the metals.

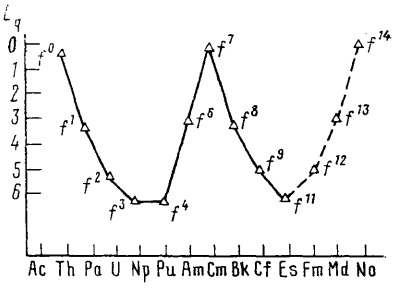

Figure 12. Change in the orbital quantum numbers L_q of the normal terms of the actinide ions with change in q.

3. Bond lengths in the metals and atomic volumes

The bond lengths in metals are fundamental characteristics and determine many of their properties—atomic volumes, band width, bond strength, etc. Data on the dependence of the atomic radii on the atomic number of the element have been compared for the metals of the *d*-series and the actinides.[31] For the metals of the 3*d*-series, the dependence is close to parabolic, and shows a double–double effect similar to that observed for the ionic radii in various compounds of these elements. This effect is revealed more clearly for the metals of the 3*d*-series than for the metals of the 4*d*- and 5*d*-series, since the 3*d*-electrons are more localised.

The almost parabolic dependence of the metallic radii on the atomic number is responsible for the same behaviour of the atomic volumes of the metals of the *d*-series.

The lanthanides Eu and Yb show anomalous values of the atomic volumes. This is related to the fact that Eu and Yb are divalent. From the corresponding relationship for the atomic volumes of the metallic actinides it was concluded[35] that the light actinides (from Th to Pu) are tetravalent.

4. Energies of cohesion

a) Metals of the *d*-series

The change in the energy of cohesion E_c for the metals of the 3*d*-series[35] is described by a curve which is close to parabolic, with a minimum at the middle of the series. The parabolic relationship breaks down for metallic manganese, although significant anomalies are not observed for the manganese analogues technetium and rhenium.

Among the metals of the 3*d*-series, Ca, Ni, and Cu have a face-centred cubic structure, Sc, Ti, and Co a double hexagonal structure, and V, Cr, and Fe a body-centred cubic structure; metallic manganese has a complex crystal structure with several non-equivalent atoms in the cell. The metals of the 4*d*-series have different crystal structures: Sr, Rh, Pd, Ag have a face-centred cubic structure; Ru and Cd a double hexagonal structure; and Nb and Mo a body-centred cubic structure. In these crystals, the metal atoms have the electron configurations $d^{q-x} sp^x$ and $d^q s$; the

contribution of the *p*-orbitals is greater for the double hexagonal system than for the face-centred or body-centred cubic structures.

Spectroscopic data[5] can be used to estimate the sum of the energies of excitation from the electron configurations $3d^q4s^2$ of the ground state of the neutral atoms Sc, Ti, V, Mn, Fe, Co, and Ni into the electron configurations $3d^{q+1}4s$ and $3d^{q+1}4s4p$. Since in the ground state the Cr and Cu atoms have the electron configurations d^5s and $d^{10}s$ respectively, for these elements it is possible to take account of only the excitation into the electron configurations d^5p and $d^{10}p$. For the calcium atom, account was taken of the sum of the excitation energies $4s^2 \rightarrow 4s4p + 4s3d$, and for the zinc atom only the energy of the single excitation $4s^2 \rightarrow 4s4p$ was considered.

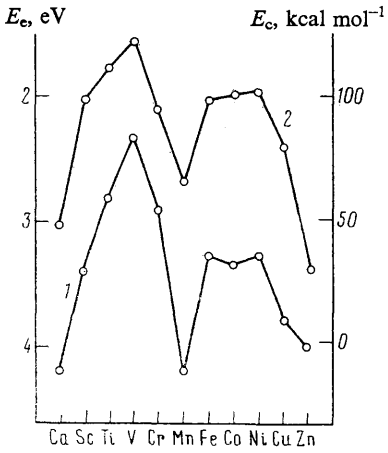

Figure 13. Correlation between the energy of cohesion of the metals and the sum of the energies of excitation from the electron configuration of the ground state d^qs^2 (Ca, Sc, Ti, V, Mn, Fe, Co, Ni, Zn) and d^qs (Cr, Cu) into the electron configurations d^qsp and d^qs; for each excited electron configuration, the multiplet of lowest energy is used.

It is obvious that the greater the excitation energy (E_e) corresponding to the electron configuration of a given type of crystal lattice, the lower the energy of cohesion, that is an inverse relationship exists between these quantities. The sum of the excitation energies reflects completely the energies of cohesion of the metals of the 3*d*-series (Fig. 13). The existence of the plateau section on the graph giving the dependence of E_c on the atomic number for metallic Fe, Co, and Ni (Fig. 13) is due to the opposed trends in the change in the excitation energies of the free atoms. The values of the energies of excitation from the electron configurations of the ground state d^qs^2: Fe(d^6s^2, ^5D), Co(d^7s^2, ^4F), and Ni(d^8s^2, ^3F), into the electron configurations $d^{q+1}s$ and d^qsp can be considered. These values (in eV), together with the electron configurations and their terms, are given below:

	$3d^{q+1}4s$	$3d^q4s4p$
Fe (d^6s^2; ^5D):	2.4 ($^5F_5$);	0.86 ($^7D_5$)
Co (d^7s^2, ^4F):	2,93 ($^4F_{9/2}$);	0.43 ($^6F_{11/2}$)
Ni (d^8s^2, ^3F):	3.44 ($^3D_4$);	0.03 ($^5D_4$) .

The sums of these quantities differ little, leading to similar values of the excitation energy for the atoms and approximately equal energies of cohesion for these metals. Thus the properties of the free atoms correlate well with the properties of the metals; this applies both to the energies of cohesion and the moduli of compression of the metals (Fig. 14). Thus the relationship between the corresponding energies of excitation and energies of cohesion or moduli of compression is apparently close to linear.

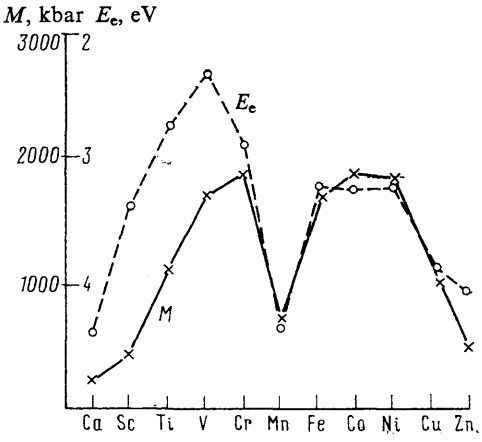

Figure 14. Correlation between the modulus of compression (M) for the metals of the 3*d*-series and the energies of excitation (E_c) into the hybrid state.

b) Metallic actinides

The dependence of E_c for the metallic actinides on the excitation energies has been studied.[33–36] Account was taken of the excitation energies[7,8] $f^qs^2 \rightarrow f^{q-1}ds^2$ and $f^{q-1}ds^2 \rightarrow f^{q-2}d^2s^2$ on going from the divalent to the trivalent and then to the tetravalent state. From this approach it was concluded[36] that Am, Cm, and Bk are trivalent. The valence of Cf is intermediate between 2 and 3, and the heavy metallic actinides, beginning with einsteinium, are divalent. For metallic Np and Pu, the picture is more complex and indefinite. From estimates of the excitation energies $f^{q-1}ds^2 \rightarrow f^{q-2}d^2s^2$ it follows that Np and Pu in the metallic state are apparently trivalent, but estimates of the atomic volumes and other properties indicate that they are tetravalent.

If for the light actinides (from thorium to plutonium) account is taken of the energies of excitation into the formally tetravalent states, accompanied by unpairing of the $7s^2$ electron pair, $f^{q-2}d^3s$ and $f^{q-2}d^2sp$, then the nature of the change in the excitation energy for Np, Pu, and Am will not reflect even the trend in the change in E_c. If however it is assumed that the hybrid functions in the metallic state are complex and are formed from several electron configurations: $f^{q-1}d^2s + f^{q-1}dsp + f^{q-2}d^3s + f^{q-2}d^2sp$, and that the contribution of the last two electron configurations is small, then it is possible to obtain not only a qualitatively correct description but also a quantitative description of the dependence of E_c on the excitation energy. In the second half of the series, the values of the energy of cohesion correlate with the energies of

excitation into both the divalent and the trivalent states. If it is assumed that Bk and Cf are trivalent in the metallic state, and that all the actinides from einsteinium onwards are divalent, the energies of cohesion of the metallic forms of these elements again do not agree with the experimental data. For the berkelium atom, the energies of excitation into the formal divalent and trivalent states are approximately equal. Thus the metallic state apparently corresponds to several electron configurations: f^8d^2s, f^8dsp, f^9sp.

Thus for the heavy metallic actinides, the change from Cm^{III} to No^{II} takes place in stages. To conclude this section, it may be noted that in the interpretation of the properties of the actinides it is incorrect to take account of only one electron configuration for each valence state: f^qs^2 for An^{II}, $f^{q-1}ds^2$ for An^{III}, and $f^{q-2}d^2s^2$ for An^{IV}, with integral values of the populations of the *f*-, *d*-, and *s*-orbitals. On going from Th to Pu there is an increase in the energies of excitation into the electron configurations $f^{q-2}d^3s$, $f^{q-2}d^2sp$, and $f^{q-2}d^2s^2$, indicating a decrease in their contribution to the overall electron configuration in the metals. Similarly, in the second half of the series, there is a gradual decrease in the contribution of the electron configurations $f^{q-1}d^2s$ and $f^{q-1}ds^2$ to the electron configurations of the metals, and the contributions from the f^qsp- and f^qsd-electron configurations increase.

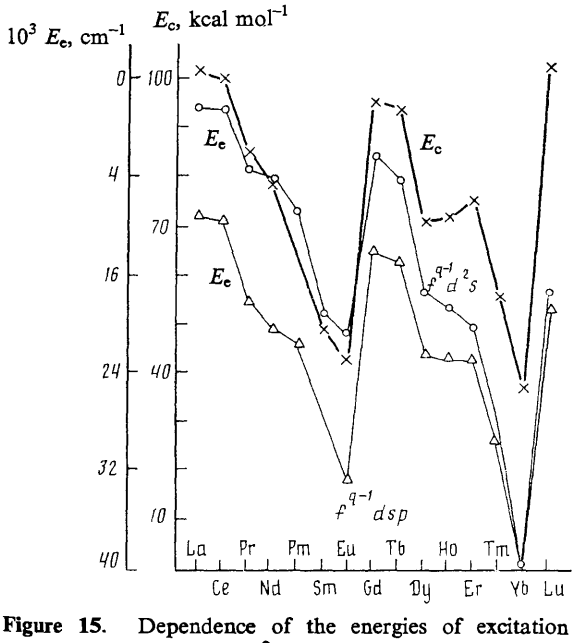

Figure 15. Dependence of the energies of excitation from the electron configuration f^qs^2 into the electron configurations $f^{q-1}d^2s$ and $f^{q-1}dsp$ on the atomic number of the element; in the first case the configurations $f^7ds + f^7d^2$ for Eu and $f^{14}ds + f^{14}d^2$ for Yb were used, and in the second case $f^7p^2 + f^7sp$, $f^7dp + f^7ds$ for Eu and $f^{14}ds + f^{14}dp$ for Yb; it can be seen that there is a correlation between the energies of excitation and cohesion E_c.

c) Metallic lanthanides

The dependence of the energy of cohesion of the metallic lanthanides on the atomic number reflects the periodicity in the properties of the free atoms more clearly than any other property. Fig. 15 gives the dependence of the energies of excitation from the electron configuration of the ground state f^qs^2 into the electron configurations $f^{q-1}d^2s$ and $f^{q-1}dsp$ for all the elements except Eu and Yb, for which the energies of excitation into the divalent states were used.[4] The changes in the energies of cohesion and in the energies of excitation with change in the atomic number show a remarkable similarity.

Comparison of the energies of cohesion for the metals of the *d*-series, the lanthanides, and the actinides shows that the atomic factor is preserved to the greatest extent for the metals of the 3*d*-series and the lanthanides, in accordance with the fact that the 4*f*-electrons are more localised than the 5*f*-electrons, and the 3*d*-electrons more localised than the 4*d*- and 5*d*-electrons.

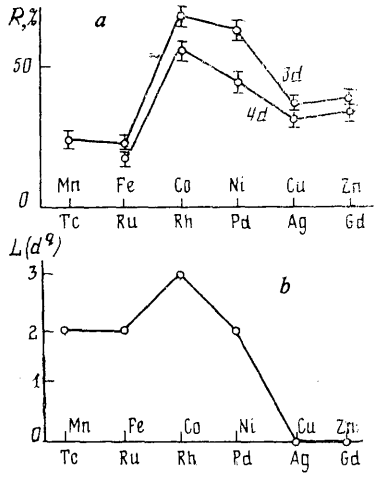

Figure 16. Ranges of change in composition (R) for the intermetallic compounds with metals M (*a*) and the dependence of the quantum numbers L for the electron configurations of the atoms M (*b*) in the metals ($d^qs^xp^y$) on the atomic number of M.

5. Intermetallic compounds of the lanthanides

The lanthanides form a large number of compounds with different compositions with the metals of the *s*-, *p*-, and *d*-series, and the regularities in the change in their properties can be followed. The most widely encountered compounds of the lanthanides with metals are the following: Ln_3M, Ln_5M_2, Ln_7M_5, Ln_9M_4, $Ln_{24}M_{11}$, Ln_2M, Ln_2M_{17}, Ln_5M_3, Ln_3M_2, Ln_4M_3, Ln_5M_4, $Ln_{11}M_{10}$, LnM, Ln_5M_{41}, Ln_6M_7, Ln_3M_4, Ln_7M_{10}, Ln_3M_5, LnM_2, LnM_3, Ln_2M_7, $Ln_{14}M_{51}$, Ln_3M_{11}, Ln_5M_{19}, Ln_6M_{23}, Ln_3M_{22}, LnM_4, Ln_4M_{17}, Ln_5M_{22}, $Ln_{13}M_{58}$, Ln_5M_{24}, LnM_5, LnM_6, LnM_7, LnM_{11}, LnM_{13}, LnM_{66}, etc. The relative concentration of Ln in the two-component compounds is restricted. The highest concentration of Ln in these compounds is apparently achieved in Ln_3M. The composition of the simplest compounds changes regularly for each system. These compounds are LnM_2 for the elements Mn, Tc, Re, and Fe, Ln_3M for the other transition elements, LnM for the elements of groups IB and IIB (except Au), and Ln_3M again for the elements of groups IIIA, IVA, and VA. A definite periodicity in the composition is observed. The most varied compositions with respect to M are shown by the compounds of the lanthanides with the group IIB

elements, whereas the elements from Al to Bi are characterised chiefly by the compounds LnM_3. Boron gives a large number of compounds with different compositions.

The composition of the compounds is determined chiefly by the electronic structure of M, that is by the number of *d*-, *s*-, and *p*-electrons for M. All the lanthanide compounds can be divided into three groups, depending on the electronic structure of M: 1) compounds with transition elements, 2) compounds with IB and IIB elements (except Au), and 3) all other compounds. If the range of change in the composition (R) of the compounds with respect to M is defined as the difference $R = R_u - R_l$, where R_u and R_l are the upper and lower percentage concentrations of M in the compounds with the highest and lowest concentrations of M, then an extremal value of R is reached in the middle of the second half of the series of *d*-elements (Fig. 16). This reveals a characteristic of the *d*-levels occupied to the extents of 1/2, 3/4, and 1, that is the values of R should correlate qualitatively with the values of the quantum numbers L_q for the normal term and the d^q-electron configurations corresponding to the hybridisation of the atoms in the pure metals: Mn, Tc (d^6s); Fe, Ru ($d^{6-x}p$); Co, Rh ($d^{8-x}sp^x$); Ni, Pd (d^9s); Cu, Ag ($d^{10-x}sp^x$); Zn, Cd ($d^{10}sp$).

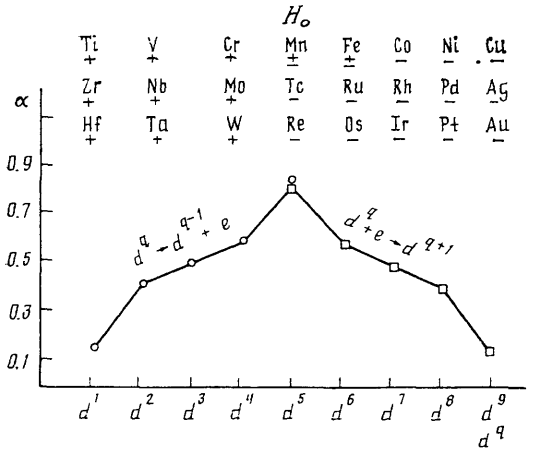

Figure 17. Dependence of α on q, showing that the most stable compounds of the 3*d*-metals with the lanthanides should be formed by the heavy 3*d*-metals; the upper part of the Figure gives the signs of the heats of formation of the compounds LnM.

The curve describing the dependence of the percentage concentration of the compounds LnM relative to the total number of compounds on the percentage concentration of M in the given type of compound is bell-shaped (the apex of the bell corresponds to the compounds LnM_2, the largest class of compound). The number of compounds with a given composition increases in the order: $Ln_5M_3 < LnM_3 < LnM < LnM_2$. In the reaction of the metals of the 5*d*-series and the lanthanides, the greatest bonding is achieved with the *d*-elements of the second half of the series. In their reaction with the elements of the first half of the 3*d*-series, the lanthanides should be reduced, and in their reaction with the elements of the second half they should be oxidised. Correspondingly, the 3*d*-elements in the first half of the series are oxidised, and those in the second half are reduced. The dependence on q of the values of $\alpha = [2L_{q+1} + 1][2L_{q+1} + 2L_q + 2]^{-1}$ for the first half of the series and $\alpha = [2L_{q-1} + 1][2L_{q-1} + 2L_q + 2]^{-1}$ for the second half determines the tendency to undergo oxidation on going from the d^5- to the d^1-electron configuration and to undergo reduction on going from the d^5- to the d^9-configuration. These trends are shown schematically in Fig. 17, which also gives the signs of the heats of formation of the intermetallic compounds H_0. The electron configuration d^5s^2 was used for all the *d*-elements.

The heavy *d*-elements act as electron acceptors $Ln^{\delta+}M^{\delta-}$, and the acceptor properties increase towards the end of the series (Fig. 17). The light *d*-elements should be electron donors, $Ln^{\delta-}M^{\delta+}$, and the donor properties should increase from the middle to the beginning of the series. Thus since they have a low electron affinity, the lanthanides should not tend to form intermetallic two-compounds with the light *d*-elements. The sign of the heat of formation is not always known for the middle of the series.

- - -o0o - - -

The present review has analysed the general regularities in the change in the redox properties of the lanthanides, actinides, and elements of the *d*-series. This phenomenon is determined by the specific features of the electrostatic interaction of the *d*- or *f*-electrons. It leads to a characteristic change in the properties with increase in the number of electrons: a sharp–retarded–sharp change in each half of the series, and the sharpest change on going from one half of the series to the other.

Specific features of the chemical structure of the oxo-complexes of d^0 and d^2 metals with monodentate and polydentate ligands

M A Porai-Koshits, V S Sergienko
Kurnakov Institute of General and Inorganic Chemistry, USSR Academy of Sciences, Moscow

ABSTRACT. The structure of the oxo-complexes of transition d^0 and d^2 Group V–VII metals is discussed. Two types of distortion isomerism are considered: the *trans*-influence isomerism (the lengthening of the M=O multiple bond on passing from one isomer to another is accompanied by a shortening of the M–L_{trans} bond) and the multiple bond isomerism (the lengthening of the M=O bond is not accompanied by a shortening of the M–L_{trans} bond). The choice of the *trans*-partner out of the set of competing functional groups for the d^0 metal is determined by the self-consistency principle, while for the d^2 metal the rule becomes more complex and the choice of the *trans*-partner of the oxo-ligand depends on the individual features of the *trans*-ligand (on the combination of its σ- and π-donor properties). It is shown in relation to the d^0-MoO_2 and d^2-ReO complexes with isotypical chelate O, N-donor ligands that the latter are coordinated to the metal in different ways.

I. Introduction

The stereochemistry of transition metal complexes with ligands linked by multiple bonds and in particular the stereochemistry of d^0 and d^2 metals has now been investigated comprehensively by Soviet and foreign workers. It is distinguished by the following principal features.

1. The mutual disposition of the ligands X linked by multiple bonds in octahedral dioxo-complexes of Group V–VII is determined by the electronic configuration of the metal: *cis*- and *trans*-dispositions occur for the d^0 and d^2 metals respectively.[1–3] This rule has a completely evident model quantum-chemical interpretation. The *cis*-disposition of two or (three) ligands linked by multiple bonds in complexes of d^0 metal ensures the maximum involvement of all three t_{2g} orbitals of the octahedral metal polyhedron (or, in other words, the d_{xy}, x_{xz}, and d_{yz} orbitals) in the π-acceptance of electrons by the multiple bond-linked ligands X. The *trans*-disposition of two multiple bond-linked ligands in complexes of the d^2 metal is determined by the fact that this ensures the minimum electron-electron repulsion between the orbital occupied by the lone electron pair of the metal and the π- and σ-electrons of the bond formed by the ligands X (Fig. 1)†.

2. The *trans*-influence of the X≡M...L multiple bond, manifested by the lengthening (weakening) of the bond with the *trans*-partner, depends on the nature and multiplicity of the bond involving the ligand X, the nature of the *trans*-partner L, and the electronic configuration of the metal M:[4] (a) the *trans*-influence diminishes in the following series of ligands X:

$$M\equiv > N\equiv > O\equiv > RN\equiv > =O\equiv > ON\rightleftarrows, OC\rightleftarrows;$$

(b) the bond with a neutral donor ligand L (the *trans*-partner of the multiple bond-linked ligand X) is weakened to a greater extent than the bond with the acido-ligand L^{n-}; (c) depending on the electronic configuration of the metal, the *trans*-influence diminishes in the sequence $d^0 \geqslant d^1 > xd^2$.[5]

3. The choice of the *trans*-partner from the set of competing functional groups is determined by the self-consistency principle.

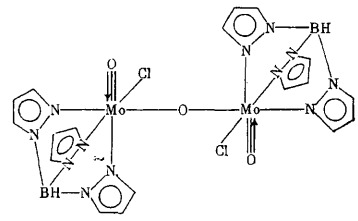
It has been shown[6] that the *trans*-influence of the multiple bond-linked ligand is transmitted via the σ-mechanism: the π-interaction, leading to the shortening of the X–M distance, increases σ-overlap and hence the σ-exchange integral between X and M, diminishing it in the region of M and L_{trans}. The most "convenient" *trans*-partners are therefore as a rule *N*- and *O*-donors (in particular ammonia and water molecules), the degree of localisation of the lone pairs of which can vary within wide limits in such a way that the equilibrium X–M–L_{trans} configuration is obtained for the given multiple bond-linked ligand X.

Thus the labilising effect exerted by the multiple bond-linked ligand on the bond between the metal and the *trans*-partner makes preferable the participation of the least polarisable σ-donor in this bond. As will be shown below, the application of this rule to d^2 metals is complicated by other factors.

The structural manifestation of the *trans*-influence of the multiple bond—the lengthening of the bond with the *trans*-partner—can be conveniently characterised quantitatively by the parameter Δ, which is defined as the differences between the lengths of the bonds formed by the metal with the *trans*-partner and with the analogous ligand located in the *cis*-position relative to the multiple bond. In the absence of like ligands simultaneously in the *cis*- and

† The complexes of d^1 metals with multiple bond-linked ligands X usually have a dinuclear structure with a *cis*-disposition of the terminal and bridging ligands X, which is also characteristic of d^0 metals.

trans-positions, it is necessary to use the parameter Δ', defined as the difference between the length of the bond with the *trans*-partner and the standard (ST) mean statistical length of the bond with an atom of the same kind in the usual complexes (not containing multiple bond-linked ligands). In order to estimate such standard Mo–O, Mo–N, and Mo–S distances, we employed the structural data presented in a monograph‡.[5] On their basis, one can postulate the following typical ranges of bond lengths: $Mo-O_{trans}$ = 2.11–2.38 Å, $Mo-O_{ST}$ = 1.94–2.08 Å (Δ_{av}' = 0.25 Å), $Mo-N_{trans}$ = 2.26–2.45 Å, $Mo-N_{ST}$ = 2.11–2.26 Å (Δ_{av}' = 0.20 Å); $Mo-S_{trans}$ = 2.63–2.80 Å, $Mo-S_{ST}$ = 2.42–2.51 Å (Δ_{av}' = 0.25 Å).

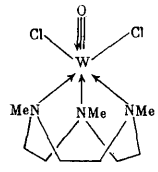


As already mentioned, the *trans*-influence diminishes in the sequence d^0 metals > d^1 metals > d^2 metals. We shall quote two examples. In the series of oxo-halogenometal complexes having the general formula $K_2[M^VOX_5]$, where M = d^0-Nb and X = F,[7] M = d^1-Mo and X = Cl,[8] and M = d^2-Re and X = Cl,[9] the quantity Δ diminishes correspondingly from 0.23 to 0.21 and 0.08 Å on passing from d^0 to d^1 and d^2 metals. Admittedly in the given instance, not only the electronic configuration but also the nature of the metal varies, so that this example is not entirely convincing. The comparison of compounds of heptavalent and pentavalent rhenium, namely $Re^{VII}O_3(ReO_4)(H_2O)_2$ [10] and $Re^VOI_2(ReO_4)(PPh_3)_2$, is much clearer.[11] At first sight, the difference between the lengths of the bonds with the *trans*-partner of the oxo-ligand—the oxygen atom of the perrhenate anion—is not very great: the decrease in the $Re-O_{trans}$ distance on passing from d^0-Re(VII) to d^2-Re(V) is only 0.07 Å (2.10 and 2.03 Å respectively). However, one should bear in mind that in the case of Re(VII) we are dealing with the trioxo-complex ReO_3^+, where the Re=O bonds are purely double bonds, while in the case of Re(V) we are dealing with a monoxo-complex ReO^{3+} formally containing a triple bond (Re≡O), which affects the Re–O (oxo) bond length (1.76 and 1.67 respectively). The increase in the multiplicity of the bond in the second compound enhances the *trans*-influence; therefore in the case of a pure Re=O double bond in the Re(V) complex, the $Re=O_{trans}$ distance should be significantly smaller than 2.03 Å.

II. The lability of the length of the M=O multiple bond in complexes of d^1 and d^2 metals

The vast majority of data concerning the structures of octahedral complexes with multiple bond-linked ligands refers to oxo-compounds. The the complexes of d^0 metals, the length of the metal–oxygen multiple bond is fairly stable and depends on the number of oxo-oxygen atoms in the complex (on the multiplicity of the bond). Thus, in the most numerous Mo(VI) compounds, the length of the formally triple Mo≡O bond (monoxo-complexes) is 1.61–1.68 Å, while the length of the bond having formally a multiplicity of 2.5 (dioxo-complexes) is 1.67–1.72 Å. In some of the trioxo-complexes investigated, the MoO=O double bonds have a length of approximately 1.74 Å.

‡Strictly speaking, in an estimate of this kind one should take into account in addition data obtained in recent years and a definite classification of O-, N-, and S-containing ligands (neutral-donor and acido-ligands, monodentate and polydentate ligands, ligands without multiple bonds in metallocycles and with multiple bonds, etc.) should be made.



In the complexes of d^1 and especially d^2 metals, the length of the multiple bond is less constant regardless of the number of oxo-oxygen atoms. This is clearly seen from the data presented in Table 1. Depending on the nature of the outer-sphere cation and the number of molecules of water of crystallisation, the Mo–O distance in the three $[Mo^{IV}O(CN)_4(H_2O)]^{2-}$ complexes varies within the limits of 0.12 Å.[12,13] The Mo=O distances differ even more in two conformational isomers of the dinuclear complex $[Mo^VOCl\{HB(Pz)_3\}]_2(\mu\text{-}O)$ with a bridging oxygen atom.[14] The isomers differ in the local symmetry of the complexes: in the C_i isomer (I)

(I): isomer C_i

the bridging oxygen atom is located at the centre of inversion, while in the other isomer (C_2) it is located on the two-fold symmetry axis passing at right angles to the N–Mo–O–Mo–N axial coordinate. In the C_i isomer, the $Mo=O_{end}$ bond is longer by 0.109 Å than in the C_2 isomer.

The two crystalline modifications of the paramagnetic complex $[WOCl_2L](PF_6)$ (II), presented in Table 1, have different colours and are not geometrical isomers, but are almost identical as regards the conformation of the tridentate ligand L.[15]

(II)

These two forms differ mainly only by the length of the bond between the tungsten and oxygen atoms and the bond between the tungsten atom and the nitrogen atom (of the ligand L) in the *trans*-position. In the blue form, the first distance is smaller by 0.17 Å and the second distance is greater by 0.05 Å than in the green form (Δ = 0.13 and 0.17 Å respectively).

It is remarkable that these two forms persist also in solution: in anhydrous acetone they do not undergo a change in the colour characteristic of their solid state. One is therefore dealing not with crystalline modifications but with a special type of isomerism.

Table 1 shows that the range of variation of the M≡O bond lengths in the Mo complexes examined reaches 0.18 Å and, when account is taken of the compound of tungsten whose atomic radius differs little from that of molybdenum, the range increases to 0.29 Å. In all the compounds compared, a decrease in the stretching vibration frequency ν(M=O), accompanied by a change in the colour of the crystals from blue to green, corresponds to the increase in the length of the M=O bond.

Table 1. Geometrical parameters and vibration frequencies $\nu(M=O)$ of the complexes of d^2 and d^1 metals with a labile M=O double bond.

Formula	Colour of complex	Electronic configuration	Bond lengths, Å			Δ(Δ′)	$\Delta_{M=O}$*, Å	$\nu_{M=O}$, cm^{-1}	Refs.

	Brown (C_i)		1.779	2.277 (NR_2)	2.179 (NR_2)	+0.098	—	960	[14]

*$\Delta_{M=O}$ is the difference between the M=O bond lengths in two isomers (green−blue or C_2-C_i).
**L = *N*, *N*′, *N*″-trimethyl-1,4,7-triazacyclononane.

The correlation between the M=O and M−L_{trans} bond length is also evident: the longer (weaker) the M=O bond, the weaker the *trans*-influence (the parameter Δ diminishes). Comparatively small variations in the lengths of the bonds between the metal and the *cis*-ligands are not regular in character.§

In the examples examined, the *trans*-ligand plays a relatively passive role: its bond with the metal is weakened to a greater or lesser extent in accordance with the requirements of the O−M multiple bond. The isomeric forms arising under these conditions can be naturally referred to as isomers of the metal−ligand multiple bond. Another very similar type of isomerism, in which the *trans*-ligand plays a more active role, is considered below in Section IV.

III. The choice of the *trans*-partner in complexes of d^0 and d^2 metals

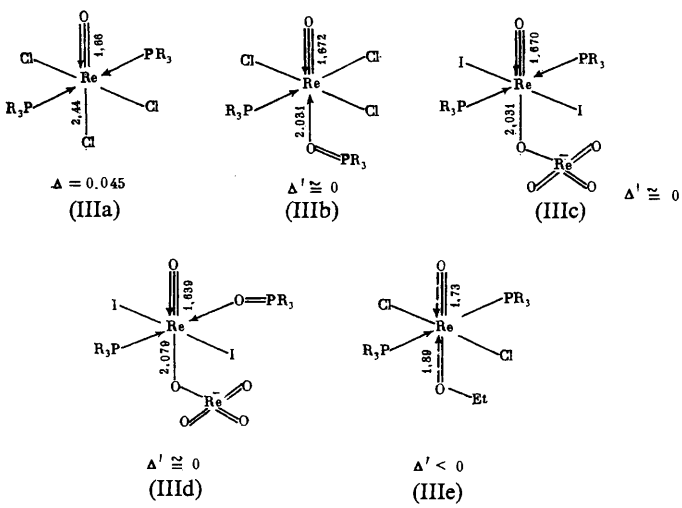
The available structural data make it possible to establish series based on the preferential location in the *trans*-position relative to the oxo-ligand of ligands such as terminal halogen atoms, anionic *O*-organo-groups, water molecules, molecular *O*- and *N*-organo-donors, bridging halogen atoms, and asymmetric bridging oxygen atoms. For d^0 metals, the series assumes the following form:

$$Cl-,\ Br-,\ I-,\ RO-,\ R_2N-<H_2O\rightarrow,\ O_L\rightarrow,\ N_L\rightarrow,$$
$$-Cl_M\rightarrow,\ -R_2N\rightarrow<\rightleftarrows O_M\rightarrow,\ F-<-F_M\rightarrow,\ \rightleftarrows F_M\rightarrow.$$

The halogen atoms (Cl, Br, I), occupying the *trans*-position relative to the oxo-ligand, give way to water molecules and any neutral donor *O* and *N*-ligands; bridging donor oxygen atoms, forming a multiple bond with another metal atom, are even more preferable.

The exact position of the weakly polarisable F^- anion is not evident, since, so far as we are aware, the available structural data are restricted to only one example—the compound $(NH_4)[VO(O_2)\cdot F_2(bipy)]\cdot 2H_2O$.[16] In this complex, obtained by the reaction of $(NH_4)[VO(O_2)_2(bipy)]\cdot 4H_2O$ with HF, an inner-sphere rearrangement takes place in addition to the replacement of one peroxo-group in the initial compound by two fluorine atoms. The rearrangement consists in the migration of the axial N atom of the bidentate bipyridyl (bipy) ligand, in the *trans*-position to the oxo-ligand, to the equatorial position and the substitution of this position by one of the fluorine atoms. Thus in the given instance the fluoro-ligand in the *trans*-position to the oxo-ligand is preferable to the neutral donor nitrogen atom of bipy.

In addition, attention may be drawn to the fact that in the numerous hydrates of molybdenum oxide fluorides [not only Mo(VI) but also Mo(V) and Mo(IV)], the water molecules are not as a rule incorporated in the inner sphere of the complex and the inner sphere of a purely fluoride type. When the number of terminal fluorine atoms is insufficient, oligomerisation or polymerisation takes place more readily than the incorporation of a solvent molecule in the inner sphere. Of the two types of fluoride anions, the bridging



§The authors of a structural study of the green form of $(PPh_4)_2\cdot[MoO(CN)_4(H_2O)]\cdot 4H_2O$ [12] found that the Mo−$(H_2O)_{trans}$ bond length is 2.96 Å (this actually means that the coordination number of the metal is five). This result is very doubtful bearing in mind that the given compound is isotypical (pseudo-isostructural) with the compound $(AsPh_4)_2[MoO(CN)_4(H_2O)]\cdot 4H_2O$.[12] It is difficult to suppose that the difference between the Mo−H_2O distances, amounting to 0.5 Å, is caused by the different degrees of involvement of the water molecule in the hydrogen bonds or by the replacement of the cation PPh_4^+ by $AsPH_4^+$. It is apparently a result of the poor quality of the crystals employed and the low accuracy of the investigation, which was noted by the authors themselves.[12]

$-F_b\rightarrow$ or $\overleftarrow{=}F_b\rightarrow$ anion is preferable to the terminal F^- anion as the *trans*-partner of the multiple bond-linked ligand ($O\overleftarrow{=}$ or $-O\overrightarrow{=}$).

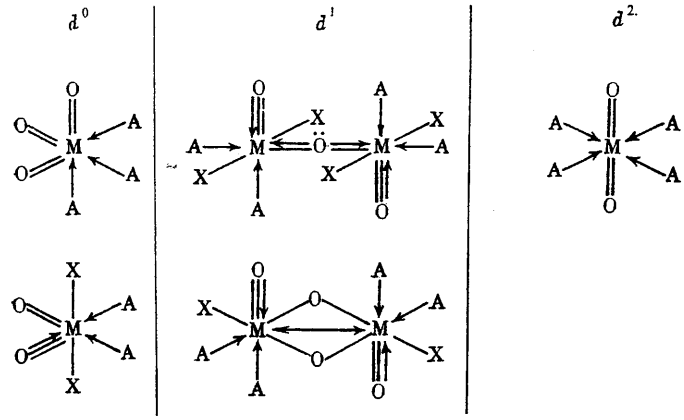
Overall, in the series presented above the trans-length parameter $\Delta(\Delta')$ increases from left to right and the self-consistency principle is satisfied:[17] the ligand whose σ-bond with a d^0 metal can be most readily weakened, i.e. the least polarisable [least "hard" according to Pearson[18]] donor among all the ligands present in the complex, enters most readily the *trans*-position relative to the multiple bond.

Initially it seemed that this principle is general and applies to not only d^0 metals but also to d^2 metals. Mixed halogeno-phosphine oxo-complexes are well known for Re(V) and Mo(IV). Structural studies have shown that phosphine, a powerful σ-donor, never occupies the *trans*-position relative to the multiple bond involving oxygen (the π-acceptor properties of PR_3 play no role) and gives way to a halogen (Cl, Br, I), for example, in the structure of *trans*-[$ReOCl(PEt_2Ph)_2$] (IIIa).[19]

It is just as natural that the halogen (Cl, Br) gives way to L_{trans}, which is a neutral oxygen-containing ligand—phosphine oxide in the complex [$ReOCl_3(OPPhEt_2)(PPhEt_2)$] (IIIb)[20]—and passes to the *trans*-position relative to PR_3. In the complex [$ReO(ReO_4).I_2(PPh_3)_2$] [11] containing two acido-ligands (iodine and perrhenate), ReO_4^- occupies the *trans*-position relative to the oxo-ligand [compound (IIIc)]. This can be regarded as evidence that the less-electron-donating ReO_4^- is preferred to the readily polarisable I^-, i.e. can be treated as a revision of the left-hand part of the series presented above. However, the perrhenate ligand occupies the same *trans*-position also in the complex [$ReO(ReO_4)I_2(OPPh_3)(PPh_3)$] (IIId),[11] containing also the neutral phosphine oxide ligand. Thus, in the case of Re(V) the singly-charged acido-ligand ReO_4 is preferable to the neutral phosphine oxide in the *trans*-position relative to O(oxo).

Furthermore, the *trans*-weakening Δ′ in the *trans*-preference series for d^2 metals does not increase from left to right, as for d^0 metals, but diminishes (regardless of the Re≡O multiple bond length). The *trans*-position relative to the oxo-ligand in the structure [ReO(OEt).$(PPh_3)_2Cl_2$] (IIIe)[20,21] is also occupied by an acido-ligand (the ethoxy-group) having one unpaired electron. Here Δ′ is altogether negative (it is smaller by 0.15 Å than the sum of Pauling's covalent radii of Re and O), i.e. the $M-L_{trans}$ bond is shortened (strengthened) and not lengthened (the Mo=O bond with the terminal oxo-ligand is simultaneously lengthened).

The reason for such "anomalous" choice of the *trans*-partner in the d^2 complexes becomes understood if one recalls that, in contrast to the complexes of d^0 metals, the multiple bond-linked ligands in these compounds always occupy opposite and not neighbouring vertices of the octahedron (see Fig. 1). Hence follows the conclusion that the ethoxy-group can also be regarded as a multiple bond-linked ligand¶.



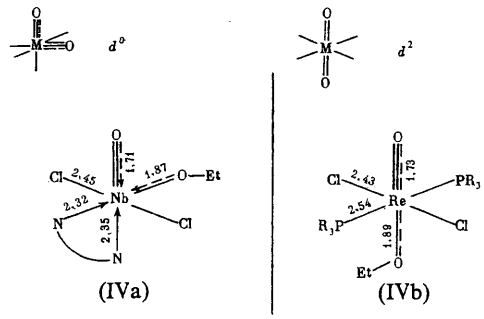


Figure 1. The disposition of multiple bond-linked ligands in the oxo-complexes of d^0 and d^2 Group V–VII transition metals.

This conclusion is well illustrated by the comparison of complexes of the d^0 metal Nb(V) and the d^2 metal Re(V): [NbO(OEt).(bipy)Cl_2] (IVa)[23] and [$ReO(OEt)(PPh_3)_2Cl_2$] (IVb).[20,21]

In complex (IVa), the ethoxy-group is in the *cis*-position relative to the O(oxo) atom and the Nb–O (OEt) distance (1.87 Å) is significantly smaller than the usual value, while in complex (IVb) the group is located in the *trans*-position relative to the O(oxo) atom at approximately the same distance from the metal. The Nb–O (OEt) and Re–O (OEt) distances are shorter by 0.20 and 0.13 Å

¶ The conclusion that the M–OEt bond is multiple was first reached from NMR data.[22]

respectively than the standard ("expected") M–OR bond lengths (2.07 and 2.02 Å respectively[4]). The increased multiplicity of the Nb–O (OEt) bond is also indicated by the Nb–N distances to the nitrogen atoms of bipyridyl: they are greatly lengthened (to approximately the same extent) in the *trans*-positions relative to both the multiple bond-linked oxygen and to the ethoxy-group (to 2.35 and 2.32 Å respectively).

The location of the ethoxy-group in the *trans*-position relative to the M=O bond and the shortening of the M–O(OEt) bond in the Re(V) complexes is not fortuitous, which is indicated by the geometrical parameters of the O⇶Re⇀ OEt fragment in all four structures investigated having the general formula $[ReO(OR)]X_2L_2$ (X = halogen)[20,21,24,25] (Table 2). In all these compounds, the OR^- (R = Et, Me) group is in the *trans*-position relative to the oxygen atom and in all cases the length of the bond between the Re atom and the methoxy- and ethoxy-groups is shortened (to 1.859 to 1.896 Å)‡. For comparison Table 2 presents the geometrical parameters of the O⇶Re–$OReO_3$ linkage in two complexes with the perrhenate group in the *trans*-position relative to oxygen.[11] The Re–O(ReO_4) *trans*-bond in $[ReO(ReO_4)I_2(PPh_3)_2]$ and $[ReO(ReO_4)\cdot(OPPh_3)(PPh_3)I_2]$ is lengthened to 2.031 and 2.079 Å respectively. The difference between the Re–O (OEt) and Re–O (ReO_4) bond lengths is quite natural (Fig. 2). While the π-electrons of the oxygen of the OR^- group can participate in the formation of a bond with the central rhenium atom, the similar electrons of the oxygen in the perrhenate anion are involved to a considerable extent in the molecular orbitals of the ReO_4^- anion itself and participate to only a slight extent in the formation of a bond with the central atom.

If the *trans*-ligand is a pure σ-donor, then the self-consistency principle operates: the *trans*-position relative to the oxo-oxygen atom is occupied preferentially by the hardest donor with a simultaneous increase in the length of the *trans*-bond. However, if the complex contains a ligand capable of π-donation to the metal, then in the case of a d^2 metal precisely this ligand occupies preferentially the *trans*-position relative to the oxygen-ligand and the *trans*-shortening via the π-mechanism is then superimposed on the *trans*-lengthening via the σ-mechanism, and the former may predominate.

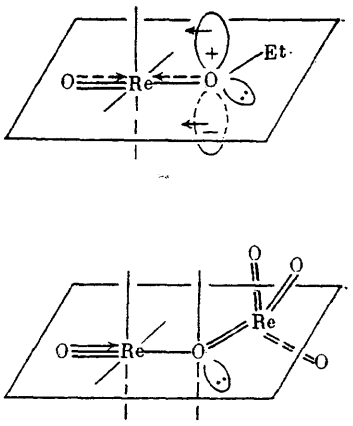

Figure 2. The structure of the ORe(OEt) and ORe(ReO_4) fragments in the mixed halogeno-phosphine monoxo-complexes of d^2-Re(V).

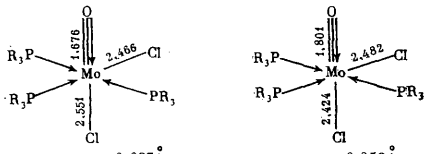
Table 2. Geometrical parameters of the MO(OR) (R = Me, Et, ReO_3) fragment in the Re(V) and Tc(V) d^2-complexes.

Compound	Bond lengths, Å		Refs
	O⇶M	M⇀OR_{trans}	
$ReO(OEt)Cl_2(PPh_3)_2$	1.73	1.89	[16, 17]
$ReO(OEt)I_2(PPh_3)_2$	1.715	1.880	[20]
$ReO(OMe)I_2(PPh_3)_2$	1.698	1.859	[20]
$ReO(OEt)Cl_2(Py)_2$	1.684	1.896	[21]
$TcO(OEt)Br_2(NPy)_2$	1.684	1.855	[22]
$ReO(OReO_3)I_2(PPh_3)_2$	1.670	2.031	[11]
$ReO(OReO_3)(OPPh_3)I_2(PPh_3)$	1.639	2.079	[11]

The following hypothesis may be put forward on the basis of the characteristic features of the stereochemistry of the complexes of d^0 and d^2 metals examined. Two opposite tendencies may be superimposed in the selection of the *trans*-partner and in the structural manifestation of the *trans*-influence in the case of oxo-complexes of a d^2 metal.



† The pentavalent technetium complex d^2-$[TcO(OEt)Br_2\cdot(NPy)_2]$ complex has a similar structure:[26] the Tc–O (OEt) bond in the *trans*-position relative to the Tc=O bond is shortened to 1.855 Å (the Tc=O bond length is 1.684 Å).

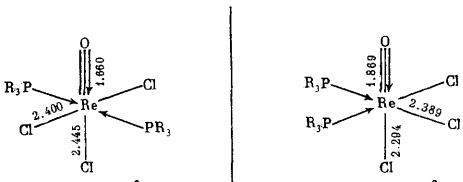
IV. The *trans*-influence isomerism in mixed halogeno-phosphine complexes of d^2 metals

In 1970, Butcher and Chatt[27] synthesised a series of diamagnetic mixed complexes of tetravalent molybdenum having the composition $MoOX_2(PR_3)_3$, where X is a halogen or a pseudo-halogen and PR_3 is a tertiary phosphine ligand. Depending on the individual characteristics of the ligand X and the nature of the substituents R, the two series of compounds obtained differed in colour. The series A complexes with X = NCO or NCS and PR_3 = $PPhMe_2$ or $PPhEt_2$ were blue, while the series B complexes with X = Cl, Br, or I and PR_3 = $PMePh_2$ or $PEtPh_2$ were green. As a rule, the stretching vibration frequency ν(Mo=O) in the series A complexes was higher by 5–10 cm^{-1} than in the series B complexes. Other characteristics, especially the ^1H NMR spectra[28] and the ^{95}Mo NMR spectra[29] of compounds of both series, were virtually indistinguishable. However, it was shown subsequently[30,31] that both the colour and the ν(Mo=O) frequency are not decisive parameters for the assignment of the compound to a particular series.

In two cases, for X = Cl and PR_3 = $PPhMe_2$ and for X = Cl and PR_3 = PMe_3, two isomers were obtained in each instance.[27] The isomers of the first of these compounds, $MoOCl_2(PPhMe_2)_3$, differed both in colour and in the μ(Mo=O) frequency [ν(MO=O) = 954 cm^{-1} for the blue isomer and 943 cm^{-1} for the green isomer]. The unstable green isomer was irreversibly converted into the stable blue isomer on heating in organic solvents. The authors[27] assumed that the different colours are due to the geometrical isomerism of the complexes: it was postulated that the *trans*-position relative to the oxo-oxygen atom is occupied by X in the series A complexes and by

PR_3 in the series B complexes. However, X-ray diffraction studies on the blue isomer of $MoOCl_2(PPhMe_2)_3$ (Va) [32] and on the unstable green isomer of $MoOCl_2(PPhEt_2)_3$ (Vb) [33,34] showed that they both have the *cis*-meridional geometry as regards to the disposition of the C atoms (one of the Cl atoms is in the *trans*-position relative to the oxo-oxygen atom).

However, the principal difference between the isomers consists in the unequal lengths of the bonds along the $O=Mo-Cl_{trans}$ coordinate: the multiple bond in the blue complex ($PR_3 = PPhMe_2$) is shorter than in the green complex ($PR_3 = PPhEt_2$) by 0.125 Å and instead of the *trans*-lengthening of the $Mo-Cl_{trans}$ bond in the blue complex, the bond undergoes *trans*-shortening in the green complex ($\Delta = +0.087$ and -0.058 Å respectively). The crystal structure of the green isomer $MoOCl_2(PPhMe_2)_3$ has been recently determined (at −160 °C [35]). As in the green $MoOCl_2(PPhEt_2)_3$, the Mo−O bond in this compound is greatly lengthened and its length is 1.80(2) Å. Other geometrical parameters of the complex are not quoted; only structural disorder, reducing the accuracy of the study, is noted.



Thus, in compounds of this class the isomerism of the multiple metal−ligand bond is manifested in the sharpest and most clear-cut form: a shortening and not a lengthening of the *trans*-bond corresponds to the second isomer. It is quite evident that the bond with the *trans*-partner also plays an active role in the given instance in the formation of the second isomer. The negative parameter Δ ("*trans*-fixation") can be most naturally accounted for by the replacement of the pure $M-L_{trans}$ σ-bond by a multiple bond with a significant contribution by the π-donor component $M \rightleftarrows L_{trans}$, which is consistent with the tendency of the complexes of d^2 metals towards a *trans*-disposition of their multiple bond-linked ligands. This variety of the multiple bond isomerism can therefore be conveniently designated as the isomerism of the mutual influence of the ligands or the isomerism of axial π-bonding.

Some workers refer to differences of this kind between the structures of the complexes as "distortion isomerism". This name appears inappropriate: it is too indefinite and can include effects of a completely different nature [for example, the distortion of the Cu(II) octahedra induced by the Jahn−Teller effect or the distortion of the octahedra of the d^{10} metals Ag(I), Hg(II), Ga(III), and Sn(IV) caused by the hypervalence of the equatorial bonds].

Henceforth we shall refer to complexes with a short $Mo \equiv O$ bond and a greatly weakened $Mo-L_{trans}$ bond as A-isomers and to complexes with a longer Mo=O bond and a shortened $Mo=L_{trans}$ bond as B-isomers.

The crystal structures of a further two compounds of the class considered were determined in 1987: $MoO(NCO)_2(PPhEt_2)_3$ and $MoOCl_2(PMePh_2)_3$.[30] Although the former has a blue colour and the latter is green, it was found that both are A-isomers: their Mo=O distances are virtually the same (1.684 and 1.667 Å respectively), while the opposite $Mo-L_{trans}$ bonds are as usual lengthened as a consequence of the *trans*-influence ($\Delta_{av} = +0.085$ and $+0.043$ Å respectively).

We observed the *trans*-influence isomerism also in compounds of another d^3 metal, namely rhenium(V).[19,31] A structural study of two $ReOCl_3(PPhEt_2)_2$ isomers, having different colours, showed that they differ not only in the Re=O and $Re-Cl_{trans}$ bond lengths but also in the relative disposition of the Cl and PR_3 ligands in the equatorial plane. The green form (VIa)[19] is a meridional (with respect to Cl atoms) *trans*-isomer and at the same time a mutual *trans*-influence A-isomer, while the blue form (VIb)[31] is a facial (with respect to Cl atoms) *cis*-isomer and at the same time a mutual *trans*-influence B-isomer.

The short Re=O bond is lengthened by 0.209 Å on passing from the first isomer to the second, while the $Re-Cl_{trans}$ bond is shortened by 0.151 Å ($\Delta = +0.045$ and -0.095 Å respectively). The equatorial $Re-Cl_{cis}$ bonds have similar lengths in both isomers (their average values are 2.400 and 2.389 Å).

A stronger $Re-Cl_{trans}$ bond in the blue isomer compared with the green isomer is consistent with their different behaviour in solution.[36] Refluxing of the green *trans*-$[ReOCl_3(PPhEt_2)_2]$ isomer in alcohol leads to the ready substitution of the chloride ion in the *trans*-position relative to the oxo-ligand and to the formation of the violet complex *trans*-$[ReO(OR)Cl_2(PPhEt_2)_2]$. On the other hand, refluxing of the blue *cis*-$[ReOCl_3(PPhEt_2)_2]$ in methanol even for several days does not lead to methanolysis—the strong $Re-Cl_{trans}$ bond is not ruptured and the chloride ion occupying the *trans*-position relative to the oxo-oxygen atom is not substituted by the OMe^- group. However, on heating to 160 °C in the crystalline state, the blue complex is irreversibly converted into the green complex (the *cis* → *trans* and B → A isomerisations take place simultaneously).

The authors[30] believe that the colour of the compounds of the class considered is determined by the basicity of the ligands X and PR_3: the blue complexes contain more basic ligands X and PR_3 ($X = NCS^-, NCO^-$, $PR_3 = PMe_3, PPhMe_2, PPhEt_2$), while the green complexes contain the less basic ligands ($X = Cl, Br, I$; $PR_3 = PMePh_2, PEtPh_2$). A combination of ligands of different basicity gives rise to the possibility of the coexistence of the blue and green isomers. This applies, in particular, to the combination X = Cl and $PR_3 = PPhMe_2$ or PMe_3.

The M−L bond lengths, the *trans*-influence parameters Δ, the differences between the M=O bond lengths in the two isomers $\Delta_{M=O}$, and the stretching vibration frequencies ν(M=O) for certain halogeno-phosphine complexes are listed in Table 3. It follows from these data that a complete correlation is not observed between the colour, the frequencies ν(M=O), and the parameter Δ. The colour and the frequencies ν(M−O) can be regarded as correlated for only two forms of the same compound: the higher and lower frequencies correspond respectively to the blue and green forms (the first two pairs in Table 3). On the other hand, if the complexes are different, then the absolute values of ν(M=O) even for compounds with similar compositions are not correlated with colour. In

Table 3. Geometrical parameters and vibration frequencies ν(M=O) of the *trans*-influence isomers of mixed halogeno-phosphine complexes of d^2 metals.

*$\Delta_{M=O}$ is the difference between the M=O bond lengths in the two isomers ["blue"−"green" for Re(V) and "green"−"blue" for Mo(IV)].

particular, ν(Mo=O) for the blue complex *cis*-$[MoO(NCO)_2.(PPhEt_2)_3]$ is located in the region characteristic of the green isomers of the mixed halogeno-phosphine complexes of molybdenum (IV).

The correlation between the colour and sign of Δ is still weaker. Not only the blue forms *cis*-$[MoOCl_2(PPhMe_2)_3]$ and *cis*-$[MoO(NCO)_2(PPhEt_2)_3]$ but also the green forms *cis*-$[MoOCl_2.(PPhMe_2)_3]$ and *trans*-$[ReOCl_3(PPhEt_2)_2]$ belong to type A (positive Δ), while type B (negative Δ) includes not only the green forms *cis*-$[MoOCl_2(PPhEt_2)_3]$ and *cis*-$(MoOCl_2(PPhMe_2)_3]$ but also the blue form *cis*-$[ReOCl_3(PPhEt_2)_2]$. In essence, the blue and green forms of the Re(V) complexes considered [and the ν(Re−O) frequency characteristics] change places: the green form with the lower ν(Re=O) frequency corresponds to the A-isomer and the blue form corresponds to the B-isomer.

The absence of a complete correlation between the length of the M=O double bond and its stretching vibration frequency, mentioned above, is somewhat unexpected. It shows that the ν(Mo=O) frequency is not characteristic: it clearly depends on fine nuances of the composition of the compound as a whole.

Furthermore, the type of the *trans*-influence isomer is determined not by the basicity of the entire set of ligands but by the basicity and capacity for π-donor interaction with the metal of the L_{trans} ligand: its relatively low donor capacity is due to the stability of the A-isomer and its tendency towards π-donation promotes the transition to the B-form. Chlorine satisfies both these requirements. Depending on the conditions, it can either virtually not participate or can significantly participate in π-donation to the metal.

Summarising the foregoing, we may note two factors. Firstly, the *trans*-influence isomerism is determined by the distribution of the σ- and π-interactions along the O=M−L_{trans} coordinate. Within the framework of the limiting canonical forms, the A-isomer can be written as O≡M−L_{trans}, while the B-isomer can be formulated as O=M≡L_{trans}. In essence, the O−M bonds in the compounds $[MoOCl_2(PPhEt_2)_3]$ (Vb) and *cis*-$[ReOCl_3(PPhEt_2)_2]$ (VIb) should be regarded as double bonds and not as triple bonds, while the M−Cl_{trans} bonds should be regarded as double bonds and not as single bonds, i.e. the axial π-bonding isomerism obtains.

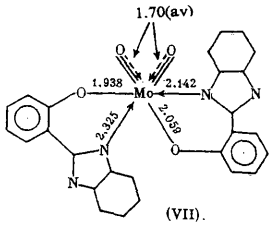
The above examples show that the chlorine atom can function also as the usual σ-acido-ligand and under certain conditions as a multiple bond-linked ligand (with a significant involvement in π-donation).

Secondly, the preferential formation of a particular *trans*-influence isomer (and the corresponding redistribution of electron density along the axial coordinate) depend under certain conditions not only on nuances in composition but also on the characteristic features of the disposition of the remaining ligands (Re complexes).

One cannot rule out the possibility that the transition from one isomer to another in the acido-phosphine anionic or cationic complexes, for example, $[Mo^{IV}OCl_3(PR_3)_2]^-$ or $[Re^{V}OCl_2(PR_3)_3]^+$, can be determined also by the nature of the outer-sphere ion or even by the presence or absence of the molecules of water of solvation, as in the case of the anionic Mo(IV) complexes $Kat_2[MoO(CN)_4.(H_2O)].nH_2O$ examined above.

V. Analysis of the disposition of the chelate organic ligands in oxo-complexes of d^0 and d^2 metals

We shall consider yet another important aspect of the choice of the *trans*-partner of the oxo-ligand in the complexes of d^0 and d^2 metals. This concerns the disposition in the oxo-complexes of anionic chelate ligands having acido- (X^-) and neutral-donor (A) coordinatively active atoms.



For d^0 metals, this problem has been solved unambiguously, fully in conformity with the principle of self-consistency. The *trans*-position relative to the multiple bond always contains the neutral-donor "end" of the chelate ligand A, whose lone electron pair "adjusts" readily to the requirements of the *trans*-active multiple bond-linked ligand. The structures of the molybdenum(VI) dioxo-complexes with hydroxamic acid anions containing different solvating molecules, i.e. $MoO_2L_2.A$, may serve as examples. Here HL = PhCoNHOH and A = MeCOEt,[38] $^2/_3$EtCOOH,[39] and Bu^nOH[40] or HL = HOC_6H_4CONH and A = $2H_2O$.[41] Their *trans*-positions relative to the oxo-ligands are occupied by the donor atoms of the

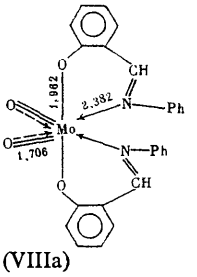
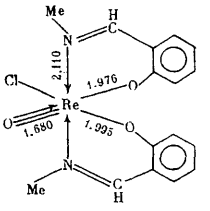
Notation: Sal = salicylideneaminate; Salen = ethylenebis- (salicylideneaminate).

ligand O(C), while the *cis*-positions are occupied by the acido-atoms O(N). In all these and other oxo-complexes of d^0 metals‡ the *trans*-lengthening is as a rule 0.15−0.30 Å. We are aware of only one example of the infringement of this general rule governing the orientation of the acido-donor chelate ligand in d^0 metal complexes. In the structure of [Mo^{VI}O$_2$L$_2^{(2)}$].2EtOH (VII),[44] where $L^{(2)}$ = 2-*o*-hydroxyphenylbenzimidazole, the two chelate *O, N*-ligands $L^{(2)}$ are coordinated to the metal in different ways.



Δ_O = + 0.121Å
Δ_N = + 0.183Å



(VII).

One of them is coordinated in the usual way—the neutral donor N atom is located in the *trans*-position relative to the multiple bond, while the other ligand is "rotated", as a result of which the acido-"end" of $L^{(2)}$, i.e. the O atom, is in the *trans*-position relative to the second oxo-oxygen atom. Both ligand−metal bonds, occupying *trans*-positions relative to the M=O bonds, are weakened under these conditions albeit to different extents. The quantity Δ is +0.183 Å for the Mo−N bond and +0.121 Å for the Mo−O bond. The reason for the rotation of one of the ligands $L^{(2)}$ is not evident. Possibly it is associated with the way in which the complex is obtained. One should also draw attention to the fact that the M−L_L bond in the first of the two ligands, occupying the third *cis*-position relative to both M=O bonds, is also significantly shortened (to 1.938 Å), i.e. is in essence also multiple. Therefore the preference for one orientation over another possible orientation is not all that important for the second chelate ligand: at any rate, the N_L atom is in the *trans*-position relative to the M=O or M⇄O_L multiple bond.

We may quote yet another example of the disposition of the chelate ligand typical for the oxo-complexes of d^0 metals. In the silicylideneanilinato-complex [MoO$_2$(Ph-Sal)$_2$] (VIIIa) which we investigated[43] both chelate ligands are oriented in accordance with the requirements for self-consistency: the *trans*-positions relative to the multiple bonds contain the donor "ends" of the chelates (the imine N atoms), while the *cis*-positions contain the acido-"ends" (the hydroxyl O atoms). The *trans*-lengthening Δ′ is on average 0.21 Å.

(VIIIa)

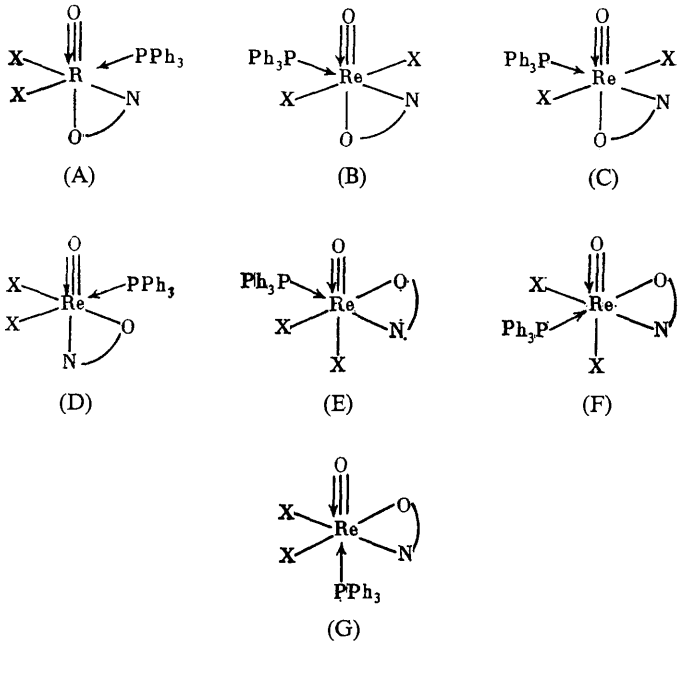
(VIIIb)

This example is especially interesting when compared with the isotypical complexes of d^2 metals [Re(V) and Tc(V)]:[ReOCl.(Me-Sal)$_2$] (VIIIb)[45] and [TcOCl(Ph-Sal)$_2$].[46] Comparison of these complexes makes it possible to reveal clearly the differences in the coordination of chelate monoionic ligands in d^0 and d^2 complexes. Firstly, the chelate ligand is "rotated": the acido-O atom of the ligand R-Sal moves to the *trans*-position relative to the multiple bond in the d^2 complexes. Secondly, the *trans*-lengthening in the complexes of d^0 metals is replaced in the case of d^2 metals by a

‡A complete compilation of the geometrical parameters of monomeric octahedral molybdenum complexes with chelate ligands and Mo−O and Mo−N bonds occupying *trans*-positions relative to Mo=O has been published.[42,43]

slight but clearly manifested *trans*-shortening of the M–O(Sal) bonds [in the given instance by 0.019 and 0.05 Å respectively in the Re(V) and Tc(V) complexes].

This result is not fortuitous, since the same feature is characteristic of a whole series of monomeric octahedral d^2-Re(V) complexes of a similar composition incorporating R-Sal ligands[47–49] (Table 4). In all these structures the *O, N*-chelate ligands are coordinated to the metal in a similar manner (the acido-O atom occupies the *trans*-position, while the donor N atom occupies the *cis*-position relative to O_{oxo}), i.e. a "rotation" is observed compared with the complexes of d^0 metals. In particular, out of the seven theoretically possible isomers of [ReOCl(PPh$_3$)(Me-Sal)] (Fig. 3), only two have been isolated in the crystalline state—the *cis*- and *trans*-isomers (A) and (B)—and in the structures of both an O (and not N) atom of the Me-Sal ligand is in the *trans*-position relative to the oxo-oxygen atom.[47] Exactly the same situation is obtained in the conformational isomers of *trans*-[ReOBr$_2$(PPh$_3$)(Ph-Sal)],[48,49] where the *trans*-position relative to the O (oxo) atom is occupied by the O (Ph-Sal) atom, while the N (Ph-Sal) atom is in the *trans*-position relative to the phosphine ligand.



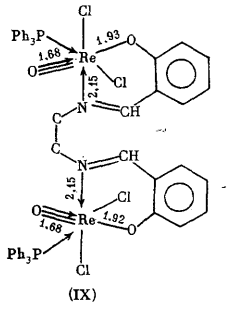


Figure 3. The theoretically possible geometrical isomers of the d^2-Re(V) complexes of the type ReOX$_2$(PPh$_3$)(R-Sal), where X = Cl or Br and R = Ph or Me.

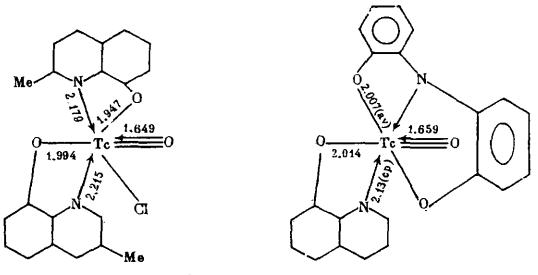
The reason for this is fairly evident. The oxygen atom linked directly to the benzene ring is a conductor of the π-interaction from the ring to the metal, while the nitrogen atom, separated from the unsaturated group by the CH_2 group is not such a conductor. Accordingly, the M–O(Sal) bond in the complexes of d^0 metals is located in the *cis*-position, while in the complexes d^2 metals it is in the *trans*-position relative to the M=O bond.

It is seen from Table 4 that the R–O (chelate) bond, *trans* to Re=O, is on average shorter by 0.03 Å in six complexes than the only Re–O (chelate) bond *cis* to Re=O in the compound [ReOCl.(M-Sal)$_2$];[47] at the same time, the length of these bonds is smaller by the same amount than the standard Re–OH distance, which is 2.00 Å[4] (Δ' = 0.032 Å) and smaller by ~0.07 Å than the sum of the covalent radii of rhenium and oxygen (2.04 Å according to Pauling).



The Re–O (Sal) bond, in the *trans*-position relative to Re=O in the dimeric d^2-Re(V) complex [ReOCl$_2$(PPh$_3$)]$_2$(μ-Salen).CHCl$_2$ (IX), is shortened even more drastically.[50]

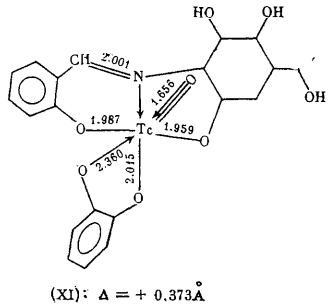
The length of this bond is on average 1.925 Å (Δ' = 0.075 Å). On the whole, the Re–O (Sal) distances (*trans* to Re-O) are in the range 1.925–1.976 Å (the mean is 1.963 Å) in the six d^2-Re(V) complexes containing salicylidene-aminato-ligands[45,47–50] and are on average somewhat shorter than the Re=O (Sal) distances (*trans* to Re–Cl) in the complexes *mer*-[Re^{IV}Cl$_3$(Ph-Sal)(PPhMe$_2$)] (1.970 Å)[51] and *cis*-[Re^{III}Cl$_2$(Ph-Sal)(PPhMe$_2$)$_2$] (1.990 Å).[52]

The same mode of coordination of the bidentate Ph-Sal with a similar shortening of the M–O (Sal) bond has been observed also in the pentavalent technetium compound TeOCl(Ph-Sal)$_2$:[46] the Tc–O (Sal) bond in the *trans*-position relative to Tc≡O (1.94 Å) is shorter by 0.5 Å than the analogous Tc–O (Sal) bond the second bidentate ligand.

In certain cases, the "rotation" of the ligand shifting the acido-centre to the *trans*-position relative to the multiple bond-linked ligand is not accompanied by a shortening of the M–L$_{trans}$ bond. This applies particularly to the complexes [ReOCl$_2$(PPh$_3$).{PhC(O)NNCMe$_2$}],[53] [TcOCl(ONC$_9$H$_5$Me)$_2$] (Xa),[54] and TcOL$^{(2)}$L$^{(3)}$ (Xb), where L$^{(2)}$ is the bidentate 8-hydroxyquinolinate ligand, while L$^{(3)}$ is the tridentate *N*-(2-oxidophenyl)salicylidenc-aminate ligand.[55]

In the first complex, the Re–O$_{trans}$ bond is 2.013 Å long, in the second complex (Xa) the Tc–O$_{trans}$ bond is 1.994 Å long (longer by 0.047 Å than the analogous Te–O$_{cis}$ bond of the second bidentate

ligand, while in the third complex (Xb) the $Tc-O_{trans}$ bond is 2.014 Å long (on average longer by 0.007 Å than both $Tc-O_{cis}$ bonds). However, in all three compounds the $M-O_{trans}$ distances do not exceed the standard length of the single bond in the hexacoordinate and heptacoordinate complexes (for example, the Tc–O bond length is 2.02 Å according to the data of Bandoli et al.[56]).



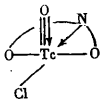
According to spectroscopic data (IR, ^{1}A NMR, and mass spectra), a further seven complexes having the general formula $Mo(L^{(3)})$ (R-Sal), where M = Tc or Re and R = H, Me, or Ph, have structures similar to those described above:[55] the phenolic (charged) oxygen atom of the bidentate salicylideneaminate ligand R-Sal is located in the *trans*-position relative to the O (oxo) atom.

Thus it follows from the foregoing that, in contrast to complexes of d^0 of metals, the *trans*-partner of the oxo-ligand in the d^2 complexes of Re(V) and Tc(V) is the acido-"end" (and not the neutral-donor "end") of the chelate ligand.

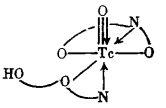
The authors of the original investigations[45–50, 53–55] apparently missed the importance of this result. To us there seems to be no doubt that it is a consequence of the simultaneous manifestation of the two tendencies described above—the set of σ-donor and π-dative properties of the ligand§. Therefore it is not to be expected that the analogous "rotation" of the chelate ligands in the complexes of d^2 metals will occur in all cases; everything depends on the possibility and degree of involvement of the acido-"end" of the chelate in bonding to the metal. Evidently the "rotation" should be a characteristic feature of unsaturated chelate systems. The degree of involvement of the chelate ligand's π-electrons in the formation of a bond with the metal can be inferred from the disposition of the chelate ligand in the oxo-complexes of d^2 metals and from the degree of shortening of the $M-O_L$ bond.

An example of a complex of a d^2 metal in which the *trans*-position relative to the M=O bond is occupied by the donor "end" of the chelate ligand may be provided by $TcOL^{(3)}L^{(2)}$, where $L^{(3)}$ is the dianion of *N*-salicylidine-D-glucosamine (Glusal) and $L^{(2)}$ is the monoanion of salicylaldehyde (Sla) (XI).[58]

In this compound, the carbonyl O atom of the Sla ligand is in the *trans*-position relative to the oxo-ligand, while the acidic phenolic O (Sla) atom occupies the *cis*-position relative to the Tc=O bond (in the *trans*-position relative to the N atom of the Glusal ligand).



(XI): Δ = + 0.373Å



§One should recall the hypothesis that *trans*-dioxo-complexes of d^2 metals are formed only in the presence of ligands L which are pure σ-donors (weak π-donors), for example, in the presence of tetraazocyclotetradecane—the structure *trans*-$[Tc^VO_2(L)](ClO_4).H_2O$.[57] According to the authors,[57] the *trans*-TcO_2^+ compounds cannot be formed in the presence of salicyclidene-aminate ligands.

The $Tc-O_{trans}$ = 2.360 Å bond is greatly lengthened compared with the $Tc-O_{cis}$ bonds (1.959–2.015 Å): Δ = +0.373 Å. However, this example cannot be regarded as characteristic, since the phenolic oxygen atom is in principle a good conductor of the π-interaction and one may expect that it will in fact occupy the *trans*-position relative to the Tc=O bond.

The most probable cause of the reorientation of the ligand $L^{(2)}$ is believed[58] to be the specific features of the initial reaction occurring under the conditions of kinetic control. The complex [TcO(Glusal)(Sla)] was obtained by the reaction of $TcOCl_4^-$ with a fivefold excess of $GlusalH_2$ in methanol. The presence of the chelating ligand Sla in the final product is not the result of the hydrolysis of the ligand $Glusal^{2-}$ before coordination, since the direct reaction of $TcOCl_4$, $GlusalH_2$, and SlaH, taken in the stoichiometric proportions of 1:1:1, does not lead to the formation of [TcO(Glusal)(Sla)]. Furthermore, the initial reaction proceeds readily only in methanol (and also in ethanol but with a low yield), whereas in acetone, tetrahydrofuran (THF), and dimethyl sulphoxide (Me_2SO) it does not occur. According to the authors, the role of the solvent is very great: THF, Me_2SO, and actone promote the rapid hydrolysis of $GlusalH_2$ with formation of SlaH and glucosamine, whereas in methanol the ligand $GlusalH_2$ is stable for a long time. The authors suggest that the initial reaction can take place in stages with the successive addition of two $GlusalH_2$ ligands and the formation of two intermediates: the square-pyramidal [TcOCl(Glusal)] (XIIa) with the tridentate (O,N,O)-ligand $Glusal^{2-}$ in the plane of the base of the pyramid and the octahedral [TcO(Glusal)(GlusalH)] (XIIb) in which the bidentate ligand $GlusalH^-$ is coordinated to the acidic phenolic O atom in the *cis*-position and to the neutral N (imine) atom in the *trans*-position relative to the oxo-ligand.

(XIIa)

(XIIb)

This mode of coordination facilitates the direct addition of the ligand Sla^-, formed on hydrolysis of $GlusalH^-$, via the carbonyl O atom, since the Tc–N (Glusal) bond is weakened to the greatest extent.

Thus one can postulate that in the given instance the thermodynamically less favourable mode of coordination of the ligand Sla to the metal is determined by the reaction conditions.

- - -o0o- - -

The data presented permit the conclusion that the problem of the relative disposition of the ligands in complexes containing multiple bond-linked ligands is far from being exhausted and that further studies may reveal many new and unexpected nuances both in the overall structure of the complexes and in the geometrical parameters characterising the mutual influence of the ligands. In particular, this concerns the complexes of d^2 metals whose structure is determined, judging from all the available data, by the combined effects of several opposed tendencies, including kinetic factors.

The mechanism of the dehydration of alcohols and the hydration of alkenes in acid solution

M I Vinnik, P A Obraztsov
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. Kinetic data for the hydration of unsaturated compounds, the dehydration of alcohols, and the isotope exchange of the oxygen atom in alcohols and aqueous solutions of strong acids are analysed to establish the detailed mechanisms of these reactions. The catalytic action of the acid is caused not only by its ability to protonate the reactant but also by the possibility of the formation of reactive complexes of the reactant with the acid hydrates or the molecules of the undissociated acids. Equations are presented whereby the influence of the ionising capacity of the medium on the effective rate constants for the reactions indicated can be taken into account quantitatively. The question of the involvement of carbonium ions as reactive intermediates in reactions involving the dehydration of alcohols, the hydration of unsaturated compounds, and the isotope exchange of the oxygen atom in alcohols is examined. Complexes of the reactant with a solvated proton, the acid molecules, and the acid hydrates are the intermediates in these reactions. The relative contributions of the complexes to the effective rate constant depend on the acid concentration in the aqueous solution.

I. Introduction

The study of the detailed mechanisms of the strong acid-catalysed reactions involving the hydration of unsaturated compounds (UC) and the dehydration of alcohols (ROH) in aqueous solutions is of interest for the development of a theory of acid catalysis and for the quantitative estimation of the influence of the structure of organic substances on their reactivity. Systematic studies on the kinetics and the detailed mechanisms of these reactions were initiated at the beginning of the 1940s. Certain data on this question are contained in a monograph (Ref. 1, p. 210) and a review.[2]

Judging from the kinetics, the dehydration of ROH and the hydration of UC in aqueous solutions are complex reactions. As a rule, the kinetic data were analysed previously from the concept that in aqueous solutions of strong acids a proton adds to the reactant base and that the protonated form is the intermediate reactive complex which can be formed either in the equilibrium stage or in the rate-limiting stage. This idea constitutes a gross simplification of the real picture of the complex interaction in solutions.

Many facts have now accumulated which make it possible to expand our knowledge about the nature of the ionising and catalytic action of acids.

Protonation is only one of the forms of ionisation in aqueous solutions of strong acids. Ionisation can entail the formation also of complexes of the base with the molecules of the undissociated acid and with the acid hydrates,[3] some of which may be reactive in the reactions investigated. It has been established that in aqueous solution, protons are present not as H_3O^+ ions but as $H_5O_2^+$ ions, which exist as a result of the formation of the strong hydrogen bond

(Ref.4)

Naturally, these ions are solvated by the solvent. Protonation in aqueous solution is a reaction involving the substitution of a water molecule in the $H_5O_2^+$ ion by the base B:

(1)

The protonated form BH_3O^+ is a complex of the base with the H_3O^+ ion, which also exists by virtue of the presence of a strong hydrogen bond.[5] The reaction products can be formed simultaneously via several pathways.

It is of interest to analyse the available literature kinetic data on the hydration of UC and the dehydration of ROH taking into account the ideas described above concerning the ionising capacity and catalytic activity of strong acids in aqueous solutions. This paper is in fact devoted to this problem. Valuable information about the detailed mechanisms of these reactions can be obtained from experimental data for the isotope exchange of the oxygen atom of the OH group in alcohols and the racemisation of optically active alcohols in acid media and also by measuring the isotope effects on replacement of a hydrogen atom by deuterium. These questions are examined in this review for this reason.

II. Kinetics of the hydration of alkenes and the dehydration of alcohols on the basis of the carbonium ion concept

Kinetic measurements are usually made using low concentrations of the UC and the ROH which do not affect the catalytic properties of the solution. In this case the UC hydration and the ROH dehydration reactions at constant acid concentration are first order relative to the concentration of the organic reactant. As a rule, these reactions are reversible:

$$R'-CH=CH_2+H_2O \underset{k_{dehydr}}{\overset{k_{hydr}}{\rightleftarrows}} R'-\underset{OH}{\underset{|}{CH}}-CH_3$$

and

$$-dc_{UC}/dt = dc_{ROH}/dt = k_{hydr}\,c_{UC} - k_{dehydr}\,c_{ROH}, \quad (2)$$

where k_{hydr} includes also a function characterising the concentration of water in solution.

Interpretation of the results of kinetic measurements carried out in a medium with a constant acid concentration yields the rate constant $k_{sum} = k_{hydr} + k_{dehydr}$. The equilibrium concentrations of the UC and of the alcohol obtained (c^{∞}_{UC} and c^{∞}_{ROH}) are measured for the separate determination of k_{hydr} and k_{dehydr}. According to Eqn. (2),

$$c^{\infty}_{ROH}/c^{\infty}_{UC} = k_{hydr}/k_{dehydr}.$$

It is noteworthy that most of the kinetic studies on the UC hydration and the ROH dehydration reactions have been carried using aqueous solutions of strong acids—sulphuric, perchloric, and nitric. The acidity functions H_0 and also the thermodynamic activities of the acid and water at 25 °C are known for such solutions. For sulphuric acid solutions, these quantities have been measured also at other temperatures.

An increase in the concentration of the strong acid in moderately concentrated and concentrated aqueous solutions leads to a sharp increase in k_{hydr} and k_{dehydr}. As a rule, a linear relation is observed between lg k_{hydr} and H_0:

$$\lg k_{hydr} + \alpha' H_0 = \text{const}. \quad (3)$$

The quantity α' is sometimes close to unity but in the vast majority of cases $\alpha' > 1$ and is in the range 1.1–1.4. The linear relation between lg k_{hydr} and H_0 can be explained by the formation of the protonated form of the alkene, which is regarded as the intermediate complex in the hydration of the UC. According to Whitmore,[6] this ion includes a positively charged carbon atom with six electrons:

$$R-CH=CH_2+H^+ \rightleftarrows R-\overset{+}{C}H-CH_3.$$

The Whitmore carbonium ion is a σ-complex.

The earlier studies on the kinetics and mechanism of the hydration of UC and the dehydration of ROH were devoted to the detection of the existence in acid solutions of Whitmore carbonium ions as intermediate reactive species. According to Whitmore, one of the ways of obtaining such carbonium ions involves the addition of a proton to the double bond of the UC. It is suggested that this reaction is reversible. It is also assumed that the reactions involving the elimination of an alkene from alkyl halides and alcohols are unimolecular and proceed via the same mechanism (Ref. 7, p. 540). In the case of alkyl halides, the reactant dissociates in the slow step into the carbonium ion and the anion X^-:

$$R_2CH-CR_2X \rightarrow R_2CH-\overset{+}{C}R_2 + X^-.$$

The step in which the carbonium ion decomposes into an alkene and a proton is rapid:[7]

$$R_2CH-\overset{+}{C}R_2 \rightleftarrows R_2C=CR_2 + H^+.$$

According to Whitmore,[6] as a result of the protonation of the ROH in the formation of an alkene from an alcohol in an acid a stable oxo-compound (the protonated form of the alcohol) is formed initially and then decomposes in the slow step into a carbonium ion and water:

$$CH_3CH_2OH + H^+ \overset{\text{fast}}{\rightleftarrows} CH_3-CH_2\overset{+}{O}H_2,$$

$$CH_3-CH_2OH_2^+ \overset{\text{slow}}{\rightleftarrows} CH_3-\overset{+}{C}H_2 + H_2O,$$

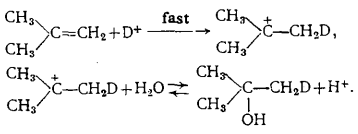
$$CH_3-CH_2^+ \overset{\text{fast}}{\rightleftarrows} CH_2=CH_2 + H^+.$$

As in the majority of the available publications, H^+ for simplicity is a solvated proton with solvation shell of indefinite composition and ROH_2^+ denotes the protonated form of the alcohol.

If the mechanisms of the formation of carbonium ions presented above do indeed occur and the ions have the properties attributed to them, then the following features due to the high reactivity of carbonium ions and their rapid equilibration with the UC in an acid medium should be manifested.

1. The hydration should be accompanied by the still more rapid isomerisation of one UC to another, provided that the same carbonium ion is formed on protonation.

2. In the presence of deuterium or tritium oxides in the medium, isotope exchange of the hydrogen atoms attached to the carbon atoms of the double bond of the UC should be observed. This exchange should precede the rate-limiting step of the hydration of the UC.



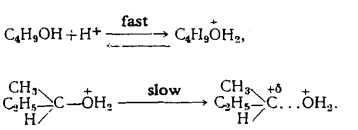
In order to observe the postulated effects, mainly aliphatic alcohols and the UC obtained from them have been used. As early as 1940, a study was published[8] from which it followed that, even if the Whitmore ions are formed, they are incapable of exchanging a hydrogen atom at the carbon atoms of the double bond: the dimer obtained on dimerisation of anethole in a solution of DCl in methanol contained no more deuterium than the initial monomer. Unfortunately, at the time this result did not receive due attention.

The study of the hydration in 0.973 M HNO_3 solution in water at 25 °C of the two isomeric alkenes 2-methylbut-2-ene and 2-methylbut-1-ene, from which the same carbonium ion should be formed on protonation, i.e.

$$\left.\begin{array}{l} H_3C-\underset{CH_3}{\underset{|}{C}}=CH-CH_3 + H^+ \\ H_2C=\underset{CH_3}{\underset{|}{C}}-CH_2-CH_3 + H^+ \end{array}\right\} \rightarrow CH_3-\overset{CH_3}{\overset{|}{\overset{+}{C}}}-CH_2-CH_3,$$

showed[9] that at 50% conversion of the UC into an alcohol there is no appreciable isomerisation of the initial alkene. The hydration of these alkenes results in the formation of only one product—t-pentyl alcohol. Consequently, on dissolution of the alkene in an acid, there is no rapid and reversible addition of the proton to the alkene with the subsequent interaction of the ion formed with a water molecule in the rate-limiting step. The exchange for deuterium of the hydrogen atoms attached to the carbon atoms of the double bond was not observed[10–12] in solutions of alkenes and alcohols in acids. Thus the alkene isolated from the reaction mixture after the fiftieth conversion of 2-methylbut-2-ene into an alcohol in 1 M HNO_3 solution in deuteriated water (50% deuterium) did not contain measurable amounts of deuterium.[10] In the alcohol obtained on hydration of isobutene to D_2SO_4, there is only one C–D bond.[11]

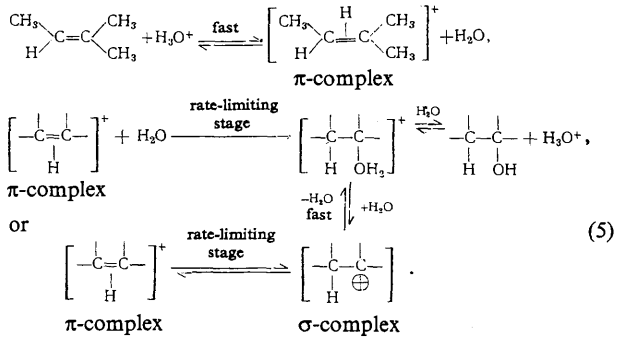
This result was subsequently confirmed experimentally[12] in the hydration of isobutene in deuterium-containing perchloric acid. Indeed, if the "classical" carbonium ion is formed and is not in equilibrium with the alkene, then the t-butyl alcohol obtained on hydration of isobutene in the deuteriated acid will contain only one C–D bond:



The measurements were performed under conditions where the contribution of the alcohol dehydration reaction to the overall rate of reaction can be neglected. As a rule, the equilibrium hydration of the UC is displaced towards the alcohol and $k_{dehydr} \ll k_{hydr}$. It has also been shown[11] that, on formation of an alkyl sulphate from ethylene, the hydrogen atom does not undergo isotope exchange.

The exchange of a hydrogen atom for deuterium, expected in the presence of Whitmore carbonium ions (σ-complexes), was also not observed in the experiments with arylalkenes. Thus the interaction of 2-phenylpropene has been investigated[13] in ethanol in the presence of a 17% D_2SO_4 solution. After the attainment of 24% and 54% conversions, the deuterium content in the unreacted UC in the five positions of the hydrogen atoms not incorporated in the aromatic ring was only 0 ± 2% in the former case and 10 ± 5% in the latter case. In the same study, it was shown by NMR that, in the formation of the ethyl ether derived from *cis*-2-phenylbut-2-ene (11% D_2SO_4 in C_2H_5OD), the unreacted 2-phenylbut-2-ene contains no hydrogen atoms.

For 15% conversion of styrene-ββ-d_2 to the carbinol in 43.4% $HClO_4$ solution, the unreacted styrene-ββ-d_2 contained no additional D atoms.[13] This fact shows that the exchange of hydrogen atoms cannot precede the rate-limiting step of the hydration reaction and even if a Whitmore carbonium ion is formed it is not in equilibrium with the UC. It is noteworthy that the formation of such carbonium ions is believed to be a thermochemically unfavourable reaction.[14] The results described led investigators to revise the principle postulates of the carbonium ion concept.



It is believed[15,16] that the intermediate reactive species in the exchange reaction of the oxygen atom in s-butyl alcohol is not a Whitmore carbonium ion but a carbonium ion linked to a water molecule; it is formed from the protonated alcohol in the slow stage and is converted into the product in the rapid stage:

(4)

Such an ion does not exchange the hydrogen atom of the C–H bond for either deuterium or tritium.

It has been suggested[17] that the carbonium ion has the structure of the π-complex proposed by Dewar in which the bond between the proton and the UC is formed via the π-orbitals of the double bond.[18] This proton is not equivalent to the protons attached to the carbon atoms of the double bond. It has been postulated that the π-complex is in equilibrium with the UC and that the concentration of such complexes determines the rate of the limiting step of the hydration of the UC. The proposed equilibrium and rate-limiting steps of the hydration of 2-methylbut-2-ene are described by the equations

(5)

The conclusion that there is an equilibrium between the UC and the π-complex was reached from results of experiments on the hydration of 2-methylbut-2-ene in 0.973 M HNO_3 at 30 °C in a mixture of D_2O and H_2O with different ratios $n = c_{D_2O}/(c_{D_2O} + c_{H_2O})$.[17] An increase in n altered the effective hydration rate constant in the mixed solvent k^n_{hydr}. The observed effect was described quantitatively on the following assumptions: the protonated form of the UC, produced in the equilibrium step, is the reactive form in its hydration; the observed reaction rate is the sum of the rate of hydration via pathways involving the participation of the solvated proton and deuteron; the specific rate constants for these pathways can be measured by employing solutions with $n = 0$ and $n = 1$ respectively; the activity of the protons and deuterons for different n can be calculated from literature data.[19]

It was shown subsequently[12,20] that, in order to describe the dependence of the observed hydration rate constant on n, it is necessary to take into account not only the ratio of the concentrations of protons and deuterons but also the differences between the isotope enrichments of the solvent and the C–H bonds of the alcohol formed on hydration of the UC. According to Scheme (5), the π-complex is obtained from the UC in the rapid and equilibrium stages, while the rate-limiting step of the hydration reaction can be both bimolecular and unimolecular. In the former case, the π-complex reacts with H_2O to produce the protonated form of ROH. In the unimolecular rate-limiting step, the π-complex is converted into a σ-complex, which is subsequently rapidly converted into the protonated alcohol. In the reverse alcohol dehydration reaction, the π-complex should be converted in the rapid and equilibrium step into the σ-complex which is formed according to the mechanisms presented above, on protonation of ROH and then splits off water.

We believe that Scheme (5) can operate only in rare cases, because, in conformity with this Scheme, it has been assumed that the ionisation of ROH and UC reduces solely to the protonation reaction and because the hypothesis of the formation of a π-complex from the UC in the rapid and equilibrium stages is controversial.

As experimental data on the UC hydration and ROH dehydration reactions accumulated, the view according to which the transfer of a proton to the UC in the hydration reaction takes place in the rate-limiting step became increasingly firmly established. Such transfer is indicated by the catalytic acceleration of the hydration reaction by weak acids. For example, the hydration of *p*-methoxy-α-methylstyrene,[21,22] cyanoketen dimethylacetal,[23] and 2-dichloromethylene-1,3-dioxolan[24] is catalysed by carboxylic acids and buffer mixtures. A similar phenomenon has also been observed for other UC.[25,26] It has been suggested that, in catalysis by undissociated molecules of weak acids, the proton is transferred in the rate-limiting step.

The reaction rate constant k and the acid dissociation constant K_{dis} are related by the Brønsted equation

$$k/p = (qK_{dis}/p)^{\alpha},$$

where p and q are statistical corrections and α is a coefficient to which the significance of a measure of the degree of proton transfer in the transition state has been attributed (Ref. 27, p. 345). If $\alpha = 1$, it is assumed that the proton transfer takes place in the equilibrium step. The Brønsted equation has also been used to obtain information about the degree of proton transfer in the rate-limiting step of the hydration of the UC in catalysis by strong acids. For this purpose, measurements were made of the dependence of the rate constant k_{hydr} on n, i.e. on the mole fraction of D_2O in a mixed solvent consisting of D_2O and H_2O or the mole fraction of T_2O and H_2O.[12,23,24] It was found that the dependence of lg k_{hydr} on n for reactions with proton transfer in the equilibrium and rate-limiting steps is described by identical formulae. It is logical to postulate that in the catalysis of the hydration of UC by strong acids in aqueous solutions proton transfer to the UC can also be achieved in the rate-limiting step.

Attempts have also been made on the basis of such ideas to calculate the lifetime of the carbonium ions (carbocations). For example, it has been shown[28] that the lifetime of the carbocations formed from 2,3-dimethylbut-2-ene in dilute aqueous acid solutions ($HClO_4$, H_3PO_4, HSO_4^-) at 25 °C is $\sim 10^{-10}$ s.

The proton transferring agents can be ion pairs, solvated protons, and the molecules of the undissociated acid. This does not naturally rule out the possibility of proton transfer to the UC in the rapid and equilibrium steps.

As already mentioned above, in catalysis by strong acids lg k_{hydr} frequently varies more markedly than H_0. This fact and also the correlation between lg k_{hydr} and the σ^+ constants of the substituents have been explained by proton transfer to the reactant in the rate-limiting step.[13]

In order to test the concept of "classical" carbonium ions, the kinetics of the exchange of ^{16}O for ^{18}O in alcohols have been studied. The results of measurements under identical conditions of the rate constants for such exchange (k_{exch}) and the dehydration of ROH cannot be explained on the assumption that the "classical" carbonium ion is the intermediate reactive species in these reactions. As already mentioned above, it has been suggested[15,16] that the carbonium ion incorporates a water molecule. In the view of the above workers, the exchange of the oxygen atom in the alcohol takes place in the rapid step and the unimolecular step involving the formation of this ion is rate-limiting, as shown in Scheme (4). In the study of the kinetics and mechanism of the exchange of the oxygen atom in alcohols, measurements have been made as a rule also of the rate constant for the dehydration of ROH in order to be certain that the exchange does not occur as a consequence of the reversibility of the ROH dehydration and UC hydration reactions. As a result, a bimolecular mechanism has been proposed for the exchange of the oxygen atom in alcohols.

It has been found[15] that under identical conditions k_{dehydr} for s-butyl alcohol is much smaller than k_{exch}. Subsequent studies demonstrated that this rule holds also in the majority of other cases, but there are exceptions. However, in elucidating the causes of these deviations, additional confirmation of the validity of the bimolecular exchange mechanism was obtained.

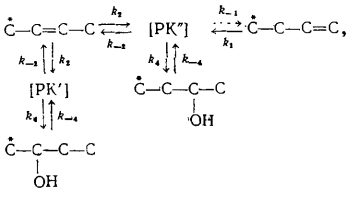
Comparison of the rate constants for the exchange involving t-butyl alcohol in ^{18}O-enriched sulphuric acid with the rate of dehydration of the alcohol in the unlabelled acid showed that at 55 °C in 0.045 and 0.45 M H_2SO_4 solutions, the constant k_{exch} is greater than k_{dehydr} by factors of 30 and 27 respectively.[29] At 75 °C in 0.045 M H_2SO_4 solution, $k_{exch}/k_{dehydr} = 20.7$. The alcohol concentration in the experiments was 1.04 M. The constant k_{exch} was greater than k_{dehydr} also in the case of t-pentyl alcohol:[30] at 25 °C, $k_{exch} = 7.72 \times 10^{-4}$ min^{-1} in 0.96 M H_2SO_4 solution, while $k_{dehydr} = 1.59 \times 10^{-4}$ min^{-1} in 1.5 M H_2SO_4 solution. The ROH concentration was 0.5 M in these experiments.

Comparison of the constants k_{exch} and k_{dehydr} for n-butyl and neopentyl alcohols proved to be more complex because the alkenes formed from them at 125 °C in 0.5 M sulphuric acid solution undergo further reactions.[31] The products of the reaction of n-butyl alcohol are s-butyl alcohol, di-n-butyl ether and a mixture of butenes. t-Pentyl alcohol and a mixture of pentenes are formed from neopentyl alcohol. The rate of the decomposition reaction was determined from the decrease in the concentration of the initial alcohol. Table 1 presents the measured[31] k_{exch} and the decomposition rate constants k_{decomp} for n-butyl and neopentyl alcohols.

Table 1. The constants k_{exch} and k_{decomp} for n-butyl (0.729 M) and neopentyl (0.242 M) alcohols at 125 °C (according to the data of Dostrovsky and Klein[31]).

Alcohol	$[H_2SO_4]$, M	$10^2 k_{exch}$, min^{-1}	$10^2 k_{decomp}$, min^{-1}
n-Butyl	0.46	33.6	9.84
Neopentyl	0.48	0.84	30.6

There are good grounds for the assumption that the primary products of the decomposition of n-butyl and t-pentyl alcohols are alkenes whose hydration entails the formation of s- and t-butyl alcohols. One can therefore assume that $k_{decomp} = k_{dehydr}$. According to the data in Table 1, $k_{exch} > k_{dehydr}$ for n-butyl alcohol. On the other hand, $k_{exch} < k_{dehydr}$ for neopentyl alcohol. Thus n-butyl alcohol is more reactive in the exchange reaction than neopentyl alcohol. The experimental data for the exchange of the oxygen atom in ROH[15,29,30] show that the exchange and dehydration proceed via different mechanisms. The same conclusion follows from the results of a study[31] where it was shown that but-1-ene and but-2-ene are formed from n-butyl alcohol in an acid medium, but the product of the hydration of both alkenes is s-butyl alcohol. The formation of the latter from but-1-ene has been demonstrated by experiments on the hydration of [^{14}C]-but-1-ene under conditions similar to those used in the study of the exchange of the ^{16}O atom. s-Butyl and n-butyl alcohols have been obtained from [^{14}C]-but-1-ene, but the content of n-butyl alcohol in the hydration products was only 0.001. Consequently the exchange of ^{16}O in n-butyl alcohol is not a consequence of the dehydration of the latter with subsequent hydration of but-1-ene. It was therefore concluded[31] that the exchange of the oxygen atom in n-butyl alcohol proceeds exclusively via a bimolecular mechanism:



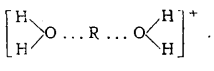
$$H_2{}^{18}O + CH_3(CH_2)_2CH_2OH \rightleftarrows H_2O + CH_3(CH_2)_2{}^{18}OH.$$

It follows from Table 1 that under identical conditions k_{exch} is greater for n-butyl alcohol than for neopentyl alcohol. This can be explained by steric hindrance in the bimolecular exchange mechanism involving neopentyl alcohol.

Fundamental conclusions concerning the mechanisms of the dehydration of ROH, the hydration of UC, and the exchange of the oxygen atom in alcohols have been reached by Manassen and Klein.[32] They investigated the reactions of but-1-ene and s-butyl alcohol in 0.555 M $HClO_4$ solutions at 101.4 °C.

1) $CH_3CH_2CH=CH_2 + H_2O \rightleftarrows CH_3CH_2CH(OH)CH_3$,
2) $CH_3CH_2CH=CH_2 \rightleftarrows CH_3CH=CHCH_3$,
3) $CH_3CH_2CH(OH)CH_3 \rightleftarrows CH_3CH=CHCH_3 + H_2O$,
4) $CH_3CH_2CH(^{18}OH)CH_3 + H_2{}^{16}O \rightleftarrows CH_3CH_2CH(^{16}OH)CH_3 + H_2{}^{18}O$.

Overall, the reactions investigated can be represented by the following Scheme:



where [PK′] and [PK″] are reactive complexes.

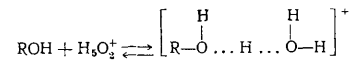
Analysis showed that

$$k_{isom} = k_{-1}k_2/(k_2 + k_4),$$

where k_{isom} is the isomerisation rate constant.

Using 2-butanol labelled with ^{18}O and ^{14}C, it was possible to investigate under the same conditions the exchange of the oxygen atom of the alcohol with water and the isomerisation of the alcohol. It was found that $k_{isom} = (3.102 \pm 0.072) \times 10^{-4}$ min^{-1} and $k_{exch} = (4.490 \pm 0.093) \times 10^{-4}$ min^{-1}. The authors[32] believe that the data for all four reactions investigated can be best described by assuming that the intermediate is a planar carbonium ion linked to a water molecule on either side of the plane; the central carbon atom is thus "pentavalent". The intermediate in the reaction involving the exchange of the oxygen atom in ROH has in their view the composition

This composition of the intermediate was also adopted in subsequent studies (see, for example, McClellend[33]).



The ideas about the equilibrium and rate-limiting steps in the dehydration of ROH, the hydration of UC, and the exchange of the oxygen atom in alcohols described above do not permit a quantitative description of the effect of the ionising capacity of the aqueous acid solution on the experimental (effective) rate constants for these reactions. This situation can be accounted for by the fact that, in the analysis of kinetic data obtained in solutions at a variable concentration of the acid catalyst, no account is taken of the fact that (1) the protonated form of the reactant B is the complex BH_3O^+ [see Eqn. (1)], (2) the intermediates are not only such ions but also complexes of the reactant-base with acid molecules, acid hydrates, etc., and (3) when the concentration of the acid in solution is varied within wide limits the hydration and dehydration reactions can proceed via several pathways, i.e. all the ions and molecules capable of forming a reactive complex with the reactants can exhibit a reactivity. The relative contribution of each pathway to the effective rate constant depends on the acid concentration.

An attempt is made below to explain certain literature data taking into acocunt the mechanism proposed for the ionisation of acids.

III. A method for the determination of the mechanism of the dehydration of alcohols and the hydration of unsaturated compounds from kinetic data

The modern physical methods do not permit the determination of the concentration and composition of the intermediate reactive complexes RC in the course of a kinetic experiment on the hydration of UC and the dehydration of ROH. Conclusions concerning the composition of RC and the influence of the medium on their concentration have been made on the basis of the dependence of k_{hydr} and k_{dehydr} on the ionising properties of the medium. The mechanism of the ionisation of alcohols in acid media has not so far been studied in detail and there are no reliable data for the basicity constants of aliphatic alcohols. However, there is no doubt that the ionisation of alcohols can lead to the formation of protonated forms, ion pairs, and complexes with components of the solution (for example, with the acid molecules HA).

According to Vinnik et al.,[5] the formation reaction of the protonated form of the alcohol ($ROH.H_3O^+$) can be described by the equation

The hypothesis of the formation of the ion pair $ROH.H_3O^+.A^-$ and the complexes ROH.HA has been justified by experimental data for the ionisation of tertiary amines, azulene and its derivatives,[3] and also indole derivatives[34] in moderately concentrated and concentrated aqueous solutions of strong acids. It follows from the literature data described above that hitherto there have been no clear-cut ideas about the structure and properties of the ionised form of the alkene in aqueous acid solutions. The function which would make it possible to take into account the influence of the acidity of the medium on the degree of conversion of the UC into the ionised form is also unknown. The ionised form can be produced either in the equilibrium or in the rate-limiting states. Unfortunately, most investigators assume that in aqueous solutions of strong acids the ionisation of bases reduces solely to their protonation and in cases where it is not possible to describe the experimental data they assume that the ratio of the activity coefficients of the unionised and protonated forms of the test base and of the Hammett indicators depends on the acid concentration in different ways.

There have also been attempts to select correlation equations for the description of such reactions. It has been suggested that the ionisation of each base is described by its own acidity function.[35–37] For example, we may designate such a function for the UC by H_s. The function H_0 measured by means of indicators and the function H_s are linked by the equation

$$H_s + \lg c_{H^+} = (1 - \Phi_c)[H_0 + \lg c_{H^+}], \quad (6)$$

which has been obtained on the assumption that

$$\lg f_{H^+} - \lg \frac{f_{SH^+}}{f_S} = (1 - \Phi_c)\left[\lg f_{H^+} - \lg \frac{f_{BH^+}}{f_B}\right],$$

where f are the concentration activity coefficients of the corresponding species, c_{H^+} is the concentration of solvated protons, and Φ_c is a coefficient independent of the H_0 for the medium according to its significance.

If the reactive species is a protonated form of the UC produced in the equilibrium stage and converted into the reaction products in the

rate-limiting stages, then, provided that the degree of protonation of the UC is low, we obtain according to Lucchini et al.[35]

$$\lg k_{hydr} + H_0 = \lg k_0 + (\Phi_{RC} - \Phi_c)[H_0 + \lg c_{H^+}],$$

where k_0 is a constant and Φ_{RC} is a coefficient corresponding to Φ_c when the base is RC.

On the other hand, if the proton adds to the UC in the slow stage, i.e.

$$UC + H_5O_2^+ \xrightarrow{slow} RC \rightarrow \text{products},$$

then

$$\lg k_{hydr} + H_0 = \lg k_0 + \Phi_{RC}[H_0 + \lg c_{H^+}].$$

When this method of analysis of kinetic data is used, one cannot naturally obtain information about the specific reaction mechanism, the composition of the RC, and about the equilibrium and rate-limiting stages.

If the rate-limiting stage is the formation of the protonated form, then it is believed[38,39] that the rate of protonation of bases can be characterised by means of the kinetic activity function H_c^*. An attempt has been made to apply this function in the analysis of data for the kinetics of the hydration of styrene and its derivatives.[40]

It is important to note that the attempts to explain the kinetics of the UC hydration and ROH dehydration reactions solely on the basis of the concept of carbonium ions as intermediate reactive species simplified the real mechanism of these reactions because no account was then taken of the catalytic action of other ions, neutral species, and ion pairs in the aqueous solution of strong acids.

As can be seen from Eqn. (2), k_{hydr} and k_{dehydr} are effective overall constants. In order to elucidate their physical significance, it is essential to establish how they depend on the ionising capacity of the acid solutions a_δ. The ionisation reaction of UC and alcohols can be described with the aid of the equations

$$UC + \delta \overset{K_i^{UC}}{\rightleftarrows} UC.\delta,$$

$$ROH + \delta \overset{K_i^{ROH}}{\rightleftarrows} ROH \cdot \delta,$$

where K_i^{UC} and K_i^{ROH} are the ionisation equilibrium constants. Ions or molecules whose addition converts the reactant into the ionised form are designated by

$$K_i^{UC} = \frac{a_{UC}a_S}{a_{UC.\delta}} = \frac{c_{UC}}{c_{UC.\delta}} a_\delta \frac{f_{UC}}{f_{UC.\delta}},$$

$$K_i^{ROH} = \frac{a_{ROH}a_\delta}{a_{ROH\cdot\delta}} = \frac{c_{ROH}}{c_{ROH\cdot\delta}} a_\delta \frac{f_{RCH}}{f_{ROH\cdot\delta}}.$$

In many reactions in acid solutions, the intermediate RC is either the ionised form of the reactant or its complex with the molecules and ions from the solution. Equations designed to take into account the influence of the medium on the rates w and the hydration and dehydration rate constants, derived on the assumption that the catalytic action of the acid is due to the conversion of the reactant into the ionised form, which is either itself the RC or is capable of forming such RC rapidly and reversibly on interaction with species from the solution, are presented below. If the RC in the dehydration reaction has the composition ROH.δ, then

$$w_{dehydr} = k\frac{a^*}{f^*} = k\frac{a_{RC}}{f^*} = \frac{k_{true}}{K_i^{ROH}}\frac{a_{ROH}a_\delta}{f^*} = \frac{k_{true}}{K_i^{ROH}} c_{ROH}a_\delta \frac{f_{ROH}}{f^*},$$

$$\frac{w_{dehydr}}{c_{ROH}} = \frac{k_{true}}{K_i^{ROH}} a_\delta \frac{f_{ROH}}{f^*} = k_{dehydr}, \qquad (7)$$

where k_{true} is the true rate constant independent of the acid concentration in the aqueous solution, a^* and f^* are respectively the activity and the activity coefficient of the activated complex, and a_{RC} is the activity of the RC expressed in terms of the activity of the unionised alcohol ROH and the species δ.

Since the UC hydration and ROH dehydration reactions proceed via the same RC, in its formation from the UC a water molecule should add to the ionised form UC.δ:

$$UC.\delta + H_2O \overset{K_{RC}^{UC}}{\rightleftarrows} RC,$$

$$K_{RC}^{UC} = a_{UC.\delta}\, a_{H_2O}/a_{RC}. \qquad (8)$$

Then

$$w_{hydr} = k\frac{a^*}{f^*} = k\frac{a_{RC}}{f^*} = \frac{k_{true}}{K_{RC}^{UC}}\frac{a_{UC.\delta}a_{H_2O}}{f^*} =$$

$$= \frac{k_{true}}{K_{RC}^{UC}}\frac{a_{UC}a_\delta a_{H_2O}}{K_i^{UC}f^*} = \frac{k_{true}c_{UC}a_{H_2O}f_{UC}a_\delta}{K_{RC}^{UC}K_i^{UC}f^*}, \qquad (9)$$

$$\frac{w_{hydr}}{c_{UC}} = \frac{k_{true}}{K_{RC}^{UC}K_i^{UC}} a_{H_2O}a_\delta \frac{f_{UC}}{f^*} = k_{hydr}.$$

In Eqns. (7) and (9), w_{dehydr} and w_{hydr} are the rates of dehydration of ROH and hydration of UC in an aqueous solution with a specified acid concentration. These equations were obtained subject to the condition that the degree of conversion of ROH and UC into the ionised form is low. In Eqns. (7) and (9), δ denotes the following species:

(1) the H_3O^+ ions participating in the protonation of the base, whereupon $a_\delta = h_0$,

(2) the $H_5O_2^+$ ions participating in the formation of the RC in accordance with the equation

$$ROH + H_5O_2^+ \rightleftarrows ROH\cdot H_5O_2^+; \qquad (10)$$

whereupon $a_\delta = a_{H_5O_2^+} = h_0 a_{H_2O}$, since one can assume that $h_0 = a_{H_3O^+}$,[5]

(3) the ion pairs $H_3O^+.A^-$ participating in the formation of the complex in accordance with the equation

$$ROH + H_3C^+\cdot A^- \rightleftarrows ROH\cdot H_3O^+\cdot A^-; \qquad (11)$$

whereupon $a_\delta = a_{HA}.a_{H_2O}$, i.e. the activity of the ion pair of the strong acid $H_3O^+.A^-$ is expressed in terms of the product of the thermodynamic activities of the acid (a_{HA}) and water (a_{H_2O}), and

(4) the acid molecules HA participating in the formation of the complex of the base with one or two molecules of the undissociated acid:

$$ROH + HA \rightleftarrows ROH\cdot HA, \qquad (12)$$

$$ROH + 2HA \rightleftarrows ROH\cdot 2HA; \qquad (13)$$

in the first case $a_\delta = a_{HA}$ and in the second $a_\delta = a_{HA}^2$.

Naturally, these examples do not exhaust the possibilities for the complex formation (ionisation) of bases in aqueous solutions of strong acids.

Eqns. (7) and (9) can be used to find the composition of the RC from kinetic data. For this purpose, it is essential to establish the dependence of k_{dehydr} on known functions characterising the ionising capacity of the acid solution. The problem reduces to the selection of a function a_δ for the description of the influence of the medium on the effective rate constant subject to the conditions that the multipliers f_{ROH}/f^* and f_{UC}/f^+ in Eqns. (7) and (9) respectively are independent of the acid concentration in solution.[41]

Unfortunately, it has not so far been established unambiguously how the ratios $f_{ROH}/f_{ROH.\delta}$ and $f_{UC}/f_{UC.\delta}$ really change when the acid concentration in solution is varied. In many cases, the reactive form of alcohols is the protonated form, its complexes with water molecules, and ion pairs, and the influence of the medium on the effective rate constant can frequently be described by assuming that $f_{ROH}/f_{ROH.\delta}$ is independent of the acid concentration in solution. This can be explained by the fact that, as in the ionisation of nitroanilines, in the ionisation of alcohols the rearrangement of the electronic structure of the molecule has little effect on its solvating capacity.

The formation of the arenium carbonium ion is accompanied by a significant rearrangement of the electronic structure of the UC.[42,43] Although the structures of the ionised form of aliphatic UC have not so far been established, there are grounds for the assumption that in the given instance the electronic structure of the UC rearranges. Hence it follows that, depending on the medium, there is a possibility that in the ionisation of the UC the ratios of the activity coefficient of the unionised and ionised forms of the UC may change.

It is known that, when the acid concentration in aqueous solution is varied, the activity coefficients of the unionised forms of the UC (f_{UC}) and of the alcohol obtained from it (f_{ROH}) do not vary in the same way. Consequently, depending on the composition of the medium, the quantities $f_{ROH}/f_{ROH.\delta}$ and f_{UC}/f^* should also vary in different ways.

The reactive complex ROH.δ is one of the ionised forms of the alcohol; Eqns. (10)–(13) reflect the stoichiometry of their formation. Taking into account the arguments described above stating that the composition of the medium does not influence the ratio $f_{ROH}/f_{ROH.\delta}$, one may postulate that in the ROH dehydration reaction it is also independent of the acid concentration. The reactions analysed in this review are slow and we therefore assume that the reactive complex and the activated complex obtained from it are in equilibrium with the reactants. This enables us to assume that the ratios f_{ROH}/f^* and f_{ROH}/f_{RC}^{ROH} vary in the same way as the acidity of the medium is varied (the activity coefficient of RC in the ROH dehydration and UC hydration reactions is designed by f_{RC}^{ROH}).

We replaced f^* in Eqn. (2) by f_{ROH}/f_{RC}^{ROH}, whereupon

$$k_{dehydr} = \frac{k_{true}}{K_i^{ROH}} a_\delta \frac{f_{ROH}}{f_{RC}^{ROH}}. \quad (14)$$

By adjusting f_{ROH} and f_{RC}^{ROH} to water as the standard and by setting them equal to unity, we obtain

$$k_{dehydr} = \frac{k_{true}}{K_i^{ROH}} a_\delta. \quad (15)$$

Eqn. (14) can be used to establish the composition of the RC from kinetic data.

In order to determine the composition of the activated complex in the ROH dehydration reaction, it is necessary to select a species δ such that Eqn. (7) for k_{dehydr} includes the multiplier f_{ROH}/f^*, which is independent of the acid concentration in solution. The function a_δ found in this way does in fact characterise the composition of the RC. For this purpose, it is essential to know the rate constant for the hydration of the UC and for the dehydration of the ROH obtained from it under identical conditions.

Unfortunately, despite the comparatively large number of studies on the hydration of UC and the dehydration of ROH, the equilibrium concentrations of the UC and the ROH and hence the constants k_{dehydr} and k_{hydr} found under identical conditions are quoted in only an insignificant proportion of the relevant communications.

The available data (which are admittedly very few in number) confirm the above postulate: the multiplier f_{ROH}/f_{RC}^{ROH} in Eqn. (14), reflecting the influence of the medium on k_{dehydr}, does not change within the limits of the error of the measurement as the acid concentration in aqueous solution is varied. This is illustrated by the data in Tables 2–4, which present the constants k_{hydr} and k_{dehydr}, the function a_δ, and the ratios k_{dehydr}/a_δ and $k_{hydr}/a_\delta a_{H_2O}$ for the hydration and dehydration reactions.

Judging from the data in Table 2, a virtually constant ratio $k_{dehydr}/h_0 a_{H_2O}$ is retained during the dehydration of 2-cyclohexenol in the H_2SO_4 concentration range 4.9–42.0%. The function a_δ is in this case equal to $h_0 a_{H_2O}$ and the RC and the activated complex are therefore formed via the addition of the $H_5O_2^+$ ion to the ROH molecule and in the case of UC via the addition of the $H_5O_2^+$ ion and the H_2O molecule. The ratio $c_{ROH}^\infty/c_{UC}^\infty = f_{UC}/f_{ROH}$ depends significantly on the acid concentration in solution. Consequently the function $a_\delta a_{H_2O} = h_0 a_{H_2O}^2$ does not describe the influence of the medium on the ionisation of cyclohexa-1,3-diene.

Table 2. Kinetics of the hydration of cyclohexa-1,3-diene and the dehydration of 2-cyclohexenol (according to the data of Jensen et al.[44]).

*The equilibrium UC and ROH concentrations are not quoted by Jensen et al.[44] They were calculated using the values of $c_{ROH}^\infty/c_{UC}^\infty$ at 70 and 80 ° C.

Similar conclusions follow from the results obtained in the study of the hydration of 2-phenylpropene and the dehydration of 2-phenyl-2-propanol in H_2SO_4 solutions[13] (Table 3) and of the dehydration of t-pentyl alcohol in HNO_3 solutions[30] (Table 4).

The virtual constancy of the quantity $k_{dehydr}/h_0 a_{H_2O}$ when the composition of the medium is varied implies that the activity of the RC in these reactions should be expressed in terms of the product of the activities of ROH and the $H_5O_2^+$ ion for the dehydration of ROH and in terms of the activities of the $H_5O_2^+$ ion and the water molecule in the hydration reaction.

There are instances where k_{hydr} and k_{dehydr} vary in the same way as the acid concentration is varied. Evidently, in the determination of the reaction mechanism from the influence of the composition of

the medium on k_{hydr} in such cases one must take into account the fact that, in the formation of the RC, one H_2O molecule more adds to the UC than to the ROH.

Table 3. Kinetics of the hydration of 2-phenylpropene and the dehydration of 2-phenyl-2-propanol at 25 °C (according to the data of Deno et al.;[13] k_{hydr} and k_{dehydr} are expressed in min^{-1}).

Table 5 presents data for the hydration of 2-(4-methoxyphenyl)-propene and the dehydration of the corresponding alcohol in aqueous H_2SO_4 solutions, from which it follows that, when the acid concentration is varied from 4.8 to 14.1 wt.%, $c^{\infty}_{ROH}/c^{\infty}_{UC}$ and hence f_{ROH}/f_{UC} vary by a factor of 3.17. The ratios $k_{dehydr}/a_{H_2SO_4}a_{H_2O}$ and k_{hydr}/h_0 hardly vary with composition.

From the above, one must assume that in the given instance the constancy of the quantity $k_{dehydr}/a_{H_2SO_4}a_{H_2O}$ indicates the formation of an RC from the ROH, an H_2SO_4 molecule, and an H_2O molecule. The constancy of k_{hydr}/h_0 does not characterise the mechanism of the rate-limiting step.

From the results presented, we assume that, when the strong acid concentration in aqueous solution is varied, the ratio f_{ROH}/f^{ROH}_{RC} hardly changes.

Thus, in order to establish the mechanism of the rate-limiting step of the hydration of the UC and of the dehydration of the ROH, it is necessary to find by Eqn. (15) the function a_δ in order to determine the influence of the acid concentration in solution on k_{dehydr}. The function a_δ is the activity of the species or complex which adds to the reactant and converts it into the RC. The latter is in equilibrium with the activated complex and with the molecules and ions from which it is formed. There is also a possibility of reactions where the RC is not formed. In such cases, a_δ is a function describing the influence of the medium on the activity of the activated complex and the term ka_{RC}/f^* should be eliminated from Eqns. (7) and (9).

Thus the determination of the mechanism of the UC hydration and ROH dehydration reactions reduces to finding the function a_δ from data for the dependence of k_{dehydr} on the ionising properties of the medium. We suggest that such information about the dependence of k_{hydr} on the ionising properties of the medium cannot be obtained without taking into account the contribution by the multiplier f_{UC}/f^* [see Eqn. (16)] to k_{hydr}. For this purpose, it is essential to measure the equilibrium concentrations c^{∞}_{ROH} and c^{∞}_{UC} in experiments on the hydration of the UC.

Since the ratio f_{ROH}/f^* does not change as the acid concentration in solution is varied, f^* in Eqn. (9) can be replaced by f_{ROH}, whereupon

$$k_{hydr} = \frac{k_{true}}{K^{UC}_{RC} K^{UC}_{i}} a_{H_2O} a_\delta \frac{f_{UC}}{f_{ROH}}. \qquad (16)$$

The ratio f_{UC}/f_{ROH} can be found knowing the equilibrium constant K_{eq} for the UC hydration reaction:

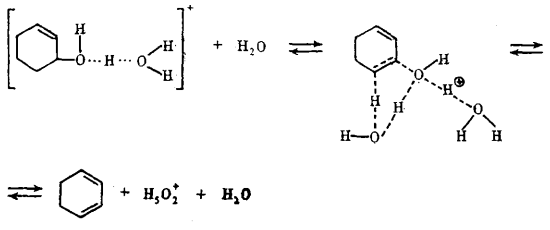
$$K_{eq} = \frac{c^{\infty}_{ROH}}{c^{\infty}_{UC} a_{H_2O}} \frac{f_{ROH}}{f_{UC}}. \qquad (17)$$

Simultaneous solution of Eqns. (16) and (17) yields the formula for the determination of a_δ using k_{hydr}:

$$k_{hydr} = \frac{k_{true}}{K^{UC}_{RC} K^{UC}_{i} K_{eq}} a_\delta \frac{c^{\infty}_{ROH}}{c^{\infty}_{UC}}. \qquad (18)$$

There are cases where the ratio $c^{\infty}_{ROH}/c^{\infty}_{UC}$ is independent of the acid concentration in the aqueous solution and k_{dehydr} and k_{hydr} vary in the same way as the ionising properties of the medium are varied.[22,45,46] The function a_δ found with the aid of Eqns. (16) and (18) yields in this case information about the species which reacts with ROH rapidly and reversibly to form the RC. For the formation of such a complex from the UC, the particiption of a water molecule is also necessary. Examples illustrating the wide variety of the mechanisms of the dehydration of ROH and the hydration of the UC are presented below. It follows from the data in Table 2 that the RC in the 2-cyclohexenol dehydration reaction and cyclohexa-1,3-diene hydration reaction is formed from an ROH molecule and the $H_5O_2^+$ ion in conformity with Eqn. (10). In the rate-limiting stage, this complex decomposes to the reaction products

(UC, H_2O, ROH) and the catalyst $H_5O_2^+$ is regenerated simultaneously:



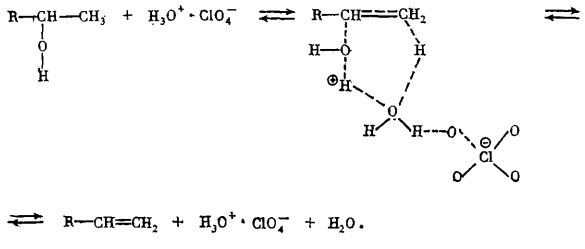


Table 6. Kinetics of the dehydration of 1-phenylethanol and the hydration of styrene in perchloric acid at 25 °C [the values of k_{hydr} (min^{-1}) and k_{dehydr} (min^{-1}) were taken from Schubert and Keefe[22]].

[$HClO_4$], wt.%	$\lg k_{hydr}$	$\lg k_{dehydr}$	$\lg(k_{dehydr}/a_{HClO_4}a_{H_2O})$
36.40	−2.48	−4.11	−6.67
39.50	−2.13	−3.76	−6.69
43.40	−1.62	−3.23	−6.68
47.10	−1.04	−2.65	−6.67
49.25	−0.69	−2.30	−6.65
51.90	−0.30	−1.87	−6.67

In the hydration reaction of styrene and its derivatives and in the dehydration reactions of the corresponding alcohol in perchloric acid, the $H_3O^+.ClO_4^-$ ion pairs are catalytically active (Table 6).[22] In this reaction, the RC are formed from ROH and an ion pair of the type $H_3O^+.A^-$, where A^- is the ClO_4^- anion [see Eqn. (11)]:

The sums $k_{dehydr} + k_{hydr}$ and the ratios $c^{\infty}_{ROH}/c^{\infty}_{UC}$ have been obtained in experiments at 25 °C in perchloric acid not only with styrene (36.4−51.9% $HClO_4$) but also with *p*-ethylstyrene (29.5−41.9% $HClO_4$), *p*-chlorostyrene (36.45−51.9% $HClO_4$), *p*-methoxy-α-methylstyrene (1.03−29.5% $HClO_4$), and *p*-nitrostyrene (59.0−68.5% $HClO_4$).[22] The reactions of the reactants enumerated, except the last two, proceed only via the mechanism with $a_\delta = a_{HClO_4}a_{H_2O}$. In this case, the quantities

$$\lg(k_{dehydr}/a_{HClO_4}a_{H_2O}) = \lg(k_{true}/K_i^{ROH})_{HA.H_2O}$$

are −7.11 ± 0.003, −6.67 ± 0.04, and −5.49 ± 0.08 for *p*-chlorostyrene, styrene, and *p*-methylstyrene respectively. The same mechanism operates in the reaction of *p*-methoxy-α-methylstyrene in solutions at $HClO_4$ concentrations of 20.65% and above, where $\lg(k_{true}/K_i^{ROH}) = -3.82 \pm 0.03$. In more dilute $HClO_4$ solutions, the reaction also proceeds via the mechanism with $a_\delta = h_0 a_{H_2O}$. Schubert and Keefe[22] quote $c^{\infty}_{ROH}/c^{\infty}_{Cu}$ for *p*-nitrostyrene only in the experiment with 63% $HClO_4$ solution. We assumed that, as for the other reactants listed above, this quantity is independent of the $HClO_4$ concentration. The ratio $k_{dehydr}/a_{HClO_4}a_{H_2O}$ for *p*-nitrostyrene is not constant. We explain this by the fact that the dehydration of 1-(*p*-nitrophenyl)-ethanol and the hydration of *p*-nitrostyrene proceeds via two pathways and that their contributions to k_{dehydr} and k_{hydr} are comparable in the test solutions. For one pathway, $a_\delta = a_{HClO_4}a_{H_2O}$ at 25 °C and $\lg(k_{true}/K_i^{ROH})_{HA} = -9.96$ while for the other pathway $a_\delta = a_{HA}$ and $\lg(k_{true}/K_i^{ROH})_{HA} = -10.89$ (in the given case HA is $HClO_4$).

This mechanism of the catalytic action of aqueous acid solutions operates, as will be shown below, also in reactions with other reactants. The constancy of the ratio $k_{dehydr}/a_{HClO_4}a_{H_2O}$ is evidence that the catalytic action is manifested in this reaction by ion pairs with participation of the acid. The effect of the anion reduces in our view to the facilitating the abstraction of the H atom from a C−H bond in the ROH and in transferring it to a carbon atom in the UC. It follows from the data in Table 5 that, in the dehydration of 2-(4-methoxyphenyl)-2-propanol in sulphuric acid, the ratio $k_{dehydr}/a_{H_2SO_4}$ also remains constant. Unfortunately experiments were performed in dilute sulphuric acid solutions where the activity of water changes little. Therefore in the present instance there is no certainty that the function a_δ is equal to the activity of sulphuric acid $a_{H_2SO_4}$ and not to the activity of the $H_3O^+.HSO_4^-$ ion pairs.

The catalytic action of sulphuric acid molecules can be illustrated by data for the dehydration of β-hydroxy-β-phenylpropionic acid (Table 7).[47] The quantity $k_{dehydr}a_{H_2SO_4}$ in 38.32% H_2SO_4 solution is greater than its average value for the range 39.68−69.0% H_2SO_4. This can be explained by the contribution of yet another dehydration pathway which is manifested in more dilute solutions. The numerical values of $\lg(k_{true}/K_i^{ROH})_{HA}$ are −5.78 ± 0.01 at 45 °C and −6.50 ± 0.11 at 25 °C.

The values of k_{dehydr} for β-(*p*-chlorophenyl)-β-hydroxypropionic acid in 53.46−64.13% sulphuric acid solutions at 45 °C have been published.[48] In these solutions, $a_\delta = a_{H_2SO_4}$ and $\lg(k_{true}/K_i^{ROH})_{HA} = -5.25 \pm 0.1$. It follows from Eqn. (12) that the reaction complex with $a_\delta = a_{HA}$ is formed from ROH and an acid molecule (in our case H_2SO_4):

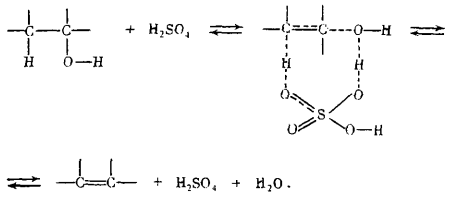

Table 7. Kinetics of the dehydration of β-hydroxy-β-phenylpropionic acid in sulphuric acid at 44.7 °C [the values of k_{dehydr} (min^{-1}) were taken from Noyce and Lane[47]].

[H_2SO_4], wt.%	$\lg k_{dehydr}$	$\lg a_{H_2SO_4}$	$\lg(k_{dehydr}/a_{H_2SO_4})$
38.32	−3.69	−0.89	−4.58
39.68	−3.62	+1.06	−4.68
51.87	−2.19	+2.53	−4.72
58.05	−1.36	+3.40	−4.76
65.45	−0.36	+4.51	−4.87
65.45	−0.32	+4.51	−4.83
69.00	+0.25	+5.03	−4.78
69.00	+0.26	+5.03	−4.77

ROH dehydration and UC hydration reactions are also known in which the catalytic action of the acid is caused by the formation of a complex from the ROH and two acid molecules, i.e. $a_\delta = a_{HA}^2$—for example, the dehydration reactions of the alcohols $XC_6H_4CH.(CF_3)CH_2OH$ and the hydration reactions of the alkenes $XC_6H_4C.(CF_3)=CH_2$ (X = *p*-Me, H, or *p*-Cl) in concentrated sulphuric acid at 25 °C. Calculation based on literature data[49] shows that the quantities $\lg(k_{dehydr}/a^2_{H_2SO_4}) = \lg(k_{true}/K_i^{ROH})_{HA^2}$ are respectively -18.51 ± 0.11 (X = H), -18.86 ± 0.05 (X = *p*-Me, in the range 76.3–83.6% H_2SO_4), and -18.95 ± 0.08 (X = *p*-Cl, in the range 83.6–87.1% H_2SO_4). Judging from the above data,[49] for X = *p*-MeO the reaction at H_2SO_4 concentrations in the range 70.1–76.1% proceeds mainly via the formation of an RC with $a_\delta = a_{H_2SO_4}$; under these conditions, $\lg(k_{dehydr}/a_{H_2SO_4}) = \lg(k_{true}/K_i^{ROH})_{HA} = -10.3$.

Thus it follows from the data in Tables 2–8 that the catalysis of the ROH dehydration and UC hydration reactions in aqueous solutions of acids is determined by the formation of complexes of the reactants with $H_5O_2^+$ ions, $H_3O^+.A^-$ ion pairs, and HA acid molecules. These examples illustrate the catalytic activity of species of predominantly one type among those listed above. However, when the range of acid concentrations is extended and also when the temperature is varied, other reaction pathways also operate. This is seen, in particular, from the data in Table 7.[47] At relatively low sulphuric acid concentrations, the quantity $k_{dehydr}/a_{H_2SO_4}$ for the dehydration reaction of β-hydroxy-β-phenylpropionic acid is greater than in more concentrated solutions, which can be explained by the contribution of yet another reaction pathway. As noted above, the influence of the medium on k_{dehydr} for 1-*p*-nitrophenylethanol and k_{hydr} for *p*-nitrostyrene[22] may be caused by the operation of two pathways: via the formation of an RC with $a_\delta = a_{H_2SO_4}$ and an RC with $a_\delta = a_{H_2SO_4}a_{H_2O}$. the latter variant was first examined by Osipova et al.[50] In this case, the following equation should hold:

$$k_{dehydr} = k_{dehydr}^{HA.H_2O} a_{H_2SO_4} a_{H_2O} + k_{dehydr}^{HA} a_{H_2SO_4}.$$

Table 8. Kinetics of the hydration of $C_6H_5C(CF_3)=CH_2$ and the dehydration of the corresponding alcohol [the values of k_{dehydr} (min^{-1}) and k_{hydr} (min^{-1}) were taken from Koshy et al.[49]].

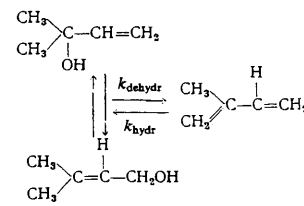
$[H_2SO_4]$, wt.%	$\lg k_{dehydr}$	$\lg k_{hydr}$	$\lg(k_{dehydr}/a^2_{H_2SO_4})$
87.1	−1.27	−1.83	−18.53
87.1	−1.23	−1.79	−18.48
84.9	−1.92	−2.28	−18.62
83.6	−2.14	−2.43	−18.43
80.9	−2.94	−3.01	−18.48
79.9	−3.30	−3.28	−18.52

The dehydration of β-hydroxy-β-(*p*-methoxyphenyl)propionic acid also proceeds via two pathways. This follows from data in a communication[48] in which the values of k_{dehydr} at 45 °C for 1.0–24.85% H_2SO_4 solutions and at 25 °C for 24.18–47% H_2SO_4 solutions are presented. In experiments with relatively low acid concentrations, it was seen that, with increase in the H_2SO_4 concentration, the main reaction pathway becomes the second one. Table 9 shows that, in the H_2SO_4 concentration range 1.0–18.7%, the quantity $k_{dehydr}/h_0a_{H_2O}$ is practically constant. This permits the assumption that in such solutions the reaction proceeds via only one pathway—via the formation of an RC with $a_\delta = h_0a_{H_2O}$ and that

$$\lg(k_{dehydr}/h_0\,a_{H_2O}) = \lg(k_{true}/K_i^{ROH})_{H_2O_2^+} = -1.60 \pm 0.08.$$

In more concentrated solutions, the quantity $\lg(k_{dehydr}/h_0a_{H_2O})$ increases but the data are insufficient for a quantitative estimation of the contribution by the second pathway. At 25 °C the experiments were performed in more concentrated solutions, which made it possible to calculate the rate constants for the first and second pathways with the aid of the equation

$$k_{dehydr} = k_{dehydr}^{H_5O_2^+} h_0 a_{H_2O} + k_{dehydr}^{HA} a_{H_2SO_4}.$$



Thus at 25 °C we have

$$\lg(k_{true}/K_i^{ROH})_{H_5O_2^+} = -3.77; \quad \lg \left.\frac{k_{true}}{K_i^{ROH}}\right|_{HA} = -2.44.$$

The dehydration reactions in sulphuric acid solutions of an equilibrium mixture of dimethylvinylmethanol and dimethylallyl alcohol and the hydration reaction of isoprene (Table 10)[50] proceed via two pathways: via the formation of an RC with $a_\delta = h_0a_{H_2O}$ and with $a_\delta = a_{H_2SO_4}a_{H_2O}$:

When the composition of the medium is varied, k_{dehydr} changes in accordance with the equation

$$k_{dehydr} = k_{dehydr}^{H_5O_2^+} h_0 a_{H_2O} + k_{dehydr}^{HA.H_2O} a_{H_2SO_4} a_{H_2O}.$$

The linearity of the relation presented in Fig. 1, where $k_{dehydr}/h_0\,a_{H_2O}$ is plotted against $a_{H_2SO_4}/h_0$, confirms the applicability of this equation in the given instance.

The quantity k_{dehydr} for the highest (in the range investigated) H_2SO_4 concentration of 35.11% proved to be significantly lower than expected according to the experimental data for less concentrated acid solutions. This can be explained by the conversion of a large proportion of the unsaturated alcohols into the ionised form.

As noted above, Eqns. (7) and (9) were derived for the case where the degrees of conversion of the ROH and the UC into the ionised form and the RC are low. If the degree of their ionisation is significant, then, provided that only one reaction pathway is retained, these formulae must be supplemented by a multiplier taking into account the concentration of the ionised forms: $1/(1 + \sum a_\delta/K_\delta^i)$, where K_δ^i denotes the equilibrium constants of the formation reactions of the ionised forms.

Table 10. Kinetics of the dehydration of the equilibrium mixture of dimethylvinylmethanol and dimethylallyl alcohol and the hydration of isoprene [the values of k_{hydr} (min^{-1}) and k_{dehydr} (min^{-1}) were taken from Osipova et al.[50]].

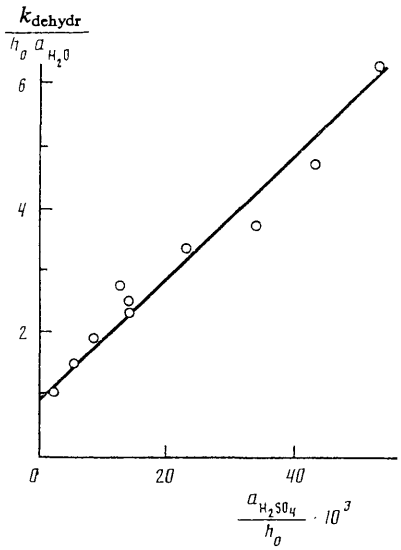

Figure 1. The influence of the H_2SO_4 concentration on k_{dehydr} for the equilibrium mixture of dimethylvinylmethanol and dimethylallyl alcohol (according to the data of Osipova et al.[50]).

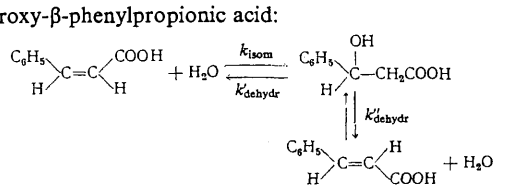
The examples presented naturally do not cover all the possible mechanisms of the alcohol dehydration and UC hydration reactions. An illustration may be provided by the dehydration of β-hydroxyketones in acid solutions. Investigators have drawn attention to the fact that substituents in the benzene ring have little influence on the rate of dehydration of β-hydroxyketones.[51] On these grounds, they concluded that the atoms of the benzene ring remote from the reaction centre participate in the rate-limiting stage of the dehydration of these substances and that in certain cases the rate-limiting stage is enolisation. The dependence of k_{dehydr} on the acid concentration in aqueous solution confirms this hypothesis. It has been shown[52] that, when the acid concentration is varied, the enolisation rate constants k_{eff} for acetone varies in accordance with the equation

$$k_{eff} = k_1 c_{H_3O_2^+} + k_2 c_{H_3O_2^+} c_{A^-}, \quad (19)$$

where k_1 and k_2 are respectively the rate constants for pathways with participation of the $H_5O_2^+$ ion and with participation of $H_5O_2^+ + A^-$.

Eqn. (19) is applicable also to the description of the influence of the medium on k_{dehydr} for certain β-hydroxyketones. For example, only the second pathway operates in the dehydration of 4-hydroxy-4-(*p*-nitrophenyl)-2-butanone (Table 11) in the H_2SO_4 concentration range 22.1 − 51.0%. The RC concentration is determined by that of the ions $H_5O_2^+$ and HSO_4^-, so that in this reaction $k_1 = 0$ and $a_\delta = c_{H_3O_2^+} c_{A^-}$.

Table 11. Kinetics of the dehydration of 4-hydroxy-4-(*p*-nitrophenyl)-2-butanone at 25 °C (the values of k_{dehydr} were taken from Noyce and Reed[51]].



$[H_2SO_4]$, wt.%	$[H_2SO_4]$, M	$10^3\, k_{dehydr}$, min^{-1}	$10^4(k_{dehydr}/c_{H_3O_2^+} c_{A^-})$, $litre^2\, mol^{-2}\, min^{-1}$
9.45	1.02	0.095	9.2
22.1	2.59	0.36	5.4
36.25	3.75	0.74	5.3
41.7	5.61	1.70	5.4
51.0	7.30	3.46	6.5

Note. The degree of dissociation of the HSO_4^- anions may be neglected in the experimental range. In the calculation, it was assumed that c_{A^-} and $c_{H_3O_2^+}$ are numerically equal to the analytical molar concentration of the acid, since the dissociation constant of the HSO_4^- ions is 1.2×10^{-2} [Dobos (Ref. 53, p. 131)].

Judging from the experimental data,[51] when the nitro-group in the *para*-position in the benzene ring is replaced by the methoxy-group, the reaction mechanism changes and the influence of the medium on k_{dehydr} is determined by the functions $a_\delta = a_{H_3O_2^+} = h_0 a_{H_2O}$ and $a_\delta = a_{H_2SO_4} a_{H_2O}$.

In the determination of the reaction mechanism from the dependence of the effective rate constant on the function a_δ, characterising the ionising capacity of the medium, account must be taken of the fact that in the experimental acid concentration range it is possible to select several functions a_δ varying in the same way. This hinders the choice of the reaction mechanism. In order to solve the problem, it is essential to measure the rate constants over wider acid concentration and temperature ranges and to determine the influence of the medium on the activity coefficients of the UC and the corresponding alcohol. If even these experiments do not provide an unambiguous answer, it is necessary to select such a function and hence the reaction mechanism which agrees best with results obtained by other methods. As an example, we shall

examine the isomerisation of *cis*-cinnamic acid in H_2SO_4 at 45 °C to *trans*-cinnamic acid.[54] In this reaction, the intermediate is β-hydroxy-β-phenylpropionic acid:

The rate-limiting stage of the isomerisation reaction is the hydration of *cis*-cinnamic acid, since the rate constant for the hydration of β-hydroxy-β-phenyl-propionic acid is much greater than k_{isom}. Consequently k_{isom} is the rate constant for the hydration of *cis*-cinnamic acid. The data in Table 12 show that in the range 38.43–69.88% H_2SO_4 the quantity $\lg(k_{isom}/a_{H_2SO_4}a_{H_2O})$ is constant within the limits of the error of the measurements, while $\lg(k_{isom}/h_0)$ varies, albeit only slightly. In order to solve the problem of the composition of the RC in this reaction, it is essential to have information about the dependence of f_{UC}/f_{ROH} on the concentration of the catalyst in solution. Unfortunately, such data were not provided in the above study.[54] If it is found that the ratio f_{UC}/f_{ROH} does not change, it will be necessary to conclude that the RC in the given instance is a complex consisting of a molecule of β-hydroxy-β-phenylpropionic acid and a molecule of H_2SO_4 (or *cis*-cinnamic acid, H_2SO_4, and H_2O). On the other hand, if the ratio $(f_{UC}/f_{ROH})a_{H_2O}$ is constant, this will imply that the RC is formed from a molecule of β-hydroxy-β-phenylpropionic acid and the ion pair $H_3O^+.HSO_4^-$.

IV. The mechanism of the exchange of the oxygen atom in alcohols and of the racemisation of optically active alcohols

In order to derive an equation in which account is taken of the influence of the medium on the rate w_{exch} and the rate constants k_{exch} for the exchange of the oxygen atom in alcohols, we express the activity of the RC in terms of the equilibrium constant of its formation reaction, the ROH concentration, and the functions a_δ, as was done above [Eqns. (7) and (8)]:

$$w_{exch} = k_{true}^{exch}\frac{a_{ROH}\,a_\delta}{f^*} = \frac{k_{true}^{exch}}{K_i^{exch}}\,c_{ROH}a_\delta\frac{f_{ROH}}{f^*};$$

$$k_{exch} = \frac{k_{true}^{exch}}{K_i^{exch}}\,a_\delta\frac{f_{ROH}}{f^*};\quad K_i^{exch} = \frac{a_{ROH}\,a_\delta}{a_{ROH.\delta}},$$

where k_{true}^{exch} is the elementary rate constant, K_i^{exch} the equilibrium formation constant, expressed in terms of activities, of the RC in the reaction involving the exchange of the oxygen atom. We believe that, after a correct choice of the function a_δ, the multiplier f_{ROH}/f^* is independent of the acid concentration in the aqueous solution and that

$$k_{exch} = (k_{true}^{exch}/K_i^{exch})a_\delta.$$

An equation of this type can also be used to take into account the influence of the medium on the rate constant for the racemisation of optically active alcohols k_{rac}.

Unfortunately, there are few literature data concerning the dependence of k_{exch} and k_{rac} on the acid concentration in aqueous solution, but on the basis of their analysis one can nevertheless reach conclusions about the mechanism of the catalytic action of acids in these reactions.

Measurements have been made[33] of the constants k_{exch} for methanol at 67.2 °C in sulphuric (20.1–69.3%) and perchloric (26.3–59.9%) acids. The methanol concentration in solution was ~0.3 M. The addition of such amounts of the alcohol to the aqueous acid solution has little effect on the degree of protonation of indicators of the nitroaniline series.[55] However, it has been shown[52] that the basicity of the alcohol itself is independent of its concentration in the mixture with water. Therefore, in analysing the above kinetic data,[33] one can use the values of H_0 and a_{H_2O} for aqueous solutions with the same acid concentration (molar ratio).[52]

The influence of the medium on k_{exch} is determined by the function $a_\delta = h_0a_{H_2O}^2$, since, according to experimental data[33] $k_{exch}h_0a_{H_2O}^2 = \text{const}$. (Tables 13 and 14). This means that the activity of the RC can be expressed either in terms of the product of the activities of the non-protonated CH_3OH, the $H_5O_2^+$ ion, and

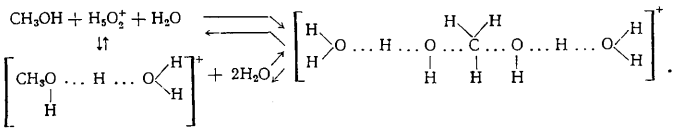

Table 13. Kinetics of the exchange of ^{18}O for ^{16}O in methanol in aqueous H_2SO_4 solutions at 67.2 °C [the values of k_{exch} (min^{-1}) were taken from McClellend[33]].

water (with a power exponent of unity) or in terms of the product of the activity of the protonated CH_3OH and the square of the activity of water. The equation of the formation reaction of such RC is

The participation of two water molecules is essential for the intermediate (RC) to have a symmetrical structure. In this RC, the carbon atom is bound covalently to three hydrogen atoms and two water molecules are coordinated to it on either side.

In sulphuric and perchloric acids, the ratios $\lg(k_{exch}/h_0 a_{H_2O}^2)$ are respectively -6.84 ± 0.1 and -6.80 ± 0.06. The similarity of the values of $k_{true}^{exch}/k_i^{exch}$ in these acids constitutes additional confirmation of the reaction mechanism described.

There exist examples of the racemisation of optically active alcohols via this mechanism. For example, the rate constant for the racemisation of 1-methyl-3-phenyl-allyl alcohol in perchloric acid at 25 °C varies in proportion to h_0.[45] The activity of water in solutions with $HClO_4$ concentrations in the range 0.0225–0.333 M is almost constant.

The catalytic action of an acid in alcohol racemisation and oxygen atom exchange reactions is not determined solely by the formation of an RC with $a_\delta = h_0 a_{H_2O}^2$ as in the case of CH_3OH. Thus the influence of the medium on k_{rac} for (+)-β-hydroxy-phenyl-propionic acid in sulphuric acid[47] can be described on the assumption that $a_\delta = a_{H_2SO_4} a_{H_2O}$ (Table 15). In this reaction the activity of the RC should be expressed in terms of the activity of the ROH, the acid, and water with an exponent of unity. The intermediate reactive complex has a symmetrical structure:

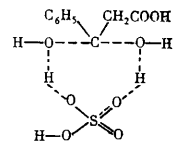

Table 15. Kinetics of the racemisation of (+)-β-hydroxy-β-phenyl-propionic acid in sulphuric acid at 25 °C [the values of k_{rac} (min^{-1}) were taken from Noyce and Lane[47]].

$[H_2SO_4]$, wt.%	$\lg k_{rac}$	$\lg(k_{rac}/a_{H_2SO_4}a_{H_2O})$
39.77	−2.97	−4.24
47.70	−2.17	−4.21
52.03	−1.56	−4.24
58.84	−0.72	−4.18
58.84	−0.72	−4.16
58.84	−0.74	−4.20

The values of $\lg k_{rac}$ at 45 °C have been published.[47] They amount to −1.87 and −1.13 in 39.77% and 47% H_2SO_4 solutions (the k_{rac} are expressed in min^{-1}). Calculation shows that $\lg(k_{rac}/a_{H_2SO_4}a_{H_2O}) = -2.69 \pm 0.01$ at 45 °C and -4.20 ± 0.04 at 25 °C; the temperature dependence of k_{true}^{rac}/K_i^{rac} is characterised by the quantity 137 J mol^{-1}.

In the oxygen atom exchange and 1-phenylethanol racemisation reactions in perchloric acid,[56] the pathways with $a_\delta = h_0 a_{H_2O}^2$ and $a_\delta = a_{HClO_4} a_{H_2O}$ have been observed. The values of k_{rac} for 1-phenylethanol at 30.4 °C in the $HClO_4$ concentration range 0.0172–1.00 M have been published;[56] in 0.0472 and 0.0826 M $HClO_4$ solutions, the ratios k_{exch}/k_{rac} are respectively 0.84 and 0.82. In the concentration range 0.02–0.47 M, the constants k_{rac} in hydrochloric, hydrobromic, and perchloric acids are almost identical. In the acid concentration range 0.0172–1.0 M, k_{rac} is described by the equation

$$k_{rac} = \left(\frac{k_{true}^{rac}}{K_i^{rac}}\right)_{h_0} h_0 a_{H_2O}^2 + \left(\frac{k_{true}^{rac}}{K_i^{rac}}\right)_{HA.H_2O} a_{HClO_4} a_{H_2O}. \qquad (20)$$

Fig. 2 presents experimental data for the influence of the medium on the rate constant for the racemisation of 1-phenylethanol.[56]

It follows from the analysis of the kinetic data described that the alkene hydration and alcohol dehydration reactions proceed via a synchronous mechanism without the particpation of "classical" carbonium ions.

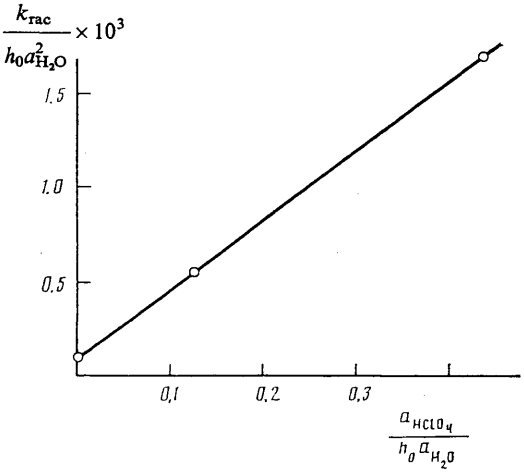

Figure 2. The application of Eqn. (20) to describe the influence of the medium on k_{rac} for 1-phenylethanol (according to the data of Grunwald et al.[56]).

In order to increase the solubility of the reactants, ethanol was added to the acid solution in a number of investigations (see, for example, the studies of Noyce and co-workers[57–59]). The acid concentration and the composition of the mixed water–ethanol solvent (the alcohol/water molar ratio) were varied simultaneously. In the present review, such data are not analysed because it is impossible to take into account the influence of the alcohol on the ionising properties of the solution.

In the analysis of kinetic data, we used the known values of H_0 for sulphuric acid,[60] concentrated perchloric acid solutions at 25 °C,[61] and dilute solutions of perchloric acid[62] and nitric acid at 20 °C.[63] The acitivities $a_{H_2SO_4}$ of concentrated sulphuric acid solutions at 25 °C were taken from Giauque et al.,[64] the activities of dilute sulphuric acid solutions (up to 30 wt.%) were calculated using the values of $\gamma_\pm$ from Dobos,[53] and the activities a_{H_2O} in sulphuric acid were taken from Giauque et al.[64] The activities $a_{H_2SO_4}$ in solutions with acid concentrations up to 60 wt.% at 45 °C were

calculated from the values of $\gamma_{\pm}$ at this temperature, which were found using the relation $\lg \gamma_{\pm} = f(1/T)$ for the range 25–60 °C, quoted by Dobos.[53] The activities a_{H_2O} in perchloric acid at 25 °C were taken from Landolt and Börnstein.[65]

V. Conclusion

The above analysis of kinetic data shows convincingly that, for the determination of the detailed mechanism of the hydration of alkenes in aqueous solutions of acids, it is necessary to know not only the values of k_{hydr} for the alkene but also those of k_{dehydr} for the corresponding alcohol over a wide range of acid concentrations. The composition of the RC in the alcohol dehydration reactions and in the hydration reactions of the corresponding alkenes can be found from the dependence of k_{dehydr} on the parameters of the medium characterising the ionising capacity of the solution. If the ratio of the equilibrium concentrations of the alcohol and the alkene ($c^{\infty}_{ROH}/c^{\infty}_{UC}$) varies with the acid concentration, then the influence of the medium on k_{hydr} can be determined from the values of k_{dehydr} and the experimental equilibrium concentrations c^{∞}_{ROH} and c^{∞}_{UC}. If this ratio remains unaltered at different acid concentrations in solution then the detailed mechanism can be determined using the dependence of k_{dehydr} and k_{hydr} on the parameters of the ionising capacity of the medium.

When the acid concentration is varied within wide limits, the alkene hydration and alcohol dehydration reactions can proceed via several pathways. Therefore, when account is taken of the influence of substituents on the reactivity of substances in concentrated acid solutions, one must be completely certain that the reactions of these substances proceed via identical mechanisms.

In concentrated aqueous acid solutions, catalysis is effected not only by solvated protons, but also by dissociated acid molecules as well as acid hydrates. Kinetic data for the hydration of UC, the dehydration and racemisation of ROH, and the exchange of the oxygen atom in alcohols are susceptible to a quantitative description on the assumption that in these reactions the RC are complexes of the reactant with the above ions and species in the aqueous acid solution.

Polymeric composite materials reinforced with polyacrylonitrile fibres

S E Artemenko, L P Nikulina
Branch of the Saratov Polytechnic Institute, Engels

ABSTRACT. The results of studies of the influence of polyacrylonitrile fibres on structure formation in and the properties of polymeric composite materials are surveyed. The new modification methods which have been developed, studies on the properties, and possible applications of such polymeric composite materials are described.

The bibliography includes 74 references.

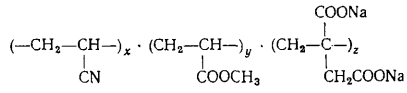
IV. The possible applications of polymeric composite materials 86

I. Introduction

The needs of the National Economy require the creation of new building and constructional materials which would make it possible to reduce sharply the use of metals in finished articles and would increase the strength and anticorrosion properties of constructions and would reduce their mass.[1]

A tendency towards the replacement of components made of traditional materials (wood, metals, ceramics, and glass) in the construction of buildings by polymeric materials has arisen. The requirement for metal is reduced sharply in the first place in those cases where the operating conditions do not involve the application of high pressures and temperatures and where the finished articles are subject to corrosion. Polymeric composite materials (PCM), which are fairly strong and long-lived and are lighter and more resistant to corrosion and erosion than metals, are promising in this instance.[2]



PMC reinforced with chemical fibres (carbon, aramide, etc. fibres) constitute a new class of materials distinguished by a set of valuable properties. PCM based on cheap polyacrylonitrile (PAN), polyester, viscose, polyamide, and other fibres, produced industrially on a large scale, are extremely promising for different branches of the National Economy.[3]

Although the industrial forms of chemical fibres have not been until recently a valuable reinforcing material because of their low strength, relatively low modulus of elasticity, and low heat resistance and thermal stability, nevertheless the possibility of varying their properties widely by modification as well as the set of the specific properties of PCM based on such fibres suggest that in the next few years their application in the reinforcement of plastics will become one of the effective ways of regulating the properties of PCM in accordance with the requirements of different branches of industry.

This review concentrates mainly on PCM reinforced with industrial PAN fibres in view of the increasing scale of their manufacture[4] and their specific properties: low density (1170–1190 kg m^{-3}), low water absorption (0.5–1%), a relatively high thermal stability (200–250 °C), the presence of reactive groups, and a fairly high strength.

Various methods for the modification of both the polymer matrix and the reinforcing fibre system are being developed in order to solve the problem of imparting to PCM the required properties in conformity with their functional purposes.

In the present review, an attempt is made to survey the results of studies and developments concerning different methods for the modification of PCM based on industrial PAN fibres obtained from the ternary copolymer

(0.92% of PAN, 6.3% of methyl acrylate, and 1.7% of sodium itaconate), formed under different conditions, and distinguished by specific physicomechanical properties.

II. Changes in the properties of polyacrylonitrile fibres on formation of polymeric composite materials

The technology of the manufacture of PCM based on chemical fibres differs in many respects from the technology of PCM with mineral fillers, such differences being associated with the specific features of the structure of the chemical fibres and the character of the physicochemical processes occurring at the polymeric fibre–polymeric binder interface.

The formation of PCM on the basis of polymeric fibres is accompanied to a greater or lesser extent—depending on the nature of the selected fibres and binders and the conditions in the pressing of the material (temperature, duration, and pressure)—by the mutual diffusion of the components: of the binder into the fibre and of low-molecular-weight components from the fibre into the polymeric binder.[5] Chemical fibres are structurally inhomogeneous and consist of an oriented high-density shell with an increased degree of crystallinity and a relatively loose core containing crystalline and amorphous sections. Longitudinal folds, 15–200 Å pores, 100–500 Å cracks,[6] and other defects may be present on the surfaces of the fibres.

Since the rate of diffusion into the amorphous regions of the polymers is appreciably higher than the rate of diffusion into the crystalline regions, the components of the binder penetrate the surface layers of the fibres, filling non-uniformly principally the microdefects.[3] This alters the structure of the surface layers of the fibres and hence their properties.[5,7–14]

Depending on the type of fibres and binders chosen, these changes can be both positive and negative.[3,15–18] The change in the supermolecular structure of highly oriented polyamide fibres under the influence of epoxide binders and their components has been investigated[18] by X-ray diffraction.[19] The different character of the interactions of the polyamide fibres based on poly-*p*-phenyleneterephthalamide (PPTA) and on poly-*p*-amidobenzimidazole (PABI) with the components of the EDT-10 and EKhD-MK binders has been established. The chlorine-containing EKhD-MK binder and its principal component, the EKhD resin, impair the structure of the bulk phase of the binders of both types when they interact with them.

The impregnation of nitron, lavsan, and vinol by the latexes of the SKD-1 and SKN-40-1 GP elastomers loosens the fibrillar structures as a result of the diffusion of the elastomer into the surface layer of the fibres.[16]

When technical viscose thread is treated with epoxide and phenolic binders, the strength of the thread is reduced[20] as a result of the penetration of the oligomer molecules into the fibre, the extent of the molecular interaction is diminished, and a disorder in the structure of the fibre is observed.

For poly(vinyl alcohol) (PVA), polyester, and viscose fibres[21] and also for heteroarylene[22] and highly-modular CBM fibres,[23] a plasticisation effect has been observed on treatment with various thermoreactive binders and their components.

After a correct choice of the PCM components and optimum contact conditions between them, it is possible to achieve the improvement of the physicomechanical properties of the fibres. First, under the influence of an epoxide resin accompanied by an increase in temperature up to 180–200 °C, the strength and rigidity of lavsan increase somewhat (by 15–20%). The nature of the hardener in this case has little influence on the rigidity of the fibres, but, up to 100 °C, it does promote an increase in their strength. At temperatures above 100 °C, there is a sharp decrease in the strength of lavsan under the influence of the hardener.

X-Ray diffraction analysis of PAN fibres treated with ED-20 epoxide oligomers, polyethylenepolyamine (PEPA), and a binder based on them showed that impregnation of the PAN fibres leads to the diffusion of the epoxide oligomer and PEPA into the bulk of the fibre, as a result of which the structure[24] and the strength[25] of the fibre change. The change in structure is indicated by the decrease in the intensity of the X-ray reflections: the intensities of the X-ray reflections for unimpregnated PAN fibres and TAN fibre treated with EG-20, PEPA, and binders based on them are respectively, 1, 0.34, 0.41, and 0.08 relative units.

The strength of fibres depends on the nature of the components, the temperature, and the duration of their contact. Thus treatment of PAN fibre with an epoxide oligomer and PEPA for 0.25 h at 80 °C (which corresponds to the PCM pressing conditions) hardly affects the strength and elongation of the fibres, while further increase in temperature and in the duration of treatment of the fibre by the binder components induces its elongation and greatly reduces its strength (Table 1). Consequently, in the making of PCM from chemical fibres, it is necessary to take into account the influence of the binder on the structure and properties of the fibres and to select the appropriate resin–fibre pairs and formation parameters, being guided by the principles formulated by Mashinskaya[3] and Artemenko,[15] which make it possible to bring out most fully the strength properties of reinforced fibres.

Table 1. The change in the strength and elongation of PAN fibres after their treatment with the epoxide oligomer and polyethylene polyamine.

Binder components	Change in properties on heat treatment, %			
	80 °C; 0.25 h		100 °C; 3 h	
	strength	elongation	strength	elongation
ED-20	+8.5	0	−46	+58
PEPA	+1.6	−7.9	−22	+53

III. The structure and physicomechanical properties of polymeric composite materials

1. The influence of polyacrylonitrile fibres on the hardening of polymeric binders

A characteristic feature of PCM reinforced with polymeric fibres is the presence of a diffuse transition layer on the polymeric binder—polymeric fibre interface, arising as a result of the different rates of diffusion of the components of the binder into the amorphous and crystalline sections of the fibres.[5,7–10]

The structure and properties of this layer differ from those of the PCM component. Their different structural organisations are characterised by different molecular mobilities, which is reflected in the rates of relaxation processes.

For example, it has been shown[26] that new levels of structural organisation arise in the bulk phase of an organoplastic based on very strong organic fibres and the epoxyphenol binder. Their molecular mobility is manifested by α'_1- and α'_2–relaxation processes in the region of 453 and 503 K respectively (Fig. 1). The manifestation of a multiplicity of relaxation processes in organoplastics is caused, according to the authors, by the presence of four macroscopic structural organisation levels associated with the binder in the bulk phase of the plastic and in the region remote from the surface of the fibre (α_1), with the binder at the surface of the fibre (α'_1), with the surface layer of the reinforcing organic fibre (α'_2) modified by the diffusing component of the binder, and with the structure of the fibre core (α_2).

Under the influence of the fibres, the conformations of the binder molecules in the transition layer differ from the conformations in the bulk of the polymer, which leads to a non-monotonic variation of the packing density of the macromolecules and going away from the interface.[10] The increase in the order of the arrangement of the epoxide oligomer under the influence of the fibre during the hardening process is confirmed by the increase in the density of the PCM from 1162 to 1319 kg m^{-2} [27] and by the presence on the surface of the fibrous filler of a macrolattice repeating its layered organisation.[25,28] Thus when the fibre is impregnated with the epoxide binder, a diffuse transition layer arises at the fibre–resin interface. The orientation of the globular resin formations at the

surface of the PAN fibre and a decrease in the size of the globules can then be clearly seen. Furthermore, on the fibre (in a unidirectional PCM) the macromolecules of the epoxide binder are oriented on the fibre surface, while in the bulk of the polymer they have a globular structure, which indicates the influence of the surface of the fibre on structure formation in the binder.

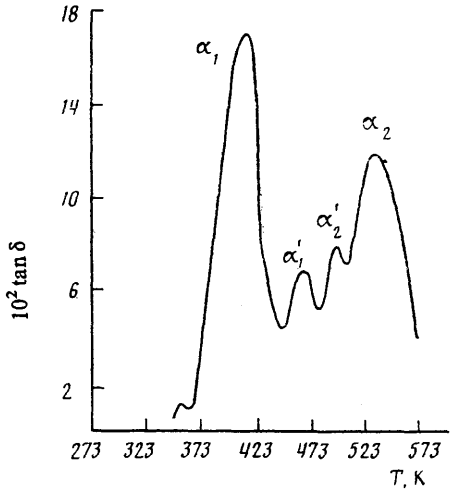


Figure 1. Temperature dependence of the mechanical losses coefficient tan δ of an organic plastic based on an epoxyphenolic binder.

Yet another cause of the formation of a transition layer is the adsorption of one component on the surface of another.[29] A change in the concentration of the cross-linking agent (PEPA) on the surface of the filler as a function of the nature of the chemical fibre has been demonstrated.[30,31] The redistribution of PEPA in the epoxide binder takes place as a result of its selective sorption by chemical fibres.

The structural changes occurring in the binder under the influence of polymeric fibres cannot fail to influence the kinetic parameters of the binder hardening process.

It has been shown[15,29–34] that the introduction of chemical fibres into polymeric binders affects the kinetics of the hardening of the latter in different ways: acetate, polypropylene, and polyamide fibres accelerate while modified viscose fibres retard the hardening process. The retarding effect of the viscose fibre on the hardening of anilinophenol-formaldehyde resin can be explained by the large surface area of the viscose fibre with active hydroxy-groups promoting the sorption of the oligomer and its fairly strong retention on the surface of the fibre. Part of the reactive groups of the oligomer blocked in this way do not participate in the formation of the three-dimensional structure, which diminishes the rate of reaction and lowers the degree of hardening of the polymer.

Lavsan and PAN have a dual effect on polymeric binders. Lavsan retards the hardening of the phenolic binder at 120–140 °C, while at 170 °C it accelerates it. The influence of the PAN fibre is determined by its content in the composition. The introduction of small amounts (up to 5 wt.%) of the PAN fibre into the epoxide binder accelerates the hardening process, while following an increase in its content to 20 wt.% and above (50 wt.%) the formation of the three-dimensional network is retarded both for the epoxide[30] and for the phenolic binders (Fig. 2). Fig. 2 shows that staple fibre exhibits the greatest inhibiting effect, which is due to its high sorption capacity (the specific surfaces of staple fibre and technical twisted cord, determined by gas chromatography, are respectively 7.4 and 4.6 $m^2 g^{-1}$).

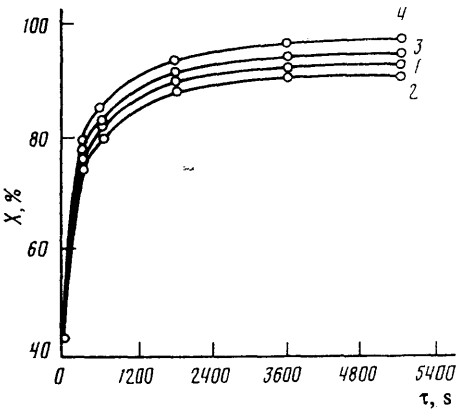

Figure 2. The influence of staple (curves *1* and *2*) and technical PAN fibre on the degree of hardening *X* of SF-342A resin: (*4*) unfilled resin; (*1*) and (*3*) PCM based on PAN fibre (50 wt.%) washed free of the lubricant; (*2*) ditto for the unwashed PCM.

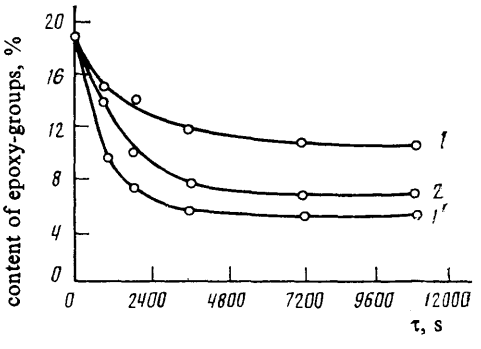

Figure 3. The influence of PAN fibre and temperature on the content of epoxy-groups in an epoxide oligomer: (*1*) and (*1'*) ED-20; (*2*) PCM based on PAN fibre (10 wt.%) [(*1*) and (*2*) at 20 °C; (*1'*) at 100 °C].

The rate and degree of hardening are also influenced by factors such as temperature and pressure.[15,24,33] An increase in temperature from 20° to 100 °C accelerates the hardening of the epoxide binder (Fig. 3). Thus the residual content of epoxy-groups 900 s after the start of the polycondensation process is 14.4% at (20 °C) and 9.8% (100 °C), while 7200 s from the start of the polycondensation process the residual contents are 11.6% (20 °C) and 5.2% (100 °C). The

introduction of PAN fibre into the composition also diminishes the content of epoxy-groups. When 7200 s has elapsed from the start of the polycondensation process, their residual content in the unfilled binder is 11.6%, while in PCM it is 6.8%, which indicates the influence of the fibre on the degree of cross-linking of the epoxide binder.

Thus, by altering the formation parameters and the amount of fibre in the composition, it is possible to regulate specifically the topological structure of the polymeric matrix and hence the properties of the PCM.

2. Methods for the modification of polymeric composite materials based on polyacrylonitrile fibres

Under the conditions of the dynamic scientific and technological development of the National Economy, the regulation of the properties of polymeric composite materials is important in order to meet to the optimum extent technological, operating, and economical requirements of industry. The properties of PCM are regulated by the formation of their specific chemical and physical structure, which is achieved by the modification, using various methods, of both the polymeric matrix and of the reinforcing filler.

Various PCM ensure a wide range of valuable properties—chemical stability, electrical conductivity, mechanical strength, etc. There is much scope for the improvement of the properties of PCM.

One of the most important factors influencing the properties of PCM is internal stresses arising both in the bulk of the binder and, especially, at the binder–chemical fibre interface, caused by the differences between the temperature coefficients of the linear expansion of the polymer and the filler and also by the contraction of the binder during the hardening process.[35,36]

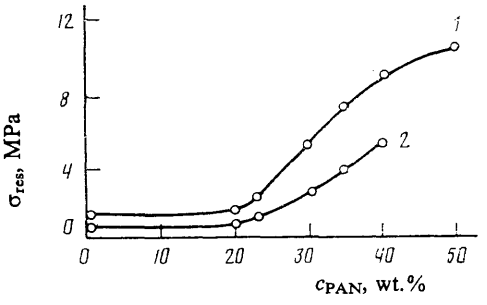

Figure 4. Dependence of the residual internal stress in the initial (curve *1*) and Thiokol-plasticised (curve *2*) composite material on the content of PAN fibre.

The residual internal stresses in the PCM reinforced with PAN fibres have been determined by the polarisation-optical method[37] on model PCM specimens containing between 0.5 and 50 wt.% of the fibre and consisting of transparent films 0.1–0.3 mm thick.

It has been established[25] that a more strained structure compared with the structure of the unfilled resin is produced in epoxide compositions under the influence of the PAN fibre: the introduction of 50 wt.% of PAN fibre into the composition increases by a factor of more than 5 the residual internal stresses [for the unfilled resin and the PCM, the internal stresses amount respectively to 1.8 and 10.3 MPa (Fig. 4, curve *1*)]. This is associated with the fact that fibres have a negative linear expansion coefficient, while the polymeric binder has a positive coefficient. The rigid compression of the fibres by the polymeric matrix prevents the free variation of the volume of the binder during its hardening.

As a rule, the introduction of different plasticisers facilitates the occurrence of relaxation processes in the polymer network being formed, which reduces the residual stresses.[38–40]

A polysulphide rubber (Thiokol) is an effective plasticiser for PCM reinforced with PAN fibre. The introduction of 15 wt.% of Thiokol into the composition makes it possible to reduce greatly the residual internal stresses (Fig. 4, curve *2*)[25] and, with increase in the content of the fibre in the composition, the influence of Thiokol on the internal stresses is enhanced.

The diminution of the residual internal stresses in the PCM following the introduction of Thiokol entails an increase in the impact and water resistance of epoxide PCM and in their strength (Table 2).[41] The phenomenon of "antiplasticisation", expressed by an increase in the bending strength (σ_b) and tensile strength (σ_t) by a factor of 1.2, in impact strength (a_{sp}) and the modulus of elasticity (E_e) by a factor of 1.5, and in elasticity ε by a factor of 1.8 is observed for such systems.[42]

Table 2. The influence of the plasticisation of the epoxide oligomer on the physicochemical characteristics of the PCM.

Plasticiser	Content of plasticiser, wt.%	Physicomechanical properties of PCM					
		σ_s, MPa	σ_b, MPa	a_{im}, kJ m^{-2}	$10^3 E_e$, MPa	ε_{rel}, %	W, %
Without plasticising agent	0	89	140	50	5.2	4.6	0.3
Dibutyl phthalate	10	60	30*	78	4.4	9.7	0.48
	20	—	60*	110	2.2	11.6	0.9
Thiokol	15	100,6	170	73	7.6	8.3	0.106

* The bending moment corresponding to the bending of the specimen by an amount equivalent to 1.5 times its thickness is presented.

The mechanism of "antiplasticisation" in network polymers, especially in unfilled epoxide binders, has been investigated.[43–46] It was established that "antiplasticisation" is the result of the simultaneous alteration of the structure and properties of the matrix and the plasticiser associated with their compaction, which in fact improves the mechanical and other properties.

For PCM reinforced with PAN fibre and plasticised with Thiokol, the increase in strength characteristics and the decrease in water absorption may be associated with the formation in the individual units of the three-dimensional structures of flexible transverse bridges, which promotes the formation of a more close-packed and less strained structure:

$$2R{-}CH{-}CH_2 + HS{-}R'{-}SH \rightarrow R{-}\underset{OH}{CH}{-}CH_2{-}S{-}R'{-}S{-}CH_2{-}\underset{OH}{CH}{-}R.$$
(the first epoxide group: $R{-}CH(O)CH_2$)

As a result, a better compatibility of such polymeric matrix with the fibre is ensured and the operational effectiveness of the PCM as a whole is improved. This is also indicated by the character of the

break. The plasticised material breaks without the separation of the reinforcing component and of the polymeric matrix at high loads (101 MPa) and for large elongations (8.3%), whereas the usual PCM gives rise to a serrated break for lower loads (90 MPa) and elongations (4.6%).

In the plasticisation with Thiokol of PCM reinforced with caproic thread, an increase in the modulus of elasticity and in strength was not observed.[47] On the contrary, in this case the classical plasticising effect was noted, being manifested by an increase in impact strength and in the relative elongation on rupture and by a decrease in the modulus of elasticity.

Thus the plasticising effect of Thiokol in PCM reinforced with chemical fibres is manifested in different ways depending on the nature of the reinforcing fibres.

The method involving modification with small amounts of additives of different chemical nature has been used in recent years for the specific regulation of the properties of various polymers.[49–59]

The modification of polymers by acting specifically on structure formation processes as a rule extends only over the region of physical transformations and all positive effects are achieved as a result of the change in the character of the intermolecular interaction.[53]

The modification of a PCM reinforced with PAN fibre by the introduction of the optimum (2 wt.%) amount of an alloying additive — oligo-oxypropylene glycol (OOPG) — makes it possible to increase the bending strength of the PCM by 50%, the impact strength by 40%, and the tensile strength by 20% (Fig. 5). The alloying additive, which increases the mobility of the polymer chains, stimulates their closer packing, as a consequence of which the free volume diminishes and the viscosity of the system rises.

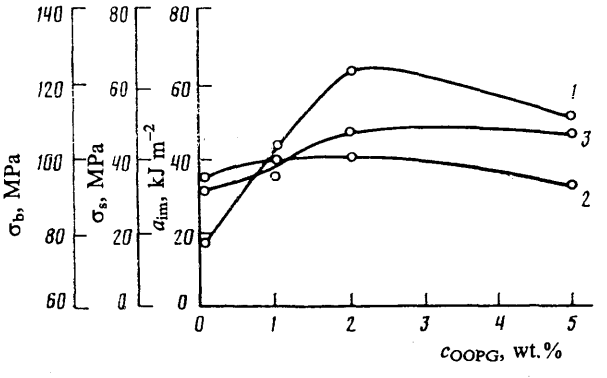

Figure 5. Dependence of the bending (σ_b) (curve *1*) and stretching (σ_s) (curve *2*) breaking stresses and of the impact strength (a_{im}) (curve *3*) of the composite material on the content of the alloying additive.

The increase in the viscosity of the system under the influence of the alloying additive is indicated by the fact that the capacity of the modified oligomer for wetting (determined by the capillary rise method[53]) is impaired.[25]

Furthermore, PCM containing 2 wt.% of oligooxypropylene glycol swells much less in acetone compared with the initial material: the equilibrium degrees of swelling of the modified and unmodified PCM are 15 and 225 mg g^{-1} respectively.

The results obtained show that the modification of PCM reinforced with PAN fibre and small amounts of added organic substances, in particular oligooxypropylene glycol, makes it possible to increase the strength of the material, probably as a result of the better compatibility of the polymeric matrix and the reinforcing fibre.

One of the disadvantages of PCM based on PAN fibres is high combustibility, which limits their applications in branches of industry such as aeroplane construction, building, etc.

The possibility of reducing the combustibility of PCM based on PAN fibres by introducing into them a ternary system comprising bromine-, chlorine-, and phosphorus-containing compounds has been demonstrated.[53] It was established that the efficiency of the modifying additives (combustion inhibitors) is greater if they are introduced into the reinforcing fibre and not into the polymeric binder.

The decrease in the combustibility of such PCM leads to additional possibilities for their use in various branches of industry. Different inorganic additives, in particular antifriction and other additives (graphite, carbon black, molybdenum disulphide, metal powders, etc.) are used nowadays to modify PCM in order to impart to them specific properties.[55,56] However, in most cases the introduction of disperse carriers lowers the strength of the compositions.[57] One of the ways of simultaneously increasing the strength and of improving the antifriction properties of polymeric materials for the manufacture of various sliding components involves the use of hybrid compositions containing both fibrous and disperse fillers.[58] The modification of polymeric materials by such hybrid compositions impart to the PCM a series of new specific properties and the cost of the material is also reduced. Thus the introduction of antifriction additives (molybdenum disulphide and graphite) into the PCM based on PAN fibres in an amount up to 5% not only reduces the coefficient of friction μ but also increases the hardness and bending strength of the material[59] (Table 3). Table 3 shows that the replacement of flaky graphite by highly disperse graphite leads to an additional reduction of the coefficient of friction of the PCM and to an increase in its strength and hardness.

Table 3. Dependence of the coefficient of friction and the physicomechanical properties of the PCM on the type and content of additives.

Additive	Content, wt.%	Physicomechanical properties of PCM			μ
		σ_b, MPa	σ_s, MPa	N_B, MPa	
Initial PCM	0	87	67	28	0.25
Molybdenum disulphide	1	103	54	36	0.18
	3	98	53	38	—
	5	83	50	40	—
Flaky graphite EUT-1	1	99	59	30	0.21
	5	72	62	35	0.20
	10	50	56	38	0.18
Highly dispersed graphite	1	132	—	41	0.14
Acetylene carbon black	1	80	64	—	0.2
	5	84	57	—	0.12
	10	57	48	—	0.13

Although a further increase in the content of antifriction additives in PCM (> 5 wt.%) does in fact reduce the coefficient of friction of the materials, yet at the same time it increases the porosity of the PCM and leads to a decrease in their strength.[59,60]

The antifriction properties of PCM reinforced with PAN fibre depend on temperature. On heating such PCM, the coefficient of friction passes through a maximum (Fig. 6) and the maximum value of the coefficient of friction is observed in the region of the glass point of the polymer (100 °C). (Tests were carried out at a slip rate of 7.5×10^{-3} m s^{-1} and a pressure of 1.5 MPa.) This can be explained by the decrease in the hardness of the material, which increases the area of the actual contact. The hardness of the PCM, both initial and of the material containing 1% of molybdenum disulphide, decreases by 76 and 64% respectively on heating to 100 °C.

The fibres present in the surface layer of the specimen exhibit an additional resistance to friction, which is associated with the transition of the PAN from the vitreous to the highly elastic state. Further increase in temperature leads to an appreciable local overheating of the friction surface, entailing partial degradation of the polymer, as a result of which a charred film is produced, playing the role of a lubricant which reduces the coefficient of friction.

PCM containing graphite behaves differently on heating: on raising the temperature, the coefficient of friction hardly changes (Fig. 6, curve *4*). In all probability, the introduction of even small amounts of graphite (in the given instance 1%) promotes the formation on the friction surface of a layer of graphite, which plays the role of a lubricant.

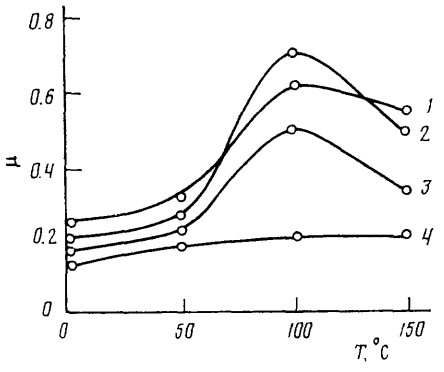

Figure 6. Temperature dependence of the coefficient of friction: (1) initial composite material; (*2*) and (*3*) composite material with molybdenum disulphide [(*2*) reinforcing fibres perpendicular to the friction surface; (*3*) reinforcing fibres parallel to the friction surface]; (*4*) composite material with graphite.

One of the promising aspects of the development of PCM is the creation of hybrid materials, i.e. blends containing three or more components of different chemical composition.[2,61,62] By combining fibrous fillers of different chemical nature, it is possible to obtain PCM with a high resistance to fatigue and the required anisotropy of the properties—in other words it is possible to create materials with the planned properties. The use of polyfibrous fillers makes it possible to obtain materials with the optimum combination of mechanical characteristics, which cannot be achieved in a monoreinforced PCM.

PCM based on inorganic and organic highly modular fibres have been most thoroughly investigated. Questions concerning the classification of the structures, the decomposition mechanisms, and the prospects for the development of such PCM have been described in reviews.[58,62]

One of the features of hybrid PCM is the presence of a hybrid (synergistic) effect. The introduction into PCM reinforced with PAN fibre of viscose (VF) and caproic (CF) fibres, differing from the PAN fibre by their strength and rigidity, makes it possible to reduce the brittleness of the material.

Polyfibrous compositions have been obtained by the joint impregnation of threads of different chemical nature with the binder. The threads were subsequently cut up.

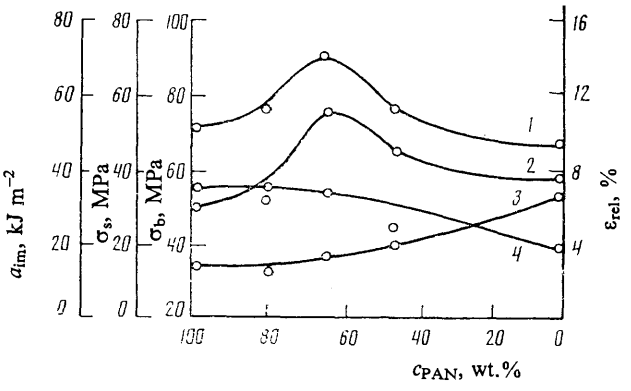

Figure 7. Dependence on the bending (curve *1*) and stretching (curve *4*) breaking stresses, the impact strength (curve *2*), and the relative elongation on rupture (curve *3*) on the ratio of the PAN and caproic fibres in the hybrid filler.

Table 4. Weight losses by hybrid PCM during dynamic heating.

Ratio of PAN and viscose fibres in hybrid filler, wt.%	Weight losses (%) at different temperatures			
	300° C	360° C	400° C	500° C
100:0	10	14	17	25
75:25	12	19	23	32
50:50	14	24	28	38
38:62	13	26	30	41
0:100	35	40	49	59

In the manufacture of polyfibrous compositions based on a mixture of PAN and caproic fibres, the strength of the fibres is not of decisive importance:[63] PCM reinforced with the stronger caproic fibre (62 cN tex^{-1}) has smaller bending and tensile strengths than PCM based on the weaker (41 cN tex^{-1}) PAN fibre as a result of the difference between the elastic properties and the coefficients of thermal expansion of the fibres and the polymeric matrix (Fig. 7).

The combination of these fibres in the PCM in proportions of 65:35 (wt.%) increases appreciably the resistance of the PCM to bending and impact as well as its elasticity. The appearance of a synergistic effect is then observed: the experimental bending and impact strengths of the PCM exceed the additive values on average by 40 and 70%.

A synergistic increase in strength (Fig. 8) and thermal stability (Table 4) has also been noted for polyfibrous compositions containing viscose and PAN fibres taken in equal amounts (50 wt.%) as the reinforcing system: the experimental bending strengths of the PCM exceed by 20% the additive values, while the weight losses, determined by thermogravimetric analysis, exceed the additive values by 5–10%.

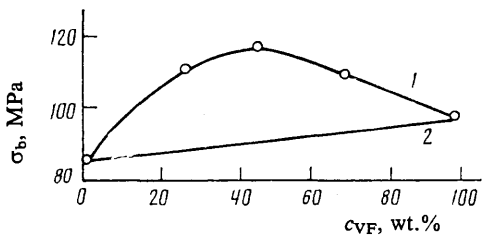

Figure 8. The synergistic increase in the bending strength of the composite material reinforced with a mixture of PAN fibres and viscose thread: (*1*) experimental curve; (*2*) additive curve.

In the preparation of hybrid PCM, the scheme employed for the reinforcement of the polymer matrix with the polyfibrous filler is very important. For example, when fabrics made up of chemical fibres of different chemical nature were impregnated separately with the binder and were subsequently arranged in alternate layers in the composition, the appearance of a synergistic effect was not observed regardless of the type of binder (Table 5).

Table 5. Dependence of the properties of the PCM on the ratio of different fibres in the hybrid filler (on the basis of fabric sheets).

Binder	Ratio of PAN and viscose fibres (wt.%)	Physicomechanical properties of PCM			
		σ_b, MPa	σ_s, MPa	a_{im}, kJ m^{-2}	ε_{rel}, %
Epoxide	100:0	114	58	20	3.8
	50:50	142	88	30	7.0
	0:100	178	130	50	10.2
Phenolic	100:0	104	62	12	4.0
	50:50	119	87	25	5.0
	0:100	190	138	6	—

Thus the combination of PAN fibre with other chemical fibres differing from it in strength and elastic properties makes it possible to increase bending and impact strengths of PCM by 30–40% and their thermal stability by 15–30%.

The fact that the PCM reinforced with PAN fibre combined with viscose fibre has a lower density and a higher resistance to water compared with the PCM reinforced with the viscose fibre alone is fairly important.

A vigorous search has been prosecuted in recent years for new polymeric materials with a high electrical conductivity. Electrically conducting plastics are obtained either by synthesising polymers containing free or mobile electrons, responsible for the semiconducting properties of the plastics, or by introducing electrically conducting additives into polymers.[57] Both powdered and fibrous electrically conducting fillers are usually employed: carbon black, metallic powders, metallic fibres, metallised glass fibre, carbon fibre, etc.[56,57,65,66] However, in order to ensure sufficiently effective electrically conducting properties of the PCM, it is necessary to introduce into the composition an appreciable amount (30–55 wt.%) of a powdered additive, which usually weakens the mechanical properties of the PCM. The introduction into the composition of the PCM of additional carbon and other fibres eliminates this disadvantage but increases significantly the cost of the material (for example, the cost of carbon fibres amounts to between 20 and 200 dollars per kilogram[57]).

A promising aspect of the manufacture of antistatic and electrically conducting PCM involves the introduction into the binder of a fibrous reinforcing filler modified by the method in which metal salts are included (metal salts are incorporated into the structure of the freshly formed fibres).[67,68]

The PCM fibres modified by the inclusion of nickel salts with their subsequent reduction, which ensures a uniform distribution of nickel in the fibre, make it possible to obtain PCM which are fairly strong and have fairly high electrical conductivities in the presence of a very small (2–3 wt.%) metal content.[69]

Table 6. Comparative properties of composite materials based on normal and nickel-containing PAN fibres.

Properties	PAN fibre	
	initial	nickel-containing
Strength of fibre, cN tex^{-1}	22	23
Breaking stress (MPa) in		
bending	110	120—130
stretching	59	54
Impact strength, kJ m^{-2}	16	18
Bulk-phase electrical resistivity, Ωm	$1.9 \cdot 10^{11}$	$4.4 \cdot 10^{6}$
Tangent of dielectric losses angle	0.43	0.004
Electrical strength, kV mm^{-1}	15	3

Thus the introduction of a nickel-containing PAN fibre into an epoxide binder increases the electrical conductivity of the PCM (Table 6). The bulk phase resistivity of such PCM is then reduced compared with the unmodified material by a factor of 10^5 (from 1.9×10^{11} to 4.4×10^6 Ωm), the electrical strength diminishes by a factor of 5, and the tangent of the dielectric losses angle increases by a factor greater than 2. The physicomechanical properties of the modified PCM are then not impaired and a 25% increase in the bending strength is actually observed. The increase in the electrical

conductivity of the PCM indicates the current conducting role of nickel distributed in the fibre in the form of a polyatomic layer. With increase in the weight fraction of the modified fibre in the PCM and also with increase in the nickel content in the fibre structure, the electrical conductivity of the PCM rises as a result of the increased content of the current-conducting component (Table 7). The bulk phase resistivity of the PCM containing 50 and 60 wt.% of the nickel-containing fibre is 4.4 × 10^6 and 8.5 × 10^5 Ωm respectively. The same parameters for the PCM containing fibre with 2.5 and 3.2 wt.% of nickel and respectively 8.5 × 10^5 and 7.1 × 10^3 Ωm.

The dependence of the decrease in the bulk phase resistivity of the PCM on the content of the current-containing component can be explained from the standpoint of the theory of chain conductivity,[65,66] according to which the electrical conductivity is ensured by the significantly greater number of contacts between the electrically conducting elements.

Table 7. Dependence of the electrical properties of the PCM on the content of the nickel-containing fibre (nickel content in fibre 2.5 wt.%).

Content of PAN fibres in PCM, wt.%	Properties of PCM		
	ρ_v, Ωm	E_{br}, kV mm^{-1}	tan α
40	$1.2 \cdot 10^{10}$	7	0.075
50	$4.4 \cdot 10^{6}$	3	0.094
60	$8.5 \cdot 10^{5}$	2	0.90
60*	$7.1 \cdot 10^{3}$	—	—

*The fibre contains 3.2 wt. % of nickel.

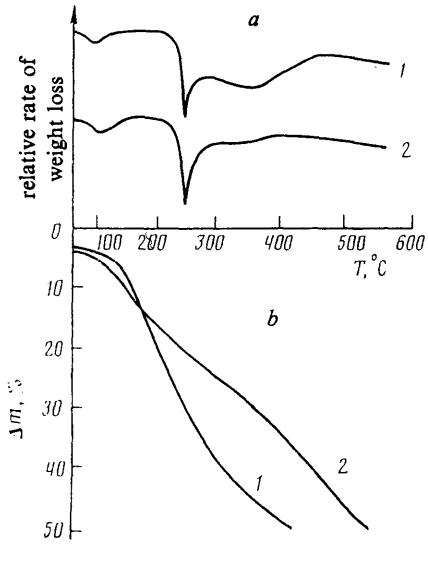

Figure 9. Thermogravimetric analysis of PCM based on the initial (curve *1*) and nickel-containing (curve *2*) PAN fibre: (*a*) relative rate of weight loss; (*b*) weight loss.

Under the influence of the nickel-containing PAN fibre, a more thermally stable PCM structure is formed: the mechanism of the degradation of the modified material is different from that of the initial material and is characterised by the presence of a single peak at 272 °C, whereas the presence of two maxima on the weight loss rate curve is characteristic of the unmodified PCM—at 260° and 348 °C (Fig. 9*a*).[25]

The introduction of nickel into the structure of the PAN fibre increases the stability of the PCM in relation to thermooxidative degradation: the weight losses by the modified PCM are appreciably lower at all temperatures above 160 °C than the weight losses of the initial material (Fig. 9*b*). This is also indicated by the greater stability of the strengths of the PCM after the exposure to different temperatures: the residual strengths of the unmodified and modified PCM after heating the latter for 7 h at 200 °C are respectively 65 and 83% (Fig. 10).

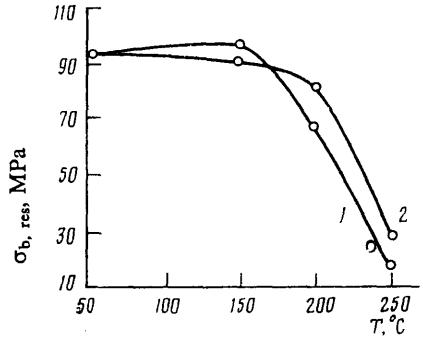

Figure 10. The change in the residual bending strength of the PCM based on the initial (curve *1*) and inclusion-modified (curve *2*) nitron after heating.

On the basis of the data obtained, the PCM reinforced with nickel-containing PAN fibre can be classified as a member of the group of antistatic materials,[65] which can be used to prepare current-conducting elements and also as a facing material for the covering of walls and ceilings.

3. The influence of external media on the properties of polymeric composite materials

The introduction of fibre-fillers into PCM affects not only the character of the structure formation in the filled polymer but also its behaviour on exposure to different external influences. When PCM come into contact with corrosive liquids and their vapours, the latter penetrate into the material owing to the presence of structural defects and the properties of the reinforcing fibres and of the polymeric matrix. Such penetration is accompanied by a change in the weight and strength of the material.

Thus when PCM reinforced with viscose fibre is treated with a reagent capable of inducing appreciable changes only in the polymeric matrix (acetone), the decrease in the strength of the composition is determined by the structure and properties of the three-dimensional network and the hardened polymeric binder.[70]

When PCM is exposed to water, the change in its strength is now limited by the behaviour of the fibres, since the strength of the polymeric matrix, determined by the character of the three-dimensional network, hardly changes under these conditions.

The reinforcement of PCM with hygroscopic viscose fibre, which has a porous surface, leads to appreciable swelling of the PCM in water and to a change in its strength: the decrease in the bending strength and the increase in the mass of the PCM specimens after exposure to water for 1000 h are respectively 30% and 58.3 mg g^{-1}.[7] The modification of the surface of viscose fibre by the chemical grafting of polystyrene, which reduces its sorption capacity, increases the resistance of the PCM to the action of corrosive media.[71]

The same effect is observed when PCM is reinforced with hydrophobic fibres. For example, in phenolic compositions based on kapron and lavsan, the increase in the mass of the material is much smaller than in the PCM reinforced with unmodified viscose fibre.[72]

Table 8. The change in the weight of the specimens after treatment with corrosive media.

Composite material	Medium			
	H_2O	CCl_4	3% H_2SO_4	1% NaOH
Epoxide	−1.4	0.2	−7.5	−1.9
Phenolic	0.4	0.02	0.5	0.4

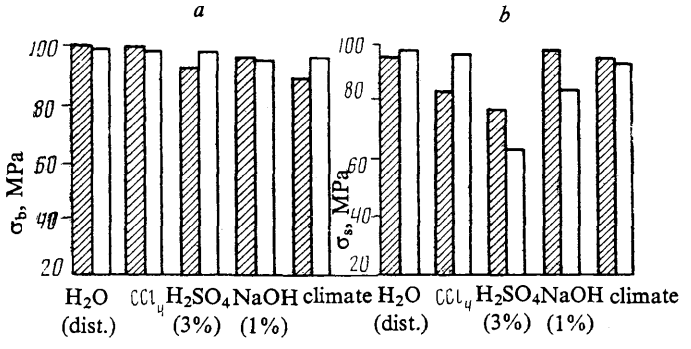

Figure 11. The residual bending strength (*a*) and tensile strength (*b*) of epoxide (shaded columns) and phenolic (unshaded columns) PCM after treatment with corrosive media.

The exposure of PCM based on PAN fibre for a long time (120 days) to corrosive media does not induce an appreciable change in the mass and strength of the specimens (Table 8, Fig. 11). Sulphuric acid is an exception, its action reducing the mass of the epoxide PCM by 7.5% (as a result of some decomposition) and its tensile strength by 22%. The effect of sulphuric acid on phenolic PCM reduces its tensile strength by 36%.

Carbon tetrachloride and dilute alkali do not induce an appreciable change in the strength, mass, and external appearance of such PCM.

The effect of natural climatic factors (climate) during the same period reduces only slightly the strength of the PCM (by 5–10%) (Fig. 11), but there are no changes in the linear dimensions, mass, and external appearance of the specimens under these conditions.

Thus the behaviour of PCM (reinforced with chemical fibre) on treatment with various corrosive media is determined by a whole series of factors, the most important of which are the nature of the fibre and the structure of the PCM surface and also the nature of the binder.

IV. The possible applications of polymeric composite materials

The composite material based on PAN fibre has effective technological properties: the rate of spreading of the moulding material and the fluidity (thickness of the disc), determined by the method of Dyukhin and Stavrov,[73] are respectively 0.25 mm × s^{-1} and 1.6 mm.[74] Articles made from this material have a pleasant external appearance and a shiny surface and can be subjected to all kinds of mechanical treatment: milling, drilling, turning, polishing, etc.

The PCM which have been developed have a set of specific properties: an increased resistance to bending and impact loads, a low density, a fairly high atmospheric and chemical stability, an improved thermal stability, and antifriction properties.

The results obtained show that it is useful to employ PCM based on PAN fibre in chemical machine construction and also as building materials for the protection of constructions against corrosion.

In the building industry, PCM are used to prepare facing materials and sanitary-technical articles, in particular, for the manufacture of various connecting components used in the assembly of pipelines. Articles made of PCM have a number of advantages over metallic articles. These include primarily corrosion resistance and low density.

Industrial tests on facing plates made of PCM reinforced with PAN fibre demonstrated the possibility of using them to cover industrial environments.

No changes in the physicomechanical characteristics of the PCM and its external appearance on treatment with water and acetic acid vapour were observed during the tests.

A modified PCM containing graphite (1%) can be usefully employed as an antifriction material. Tests on experimental specimens (inserts in slip bearings) showed that metal-PTFE inserts can be usefully replaced by inserts made from antifriction PCM. The intrinsic cost of the components is then reduced and their useful operating life is increased. In addition, the possibility of employing PCM with added graphite in dry friction components makes it possible to abandon the use of scarce and expensive lubricating materials.

The PCM which have been developed, reinforced with PAN fibres, can be recommended for the manufacture of components and constructions withstanding impact loads, for example, for the manufacture of the shells of shuttles in looms.

Industrial tests on experimental specimens demonstrated that PCM reinforced with chemical fibres are economical and their application is technically and socially useful. In the first place the intrinsic cost of the material is reduced and in the second it is possible to replace the natural fibres which are still used in technical applications as reinforcing fillers for PCM, for example in the manufacture of blades for looms, textolite, etc.

A polymeric composite material based on nitron, which has effective strength properties, is susceptible to manufacture by modern technology, has a pleasant external appearance, and can be used as a constructional material for the manufacture of various components.

Tests have demonstrated that PCM based on PAN fibre can be usefully employed for the manufacture of bowls for fuel filters. The bowls made from the PCM are light and strong, are oil and petrol resistant, and can successfully replace containers made from metal and AGH-4V material.

β-Fluoro-substituted aminoacids

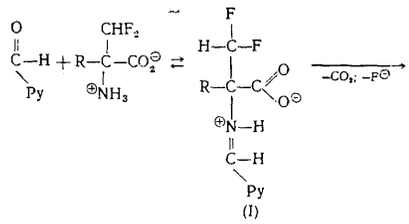
V P Kukhar', Yu L Yagupolskii, V A Soloshonok

ABSTRACT. The review gives a systematic account of data concerning the methods of synthesis of α-, β-, and γ-aminoacids containing fluorine atoms in the β-position relative to the amino-group. The interest in these compounds is in many respects due to the fact that most of them have proved to be highly selective irreversible inhibitors of pyridoxal-5-phosphate-dependent enzymes acting via the "suicide-substrate" mechanism. Attention is concentrated on β-fluoro-derivatives of natural α-aminoacids.

The bibliography includes 114 references.

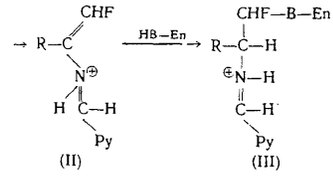
Contents

I. Introduction 89
II. Classical methods of synthesis of β-fluoro-substituted aminoacids 90
III. Special methods of synthesis of β-fluoro-substituted aminoacids 93
IV. Conclusion 100



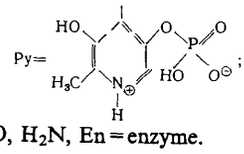
I. Introduction

Even if one disregards the unique importance of aminoacids in the initiation of life on Earth, compounds of this class possess a sufficient number of biological functions to be placed in the forefront of substances without which living organisms could not exist. The synthesis of aminoacids and their organoelement analogues therefore constitutes a most important aspect of modern bioorganic chemistry concerned with the creation of new medicinal preparations and fine biochemicals.



The vigorous development of organofluorine compounds after the 1940s and certain advances in the use of fluorinated analogues of natural products have created objective grounds for the initiation of vigorous research into fluorine-containing aminoacids. At the present time these compounds are one of the most promising types of low-molecular-weight bioregulators.[1]

Analysis of a considerable amount of data on the biological activity of fluoro-substituted aminoacids made it possible to differentiate in the first place compounds which are highly selective irreversible inhibitors of enzymes with the pyridoxal phosphate group, such as aminoacid racemases, transaminases, and decarboxylases. A common structural feature of substances exhibiting the properties of inhibitors of this type was found to be the presence of fluorine atoms in the β-position relative to the amino-group.



On the basis of numerous studies undertaken to explain the biochemical activity of β-fluoro-substituted aminoacids, a mechanism has been proposed[2–4] whose idea is that the enzyme itself synthesises the substance inhibiting it—the "suicide-substrate". Thus in the case where the substrate of decarboxylase is a β-fluoro-α-aminoacid, the reversible formation reaction of the Schiff base (I) is followed by the irreversible decarboxylation stage with elimination of the fluorine atom from the β-position and the formation of the Michael acceptor (II). The latter reacts with the nucleophilic groups of the enzyme located near the active centre. This reaction is irreversible; the enzyme, bound covalently to the aminoacid residue (III), loses its ability to interact further with the substrate and is deactivated.

(I)

(II) (III)

HB = HO, H_2N, En = enzyme.

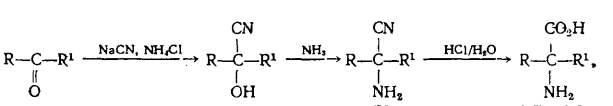
The deactivation of transaminases or racemases by β-fluoro-substituted aminoacids also proceeds via an elimination stage or a stage involving activation with respect to the nucleophilic substitution of the fluorine atom with the subsequent chemical binding of the aminoacid residue to the nucleophilic centre of the enzyme. The suppression of the enzymic reaction via the mechanism described above leads to the appearance of bactericidal and other types of biological activity in β-fluoro-substituted aminoacids.[5,6]

The determination of the biochemical mechanism of the inhibition of enzymes by β-fluoro-derivatives of aminoacids has greatly stimulated studies on these compounds.

The syntheses of β-fluoro-substituted aminoacids achieved hitherto are various from the standpoint of both the methods and the initial compounds employed. However, certain types of aminoacids have been obtained using mainly the methods of organic or organofluorine chemistry. This made it possible to differentiate in this review two main sections: the classical and special methods of synthesising β-fluoro-derivatives of aminoacids.

The reviews available in the literature[7,8] deal with the methods of synthesis of all types of fluorine-containing aminoacids, including β-fluoro-derivatives, published up to 1968. Later publications[9–11] deal with the methods of synthesis and biological activity of only

individual types of β-fluoro-substituted aminoacids, for example, such as α-polyfluoromethyl-substituted aminoacids. The present review surveys studies on the synthesis of α-, β-, and γ-aminoacids containing fluorine atoms in the β-position relative to the amino-group, carried out mainly during the last twenty years, earlier sources being referred to when necessary.



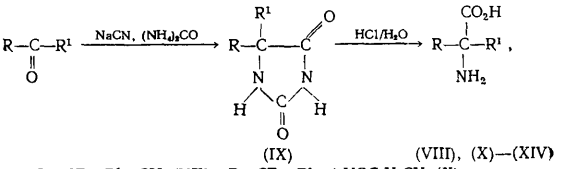
Data on the biological activity of the compounds examined are quoted only in those cases where in the sources referred to the biological activity of the aminoacids is reported together with their synthesis. A number of reviews have been devoted to the biological properties of β-fluoro-substituted aminoacids.[3,4,9–12]

II. Classical methods of synthesis of β-fluoro-substituted aminoacids

Almost all the known methods of synthesis of non-fluorinated aminoacids have been used to obtain their fluorinated analogues. However, only a few of these methods proved to be preparatively valuable and remained of current interest up to the present time. The applicability of the classical methods of synthesis of aminoacids to the series of fluorine-containing compounds is limited by the specific influence of fluorine or perfluoralkyl groups as a result of which many reactions may alter their character during the synthesis. The influence of fluorine atoms next to reaction centres is especially marked. The classical methods have therefore found only limited applications in the synthesis of β-fluoro-derivatives of aminoacids.,

1. Synthesis of β-fluoro-derivatives of aminoacids from fluorine-containing carbonyl compounds

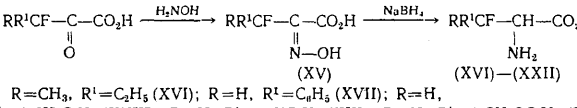
The Strecker synthesis of aminoacids was one of the first used to obtain mono- and di-fluoroaminoacids. However, in contrast to the non-fluorinated ketones, the reactions mainly stop in the first stage—the formation of the corresponding cyanohydrins (IV). Thus a mixture of nitriles of 3-fluoro-2-hydroxyisobutyric and 3-fluoro-2-aminoisobutyric acids in proportions of 13:87 has been obtained from monofluoroacetone, while 3,3′-difluoro-2-hydroxyisobutyric acid has been obtained as the only reaction product from 1,3-difluoroacetone.[13,14]



R=CH_2F, $R^1=CH_3$ (VI); $R=R^1=CH_2F$ (VII).

In order to obtain aminoacids, the cyanohydrins (IV) were converted by treatment with ammonia into the aminonitriles (V), from which mono- and di-fluoro-derivatives of α-aminoisobutyric acid (VI) and (VII) were obtained by acid hydrolysis.

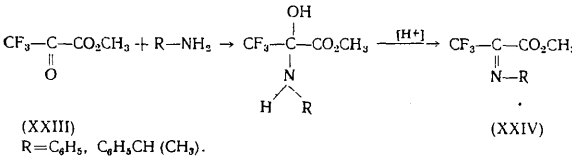
3,3,3-Trifluoro-α-aminoisobutyric acid (VIII) was obtained from 3,3,3-trifluoroacetone via a stage involving the formation of 5-methyl-5-trifluoromethylhydantoin (IX), whose yield was 23%.[15]



A series of α-trifluoromethylphenylalanines (X)–(XII) have been obtained by the same methods from the corresponding fluorinated ketones. The yield of the hydantoins (IX) formed initially did not exceed 50%.[16] Compounds (X)–(XII) can be used to regulate the level of noradrenalin.

R=CF_3, $R^1=CH_3$ (VIII); R=CF_3, R^1=4-$HOC_6H_4CH_2$ (X);
R=CF_3, R^1=3, 4-$(OH)_2C_6H_3CH_2$ (XI); R=CF_3,
R^1=3, 4, 5-$(OH)_3C_6H_2CH_2$ (XII);
R=CHF_2, R^1=4-$HOC_6H_4CH_2$ (XIII); R=CH_2F,
$R^1=HO_2C(CH_2)_2$ (XIV).

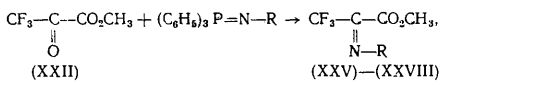
The introduction of ketones containing less electron-accepting mono- and di-fluoromethyl groups into the Bucherer reaction affords the hydantoins (IX) in higher yields. α-Difluoromethyltyrosine (XIII)—an effective hypotensive preparation[17]—and α-fluoromethyl-glutamic acid (XIV)—an irreversible inhibitor of glutamate decarboxylase[18]—were also obtained by this method.



A widely used method of synthesis of aminoacides and amines, based on the reduction of compounds with a C=N bond, has also been employed to synthesise β-fluoro-derivatives of aminoacids. A disadvantage of this method is the low availability of β-fluoro-α-keto-acids. Fluorine-containing ketoacids were introduced into the reaction with hydroxylamine and the corresponding aminoacids were obtained by the subsequent reduction of the oximes (XV) formed. β-Fluoroisoleucine (XVI),[19] a series of β-fluorophenylalanines (XVII)–(XXI), exhibiting antimicrobial and anticancer activities,[20,21] as well as ββ-difluoroaspartic acids (XXII), which is an irreversible inhibitor of aspartate aminotransferase,[22] were obtained by this procedure.

R=CH_3, $R^1=C_2H_5$ (XVI); R=H, $R^1=C_6H_5$ (XVII); R=H,
R^1=4-$CH_3C_3H_4$ (XVIII); R=H, R^1=4-ClC_6H_4 (XIX); R=H, R^1=4-$CH_3OC_6H_4$ (XX);
R=H, R^1=4-$O_2NC_6H_4$ (XXI); R=F, $R^1=HO_2C$ (XXII).

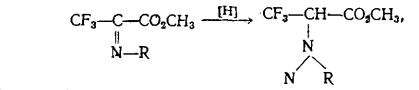
The stereochemical aspects of the formation of *erythro*- and *threo*-β-fluorophenylalanines (XVII)–(XXI) during the reduction of the oximes (XV) have also been investigated in a series of studies[21,23,24] and it has been shown that mainly the *erythro*-isomers of β-fluoro-substituted aminoacids are obtained.



A method of synthesis of trifluoroalanine and of a series of its *N*-alkyl- and *N*-aryl-derivatives from the readily available methyl trifluoropyruvate (XXIII) have been developed recently.[25] The corresponding imines cannot be obtained by the direct interaction of the ketoester (XXIII) with ammonia or amines. An exception is provided by α-phenylethylamine and aniline, whose adducts with the ketoester (XXIII) are dehydrated in the presence of acid catalysts to the corresponding imines (XXIV).

(XXIII)
R=C_6H_5, $C_6H_5CH(CH_3)$.

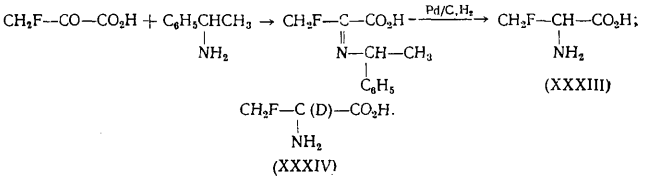
(XXIV)



The most general method of synthesis of imines of methyl trifluoropyruvate is the Staudinger reaction, which makes it possible to obtain the imines (XXV)–(XXVIII) in 60–95% yields.

(XXII) (XXV)—(XXVIII)

R = C_6H_5 (XXV), n-C_4H_9 (XXVI); $C_2H_5CH(CH_3)$ (XXVII), CH_3O_2C (XXVIII)



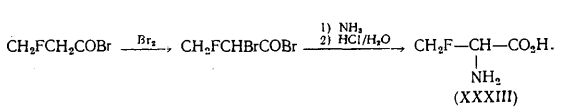
Sodium tetrahydroborate and hydrogen on palladium black have been used to reduce compounds (XXIV), (XXV), (XXVII), and (XXVIII) to the corresponding alanines (XXIX)–(XXXII), but reduction with zinc in acetic or formic acid proved to be the most convenient.

(XXIV), (XXV), (XXVII), (XXVIII) (XXIX)—(XXXII)

R = $C_6H_5CH(CH_3)$ (XXIX); C_6H_5 (XXX), $C_2H_5CH(CH_3)$ (XXXI), CH_3O_2C (XXXII).

The reduction of the optically active *N*-phenylethylimine (XXIV) with various reducing agents proceeds with a slight asymmetric induction (the ratio of the diastereoisomers is 5 : 4). However, in the case of monofluoropyruvic acid the use of the optically active L-α-phenylethylamine makes it possible to achieve the asymmetric synthesis of a highly effective antibacterial agent—3-fluoro-D-alanine (XXXIII)[26]—in accordance with the following scheme:

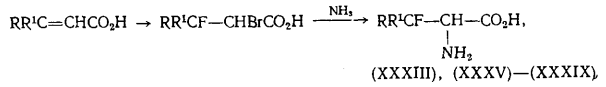
(XXXIII)



(XXXIV)

A deuteriated analogue of fluoroalanine (XXXIII)—"fludalanine" (XXXIV)—has been obtained by a similar procedure from monofluoropyruvic acid using $NaBD_4$ as the reducing agent.[27]

2. The substitution of the α-halogen atom or the α-hydroxy-group by the amino-group

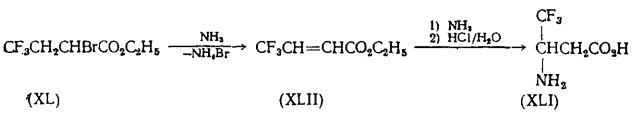


The method of synthesis of aminoacids by the introduction of an amino-group into carboxylic α-halogeno- or α-hydroxy-acids has been used successfully to synthesise a wide variety of fluorine-containing aminoacids.[7,8] However, this method proved to be applicable to the synthesis of β-fluoro-substituted aminoacids only in the case of the monofluoro-derivatives. This is associated with the fact that fluoroalkyl and especially perfluoroalkyl groups hinder nucleophilic substitution in the neighbouring carbon atom.

Thus monofluoroalanine (XXXIII) has been obtained in a low yield from the bromide of 3-fluoropropionic acid by the successive bromination and treatment with ammonia of the bromide of α-bromo-β-fluoropropionic acid formed.[28]

(XXXIII)

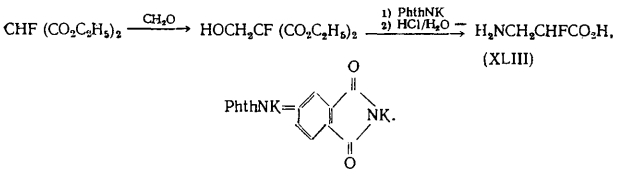
Subsequently the method was improved by employing acrylic acid derivatives as the starting compounds.[29] The coupled addition of fluorine and bromine to 3-alkylacrylic acids was carried out by treatment with *N*-bromosuccinimide in liquid hydrogen fluoride with formation of carboxylic α-bromo-β-fluoroacids. The latter were converted into the corresponding aminoacids (XXXIII), and (XXXV)–(XXXIX) in 10–63% yields by treatment with ammonia.



(XXXIII), (XXXV)—(XXXIX)

R = R^1 = H (XXXIII); R = R^1 = CH_3 (XXXV); R = H, R^1 = CH_3 (XXXVI); R = H, R^1 = C_2H_5 (XXXVII); R = H, R^1 = n-C_3H_7 (XXXVIII); R = H, R^1 = n-C_4H_9 (XXXIX).

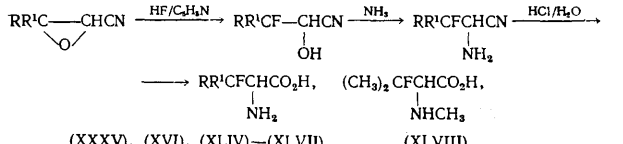
This method made it possible to increase the yield of fluoroalanine (XXXIII) and to obtain a series of new aliphatic β-fluoro-α-aminoacids with antifungal or antimicrobial activity.[29]



Instead of the expected derivative of 4,4,4-trifluoro-2-aminobutyric acid, the ammonolysis of ethyl 2-bromo-4,4,4-trifluorobutyrate (XL) afforded the β-alanine ester—4,4,4-trifluoro-3-aminobutyric acid (XLI).[30,31]

(XL) (XLII) (XLI)

It was found that, on treatment of the bromo-derivative (XL) with ammonia, hydrogen bromide is split off and ethyl trifluorocrotonate (XLII) is formed, which can be explained by the inductive effect of the trifluoromethyl group, facilitating the elimination of the proton in the β-position. In the next stage of the reaction, ammonia adds in the usual way to the β-carbon atom. The above mechanism of the formation of the β-alanine (XLI) has been confirmed by its synthesis from trifluorocrotonic acid (XLII).[32] Biological tests have shown that β-trifluoromethyl-β-alanine (XLI) possesses antibacterial activity.[32]



The synthesis of β-fluoro-derivatives of aminoacids with the replacement of the hydroxyl by the amino-group proved successful only in the synthesis of monofluoro-derivatives. α-Fluoro-β-alanine (XLIII), first isolated as a 5-fluorouracil metabolite,[33–35] has been synthesised from diethyl fluoromalonate in accordance with the following scheme:[36]

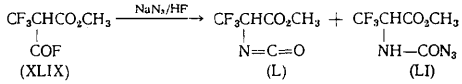
(XLIII)

α-Fluoro-β-alanine (XLIII) has been synthesised similarly from α-fluoro-β-hydroxypropionic acid.[37]

A general method of synthesis using 2-cyanoepoxides has been developed recently to obtain β-fluoro-α-aminoacids.[38]

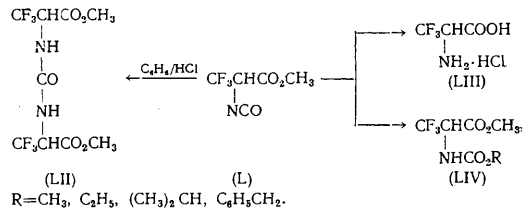
(XXXV), (XVI), (XLIV)—(XLVII), (XVII), (XXXVI) (XLVIII)

R = R^1 = CH_3 (XXXV); R = CH_3, R^1 = C_2H_5 (XVI); R = R^1 = C_2H_5 (XLIV); R = H, R^1 = C_6H_5 (XVII); R = CH_3, R^1 = C_6H_5 (XLV); R = H, R^1 = CH_3 (XXXVI); R + R^1 = $(CH_2)_4$ (XLVI); R + R^1 = $(CH_2)_5$ (XLVII).



The opening of the epoxide ring with the aid of the Olah reagent (a solution of hydrogen fluoride in pyridine) leads to a high yield of β-fluoro-α-hydroxynitriles, from which the corresponding amino-derivatives were obtained in 13–85% yield by treatment with ammonia in the presence of $MgSO_4$. Hydrolysis of these compounds afforded the free β-fluoro-α-aminoacids (XVI), (XVII), (XXXV), (XXXVI), and (XLIV)–(XLVII).

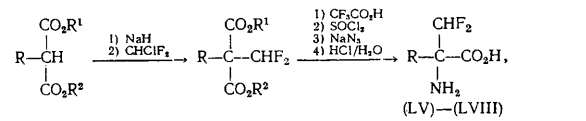
The use of methylamine in this reaction instead of ammonia made it possible to synthesise the corresponding *N*-methyl derivatives of β-fluoroaminoacids (XLVIII).[38]



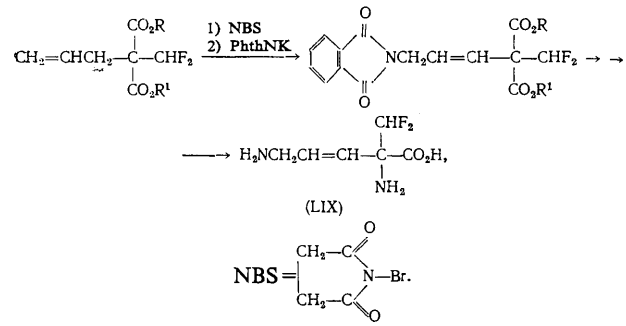
3. Other methods of synthesis of β-fluoro-derivatives of aminoacids

The conversion of the carboxy-group into the amino-group by the Curtius method has been used to obtain α-trifluoromethyl- and α-difluoromethyl-substituted aminoacids.

A method[39] based on the conversion of the fluoride of 2-methoxycarbonyl-3,3,3-trifluoropropionic acid (XLIX) has been proposed for the synthesis of trifluoroalanine. The acid fluoride (XLIX) was converted by treatment with sodium azide or trimethylsilyl azide into the corresponding isocyanate (L). When the initial acid fluoride (XLIX) contains an admixture of hydrogen fluoride, the reaction is complicated by the formation of the carbamoyl azide (LI).

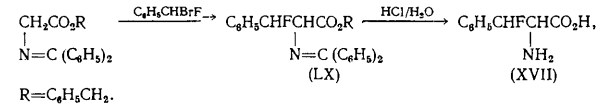


The interaction of the isocyanate (L) with water proceeds in different ways depending on the reaction conditions. Thus hydrolysis of a benzene solution of compound (L) with concentrated hydrochloric acid proceeds with formation of the symmetrical urea (LII). The hydrochloride of trifluoroalanine (LIII) has been obtained by treating the isocyanate (L) with hydrochloric acid in the absence of a solvent.



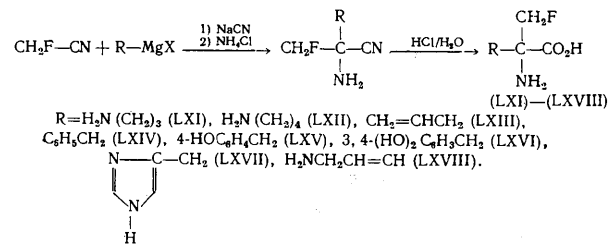
The introduction of the isocyanate (L) into a reaction with alcohols made it possible to obtain the methyl esters of trifluoroalanine (LIV) containing *N*-alkoxycarbonyl groups.

The Curtius reaction has also been used as the key stage in the synthesis of α-difluoromethyl-substituted aminoacids. Treatment of substituted malonates, having two different substituents in the ester groups, with Freon subsequently made it possible to eliminate selectively one of these substituents (OBu^t) by treatment with trifluoroacetic acid. The subsequent treatment of the intermediate acid ethyl malonates with thionyl chloride and sodium azide yielded the corresponding isocyanates, which were hydrolysed to the aminoacids without isolation.[40–42]



The difluoromethyl derivatives of aspartic acid (LV), alanine (LVI), and phenylalanine (LVII) have been obtained by this method.

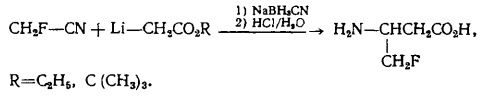
By bromination and subsequent replacement of the bromine atom by the phthalamide group, 2-allylmalonic ester has been converted into the protected δ-amino-derivative from which δ-difluoromethyldehydroornithinine (LIX)—an irreversible inhibitor or ornithinine decarboxylase—was obtained in accordance with the scheme presented above.[40]



Yet another example of the use of classical methods of synthesis of aminoacids for the preparation of their β-fluorinated analogues is the alkylation of the benzyl ester of *N*-(α-phenylbenzylidene)glycine by bromofluorophenylmethane.[43]

The Schiff base was alkylated in methylene chloride in the presence of $(C_4H_9)_4N^{\oplus}HSO_4^{\ominus}$ and the alkylated product (LX) was obtained in 71% yield. It was hydrolysed to β-fluorophenylalanine (XVII).

The involvement of carboxylic acid nitriles in reactions with organometallic reagents has been rarely used to synthesise non-fluorinated aminoacids. However, in the synthesis of α-monofluoromethyl derivatives of aminoacids, this approach proved to be a successful alternative method of the direct fluoromethylation of the C-anions of protected aminoacids, which will be examined in the next section.



The reactions of monofluoroacetonitrile with organomagnesium reagents have been carried out at −40 °C in solution in tetrahydrofuran. The imines formed under these conditions were treated, without isolation, with sodium cyanide and then ammonium chloride was added.[44,45]

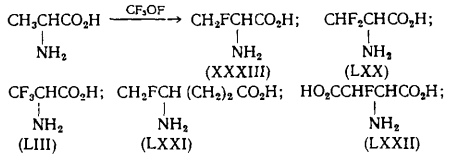
α-Monofluoromethyl-substituted derivatives of ornithine (LXI), lysine (LXII), 2-allylglycine (LXIII), phenylalanine (LXIV), tyrosine (LXV), dihydroxyphenylalanine (LXVI), and histidine (LXVII) were obtained by this method. A patent[45] states that monofluoroornithine (LXI) can be used as an effective antifertility agent.

α-Monofluoromethyldehydroornithine (LXVIII) has been obtained by introducing a functional group into 2-allyl-3-fluoroalanine (LXIII) similarly to the scheme employed for the synthesis of α-difluoromethyldihydroornithine (LX).

The application of lithium derivatives of acetate esters in the reaction of monofluoroacetonitrile made it possible to achieve the synthesis of 3-amino-4-fluorobutyric acid (LXIX)—an inhibitor of γ-aminobutyric acid transaminase.[46]

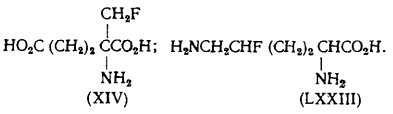
$R=C_2H_5$, $C(CH_3)_3$.

III. Special methods of synthesis of β-fluoro-substituted aminoacids



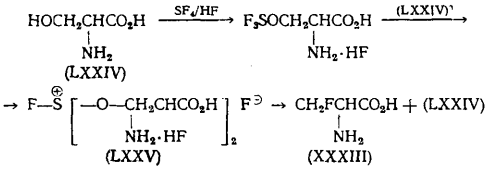
The methods of organofluorine chemistry have been recently used extensively for the synthesis of fluorine-containing aminoacids. The procedures for the introduction of fluorine into the molecules of organic compounds with the aid of elemental fluorine transferring agents, such as trifluoromethyl hypofluorite and perchloryl fluoride and fluorinating agents—antimony trifluoride, sulphur tetrafluoride and its derivatives, as well as metal fluorides (KF, AgF)—proved especially useful.

1. The replacement of hydrogen and halogen atoms and of hydroxy-, mercapto-, and amino-groups by fluorine atoms in the molecules of aminoacids of their derivatives

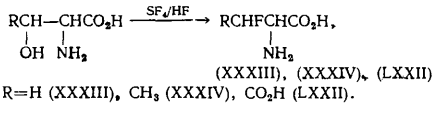


One of the most promising but little used methods of synthesis of fluorine-containing aminoacids involves the direct fluorination of aminoacid molecules. An important disadvantage of this method still remains its low selectivity, as a result of which mixtures of reaction products are formed, which hinders the isolation of the target product.

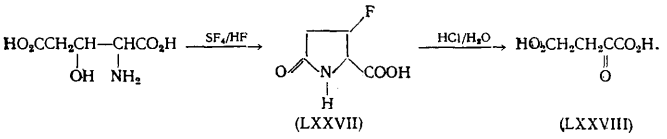
A synthesis of this type was first achieved in the preparation of 4-fluoroglutamic acid using perchloryl fluoride.[47–49]



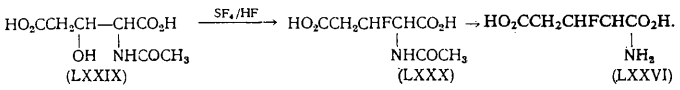
The most effective fluorinating agent for the synthesis of β-fluoro-derivatives of aminoacids is trifluoromethyl hypofluorite.



The reactions were carried out under UV irradiation in hydrogen fluoride. Monofluoroalanine (XXXIII),[50–52] difluoroalanine (LXX), trifluoroalanine (LIII),[53] γ-fluoromethyl-γ-aminobutyric acid (LXXI),[54] β-fluoroaspartic acid (LXXVII),[53] and α-fluoromethylglutamic acid (XIV)[55,56] were synthesised in this way from non-fluorinated aminoacids. In the fluorination of lysine with CF_3OF, one of the reaction products was 5-fluorolysine (LXXIII).[57] The lack of selectivity is the main disadvantage of the method.



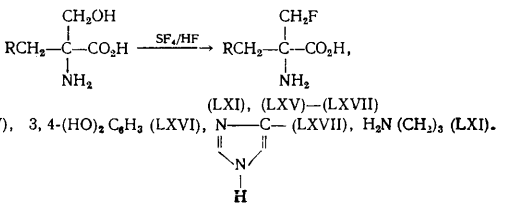
The method involving the replacement of the hydroxy-group by fluorine with the aid of sulphur tetrafluoride or its derivatives, widely used in organofluorine chemistry, has been applied successfully in the synthesis of β-monofluoro-derivatives of aminoacids. Since sulphur tetrafluoride reacts with amino- and carboxy-groups, liquid hydrogen fluoride, which converts the amino-group into the ammonium group $NH_3^{\oplus}$ which is inert to the action of sulphur tetrafluoride, was used as the solvent in this reaction. In order to prevent the fluorination of the carboxy-group to the trifluoromethyl group, the reaction was performed at low temperatures. In the case of β-hydroxy-α-aminoacids, the fluorination must be carried out also at low reactant concentrations in addition to the conditions indicated above. It has been shown for the interaction of sulphur tetrafluoride with serine (LXXIV) that the reaction is complicated by the formation of the sulphenium salt (LXXV). Further reaction of compound (LXXV) leads to the formation of the initial aminoacid and monofluoroalanine (XXXIII) in proportions of 1 : 1.[58] When the reaction is carried out at high dilution, the formation of the product (LXXV) is prevented, which makes it possible to obtain monofluoroalanine (XXXIII) with a very low serine content (the ratio is 99 : 1).



This method, which has been called fluorodehydroxylation, made it possible to obtain 3-fluoro-2-aminobutyric acid (XXXIV)[59] and 3-fluoroaspartic acid (LXXII)[59,60] in moderate yields, apart from monofluoroalanine (XXXIII),[58,59] from the corresponding hydroxy-derivatives.

3-Fluoroglutamic acid (LXXVI) could not be obtained by the fluorodehydroxylation of 3-hydroxyglutamic acid because the lactam (LXXVII) is formed in the fluorination reaction. It was found that acid hydrolysis of compound (LXXVII) takes place only under severe conditions and is accompanied by the elimination of hydrogen fluoride, as a result of which ketoacid (LXXVIII) was isolated as the main reaction product.[61]

The formation of the lactam (LXXVII) can be prevented by using β-hydroxyglutamic acid with a protected amino-group (LXXIX) in the fluorodehydroxylation reaction.

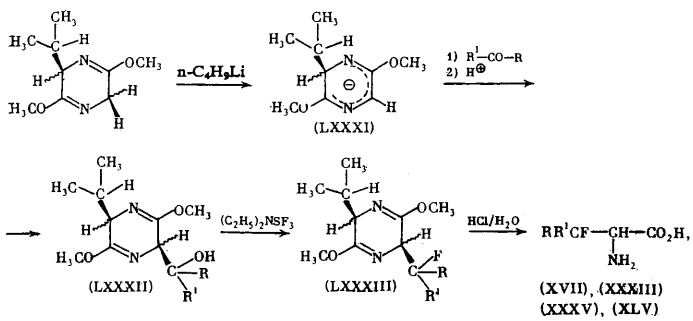


(LXXIX) (LXXX) (LXXVI)

When the acetyl protecting group in compound (LXXX) was removed with the aid of acylase, L-*threo*- and L-*erythro*-isomers of 3-fluoroglutamic acid (LXXVI) were obained in a pure state.[61]

The advantage of the fluorodehydroxylation method is that it is based on readily available initial compounds. Furthermore, optical activity is not lost in the fluorination of pure enantiomers of β-hydroxy-α-aminoacids, since the chiral carbon atom is not involved in the reaction. A disadvantage of the method is the incomplete conversion of the initial aminoacids in many cases, which complicates the isolation of the final products, as well as the formation of fluoro-substituted aminoacids as the hydrofluorides.

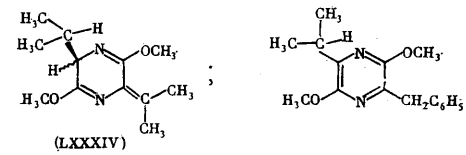
The replacement of the hydroxy-group by fluorine in α-hydroxy-derivatives of natural aminoacids with the aid of sulphur tetrafluoride is one of the convenient methods of synthesis of α-(fluoromethyl)-substituted aminoacids, which are irreversible inhibitors of decarboxylases. The initial α-hydroxymethyl derivatives are formed readily on treatment of copper complexes of the corresponding aminoacids with formaldehyde.



(LXI), (LXV)—(LXVII)

R=4-HOC$_6$H$_4$ (LXV), 3, 4-(HO)$_2$C$_6$H$_3$ (LXVI), N—C— (LXVII), H$_2$N(CH$_2$)$_3$ (LXI).

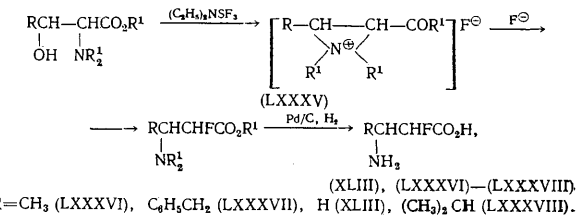
This method makes it possible to obtain α-fluoromethyl derivatives of aliphatic, aromatic, and heterocyclic aminoacids.[62]



The asymmetric synthesis of certain β-fluoro-substituted aminoacids has been achieved by fluorinating optically active derivatives of dihydropyrazine with diethylaminotrifluorosulphurane $(C_2H_5)_2NSF_3$.[63]

(LXXXI) (LXXXII) (LXXXIII) (XVII), (XXXIII) (XXXV), (XLV)

R = R^1 = H (XXXIII); R = H, R^1 = C$_6$H$_5$ (XVII); R = R^1 = CH$_3$ (XXXV); R = CH$_3$, R^1 = C$_6$H$_5$ (XLV).

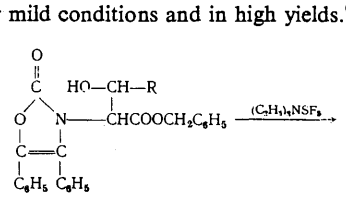


Alkylation of the anion (LXXXI) with carbonyl compounds (acetone, benzaldehyde, acetophenone, formaldehyde) takes place with different optical yields, which are not, however, below 85%. In the case of compound (LXXXII) with R = H and R^1 = C$_6$H$_5$ or R = CH$_3$ and R^1 = C$_6$H$_5$, the ratios of the *erythro*- and *threo*-isomers are 6:1 and 12:1 respectively. Further conversion of the hyroxy-derivatives (LXXXII) into the fluoro-substituted products (LXXXIII) proceeds with moderate yields (~45%) owing to the formation of side products—3-isopropylidenedihydropyrazine (LXXXIV) or a pyrazine derivative.

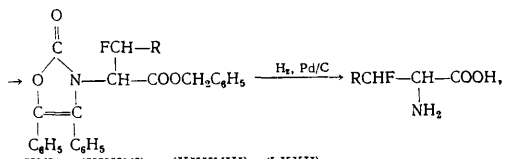
(LXXXIV)

In compound (LXXXII, R = R^1 = H), the hydroxy-group could not be substituted by the fluoro-group with the aid of diethylamino-trifluorosulphurane (diethylaminosulphur trifluoride, DAST. Ed. of translation). In order to obtain monofluoroalanine, the anion (LXXXI) was therefore made to react with fluoroiodomethane, as a result of which the corresponding monofluoromethyl derivative (LXXXIII, R = R^1 = H) was obtained in 80% yield. The optical yield did not then exceed 45%.

The use of DAST for the fluorination of *NN*-dibenzyl derivatives of β-hydroxy-α-aminoacid esters leads to α-fluoro-β-amino-derivatives.[64]



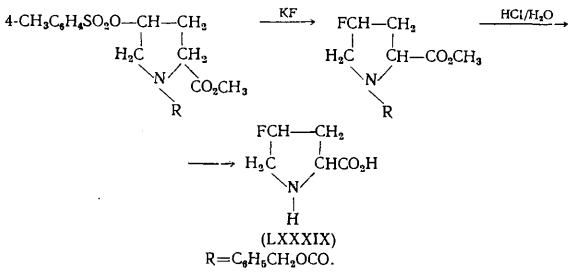
(LXXXV) (XLIII), (LXXXVI)—(LXXXVIII)



R=CH$_3$ (LXXXVI), C$_6$H$_5$CH$_2$ (LXXXVII), H (XLIII), (CH$_3$)$_2$CH (LXXXVIII).

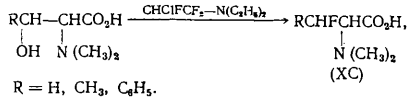
The formation of β-aminoacids from their α-amino-derivatives is believed[64] to be explained by the intermediate formation of the aziridinium ion (LXXXV), which is attacked by the fluoride anion at the α-carbon atom, affording substituted β-aminoacids in 90% yield. An advantage of this method is its high stereospecificity. Thus the double inversion of the configuration of the α-carbon atom (the formation of the aziridinium ion and the opening of its ring by the fluoride anion) results in the formation from the optically active L- or D-aminoacids of the corresponding optically active α-fluoro-derivatives. Furthermore, in the case of β-hydroxy-α-aminoacids having two asymmetric centres (α- and β-carbon atoms), the initial *erythro*- or *threo*-configuration is retained during their conversion into α-fluoro-β-amino-derivatives.[64]

Free α-fluoro-β-aminoacids (XLIII) and (LXXXVI)—(LXXXVIII) have been obtained by the hydrogenolysis of *NN*-dibenzyl derivatives in the presence of a palladium catalyst.



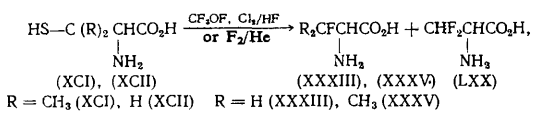
The decrease in the nucleophilicity of the nitrogen atom when the amino-group is protected by employing 4,5-diphenyl-4-oxazolin-2-one rules out the possibility of the isomerisation of α-amino-β-hydroxy-derivatives of carboxylic acid via the aziridinium ion (LXXXV). The employment of DAST in this instance makes it possible to obtain β-fluoro-derivatives of various natural aminoacids under mild conditions and in high yields.[65]

(XVII), (XXXVI) — (XXXVIII), (LXXII)
R=C_6H_5 (XVII), CH_3 (XXXVI), C_2H_5 (XXXVII),
n-C_3H_7 (XXXVIII), COOH (LXXII).



Another method for the substitution of the hydroxy-group by a fluorine atom consists in treatment of *O*-tosyl derivatives of β-hydroxyaminoacid with anhydrous potassium fluoride. This procedure led to the formation of *cis*- and *trans*-4-fluoroprolines (LXXXIX) from hydroxyproline and hydroxyalloproline.[66,67]

(LXXXIX)
R=$C_6H_5CH_2OCO$.

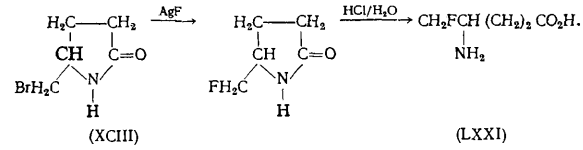


The experiments with *E. coli* have shown that *cis*-4-fluoroproline inhibits protein biosynthesis.

It is noteworthy that the use of 2-chloro-1,1,2-trifluoroethyl-(diethyl)amine (the Yarovenko reagent) as the fluorinating agent for the replacement of the hydroxy-group by fluorine proved to be possible only for aminoacids with a tertiary amino-group. A series of β-fluoro-derivatives of *NN*-dimethylaminoacids (XC) have been obtained by this procedure.[68]

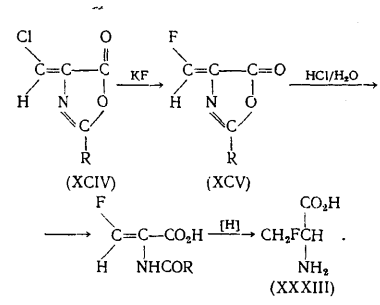
(XC)
R = H, CH_3, C_6H_5.

The synthesis of β-fluoro-substituted aminoacids by the replacement of the mercapto-group by fluorine has been demonstrated in relation to the conversion of D-penicillamine (XCI) into 3-fluoro-D-valine and also by the synthesis of mono- and di-fluoroalanines from 3-mercaptoalanine (XCII).[69]



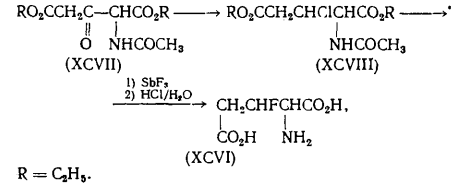
(XCI), (XCII) (XXXIII), (XXXV) (LXX)
R = CH_3 (XCI), H (XCII) R = H (XXXIII), CH_3 (XXXV)

This method, which has been called fluorodesulphurisation,[69] is apparently relatively unsuitable for laboratory practice, since the yields of the final products are low and it requires the employment of trifluoromethyl hypofluorite or elemental fluorine.



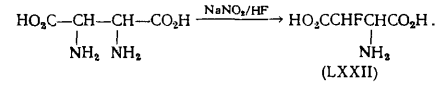
The method of synthesis of fluorinated aminoacids involving the replacement of a halogen atom by fluorine has not found a wide scale application, which is apparently due to the low availability of the initial compounds.

The replacement of a bromine atom in 5-bromomethyl-2-pyrrolidinone (XCIII) by fluorine on treatment with AgF in anhydrous acetonitrile and subsequent acid hydrolysis afforded γ-fluoromethyl-γ-aminobutyric acid (LXXI), which proved to be an effective inactivator of γ-aminobutyric acid transaminase.[70,71]



(XCIII) (LXXI)

3-Fluoroalanine (XXXIII) was first obtained by the replacement of the chlorine atom by a fluorine atom on treatment of 4-chloromethylene-2-phenyloxazolinone (XCIV) with potassium fluoride and subsequent hydrolysis and reduction of the fluoro-derivative (XCV).[72]

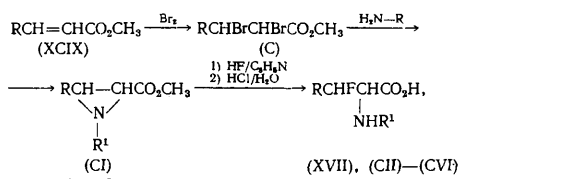


(XCIV) (XCV) (XXXIII)

The employment of antimony trifluoride as the fluorinating agent made it possible to achieve the synthesis of β-fluoroglutamic acid (XCVI) from diethyl 2-acetamidoacetonedicarboxylate (XCVII).[73] The diethyl ester of the ketoacid (XCVII) was reduced and converted by subsequent chlorination into the chloro-derivative (XCVIII), from which the aminoacid (XCVI) was obtained by treatment with antimony trifluoride and subsequent hydrolysis.

(XCVII) (XCVIII) (XCVI)
R = C_2H_5.

A single example of the replacement of the amino-group by a fluorine atom in the synthesis of β-fluoroaspartic acid (LXXII) by the diazotisation of diaminosuccinic acid by treatment with sodium nitrite in liquid hydrogen fluoride is known.[74] By carrying out the reaction at a reduced temperature, it is possible to replace selectively only one amino-group by fluorine.

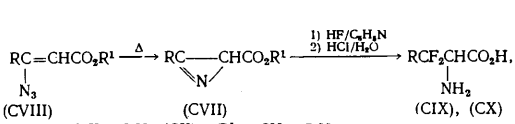


(LXXII)

2. Syntheses based on the opening of the rings of fluorine-containing heterocyclic compounds

The majority of methods considered in this section are feasible because of the specific effect of fluorine atoms or perfluoroalkyl groups. In the case of non-fluorinated compounds, these reactions are inapplicable or lead to other products. Syntheses of this type give rise to the possibility of obtaining individual β-fluoro-derivatives of aminoacids, but in many instances the approaches are general and can be used to synthesise a series of fluorinated aminoacids.

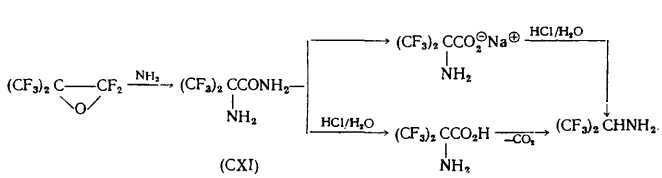
The procedure based on the opening of the aziridine[75–79] or azirine[80] ring by the Olah reagent ($HF.C_5H_5N$) can be regarded as one of the most modern and general methods of synthesis of β-fluoro-derivatives of aminoacids (mono- and difluorinated).



The starting materials for the synthesis of monofluoro-compounds were substituted acrylic esters (XCIX), which were converted by bromination into the dibromo-derivatives (C) and the aziridines (CI) were obtained by subsequent treatment with ammonia. The aziridines afford the corresponding aminoacids in high yields on treatment with the Olah reagent. The use of alkylamines instead of ammonia in this reaction permits the synthesis of *N*-substituted derivatives of fluorinated aminoacids.

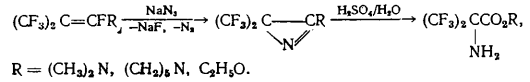
(XCIX) (C) (CI) (XVII), (CII)—(CVI)

R = H, $R^1 = (CH_3)_3C$ (CII); R = $R^1 = CH_3$ (CIII); R = C_6H_5, R^1 = H (XVII); R = C_6H_5, $R^1 = CH_3$ (CIV); R = 4-ClC_6H_4, R^1 = H (CV); R = 4-ClC_6H_4, $R^1 = CH_3$ (CVI).



Treatment with the Olah reagent of the azirinecarboxylates (CVII), formed on thermal decomposition of the azides (CVIII), is a convenient method of synthesis of ββ-difluoro-derivatives of aminoacids (yield 37–42%).

(CVIII) (CVII) (CIX), (CX)

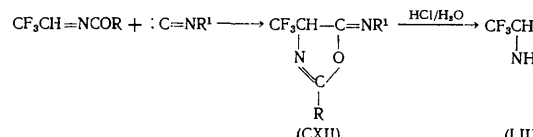


R = CH_3 (CIX), C_6H_5 (CX); $R^1 = CH_3$, C_2H_5.

The opening of the three-membered oxiran and azirine rings containing perfluoroalkyl groups has also been used to synthesise β-fluoro-derivatives of aminoacids. Thus interaction of perfluoroisobutene oxide with ammonia[81] affords the amide of 3,3,3,3′,3′,3′-hexafluoro-2-aminoisobutyric acid (CXI). The attempt to hydrolyse the amide (CXI) with dilute hydrochloric acid causes the decarboxylation of the aminoacid with formation of hexafluoroisopropylamine. Nevertheless, by means of alkaline hydrolysis it has been possible to isolate the sodium salt of hexafluoro-2-aminoisobutyric acid, which, however, also decarboxylates on acidification.[82]

(CXI)

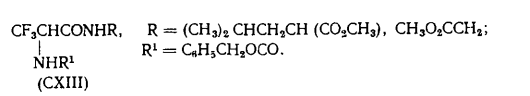
Other derivatives of hexafluoro-α-aminoisobutyric acid—dialkylamides and the ethyl ester—were obtained by the hydrolysis of the corresponding azirines, which are formed readily on treatment of dialkylamino- or ethoxy-derivatives of perfluoroisobutene with sodium azide.[83,84]



R = $(CH_3)_2N$, $(CH_2)_5N$, C_2H_5O.

It is noteworthy that derivatives of hexafluoro-α-aminoisobutyric acid do not form stable salts even with H_2SO_4, which has been explained by the electron-accepting influence of the two trifluoromethyl groups in the α-position relative to the amino-group.

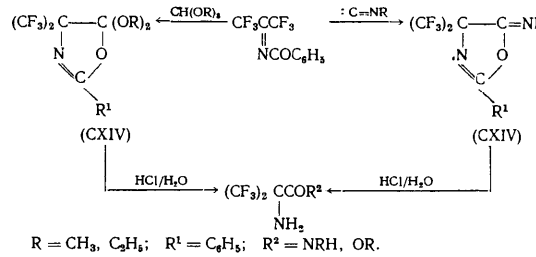
A series of methods based on the formation and opening of the oxazole ring have been proposed for the synthesis of 3,3,3-trifluoroalanine. A disadvantage of these methods is their multistage nature, which reduces appreciably the yield of the product.



Trifluoroalanine (LIII) was first obtained by the acid hydrolysis of the oxazolines (CXII) formed on [1 + 4]cycloaddition of *N*-acyltrifluoroacetaldimines to isonitriles.[85]

(CXII) (LIII)

R = $C_6H_5CH_2O$; $R^1 = n\text{-}C_6H_{11}$.

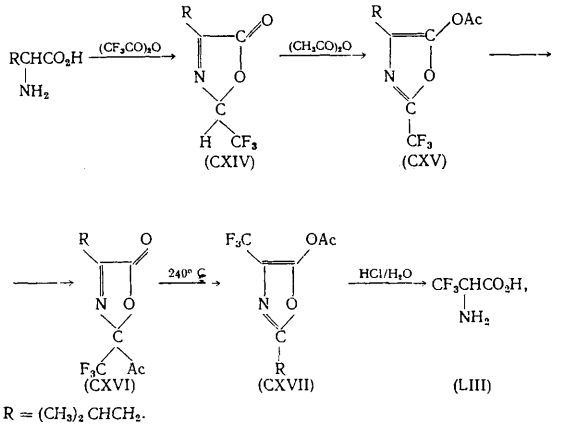


The use in this reaction of isonitriles synthesised from *N*-formylaminoacid esters made it possible to obtain trifluoroalanyl peptides (CXIII).[85]

(CXIII)

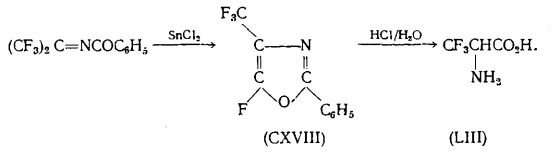
It is noteworthy that alkaline hydrolysis of alanine derivatives (LIII) takes place with conversion of the trifluoromethyl group into the carboxy-group.

Like *N*-acyltrifluoroacetaldimines, hexafluoroacetone *N*-benzoylimine readily enters into the [1 + 4]cycloaddition reaction with isonitriles and orthoformic ester. Hydrolysis of the oxazolines (CXIV) formed affords derivatives of the unstable 3,3,3,3′3′,3′-hexafluoro-2-aminoisobutyric acid.[86,87]



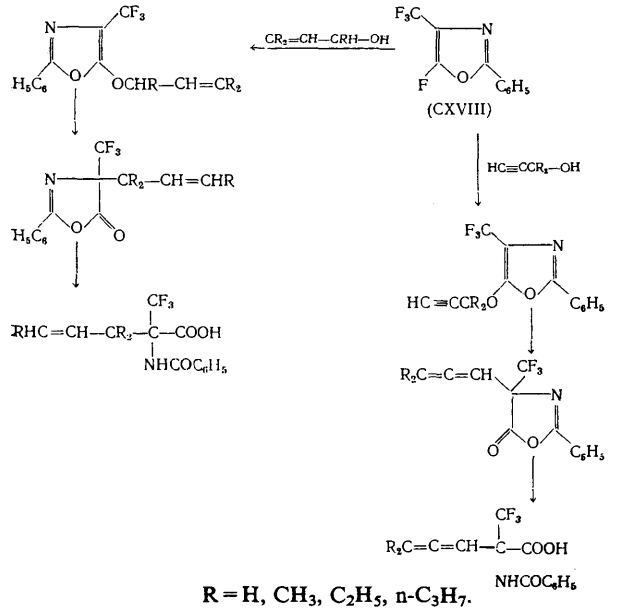
(CXIV) (CXIV)

R = CH_3, C_2H_5; $R^1 = C_6H_5$; R^2 = NRH, OR.



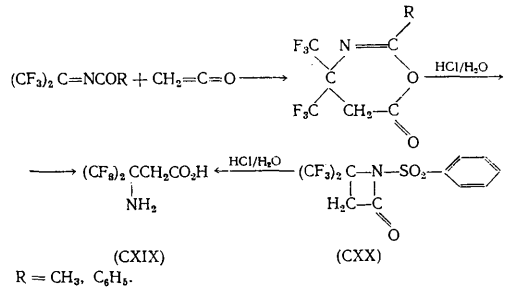
Another approach to the synthesis of trifluoroalanine (LIII) involves the cyclisation of *N*-trifluoroacetyl derivatives of aminoacids to the oxazolines (CXIV), their subsequent conversion into the oxazoles (CXV), and the isomerisation of the latter by treatment with γ-(*NN*-dimethylamino)pyridine to the oxazolines (CXVI), whose

brief heating at 240 °C affords the oxazoles (CXVII). Acid hydrolysis of the latter yields trifluoroalanine (LIII).[88,89]



R = $(CH_3)_2CHCH_2$.

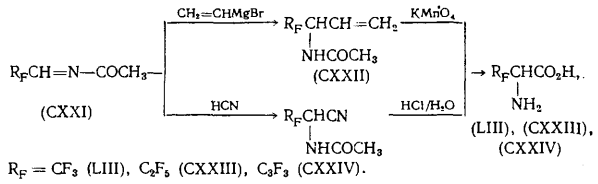
An interesting method of synthesis of trifluoroalanines (LIII) from hexafluoroacetone benzoylamine has been proposed.[90] It was found that hexafluoroacetone *N*-benzoylamine cyclises on treatment with tin dichloride to the oxazole (CXVIII) whose hydrolysis affords trifluoroalanine (LIII) in a overall 20% yield.



The possibility of substituting the fluorine atom in the 5-position of the oxazole ring of compound (CXVIII) in reactions with alcohols has been used successfully in devising a general method of synthesis of novel compounds—2-allyl- and 2-allenyl-3,3,3-trifluoroalanines.[91]

R = H, CH_3, C_2H_5, n-C_3H_7.

The introduction of hexafluoroacetone N-acylimines into the [4+2]cycloaddition reaction with the keten and subsequent hydrolysis of the resulting oxazinones leads to β-amino-ββ-bis-(trifluoromethyl)propionic acid (CXIX).[87]

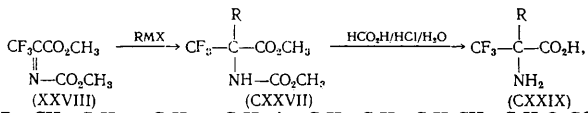


R = CH_3, C_6H_5.

The β-alanine derivative (CXIX) has also been obtained by the reaction of keten with hexafluoroacetone *N*-toluene-*p*-sulphonylimine and subsequent hydrolysis of the propiolactam (CXX).[92]

3. Synthesis of α-perfluoroalkylaminoacids from the *N*-acylimines of fluorinated aldehydes and ketoacids

A general method of synthesis of α-perfluoroalkylglycines from the *N*-acylimines of perfluorinated aldehydes (CXXI) has been developed.[85,93–96] Vinylmagnesium bromide adds readily to the C=N bond of the azomethines (CXXI) with formation of the derivatives (CXXII). Oxidation of the C=C bond in compounds (CXXII) with potassium permanganate and subsequent hydrolysis leads to the α-perfluoroalkyl-substituted aminoacids (LIII), CXXIII), and (CXXIV). The possibility of synthesising such aminoacids by adding hydrocyanic acid to the acylimines (CXXI) and the hydrolysis of the resulting nitriles has been demonstrated.

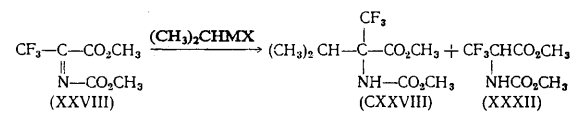


R_F = CF_3 (LIII), C_2F_5 (CXXIII), C_3F_3 (CXXIV).

The sulphone (CXXV) or the halogeno-derivatives (CXXVI) can be used as species equivalent to the imines (CXXI) in the above reaction, but the presence of a base (triethylamine) is then essential.

Trifluoroalanine (LIII) has also been obtained by substituting the chlorine atom by the CN group on treatment of the chloro-derivative (CXXVI) with CuCN[97] and subsequent hydrolysis of the corresponding cyanamide.

A method based on the alkylation of the *N*-methoxycarbonylimine of methyl trifluoropyruvate (XXVIII) for the synthesis of β-fluoro-substituted aminoacids which are most difficult to obtain, namely α-trifluoromethylaminoacids, has been proposed recently.[98,99]

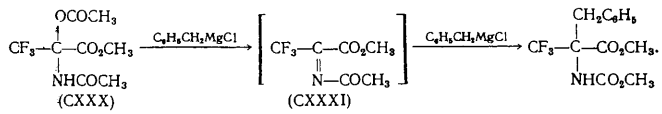


(XXVIII) (CXXVII) (CXXIX)

R = CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, iso-C_4H_9, C_6H_5, $C_6H_5CH_2$, $C_2H_5O_2CCH_2$;
M = Mg, Zn, Cd; X = Cl, Br, I.

The regioselective alkylation of the *N*-methylcarbonylimine (XXVIII) with organomagnesium compounds can be achieved only by mixing the reactants at the liquid nitrogen temperature with subsequent heating of the reaction mixture at 20 °C because of the high electrophilicity of the imine (XXVIII). The use of less reactive organocadmium compounds permits the alkylation of the imine (XXVIII) at 4 °C. The yields of the aminoesters (CXXVII) are almost independent of the metal employed and amount to 60–90%.

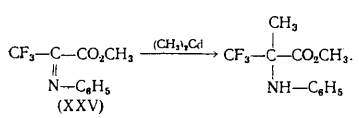
In the synthesis of α-trifluoromethylvaline by alkylating the *N*-methoxycarbonylimine (XXVIII) with diisopropylcadmium or isopropylmagnesium bromide, the reaction is complicated by the reduction of the imine (XXVIII) to the methyl ester of *N*-methoxycarbonyl-3,3,3-trifluoroalanine (XXVII).[100]



(XXVIII) (CXXVIII) (XXXII)

M = Mg, X = Br; MX = CdCH $(CH_3)_2$.

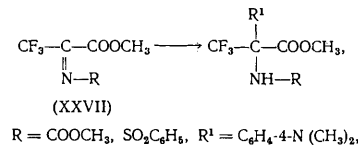
In the case of isopropylmagnesium bromide, the ratio of compounds (CXXVIII) and (XXXII) is 1.5:1, while the use of diisopropylcadmium makes it possible to obtain predominantly the valine derivative (CXXVIII).



The amidoesters (CXXVII) and (CXXVIII) proved to be resistant to acid hydrolysis. In order to obtain the hydrochlorides of α-trifluoromethylaminoacids (CXXIX), it is essential to heat compounds (CXXVII) and (CXXVIII) in a mixture of concentrated hydrochloric and formic acids at 100 °C for 40 h.

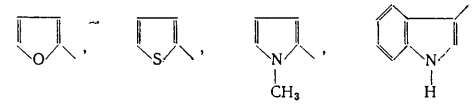
The possibility of synthesising α-trifluoromethylaminoacids by treating with two moles of an organomagnesium reagent the diacetyl derivative (CXXX), which can be regarded as a species equivalent to the *N*-acetylimine (CXXXI), has been demonstrated.[99]

(CXXX) (CXXXI)



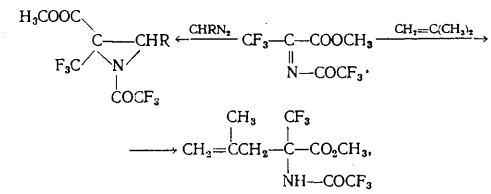
The use of the *N*-alkylimines of methyl trifluoropyruvate in reactions with organometallic reagents in order to synthesise *N*-alkyl-substituted α-trifluoromethylaminoacids proved unsuccessful. However, the *N*-phenylimine (XXV) was alkylated with dimethylcadmium to form the methyl ester of *N*-phenyl-α-trifluoromethylalanine.[99]

(XXV)



An advantage of the method considered is the availability of the reagents employed and also the high yields of α-trifluoromethylaminoacids. However, its disadvantage is that its application in the synthesis of heterocyclic or polyfunctional natural aminoacids is problematical.

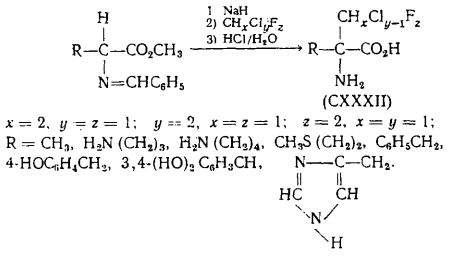
One of the prospects for the further application of imines of methyl trifluoropyruvate in the synthesis of α-trifluoromethyl-substituted aminoacids apparently involves the use of these compounds in *C*-alkylation and cycloaddition reactions. Thus the high electrophilicity of the *N*-acylimines (XXVII) makes it possible to synthesise derivatives of 2-aryl- and 2-heteroaryl-3,3,3-trifluoroalanines by the regioselective alkylation of *NN*-dimethylalanine and a series of heterocycles.[101,102]



(XXVII)

R = $COOCH_3$, $SO_2C_6H_5$, R^1 = C_6H_4-4-N $(CH_3)_2$,

Furthermore, the introduction of the *N*-trifluoroacetylimine of methyl trifluoropyruvate into the reaction with diazo-compounds and alkenes made it possible to obtain derivatives of α-trifluoromethylcoronamic acid and α-trifluoromethyl-γδ-dehydroleucine.[103]



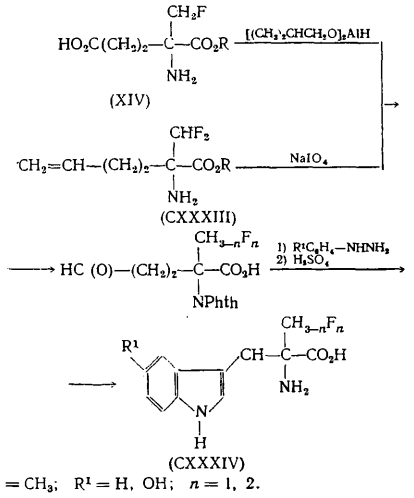
R = H, $COOC_2H_5$.

4. Halogenoalkylation of the α-C-anions of protected aminoacids

A method involving the fluoromethylation of the α-C-anions of protected aminoacids has been developed comparatively recently for the synthesis of α-monofluoromethyl- and α-difluoromethyl-substituted aminoacids.

The carboxy-group in the initial aminoacids was protected by conversion into the methyl ester and the amino-group was protected by conversion into a Schiff base by treatment with benzaldehyde. In those cases where the aminoacid molecules contained OH and SH groups, the latter were converted into ether and sulphide groups; in order to protect the NH groups, for example, in histidine, the *N*-trityl derivative was obtained. The α-C-anions of aminoacids protected in this way were obtained by employing strong bases such as lithium diisopropylamide, sodium hydride, and potassium t-butoxide. The aminoacid C-anions proved to be most stable in tetrahydrofuran (for 24 h), which was used as the solvent. The subsequent alkylation of the C-anions with chlorofluoro- or chlorodifluoro-methane leads to the formation of the α-monofluoroethyl or α-difloromethyl derivatives of aminoacids (CXXXII) after the removal of the protecting group.[45,104,105] The use of the Freon

$CHCl_2F$ makes it possible to obtain the corresponding α-chlorofluoromethyl derivatives. The latter proved to be less stable than the difluoromethyl-substituted aminoacid.



(CXXXII)

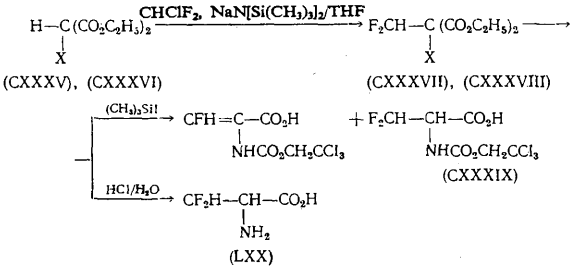
$x = 2$, $y = z = 1$; $y = 2$, $x = z = 1$; $z = 2$, $x = y = 1$;
$R = CH_3$, $H_2N(CH_2)_3$, $H_2N(CH_2)_4$, $CH_3S(CH_2)_2$, $C_6H_5CH_2$, 4-$HOC_6H_4CH_2$, 3,4-$(HO)_2C_6H_3CH$,

This method proved to be applicable to both aliphatic and aromatic and to heterocyclic and polyfunctional aminoacids. The yields of the fluorinated aminoacids are 20–50%.

The formation of a dihalogenocarbene on halogenoalkylation[104] of aminoacid Schiff bases precludes the formation of α-trifluoromethyl derivatives of aminoacids by this reaction using chlorotrifluoromethane or bromotrifluoromethane.

The possibility of the introduction of further functional groups into fluorine-containing aminoacids greatly extends the limits of the applicability of known methods. Thus α-fluoromethylglutamic acid (XIV) and 2-butenyl-3,3-difluoroalanine (CXXXIII), obtained by the halogenoalkylation of the corresponding Schiff bases of the methyl esters of the aminoacids, were used as the starting compounds in the synthesis of α-monofluoromethyl- and α-difluoromethyl-tryptophans and their 5-hydroxy-derivatives (CXXXIV) in accordance with the following scheme:[106]

(XIV)



(CXXXIII)

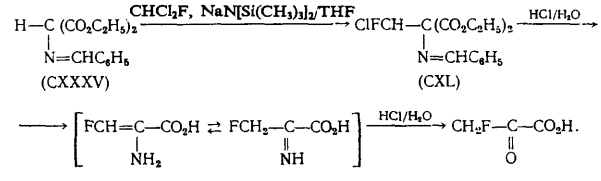
(CXXXIV)

$R = CH_3$; $R^1 = H$, OH; $n = 1$, 2.

α-Monofluoromethyl- and α-difluoromethyl-tryptophans (CXXXIV) proved to be inhibitors of aromatic aminoacid decarboxylases.[106]

It is noteworthy that monofluoro- or difluoro-alanine could not be obtained directly from protected glycine. Therefore, *N*-substituted derivatives of aminomalonic ester (CXXXV) were used as the initial compounds for the synthesis of difluoroalanine (LXX).[107,108] The C-anions were obtained from compounds (CXXXV) in tetrahydrofuran using sodium hexamethyldisilazanide as the base. Subsequent alkylation of the C-anions obtained in this way with chlorodifluoromethane leads to the formation of the difluoromethyl derivatives (CXXXVII) in a yield which is high for reactions of this type (50%).

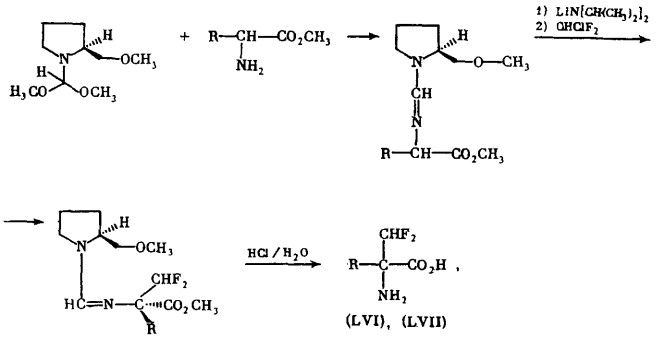
(CXXXV), (CXXXVI) (CXXXVII), (CXXXVIII)



(CXXXIX)

(LXX)

$X = N{=}CHC_6H_5$ (CXXXV), (CXXXVII); $NHCO_2CH_2CCl_3$ (CXXXVI), (CXXXVIII).



The hydrolysis and decarboxylation of the Schiff base (CXXXVII) take place readily with formation of difluoroalanine (LXX), while the carbamate (CXXXVIII) proved to be extremely resistant to acid hydrolysis. Alkaline hydrolysis proved to be inapplicable in the given instance in view of dehydrofluorination. The employment of trimethylsilyl iodide made it possible to remove only the ester group with formation of the acid (CXXXIX). Together with compound (CXXXIX), the product of the dehydrofluorination of the urethane (CXXXVIII), namely *N*-acyl-β-fluorodehydroalanine, was detected in this reaction.

The use of dichlorofluoromethane for the alkylation of the C-anion obtained from the Schiff base (CXXXV) permitted the synthesis of the chlorofluoromethyl derivative (CXL). However, the corresponding β-chloro-β-fluoroalanine could not be isolated because of the lack of resistance of compound (CXL) even to acid hydrolysis. The main reaction product proved to be monofluoropyruvic acid formed in accordance with the scheme[107]

(CXXXV) (CXL)

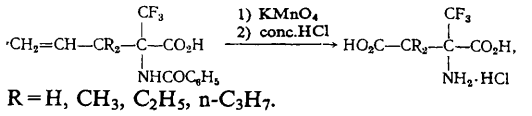
The employment of (*S*)-(−)-1-dimethoxymethyl-2-methoxymethylpyrrolidine to protect the amino-group made it possible to achieve the asymmetric synthesis of α-difluoromethyl-substituted alanine (LXI) and phenylalanine (LVII).[109,110]

(LVI), (LVII)

$R = CH_3$ (LVI), $C_6H_5CH_2$ (LVII).

IV. Conclusion

The literature data examined show that the methods of synthesis of β-fluoro-substituted aminoacids available at present permit the preparation of almost all possible types of these compounds containing between one and three fluorine atoms in the β-position relative to the amino-group. Nevertheless, the impressive results of studies on the biological properties of fluorine-containing aminoacids have stimulated the search for new more convenient methods of synthesis of these compounds.

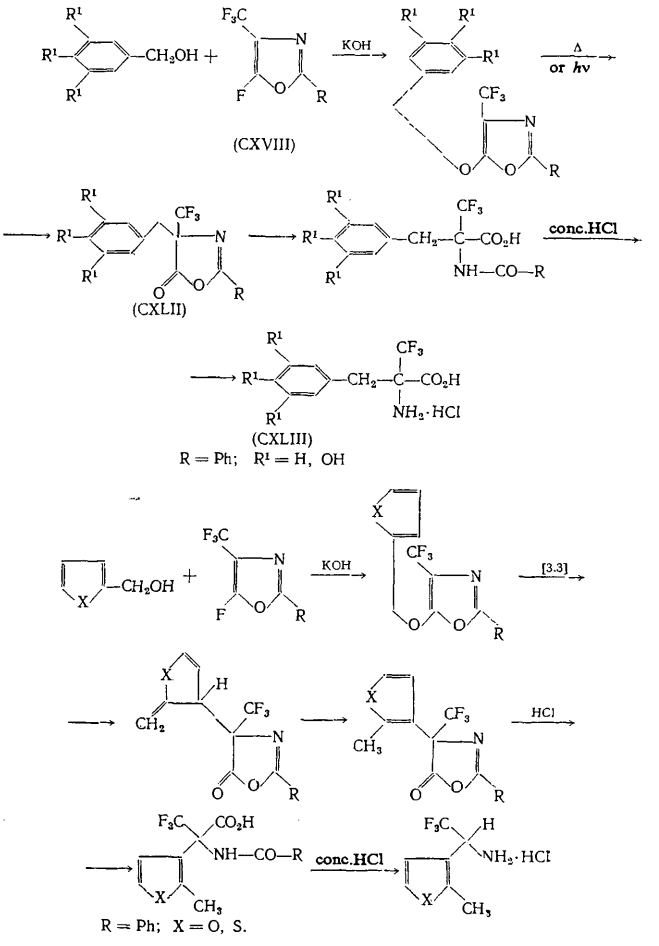


Together with advances in the synthesis of β-fluoro-substituted aminoacids, there still exist problems for which optimum solutions have not been found. This applies particularly to polyfunctional and optically active compounds.

It is to be expected that further studies on the synthesis of β-fluoro-substituted aminoacids will be directed in the first place mainly towards the creation of new simpler and more convenient methods of synthesis of known as well as still unknown representatives of the series of β-fluoro-derivatives of aminoacids and secondly, they will be directed towards the development of an asymmetric synthesis of these compounds, which will permit a more detailed investigation of the biological activity of β-fluoro-substituted aminoacids and also their use in the synthesis of peptides.

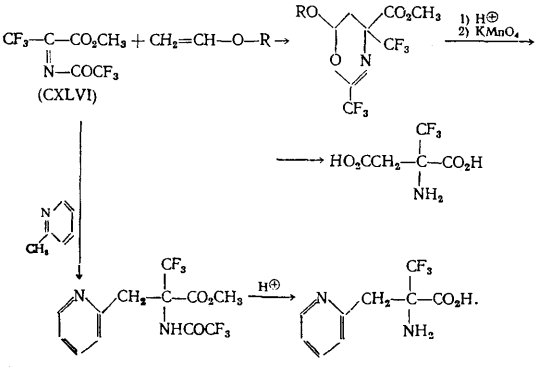
- - -oOo- - -

During the preparation of the review for the press, several new studies illustrating further utilisation of the synthetic possibilities of the methods described above for the preparation of α-trifluoromethyl-α-aminoacids were published.



α-Trifluoromethylaspartic acid as well as its previously unknown 3-alkyl- and 3,3-dialkyl-derivatives were obtained by oxidising the C=C double bond in 2-allyltrifluoroalanines (CXLI), synthesised from 5-fluoro-4-trifluoromethyloxazole (CXVIII) and the corresponding allyl alcohols.[111]

R = H, CH_3, C_2H_5, n-C_3H_7.



A series of 4-benzyl-4-trifluoromethyl-5(4*H*)-oxazolones (CXLII) were synthesised by the reaction of benzyl alcohols (the allyl double bond is a purely aromatic system) with 5-fluoro-4-fluoromethyloxazole (CXVIII) and subsequent rearrangement of the resulting products. The hydrolysis of the oxazolones affords α-trifluoromethylphenylalanines (CXLIII).[112]

The use of 2-hydroxymethyl-substituted furan and thiophene in the analogous reactions with oxazole (CXVIII) is limited to the formation of only *N*-acyl derivatives of 3-heteroaryltrifluoroalanines (CXLIV). This is associated with the fact that under the conditions corresponding to the removal of the *N*-protecting group (refluxing in concentrated HCl), decarboxylation takes place readily with formation of the corresponding amines (CXLV).[112]

Yet another general approach to the synthesis of α-trifluoromethyl-α-aminoacids, based on the reactions of the *N*-acylimines of methyl trifluoropyruvate has also been developed further.

The introduction of *N*-trifluoroacetylimine (CXLVI) into the [4+2]cycloaddition reaction with vinyl ethers and the subsequent hydrolysis and oxidation reactions of the product constitute yet another convenient method of synthesis of α-trifluoromethylaspartic acid.[113]

The regioselective *C*-alkylation of 2-methylpyridine with the *N*-trifluoroacetylimine (CXLVI) is of special interest.[114] This reaction opens a pathway to the synthesis of the virtually uninvestigated β-heteroaryl-α-trifluoromethylalanines.

Laser-induced chemical deposition from the gas phase

V V Teslenko

ABSTRACT. The results of the study of the chemical reactions involved in the deposition of various substances from the gas phase using the pulsed, quasi-continuous, and continuous laser radiation in the wavelength range 0.193–10.6 μm have been summarised. Particular attention has been paid to the deposition of inorganic substances, including non-metals (C, Si, Ge, etc.), metals (Cu, Au, Zn, Cd, Al, Cr, Mo, W, Ni), and a number of simple compounds. Detailed experimental data are given on the influence of the radiation parameters (wavelength, duration and spacing of the pulses, intensity of radiation, shape and position of the laser beam) and the nature of the reagents (hydrides, halides, carbonyls, alkyl organometallic compounds, etc.) on the rate of deposition and the composition of the deposit. The characteristics of photolytic deposition reactions and their possible applications have been examined.

I. Introduction

Reactions involving chemical deposition from the gas phase are finding extensive practical application. In addition to the traditional method in which the reagents are heated, the attention of chemists in recent years has been drawn to other methods of initiating chemical reactions, such as plasma excitation and laser irradiation.

The first paper on the chemical deposition of carbon induced by the radiation of a CO_2 laser appeared in 1972.[1] In the period up to 1980, not more than ten papers on this topic[2–9] were published, but by 1988 the number of papers, reports, and patents exceeded 200. Most of the credit for this goes to specialists in electronics, who not only carried out a large number of studies but also published a whole series of reviews,[10–18] although these are short and highly specialised.

The chemical processes of deposition from the gas phase induced by laser radiation have a wider practical importance, however.[19–24] They can be regarded as a new field of laser chemistry, adjoining, for example, the field of gas-phase laser chemistry.[25–27] This has made it appropriate to publish the present review, which has the following aims: 1) to summarise the experimental data for the period 1980–1987; 2) to describe the principal characteristics of laser-induced chemical deposition reactions; and 3) to examine the possible applications of the process.

The possibility of laser-induced chemical deposition reactions was studied in detail by a number of authors.[8,16,23,28] Here it is sufficient to note that this method can apparently be used to bring about all reactions of chemical deposition from the gas phase (a list of reactions has been published[29–31]), and also a number of other reactions, in particular the decomposition of transition metal halides, such as $TiCl_4$.[32] Two main types of reaction are distinguished, depending on the nature of the interaction of the laser-radiation with the substance: 1) laser-chemical reactions, in which the electromagnetic energy is used up only in the rupture of bonds in the starting materials, and is not converted into thermal energy; and 2) laser-thermal reactions, in which the reagent is first heated, and then undergoes thermochemical transformation. In the English-language literature, these reaction types are described as photolytic and pyrolytic respectively.

The minimum size of the reaction zone is comparable with the wavelength of the radiation; the value attainable in practice is 0.5 μm for photolytic processes, and several μm for pyrolytic processes.[33] Assemblies for carrying out laser-induced deposition are of three main types: in the first type, the laser radiation interacts with a gas in a free space (power synthesis),[34] in the second it interacts close to the surface of a support (deposition of amorphous and microcrystalline coatings),[35–38] and in the third it interacts when the beam reaches the surface of the support (formation of point deposits and non-planar bands, growth of rods, preparation of polycrystalline coatings).[39–41] In addition, there are combined assemblies, for example assemblies using crossed beams.[42–49] The most frequently used are assemblies with the perpendicular configuration, in which the laser beam is directed on to the support, and assemblies with the parallel configuration, in which a beam with a circular or rectangular cross-section is passed several millimetres above the surface of a planar support.

II. Deposition of non-metals

Carbon is obtained by the pyrolysis of hydrocarbons.[1,3,50–56] The production of spiral bands with a width of 0.35 mm on a ceramic rod with a diameter of 3.5 mm by irradiating it in a hydrocarbon atmosphere with a CO_2 laser has been described.[3] The same radiation with metallic supports was used to grow fibrous graphite crystals with a diameter of less than 1 μm and diamond-like films.[50,51] The technical assembly "Kvant-12" has been used to obtain films with a thickness of up to 40 μm on a metal or ceramic support.[52] The decomposition of acetone vapour by heating glass, mica, and crystalline glass supports by radiation with a power of up to 1 W and wavelength λ = 0.53 um (diameter of the focal spot

50 μm) made it possible to obtain rods of polycrystalline graphite with a diameter of 40 μm and a length of up to 3 mm; except for the initial period, the rate of growth (70–230 μm min^{-1}) was proportional to the radiation power.[56] The deposition of carbon from C_2H_2, C_2H_4, and CH_4 on graphite, tungsten, and aluminium oxide supports heated by the radiation of an Ar^+ laser has been described.[53,54] The deposit was obtained in two forms. When the laser beam scanned the surface of the support at a rate of 42 μm s^{-1}, non-planar polycrystalline bands with widths of 5–26 μm were deposited. Stationary irradiation of the support gave cylindrical carbon rods with a diameter of 10–70 μm and a length of up to 1 mm. The volume rate of deposition of carbon from acetylene increased non-linearly with increase in the intensity of the irradiation (I); no deposition was detected at I < 54 kW cm^{-2}, and at I > 292 kW cm^{-2}, homogeneous deposition took place close to the surface of the support to give flakes of carbon black. The range of values of I in which heterogeneous deposition of carbon was observed with C_2H_4 and CH_4 were used was greater, and corresponded to 82–760 kW cm^{-2} and 1055–2190 kW cm^{-2} respectively.[53] The measured axial rates of growth of the carbon rod at different temperatures and pressures are given in Fig. 1. The rate of deposition in the temperature range 1500–2500 °C at partial pressures $p_{C_2H_2}$ in the range 6.7–98 kPa had values in the range 0.2–35 μm s^{-1}; up to 2000 °C, the activation energy was 200 kJ mol^{-1}, and the order of the reaction with respect to C_2H_2 was close to 1. Above 2200 °C, the activation energy decreased, apparently indicating that the process moves from the kinetic into the diffusion range.[54] All the processes described were pyrolytic.

The photolytic decomposition of C_2H_4 under the influence of a CO_2 laser (pulse energy E = 0.7 J) at a pressure of 665 Pa has been carried out on an assembly with the parallel configuration.[55] A carbon layer with an area of 5 mm^2 and a thickness of 0.1 μm was deposited on an NaCl support at a distance of 1 mm from the focus (dose D = 300 J cm^{-2}) after pulse irradiation with 50 000 pulses. The carbon had an amorphous structure with the inclusion of individual crystallites of carbyne and lamellar graphite. In the pulse irradiation of ethylene, thermal equilibrium was not established, so that unstable phases were deposited.

High-intensity ultraviolet radiation brings about the formation of a plasma, from which carbon-containing radicals and ions may diffuse to the surface of a support situated 2–3 mm from the focus, and react on it to give carbon. Thus focussing radiation with λ = 308 nm and a power W = 5 MW with a pulse duration τ = 7.5 ns and a pulse repetition frequency ν = 5 Hz gave an intensity of radiation I = 10^5 kW cm^{-2}.[55] On passage through the laser plasma, naphthalene vapour decomposed, and carbon was deposited on the support (polished SiO_2) as a diamond-like coating with a thickness of about 1 μm. The degree of transformation (and rate of deposition) increased when a magnetic or electric field was used,[40,55] as a result of the increase in the rate of the transport of the active species from the generation zone to the surface of the support.

The largest number of papers has been devoted to the deposition of silicon,[5,7,38,42–44,46,48,54,57–83] indicating the considerable practical interest in this process.

When assemblies with the perpendicular configuration were used, the support was heated by the radiation to 900–1400 °C, so that the deposit had a crystalline structure. Silicon is often deposited using a CO_2 laser,[57,59,69,73] and SiH_4 or a mixture of $SiCl_4$ and H_2 as the reagent.[59] In the last study, polycrystalline coatings with a particle size of 8 μm were obtained at a temperature of the quartz support equal to 900 °C (W = 18.9 W). The rate of deposition v was 5.1 μm min^{-1}, and increased with increase in temperature; saturation took place at a radiation power W = 20 W. The activation energy of the process E_a = 154 kJ mol^{-1}. When the support is heated by the radiation of an Ar^+ laser[74] to 1400 K (at p_{SiH_4} = 13.3 kPa), the temperature dependence of the rate of deposition of polycrystalline silicon is described by an Arrhenius equation with E_a = 195 kJ mol^{-1}. The characteristic deviation of the experimental points from the Arrhenius straight line at temperatures above 1400 K indicates that the process moves from the kinetic into the diffusion range. Under these conditions, the process remains in the kinetic range to a higher temperature than in the ordinary pyrolysis of SiH_4.

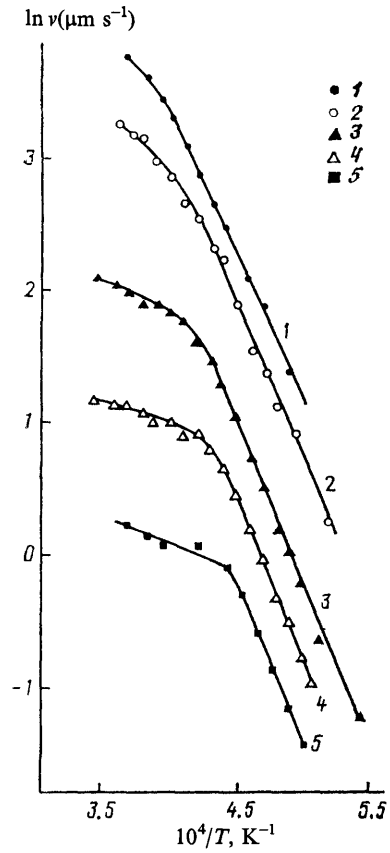

Figure 1. Temperature dependence of the rate of deposition of carbon from C_2H_2 at different partial pressures, kPa: *1*, 98.0, *2*, 66.5, *3*, 26.6, *4*, 13.3, *5*, 6.7.[54]

Single crystals of Si have been deposited using laser radiation with a wavelength of 530.9 nm.[63] Faceted rods with a length of several millimetres and a diameter of about 0.1 mm have been grown on silicon supports with the (100), (110), (111) orientation at 1650 K and p_{SiH_4} = 13.3 kPa at a rate of 30 μm s^{-1}. The axes of the rods coincided with the [100] or [110] directions, irrespective of the orientation of the support. The profile of the growing end of the rod resembled a parabola. Silane and a laser beam with a diameter d = 22 μm were used in the experiments. At deposition temperatures of 1450 K and 1550 K the rods were polycrystalline.

The dependence of the rate of deposition and structure of silicon on the angle of incidence of the radiation, I, p_{SiH_4}, and the temperature of the support (T_s) has been studied.[43,71] With decrease in the angle of incidence from 90° to 0°, the structure of the deposit changed from polycrystalline to amorphous,[71] and the deposition was quenched at a low radiation intensity.[43]

The production of films of amorphous hydrogenated silicon (*a*-Si:H) on assemblies with the parallel configuration is based on the excitation and dissociation of SiH_4 molecules, which show strong resonance absorption at certain wavenumbers in the infrared range (mainly 913.3 cm^{-1}). Mass-spectrometric measurements showed that the action of the laser beam increases the concentration of H_2 and SiH_n^+ (n = 0–4); $Si_2H_n^+$ (n = 1–7) peaks were also observed, indicating the formation of disilane as a result of the high density of radicals in the irradiated volume.[65,66]

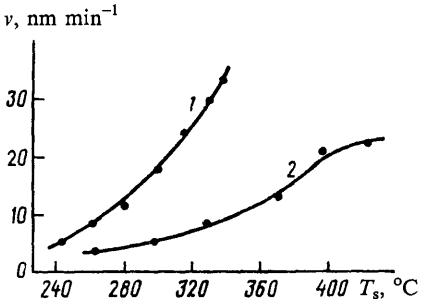

Figure 2. Temperature dependence of the rate of deposition of amorphous silicon at I = 250 W cm^{-2}: *1*, p_{SiH_4} = 0.57 kPa, p_{tot} = 1.33 kPa, gas consumption 5.75 cm^3 s^{-1}; *2*, p_{SiH_4} = 0.43 kPa, p_{tot} = 1.05 kPa, gas consumption 4.25 cm^3 s^{-1}.[57]

Although dissociation in the gas phase takes place even at room temperature, an appreciable rate of heterogeneous deposition is achieved only on a support heated above 200 °C. Fig. 2 gives data on the temperature dependence of the rate of deposition of silicon.[57] The maximum rate of deposition is limited on the one hand by the formation of a powder, and on the other hand by the decrease in the silane concentration as it is used up. The diameter of the laser beam d and the distance from the support are also important. Thus at T_s = 310 °C and W = 65–80 W, the rate of deposition at d = 7.5 mm is approximately twice that at d = 4.0 mm. The explanation for this unexpected result was that in a narrow beam, the degree of dissociation rapidly reaches a limiting value with increase in I, whereas in a broad beam, a larger number of reagent molecules are involved in the process.

The concentration of hydrogen in the deposit and the nature of the bonds it forms with silicon depend markedly on T_s. The infrared spectra showed that films with a thickness of 1 μm contained SiH_2 and SiH groups. Heating at 350–450 °C led to a decrease in the hydrogen concentration (mainly as a result of the decomposition of SiH_2), and heating at 550–650 °C led to crystallisation of the deposit.

Similar results were obtained[64,68–70] on supports of borosilicate glass (including glass coated with Pt, Mo, or a mixture of In and Sn oxides), aluminium, single crystals of silicon, and aluminium oxide. Radiation with λ = 10.6 μm and I = 0.1–1.0 kW cm^{-2} was used. The temperature of the support was 200–650 °C. In studies by Gattuso and co-workers,[64] the main experiments were carried out at T_s = 300 °C, p_{SiH_4} = 800 Pa, W = 70 W, and d = 6 mm. The rate of deposition increased linearly at first, for 60 min, after which a stationary value was established. The stationary value v depends on the rate of consumption of the gas, and with change in the latter from 2 $cm^3 s^{-1}$ to 4 $cm^3 s^{-1}$, v increased from 6.0 nm min^{-1} to 16 nm min^{-1}. The rate of deposition also increased with increase in T_s, W, and p_{SiH_4}. The maximum value of v was limited by the side process of powder formation. The addition of H_2 or HCl to silane was recommended, to suppress homogeneous deposition.

A model of the deposition including the gas-phase decomposition of SiH_4 to SiH_2 and H_2, the diffusion of SiH_2 free radicals to the support, and their reaction on the solid surface to give a deposit has been proposed.[68] In the opinion of the authors cited, the limiting stage is the first of these stages, which determines the exponential dependence of the rate of growth of the deposit on the temperature of the gas T_g. T_g was calculated by assuming that the absorbed energy of the laser beam is equal to the energy lost as a result of thermal conductivity. For pure silane at a pressure p_{SiH_4} = 665 to 1064 Pa, T_s = 200–400 °C, and W = 20–40 W, the value of T_g was 440–550 °C. The dependence of v on T_g gave E_a = 190 kJ mol^{-1}.[69,70] This value coincides with the activation energy of the pyrolysis of SiH_4, and is close to the value 220 kJ mol^{-1} obtained for the decomposition of SiH_4 to Si_2H_6, H_2, and *a*-Si:H powder under the influence of laser radiation with λ = 9.77 μm.[73]

Radiation with λ = 193 nm has been used to obtain an *a*-Si:H coating from disilane.[67,78] At a temperature of the glass support of 200–400 °C and a pressure in the system of 133 Pa, the rate of deposition reached 5.5 nm s^{-1}. The concentration of hydrogen in the deposit depended on T_s, and had the values 17, 9.3, and 7.2 at.% at 200, 300, and 400 °C respectively.

The deposition of germanium from GeH_2 has been carried out[60,62,83] in an assembly with the perpendicular configuration using excimer ArF, KrF, and XeCl lasers (ν = 20 Hz). The laser beam was focussed at a point 1–4 cm from the base of the reactor. By moving the latter along the optical axis, the value of I was varied in the range 1–20 mW cm^{-2}. The duration of the process was about 400 s. Fig. 3 gives the dependence of the initial rate of growth v_0 of the germanium film on the intensity and wavelength of the radiation. The XeCl laser did not induce the reaction. The difference in the action of the radiation of the ArF and KrF lasers is due to the characteristics of the absorption of the radiation by the gas and the deposit. In the opinion of the authors cited,[62] the decrease in v_0 on intensive irradiation is due to the volatilisation of the substance. The average temperature of the support, however, did not exceed 120 °C. It is suggested that a chain reaction is initiated by the two-photon dissociation of GeH_4 to GeH_2 and then takes place according to the scheme shown in Fig. 4. The deposition takes place as a result of the gas-phase diffusion of atomic Ge and Ge_2H_6 to the surface of the support; the concentration of germanium in the gas phase as the support was approached passed through a maximum at a distance of approximately 1.5 mm from it. In the opinion of the authors cited,[83] the low activation energy of this process (E_a = 8.3 kJ mol^{-1}) compared with the pyrolysis of group IV hydrides indicates that the deposition is limited by one of the gas-phase reactions or by the desorption of hydrogen.

An amorphous hydrogenated *a*-SiGe:H alloy was obtained on a support heated to 200 °C by irradiating a mixture of Si_2H_6, GeH_4, and H_2 (λ = 193 nm, τ = 10 ns, ν = 100 Hz, pulse energy E = 15–20 J).[84] Chain radical reactions in the gas phase at a total pressure of 133–250 Pa began as a result of the absorption of one photon by the Si_2H_6 molecule. The intermediate reaction products were Si_2H_5, SiH_3, SiH_2, SiH, and H. The reaction of these radicals with GeH_4 gave $SiGeH_6$, GeH_2, and GeH_3. The proportion of silicon transferred to the deposit was higher than that of germanium.

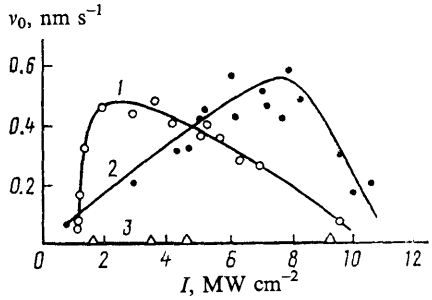

Figure 3. Dependence of the initial rate of deposition of Ge on the energy density of ArF (*1*), KrF (*2*), and XeCl (*3*) lasers.[62]

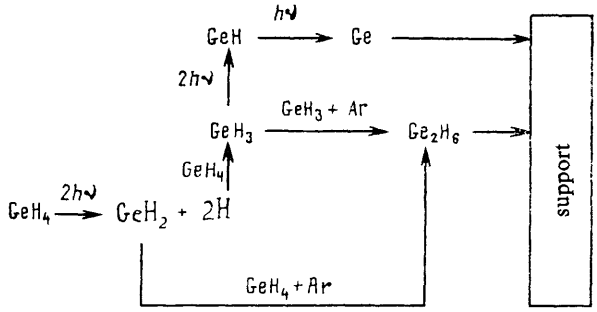

Figure 4. Principal reactions taking place on the irradiation of GeH_4 using a KrF laser (λ = 248 nm).[83]

The rate of decomposition of PH_3 in the optical breakdown of the gas with the formation of a PH_x deposit[85] remains unchanged on going successively from the $P(10)$ line to the $P(32)$ line of a CO_2 laser, and shows a clearly defined threshold. The deposition threshold is determined by the energy and frequency of the pulses, and also by the pressure of PH_3 and the inert gas (Ne).

Data have also been published[86] on the deposition of As from AsH_3, Se from $SeMe_2$, and Te from $TeMe_2$, Te_2Me_2, and $TeEt_2$.

Thus hydrides are most frequently used for the deposition of non-metals. In photolytic processes, radiation in the infrared or visible ranges is used. The principal characteristics of these processes are the increased extent of the kinetic range of the reaction on coordinates concentration–temperature and the possible use of high reagent concentrations without the risk of powder deposition. Photolytic processes are generally carried out in one of three ways: 1) using multi-photon absorption of the radiation of a CO_2 laser (often accompanied by relaxation and heating of the hydride); 2) by chain reactions induced by the absorption of photons with an energy greater than 4 eV; and 3) by optical breakdown of the gas. The last method is apparently complicated by the fact that the threshold conditions of breakdown and the stability of the laser plasma depend to a marked extent on the local composition of the gas and the hydrodynamic characteristics of the system.

III. Deposition of metals

In modern industry, the deposition of metals from the gas phase by the reduction of halides using hydrogen has acquired the greatest importance. In laser-induced chemical deposition, decomposition reactions have found preferential application.

Copper has been deposited from its bis(hexafluoroacetylacetonate) at pressures of 1.3 Pa [87] or 0.4 Pa [88] on silica supports heated by the radiation of an Ar^+ laser. The volume rate of deposition increased from 50 $\mu m^3 s^{-1}$ to 300 $\mu m^3 s^{-1}$ with increase in I from 400 kW cm^{-2} to 600 kW cm^{-2}. The main impurity was oxygen (up to 10 mass %). Au was deposited similarly from its dimethyl(pentane-2,4-dionate) at a pressure of 1.0 Pa; at I = 400 kW cm^{-2} the rate of the process was 1 $\mu m\ s^{-1}$.[89]

Zinc and cadmium have been deposited using $ZnMe_2$ and $CdMe_2$. The thermal and spectral properties of these compounds are similar,[90,91] so that they show identical behaviour in laser decomposition processes. These processes can be examined for the case of the deposition of cadmium.[48,92–104]

The radiation of a Kr^+ laser with λ = 520.8–568.2 nm has been used to heat GaAs supports.[98] At W = 70–300 mW and d = 10 μm the temperature of the support was 235–1000 °C. The process was carried out by decomposing $CdMe_2$ at atmospheric pressure in a hydrogen carrier; the partial pressure of $CdMe_2$ was 20 Pa. The cadmium deposit obtained at T_s < 550 °C was formed within the focal spot. At higher values of T_s, the deposition also took place beyond its limits. A typical rate of deposition was 20 nm s^{-1}.

When radiation with a shorter wavelength, λ = 257 nm, was used, the process took place mainly by the non-thermal decomposition of $CdMe_2$, and mainly in the gas phase, and not in the adsorbed layer. The rate of deposition was linearly dependent on the partial pressure of $CdMe_2$ and the intensity of the irradiation. At I > 2 W cm^{-2}, a deviation from the linear relationship towards lower values of v was observed, due to the decreased concentration of the reagent in the volume of the laser beam. The addition of an inert gas led to a sharp decrease in the total rate of deposition as a result of the decreased rate of gas-phase diffusion of atomic cadmium to the surface of the support. Under these conditions, the role of adsorbed $CdMe_2$ increased, with a simultaneous increase in the sensitivity of the process towards energetic non-uniformity of the surface and interference of the incident and reflected laser beams.[97]

When radiation with λ = 193 nm was used, the deposition took place only as a result of the decomposition of $CdMe_2$ in the gas phase.[99] The concentration of Cd in the gas phase on irradiation with a pulse ArF laser was proportional to I, corresponding to single-stage photodissociation. A definite role was also played, however, by processes in the adsorbed layer, which the authors cited[99] called "prenucleation". In an experiment in which the support (Si or SiO_2) was kept in a $CdMe_2$ atmosphere, the

non-adsorbed $CdMe_2$ was removed, and the support was irradiated by a beam with a characteristic shape, the formation of a deposit was not observed. The reaction vessel was then filled with $CdMe_2$ again to a pressure of up to 0.20 kPa, and the support was irradiated by a broad uniform beam. This gave a deposit whose shape coincided with that of the beam used in the first stage of the experiment. If however in the first stage the irradiated support did not carry an adsorbed layer of $CdMe_2$, a deposit with the characteristic shape was not formed in the second stage.

Aluminium has been obtained by decomposing the compound $AlC_{12}H_{27}$,[105,106] but more frequently by decomposing $AlMe_3$.[10,11,14,98–100,105–110] As with $CdMe_2$, several types of radiation have been used for the deposition.

For example, when a GaAs support was heated to 400 °C by the radiation of a continuous Kr^+ laser with λ = 520.8–568.2 nm, and a mixture of hydrogen and $AlMe_3$ with a partial pressure of 1.3 kPa was passed through the reaction vessel at atmospheric pressure, rods with a diameter of 20–90 μm were obtained at the focal spot.[98] The deposit contained amorphous Al and crystalline Al_3C_4. The length of the rods depended on the intensity of the radiation, and did not exceed 0.5 mm. The roughness of the surface of the rods obtained was attributed[98] to the turbulence of the gas stream. Change in the gas consumption from 1.0 litre h^{-1} to 4.4 litre h^{-1}, however, had no influence on the course of the process or the form of the deposit. The rate of growth of the rods decreased continuously with time (for example, in the first 120 s the rate decreased from 7 μm s^{-1} to 1 μm s^{-1}) as a consequence of the non-isothermal nature of the process; with increase in the thickness of the layer, the growth surface moved out of the focus, and the intensity of irradiation (and hence the temperature) decreased. When the beam was focussed at a point 30 μm from the surface of the support, an increase in the rate of growth to a maximum value at the focus of the laser beam was observed at first, after which the rate decreased.

In the range 442–460 nm, $AlMe_3$ has three absorption bands at 443.6, 445.1, and 446.2 nm. Radiation with these wavelengths has been used to deposit aluminium.[100] A potential of up to 2 kV was applied to the support to attract the ions. The latter reached the surface having a higher energy, and this increased considerably the quality of the coatings obtained.

Radiation with λ = 257 nm did not lead to heating of a support of silicon or its oxide, but acted directed on $AlMe_3$ in the gas phase or in the adsorbed layer.[10] At room temperature and a pressure of several hPa, trimethylaluminium is extensively dimerised. The quantum yield of aluminium in the gas phase was appreciably lower than that in the adsorbed layer.

At λ = 248 nm, Al atoms in the gas phase are formed by a cascade process, each stage of which is initiated by one-photon absorption.[109] The main chain of transformations is described by the scheme

$$Al_2Me_6 \rightarrow AlMe_3 \rightarrow AlMe_2 \rightarrow AlMe \rightarrow Al.$$

C_2H_6 is a side product of the deposition.

An advantage of the use of radiation with λ = 193 nm is that when it is directed on to the surface, a high quantum yield is achieved in the non-thermal photo-desorption of methyl groups. This makes it possible to obtain highly pure aluminium.[107]

The reactions of $GaMe_3$ and $InMe_3$ in the visible and ultraviolet ranges are similar.[111–113] The deposition of In by the decomposition of InI at λ = 193 nm has also been proposed.[114] The deposit, with a thickness of 0.3 μm, did not contain iodine.

Tetraethyllead has an absorption band at 242 nm, and is characterised by an appreciable photon absorption cross-section at 257.3 nm. The rate of deposition of lead at this wavelength is directly proportional to the $PbEt_4$ pressure and the intensity of the radiation; at p_{PbEt_4} = 500 Pa and I = 600 W cm^{-2}, the rate of deposition reaches 8 nm s^{-1}.[115] Increase in the partial pressure of He from 13.3 kPa to 79.8 kPa leads to an almost two-fold decrease in the rate of deposition. This is due to the decrease in the rate of diffusion of Pb atoms in the gas phase, which indicates that a predominant role is played by photolytic decomposition.[115]

Titanium has been obtained by decomposing its tetrachloride on supports of $LiNbO_3$ and SiO_2 at the focal spot (d = 4 μm) of a quasi-continuous Ar^+ laser (W = 5 mW, λ = 257 nm).[32] At an intensity of radiation of 50 kW cm^{-2}, the temperature in the spot did not exceed 30 °C. In the opinion of the authors cited,[32] the main reactions take place in the adsorbed layer. Irradiation of gas with a high concentration of the tetrachloride ($\geqslant$1.0 kPa) or gas containing hydrogen leads to the reduction of $TiCl_4$ to $TiCl_3$ and its deposition on the surface of the support as "hail". Sharp focussing of the radiation on the surface suppresses the gas-phase deposition, and the reactions in the adsorbed layer are complete with the formation of metallic titanium. In this case the deposition mechanism is possibly autocatalytic.[32]

Chromium can be obtained by decomposing its hexacarbonyl.[14,116–119] The use of radiation with λ = 248 nm gave black fragmentary films with a columnar structure in an assembly with the parallel configuration, and light silvery coatings in an assembly with the perpendicular configuration.[14] The main impurity was oxygen (up to 7 mass %), but its concentration can be decreased by using an improved reactor and an improved vacuum system.

The decomposition of $Cr(CO)_6$ under the influence of radiation with wavelengths of 193, 249, and 308 nm has been carried out with both the parallel and the perpendicular relative arrangements of the beam and the support.[118] In the last case, coatings with strong adhesive power were obtained on quartz, Pyrex, Suprasil, and aluminium. At τ = 10 ns, E = 8–12 mJ, and ν = 10–60 Hz, the pulse rate of deposition was independent of ν, and had the values 0.010, 0.028, and 0.005 nm $pulse^{-1}$ for λ = 193, 249, and 308 respectively (the thickness of the coatings did not exceed 300 nm).

Japanese workers[119] obtained chromium films on an assembly with the perpendicular configuration (λ = 248 nm, ν = 50 Hz, I = 1–9 MW cm^{-2}, average energy density 140 J cm^{-2}). The quartz support was not heated specially during the process. The deposition was carried out from argon at atmospheric pressure and $p_{Cr(CO)_6}$ = 40–90 Pa. The deposits contained approximately 50% chromium, 20–50% oxygen, and up to 30% carbon, depending on the intensity of the radiation. The films with the lowest concentration of oxygen had a metallic lustre and strong adhesive power, but their electrical conductivity was lower than that of chromium by a factor of 500. The purity of the films obtained was much lower than that of the coatings described by Boyer and co-workers,[14] apparently due to the high partial pressure of Ar in the reactor.

Molybdenum has been obtained from $Mo(CO)_6$.[14,116,118,120,121] At a low temperature of the support, the deposit contained large quantities of oxygen and carbon. Thus the pulse irradiation (λ = 248 nm) of molybdenum carbonyl adsorbed on Si (100) gave at 150–200 K a deposit with the composition $MoCO_{0.3}$ with a quantum yield close to 1.[120] By comparing the deposition processes taking place at room temperature under the influence of radiation with λ = 157, 193, 248, and 308 nm, Solanki and co-workers[116] found that the lowest concentration of carbon in the deposit and the

highest rate of deposition were achieved at 248 nm. According to Flynn and co-workers,[118] however, the rate of deposition at 193 nm is slightly greater than that at 248 nm.

The deposition of Mo by the optical breakdown of the gas using the radiation of a pulse CO_2 laser has been described.[121] Argon was added to the gas to facilitate breakdown.

Tungsten deposits have been obtained by two reactions: by decomposing tungsten carbonyl,[14,116,118,122] and by reducing tungsten hexafluoride with hydrogen.[122–127]

The deposition of tungsten from its carbonyl is similar to that of molybdenum. The rate of deposition at 257 nm increases in proportion to the increase in I to 1 kW cm^{-2} (Fig. 5). At λ = 193 nm, other conditions being equal, the rate of deposition is three times greater.[118]

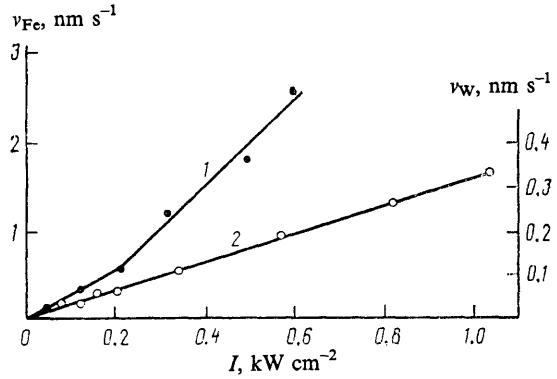

Figure 5. Dependence of the rate of deposition of W (*2*) and Fe (*1*) on a quartz support on the intensity of radiation with λ = 257 nm at pressures $p_{W(CO)_6}$ = 27 Pa and $p_{Fe(CO)_5}$ = 67 Pa.[128]

Tungsten has been deposited from WF_6 by irradiating a quartz support with a CO_2 laser with a power of 40 W.[122] Under these conditions, the greatest thickness of the tungsten film obtained was limited to 250–500 nm, depending on the conditions of irradiation and the concentration of the reagents. Three stages of the process are readily distinguished: 1) induction, 2) intensive, 3) attenuated. The duration of the induction stage decreases with increase in the radiation power; this can be attributed to the increased rate of attainment of the "threshold temperature" of the surface of the support. The second stage is short; it corresponds to the attainment of the maximum rate of deposition, the magnitude of which depends on I (or more accurately on T_s) and p. The decrease in the rate of deposition in the third stage is due to the decrease in the temperature of the support as a result of the reflection of the radiation by the tungsten film formed. Increase in the intensity of the radiation should of course have led to continuation of the deposition process, but this possibility was not studied experimentally.

The deposition of tungsten on a silicon support heated by the radiation of a Kr^+ laser (λ = 468–530 nm), not absorbed by the gaseous reagents (p_{H_2} = 53.2 kPa, p_{WF_6} = 26.6 kPa), has been described.[123] The beam with a power of 3–4 W was focussed on the support to give a spot with a diameter of 20 μm, and moved over the surface at a rate of 0.2–2.0 mm s^{-1}. With slower movement and a power greater than 4 W, fusion of silicon was observed. Since in the wavelength range used Si and W have similar absorbing power, it was possible to obtain thick deposits and to grow coatings by repeated irradiation. Similar results were obtained by other workers.[126]

Manganese has been obtained by decomposing $Mn_2(CO)_{10}$ under the influence of radiation with a power of 1–40 mW (λ = 337.4–356.4 nm, I = 3–150 kW cm^{-2}). When the beam scanned a ZnS support heated to 100 °C, bands of Mn with a thickness of 30–800 nm were deposited.[129]

$Fe(CO)_5$ has been used to obtain iron coatings.[122–124,127] The irradiation of a quartz support with a CO_2 laser with a power of 5.5 W gave the same self-limiting process as in the deposition of tungsten from its hexafluoride. Thus at $p_{Fe(CO)_5}$ = 3.6 kPa, the thickness of the film after 3 ms was 50 nm, which did not increase on subsequent irradiation. An interesting feature is that for a lower radiation power, the growth was more prolonged; for example, for a radiation power of 2.2 W, a coating with a thickness of 1 μm was formed in 1 s. The radiation of an Ar^+ laser has also been used to heat the support.[130]

In the ultraviolet range, photolytic deposition of iron takes place. The use of radiation with λ = 257 nm led to the continuous growth of the deposit at a rate which depended on the intensity of the radiation (see Fig. 5). The break on the straight line apparently indicates a change in the deposition mechanism.[128] The decomposition of $Fe(CO)_5$ has also been carried out using the fourth harmonic of a neodymium laser (λ = 266 nm, τ = 15 ns, ν = 25 Hz, W = 0.01–0.3 mW).[131] The film, deposited in a focal spot with d = 150 μm, had strong adhesive power, but the film deposited beyond the spot had low adhesive power. This indicates that the deposition was not due to the thermal decomposition of the carbonyl. The rate of deposition at p = 130 Pa and W = 0.25 mW was 0.25 nm s^{-1}; it decreased non-linearly with increase in the Ar pressure to 80 kPa, and increased in proportion to p and W. In the opinion of the authors cited, this indicates an unsaturated one-photon decomposition mechanism.

Nickel has been deposited from $Ni(CO)_4$.[8,123,124,132–136] When a quartz support was irradiated by a low-power CO_2 laser, self-limitation of the deposition was observed.[123,124,132,136] The maximum rate of deposition increased non-linearly with increase in the power from 0.3 μm s^{-1} at W = 0.4 W to 3 μm s^{-1} at W = 2 W. The dependence of the duration of the induction stage on the intensity of the radiation indicates that the reaction rate is determined not only by the temperature of the support. For a high value of I, a decisive influence on the course of the deposition may be shown by the rates of nucleation and the gas-phase reactions.[124] The activation energy of the deposition of nickel on steel, glass, and silicon supports was 90 kJ mol^{-1}, which is characteristic of a pyrolytic process. When the radiation of a Kr^+ laser was used, the diameter of the undulating deposit was much greater than the value of d, and increased during continuous radiation, evidently as a result of the heating of the non-irradiated parts of the support due to its thermal conductivity. The dependence of the rate of growth of the Ni rods on I is shown in Fig. 6. It can be seen from Fig. 6 that deposition does not take place below a certain threshold value of I. This is followed by a plateau, on which the rate of deposition remains unchanged, after which it begins to increase with subsequent increase in I. When helium, which has a high thermal conductivity, is added to the reactor, the rate of deposition decreases as a result of

the cooling of the surface by the increase in the removal of heat.[133,135] The nickel specimen obtained in this way does not contain carbon (accuracy of the determination 1%). Its electrical resistance is 1.9×10^{-5} Ω.cm (three times the tabulated value), indicating that the deposit is highly pure.

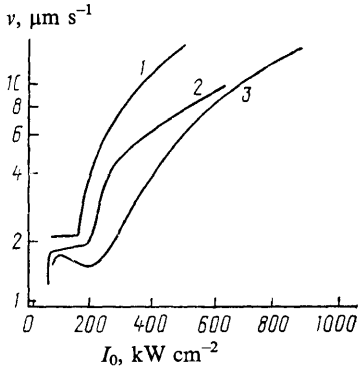

Figure 6. Dependence of the rate of growth of Ni rods on the intensity of the radiation at $p_{Ni(CO)_4}$ = 40 kPa and different focus spot diameters, μm: *1*, 22, *2*, 27, *3*, 13.5; in the experiments corresponding to curve *2*, He was added to $Ni(CO)_4$ (p_{He} = 53.3 kPa).[133]

Platinum has been deposited from $Pt(PF_3)_4$ at a pressure of 60 Pa on silicon, aluminium, graphite, quartz, and copper supports using a pulse Kr^+ laser.[137,138] The yield of the deposit decreased in the order of the supports given above (energy density in each pulse 200 mJ cm^{-2}). The quantum yield of platinum amounted to thousandths of the original quantity of $Pt(PF_3)_4$ (for example, 3.7×10^{-3} on the aluminium support). It was shown that the deposition takes place under the influence of electrons produced by the interaction of the laser radiation with the surface of the support.[137,138] The similar decomposition of $Fe(CO)_5$ and $CoEt_2(CO)_2$ under the influence of slow photoelectrons on the irradiation of glass and silver supports with the light of an Xe–Hg lamp (λ = 200–400 nm) has been described.[139] The other reactions examined above possibly also take place by this photoelectron mechanism.

Thus the metals of groups I, II, and III are most frequently deposited from organometallic compounds, and metals of groups VI, VII, and VIII from their π-complexes. The efficiency of the photolytic decomposition of these compounds at different values of λ correlates with the form of the absorption spectra. The deposits generally contain appreciable quantities of carbon and oxygen, which apparently originate in the ligands and in the air entering the reaction vessels. Dilution of the reagents with large quantities of inert gases leads to a significant decrease in the total rate of deposition and in the purity of the deposits. In contrast to the deposition of non-metals, an additional photoelectron mechanism operates in the deposition of metals.

IV. Deposition of inorganic compounds

Silicon carbide has been deposited using a CO_2 laser and a mixture of H_2 and $SiMeCl_3$.[9,50] Radiation with a power of 25 W was focussed on the surface of W, SiC, C, SiO_2, and ZrO_2 supports, so that the temperature reached 1100–1450 °C. The rate of deposition was directly proportional to p_{SiMeCl_3} in the range 0.27–13.3 kPa and inversely proportional to p_{H_2} in the range 0–10.6 kPa. The material of the support had no influence on the rate of deposition at a deposit thickness greater than 1.0 nm. The value of E_a in the absence of H_2 was 335 kJ mol^{-1}, and at p_{H_2} = 13.3 kPa, E_a was 400 kJ mol^{-1}. In the opinion of the authors cited,[9,50] the limiting stage was the decomposition of the methyl radical. The deposit was polycrystalline, and the particle size depended on the temperature of the process. Silicon carbide has also been obtained by decomposing $SiMeCl_3$ and $SiMe_2Cl_2$ on crystalline glass supports heated by the beam of an Ar^+ laser.[140] The rate of growth of the rods reached 70 μm s^{-1}. Stoichiometric SiC was deposited from $SiMe_2Cl_2$ in a nitrogen atmosphere. In a CO_2 atmosphere, codeposition of silicon and its dioxide took place. The decomposition of $SiMeCl_3$ in a stream of nitrogen led to the formation of graphite.

SiC powder has been synthesised from a mixture of SiH_4 and C_2H_4, which absorb radiation with λ = 10.59 μm.[141] In the tubular reaction vessel, the beam of a CO_2 laser with a diameter of 6 mm was directed at right angles to the stream of reagents. At the point of intersection, I = 530 W cm^{-2}, and T_g = 1100 °C. In a narrow beam (d = 2 mm) the corresponding values were 5.25 kW cm^{-2} and 1550–1750 °C. Since the time for which the reagents were in the reaction zone was constant, the diameter of the particles of the powders obtained showed little scatter. The chemical composition of the deposit could be varied by altering the reagent ratio, pressure, and intensity of the radiation.[141]

The formation of surface periodic structures from a mixture of SiH_4 and CH_4 at the points of a surface interference wave at λ = 9.27 μm has been described.[142]

The deposition of titanium carbide[127,132,143] using a carbon steel support required the powerful radiation of a CO_2 laser (0.5–1.2 kW in a spot with d = 1–2 mm). The original mixture consisted of $TiCl_4$ (1.6 kPa), CH_4 or C_2H_2 (26.6 kPa), and, sometimes, H_2 (26.6 kPa). The presence of H_2 was not necessary for the deposition of the carbide.

Titanium silicide was obtained similarly using SiH_4 instead of the hydrocarbon.[144–147] The single-crystal silicon support was heated to 400–500 °C by the radiation of a CO_2 laser with a power of 160 W. In addition, the gas was irradiated by an ArF laser (I = 100 MW cm^{-2}). Increase in the molar ratio SiH_4:$TiCl_4$ from 3 to 18 led to a change in the Si:Ti ratio in the deposit; for example, at T_s = 400 °C this ratio changed from 1.0 to 2.3. The silicide was amorphous at 400 °C, and partly crystalline at 450 °C and 500 °C. The concentration of oxygen in the deposit was 2–4 at.%, and the chlorine concentration 0.2 at.%.

Zinc oxide has been deposited in an assembly with the parallel configuration from a mixture of dimethylzinc and oxides of nitrogen, using radiation with λ = 248 nm with N_2O, and radiation with λ = 193 nm with NO_2.[14,148] The highest purity of ZnO and the highest rate of its deposition were achieved at a total pressure of 266 Pa and a $ZnMe_2$ partial pressure of 4.0 Pa. The temperature of the support varied from 20 °C to 220 °C. The coatings, with a thickness of 0.5 μm, contained less than 1% carbon and traces of nitrogen. Increase in the ratio $ZnMe_2$:NO_2 led to a change in the stoichiometry of the deposit, and this was reflected in its electrical conductivity

(the extreme values of the electrical conductivity differed by a factor of 10^4).

Aluminium oxide was deposited similarly. 50–1000 $cm^3 s^{-1}$ N_2O, 100 cm^3 s^{-1} He, and $AlMe_3$ at a partial pressure of 10.6 Pa were passed through the reaction vessel at a pressure of 133 Pa.[149] A blue fluorescence was observed along the laser beam. The rate of deposition was approximately 200 nm min^{-1} at W = 10 W and λ = 248 nm. At W = 8.2 W and λ = 193 nm, the rate was higher, but the deposit was less uniform along its thickness. The coatings obtained at a rate of deposition of 1 μm min^{-1} separated from the support on contact with air. Loose grey films were obtained at a high rate of deposition. The best coatings, containing less than 1% carbon, were obtained at T_s = 450 °C, p_{AlMe_3} = 10–15 Pa, and an N_2O consumption of 200–800 cm^3 s^{-1}.

Al_2O_3 was deposited from a mixture of $AlMe_3$ and NH_3 at a support temperature below 100 °C (radiation with λ = 193 nm was used).[150] The source of oxygen was the air entering the reactor. At a support temperature above 100 °C, ammonia became chemically active, and up to 400 °C the deposit formed consisted of a mixture of Al_2O_3 and AlN.

The preparation of indium and gallium oxides by methods similar to that used for Al_2O_3 has been proposed.[149]

Silicon oxide has been deposited in an assembly with the parallel configuration by irradiating a mixture of SiH_4 and N_2O using an ArF laser (λ = 193 nm).[14,151] At a pulse frequency of 100 Hz, the average intensity of the radiation was 40 W cm^{-2}. The laser beam passed over the support at a distance of 0.3 mm. The pressure in the reactor did not exceed 1.0 kPa. The consumption of N_2O was 800 cm^3 s^{-1}, and the consumption of N_2 containing 5% SiH_4 was 70 cm^3 s^{-1}. The silicon support was heated from 20 °C to 600 °C. The deposits obtained at temperatures up to 200 °C appeared non-uniform, and readily separated from the support. At $T_s \geqslant$ 250 °C, uniform strong deposits were obtained. The rate of deposition reached 5 nm s^{-1}. The concentration of nitrogen (as Si_3N_4) was less than 5 mass %, and the concentration of hydrogen (combined with Si atoms) was 1–4 at.%.

SiO_2 coatings were obtained similarly.[152] The laser beam has a cross-section of 5 × 20 mm, and the pulse frequency was varied from 3 Hz to 70 Hz. The dependence of the rate of deposition v on the partial pressure of N_2O was non-linear, and had a maximum at p_{N_2O} = 3.0 kPa. The rate was directly proportional to the power of the pulses. The rate of deposition was also influenced by the $N_2O:SiH_4$ ratio. With increase in the latter, the rate increased, but only to a limiting value. This saturation phenomenon is due to the existence of a limit to the transport properties of SiH_4. According to some authors,[152] the highest rate of deposition was observed at $N_2O:SiH_4$ = 50, and according to others,[153] at $N_2O:SiH_4$ = 20 (deposition in the absence of N_2 diluent). Analysis of these values led the authors cited[152] to the conclusion that the quantum yield of the photodissociation of N_2O is close to 0.01, but that the O atoms liberated in turn initiate the additional dissociation of N_2O or react with N_2O to form more photosensitive compounds, for example NO or NO_2. As a result, the extent of the transformation of N_2O to yield O is increased two-fold.

Titanium oxide has been obtained by the reaction of $TiCl_4$ with CO_2 in hydrogen by heating a quartz support by the radiation of a carbon dioxide laser with a power of 5–10 W.[6,8,127,132,144] The partial pressure of the reagents was $TiCl_4$ 1.65, CO_2 2.73, and H_2 2.73 kPa. The rate of deposition had values of 30–100 nm s^{-1} (d = 0.8–3.0 mm, τ = 0.1–1.0 s). Titanium dioxide absorbs radiation more strongly than SiO_2, so that repeated pulse irradiation of the same section of the surface gave a thicker deposit than continuous irradiation with the same duration. Moreover, on continuous irradiation the form of the surface of the deposit resembled a Gaussian curve, whereas on pulse irradiation (for example with 20 pulses in 0.1 s), the deposit had the form of a plateau; this can apparently be attributed to the ratio of the rates of diffusion and heat transfer.

Titanium oxide can be obtained by decomposing oxygen-containing organometallic compounds, for example $Ti(OCHMe_2)_4$.[154]

The laser-induced decomposition of CrO_2Cl_2 has been studied.[155] Radiation with λ = 488–515 nm was focussed on a spot with a diameter of 5 mm or 2 mm on supports of glass, fused SiO_2, or single crystals of Si and Al_2O_3. The radiation power varied from 1 mV to several W, and the CrO_2Cl_2 pressure was 13 Pa. Mass spectrometry detected an appreciable quantity of chlorine atoms in the irradiated gas. This indicates an appreciable rate of photolytic decomposition of the oxide chloride, although CrO_2Cl_2 itself absorbs at λ = 420 nm. To study the heterogeneous reactions, an irradiated fused SiO_2 support was placed in the chamber of the mass spectrometer, and the measurements were made during the reaction. The deposition took place in three stages. In the first stage, which lasted tens of seconds, slow growth of the CrO_2 film took place, and this process was accompanied by the production of a small flux of chlorine atoms. The deposition apparently involved the decomposition of CrO_2Cl_2 molecules in the gas phase or in an adsorbed layer. In the second stage, the flux of the species Cl, Cl_2, and O_2 increased sharply. The increase in the rate of the process was due to the thermal activation of the decomposition of CrO_2Cl_2 as a result of local heating of the surface by the absorption of radiation by the deposit formed in the first stage. The spontaneous acceleration took place until the thickness of the deposit was greater than the characteristic thickness of the absorbing layer. This was followed by the third stage, characterised by a stationary rate of deposition with a new increased surface temperature. Since the deposit contained Cr_2O_3, and O was detected in the gas phase, in the second and third stages the deposition was accompanied by the thermal decomposition of CrO_2, which takes place at temperatures above 400 °C. At a radiation intensity lower than 1 W cm^{-2}, only the dioxide was deposited.

Experiments carried out with the radiation of an excimer laser (λ = 193 nm) at a CrO_2Cl_2 pressure of 13 Pa showed that the composition of the deposit can be regulated by adding HCl to the gas phase; the deposit had the composition $CrO_{0.83}$ at an HCl pressure of 26.6 kPa, and $CrO_{1.5}$ in the absence of hydrogen chloride.[155]

Films of WO_3 or Fe_3O_4 have been deposited by irradiating (λ = 308 nm) a mixture of NO_2 with $W(CO)_6$ or $Fe(CO)_5$ in a reactor heated to 50 °C.[156] The carbonyls were mixed with an inert gas (Ne or He), whose partial pressure was 70–90 kPa. The deposition of WO_3 was more rapid than that of Fe_3O_4, since the absorption cross-section of $W(CO)_6$ is almost 10^2 times that of $Fe(CO)_5$.

Aluminium nitride has been deposited in an assembly with the parallel configuration from a mixture of $AlMe_3$ and NH_3 (λ = 193 nm).[150] Ammonia reacted at a support temperature above 100 °C, and with increase in the support temperature to 400 °C the mole fraction of AlN in the deposit increased almost linearly, reaching 1. Practically pure nitride was deposited at 400–500 °C.

Amorphous films of silicon nitride were obtained in assemblies with the parallel configuration from a mixture of SiH_4 and NH_3.[157] The radiation of a CO_2 laser with a power of up to 160 W (λ = 10.6 μm) was used. The temperature of the Si support was

250–450 °C, and the pressure in the reactor 1.33–2.0 kPa. The Si:N ratio in the deposit depended on the reagent ratio, and was 1.2 at $SiH_4:NH_3$ = 1000. The infrared spectrum of the deposit contained bands characteristic of Si–N, Si–H, Si–O, and N–H bonds. The concentration of hydrogen in the deposit decreased with increase in the temperature of the support. The rate of deposition was low (15 nm min^{-1}), and independent of temperature.

Coatings were obtained[158] using a low-power ArF laser (W = 0.2 W). The rate of deposition of the coatings on an area of 7.5 cm^2 was independent of the temperature of the support (200 to 600 °C), and equal to 5 nm min^{-1}. A similar study[14] showed that the rate of deposition may reach 70 nm min^{-1} (temperature of the support 200–425 °C, pressure in the reactor 266 Pa, gas consumption (cm^3 s^{-1}): SiH_4 10, NH_3 10, N_2 50). The Si:N ratio in the deposit was less than 1, the hydrogen concentration 20–30 at.%, and the oxygen concentration did not exceed 5 at.%.

The deposition of indium phosphide from the trimethyl compounds (on supports of Si, InP, InGaAs, and GaAs) was carried out using an excimer laser (E = 100–200 mJ, τ = 15 ns, ν = 20 Hz).[159–161] The dependence of the nature of the deposition on the wavelength was studied at T_s = 323 °C, a total pressure of 0.8 kPa, and gas consumptions of (cm^3 s^{-1}): Me_3InPMe_3 9, PMe_3 38, H_2 150, and He 230. At 351 nm, the reagents were transparent, but a small quantity of deposit consisting of In and O was obtained. Radiation at λ = 248 nm was absorbed by $InMe_3$, so that mainly indium was deposited. At 193 nm, both reagents absorbed radiation strongly, and InP was deposited. A typical rate of deposition was 0.03 nm $pulse^{-1}$. The composition of the deposit depended on the photon flux: a phosphorus deficit was observed at 0.01–0.03 J cm^{-2}, and a deposit with the stoichiometric composition (InP) was formed at 0.1–0.3 J cm^{-2}. The deposit obtained for a low value of the flux was amorphous, but at values greater than 0.1 J cm^{-2} it was polycrystalline, with a particle size of 5–40 nm.

Gallium arsenide has been deposited by the reaction[143]

$$GaMe_3 + AsMe_3 + H_2 \rightarrow GaAs + 2CH_4.$$

The partial pressures of $GaMe_3$, AsMe3, and H_2 were 8.6, 13, and 20 kPa respectively. The SiO_2 support was heated at the focal spot (d = 0.6 mm) to 600–900 °C by the radiation of a CO_2 laser with a power of 2–3 W for 2–12 s. At W = 3 W, the deposition took place in a ring round the centre of the beam, and the deposit was not continuous even when the thickness reached several μm. The rate of deposition was 15–50 nm s^{-1}. The composition of the deposit varied form $GaAs_{0.37}$ to $GaAs_{2.4}$, depending on the irradiation conditions.

The deposition of GaAs was carried out at atmospheric pressure from a mixture of AsH_3 and $GaMe_3$ (or $GaEt_3$) by heating supports of single-crystal Si or GaAs to 500 °C with the beam of an Ar^+ laser (I = 1.5–35 kW cm^{-2}).[162,163] Scanning with the beam gave bands with a width of 1.5–500 μm and a thickness from 20 nm to 4 μm. Auto-epitaxy was observed at a growth rate lower than 2 nm s^{-1} (high rate of scanning and low exposure in one scanning cycle).

Stepwise layer growth of GaAs took place with the mixture of $GaMe_3$, AsH_3, and H_2 (total pressure 1 kPa) was supplied intermittently with a cycle duration of 4 s.[164] A section of the support was heated intermittently to 200–500 °C by the radiation of an Ar^+ laser. In this process, the proportion of deposited Ga was 1.0, and the activation energy was the same as that without irradiation (87 kJ mol^{-1}). A model of stepwise layer epitaxy, which assumes that photocatalytic decomposition of $GaMe_3$ takes place only on the surface As atoms (but not Ga atoms) was proposed.

The auto-epitaxy of GaAs in an $AsCl_3–Ga–H_2$ gas mixture was studied using excimer KrCl, KrF, XeCl, or XeF lasers at ν = 5–70 Hz.[165] Only the radiation with λ = 249 nm increased the rate of the process (for example by a factor of almost 4 at T_s = 600 °C and W = 1.7 W); the rate of deposition was proportional to the radiation power, and had values of 0.6–1.4 nm s^{-1}. The increase in rate is apparently due to the photolytic reduction of $AsCl_3$ by hydrogen to AsCl, as confirmed indirectly by the form of the infrared spectra.

Finally, it may be noted that there are three main methods for depositing compounds: 1) the simultaneous deposition of the elements of the compound being deposited (for example, from a mixture of SiH_4 and C_2H_4, or $GeMe_3$ and AsH_3); 2) the codeposition of a substance which is gaseous under the conditions of the experiment (oxygen, nitrogen) with another substance being deposited (for example from mixtures of $ZnMe_2$ and NO_2, or SiH_4 and NH_3); and 3) the decomposition of a complex compound with preservation of the bond between the elements being deposited [for example CrO_2Cl_2 or $Ti(OCHMe_2)_4$]. Formally, the reactions involving $MeSiCl_3$, Me_2SiCl_2, and Me_3InPMe_3 are of the last type, but in fact these compounds undergo preliminary decomposition in the gas phase, so that in reality they are of the first type.

V. Characteristics of laser-induced chemical deposition reactions

The experimental data examined reveal various characteristics of laser-induced chemical deposition from the gas phase.

1. These reactions require radiation with a definite wavelength. To transfer the molecules to higher vibrational levels, the wavelength of the radiation should lie in a relatively narrow range of values (about 0.1 μm). For example, the decomposition of silane by this method requires radiation with λ = 10.59 μm, and even at 10.55 μm the photolytic reaction does not take place. On the other hand, to transfer molecules to an excited electronic state, there is a restriction only on the maximum wavelength (minimum photon energy). The experimental data indicate that in this case it is appropriate to use photons with an energy 1.2–2.0 times the bond energy.

2. The principal parameters of the deposition: the intensity of the radiation, concentration of the reagents, pulse duration, and pulse repeat frequency, show clearly defined threshold values. Below these values, only gas-phase reactions, which probably have their own restrictions, can take place.

3. Deposition takes place most readily on irradiation of the support; prenucleation is observed close to the threshold parameters, that is a small quantity of new substances is apparently formed using the surface energy of the heterogeneous support. Another way of bringing about the process is by the irradiation of the gas close to the support, when the latter acts as a "sink" for the active species generated. Finally, the process takes place with the greatest difficulty in the reaction zone in the absence of any surfaces, since homogeneous nucleation requires a relatively high supersaturation.

4. Redistribution of the absorbed laser energy before the start of the chemical transformations leads to heating of the gas and transfer of the process to a known thermochemical path. Similarly, the absorption of radiation by the deposit formed makes probable a change from a photolytic to a pyrolytic mechanism (an example is

provided by the decomposition of chromium oxide chloride). If neither the support nor the deposit absorb radiation, the rate of the process is not sensitive to the temperature of the support; formally, this means that the apparent activation energy is zero.

5. In the deposition of compounds, their composition depends not only on the ratio of the starting materials but also on their comparative photo-activity; this provides an additional "lever" for controlling the properties of the substance obtained.

6. Under certain conditions, laser radiation leads to the formation of a plasma either as a result of optical breakdown of the gas or as a result of the emission of photoelectrons from the irradiated support, so that the deposition becomes strictly plasmochemical.

These characteristics are listed with traditional chemical deposition from the gas phase in mind.

VI. Possible applications of laser-induced deposition processes

The reactions examined are used mainly to obtain fine powders,[166–175] amorphous, polycrystalline, and single-crystal films (layers, coatings),[19,57,150,165,176–180] narrow bands of unlimited length,[50,123,133,154,181–183] regular surface structures,[184–186] and parts for drawing optical fibres.[187,188] These products have potential uses in powder metallurgy, solar energy, micro-electronics, radio technology, applied optics, and the technology of protective and decorative coatings. In each of these fields, a new technological method generally has to compete with several well established and intensively developing technologies. Thus a number of methods of deposition from liquid, gas, and plasma are used successfully to obtain fine monodisperse powders.[189] In micro-electronics, surface structures are deposited using ultraviolet and X-ray lithography, and continuous films are obtained by chemical reactions with gaseous reagents, including chemical deposition from the gas phase,[190] and also ion implantation.[191] In the preparation of elements based on *a*-Si:H, the main competing method is plasmochemical deposition.[192] Optical coatings are obtained by a range of methods: physical[193] and chemical[194] deposition, including atomisation in a glow discharge, ion-beam and magnetron atomisation,[195] and laser volatilisation.[196]

The lack of the required data makes it impossible to carry out a comparative economic evaluation of different methods. According to one estimate,[169] the cost of the production of 1 kg of silicon, silicon carbide, and silicon nitride powders in an assembly with an output of 50 ton per year using a CO_2 laser with a power of 1.5 kW is 5–25 dollars (the wide range of values is due to the difference in the cost of silane, whose contribution is considerable). The production of these powders might be economically advantageous with lasers operating for many hours (ideally, many days), but this is as yet impossible.

Thus it appears unlikely that there will be any significant practical application of laser-induced chemical deposition in the foreseeable future. The situation is slightly more optimistic for the small-scale application of this method to produce made-to-order integral circuits[197] and for the repair of photo-stencils.[198] Possible developments of the method are: 1) an increase in the number of substances that can be deposited; 2) the development of new methods for obtaining particles of relatively complex shape, for example tubes, beakers, springs, etc.; 3) the production of assemblies for obtaining coatings on planar surfaces with an area greater than 100 cm^2, and also on non-planar objects (spheres, rods, tubes, etc.); 4) the discovery of new methods for controlling the structure of the material being deposited; 5) the improvement of deposition methods to increase the uniformity of the properties of the products and the reproducibility of the results; and 6) the extension of theories of the mechanism of deposition and the modelling of specific processes.

VII. Summary

The main progress in the study of laser-induced chemical processes has been made in the decomposition of gaseous hydrides, organometallic compounds, and carbonyls. Two types of process, photolytic and pyrolytic, are developing rapidly, and to some extent supplement one another.[199] Important advantages of pyrolytic processes are the short time and the local character of the heating of the support. This to some extent prevents irreversible thermal transformations (degradation, recrystallisation of the support, etc.), decreases the risk of the formation of undesirable powdered deposits, and also makes it possible to intensify mass exchange in the deposition zone. Most progress will apparently be made in photolytic reactions in the ultraviolet range, where it is possible to select photon energies sufficient for the rupture of chemical bonds.

An independent direction of research is the study of the intramolecular selectivity of deposition processes, achieved, for example, by the two-stage infrared–ultraviolet dissociation of molecules.[200] Promising possibilities are provided by the use of extremely short (femtosecond) laser pulses[201] and multi-wave laser radiation with a mixture of inert gas halides.[202]

Current state of the problem of aromaticity

M V Gorelik
Scientific-Research Institute of Organic Intermediates and Dyes, Moscow

ABSTRACT. The different aspects of the current concept of aromaticity, which is based on the advances in the synthesis of aromatic systems and a study of their properties by experimental physical techniques and theoretical quantum-mechanical methods, are examined. Magnetic, structural, and energy properties, but not reactivity, can serve as criteria of aromaticity as characteristics of the electronic structure of cyclic conjugated systems, stabilisation of which is due to a cyclic delocalisation of electrons. A wider interpretation on which ideas about multiple types of aromaticity are based is unjustified and unsuitable.

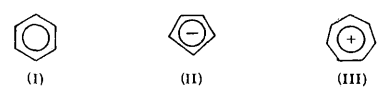
I. Introduction



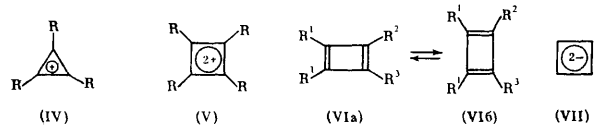
The problem of aromaticity is one of the principal problems in organic chemistry. More than 130 years since the Kekulé structure of benzene was established, it is undergoing a fruitful development through the close interaction between experiment and theory.[1–10] In the area of aromatic compounds, to which about 30% of all known organic products belong,[11] many fundamental rules of structure and reactivity have been established for the first time. During the time that the problem of aromaticity has been studied, theoretical organic chemistry has attained its most important achievements, such as the well-known Hückel rule, and at this point it has confronted a crisis, which has arisen from the proposal that the concept of aromaticity should be rejected altogether.[12–15]

The current state of the problem of aromaticity is very ambiguous. On the one hand, running in parallel to the development of the practical chemistry of aromatic compounds, the experimental and theoretical principles of aromaticity continue to be improved and extended. On the other hand, objections to aromaticity are discussed as before and all the time new types and variants of aromaticity are proposed, as a rule not being compatible with this concept. The main objects to aromaticity, which were put forward in the 1970s, are that aromaticity is not a physical quantity that could be measured directly[12] and the concept of aromaticity does not have a single meaning, as it comprises a number of postulates and theories.[13,14] The questions: "Aromaticity—myth or reality?",[14] "Aromaticity—an exercise in chemical nonsense?",[15] "Aromaticity not in fashion?",[16] "Aromaticity—theory or myth?",[17] became the titles or topics of publications, and the abundant forms of aromaticity became the subject of jokes ("schizoaromaticity"[12]). Even in studies that defended the usefulness of the concept of aromaticity,[6,10,16] together with wideness and universality, its diffuseness, physical heterogeneity, and the impossibility of a more or less rigorous determination are emphasised.

The erosion of the concept, the multiplicity of the types of aromaticity, the lack of a common view of the criteria for aromaticity, in particular the possibility of using reactivity as a criterion, have created certain complications in the chemistry of aromatic compounds. The present review aims to analyse the recent advances in the experimental and theoretical principles of aromaticity, to discuss the resulting concept of aromaticity, and to consider the ideas about the different types of aromaticity in this context.

II. Progress in the synthesis of aromatic systems

An accumulation of data from physical methods that constitute the foundation on which the concept of aromaticity is based has proved possible mainly as a result of the synthesis of different aromatic systems. During the early period of development of ideas about aromaticity[18] chemists did not even suspect that these systems existed. The modern era of the problem of aromaticity was started in 1931–1938 when Hückel developed the molecular orbital (MO) method to represent the electronic structure of unsaturated hydrocarbons, which led to the Hückel rule ($4n + 2$, $n = 0, 1, 2$, etc.) for determining the number of π-electrons with which a monocyclic, conjugated, planar carbopolyene is aromatic. Up to that time, benzene (I) and the cyclopentadienyl anion (II) as well as their heteroanalogues (pyridine, pyrrole, thiophene, etc.) were known as aromatic systems. Hückel attributed the aromaticity of benzene and the cyclopentadienyl anion to the completeness of the electron shell, in which six π-electrons completely occupied all three bonding orbitals, and he predicted the aromaticity of the cycloheptatrienyl cation (III). The synthesis of cycloheptatrienyl (tropylium) bromide in 1954[19] was the first step in a series of significant advances confirming the predictive power of the Hückel rule.

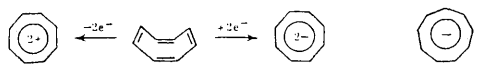


(I) (II) (III)

During the following years monocyclic, conjugated, neutral and charged polyenes were synthesised with the number of atoms (N) in the ring ranging from 3 to 30 ([N]annulenes); out of these the planar systems containing $4n + 2$ π-electrons were classed as aromatic,

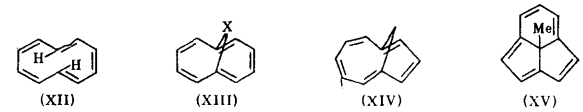
while those containing $4n$ π-electrons were classed as antiaromatic. Many new polycyclic and heterocyclic aromatic systems were also obtained. It is useful within the scope of the present review to describe briefly a selection of the main products, studies on which led to elaboration of criteria and the development of the theory of aromaticity.

Systems containing 2π-electrons are known—the cyclopropenium cation (IV) and cyclobutadienyl dication (V). Salts of cyclopropenium[20] and its trialkyl-, triaryl-, and tricyclopropyl-substituted derivatives are stable, so they can be isolated in a crystalline state. Tetramethyl and tetraphenyl derivatives of dication (V) have been synthesised in a superacid medium at a low temperature and have been characterised from their NMR spectra.[21]



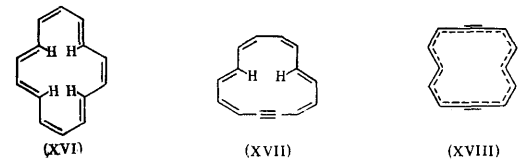
Cyclobutadiene (VI)[22] is the simplest antiaromatic system;[23] it has only been detected in an argon matrix during low-temperature photolysis (20 K). Cyclobutadiene derivatives stabilised by substituents such as t-butyl groups have been isolated in a pure form. A study of tri-t-butylcyclobutadiene using NMR spectroscopy[24] and generation of 1,2-dideuterocyclobutadiene with trapping of the isomers by dienophile[25] suggest that there is an equilibrium between the valence isomers (VIa) and (VIb), which, according to the NMR data, cannot be "frozen out" even at −185 °C.

(IV) (V) (VIa) (VIb) (VII)



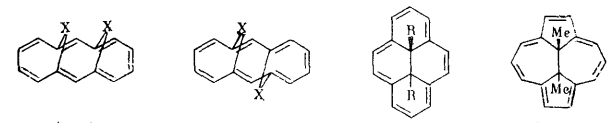
Despite the presence of 6π-electrons, the dicyclobutadienyl dianion (VII) does not possess aromaticity because of destabilisation resulting from interelectron repulsion in the small ring.[26,27]

Apart from benzene (I), the cyclopentadienyl anion (II), and the tropylium cation (III), the cyclooctatetraenyl dication (VIII) also belongs to the group of 6π-electron aromatic systems. The 1,3,5,7-tetramethyl-, tetraphenyl-, and 1,4-dimethyl-substituted derivatives of the latter are obtained when cyclooctatetraene (IX) is treated with SbF_5 at −78 °C.[28,29] When cyclooctatetraene (IX) is reduced with an alkali metal, it is converted to the cyclooctatetraenyl dianion (X)—a 10π-electron aromatic system.[30] The aromatic cyclononatetraenyl anion (XI) also has a 10π-electron shell.[31,32] In contrast to ions (VIII) and (X), cyclooctatetraene itself[33] is a typical cycloolefin; its non-planar molecule with $4n$ π-electrons ($n = 2$) has a boat conformation



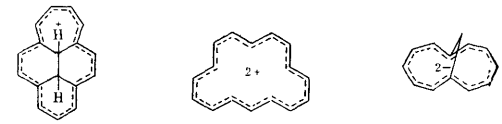
(VIII) (IX) (X) (XI)

Neutral monocyclic [10]annulenes[34] do not exhibit aromatic properties because of steric hindrance. Completely *cis*- and mono-*trans*-stereoisomers of [10]annulene have been isolated in a crystalline state at −80 °C, but they decompose when the temperature is increased. Despite the attempts undertaken, stereoisomer (XII) has not been prepared, since it is destabilised by the mutual repulsion of the hydrogen atoms at the 1- and 6-positions. Replacement of these hydrogen atoms by a bridging group (X = CH_2, CO, O, NH) leads to stable aromatic bridged 1,6-X-[10]annulenes (XIII) with a periphery as in naphthalene.[35–37] 1,5-Methano[10]annulene (XIV), with a periphery as in azulene, has also been synthesised.[38,39] Another type of bridged [10]annulene is the methano[10]annulene (XV) (7*b*-methyl-7*bH*-cyclopent[*cd*]indene).[40]



(XII) (XIII) (XIV) (XV)

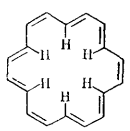
In [14]annulene (XVI), just as in [10]annulene (XII) but to a lesser degree, there is overlap of the inner hydrogen atoms, and so compound (XVI) has comparatively low stability.[41] The overlap can be eliminated by the introduction of one (XVII) or two (XVIII) triple bonds with a change to dehydroannulenes.[42]



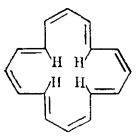
(XVI) (XVII) (XVIII)

Many bridged *syn*-1,6:8,13-bis-X-[14]annulenes (XIX) with a periphery as in anthracene, where X = CH_3, CO, CF_2, O, NH or X,X = $CH(CH_2)_nCH$ when $n = 0-3$, i.e. the bridges are joined together, have been synthesised. In contrast to the aromatic *syn*-isomers (XIX), the *anti*-isomers (XX) are extremely labile, reactive olefins. While *syn*-dioxo[14]annulene (XIX), X = CO, withstands flash pyrolysis at 500 °C, the corresponding *anti*-isomer (XX) must be kept in an atmosphere of argon at −40 °C. Another widely investigated group of bridged [14]annulenes is made up by 15,16-dihydropyrene compounds (XXI),[43] to which the bridged [14]annulene (XXII) (dicyclopenta[*ef*,*kl*]heptalene) is related.[44]

(XIX) (XX) (XXI) (XXII)



Aromatic ions containing 14π-electrons in the ring are known.[4,5] These are the bridge [15]annulenyl cation (XXIII), the [16]annulenyl dication (XXIV), the bridged 1,7-methano[12]annulenyl dianion (XXV), and others.



(XXIII) (XXIV) (XXV)

[18]Annulene (XXVI)—an example of aromatic systems with 18π-electrons—was historically the first macrocyclic annulene to be synthesised.[41] With its large ring size, the inner protons do not shield each other. The compound is relatively stable, it withstands distillation under reduced pressure, and can undergo aromatic substitution. Examples of bridged [18]annulenes are hexahydrocoronene which contains a central hydrogenated ring[45] and [18]annulene oxides, which contain the bonds of furan rings as a macrocycle.[46] Ions with 18π-electrons—the [17]annulenyl anion and [16]annulenyl dianion—have been reported. From among the higher annulenes with $4n + 2$ π-electrons, [22]annulene, a

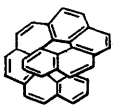
[30]annulene derivative, and bisdehydro[22]-, bisdehydro[26]-, and bisdehydro[30]-annulenes have been synthesised. From among macrocyclic systems with $4n$ π-electrons, the extremely unstable [12]annulene and bridged [12]annulenes are known. [16]Annulene (XXVII), [20]annulene, and [24]annulene have been isolated in a crystalline state as have the corresponding bisdehydroannulenes. The monocations of the bridged [13]annulene and [15]annulene, the dianion of [18]annulene, and some others[4,5] have been detected spectroscopically.

(XXVI)

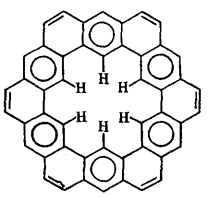
(XXVII)

The Hückel rule, strictly applicably only to monocyclic conjugated polyenes, has been extended to polycyclic compounds with the assumption, which has no theoretical basis, that the π system is determined by the periphery while the "inner" bonds and atoms do not introduce any significant perturbations (see, for example, the study of Rabinovich et al.[47]). Naphthalene (XXVIII) and azulene (XXIX) are aromatic bicyclic systems with 10π-electrons that have been thoroughly studied. The pentalene dianion (XXX) and bicyclo[6.2.0]-decapentaene (XXXI) [48] belong to the same group of 10π-electron systems. Bicyclic aromatic annulenoannulenes with one and three common bonds between the macrocycles,[49] such as a structure consisting of two rings of bisdehydro[14]annulene (XVIII), have been synthesised.

(XXVIII)



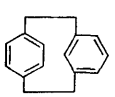
(XXIX)



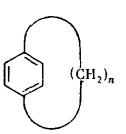
(XXX)

(XXXI)

The variety of polycyclic aromatic hydrocarbons is created through linear, angular, and peri-annelation to bicyclic structures. Linear benzannelation leads from naphthalene to anthracene, tetracene, pentacene, etc; angular benzannelation leads to phenanthrene and then to helicenes, which are hydrocarbons with their molecules in the form of cylindrical spirals, such as in octahelicene (XXXVI), since the spatial overlap of the rings makes a planar structure impossible. They have spiral asymmetry which is a special case of chirality. Helicenes containing 13 and 14 rings twisted into three coils of a single spiral have been synthesised.[50]

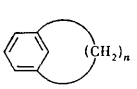


Polycyclic hydrocarbons that are built up from annelated benzene rings forming a closed loop have the group name of corannulenes.[51] The simplest example of a corannulene, for which the name was originally proposed, is the sterically strained hydrocarbon composed of five benzene rings with a pentahedron in the centre. Coronene and kekulene (XXXIII) which on the inside have a periphery of [6]- and [18]-annulene and on the outside have a periphery of [18]- and [30]-annulene respectively, belong to this group. The synthesis and study of the properties of kekulene (XXXIII) [52] and a theoretical analysis[51,53] have led to the conclusion that the electronic system of corannulenes consists of benzenoid rings with a sextet of π-electrons (XXXIIIa) rather than two electronic systems of annulenes (XXXIIIb).



(XXXII)

(XXXIIIa) (XXXIIIb)



The Hückel rule is not applicable to polycyclic peri-annelated structures that have atoms common to the three rings if all of the π-electrons are taken into account. The phenalenium cation, pyrene, and perylene are examples of peri-annelated aromatic systems with the total number of electrons being $4n$ but with $4n + 2$ π-electrons around the periphery.

Polycyclic non-condensed hydrocarbons in which the benzene rings are joined together by polymethylene chains in a ring are classed as cyclophanes.[54] For two benzene rings, three series of [m,n]cyclophanes are possible: para–para, meta–meta, and meta–para, when $m,n \geqslant 2$, for example, [2,2]metaparacyclophane (XXXIV). The benzene rings can be joined by three chains at the 1-, 3- and 5-positions, and also arranged in several layers when one ring simultaneously forms two loops. [n]Cyclophanes in which the polymethylene chain links the para- (XXXV) or meta- (XXXVI) positions of a single ring are also known. Cyclophanes with the shortest chain, in which the benzene ring is substantially bent, are of interest for studying the relationship between aromaticity and coplanarity (Section III).

(XXXIV)

(XXXV)

(XXXVI)

A whole series of heteroaromatic compounds can formally be derived from carbocyclic compounds by replacing a single CH group with a heteroatom Y that can supply one electron to the aromatic π-system or by replacing two adjacent CH groups with a heteroatom X that can supply a pair of electrons. The replacement of one or more CH groups in benzene by a heteroatom Y results in a six-membered aromatic heterocycle, and replacement of two adjacent CH groups in benzene or, from another viewpoint, replacement of a CH^- group in the cyclopentadienyl anion by a heteroatom X leads to five-membered aromatic heterocycles. Replacement of a CH^+ group in a cationic aromatic system by a heteroatom from Group III can result in the conversion to a neutral heteroaromatic molecule, for example, going from the tropylium cation to borepine.

A similar conversion is possible in other [$4n + 2$]annulenes and in polycyclic compounds. Among 10π-electron heteroaromatic systems, there have been reports on heteronines (XXXVII),[55] which are isoelectronic to the cyclononatetraenyl anion (XI) and from amongst which azonine (X = NH) is thermally stable to 50 °C and oxanine (X = O) is unstable, and on diheteronines (XXXVIII),[56] which are isoelectronic to the cyclooctatetraene dianion (X). Stable bridged aza analogues of 1,6-methano[10]annulene (XIII) with a quinoline and isoquinoline periphery and monoazoanalogues of [14]annulene (XVI) and [18]annulene (XXVI) [36,57] have been synthesised.

Dihydroporphins (around a ring that contains pyridine nitrogen atoms and excludes pyrrole nitrogen atoms) are regarded as 1,10-diaza[18]annulenes.[58]

(XXXVII)

(XXXVIII)

(XXXIX)

(XL)

In polycyclic heteroaromatic compounds, heteroatoms can simultaneously form part of two rings as in indolizine or the quinolizinium cation and in specific cases they can belong to three rings at the same time. Cyclazines,[57] which in view of the insignificant electronic interaction through the central atom can be regarded as analogues of bridged methenoannulenes, have a similar structure. Thus, [2.2.3]cyclazine (XXXIX) is analogous to the aromatic methenoannulene (XV), while [3.3.3]cyclazine (XL) is analogous to the antiaromatic [12]annulene. since in polycyclic compounds carbon atoms in different rings and different combinations can be replaced by heteroatoms, the number of known heterocyclic aromatic systems many times exceeds the number of carbocyclic systems.

III. Criteria of aromaticity

Of crucial significance is the question of choosing criteria which would make it possible to judge whether a given compound is aromatic and if possible to measure the degree of aromaticity. Properties of molecules that can be measured by experimental physical methods are used as criteria. These constitute magnetic and structural methods and data on the thermodynamic stability obtained mainly by calculation

1. Magnetic criteria

As the electronic system of organic compounds in the vast majority of cases does not have spherical symmetry, their magnetic susceptibility is anisotropic. In aromatic compounds this is reflected particularly clearly, since apart from the effect of local anisotropy caused by the electron shells of individual atoms, non-local anisotropy occurs, due to the combined system of π-electrons in the molecule, the so-called "ring current". The concept of the ring current is given by a postulated model,[59] the veracity of which has been confirmed by the agreement of the properties calculated using it and those measured experimentally. The use of magnetic criteria essentially consists of detecting magnetic properties non-local components, which would indicate the presence of a ring current.

The magnetic susceptibility on right-angled coordinates is expressed as the sum $\chi_M = 1/3(\chi_x + \chi_y + \chi_z)$. The essence of anisotropy of diamagnetic susceptibility is that the component along the axis perpendicular to the plane of the aromatic ring is always greater than that measured in the plane of the ring: $\chi_z \gg \chi_x \approx \chi_y$.

The difference between the components is a measure of the anisotropy:

$$\Delta\chi_M = \chi_z - 1/2(\chi_x + \chi_y).$$

Direct measurement of the anisotropy of molar diamagnetic susceptibility $\Delta\chi_M$ requires the growth of a monocrystal and an initial determination of the molecular orientation. Other methods are based on the Zeeman effect in microwave rotational spectra[60] and on a determination of deuteriated compounds in high-resolution ^{2}H NMR spectra.[61] Analysis shows[60,62] that only a fraction of $\Delta\chi_M$ (Table 1) for aromatic compounds, about a half for benzene,[60] can be attributed to the ring current, whereas the other fraction is due to local anisotropy. The experimental difficulties and the need to separate the contributions of the local and non-local components limit the widespread use of the anisotropy of diamagnetic susceptibility as a criterion of aromaticity.

Table 1. Anisotropy and exaltation of diamagnetic susceptibility (-10^{-6} cm^3 mol^{-1}).

Compound	$\Delta\chi_M$ (Ref.60)	χ_M (Ref.63)	$\chi_M - \chi_M^{loc}$

* Determination using the monocrystal orientation method; the remaining figures were obtained using microwave spectroscopy.

** Using the Haberditzl increments[63] to calculate χ_M^{loc}; in brackets — using Pascal constants, taken from Ingold[64] for hydrocarbons and from Pozharskii[9] for heterocycles.

*** Using Hameka parameters[65] to calculate χ_M^{loc}.

A property which is simpler to determine is the difference between the total molar magnetic susceptibility of an aromatic compound and that of an analogous hypothetical compound with localised bonds $\chi_M - \chi_M^{loc}$, known as the exaltation of diamagnetic susceptibility (Λ) [63] or non-local magnetic susceptibility (χ_M^{nonloc}).[65] The total magnetic susceptibility χ_M of the compound under study is measured experimentally by determining the force at which the sample of the substance is repelled by a magnetic field of given strength. The magnetic susceptibility of the hypothetical compound with localised bonds χ_M^{loc} is calculated as the sum of the contributions of the separate structural elements of the molecule. It is clear from the examples in Table 1 that the exaltation of diamagnetic susceptibility Λ is negative and considerable in absolute value, for the non-aromatic 1,3-cyclohexadiene it is equal to zero, and for the antiaromatic [16]annulene (XXVII) it is opposite in magnitude. It should be mentioned that, based on some of the same experimental values of χ_M, different values of Λ or χ_M^{nonloc} are given in the literature depending on which parameters are used in the calculation of χ_M^{loc} (see Table 1). A relationship between the non-local components of the diamagnetic susceptibility, its axial component, and the anisotropy has been deduced: $3\chi^{nonloc} = \chi_z^{nonloc} = \Delta\chi^{nonloc}$.[65] The index based on the anisotropy of optical polarisability[66] is similar to the exaltation of diamagnetic

susceptibility. The index based on the Faraday effect—the enhancement of the rotation of the plane of polarised light by a sample of an aromatic compound placed in a magnetic field compared to the rotation for the hypothetical model with localised bonds calculated from increments[14]—is also related to the magnetic susceptibility.

The comparative simplicity of determination and the applicability to different classes of compounds make the enhancement of diamagnetic susceptibility a practicable index for aromaticity. Its weak point lies in the need to calculate the diamagnetic susceptibility of hypothetical compounds by an additive scheme, which always holds the chance of errors, especially since anomalies are found for real compounds. Thus, for cycloheptatriene and cyclopentadiene values are obtained which would class them as aromatic compounds (Λ = 8.1 and 6.5 respectively).[63,65]

The simplest method to use in the study of aromaticity, requiring moreover a minimal quantity of substance, is the determination of chemical shifts of the protons in an aromatic ring in ^{1}H NMR spectra. As a result of the ring currents which generate an anisotropic diamagnetic field in aromatic compounds, inside the ring directed against the external magnetic field and outside the ring lying along the line of the external magnetic field, the signals from protons positioned inside the ring or above it are displaced upfield, while the signals from protons lying in the plane of the ring on the outer side are displaced downfield (diatropy). In antiaromatic compounds a paramagnetic field occurs, so that the signals from the inner protons are displaced downfield and the signals from the outer protons are displaced upfield (paratropy).

The difference between diatropic aromatic and paratropic antiaromatic systems is shown most clearly in a series of annulenes, where the recording of the chemicals shifts of protons has served as an important instrument in the classification of aromaticity, confirming the validity of the Hückel rule. The difference between the chemical shifts of the outer and inner protons in the ^{1}H NMR spectra of neutral aromatic [4n + 2]annulenes is 7–12 p.p.m., in the spectrum of the aromatic [16]annulenyl dianion it is about 16 p.p.m.[4] For antiaromatic annulenes this difference has a reverse sign and amounts to 2–7 p.p.m., while for the antiaromatic [18]annulenyl dianion it is about 30 p.p.m. The greater difference for the anions reflects the phenomenon, which has a theoretical basis,[67] that in charged aromatic–antiaromatic systems the ring current is greater than in neutral systems. In a series of diatropic tetra-t-butyl-substituted bisdehydro[N]annulenes containing t-butyl groups at the α-positions relative to the triple bonds, the difference between the chemical shifts of the outer and inner protons, taken as a measure of the ring current, decreases from 13.8 p.p.m. when N = 14 (XVI) to 4.0 p.p.m. when N = 30.[42] The fact that in the ^{1}H NMR spectrum of kekulene (XXXIII) the signal from the six inner protons occurs downfield at 8.37 p.p.m. and not far upfield as in [18]annulene has served as evidence for the benzenoid structure of (XXXIIIa) [52] (see Section II).

In bridged [4n + 2]annulenes the chemical shifts of the protons situated above the plane of the ring are strongly displaced upfield. For example, in 1,6-methanol[10]annulene (XIII), X = CH_2, the protons of the CH_2 group resonate at −0.51 p.p.m. while the ring protons resonate at 6.95–7.27 p.p.m.[41] Reduction of *trans*-15,16-dimethyl-15,16-dihydropyrene (XXI), R = Me, to the dianion, with a change from a 14π-electron aromatic system to a 16π-electron antiaromatic system causes the chemical shifts of the protons of the methyl group to change from −4.25 to 21.0 p.p.m. and the ring protons to change from 8.14–8.65 to −3.2 to −4.0 p.p.m.[41]

The vast majority of aromatic compounds contain medium or small rings which have only outer electrons. Their chemical shifts have to be compared with the chemical shifts of protons in model compounds rather than those of inner protons. In the case of benzene, for example, the signal in its spectrum is displaced 1.5 p.p.m. downfield relative to the signals from the olefinic protons of 1,3-cyclohexadiene, which can be selected as a model. It would appear to be possible to estimate the strength of the ring current from the degree of displacement of the signals, and hence estimate the degree of aromaticity. The ready availability of ^{1}H NMR spectra and the apparent simplicity in interpretation have given rise to many attempts of this type. Their failure has generally been because only a part of the chemical shift can correctly be related to the ring current. It is also necessary to take into account the contribution of the effect of local anisotropy and the influence of the distribution of electron density. An analysis applied to polycyclic benzenoid hydrocarbons[68] shows that only 50% or less of the total magnitude of the chemical shift can be attributed to the delocalisation effect, while the remaining proportion is defined as the contribution from local anisotropy. A simple comparison of the values of the chemical shifts of protons cannot give a true picture of the ratio of ring currents and is more suitable for establishing aromaticity than quantifying it.

The displacement of the signals in ^{13}C NMR spectra when a ring current occurs are approximately the same in absolute magnitude as in proton spectra, but since the range of chemical shifts of ^{13}C NMR is an order higher than for ^{1}H nuclei, the relative changes in chemical shifts in ^{13}C NMR spectra are small and are readily masked by other effects.[69]

From among the indices of aromaticity in use that are based on the measurements of chemical shifts, mention should also be made of "displacement by dilution" and "displacement from the solvent". The first of these is the displacement of a signal in the ^{1}H NMR spectrum when a liquid aromatic compound is diluted with an inert non-polar solvent multiplied by the molar volume: $\Delta\delta.V_M$. Referral of this value to the analogous one for benzene gives an index expressed in percent.[8] "Displacement from the solvent" is the difference between the chemical shifts of a polar molecule (acetonitrile) and a non-polar molecule (cyclohexane) in the liquid aromatic compound under study. It has been shown[70] that this parameter does not measure the ring current or aromaticity.

2. Structural criteria

A geometric characteristic of the molecules of aromatic compounds is their tendency to form a coplanar configuration of the atoms and bonds of equal length in the aromatic ring. Current methods for establishing the molecular structure—X-ray and neutron diffraction analysis, gas-phase electron diffraction analysis and microwave spectroscopy of free molecules—make the geometric parameters of almost all aromatic systems possible to determine.

The tendency towards coplanarity is due to the advantage of colinearity of the axes of the p orbitals for their effective overlap. An important question concerns what deviation from a planar configuration is admissible without a loss of aromaticity. A study of sterically strained aromatic compounds such as helicenes, corannulenes, and particularly cyclophanes with short bridges, provides data about this. The benzene ring in [n]paracyclophanes (XXXV) is distorted into the form of a boat with a deviation of 15–17° from planarity when n = 7,[54] 20–21° when n = 6 [71] (X-ray diffraction data), 22–24° when n = 5 (data from calculations).[72] In one derivative[5] of metacyclophane (XXXVI),

n = 5, one side of the boat is deflected by 27° and the other by 12°.[73] Despite this, the bonds in the benzene ring of these compounds are of equal length, and the values of the bond lengths and chemical shifts in the ^{1}H NMR spectra lie in the usual region for aromatic compounds. A determination of the anisotropy of diamagnetic susceptibility using high-resolution ^{2}H NMR for 8,11-dideutero[5]metacyclophane confirms that the ring is aromatic.[74] Calculations on the molecules of [5]paracyclophane [72] and [6]paracyclophane [75] using non-empirical quantum-chemical methods suggest that there is considerable destabilisation due to strain in the distorted benzene ring.

In unstrained aromatic systems the deviations from planarity that occur are usually small. From the data for strained structures and quantum-chemical calculations the view was expressed that even unstrained aromatic rings are flexible in the ground state when the deviations from planarity range from 5–20°.[76] An analysis of the vectors of the π-orbital axes in the case of bridged [10]annulenes (XIII)–(XV) shows that the molecule has a tendency to bend in order that the overlap of the π-orbitals should be at a maximum.[77]

The stability of a planar geometry of the system as determined by calculating the change in energy on bending about one of the axes has been proposed as a theoretical conformational criterion of aromaticity or antiaromaticity.[78] Systems in which the change to a non-planar conformation gives rise to a large endothermic change, a large exothermic change, or a small change in energy are classed as aromatic, antiaromatic, or non-aromatic respectively. It was found using a non-empirical MO method (6–21 G basis) that for aromatic benzene, pyridine, and pyrazine bending along the 1–4 axis by 20° requires energies of 62.8, 37.7, and 33.5 kJ mol^{-1}, while for the non-aromatic 1,4-dihydropyrazine the energy required is −9.2 kJ mol^{-1}. According to this criterion the system of the cyclobutadienyl dication (V), R = H, Me, for which non-empirical calculations[27,29] show that a non-planar conformation folded along a diagonal by about 35°, for example, when R = H, with an energy barrier of 19 kJ mol^{-1} (4–31 G basis) should be classed as non-aromatic. From the data on the distortion of a planar structure of the ring in strained aromatic molecules and the absence of a direct relationship between acoplanarity and antiaromaticity[10] it follows that the degree of planarity is not in itself sufficient as a criterion.

The carbon–carbon bond lengths in aromatic compounds have values that are intermediate between the length of a single C_{sp^2}–C_{sp^2} bond [(1.465 Å in butadiene)[80]] and a C=C double bond (1.337 Å in ethylene[80]). There is a clear difference between aromatic and antiaromatic compounds in the distribution of bonds. Thus, in the planar molecule of the aromatic [18]annulene (XXVI) there is no alternation in bonds: the 12 inner bonds have a length of 1.38 Å and the 6 outer bonds have a length of 1.42 Å, whereas in the conformationally mobile molecule of the antiaromatic [16]annulene (XXVII) single (1.44–1.47 Å) and double (1.31–1.35 Å) bonds alternate.[4]

According to the data from all known methods the benzene molecule has D_{6h} symmetry with equal bonds (1.397 Å). Despite this, the view has recently been expressed that even in this case a structure with D_{3h} symmetry and alternating bonds cannot be excluded because of the possibility of a molecular configuration with a 30° bend in crystals and the averaging out when gas-phase methods are used.[81] This point of view raises objections, particularly on the grounds that according to quantum-chemical calculations using a non-empirical method (3–21 G* basis) a structure with D_{3h} symmetry does not correspond to a minimum on the potential energy surface and has appreciably inferior stability compared to a D_{6h} structure.[82]

In a few other aromatic systems the bond lengths are also equal, according to X-ray diffraction data. For example, in the triphenylcyclopropenium cation (IV), R = Ph, they are 1.373 Å,[83] and in the cyclooctatetraenyl dianion (X) they are 1.407 Å.[84] However, a complete uniformity of bonds is rather more than the exception. In the vast majority of carbocyclic aromatic compounds, not to mention heterocyclic compounds, the C–C bond lengths are not fully equivalent. Introduction of substituents or annelation into the benzene ring disrupts the complete uniformity of the bonds. In napthalene (XXVIII) the C_α–C_β bonds are reduced to 1.371 Å, and the remaining bonds are increased to 1.412–1.422 Å;[80] in phenanthrene the C(9)–C(10) bond length is only 1.350 Å while the C(10)–C(10a) bond is elongated to 1.453 Å.[85]

The lengths of the bonds involving heteroatoms in heteroaromatic compounds vary over a wide range. Structural studies of the hetero analogues of benzene with Group V elements indicate that as its number in the Periodic Table increases, the angle in the ring at the heteroatom decreases while the length of the carbon–heteroatom bond increases, constituting 117° and 1.37 Å in pyridine, 101° and 1.73 Å in phosphabenzene (phosphorine), 97° and 1.85 Å in arsabenzene, and 93° and 2.04 Å in stibabenzene.[86] The stability of the compounds decrease in the same series. However, all molecules remain planar with C–C bond lengths equalled out to 1.38–1.41 Å, which suggests that there is a retention of aromaticity, which is weakened by an unfavourable geometry.

It has been proposed through the introduction of special indices that the degree of equivalence of the bond lengths in the ring should be used as a quantitative characteristic of aromaticity. The index of Julg[87] constitutes the product of two factors:

$$A = A_1 \cdot A_2 = [1 - 225/n\Sigma (1 - d_{rs}/\bar{d})^2] \cdot \Pi [1 - (\Delta q_{ij}/d_{ij})^2].$$

The first term strictly represents the degree of equivalence of n C–C bonds in the ring, having length d between atoms r and s with average length $\bar{d}$. This factor is not very sensitive to the variation in bond lengths: benzene 1.00, naphthalene 0.90, azulene 1.00, pyrrole 0.91. Therefore a second factor is introduced, taking into account the difference in the π-charges Δq_{ij} on the neighbouring atoms. The introduction of a corrective factor which operates with the magnitudes of charges calculated by a quantum-chemical method has the result that index A loses its purely experimental basis. Critical comments have been made and the opinion has been expressed that the Julg index is unsatisfactory.[9,88,89]

An index has been built up from an analysis of the bond lengths obtained experimentally or calculated by a quantum-chemical method. This index is based on the so-called "harmonic oscillator model of aromatic stabilisation" (HOMAS):[90]

$$I(\mathrm{HOMAS}) = 1 - \frac{98.89}{n} \sum_{r=1}^{n} (d_{\mathrm{opt}} - d_r)^2.$$

Calculation and summation of the squares of the differences are carried out separately for each type of bond using the optimum value of the length (d_{opt}): C–C 1.397, C–N 1.338, N–N 1.308, C–O 1.300 Å. When applied to polycyclic compounds, this index is more convenient for characterising the aromaticity of individual rings.[90]

Since a direct comparison of the lengths of bonds involving different atoms is impossible, a conversion from the experimental values of the bond lengths (d) to their orders (N) is used by calculation from the correlative equation: $N = ad^{-2} - b$, where a and b are empirical constants (for values, see the studies of Pozharskii[9] and Bird[91]). The problem then essentially consists of developing an index which reflects the variation in the bond orders. Pozharskii[9] proposed the index $\Delta\overline{N}$, which is the average value of the variations of the orders of n bonds, including single bonds, calculated as the sum of all the differences ΔN divided by their quantity, which is equal to the number of sets of n to the power 2: $\Delta\overline{N} = \Sigma\Delta N/C_n^2$. In order to express the aromaticity in percent, the aromaticity of benzene ($\Delta\overline{N} = 0$) is taken as 100% and that of cyclopentadiene ($\Delta\overline{N} = 0.49$) is taken as 0%, which gives a scale relative to the factor $I = 100(1 - \Delta\overline{N}/0.49)\%$.

On the same basis, Bird[91-93] introduced a similar scale, in which the variation of the bond orders is given by the ratio of the mean square deviation to the arithmetic mean of the bond orders:

$$V = \frac{100}{N}\sqrt{\Sigma(N - \overline{N})^2/n}.$$

For the aromaticity scale, the aromaticity of a completely delocalised system ($V = 0$) was taken as 100% and the index of the corresponding Kekulé structure with completely localised bonds ($V_K = 35$ for five-membered rings, $V_K = 33.5$ for six-membered rings) was taken as 0%; $I = 100(1 - V/V_K)\%$ (Table 2).

Table 2. Structural indices of aromaticity.

Compound	Aromaticity, %		Compound	Aromaticity, %	
	(Ref.9)	(Refs.91, 92)		(Ref.9)	(Refs.91, 92)
Benzene	100	100	Pyridine	82	85.7
Naphthalene	63	—	Pyridazine	65	78.9
Thiophene	45	66	Pyrimidine	67	84.3
Pyrrole	37	59	Pyrazine	75	88.8
Selenophene	37	59	1,2,3-Triazine	65	76.9
Tellurophene	20	48	1,2,4-Triazine	71	86.1
Furan	12	43	1,3,5-Triazine	100	100
Phosphole	8	35	1,2,4,5-Tetrazine	88	97.8
Tetrazole	80	72	Pyridinium	54	66.7
1,2,4-Triazole	71	81	Pyrilium	28	65.8
Pyrazole	61	73	Phosphorine	61	74.1
Imidazole	43	64	Sydnone	17	42
Thiazole	43	64	2-Pyridone	22	59

The structural indices are based on experimental results, they effectively differentiate the aromaticity of compounds, they provide a single continuous scale, and in the case of polycyclic compounds they can be used to determine both the system as a whole and its separate cyclic fragments. Inapplicability to symmetric systems is among their limitations. In comparing the two variants of structural index it is clear that the distribution of compounds in terms of aromaticity is on the whole similar, although the ratios of aromaticities in a number of cases do not agree, sometimes by a substantial amount. Thus, according to the Pozharskii index, furan is 8 times and phosphole is 12 times less aromatic than benzene, whereas according to the Bird index they are only respectively 2.3 and 2.8 times less aromatic. On the first scale 1,2,4-triazole is less aromatic than tetrazole, on the second scale it is the reverse. Since both indices are based on the same collection of data and only differ according to the way these are treated mathematically, qualitative discrepancies cannot be justified. The development of a common approach is required.

Jug[94] has proposed that the least of the complete ($\pi + \sigma$) bond orders of the system, calculated by one of the semiempirical MO methods (SINDOl) with optimisation of geometry, should be taken as a criterion of aromaticity and called the ring current index. Examination of the values given reveals a number of discrepancies with the results of experimental criteria. Thus, pyrazole proves to be a non-aromatic compound and furan is more aromatic than pyrazole as well as imidazole (cf. Table 2).

Information about the degree of fixation of the bonds in an aromatic ring can be obtained from the values of spin-spin coupling constants of vicinal protons ($^3J_{HH}$) in ^{1}H NMR spectra. The $^3J_{HH}$ constants when other conditions are equal show a linear dependence on the length (order) of the C–C bond and are larger the shorter the length (higher order) of the bond.[69] When the bonds are exactly the same length as in benzene, the ratio of constants of the neighbouring bonds $J_{rel} = 1$, when there is complete localisation of single and double bonds as in 1,3-cyclohexadiene or compound (XLI) $J_{rel} \approx 0.5$. In bicyclic aromatic compounds J_{rel} has intermediate values; in naphthalene, for example, $J_{12}/J_{23} = 0.82$.[95] As the vicinal spin-spin coupling constants depend not only on the length of the C–C bond but also on the C–C–H bond angles in planar systems, which are different in five- and six-membered systems, and on the electronegativity of the heteroatoms and substituents present in a molecule, this index has limited use. It is only suitable when comparing compounds that are similar in structure, such as the benzoheterocycles (XLII) and (XLIII), which formally have a benzenoid and orthoquinoid structure, and the values of the constants $J_{rel} = J_{45}/J_{56}$ vary from 0.89 to 0.93 and 0.70 to 0.74 respectively.

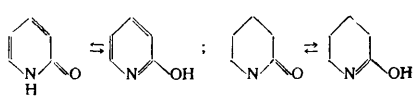
3. Energy criteria



The opportunity for aromatic systems to exist arises because cyclic declocalisation of the π-electrons leads to an increase in thermodynamic stability of the molecule, namely, to a decrease in the level of its internal energy. A gain in energy is a necessary condition of aromaticity and could serve as a sufficient criterion if there were reliable methods of determining it. The difficulty in using energy criteria occurs precisely because of the inadequacy of these methods. The principal difficulty is that the energy of a real aromatic molecule has to be compared with the energy of a hypothetical molecule with non-interacting localised double and single bonds. The difference between the energies of these structures, which is known as the resonance energy (RE), cannot be completely determined on an experimental basis since the reference structure does not exist in reality. Therefore the resonance energy as the principal energy criterion of aromaticity is either determined by combining experiment with calculation (empirical RE) or calculated theoretically using quantum-mechanical methods.

The empirical resonance energy (ERE) is determined as the difference between the heat of combustion or heat of hydrogenation of an aromatic compound determined experimentally and the corresponding value for a model structure calculated by an additive scheme as the sum of the contributions of individual bonds.

$$E(\text{ERE}) = -(\Delta H^{\text{exp}} - \Delta H^{\text{addit}})$$

(The minus sign indicates that the resonance energies of aromatic systems are defined as positive). A determination of the ERE from the heat of hydrogenation is preferred if hydrogenation is practicable, as it constitutes the difference between not such large numbers as in a determination from the heat of atomisation. The main source of uncertainty arises not because of errors in the thermodynamic experiment but in the complexity of including all the factors in calculating the heats of atomisation or hydrogenation of the model compound. In particular, there is no single method for determining the energy of a single $C_{sp^2}-C_{sp^2}$ bond in structures without conjugation. Depending on whether averaged bond contributions or bond contributions that take into account the environment are used in the calculation of the heat of combustion of 1,3,5-cyclohexatriene, the ERE value of benzene varies from 0.5 to 3 eV (see Ref. 3, p. 19). The ERE values of some compounds, determined from heats of combustion, are given below in Table 3. Attempts to deduce rational numerical values of the bond contributions based on a critical analysis of thermochemical data by compromises and assumptions do not improve the situation very much.[96]

An experimental study of reversible chemical reactions—acid–base, tautomeric, and redox reactions—can give some idea of the magnitude of the stabilisation energy. Thus, the equilibrium constants that corresponds to formation of aromatic ions clearly indicate their stabilisation. This is suggested by the high acidity of cyclopentadiene, which is deprotonated to the aromatic cyclopentadienyl anion (II) (pK_a = 15 [5]) compared to the acidity of alkanes, for example (pK_a = 68–70 [97]); the high basicity of the ketones—cyclopropenone, tropone, and phenalenone (pK_a = −3.1, −0.6, −1.4 respectively[98])—protonation of which leads to the formation of the hydroxy derivatives of the aromatic cyclopropenium (IV), tropylium (III), and phenalenium cations, compared to the basicity of acetone, for example (pK_a = −7.2); and the values of the equilibrium constants (pK_{R^+}) of the reaction: $R^+ + H_2O \leftrightarrows ROH + H^+$, for aromatic cations such as tricyclopropylcyclopropenium (IV), R = C_3H_5, (pK_{R^+} = 10.0)[99] one of the most stable carbocations, tropylium (III) (pK_{R^+} = 4.7),[100] the bridged cation of [15]annulene (XXIII) (pK_{R^+} > 8.7),[5] etc. compared to a stabilised conjugated cation such as Ph_3C^+ (pK_{R^+} = −6.4).[100] From a comparison of two reversible reactions, one of which involves aromatic compounds and the other involves non-aromatic compounds, these being similar in structure, the ERE difference between the aromatic tautomers can be determined. Thus, a comparison of the constants of the tautomeric equilibrium of the aromatic compounds 2-pyridone (XLIVa) ⇆ 2-hydroxypyridine (XLIVb) with the corresponding hydrogenated models (XLVa) ⇆ (XLVb) shows that the ERE of 2-hydroxypyridine is 0.32 ± 0.04 eV greater than that of 2-pyridone.[8]

(XLIVa) (XLIVb) (XLVa) (XLVb)

In determining the empirical resonance energy, the reference structure, the energy of which is calculated by summation of the bond contributions derived from data for alkanes and alkenes, is a model with alternating bonds, namely, with a geometry that differs from the geometry of the aromatic molecule which has equalised bonds. The resonance energy relative to the reference structure with the same geometry is known as the vertical resonance energy. It is greater than the ERE by an amount equal to the distortion energy that is necessary to stretch the double bonds and compress the single bonds. The deformation energy on going from cyclohexatriene to benzene is estimated at 1.17–1.60 eV while the vertical resonance energy is estimated at 2.73–4.83 eV.[101]

Since the total stabilisation energy of the system depends on its size, in order to compare different systems resonance energy values calculated for one π-electron are used. Standardisation of the resonance energy on the basis of one atom [102] and one bond [103] and the ratio of the resonance energy to the complete π-electron energy of the reference structure (% RE) have also been proposed.[104]

In the Hückel approximation the quantity which should correspond to the vertical resonance energy is the delocalisation energy (DE). It constitutes the difference between the π energy of the system calculated by the Hückel MO method and the π energy of double bonds represented as a Kekulé structure. The contribution of each of the latter is equated with the π-energy of an ethylene molecule (2β). Since benzene has a π-energy equal to 8β as calculated by the Hückel MO method while cyclohexatriene has a π-energy of three ethylene molecules, equal to 6β, the delocalisation energy of benzene is 2β. The delocalisation energy values of certain other hydrocarbons are given in Table 3. It is to be expected from the delocalisation energy values that all the annulenes except for cyclobutadiene, not only those that satisfy the Hückel rule but also benzocyclobutadiene or pentalene, which do not exist in a free state, should be aromatic. With respect to its resonance energy value per π-electron (Table 3) benzene is below the polycyclic hydrocarbons, and the lower polyacenes fall below the higher members, which is at variance with the actual data on the stability and properties of these compounds.

By taking into account the unsuitability of the resonance energy as a criterion of aromaticity and the rought approximation that have to be resorted to in calculating the energies of hypothetical cyclic polyenes as reference compounds, Dewar proposed that they should be replaced by acyclic polyenes with an open chain.[105] This introduced a fundamental improvement in the calculation of resonance energy. In a determination of the Dewar resonance energy (DRE), the Pariser–Parr–Pople SCF MO method is used to calculate the heats of atomisation of the cyclic compound under study, and in order to calculate the heat of atomisation of the reference structure the energies of the double and single bonds, which in a series of polyenes are given by the constants:

$$E(\text{DRE}) = -(\Delta H^{\text{cycl}} - \Delta H^{\text{acyl}}).$$

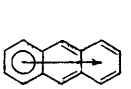
are added up. Relating this to the number of π-electrons in the system gives the Dewar resonance energy per π-electron, denoted by the acronym REPE (resonance energy per electron). This parameter (Table 3) is in much better agreement with the actual material. Its value is highest for benzene, it decreases on going from lower polyenes to higher polyenes, it is close to zero for pentalene, and for cyclobutadiene it acquires a negative value. When thermochemical data are available for acyclic polyenes, the Dewar resonance energy can be calculated from them with the same results reached as in the

calculation of the heats of atomisation of acyclic polyenes by summation of the bond energies.[106] The Dewar resonance energy (DRE) is less than the empirical resonance energy (ERE) by an amount equal to the conjugation energy in the acyclic polyene, which may be expressed in terms of the conjugation energy (CE) of butadiene:[107]

$$E(\text{DRE}) = E(\text{ERE}) - nE(\text{CE}) \text{ (butadiene)},$$

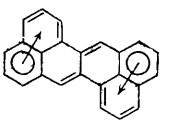
where n is the number of single bonds in the reference structure.

With the development of quantum chemistry it became possible to calculate the resonance energy on an entirely theoretical basis using a non-empirical method. The quantum-mechanical vertical resonance energy for benzene, obtained by a non-empirical MO method (DZ basis) which takes into account electron correlation, is 3.34 eV; the distortion energy is 1.30 eV; the adiabatic resonance energy, which is equivalent to the empirical resonance energy, is 2.17 eV; and the standardised energy, which is equivalent to the Dewar resonance energy calculated from the equation above, is 1.00 eV when the conjugation energy of butadiene is 0.39 eV.[107]



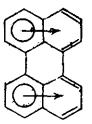
By formulating a new theoretical criterion of aromaticity, Dewar rejected at the same time hypothetic cyclopolyenes as reference models and the Hückel MO method for the calculation of energies, having expressed the view that it was unsuitable for further use in organic chemistry.[105] It transpired, however, that the main point was not the change in method of calculation but the exchange of models. Hess and Schaad showed[106,107] that in a correlation of the π-energy of a conjugated cyclic system calculated by the Hückel MO method with the π-energy of the corresponding acyclic polyene obtained by an additive method, agreement with the actual data is just as satisfactory as when using a SCF MO method (Table 3). In order to calculate the energy of an acyclic polyene in a determination of the resonance energy by the Hess–Schaad method (HSRE), the empirical parameters required for the bond energies are not of two types but eight types, depending not only on the multiplicity of the bond but also the number and position of the hydrogen atoms.[112,116]

A way of calculating the resonance energy within the scope of the Hückel MO method has been developed[114,115] with the use of graph theory techniques. In the Hückel MO method the complete π-energy of the molecule is expressed as the sum of the molecular orbital energies, taking into account how they are filled. The problem essentially consists of determining the coefficients of the characteristic polynomial, the roots of which constitute the orbital energies (in β units). By using a topological scheme based on the graph-theory theorem of Sachs, it is possible to calculate the polynomial coefficients directly from the molecular structural formula (molecular graph). The coefficients are calculated by summation of the total number of components of the molecular graph, taking into account the cyclic component. If the contribution of the cyclic component in the coefficients is omitted, a polynomial that corresponds as if to the same system but without the ring will be obtained. Summation of the roots of this polynomial, known as acyclic, gives the reference energy, which is subtracted from the π-energy of the conjugated system to give the topological resonance energy (TRE):[114,115]



$$E(\text{TRE}) = \sum_{i=1}^{n} g_i(x_i - x_i^{ac}),$$

where x_i and x_i^{ac} are the roots of the cyclic and acyclic polynomial and g_i is the degree of occupation of the π-orbitals by electrons (Table 3). While in a determination of the Dewar resonance energy and Hess–Schaad resonance energy the reference energy belongs to an acyclic polyene represented by a structural formula, in the determination of the topological resonance energy it has only a mathematical representation as an acyclic polynomial. Because of this, the topological resonance energy is applicable not only to neutral carbocyclic and heterocyclic molecules for which Kekulé structures can be drawn but also to ions, radicals, excited states, and unusual combinations of atoms.



In addition to calculations of the resonance energy based on SCF MO and Hückel MO methods, several methods have been proposed for calculating the resonance energy of carbocyclic benzenoid systems with empirical parametrisation, having similar features to the valence method and based on the sextet structures of Clar,[117] Kekulé structures,[108] or "conjugated" rings,[118] revealed in the molecular structure. Clar introduced a circle as a distinctive symbol of a sextet of π-electrons for those rings in polycyclic hydrocarbons which, as in the Kekulé structure of benzene, have three double bonds; this made it possible to make a qualitative interpretation of many properties.[119,120] Apart from sextets in the molecule there are rings which are capable of "diluting" the sextet through transfer of two π-electrons to them, which is shown by an arrow as in anthracene (XLIV), rings with fixed double bonds as in cetrene (XLV), or "empty" rings like the central ring in perylene (XLVI). It is assumed that the more aromatic a compound is, the more sextets there are in its structure and the less the sextets are "diluted" through the participation of neighbouring rings.

(XLIV)

(XLV)

(XLVI)

In order to make a quantitative determination of the resonance energy of a polycyclic benzenoid hydrocarbon, all of the Clar structures are written out and the number of sextets, isolated double bonds, and rings "diluting" an adjacent sextet are determined in each, the numbers are added up, and after that, by using numerical values of these parameters (in eV), the resonance energy is calculated from a linear equation.[117] The values of the parameters are defined from an empirical correlation with the Dewar resonance energy. This method is also suitable for characterising the local aromaticity of individual rings. In a similar manner, a calculation is carried out on the basis of Kekulé structures[108] or conjugated rings,[118] when each ring in each Kekulé structure is examined and evaluated by type. Theoretical analysis suggests that there is an inherent similarity between the different methods for calculating the resonance energy.[116]

All variants of the resonance energy which are calculated using an acyclic polyene as the reference structure are resonance energies in the Dewar sense. By using this theoretical index of aromaticity it is possible to trace the border between aromatic, antiaromatic, and non-aromatic compounds, depending on whether the resonance energy is positive, negative, or close to zero, and also to develop a continuous scale of aromaticity as the resonance energy per π-electron increases. Comparison of the three variants of the scale—DRE, HSRE, and TRE (Table 3)—shows that on the whole they agree non-linearly, although they have particular differences or

discrepancies. Thus, according to the value of the Dewar resonance energy, benzocyclobutadiene is aromatic, to a greater degree that azulene and furan, while pentalene is non-aromatic. On the other hand, according to the values of the Hess–Schaad and topological resonance energies, benzocyclobutadiene and pentalene are anti-aromatic. Attention is drawn to the fact that on the latter two scales, where the resonance energies of ions are calculated, it is not benzene that occupies the first place with respect to aromaticity, but separated by a large amount is the cyclopropenium cation, followed by the cyclopentadienyl anion and the tropylium cation. According to its Hass–Schaad resonance energy value per π-electron (-0.002β),[102] the cyclobutadienyl dication is classed as a non-aromatic system, which is consistent with the data of the conformational criterion (see Section III). The relative positions on the different scales for compounds that are similar in structure do not always coincide. For example, on the DRE and TRE scales pyrimidine is more aromatic than pyrazine while on the HSRE scale their aromaticity is the same, whereas according to the data of structural criteria (Table 2) pyrazine is more aromatic than pyrimidine.

Table 3. Resonance energy values.

It should be noted that the conclusions about aromaticity that are based on the value of the resonance energy depend to a considerable extent on the quantum-chemical calculation method being used, particularly in borderline cases. An obvious example of this is the controversy over the nature of the electronic system of bicyclo[6.2.0]decapentaene (XXXI).[48] The system was predicted to be antiaromatic using the simple Hückel MO method and other methods, and at the same time from graph theory it was concluded to be diatropic,[121] which could have fundamental importance as a refutation of the obligatory interrelationship between diatropy and aromaticity. On the other hand, a non-empirical method gave an indication that it was weakly aromatic $E(\mathrm{RE}) = 0.17$ eV,[122] which is in better agreement with the conclusions from the experimental data (NMR, X-ray diffraction, thermochemical).[48] In order to avoid similar situations, it is advisable on the basis of calculations that only those systems with a large absolute value of the resonance energy should be termed aromatic (antiaromatic).[123]

The essential significance of the theoretical methods lies in their identification of the nature of aromatic stabilisation and establishing its relationship with magnetic and structural properties used as experimental criteria. The determination of a quantitative relationship between the resonance energy and the magnetic parameters of a molecule is regarded[59] as a considerable success. A simple ratio has been derived, relating the resonance energy to the ring current (K) and the non-local diamagnetic susceptibility resulting from it for [N]annulenes with $4n + 2$ π-electrons:[124,125]

$$E(\mathrm{RE}) = -\frac{\pi^2}{mS}K, \tag{1}$$

$$E(\mathrm{RE}) = -\mathrm{const}\,\frac{\chi^{\mathrm{nonloc}}}{S^2}, \tag{1'}$$

where S is the area of the ring (for benzene S is assumed to be 1), $m = 3$ [125] or $m = 4$,[126] $\mathrm{const} = -\frac{1}{8m}\left(\frac{hc}{e}\right)^2$. . The sign of the ring current indicating its direction, which is opposite in sign to the resonance energy, denotes that diatropy is a necessary attribute of aromaticity.[104] From equation (1) it is possible to develop a linear correlation between the ratio of the difference in chemical shifts ($\Delta\delta$) of the outer and inner protons in neutral aromatic [N]annulenes (see Table 2) to the area of the ring and the value of E(RE) per π-electron:[126]

$$\Delta\delta/S = k.E(\mathrm{RE})/\mathrm{N}, \tag{2}$$

where k is a proportionality coefficient. The relationship established between the resonance energy and the ring current, which shows that delocalisation of the bonding π-electrons in the ring serves as a common origin of both aromatic stabilisation and diamagnetic exaltation, provides a theoretical basis for using experimental magnetic criteria.

It was concluded from statistical treatment of the numerical values of 12 different indices of aromaticity for 15 heterocycles and benzene using the main characteristics that the structural criteria I and ΔN and the energy criterion DRE on the one hand and the magnetic criteria χ_M and Λ on the other hand are mutually orthogonal, constituting the scales of two types of aromaticity—"classical" and "magnetic".[89] The remaining indices occupy an intermediate position. No opinions are put forward about the physical nature of the orthogonality, even though this conclusion clearly contradicts the relationships in equations (1) and (2). It cannot be excluded that this is not related to the fundamental difference between the scales but to a deficiency in determining the numerical values of the magnetic characteristics χ_M and Λ, especially for heterocycles (see Section III).

IV. Aromaticity and reactivity

For a long time reactivity was the main criterion of aromaticity. A year after the publication by Kekulé on the structure of benzene and about aromatic compounds being structurally similar to

benzene, the idea was put forward by Eilenmeyer about the chemical similarity of aromatic compounds.[18] Since electrophilic substitution reactions are typical for benzene, it was the capacity for these reactions that was considered, and in a number of studies up to the present time has been considered, to be a sign of aromaticity. The tendency of aromatic compounds to undergo substitution rather than addition reactions, the tendency to "retain their form" is due to their increased thermodynamic stability, namely, to a reduced level of free energy. However, the reactivity depends not only on the level of the free energy of the ground state of the substrate but is determined by the difference between the levels of the ground and transition states—the free energy of activation. The energy of the transition state varies in general over such a wide range that the variation of the upper limit of the activation barrier can completely mask the effect of a change in the lower limit, which depends on the degree of aromaticity.

This is clearly illustrated by an examination of the following series of aromatic compounds: sodium cyclopentadienide, pyrrole, benzene, pyridine, tropylium bromide. The cyclopentadienyl anion undergoes electrophilic substitution extremely readily; on going to pyrrole and then benzene and pyridine the ease of electrophilic substitution is decreased, and up to now it has not been possible to involve the tropylium cation in any electrophilic reaction. On the other hand, tropylium salts react very readily with various nucleophilic reagents, pyridine undergoes these reactions with more difficulty, benzene reacts with great difficulty, and sodium cyclopentadienide does not react at all. In this series the reactivity towards electrophilic reagents decreases on going from the cyclopentadienyl anion. The same applies to the ease of nucleophilic nucleophilic reagents it is in the reverse order without any apparent relationship to the degree of aromaticity. The reason for the lack of correlation between the reactivity and aromaticity in this case is precisely because the energy of activation changes mainly as a result of the reduction or increase in the energy level of the transition state. The nature of this change is clear in terms of the collision theory. It is obvious that the repulsion forces which the converging particles have to overcome are incomparably greater when the particles have the same charge as in electrophilic attack on a tropylium cation that when they have different charges as in electrophilic attack on a cyclopentadienyl anion. The same applies to the ease of nucleophilic attack on a tropylium cation and its difficulty in the case of a cyclopentadienyl anion. The same applies to the ease of nucleophilic the π-deficient heterocycle of pyridine occupy respective intermediate positions between ions and benzene.

Even under ideal conditions for comparing compounds—with the reagent standardised, a common mechanism, the absence or levelling out of solvation, catalytic, and other effects—the reactivity depends directly on the degree of aromaticity only when the energy level of the transition state remains constant. In practice, these conditions cannot usually be achieved. Therefore reactivity cannot in general serve as a criterion of aromaticity. Only in a series of compounds that are similar in structure, when the changes in energy of the transition state and ground state are proportionate, there is a linear correlation between the changes in resonance energy and the free energy of activation, as for example in the case of the Diels–Alder reaction of aromatic hydrocarbons with maleic anhydride.[127] Moreover, the tendency for "preservation of form" is typical not only for aromatic but also for certain non-aromatic conjugated systems. On the strength of this, Lloyd and Marshall[13,128] proposed that aromatic and non-aromatic compounds that exhibit this tendency should be combined into the same group, having given them the new name "meneidic", and the term "aromatic" should be rejected, but they did not meet with support.

There is a fundamental and complex interdependence between reactivity and aromaticity rather than a simple relationship. The electronic structure of the substrate not only determines the lower level of the activation barrier but also has an effect on the structure of the transition state and intermediates. Information about aromaticity is not sufficient but entirely necessary for an understanding of reactivity. However paradoxical are the general features of reactivity, which cannot serve as a criterion of aromaticity but are extremely important in the practical sense, the main concern is what binds together the chemistry of aromatic compounds and prompts its separation into an independent branch of organic chemistry.

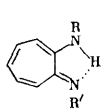
V. The concept of aromaticity

The accumulated facts and interrelationships suggest that cyclic conjugated molecules or ions have common structural features which are responsible for their stabilisation, and they are known as aromatic. The means of representing the electronic structure depends on the chosen method. When applying the MO method, which is that most widely used at the present time, the movement of electrons in delocalised orbitals is the topic under discussion, for the model with localised orbitals, their overlap (spin interaction) is being considered.[129]

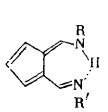
Thus, the concept of aromaticity applies to molecules whose structural features serve to combine atoms into a ring and conjugation in the ring is "an alternating sequence (in the structural formula) of single and double bonds."[130] In ions this sequence is augmented with a cation or anion site. The physical scope of aromaticity in terms of the MO method is cyclic delocalisation of electrons causing a gain in energy, which stabilises the system.

Aromaticity is a special property of electron shells, and the latter cannot be observed directly. Therefore the objection to aromaticity on the grounds that it cannot be measured directly is unjust.[12] In reality aromaticity is exhibited in magnetic, structural, energy, and magnetic properties. If the phenomenon is not confused with its effect on properties, another objection to aromaticity, namely, that aromaticity is a combination of different ideas[13,14] is eliminated.

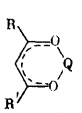
The present concept of aromaticity does not leave room for the ideas about different types of aromaticity that appear in the literature. In the vast majority of cases these ideas are based on a different, wider interpretation of aromaticity, where all distinguishing features apart from stabilisation of the system, including the occurrence of cyclic delocalisation or electrons and the ring itself, may be omitted as non-essential, and conjugation is taken to mean "overlap of the atomic *p* orbitals of three or more neighbouring atoms"[130] rather than an alternating sequence of bonds. The variety of types of aromaticity strengthens the position of critics of the concept, since if there are many "aromaticities", it may not as such exist. It is useful to examine the terms that have been introduced to denote the types of aromaticity, responding to two questions in each case: whether the type of stabilisation which is implied by the term introduced has been demonstrated, and if so, to what extent can it be justified to call this type of stabilisation aromatic.



VI. Types of aromaticity



In the literature there are about 20 terms that are formed by adding a prefix or adjective to the word "aromaticity". Some of them only stress the degree of aromaticity (arch-, super-aromaticity)[14,53] or constitute abbreviations (heteroaromaticity,[9] perfluoroaromaticity[16]). Antiaromaticity (non-aromaticity) is the opposite of aromaticity and is an inherent part of the concept. Conjugated cyclic systems in which cyclic delocalisation of electrons leads to destabilisation are considered to be antiaromatic.[23] The remaining terms put forward to denote the types of aromaticity can be divided into three categories: those arising from the basic concept of aromaticity given above; those based on a wider interpretation of it; those related to an extension of the concept of aromaticity.



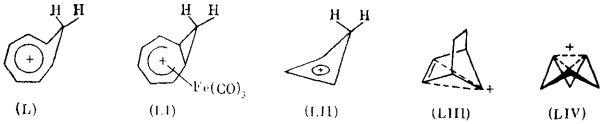
1. Ideas arising from the basic concept of aromaticity (pseudo-, non-classical, quasi-, homo-aromaticity)

Pseudoaromaticity. This term arose from the empirical rule of Craig for dividing conjugated mono- and poly-cyclic structures into aromatic and pseudoaromatic according to their formal symmetry sign in valency schemes.[131] The latter category contained those structures from which stabilisation could not be expected as a result of cyclic delocalisation of π-electrons, including all monocyclic molecules with $4n$ π-electrons starting with cyclobutadiene. Thus the concept of pseudoaromaticity in this sense completely duplicates the more contemporary concept of antiaromaticity. Moreover, single attempts were made to use the term pseudoaromaticity (and pseudoantiaromaticity) in a discussion of the *p*-orbital interactions in non-aromatic species—the cyclopropyl cation and anion,[132] and unsaturated diradicals.[133]

Non-classical aromaticity and quasiaromaticity. The terms non-classical aromaticity[134] and quasiaromaticity[135] have been put forward to represent the aromaticity of conjugated compounds with intramolecular hydrogen bonding (IHB), while quasiaromaticity has also been proposed for the aromaticity of metal chelates.[136] In these structures cyclic delocalisation of the π-electrons in a chelate ring involving vacant $2p$ orbitals of the hydrogen atom or *d* orbitals of the metal atom was proposed. For example, in compounds (XLVII) and (XLVIII) an aromatic 10π-electron system as in azulene has been proposed, with a symmetrical configuration of the hydrogen atom equidistant from the heteroatoms (when R = R′ = Ph), which would appear to be confirmed by the nature of the NMR spectra and the X-ray diffraction data. However, subsequent studies showed that this was an illusion created by the rapid prototropic tautomerism and the statistical distribution of tautomers in crystals. The asymmetric configuration of the hydrogen atom in IHB in compounds (XLVII) was demonstrated by spin-lattice relaxation,[137] and low-temperature ^{1}H NMR spectroscopy was used to demonstrate the existence of tautomers in compounds (XLVIII),[138] which excludes delocalisation via IHB, which would cause the stabilisation of a single form with equivalent bonds.

(XLVII)

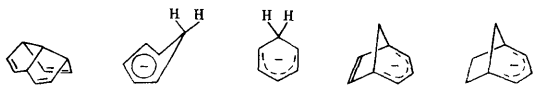
(XLVIII)



(XLIX)

The ^{1}H NMR spectra of acetylacetonates (XLIX) do not provide any evidence of a ring current.[139,140] The displacement of the signals downfield is satisfactorily shown to be due to a redistribution of positive charge of both metal chelates and borochelates, although in the latter cyclic delocalisation is impossible since the tetrahedral boron atom does not have any vacant low-lying orbitals for the formation of π-bonds.[139] Hence the π-electron system in conjugated compounds with IHB and metal chelates is acyclic in nature. Lloyd and Marshall[141] suggested that the scope of the term "quasi-aromatic" should be changed and applied to non-aromatic compounds that are similar to aromatic compounds in the tendency to "retain their form", but shortly afterwards they rejected their proposal.[13] Recently this recommendation was put foward again.[123]

Homoaromaticity. The concept of homoaromaticity was put forward by Winstein in 1959 in relation to cyclic structures in which the sequence of conjugated bonds is interrupted one or more times by a methylene group with an sp^3-hybridised carbon atom. It was suggested that cyclic delocalisation of electrons may be preserved in this case because of overlap of the atomic *p* orbitals of non-bonded carbon atoms of a type intermediate between π- and σ-overlap. Mono-, bis-, and tris-homoaromaticity has been proposed in a very large number of structures, both neutral and charged (see reviews[142–144]), but homoaromaticity can only be regarded as firmly established in certain cations.



The clearest example of monohomoaromaticity is the homotropylium cation (L), which is formed by the action of strong acids on cyclooctatetraene. Arguments in favour of the homoaromaticity of cation (L) were obtained from ^{1}H NMR spectra and X-ray diffraction data.[144] In the NMR spectra the signals from the protons of the methylene group differ markedly; the signal from the exocyclic proton occurs at 5.86 p.p.m. and that from the endocyclic proton is at −0.73 p.p.m. Such an unusual upfield shift of the latter signal for carbocations has been attributed to the effect of a ring current in the seven-membered residue, having a sextet of π-electrons. X-Ray diffraction analysis of 2-hydroxyhomotropylium hexachloroantimonate shows that the seven-membered residue has the conformation of a shallow boat, and the methylene group deviates from the average plane of this by approximately 90 degrees. The C(1)–C(7) distance of 1.626 Å suggests that there is a bonding interaction and at the same time excludes the alternative structure of a bicyclo[5.1.0]octadienyl cation. This type of bicyclic structure is exhibited by the ligand in a complex with iron tricarbonyl (LI), where the chemical shifts of the protons of the CH_2 group are almost the same (1.53 and 1.35 p.p.m.) while the C(1)–C(7) bond length in the fluoroborate is 1.474 Å.[144] A theoretical study of the structure of cation (L) reveals a minimum on the potential energy surface when the C(1)–C(7) bond length is 1.7–2.0 Å and the occurrence of a ring current.[145]

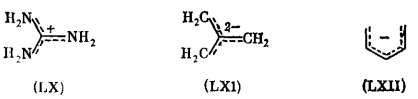
From among the other well studied homoaromatic cations, the cyclobutenyl (homocyclopropenium) (LII), 7-norbornenyl (bishomocyclopropenium) (LIII), and cyclohexenyl (trihomocyclopropenium) cations (LIV) may be mentioned.[143]

(L) (LI) (LII) (LIII) (LIV)

In neutral molecules, as was recognised in the result of detailed experimental and quantum-chemical studies, homoaromatic stabilisation is absent,[146,147] and the corresponding structures are even destabilised through repulsion between the filled orbitals. However, for the bridged trishomobenzene — triquinacene (LV) — by determining the heat of hydrogenation compared to the corresponding monoolefin, the stabilisation energy was found[148] to be E(ERE) = 0.19 eV, which would appear to require the question to be raised again.

Even more controversial is the question of homoaromaticity in anions. It was shown by means of NMR spectroscopy that the anions formed by deprotonation of 1,3- and 1,4-cyclohexadienes have the planar structure of the cyclohexadienyl anion (LVII) [149] rather than the structure of the homocyclopentadienyl anion (LVI). The main debate has revolved around the homoaromaticity of the bicyclo[3.2.1]octadienyl anion (LVIII). Deuterium exchange (DMSO/t-BuOK) in a hydrocarbon corresponding to anion (LVIII) occurs $10^{4.5}$ time faster than in its analogue without a double bond, corresponding to anion (LIX).[150] A determination of the acidity of the hydrocarbons in cyclohexylamine by treatment with caesium cyclohexylamide[151] and in the gas phase[152] shows that anion (LVIII) is more stable than anion (LIX) by 51 and 44 kJ mol^{-1} respectively. In the ^{1}H and ^{13}C NMR spectra of the anion the signals from the nuclei at the double bond in the 6- and 7-positions are displaced 2.3 p.p.m. (^{1}H) downfield and 43.8 p.p.m. (^{13}C) upfield compared to the spectrum of the conjugated acid, which suggests the delocalisation of negative charge involving the double bond.[153] The authors of the experimental studies regard these findings as proof of the bishomoaromaticity of anion (LVIII). However, it was concluded from quantum-chemical calculations carried out using semiempirical and non-empirical methods[154,155] that homoaromaticity does not play a substantial role in the stabilisation of anion (LVIII), which is attributed to the inductive effect of the double bond. Calculations by Brown et al.[156] led to the opposite conclusion, but a non-empirical calculation at a higher level[157] confirmed the absence of homoaromaticity. In order to account for the delocalisation of charge, the suggestion was made concerning salts of anion (LVIII) existing in solution as a contact ion pair in which the metal atom serves as a charge relay between the double bond and the anion site.[157] This hypothesis is supported by the agreement between the results of calculating the ion pair between the bicyclooctadienyl anion (LVIII) and lithium cation[158] and the X-ray diffraction data for the complex between lithium bicyclooctadienide and tetramethylethylenediamine.[159]

(LV) (LVI) (LVII) (LVIII) (LIX)



Thus in this group of examples only homoaromaticity relates to a proven structural form of aromaticity, characteristic of only a fairly limited group of carbocations.

2. Ideas arising from a wider interpretation of the concept of aromaticity (*Y*-, *U*-, bicyclic, spiro-, in-plane, double, trefoil, cruciform, metallo-, three-dimensional, and spherical aromaticity)

In accordance with a wider interpretation, the concept of aromaticity can be applied to various systems where there is stabilisation through orbital interactions. The forms of aromaticity differ from each other according to the manner of overlap of the atomic orbitals in the respective structures.

Y-Aromaticity. This is an application of the concept of aromaticity to a non-cyclic system. The term was introduced[160] to interpret the remarkable stability of the acyclic guanidinium cation (LX), as a result of which the basicity of guanidine (pK_a = 13.6) approaches that of the hydroxide anion. The stability of cation (LX) has been related to the completeness of its electron shell, which is formed by π-overlap of atomic p orbitals in which 6 electrons, as in the benzene molecule, are located in three bonding MOs, which gives rise to the analogy. This type of stabilisation has been proposed in other species with a *Y*-configuration,[160] in particular in the trimethylenemethane dianion (LXI).[161] However, dimetallation of 2-methyl-1,5-hexadiene does not give a substituted trimethylenemethane dianion.[162] Quantum-chemical calculations of the isolated dianion (LXI) and its derivatives indicate that D_{3h} symmetry is energetically preferred,[163,164] but in the crystalline state of the dilithium salt of the tribenzylidenemethane dianion an asymmetric structure occurs, with a geometry that is determined by the interaction with the counterions.[164] The stability of the guanidinium cation (LX) and similar heteroatomic structures is accounted for by the rule of topological stabilisation of charge[165] — the advantage in replacing carbon atoms by a more electronegative heteroatom at those positions where there is the highest electron density in the isoelectronic hydrocarbon. Stable ions with a *Y*-configuration are classified as quasiaromatic (see above), namely, they do not possess aromaticity but display a tendency to preserve their system of conjugation.[123]

U-Aromaticity. This term is used in relation to stabilisation of the *U*-conformation of 6π-electron anions of acyclic conjugated polyolefins — the 1,3-butadienyl dianion, 1,3,5-hextrienyl dianion, and pentadienyl anion (LXII) — through orbital interactions.[161]

(LX) (LXI) (LXII)

Bicycloaromaticity. The concept of bicycloaromaticity was introduced[166,167] in relation to bicyclic ions in which the charged site is formally included simultaneously in two bishomoaromatic rings with $4n + 2$ π-electrons, as in the 7-norbornadienyl cation (LXIII) or bicyclo[3.2.2]nonatrienyl anion (LXIV). It has been suggested that the orbital interaction between the two bishomoaromatic rings results in additional stabilisation through the formation of a single bicycloaromatic system. The fact that cation (LXIII) is stabilised relative to its saturated analogue (LXV) is not in doubt. Solvolysis of 7-X-norbornadiene (X = Cl, OTs), giving cation (LXIII), occurs 10^{14} times faster than the solvolysis of 7-X-norbornane, which is regarded as the "world record" for anchimeric assistance.[142] The question arises as to what proportion of the stabilisation energy is due to bishomoaromaticity and how much can be attributed to bicycloaromaticity. Comparison with the solvolysis of 7-*anti*-X-norbornene, which gives the bishomocyclopropenium cation (LIII), shows that introduction of one double bond increases the rate of solvolysis by a factor of 10^{11} while introduction of the second double bond with a conversion to cation (LXIII) increases it by a factor of 10^3.[168] Hence, the main role is played by bishomoaromaticity. Since in the 7-norbornadienyl cation (LXIII), where the

conditions for bicycloaromaticity are most favourable, the effect is small, there is no serious basis for expecting bicycloaromaticity in other cationic structures.[154,168] In order to interpret the effect of the bridging double bond in cations of the type (LXIII), which is one of a large number of cases of neighbouring group participation, it is quite unnecessary to resort to ideas of a special type of aromaticity. As far as anions of the type (LXIV) are concerned, the probable absence of homoaromatic stabilisation in anions (see above) eliminates the question of their bicycloaromaticity.

(LXIII) (LXIV) (LXV)

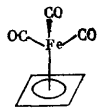
Spiroaromaticity. This has been suggested[169,170] in relation to the concept of spiroconjugation,[171] which is the stabilisation in unsaturated spiro compounds, such as in *spiro*-[4,4]nonatetraene (LXVI), through overlap of orthogonal *p* orbitals of the atoms of the double bonds adjacent to the nodal carbon atom. The consequence of spiroconjugation is a relative change in the HOMO and LUMO levels, so that experimental confirmation of the effect can be seen mainly in displacement of maxima in the electronic and photoelectronic spectra.[171] However, theoretical analysis using perturbational molecular orbital theory[172] leads to the conclusion that the total stabilisation due to spiroconjugation, called spiroaromaticity, is not significant in the molecule of (LXVI), and on increasing or decreasing the size of the rings becomes even less likely. The only case of appreciable stabilisation was predicted in *spiro*-[3.3]heptadienyl (LXVII) as a hypothetical non-classical species.[172]

(LXVI) (LXVII)

In-plane (radial), double, and trefoil aromaticity. All these variants of aromaticity assume that a cyclopolyene is stabilised through overlap of the radially positioned *p* orbitals lying in the plane of the ring. A group of compounds in which in-plane (radial) aromaticity[147] can be visualised is made up by [*n*]pericyclynes, which are cyclic hydrocarbons with a skeleton made up of *n* acetylene residues alternating with CH_2 groups. In pericyclynes the interaction between *p* orbitals lying in orthogonal planes has been studied theoretically.[173,174] The best conditions for in-plane orbital interaction exist in the first member of the series—the so far unknown [3]pericyclyne (LXVIII). Overlap of the orbitals in its molecule could be expected to lead to the formation of two 6π-electron systems—trishomoaromatic and in-plane. However, a quantum-chemical calculation (MNDO method) shows that [3]pericyclyne (LXVIII) is less stable by 2.63 eV than its valence isomer, tricyclopropanebenzene (LXIX).[174] In decamethyl-[5]pericyclyne the empirical resonance energy has been determined thermochemically as being of the order of 0.34 eV, attributed to homoconjugation[175] rather than in-plane conjugation. As a result of the calculation (MNDO) of about 100 different three-dimensional structures in which radial overlap could be expected, only in one of the isomers of dodecahedropentaene was a stabilisation energy of the order of 0.35 eV recorded.[147]

(LXVIII) (LXIX) (LXX)

The term "double aromaticity" was applied[176] to the 3,5-dehydrophenyl cation (LXX), the structure of which is assigned to the $C_6H_3^+$ ion in the mass spectrum. In cation (LXX), in addition to a sextet of π-electrons, a three-centre, two-electron bond inside the ring has been postulated, which provided a basis for suggesting aromaticity in orthogonal planes or double aromaticity.



The idea of such a three-centre, two-electron bond in annulenes with $4n + 2$ π-electrons on the periphery has been put forward as a new type of aromaticity—trefoil aromaticity—and the respective structures as a potentially new class of aromatic molecules for which a new name has been proposed—trefoilenes, for example, [5.5.5]trefoilene (LXXI).[177] However, calculations have so far not confirmed the energy preference of the trefoilene configuration in any single model.[147] In all cases the valence isomers have proved much more stable; for example, the so far unknown trisallene (LXXII) is more stable by 4.3 eV than the hypothetical [5.5.5]trefoilene (LXXI).[178] According to calculations,[179] structure (LXXI) is only possible as a transition state of the degenerate isomerisation of a bicyclic carbene.

(LXXI) (LXXII) (LXXIII)

Cruciaromaticity. This has been put forward[180] to denote the orbital interaction in planar complexes of unsaturated ligands with transition metals such as iron in (LXXIII), where intersection of two π-systems occurs as a result of the participation in them of d_{xz} and d_{yz} metal orbitals, the plane of which form a cross on the surface.

Metallo- and three-dimensional aromaticity. A considerable advance in organometallic chemistry was the synthesis of a complex between the antiaromatic cyclobutadiene molecule and iron tricarbonyl $C_4H_4Fe(CO)_3$, which proved to be a stable compound that underwent electrophilic substitution without decomposition. A large number of complexes of cyclobutadiene with other metals have been prepared (see reviews[181,182]). According to X-ray diffraction data the $C_4H_4Fe(CO)_3$ complex is in the form of a bipyramid (LXXIV), at the base of which is a square with a side of 1.44 Å and at the apex is an iron atom with an Fe–C distance of 2.05 Å. Quantum-chemical calculation using a non-empirical method[183] shows that the C_4H_4Fe residue has 6 electrons in three bonding orbitals which are formed by effective overlap of the cyclobutadiene orbitals (e_g) with d_π orbitals of iron that have a similar level of energy. The C_4H_4–Fe bond is largely covalent. On the whole the molecule can be represented as the C_4H_4Fe metalloaromatic fragment perturbed as bonding with carbonyls. In contrast to compounds (LXXIV), complexes of transition metals with benzene and the cyclopentadienyl anion having the general formula (LXXV) should more accurately be regarded as systems of benzene and the cyclopentadienyl anion perturbed by bonding with the metal[183] rather than metalloaromatic systems.

(LXXIV)

(LXXV)

(LXXVI)

Complexes with the general formula (LXXV), where X above the annulene ring at the apex of the pyramid is not necessarily a transition metal atom but may also be an atom of an element from the first period (Li, Be, B, C, N), have been assigned[184] to a special type of three-dimensional aromatic system where there is a complete electron shell with $4n + 2$ π-electrons, regardless of whether the bonding of the X-link is a decisive factor. In this case, for example, the unstable complex π-complex of benzene with the Li^+ cation (LXXVI) is classed as an example of three-dimensional aromaticity on a level with the cyclobutadiene complex (LXXIV). More justified is the approach[183] in which the weak interactions are regarded as an excitation of the planar aromatic system. Pyramidal structures of the type (LXXV) and other three-dimensional non-classical structures have been successfully represented without involving the concept of aromaticity.

Spherical aromaticity. When the surface of a graphite disk is evaporated using a laser beam, among the products is detected a stable C_{60} cluster,[186] for which the structure of a truncated icosahedron having 12 five-membered and 20 six-membered rings on the surface of a sphere has been proposed. The structure, which has been called buckminsterfullerene or footballene, has so far not been substantiated, but has attracted the attention of theoretical chemists as an example of a compound with possible spherical aromaticity.[187,188] According to the value of the resonance energy per π-electron this structure can be classed as aromatic, but judging by the ratio of the resonance energy to the total π-electron energy of the reference structure (% RE), the stabilisation energy is insufficient to isolate buckminsterfullerene in macroscopic quantities.[187] A theoretical analysis of the magnetic properties led to the conclusion that this compound should be very slightly diamagnetic.[189]

Thus, the types of stabilisation of molecules or ions that are described by forms of aromaticity constitute in the majority of cases unproven or rejected ideas. In the individual cases where the stabilisation effect has been established, it can be interpreted without difficulty independently of the concept of aromaticity. A wider interpretation of the concept of aromaticity is not appropriate since, not having a proper basis or being created through necessity, it has a destructive effect on the concept of aromaticity as a whole. The acceptance of a wider interpretation would signify a rejection of the elaborated experimental criteria of aromaticity, both magnetic, related to the ring current, and structural, which are inapplicable to non-planar or acyclic structures, and also ideas about the common nature of aromatic reactivity.

3. Extension of the concept of aromaticity. σ-Aromaticity.

The generally accepted ideas about the electronic structure of organic compounds are based on models, according to which π-electrons are distinct from the electrons of σ-bonds. It is assumed in this case that the σ-system consists of effectively localised two-centre, two-electron bonds, and that all deviations from additivity, including those related to aromaticity, are due to delocalisation of the π-system. However, both types of bond, both π and σ, can exhibit "localisation" and "delocalisation" to comparable degrees.[190] Additivity of the properties of σ-bonds is not due to the absence of σ-delocalisation but occurs because the interaction between neighbouring σ-bonds is approximately constant, does not depend on the environment, and in calculations is included in the empirical bond constants. As the individual sp^3-hybridised orbitals of a carbon atom interact effectively with each other, each CH_2 group in an alkane can be regarded as an equivalent valence group in a polyene. The system of hybrid orbitals of the C–C bonds in cyclopropane is topologically similar to the π-orbital system of benzene, while the cyclobutane system is topologically similar to the system of planar cyclooctatetraene. Therefore, by analogy with π-aromaticity and π-antiaromaticity, the question of the σ-aromaticity of cyclopropane and the σ-antiaromaticity of cyclobutane can be raised.[179,190] The concept of σ-aromaticity for cyclopropane can be used to explain its outstanding stability and other properties.[190,191] The same criteria of aromaticity as those for π-aromatic systems are applied to cyclopropane, including the cyclic delocalisation of electrons found in the magnetic properties from NMR spectroscopic data and the Dewar resonance energy, which constitutes 0.694 eV.[192] From an analysis of orbital interactions, electronic calculation rules for the determination of σ-aromaticity in cyclic structures have been formulated.[193,194] With an increase in size of the ring the degree of aromaticity decreases so rapidly that even in cyclopentane it is extremely small and cannot have any appreciable effect on its properties. Only π,σ-aromatic compounds, from which the greatest contribution is provided by σ-aromaticity in the cyclopropenium cation ($2\pi 6\sigma$), have a high stabilisation energy. In an article by Cremer[192] entitled "For and against σ-aromaticity", it is observed that the characteristics of cyclopropane may adequately be represented using the concept of "surface" overlap of the σ-orbitals instead of σ-aromaticity, while the characteristics of a tetrahedron[195] can be represented by "three-dimensional" overlap instead of three-dimensional σ-aromaticity.

It was important to determine how the inclusion of electrons from σ-bonds would effect the basic conclusions of the aromaticity concept that were derived from a model that took only π-electron delocalisation into consideration. It was shown by non-empirical calculations of the benzene molecule[196] that on going from a structure with D_{6h} symmetry to a Kekulé structure with D_{3h} symmetry and alternating bonds the π-electron energy decreases but the σ-electron energy increases to a greater degree, in other words, equalising the bonds is determined by the σ-skeleton. The question arises as to the legitimacy of using the equalising the bonds as a structural criterion of aromaticity related to the cyclic delocalisation of π-electrons. Calculation of the topological resonance energy (see Section III)[197] led to the separation of a component resulting from the cyclic π-electron delocalisation and having, as it transpired, the opposite sign to the change in total π-electron energy of the system. The decrease in the latter on distorting the symmetrical structure of benzene to a Kekulé structure occurs at the same time as an increase in energy of the cyclic π-electron delocalisation, as a result of which it is possible to balance the increase in σ-electron energy. On the other hand, in the case of the antiaromatic cyclobutadiene the change from a square structure to the structure of a rectangle with alternating bonds causes a decrease in both the total π-electron energy and the energy of the cyclic π-electron delocalisation, as a result of which the decrease in π-electron energy is not balanced by the increase in σ-electron energy and the structure with alternating bonds proves to be more stable. Thus, equivalence of bond lengths is in fact related to cyclic delocalisation of the π-electrons and can be

justified as a criterion of aromaticity. The concept of σ-aromaticity does not contradict the concept of π-aromaticity but complements it, as ideas about σ-conjugation complement the generally accepted theory of the structure of organic compounds.

- - - o 0 o - - -

The current concept of aromaticity which is based on the progress in the synthesis of aromatic systems and their study using experimental physical techniques and theoretical quantum-chemical methods relates to conjugated cyclic systems that have cyclic delocalisation of electrons. As a special property of the electron shell, aromaticity is exhibited in their properties, from which magnetic, structural, and energy characteristics can serve as criteria of aromaticity, but reactivity cannot since it depends not only on the ground state but also on the transition state. The extension of the concept of aromaticity to systems that are devoid of cyclic declocalisation of electrons, resulting in ideas about multiple types of aromaticity, is unjustified and inappropriate. The common nature of the electronic structure and properties is responsible for the chemistry of aromatic compounds being formed as a separate branch of organic chemistry.

Present ideas on the influence of the medium on acid–base equilibria. Hydrogen bonds in the gas phase and in solution

L M Epshtein, A V Iogansen
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow
State Scientific Research and Design Institute for the Nitrogen Industry, Moscow

ABSTRACT. Data on acid–base equilibria in different media and in the gas phase have been analysed. Methods for determining the protonation centre in a gas have been discussed. The change in the electronic effects of substituents on going from the gas phase to solution have been examined. The relationships between the strength of ionic hydrogen bonds and the acid–base properties of compounds in the gas phase have been demonstrated, and the results obtained by modelling solvation effects in the gas phase have been examined. New data on the structure and stability of molecular H-complexes in the gas phase and on the increase in the strength of the H-bond on solvation are presented.

The bibliography contains 130 references.

I. Introduction

The development of new methods for studying proton transfer reactions in the gas phase (ion cyclotron resonance and high-pressure mass spectrometry) has led to a new attitude to the problem of the influence of the medium on the structure and reactivity of compounds. It has become clear that in the past the part played by these factors has been greatly underestimated. Solvation effects may be comparable with the electronic influence of substituents, and sometimes significantly greater.[1,2] In many cases, the part played by hydrogen bonds is decisive.[3,4]

In recent years, important data have been obtained on the energy of formation of ionic dimers and ionic clusters involving several solvent molecules in the gas phase. The energy of formation of a large number of these clusters has been compared with the energy of solvation of the ions by the solvent. In addition, analogies have been revealed in the solvation of ion–molecule and neutral H-complexes. New methods of high-resolution spectroscopy, which make it possible to establish the structure of intermolecular hydrogen bonds in the gas phase, are being actively developed. This information is direct and reliable, in contrast to that obtained by calculation or by analysing mass-spectrometric data.

Present ideas about the role of the medium in acid–base equilibria are based on a combination of experimental studies in the gas phase and in solvents of different types with quantum-chemical calculations, including in recent years calculations by the methods of molecular dynamics and Monte Carlo methods. The present review does not claim to cover completely all topics and all the published literature, but should provide reference points in this varied and rapidly developing field. Various methodological approaches which help to distinguish the role of hydrogen bonds in the influence of the medium on acid–base equilibria are analysed.

II. The influence of hydrogen bonds with solvents on acid–base equilibria

1. Acid–base properties in water and dipolar aprotic solvents

The basic concepts of the electronic effects of substituents were formulated from the study of acid–base equilibria in aqueous media. Historically, the first acids studied in this connection were benzoic acids and phenols, which ionise in water in an acidity range convenient for study. The subsequent study of acid–base equilibria in dipolar aprotic solvents (DAS) showed that the acidity scale is extended in these solvents, making it possible to distinguish the acidity of compounds having identical pK_a value in water. This characteristic of DAS is referred to as their "differentiating action".[5,6] The pK_a values in DAS and in proton-containing solvents (PS) for organic compounds of the same class are related by linear expressions of the type

$$pK_a(S) = \alpha pK_a + \beta, \quad (1)$$

where the coefficient α characterises the sensitivity to the influence of substituents in DAS. The value of α increases in the order H_2O < ROH < DAS. Deviations from the linear relationship are observed for acids with *ortho*-substituents, which form intramolecular hydrogen bonds or create appreciable steric hindrance.

The differentiating action of DAS increases with increase in the basic strength of the solvent.[7] Thus for benzoic acids the coefficient α increases in the solvent order: H_2O (1) < CH_3OH (1.3) < $(CH_3)_2CO$ (1.72) < CH_3NO_2 (1.81) < DMF (1.98) < CH_3CN (2.5) < DMSO (2.8).[8]

In an analysis of the differences between the pK_a values in N-methylpyrrolidone (NMP) and DMSO, Bordwell and co-workers[7]

examined various acids forming oxo-anions on ionisation (naphthols, phenols, benzoic acids, salicylic acid, etc.). The values of ΔpK_a = pK_a(NMP) – pK_a(DMSO) increase with decrease in the acidity from pK_a = 0.45 to pK_a = 1.95. In more basic anions, the charge localised on the oxygen atom is greater, and the difference in the stabilisation achieved in NMP and in DMSO increases. This is also indicated by data obtained in DMF and DMAA.[9] The pK_a values in NMP and DMSO are related by the linear expression:

$$pK_a(\text{NMP}) = 0.91 pK_a(\text{DMSO}) + b.$$

In the opinion of the authors cited, the acidity values in DMSO (of which more than 600 are known) can be used to predict the pK_a values in any carboxamide solvent, and in other DAS in the absence of strong ion pairing.

In the study of acid–base equilibria in DAS it is necessary to take account of the complicating action of "homoconjugated" hydrogen bonds between the acid and the anion.[3,9] The formation constants of these bonds in NMP[7] and in DMF[9] are ten times those in DMSO. The formation of homoconjugated ions is energetically favourable even in DMSO, however. Thus the equilibrium PhOH...DMSO + PhO^- ⇄ PhO^-...HOPh + DMSO is displaced to the right. The "homoconjugated" hydrogen bond PhO^-...HOPh is 6.1 kcal mol^{-1} more stable than the H-bond between phenol and DMSO.[10]

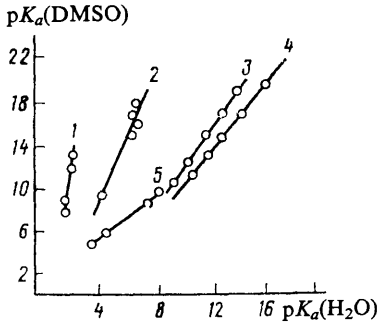

Figure 1. Relationship between pK_a (DMSO) and $pK_a(H_2O)$ for organic acids of different classes: *1*, benzoic acids; *2*, phenols; 3, nitroanilines; *4*, CH-acids; *5*, ammonium acids.[11]

The values of α in Eqn. (1) for XH-acids of different types in DMSO have been compared.[11,12] Fig. 1 shows that the value of α is greatest for benzoic acids, and decreases in the order:

$$XC_6H_4COOH\,(2.43) > XC_6H_4OH\,(2.14) > XCOOH\,(1.94) > X_2NH\,(1.55) > X_3CH\,(1.46) > X_3NH^+\,(1.14).$$

Acids in whose conjugate bases the charge is delocalised have a lesser ability to form H-bonds X^-...HOH with water as proton donor. Decrease in the stability of the H-complex with the anion is accompanied by a decrease in the difference between the acidities in water and in DMSO (OH > NH > CH > NH^+).

For charged (NH^+)-acids, substituents have practically the same influence in DMSO and in water (α = 1.1), since both solvents are good proton acceptors (NH^+...S).[11]

Another widely used method for estimating the sensitivity to the solvent of the effects of substituents is by comparing the coefficients ρ in the Hammett equation:

$$pK_a = pK_0 + \rho\sigma, \qquad (2)$$

where pK_0 is the value of pK_a in water, and σ a substituent constant. The value of ρ increases considerably on going from H_2O to DAS. This is demonstrated for benzoic acids and phenols in Table 1.

The difference in the values of ρ in the solvents CH_3OH and DMF, which belong to different groups (PS and DAS) but which have similar dielectric constants (ε), indicates that non-specific universal interactions have little influence. For benzoic acids, for example, the value of ρ in DMF is approximately 1.5 times that in CH_3OH (Table 1).

Table 1. Values of ρ in Eqn. (2) for phenols and benzoic acids in different media.

Compounds	H_2O	CH_3OH	C_2H_5OH	C_3H_7OH	DMF	CH_3CN	DMSO	Refs.
Benzoic acids	1.0	1.38	1.66	—	2.03	2.37	2.57	[8]
					2.3	2.4	2.4	[9, 10]
Phenols	2.1	—	—	2.25	4.5	4.7	4.88	[11]
							4.29	[9]
							5.3	[10]

To lower the influence of solvation factors, it is necessary to use the most inert solvents. The study of proton transfer reactions in these media is associated with a number of difficulties, including the low solubility of salts in these solvents, the formation of hydrogen bonds between the reagents, dimerisation of the acids, etc. The main complication, however, is that in media with a low polarity and low dielectric constants (ε = 2–6), ion pairs are not dissociated ($K_d \leqslant 10^{-8}$), so that the observed relative strengths of acids depend on the nature of the base chosen for comparison.[13]

The influence of the acidic and basic properties of the partners and the medium on proton transfer and the formation of ion pairs by an acid with a neutral base has been studied intensively in recent years by molecular spectroscopy and low-temperature NMR spectroscopy. This work has been reviewed in detail.[14,15] The extensive studies of the formation of strong hydrogen bonds and ion pairs with charged acids have also been reviewed.[16] †

2. Acid–base equilibria in relatively inert media

Acid–base equilibria in dimethoxyethane (DME), cyclohexylamine (CHA), and tetrahydrofuran (THF) have been studied for CH-acids which form highly delocalised carbanions and which do not tend to undergo ionic aggregation, and also for acids whose carbanions contain substituents with charges localised on them.[17,18] Data have recently been obtained on the acidity of polyarylmethanes and fluorenes in tetrahydrofuran,[19,20] and the pK values of sulphur-containing compounds in CHA and DMSO have been compared.[21]

† See also I S Perelygin *Ionnaya Sol'vatatsiya* (Ion Solvation), Izd. Nauka, Moscow, 1987, p. 164

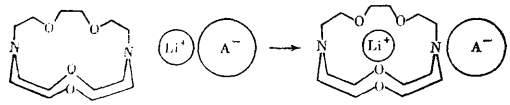
Expressions relating the ion-air acidity in comparatively inert media with the "ionic" acidity in DMSO, in which the salts are completely dissociated, have been proposed.[22-24] Two types of equilibria were compared:

$$R_iH + R_0^- \ldots M^+ \rightleftarrows R_i^- \ldots M^+ + R_0H, \quad \text{in ethers and cyclohexylamine} \qquad (3)$$

$$R_iH + R_0^- \rightleftarrows R_i + R_0H. \quad \text{in DMSO} \qquad (4)$$

The ion-pair (pK_{ip}) and free-ion (pK_i) acidities are found from the usual relationship

$$pK = pK_0 + \lg K_d$$



applied to equilibria (3) and (4). If the dissociation constants (K_d) of the ion pairs, which can be determined spectrophotometrically or conductometrically, are known, the pK_{ip} values can be used to obtain the free-ion acidity in media with a low polarity (pK'):

$$pK' = pK_{ip} + \lg(K_{d_0}/K_d), \qquad (5)$$

where K_{d_0} is the dissociation constant of the ion pair formed by a standard carbanion with the cation. The pK' values practically coincide with the pK_i values in DMSO. The differences between pK_{ip} and $pK_i \simeq pK'$ depend on the structure of the carbanion, and also on the ability of the cation to form ion pairs. They are greatest for anions in which the charge is localised on a substituent. The differences are greatest for the Li^+ cation, and decrease with increase in the cation size.

Data published in 1988 on ion-pair and ionic acidities in THF [20] show excellent agreement with these conclusions.[23,24] The difference in the values of the ion-pair and ionic acidities in DME and THF is less than 0.2 pK unit. The values of pK_a in THF, CHA, and DME are related by linear expressions, and the coefficient α is close to 1 (0.999–1.02).[21]

In a new approach to the study of acid–base properties in media with a low polarity and the analysis of the influence of solvation,[25,26] the use of the cryptates of organolithium compounds has been proposed for the construction of an acidity scale. The systematic spectral and conductometric study of the lithium salts of aliphatic and aliphatic–aromatic hydrocarbons in the presence of cryptands has established reliably that, irrespective of the polarity of the medium, they form ion pairs separated by the cryptand.

Thus 4,7,13,18-tetraoxa-1,10-diazabicyclo[8,5,5]eicosane forms a stable inclusion complex with the lithium cation, shielding it from the solvent and the anion. As a result, the ion-pair acidity in media with a low polarity is linearly related to the ionic acidity in DMSO with a coefficient α practically equal to 1. Thus for THF:

$$pK_a(\text{DMSO}) = 1.01pK_a(\text{THF}) + 17.2. \qquad (6)$$

The ionic acidity in the solvent in the absence of specific solvation was related to the acidity in the gas phase

$$\delta\Delta G^S(HA/HA_0)_i = \delta\Delta G_A^{gas}(HA/HA_0)_i + b/\varepsilon_S. \qquad (7)$$

Thus the ionic acidity under these conditions is a linear function of the quantity $1/\varepsilon$. The values of ΔG_A^{gas} obtained using Eqn. (7) coincided with the results of direct determinations (only four such determinations have as yet been carried out, however).

Thus it has now been reliably established that dipolar aprotic solvents have a differentiating action, which is due chiefly to the decrease in the strength of the solvation of the anions as a result of the formation of H-bonds. Approaches to the establishment of acidity scales for CH-acids in media with a low polarity have been found. The use of cryptands should make it possible to study the acid–base properties of acids of other types in these media.

3. Acid–base properties in the gas phase and in solution

Studies of acid–base equilibria, which are being carried out on an increasing scale, have accumulated a large amount of data on organic compounds of different classes (see the published reviews[2,3,27] and monographs[18,28]). These results have made it necessary to re-examine existing ideas about the electronic effects of substituents. The present theory of intramolecular interactions between a substituent and a reaction centre is based on non-empirical molecular orbital calculations, and the fairly approximate model of point charges is used for a qualitative examination (see the papers by Taft[2] and Koppel' [29] and references therein).

For most classes of organic compound, the sensitivity to the influence of substituents in the gas phase is greater than that in DAS, and much greater than that in water; in other words, using the terminology adopted to describe acid–base equilibria in solutions, the gas phase has the greatest "differentiating action". Since however the acidity in the gas is a characteristic "internal" acidity, it is more correct to speak of the action of the medium levelling the electronic influence of the substituents.

The chief factor for the levelling of the acidic properties in PS and in water is the formation of hydrogen bonds with the anions. Thus the sensitivity of benzoic acid derivatives to the influence of substituents is greatest in the gas phase; it is 1.6 times smaller in water, and almost 4 times smaller in DMSO.[2] An interesting feature is that the levelling action of an aqueous medium decreases with decrease in the ability of the anions formed to act as electron donors in H-complexes A^-...HOH, and is not observed for carbanions with a highly delocalised charge.[2,18] The order of change in the coefficient α in the series XC_6H_4COOH (10.6) > XC_6H_5OH (6.6) > XCOOH (3.5) > X_3CH (1) agrees with the order obtained for XH-acids of the same types in DMSO(see above).

Comparison of the heats of hydration and the thermodynamic characteristics of deprotonation in the gas phase and in water has shown that most of the gain in ionisation energy observed with increase in the electron-acceptor properties of the substituents is compensated by the decrease in the energy of hydration of the anion formed. The marked decrease in the ability of these anions to form hydrogen bonds is due to the delocalisation of the negative charge, and leads to destabilisation of the anions. The equilibrium is displaced towards the undissociated acid. As a result, the range of change in the acidity in water becomes narrower.[2,3] A generalised scheme for the influence of the solvent has been proposed;[30] it examines the specific interaction of the solvent with the acid and the conjugate anion, including the formation of H-complexes with substituents such as COR, NO_2, SO_2Ph, etc. For example, for *p*- and *m*-substituted phenols a rigorously linear relationship is observed between ΔG(gas) and $\Delta G(H_2O)$ (the coefficient α = 6.6), deviations from which are related to the specific solvation of the substituents.[30]

A detailed analysis of the influence of different solvation effects on the protonation of substituted pyridines[31-33] has established that the principal role in the decrease in the strength of the effect of

substituents in water is played by hydrogen bonds with the pyridinium ions (XPy...HOH). The energy of formation of ionic H-complexes is five times the energy of the neutral H-bonds of substituted pyridines $XPyH^+...O_2H$. The decrease in the range of change in the basic strength in water is determined by the opposed influences of the substituent on the formation of ionic H-bonds and on protonation. The solvation model of the hydrogen bond has provided a quantitative description of the levelling in water (a three-fold decrease in the strength of the effect of substituents) which shows good agreement with experiment.[31] The anomalously low basic strength of 2,6-di-t-butylpyridine in water is attributed to steric hindrance to hydration. This compound is a very strong base in the gas phase.[32] A similar effect was recently detected in the study of other sterically hindered pyridines.[33]

A comparison of the changes in the basic strengths of two groups of secondary amines in the gas phase and in water[34] showed that alkyl substituents have a marked levelling influence in H_2O ($\alpha = 4.3$). The introduction into the alkyl substituent of functional groups which contain heteroatoms and which delocalise the charge decreases this effect by a factor of 1.6 (Fig. 2). In aqueous medium there is not only a decrease in the electronic influence of the substituents but also a change in the relative contribution of the components of this influence. The effect of polarisability in the gas phase is predominant, but in water its role decreases sharply, compared with the inductive field effect. The same change in the contributions of the components of the electronic effect was also noted for other classes of organic compound.[2,29] For primary amines, the influence of solvation as a result of the formation of additional H-bonds is greater than the electronic influence of the substituent[34] (the point for R = H does not lie on the straight line in Fig. 2). The influence of hydrogen bonds on the ionic hydration of primary amines was previously examined[35] using data on monitored solvation in the gas (this approach is examined in more detail in the next section). The role of H-bonds has been confirmed by a theoretical analysis at the level of non-empirical quantum-chemical calculations.[36]

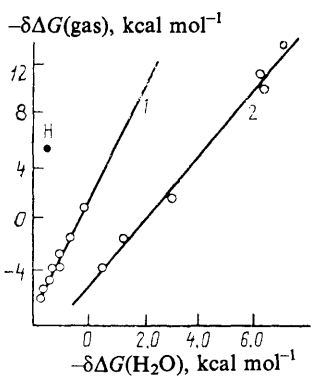


Figure 2. Relationship between the values of the basic strength $\delta\Delta G$ of secondary amines in the gas phase and in water: *1*, RNH_2 (slope 4.3); *2*, XCH_2NH_2 (slope 2.7).[34]

The study of acid–base equilibria in the gas phase has shown that solvation interactions can not only decrease the differences in the strengths of acids and bases but can also change the sequential order of compounds with similar structures.

A number of examples of opposite sequences of the change in the thermodynamic characteristics of the dissociation of substituted halogenoacetic acids, aliphatic alcohols, thiols, and amines in the gas phase and in water have been discussed.[1,2] The order of change in the acidity of aliphatic XH-acids in the gas phase is the opposite of that previously established for aqueous and aqueous-alcoholic media: in the gas phase, MeXH < EtXH < PrXH < t-BuXH, and in water t-BuXH < PrXH < EtXH < MeXH. Thus the strengths of these acids in water and alcohols are determined not by the electronic influence of the substituents but by solvation interactions with the corresponding anions.[2,37] According to quantum-chemical calculations, polarised alkyl groups may show either donor or acceptor properties, depending on the magnitude and sign of the charge on the X atom. A scale of polarisability parameters based on non-empirical calculations was recently published.[38]

The order of the acidity of alcohols in DMSO is the same as that in water,[39] that is although it is usually assumed that DAS solvate ions weakly, the energy of deprotonation in DMSO is not determined by "internal" factors. The role of ion–dipole interaction with DMSO requires further study.

The opposite order of change in the basic strength in the gas phase relative to solution was observed for methyl- and phenylphosphines.[40] The "internal" basic strength of Ph_3P (the proton affinity PA) is greater than that of Me_3P. At the same time, the basic strength of alkylphosphines in water is greater than that of phenylphosphines by several powers of ten. The same applies to the basic strength relationships for the phosphines in nitromethane.[11] Thus contrary to the published opinion,[12] nitromethane cannot be regarded as a medium in which specific solvation interactions are weak.

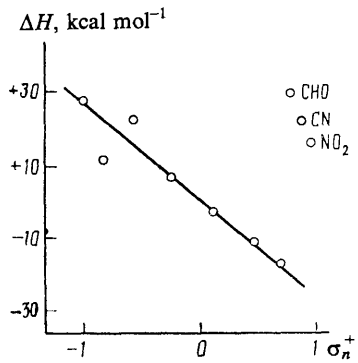

Figure 3. Correlation between the basic strength of PhX and the constants σ_n^+ of the substituents.[41]

The next step in the study of acid–base equilibria is the study of compounds in which transfer of the reaction centre is possible, and the identification of protonation centres in the gas phase.[41–47] For anilines, the coordination centre in solution is the lone pair of electrons of the nitrogen atom. The published conclusion[41] that the protonation of aniline in the gas phase involves the π-system of the ring was therefore surprising. The authors cited analysed the linear relationship between the basic strength of monosubstituted benzenes

in the gas phase and the σ^+ constants of the substituents. Fig. 3 shows that the points corresponding to compounds with strong electron-acceptor substituents do not lie on the straight line. The observed deviations towards higher basic strengths indicate that the ring is not the protonation centre in these cases. According to quantum-chemical calculations, protonation at nitrogen is energetically slightly more favourable than protonation at the ring,[42] but the differences are very small (1–3 kcal mol^{-1}). Finally, the basic strengths of fifteen substituted anilines in the gas phase have been compared[43] with the experimentally measured ionisation energies of the 1*s* electron of the nitrogen atom ($E_B N_{1s}$). A linear relationship between these quantities is observed for all the compounds except *m*-MeO-, *m*-MeS-, *m*-OH-, and *m*-NH_2-anilines, which are assumed to be protonated at the ring. Fig. 4 shows that the points corresponding to the "hydration" of these compounds in the gas phase, measured for the monitored addition of water ($BH^+ + OH_2 \rightleftarrows BH^+...OH_2$) also do not lie on a straight line. From this it was concluded that aniline in the gas phase is protonated at nitrogen, but that in various *meta*-substituted compounds with donor substituents the coordination centre is the benzene ring.

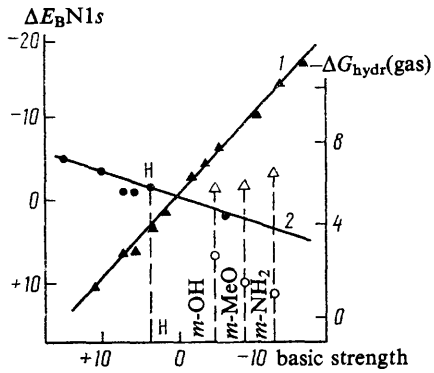

Figure 4. Dependence of the gas-phase basic strength of anilines on the ionisation energy of the N1*s* electrons (*1*) and on the energy of "hydration" in the gas phase ($BH^+ + OH_2 \rightleftarrows BH^+...OH_2$) (*2*).[43]

Single-parameter linear correlations between the PA values and the energies of the core electrons were previously observed for alcohols, ethers, carbonyl compounds, amines, and phosphines.[44] The existence of these correlations for compounds having two centres, for example amides (in which oxygen is the protonation centre), pyridines, and aminonaphthalenes,[45] made it possible to establish the protonation centres, and also to determine the conditions under which the correlation breaks down. In a number of studies, a similar analysis was based on empirical relationships between PA and the first ionisation potential (found by photoelectron spectroscopy). For example, a linear relationship was established between the proton affinity and the first ionisation potential of various compounds of phosphorus(III).[46] The points for cyclic and acyclic phosphites also lie on this straight line, indicating that the protonation centre in these compounds is the phosphorus atom, and not oxygen. The existing two-parameter expressions relating the PA to the energy of the electrons of the core and the first ionisation potentials[47] can be used to predict the protonation centre in the gas phase, since the correlation coefficients are different for O-, N-, and C-bases.

A successful solution to the problem of the protonation centre in the gas phase was recently achieved by comparing experimental data with the results of non-empirical quantum-chemical calculations.[48,49] A study of the protonation of phosphine oxide and the amides of acids of phosphorus(V) established that protonation takes place preferentially at the oxygen atom; the difference between the protonation energies of the oxygen and nitrogen atoms, according to quantum-chemical calculations, was 100 kcal mol^{-1}.[48] The basic strength of nitrogen-containing heterocyclic compounds in the gas phase has been examined.[49] A comparison of the PA values, the energies of the N_{1s} electrons, and the results of non-empirical calculations established that the protonation centre in a series of azaindoles is the nitrogen atom of the pyridine ring, and not the indole ring.

Without adding to the number of examples, mention may be made of various regular features of the change in the intramolecular interactions on going from the gas phase to solution. In this case it is possible to observe a levelling of the strengths of acids and bases, reversal of the sequence for compounds with similar structures, and a change in the protonation centre. The levelling action of the solvent indicates that solvation effects play a less important role than intramolecular effects. The reversal of the sequence indicates that the effect of the medium is stronger than the influence of the substituent.

In all cases, the influence of the solvent competes with that of the substituent. Among solvation effects, the most important role is played by the solvation of charged species (the anion A^- or the protonated base BH^+). The strength of the ion–dipole interactions and the energy of formation of hydrogen bonds are greater, the smaller the ion and the more localised the charge in it. Thus solvation effects bring about the greatest stabilisation of small ions. These ions, however, are less stable in the gas phase. Increase in the size of the anion and increase in the polarisability of the substituent increase the ability of the ions to delocalise their charge, leading to their stabilisation in the gas phase, and hence to an increase in the "internal" acid strength (basic strength). This effect is called "internal solvation".[1] At the same time, these ions are stabilised to a smaller extent under the influence of the solvation effects of solvents.

These ideas make it possible to understand the cases in which levelling of the eletronic effects should take place, and those ion which reversal of the sequences of the acid–base properties in solution or a change in the protonation centre should take place.

In those classes of organic compound including large molecules of similar size, such as aromatic and heterocyclic compounds (the benzoic acids, phenols, pyridines, etc. already examined), solvation effects decrease the difference in the acid–base properties. In *ortho*-substituted compounds with intramolecular hydrogen bonds or substituents with a large volume creating steric hindrance to solvation, however, the sequence of changes in the internal acid strength (basic strength) in solution may break down.[32,33] Deviations from the linear relationships between PA(gas) and $pK_a(H_2O)$ are also possible for substituents forming strong hydrogen bonds with water.[30]

Reversal of the order of change in the acid–base properties on going from the gas phase to solution can be expected in those

homologous series where the first members are compounds giving small ions and where the size and shape of the molecules change considerably with increase in the number of carbon atoms. This applies to aliphatic compounds such as alcohols, thiols, etc., and also to aliphatic compounds with substituents differing considerably in their polarisability and their ability to delocalise the charge on the ion. A change in the protonation position may take place if the potential protonation centres of the molecule have similar proton affinities and differ considerably in their ability to undergo solvation.[41,43]

The relative contributions of the components of the electronic effect change on going from the gas phase to solution (the polarisability effect is weakened to a greater extent than the inductive and resonance effects). The radical differences in the mechanisms of the stabilisation of ions in the gas phase and in solution require the special selection of materials for analysing intramolecular effects in compounds of different classes; it is necessary to compare compounds with similar dimensions and containing similar numbers of carbon atoms, that is compounds whose heats of solvation differ little.

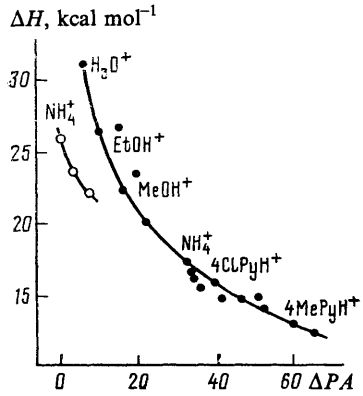
III. Ionic hydrogen bonds in the gas phase. Relationships between the strength of these bonds and the proton affinity of the partners. Modelling solvation effects

Considerable progress in the understanding of the role of solvation has been made as a result of a range of studies of ionic hydrogen bonds in the gas phase. These studies are being carried out in two related directions: 1) the determination of the energy of formation of H-bonded cationic and anionic dimers, and the analysis of the relationships between the strength of the H-bond and the acid–base properties of the partners in the gas phase; and 2) the determination of the energy of H-bonds formed on the successive addition to the protonated ion of from one (in the dimer) to 4–6 solvent molecules, that is modelling the effects of solvation in the gas phase and comparing with solvation in solution.

1. Relationship between the strength of H-bonds in ionic dimers and the acid–base properties of the partners in the gas phase

On the basis of insufficiently accurate thermochemical data it was at first concluded that an overall linear relationship exists between the energy of the hydrogen bond AH...Cl^- and the acidity in the gas phase of acids of different classes.[50] It was later established[51,52] that this conclusion is erroneous. The examination of H-bonds of the type A^-...HOH and BH^+...OH_2 showed that these relationships are more complex. Fig. 5 shows the relationship between the energy of the H-bonds formed by different acids BH^+ with H_2O (NH_3) and the quantities $\Delta PA = PA(B) - PA(B_0)$, where $B_0 = H_2O$ and NH_3. For acids BH^+ of different types, a linear relationship between ΔH_{compl} and ΔPA is not observed. The slope of the curve increases from −0.12 for weak acids BH^+ (pyridinium ions) to −0.75 for the strongest acid (H_3O^+). An approximately linear relationship ws obtained for representative series of substituted pyridinium ions.

The energy of the strong hydrogen bonds AH...F^- and AH...Cl^- has been compared with the energy of proton transfer in the gas.[53,54] Linear relationships between these quantities were established for aliphatic alcohols. The points corresponding to acids of other types do not lie on the straight line. The magnitude of the deviations from linearity for the bonds XH...F^- depends on the electronegativity of the atoms. For similar gas-phase acidity, the energies of the H-bonds decrease in an order similar to that in solution: OH > NH > SH > CH.[53] The energy of the H-bond with Cl^- is less sensitive to the heteroatom joined to the acidic proton.[54] Similar conclusions were reached[55] in an analysis of the hydrogen bonds ROH...B^- with different anions. The stability of the H-complexes MeOH...^-RO in the gas phase depends linearly on the proton affinity of the anions OR^-. The hydrogen bonds formed by anions of other types (F^-, $C{\equiv}CR^-$, etc.) with similar proton affinities have different strengths, however. Table 2 shows that the enthalpies increase with increase in the electronegativity of the anion (χ). An expression relating the X^-...HY bond energy to the values of $\chi(X)$ and $\chi(Y)$ has been published.[56]



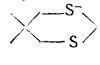


Figure 5. Relationship between the strength of the hydrogen bond BH^+...B and ΔPA (dark circles: $B_0 = H_2O$, light circles: $B_0 = NH_3$).[51]

Table 2. Stability of various bound dimers ($\Delta H_{0,1}$) and the group electronegativity of the anions (χ) in the complexes MeOH...B^-.[55]

B^-	$\Delta H_{0,1}$, kcal mol^{-1}	PA, kcal mol^{-1}	χ
F^-	29.6	371.5	4.0
$^-OCH_2$-t-Bu	18.6	371.8	3.5
$^-C{\equiv}CPh$	14.3	370.3	3.3
	14.8	372.9	2.5

The relationships between the stability of ionic dimers and the ΔPA values have been the subject of a large number of systematic studies.[57–60] Organic compounds of different classes, with a wide range of H-complex energies (ΔH_d^0) of 10–50 kcal mol^{-1} and ΔPA values 0–70 kcal mol^{-1}, were examined. The existence of the linear relationships

$$\Delta H_d^0 = \Delta H_d^0(0) - b\Delta PA, \qquad (8)$$

where $\Delta H_d^0(0)$ is the dissociation energy of the dimer with $\Delta PA = 0$, was reliably established.

Table 3 shows that these relationships are observed for many cationic complexes containing the heteroatoms of periods II and III (N, O, S). Anionic complexes have been less extensively studied; linear relationships between ΔH^0 and ΔPA were found for $O^-...HO$ systems.[60]

Table 3. Linear relationships between the energy of H-complexes ΔH_d^0 and the difference between the proton affinities of the partners ΔPA, Eqn. (8).

Type of complex	$-\Delta H_d^0(0)$, kcal mol^{-1}	b	n[a]	r[b]	Refs.
$NH^+...OH_2$	30.0	0.26	19	0.923	[57]

[a] Number of systems studied. [b] Correlation coefficient.

An interesting feature is that the differences in the values of the slopes (b) of the linear relationships for complexes of different classes are small ($b = 0.2-0.3$). Increase in the polarity of the partners leads to an increase in the sensitivity of the energy of formation of the dimers to the ΔPA values. Thus for the H-complexes with nitriles, $b = 0.38$ for the $NH^+...N\equiv C$ system, and $b = 0.43$ for the $OH^+...N\equiv C$ system.[58] A low value of the coefficient b, 0.16, was also observed for the complexes $SH^+...O$.[59] For dimers of a different type, containing a less electronegative atom (sulphur) as the base ($NH^+...S$), however, the coefficient b has the usual value (0.26). In all the compounds studied, the highest dissociation energy is shown by the dimers whose partners have equal proton affinities ($\Delta PA = 0$). The inverse relationship between the stability of the H-complexes and the ΔPA values can readily be understood if the formation of the ionic H-bonds $HX^+...B$ is regarded as partial charge transfer.[56] Increase in the proton affinity of X makes the charged acid a less effective proton donor, and decrease in the value of PA for B leads to a decrease in the proton-acceptor properties. As a result, the energy of the H-complexes decreases with increase in ΔPA.

Analysis of the deviations from the linear relationship (8) helps to identify such structural features as the presence of intramolecular hydrogen bonds, the formation of multiple H-bonds in polyfunctional ions, and the existence of steric hindrance to solvation. Thus the bonds formed by polyethers, crown ethers, and polyamides with RNH_3^+ are stronger than might have been assumed from the dependence of ΔH_d^0 on ΔPA. The energy of the H-bonds increases by 8 ± 1 kcal mol^{-1} when a second bond is formed, and by 4 ± 1 kcal mol^{-1} when a third bond is formed. An interesting feature is that the enthalpy of formation of H-bonds for compounds with bulky substituents does not decrease if the optimum geometry of the H-complexes can be achieved in even one conformation. At the same time, steric hindrance leads to marked entropy effects, as shown by substituted pyridines with bulky substituents in the *ortho*-position.[33]

Various general trends in the change in the stability of H-complexes of the ionic type were recently analysed[61] for the case of hydride dimers. It was established that the strength of the H-bond in the symmetrical dimers generally increases from left to right along a period and upwards within a group, that is the order of change in stability with change in the position of the heteroatom in the periodic system shows a similarity between ionic and neutral dimers: (F, O > N > S > P) for $(AH_n)_2H^+$ and (F > O > Cl > Br > I > S > N > P) for $(AH_{n-1}^-...AH_n)$.

Comparison showed that cationic dimers are usually more stable than the corresponding anionic dimers. This was established for dimers containing oxygen, nitrogen, and sulphur atoms. The situation was different, however, for the most stable dimers, containing fluorine atoms. The enthalpy of formation of the $(FHF)^-$ ion is 39 ± 1 kcal mol^{-1}, which is greater than the corresponding value for $(HF)_2H^+$ and $(CH_3F)_2H^+$, 32 ± 2 kcal mol^{-1}.[61]

The authors cited consider that important characteristics of symmetrically bonded hydrides are the greater stability of the systems containing more electronegative atoms (F, O > N) and the absence of a correlation between ΔH and the basic strength. An interesting feature is that the strength of the H-bonds in symmetrical dimers, for example $OH^+...O$ and , remains unchanged when the hydrogen atoms of the hydrides are replaced by the most varied substituents. With wide variation in the substituents, the energy of formation $[-\Delta H_d^0(0)]$ of oxygen-containing symmetrical dimers is 31 ± 2 kcal mol^{-1}, and that of nitrogen-containing dimers is 23 ± 2 kcal mol^{-1}.[57] Like the coefficient b mentioned above, $\Delta H_d^0(0)$ increases with increase in the polarity of the partners. Thus the stability of the ionic H-complexes with nitriles is greater than that of the corresponding complexes with amines, although nitriles are weaker bases than amines.[58] Even smaller values of $\Delta H_d^0(0)$ are observed for complexes containing a sulphur atom (an element of period II).[59]

A non-empirical quantum-chemical calculation for cationic complexes[62] showed that for distances A–B shorter than 2.55 Å, a significant contribution to the energy is made by covalent bonding. This component increases with increase in the electronegativity of the atoms. The same conclusions were reached from non-empirical calculations at the highest level for unsymmetrical anion–water dimers.[63] On going from elements of the first period to the less electronegative elements of the second period (halogens, oxo- and thio-anions), the stability of the complexes decreases by 10–12 kcal mol^{-1}. Decrease in the covalent component is revealed by a decrease in the deviation from linearity of the optimum geometry of the complex. These deviations are less than 12° for localised ions of period I, and reach approximately 20° for ions of period II; for delocalised ions of period I (carboxylates, cyanides), the bending is intermediate. An examination of the relationships between the energy of ionic complexes and the ΔPA values,[62] and later studies,[64] confirmed the existence of linear relationships of type (8). The values of the slope obtained by calculation were close to the experimental values, and differed little for compounds of

different classes ($b \simeq 0.2$); a decrease in the energy of H-complexes containing elements of period II was predicted.

The same linear relationships of type (8) as for ionic H-complexes have been given for neutral hydrogen bonds.[65]

A general expression for the non-linear relationship between ΔH and ΔPA, covering ionic and molecular complexes, was proposed. The energy $\Delta H^0(0)$ for symmetrical dimers $(AH)_2$ obtained from these relationships, however, was 10–20 times the experimental value. The differences in the energies of dimerisation of $(AH)_2H^+$ (40–20 kcal mol^{-1}) and $(AH)_2$ ($\leqslant$4 kcal mol^{-1}) are so large that it appears impossible to find a general correlation equation applying to both ionic and neutral H-bonds.

2. Modelling solvation in the gas phase

High-pressure mass spectrometry has given useful results in the study of this problem.[57,66–68] Studies of ion–molecule equilibria of the type: $X^{\pm}(S)_{n-1} + (S) \rightleftarrows X^{\pm}(S)_n$ make it possible to determine the enthalpy ($\Delta H^0_{n-1,n}$) and free energy ($\Delta G^0_{n-1,n}$) of the addition of the nth molecule of the solvent (S) on the monitored addition of the latter ($n = 1-5$). Particular attention was paid to the study of hydration.

The total energy of the addition of n solvent molecules to the ions changes in the same order as the energy of formation of dimers by these ions. Thus the energy of formation of clusters (containing two and three water molecules) is greater for the 4-CNPyH$^+$ cation than for PyH$^+$, and the same is true of the energies of the dimers: 4-CNPyH$^+$...OH$_2$ > PyH$^+$...OH$_2$.[66] Similar trends were observed in the series $RNH_3^+...nH_2O$.[35] The total energy of formation of a cluster containing several water molecules approaches the energy of solvation by water as solvent. Analysis of the results of the study of varied onium ions,[57,66–68] supplemented by a comparison of the enthalpy of addition of four water molecules in the gas phase ($\Delta H^0_{0,4}$) with the values of the differences ($\delta\Delta H_{gas\rightarrow H_2O}$),[2] leads to a number of important generalisations.

It has been reliably established that the energy of the hydrogen bonds $\Delta H^0_{n-1,n}$ decreases with increase in n. This can readily be understood by taking account of the fact that the ionic charge is delocalised with increase in the size of the cluster. For singly protonated ions, the energy of addition of a second molecule ($-\Delta H_{1,2}$) is 0.7 $\pm$ 0.05 times the energy of the dimer ($-\Delta H_{0,1}$). The enthalpy of addition of a third molecule ($\Delta H^0_{2,3}$) is even smaller, and is equal to 0.85 $\pm$ 0.05 times ($-\Delta H_{1,2}$) As a result, the ratio of the total enthalpy of solvation of the ion with the addition of four H_2O molecules to the energy of the H-bond with one molecule ($\Delta H_{0,4}/\Delta H_{0,1}$) is constant for a wide range of onium ions; for singly protonated ions the value is 2.8.

A slight increase in this ratio ($\Delta H_{0,4}/\Delta H_{0,1} = 3.1$) is observed for ions of the type ROH_2^+, RNH_3^+, etc.

For most ions, the variation in the values of the enthalpies of solvation by water as solvent is determined completely by the variation in the strength of the hydrogen bonds. The energy of the specific hydration of BH$^+$ ions by four water molecules is close to the enthalpy of transfer $\Delta H^0_{gas\rightarrow H_2O}$ ($\pm$2 kcal mol^{-1}). Deviations have been observed only for ions containing phenyl substituents. The values of $\Delta H_{0,4}/\Delta H_{0,1}$ and the linear relationship (8) between the energy of the dimers ($\Delta H_{0,1}$) and the ΔPA values can be used to predict the energies of hydration of most onium ions. Modelling the effects of solvation for DAS gave similar results. The total energy of the addition of three DMSO molecules is 92% of the energy of solvation of the proton by this solvent.[69] The results of a non-empirical quantum-chemical analysis of this process have been published.[70] The energies of solvation was a result of the formation of H-bonds ($\Delta H_{n-1,n}$) by solvents of different types (ethers, ketones, amides, nitriles, etc.) have been compared.[57] In spite of the differences in the polarisability and dipole moments, in all cases the enthalpy decreases with increase in n, and the ratios $\Delta H^0_{0,n}/\Delta H^0_{0,1}$ are comparable with those given above for hydrated clusters. An interesting feature is that a similar relationship was found for hydrated metal ions (Li^+, Na^+, K^+).[71] Comparison of the "solvation" of a series of oxonium ions by acetonitrile in the gas phase with their hydration in the gas phase and in water[72] showed that the effect of hydration is similar to the effect of the formation of an H-bond with one CH_3CN molecule. According to the data obtained,[72] the relative free energy of solvation of the oxonium ions in water is twice the energy of formation of the hydrogen bond $OH^+...N{\equiv}CMe$ and three times the energy of the addition of one H_2O molecule in the gas phase.

A theoretical analysis of the addition of several solvent molecules, carried out successfully by model quantum-chemical calculations (STO-3G basis set), covers a large number (61) or oxo-anions.[29] The influence of mono-, di-, and tri-hydration on the geometry and extent of charge transfer was examined in relation to the size of the anion and the delocalisation of its charge. An example of the successful use of quantum-chemical calculations at this level for cations is provided by the calculation of the energy of solvation of primary amines in a cluster containing three water molecules.[36] Quantum-chemical calculations for ionic bonds have been reviewed in a recent book.‡

In recent years, considerable progress in the solution of problems related to the solvation of ions has been achieved by the methods of molecular dynamics (MMD) and Monte Carlo methods (MCM) using intermolecular potentials based on the results of non-empirical quantum-chemical calculations for the dimers. An example is provided by MCM calculations for carboxylate anions and ammonium cations,§ which gave important information on the structure of the solvation layers and the number and geometry of ionic hydrogen bonds.

Thus experimental studies of ion–molecule interactions in the gas phase, supplemented by determinations of the enthalpies of transfer of an ion from the gas phase to solution and quantum-chemical calculations, have demonstrated convincingly the relationship between the strength of the ionic hydrogen bonds in the dimers and the acid–base properties of the partners (in the gas phase). They have also established that the differences in the heats of solvation of ions in solution are determined by the formation of hydrogen bonds by the ions with several solvent molecules.

IV. The structure of molecular H-complexes in the gas phase

Mass spectrometry determines the energy examined above, but gives no information on the internal structure of free ionic H-complexes, for example the position of the proton in them. At the same time, the structure of many uncharged H-complexes in the

‡C A Deakyne *Structure and Energetics*, Vol. 4, VCH Publ. Inc., 1987, p. 105

§W L Jorgensen, J Gao *J. Phys. Chem.*, 1986, **90** 2174; G Alagona, P J Kollman *J. Am. Chem. Soc.*, 1986, **108** 185; see also the references given in these papers.

free state is now well known, but their energies have as yet been little studied. This complementarity of the data, on the one hand, sets the present section apart, but at the same time it may stimulate the theoretical generalisation of the two types of hydrogen bond.

In the last ten years, remarkable progress in the study of molecular H-complexes has been achieved by the use of high-resolution spectroscopy, primarily rotational microwave (MW) and vibrational (infrared) spectroscopy. Of key importance in this work has been the preparation of the specimen, involving deep adiabatic cooling (to ~ 10 K) of a supersonic gas stream or pulse expanding in a vacuum. The "freezing" of the thermal excitations in this molecular beam greatly simplifies the spectrum, which otherwise cannot be interpreted, and the elimination of particle collisions and the usual Doppler effect decreases considerably the lines due to the remaining transitions. The corresponding spectral apparatus makes it possible to resolve effectively the fine (rotational) and hyperfine (nuclear) structure of the spectrum, and its interpretation gives the detailed structure of the H-complex. Thus it is possible to determine the accurate equilibrium geometry of the complex, its deformation (zeroth amplitudes of the mutual orientation of the partners), the elasticity of the stretching and bending of the H-bond, and the increase in the length of the A–H bond on H-bond formation (to within $10^{-3}-10^{-4}$ Å). The fine structure of the infrared band can be used to determine the contraction of A–H...B on excitation of the proton vibration ν_S, and the displacements of the ν_S frequency can be measured with an accuracy which is 10^2-10^4 times greater than that when a broad band is used. After the "cold" rotational spectrum has been interpreted, it is possible to interpret the spectrum of the gas in thermal equilibrium, to determine low frequencies which cannot be measured directly, to estimate the elasticity and dissociation energy of the H-bond, etc. All these topics have been reviewed in detail.[73,74]

The number of complexes in a molecular beam is sufficient to make it possible to record the MW spectrum by sensitive MBERS (molecular beam electrical resonance spectroscopy) methods[73,74] and Flygare Fourier spectroscopy,[74] but is often insufficient to allow direct recording of the infrared spectra of the same complexes (the proportion of radiation absorbed is too small). It is possible, however, to detect changes in the actual beam (an increase or decrease in the number of particles in a given state) as a result of vibrational excitation or photo-dissociation of the complexes by the sufficiently powerful infrared radiation of a tunable laser. This method makes it possible to obtain good high-resolution infrared spectra (and also to estimate the lifetime of the excited complexes, opening up new possibilities for the study of the kinetics of the elementary acts); the results have been reviewed.¶ Thus the new spectroscopy has successfully brought "non-rigid" molecular complexes with their unavoidably large zero-point vibrations into the general sphere of the traditional spectroscopy of simple molecules.

In a few years, intensive spectral studies have examined a wide range of systems, mainly heterodimers of the type AH.B. A published list[74] gives 68 complexes of different AH from hydrogen fluoride to fluoroform and acetylene with various partners B from ammonia to nitrogen. In addition, the simplest triatomic complexes of AH with noble gases (9 systems) and cyclic heterodimers of carboxylic acids and amides (14 systems) have been studied.[73] A large amount of information leading to important conclusions has been accumulated, and is increasing rapidly (becoming broader, deeper, and more accurate), and includes associates with a high multiplicity, new dimers, the isomerism of H-complexes, their stability and dynamics, etc. (see the Summary).

The structures of a representative series of H-complexes from the simplest to the more traditional, established from the rotational spectra, are shown in Fig. 6, and Table 4 gives as an example the parameters of selected complexes from the most widely studied series FH.B. Some of the results and conclusions may be noted.

Table 4. Parameters of various H-complexes B...HF;[73,75] R = interatomic distances; μ_a and $\Delta\mu$ are the longitudinal component of the dipole moment and its increase in the complex; k_σ is the H-bond stretching force constant.

[a] A recent recalculation of some of the R_{FB} values with improved averaging with respect to the zero-point amplitudes gave differences of 0.005–0.017 Å (A C Legon, D J Millen *Chem. Phys. Lett.*, 1988, **147** 484); this probably provides a measure of the accuracy of the values; [b] data of Peterson and co-workers[76]; [c] from the C–C line; [d] cyclopropane.

Linearity of the H-bond. It has been established by direct experiment that an isolated single H-bond is in fact linear, that is the three atoms A–H...B lie on the same straight line;[73] previously, this was only postulated, on the basis of crystallographic data. The slight deviations from linearity obtained in non-empirical calculations for the simplest H-complexes[77] are comparable with the uncertainty in the measurements (5–10° [73]), and it is not clear how real these are.

Non-rigidity of the H-bond. It has been shown that the H-bond has a low rigidity and is easily deformed, particularly round the electron-donor atom B; this also agrees with crystallographic data. Thus in $CH_3C{\equiv}N...H-F$, the force constant of the bending of the H...N≡C angle is 3–4 times lower than that for the F–H...N angle[74] (and, like the chemical bonds in molecules, is 10 times lower than the force constant of the stretching of the H-bond). This "flexibility" of the H-bond corresponds to the high zeroth amplitudes of the angles of orientation of the partners. For example, the average values of the angles of rotation (libration) of HF in its complexes with H_2O, CO_2, and Ar are 18 3, 25.17, and

¶ R E Miller *Science*, 1988, **240** 447

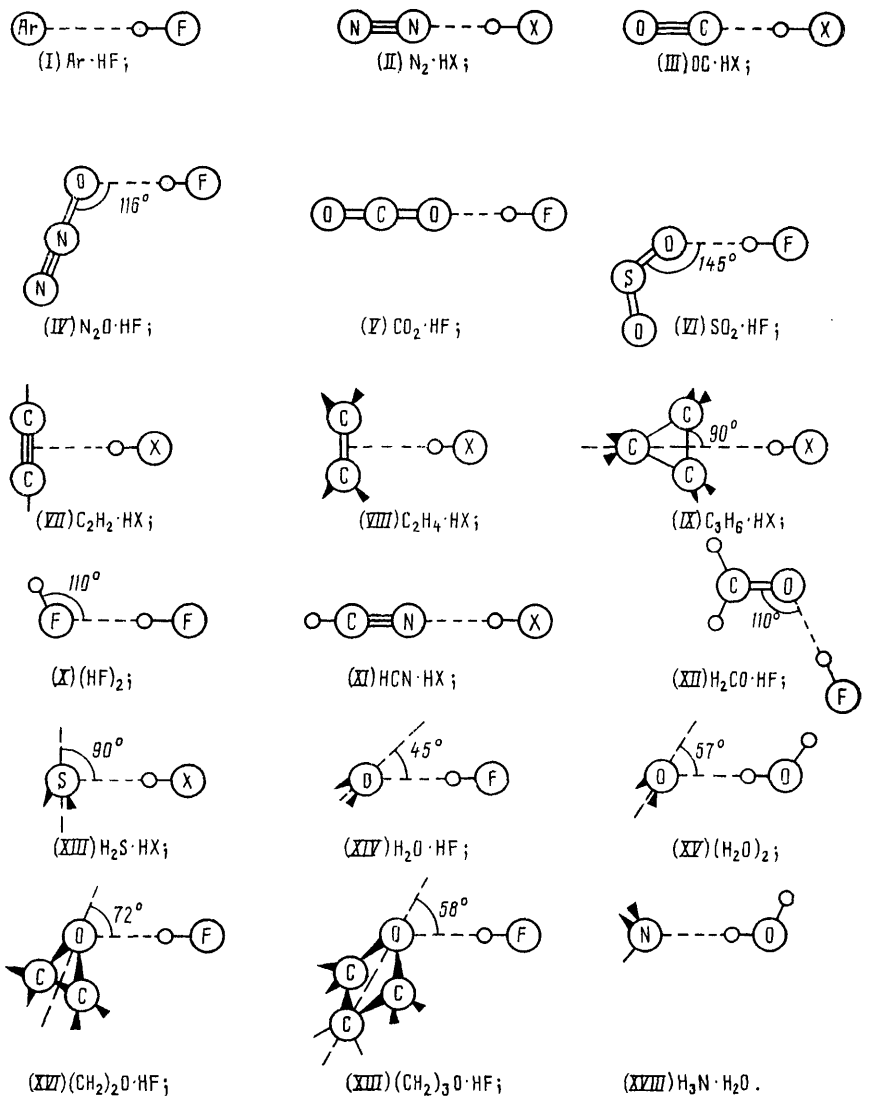

Figure 6. Configurations of various gaseous H-complexes AH.B, established from the rotational spectra;[73–75] for the interatomic distances A...B and other parameters see Table 4.

41.27° respectively.[73,76] At ordinary temperatures, when the librations are highly excited, the configuration of the H-complex should differ to an even greater extent from that shown in Figure 5 (the equilibrium configuration). It is the non-rigidity (difficulty of averaging) that limits the accuracy of the determination of the equilibrium geometric parameters of the H-complex from the extremely accurately measured rotational spectrum; the same applies to the dipole moments.

The flexibility of the complexes corresponds to the low wavenumbers of the librations of the sub-molecules (ν_β). They have not yet been observed directly in the spectrum, but are calculated indirectly from the changes in the spectra with change in temperature, or from the amplitudes of the angles. For the lightest hydrides, the values of ν_β reach 40–70 cm^{-1},[74,78–80] but in ordinary H-complexes they do not usually exceed 10–30 cm^{-1}. The excitation of these librations of the partner molecules is the main reason for the unique broadening of the vibrational bands by the H-bond at ordinary temperatures[78,79,81] (see, however, the papers by Millen[80] and Sokolov and Sakun[82]). The broadened band corresponds to a whole set of vibrational transitions, and not to one normal vibration. In this respect, the vibrational spectra of a complex AH.B and a simple molecule XYZ differ considerably. To make them comparable, it is necessary either to heat XYZ above 3000 K or to cool AH.B below 30 K, as is done in molecular beam spectroscopy.

Configuration of H-complexes. The orientation of the partners of the H-complex (in particular diatomic complexes; see the HF dimer in Fig. 6) is completely different from the favourable orientation of the dipoles. This is consistent with the known fact that there is no correlation between the dipole moment and the strength of the H-bond.[83]

The direction of the H-bond to some extent corresponds to the directions (valence angles) of the chemical bonds of the molecules (Fig. 6). Protonophiles of the first period tend to adopt the tetrahedral orientation, but hydrogen sulphide adopts the orthogonal orientation; a characteristic feature is the difference in the angles of the H-bonds with different cyclic ethers.[73]

In their systematisation of experimental data, Legon and Millen formulated the following rules. "The gas-phase geometry of a dimer B...HX can be obtained in terms of the non-bonding and π-bonding electron pairs on B as follows: (i) the axis of the HX molecule coincides with the supposed axis of a non-bonding pair as conventionally envisaged, or, if B has no non-bonding electron pairs but has π-bonding pairs, (ii) the axis of the HX molecule intersects the internuclear axis of the atoms forming the π-bond and is perpendicular to the plane of symmetry of the π-orbital. Rule (i) is definitive when B has both non-bonding and π-bonding pairs".[74]

These rules are not absolute. The pyramidal structure of $FH.OH_2$ [(XIV) in Fig. 6] has only been calculated for the equilibrium configuration, but in fact is not realised; the barrier to inversion is so low (0.36 kcal mol^{-1}) that the complex is effectively planar. Other complexes $XH.OH_2$ are even more likely to be planar, and the equilibrium pyramidal structure is only assumed.[74] Finally, the weak H-complex $HCCH.OH_2$ is recognised as definitely planar.[76] The hydrogen bond formed by AH with benzene is directed towards the centre of the ring at right angles to its plane,[74] and the (stronger!) bond with cyclopropane lies in the plane of the ring and is directed towards the centre of a C–C bond [(IX) in Fig. 6]. The dimer $CO_2.HF$, which is isoelectronic with $N_2O.HF$, is not bent like this compound, but is linear, contrary to the "rules" [(IV) and (V) in Fig. 6]. With weaker electrophiles, in particular HCN, the same CO_2 now forms a *T*-shaped complex $O_2C.NCH$ with an intermolecular C...N bond,[74] and not the isomeric linear complex OCO...HCN with an H-bond (energetically less favourable, but also observed later). A similar structure is shown by the symmetrical complex with water, $O_2C.OH_2$; this intermolecular C...O bond shows some similarity to a double bond (the internal rotation of H_2O is strongly hindered).[76] On the other hand, the "rules" are apparently applicable to stronger ("ordinary") H-bonds.

Structure of the dimers $(AH)_2$. The actual existence of the rotational absorption spectrum excludes non-dipole cyclic homodimers, and in fact all $(AH)_2$ studied are open and have a single H-bond AH...AH [(X) and (XV) in Fig. 6]. It has been shown, in particular, that the $(HF)_2$ ring is an unstable state corresponding to a saddle point of the potential.[76,77] The initial assumption that the dimer of methanol (and water) in a matrix is cyclic[83] was found to be due to the insufficient resolution of the infrared spectrum; improvement of the resolution showed clearly that the dimer is open[84] (as in the case of water also[85]). The free dimer of water [(XV) in Fig. 6] is now one of the most fully studied H-complexes.[73,74,76]

Thus prolonged argument has concluded that the dimers are open; four-membered $(AH)_2$ rings with the corresponding non-linear (90°) hydrogen bonds apparently do not exist. Other gaseous dimers, formed by CH_3OH, C_2H_5OH, H_2S, CH_3SH, CH_3NH_2, and $(CH_3)_2NH$, also have a dipole moment and therefore cannot be symmetrical rings, and are probably also open. The polymeric associates of these molecules, on the other hand, are non-polar and probably have a cyclic structure.[73]

Nature of the hydrogen bond. The data on the geometry of H-complexes have been interpreted from different viewpoints. In Dyke's opinion, the configuration of H-complexes indicates that "...the hydrogen bond is essentially covalent",[73] and the experimental results show excellent agreement with the HOMO/LUMO donor–acceptor model.[86] In the latter, the H-complex is regarded as an electron donor–acceptor complex, in which the electron pair is transferred from the highest occupied molecular orbital (HOMO) of the Lewis base to the lowest unoccupied molecular orbital (LUMO) of the Lewis acid, and the maximum overlap of the HOMO and LUMO is achieved in the dimer.[73]

In the opinion of Legon and Millen,[75] however, the orientation of the molecules is determined only by the favourable orientation of their dipole and quadrupole moments, and the experimental results are successfully described by a recent electrostatic model.[87]

It should be remembered, however, that simple electrostatics, that is the attraction of charges which remain unchanged in the interaction, cannot explain the distinctive spectroscopic and chemical properties of the hydrogen bond, namely the unique increase in the intensity and decrease in the frequency of the longitudinal vibration of the proton, the non-additivity of the dipole moments of the partners, and, finally, the cooperative effect—the significant increase in the strength of alternating H-bonds. Thus simple electrostatics apparently represents an unjustified resurrection of long abandoned ideas. Naturally, simple electrostatics cannot be identified with the so-called electrostatic (more accurately, Coulombic) contribution, distinguished in the non-empirical calculation of the energy of the H-bond. It hardly appears possible, however, to isolate the corresponding contribution from the experimental values to confirm the theory directly.

Interatomic distances. The lengths of H-bonds, which until recently were known only for crystals, have now been determined for various single H-bonds in isolated gaseous dimers, including the simplest and most important. In the complexes FH.NC the length of the hydrogen bond changes in accordance with the protophilic character of the nitrile group, but this regularity is not observed in the lengths of more varied H-bonds F–H...B (Table 4). The weak bond with CO_2 is shorter than the stronger H-bonds with π-electron donors and with cyclopropane; the H...B distances change less regularly than the classical spectral characteristics of the H-bond.

Comparison of the interatomic distances provides new and convincing confirmation of the cooperative character of H-bonds; the H-bonds of the polymer chains in HF and H_2O crystals are appreciably shorter than the bonds in the dimers; the difference is 0.30 Å and 0.14 Å respectively.[73] The O–O distances in the chain crystals of formic and acetic acids (2.58 Å and 2.61 Å respectively) are also appreciably shorter than those in the heterodimers of carboxylic acids (2.67 Å); according to Dyke,[73] this decrease in the length of the H-bond in the crystal may be due to the stronger cooperative effect in the chain of H-bonds, compared with the ring. Other factors may also be responsible, however: the higher temperature of the gas and the freedom of deformation of the dimer. A cooperative effect is also observed in gaseous trimers, that is when two H-bonds are conjugated. Thus the H-bonds in the linear trimers HCN.HCN.HA are 0.107–0.030 Å shorter than those in the dimers HCN.HA, where A = F, Cl, CN, CF_3.

The increase in the A–H distance on H-bond formation has been measured accurately in a number of dimers, and it has been shown that this increase in length rises approximately linearly with increase in the strength of the H-bond.[74] Direct confirmation has been

obtained for the long-predicted Stepanov–Sheppard effect,[88,89] that is the decrease in the length of A–H...B when the stretching vibration of the proton is excited; in HCN.HF it is 0.034 Å.[74] The existence of the opposite effect, that is a decrease in the strength of the H-bond as a result of the transverse vibration of the proton (ν_B), is indicated by the opposite "shading" of the rotational structure of the ν_B sub-bands.

Energy and elasticity of the H-bond. The values of $D_0(D_e)$ that is the energies of the dissociation of a free H-complex from its ground state (from the potential minimum), have been determined for the hydrogen bond for the first time (only a few have as yet been determined); the values, given in Table 5, were found from the measured "absolute" intensity of the lines in the spectrum of the equilibrium gas. This new and fundamental information (which will probably increase), combined with the highly accurate spectral parameters of the complexes, provides a fundamentally important supplement to ordinary thermodynamic and spectral data on H-bonds (plentiful for the condensed phase, but not for the gas phase).

Table 5. Dissociation energies of hydrogen bonds, from high-resolution spectra.

[a] D_0 and D_e—measured from the lowest level and from the potential energy minimum.

The stretching force constant of the H-bond k_σ is determined accurately from the centrifugal stretching of the H-complex from the rotational spectrum.[74] A large number of "rotational" k_σ have now been obtained (an example is given in Table 4); these values are apparently more reliable than the previous isolated determinations of ("vibrational") k_σ from the frequency of the ν_σ bands, difficult to observe, in the far infrared region of the spectrum. Far infrared spectroscopy is also developing successfully (see for example the published review†), and a significant breakthrough is possible with the appearance of tunable lasers. Because of the difference in the selection rules, the two types of spectra should usefully supplement one another.

Comparison of the published[75] values of k_σ shows a mutual proportionality of the k_σ values in corresponding series of complexes AH.B (Fig. 7), similar to the proportionality of the enthalpies of the H-bonds.[94] As in the work cited,[94] it is possible to express this mutual independence of the proton-donor (P) and electron-donor (E) functions in the H-bond of any two partners, $(AH)_i$ and B_j, as the product $(k_\sigma)_{ij} = k_{11}P_iE_j$, where k_{11} is the normalisation to the standard H-complex with $P_1 = E_1 = 1$. A key question in this extension of the product rule[94] to k_σ is whether the two P and E scales (the scale constructed from ΔH in the liquid phase[94] and the new scale constructed from k_σ for the free H-complexes) coincide. For example, the electrophilic character of hydrogen fluoride (P = 1.9) estimated from k_σ (Fig. 7) is greater than that estimated from ΔH (P = 1.5 [94]) (this is only a preliminary estimate without conclusions). In general, the new data make it possible to compare on a more reliable basis two different measures of the strength of the H-bond, namely the dissociation energy and the quasi-elastic constant.

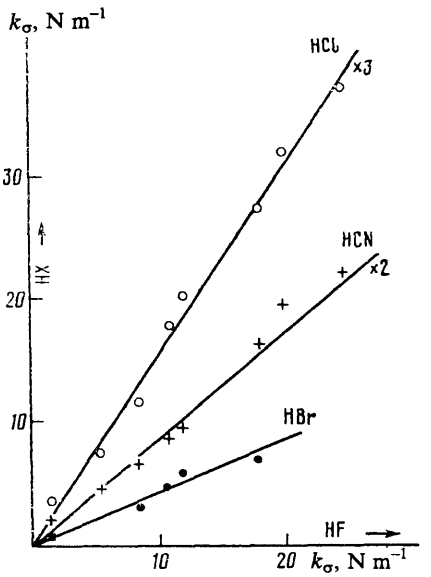

Figure 7. Relationship between the force constants of H-bonds of different proton donors HX with indentical protonophiles B in the gas phase, constructed from the data of Legon and Millen.[75]

Dipole moments. The extremely accurate dipole moment of a H-complex from measurements of the Stark effect in the microwave spectrum is the projection of μ on the prolate top axis; the total moment μ is established less accurately, because of the poor determination of the perpendicular components. For H_2S.HF, for example, the projection μ_a = 2.6239(17) D, and μ = 2.80(7) D.[73] To separate the induced moment $\Delta\mu$, it is necessary to subtract from μ_a the projections of the moments of the sub-molecules AH and B, not for the equilibrium configuration of the H-complex but with appropriate averaging with respect to the zeroth amplitudes. In spite of the difficulty of taking account of the non-rigidity of the H-complex in this way, the non-additivity of the dipole moments of the partners in the H-complex, that is the appearance of an additional excess moment $\Delta\mu$ (Table 4), has been reliably established.

†E Knozinger, O Schrems in J R Durig (Editor) *Vibrational Spectra and Structure*, Elsevier, 1987, Chapter, 3, p. 142

In some cases, the quantity $\Delta\mu$ can be attributed to the polarisation of one partner by the other, but in other cases this explanation is insufficient. For example, in $H_2S.HF$, $\Delta\mu$ is 0.2–0.6 D greater than that from the calculated polarisation and "...this contribution is very probably due to the charge transfer characteristic of the donor–acceptor model".[73]

In the particular case of the centrosymmetric protonophiles N_2 and NCCN, it is possible to estimate the redistribution of charge within the protonophile resulting from the H-bond. Movement of the two symmetrical N nuclei, identical in this case, is excluded, and the electrical asymmetry of the protonophile in the H-complex is revealed. The calculated N → N charge transfer is 0.025 e (see the paper by Legon and Millen[74] for more details). This means that not much can be expected from the traditional estimation of the values of $\Delta\mu$ for H-complexes in solutions from a simple vector scheme. The model of a "rigid" complex in this case is even less favourable, since at room temperature the deformations are much greater than in a cold molecular beam.

V. Solvation of the H-bond

The influence of a solvent on neutral H-bonds is qualitatively similar to its influence on ionic bonds, but is weaker than in the case of acid–base equilibria; in particular, it does not reverse the sequences of the strengths of acids and bases. This is partly due to the narrower range of liquids, not including associated liquids (water etc.). In addition, the magnitude of the influence differs considerably.[95] Non-polar $(AH)_n$ rings remain almost unchanged on going from the gas phase to solution; the liquid environment has no significant influence on the H-bond in this extreme case of the formation of a non-dipolar associate. At the same time, polar dimers AH.B undergo fairly marked changes in solution; the solvation effect may be greater than the primary effect of free H-bond formation. Finally, in the extreme case where the strength of the H-bond of the polar dimer AH.B is close to its limit, solution or condensation leads qualitative changes, bringing about the transformation of the molecular complex AH.B into the "conjugate" complex $A^-.H^+B$ or into the salt. The subsequent discussion deals mainly with the non-ionising solvation of the H-bond, and ionising solvation is mentioned only briefly.

Available data on the energy of H-bonds in the gas phase are insufficient for a reliable comparison with their energy in the more extensively studied liquid phase. A clearer picture of the influence of the medium on the H-bond is given by an analysis of the infrared spectra. Infrared spectroscopic data show that the solvation of a complex always leads to an increase in the strength of the H-bond.[94–96] According to these data, the transfer of a gaseous associate to the condensed phase: 1) lowers the frequency of the stretching vibrations ν_S (Table 6), 2) increases the frequency of the deformations ν_B, and 3) increases the absolute intensity of the vibrations ν_S. Each of these changes is a reliable spectral indication of an increase in the strength of the H-bond.[83,97] They all show quantitative consistency, that is they correspond to the same increase in the strength of the H-bond.[95] Thus dissolving free $FH.NCCH_3$ in acetonitrile lowers the ν_S frequency by 350 cm^{-1} (Table 6), and simultaneously displaces the ν_B band from 587 cm^{-1} to 750 cm^{-1}.[96] According to published correlations,[97] both displacements correspond to an increase in the energy of the H-bond from 5 kcal mol^{-1} to 8 kcal mol^{-1}. When gaseous $(CF_3)_2CHOH.NH_3$ is dissolved in dichloroethane, the intensity of ν_S increases by 10^5 cm $mmol^{-1}$;[95] this corresponds to an increase in the energy of the H-bond by ~4 kcal mol^{-1}, and is also consistent with the increase in $\Delta\nu$ from 500 cm^{-1} to 970 cm^{-1} (Table 6).

Table 6. Displacement $\Delta\nu = \nu_0^0 - \nu$ of the ν_S bands for various H-complexes in the gas phase and in liquids (solution in CCl_4 and in the liquid base B).[80,95,98–102]

[a] The names of the bases B are abbreviated: nitrile = acetonitrile; ether and m-ether = diethyl and dimethyl ethers; TEA = triethylamine; [b] the frequencies ν_0^0 of free AH in the gas phase are given in brackets; [c] in chloroform; [d] in dichloroethane.

The decrease in the ν_S wavenumber in solution has been most extensively studied; it was first observed by Allerhand and Schleyer[98] (although the authors cited did not attribute it to an increase in the strength of the H-bond), and was confirmed in subsequent experiments[95,96,99–109] and is shown in Table 6. The solvation effect depends not so much on the polarity of the medium as on the polarity of the associate and the dimensions of the partner molecules.[95] The solvation displacements $\Delta\nu_S = \nu_S(gas) - \nu_S(solution)$ in highly polar solvents (acetonitrile, DMSO) is only ~70% greater than $\delta\nu_S$ in the "inert" CCl_4, and in a given medium the displacements for polar complexes are ten times those for non-polar complexes (Table 6).

The medium has its weakest influence on non-dipolar cyclic associates, that is $(RCOOH)_2$, $(ROH)_4$, and $(HF)_6$.[95] The displacement of their ν_S band in solution is only 10–15% of the displacement $\Delta\nu^0$ in the gas, and the spectra of $(RCOOH)_2$ are similar to the gas-phase spectra not only in solution but also in crystals.[103–105] A surprising feature is that the ν_S bands of the gaseous cyclic formations $(CH_3OH)_4$ and $(HF)_6$ also undergo almost no displacement in liquid methanol and hydrogen fluoride (Table 6). In these associated liquids, the original rings undoubtedly are not preserved, and undergo rearrangement to give polymeric chains $(AH...)_n$, but the change in the long-range order of the H-bonds

does not influence the H-bond itself. This is consistent with the recently observed fact[107] that the infrared spectra of associated alcohols is independent of their concentration in solution (above ~1 M).

This absence of change in the spectra and hence in the H-bonds in $(AH...)_n$ is observed with a marked increase in the dielectric constant ε of the medium from 1 in the gas to 85 in liquid HF. Thus ε does not influence the H-bond, and correlations between its strength and ε are not significant. A similar lack of sensitivity to the environment is shown by the non-dipolar centrosymmetric ion $(FHF)^-$; in different media from water to the crystal, the frequency $\nu = 2500$ cm^{-1} changes by only $\pm 2\%$.[107,108] On the other hand, the formally symmetrical ion $(ClHCl)^-$ is sensitive to its environment.[109]

In contrast to the non-dipolar $(AH)_n$, the strongest interaction with a solvent is undergone by the highly polar dimers AH.B of small molecules (NH_3, CH_3CN, HF, CH_3OH). The wavenumber displacements $\Delta\nu_S$ of these dimers are much greater in the liquid phase, and are sometimes more than twice those for the gas phase, so that the solvation displacement reaches 100–140% of the primary displacement $\Delta\nu^0$, and its absolute magnitude reaches about 500 cm^{-1} (Table 6). Thus the effect of solvation of the H-complex by an aprotic solvent may be greater than the primary effect of H-bond formation. In these cases, the conclusions that the H-complex is independent of the environment and that a local H-bond A–H...B is formed are extremely approximate.

The solvation is stronger, the more polar the partner molecules in the complex and the smaller their size.[95] Thus for the complexes of NH_3 and $N(C_2H_5)_3$ with methanol (Table 6), the displacement $\Delta\nu$ in CCl_4 solution increases by 75% and 25% respectively. The "exposed" ammonia is solvated more strongly than triethylamine, which has undergone "intramolecular solvation". This means, in particular, that the electronic effects of the substituents are greatest in the gas and are levelled out in the liquid, to an extent which is greater, the more active the medium. Thus the picture of the change in the acid–base equilibria in solution examined above (section II) is partly repeated. The factors *P* and *E* characterising the ability to form a H-bond should also depend on the medium, so that, in particular, the proposed[94] extrapolation of the values of *P* and *E* from the solution to the gas is inaccurate. Thus in the gas phase, ammonia is a weaker electron donor than pyridine, whereas in CCl_4 solution the two compounds are comparable in this respect (see $\Delta\nu$ in Table 6), and in a more polar medium, reversal of the relative strengths of these compounds should be expected.

An environment of an H-bond which is similar to it increases its strength by a further factor of 2 compared with that given by the maximum solvation of a polar dimer A–H...B by an aprotic solvent. The change from the free dimer A–H...AH to the polymer $(AH...)_n$ (in the gas or in the liquid) increases $\Delta\nu$ by a factor of 4–6, from 90 cm^{-1} to 300 cm^{-1} and 500 cm^{-1} for methanol and hydrogen fluoride respectively (Table 6); the enthalpy of the H-bond also shows a corresponding increase, from ~3 kcal mol^{-1} in the dimers to 5.5 kcal mol^{-1} and 7 kcal mol^{-1} in the polymers.[83,93,97]

In this long-familiar cooperative effect, which was first proposed to explain the characteristics of liquid water,[110] the group AH, which gives up its proton for H-bond formation, attracts a neighbouring proton more strongly, and by accepting the neighbouring proton it gives up its own proton more readily. Thus charge transfer (polarisation) in a single H-bond AH...A–H partly extends to the sequence $(A–H...)_n$ formed. The effect is extinguished comparatively rapidly along the chain; the frequency ν_S decreases considerably on going from the dimer to the tetramer of an alcohol, and the subsequent multimers are spectrally indistinguishable. The cooperative effect (the non-additivity of the H-bonds) cannot be attributed to the sum of the paired interactions, but the effect is reproduced by calculation of triple interactions.[77] It is the cooperative effect that makes chains of alternating H-bonds such widely encountered structural elements in associated liquids and crystals, in particular those of alcohols and carbohydrates.[83,111]

The contrast between the solvation of polar and non-polar H-complexes indicates additional electrostatic polarisation of the dipolar H-complex by its environment. It resembles the "reactive field effect" in the Onsager model, but probably only outwardly. The only significant interaction is that with the closest solvation layer, which is not characterised by the volume macroparameters of the medium, including the value of ε.

The absolute magnitude of the solvation effect increases regularly with increase in the strength of the H-bond, but changes little relative to the latter.[95] Thus the weak methanol dimer and the strong hetero-dimer $(CF_3)_3COH.NC_5H_5$ in the gas phase are characterised by displacements $\Delta\nu_S$ = 90 cm^{-1} and 900 cm^{-1} respectively, which in solution increase to 150–200 cm^{-1} and 1200–1500 cm^{-1} (Table 6). Further increase in the "polarisation" of AH.B probably leads finally to proton transfer to give the conjugate complex (ion pair) $A^-.H^+B$, and then the separated ion pair $A^-||H^+B$. The values of ΔH also increase regularly,[112] but the changes in the spectrum are not regular, and on the contrary change sign sharply at the hypothetical point corresponding to the "quasi-symmetrical" H-bond A..H...B.[113,114] This phenomenon is not observed in free H-complexes. On the contrary, gaseous hydrochloric acid contains (in addition to free molecules) only the molecular complex $H_2O.HCl$,[74] and, similarly, the vapours over the ionic salts NH_4CN or NH_4Cl contain the molecular complexes $H_3N.HCN$ [114] or $H_3N.HCl$.‡ Intra-complex proton transfer in $H_3N.HCN$ is convincingly excluded by the detection of the semi-deuteriated complex $H_3N.DCN$ in the infrared spectrum in the gas phase (by the usual method).[114] Free associates apparently exist only as the molecular complexes AH.B; ion pairs do not exist in the free form, and are stabilised only by intermolecular interaction with the environment. Each acid AH possibly has its own stability limit or, in other words, proton transfer threshold. Thus hydrogen fluoride retains its proton both in water (pK = 3.45) and in strong bases[96] with a H-bond energy of not less than 15 kcal mol^{-1} (estimated from spectral data[96]). The energies of the H-bonds formed by organic OH acids may also reach 11–15 kcal mol^{-1} before the base is protonated. The proton transfer threshold for HCl, HBr, and CH-acids, however, does not exceed 5–7 kcal mol^{-1}, and molecular complexes of these acids with a higher bond energy are not known.

The energies of solvation of H-bonds can be considered. The enthalpies of dimerisation of carboxylic acids decrease considerably in solution,[83] but this fact cannot be generalised, the conclusion cannot be extended to polar complexes AH.B, and this cannot be regarded as a decrease in the strength of the H-bond in the dimer (as is sometimes done). The decrease in ΔH is due entirely to the solvation of the monomer (see below), and does not contradict what has been said above. The ΔH values measured in different media relate to different states of not only the H-complex but also the "free" partners, and spectral estimates of the H-bond in these media

‡ A C Legon, D J Millen *Chem. Phys. Lett.*, 1988, **147** 484

implicitly assume that there is no change in the state of the free partners; this difference in the states of the products of dissociation of the H-bond must be borne in mind.

The usual notation for complex formation AH + B ⇄ AH.B is applicable only to the gas phase, and does not take account of the influence of the medium. The qualitative model of the effect of the medium S includes two opposed factors: 1) to combine the two solvated partners AH(S) and B(S) into the H-complex it is necessary to "squeeze out" part of the solvation layer of each partner, leading to a decrease in ΔH, and 2) the overall solvation layer "compresses; the H-complex, increasing ΔH in the medium S. The overall effect of the solvent may have either sign, although the former (decrease) predominates most frequently. According to Iogansen,[94] the "desolvation" of the AH molecule involves the replacement of the weak H-bond (H-interaction) with the solvent by a stronger bond with B. The reaction in solution should therefore be described as follows:

$$AH \cdot S + B(S) \rightleftarrows AH \cdot B(S) + S, \quad (9)$$

where (S), as usual, denotes the "S environment" (the interaction B(S) is not taken into account, since there is no specific model). The solvent SD is regarded as a direct participant in reaction (9); it makes an additive (negative) contribution to the enthalpy of the reaction which is proportional to its electron-donor power E_S^0.[94] Appreciable electron-donor power is shown by all compounds up to the extremely inert perfluorohydrocarbons; the noble gases also form H-bonds with strong electrophiles AH (see above). CCl_4, traditionally used in infrared spectroscopy, is far from the most "inert";[115,116] for example, the energy of the H-bond which it forms with HF is ~2 kcal mol^{-1} (ν_S is displaced by 110 cm^{-1}).

Thus according to the model, the decrease in ΔH in solution is related to the fact that complex formation to give AH.B unavoidably breaks down the H-interaction AH.S. The magnitude of the latter is proportional to the product of two independent parameters:[94] the proton-donor power of the acid AH (P_i) and the electron-donor power of the solvent molecule S (E_S^0):

$$\delta_1 \Delta H = 6.4 P_i E_S^0. \quad (10)$$

Eqn. (10) predicts that the solvent will make an additive contribution to the enthalpy of reaction (9). The strength of the H-interaction AH.S can be determined not only using Eqn. (10) but also from the increase in the intensity of the ν_S infrared band in solution (compared with the gas phase AH), determined by "spectral calorimetry".[97] The direct determination of $\delta_1 \Delta H$ by the usual methods is difficult, because of the need to distinguish the "non-specific" interaction.

The increase in the strength of the H-bond of the dimer AH.B as a result of the polarising action of the medium can be estimated only from the ν_S frequencies. The extension to the solvation displacements of the published correlations[97] (which assumes that they are also applicable in the gas phase) leads to the expression

$$\delta_2 \Delta H = 0.055 \delta \nu_s / -\Delta H^0. \quad (11)$$

The accuracy of the prediction (11) must be examined carefully, because of the limitations of the correlations[97] and their "transfer" to the gas; independent data are consistent with Eqn. (11), but are few in number.

If the action of the solvent on an associate is slight, as with $(RCOOH)_2$, Eqn. (10) describes the total effect of the solvent. Thus the changes in $-\Delta H$ for the dimerisation of trifluoroacetic acid in solution, calculated using Eqn. (10) coincide with the measured values (Table 7), that is the H-interaction is the main component of the solvation of the acid monomer; the van der Waals interaction is weak and approximately the same for different solvents (see Table 7). The measured and calculated values of $-\Delta H$ for the dimerisation of other acids in different solvents show similar agreement;[105] in benzene, the energy of solvation of the "free" acid reaches 4 kcal mol^{-1}.

Table 7. Enthalpies of dimerisation and solvation of trifluoroacetic acid in different media, kcal mol^{-1}.

Medium	Dimerisation		Solvation of the monomer	
	measured (Ref.117)	calculated from Eqn. (10)	measured (Ref.117)	calculated from Eqn. (10)[a]
Gas	—	(7.0)[b]	—	—
Cyclohexane	5.8 (3)	5.72	2.3 (4)	1.28
Carbon tetrachloride	4.6 (2)	5.13	3.4 (6)	1.87
Benzene	(3.7)[c]	2.94	5.2 (6)	4.06
1,2-Dichloroethane	3.5 (4)	3.10	5.3 (6)	3.90

[a] Only H-interaction; [b] accepted value; [c] estimated by analogy.[117]

An example can be used to illustrate the increase in the strength of a H-bond in the non-polar CCl_4, or more accurately the positive contribution δ_2 calculated using Eqn. (11) from the experimental frequencies in Table 6. For three typical dimers, namely the non-polar $(RCOOH)_2$ and the polar methanol.ether and (smaller) methanol.ammonia, this increase in strength has values of about 0.3, 0.8, and 1.5 kcal mol^{-1} respectively, or 4, 25, and 40% of the energy of complex formation in the gas phase. With the opposed contribution δ_1, the expected change in $-\Delta H$ is appreciably negative in the first case (Table 7), close to zero in the second, and positive in the third (0.7 kcal mol^{-1}). In polar media, the same increase in the strength of the H-bond δ_2 may be appreciably greater, reaching 60–70%. Finally, the greatest increase in the strength of the H-bond by 3–4 kcal mol^{-1} or more than 100% is observed in an associated liquid, or more accurately a polymeric associate (see above). The results of direct measurements of ΔH in undiluted polar bases in general are consistent with the above spectral estimates. Although data have been obtained for the unique case of self-associates, the most interesting and illuminating data for the highly polar H-complexes of small molecules in different environments have not been obtained.

VI. Summary

Thus the analysis of published data has shown that the variety of theoretical and experimental approaches to the solution of the problem of the influence of the medium on acid–base equilibria not only reveals definite qualitative regularities but also makes it possible to take quantitative account of the influence of specific solvation. Considerable progress in the understanding of the role of hydrogen bonds can be expected from the study of ionic dimers and clusters in the gas phase and in relatively inert media. Further studies of the solvation of neutral H-complexes are required; it may be hoped

that the observed similarity in the influence of solvation on hydrogen bonds and acid–base equilibria will be described quantitatively. Important information on the role of the medium will be provided by a more extensive combination of quantum-chemical calculations for dimers and small clusters with the methods of molecular dynamics and Monte Carlo methods, which make it possible to take account of the contribution of hundreds of solvent molecules.

An important direction of future studies will probably be the development of a single approach to charged and neutral associates. The "complementary nature" of the information makes their comparison difficult; for ion–molecule complexes, a large amount of data has been obtained on their energy of formation, whereas for neutral complexes, a large amount of data has been obtained on their structure and spectral properties.

The task of research workers in physical organic chemistry and various branches of spectroscopy should be to build bridges between acid–base equilibria in the gas phase, molecular and ionic hydrogen bonds, and their solvation in different media.

While the present manuscript was being prepared for publication, a number of new papers which must be included were published.

Data on the energy of anionic H-complexes (O^-, Cl^-, N^-, S^-)[118] and complexes of carbanions,[119] and on their hydration in the gas phase, have been published. Two papers[120,121] have been devoted to the application of previously examined approaches to biological systems (proteins and enzymes). Finally, an experimental and theoretical study of the gas-phase CH-acidity in aromatic and heterocyclic compounds has been carried out.[122]

A linear relationship has been established[123] between the proton and carbon basic strength ($CH_3A \rightarrow CH_3^+ + A^-$) in the gas phase. The observed deviations in an aqueous medium have been analysed. Experimental methods and statistical thermodynamic calculations have been used to study isotopic effects in the hydration of gas-phase ions, and it has been concluded that "light" water coordinates preferentially to both cations and anions.[124] Data have been published[125] on the acidity of a number of radical-cations in the gas phase and in DMSO, and the influence of solvation on the $pK_{HA}^{+\cdot}$ values has been discussed. A method has been proposed[126] for the theoretical calculation of pK_a for organic compounds in water by a combination of non-empirical and Monte Carlo calculations.

Without attempting to list the large number of gaseous complexes for which new studies have been carried out, the development of spectra studies may be noted. These are being extended to multimers (clusters) and in particular to linear homo- and hetero-trimers,[127] where the cooperative effects of two "conjugated" H-bonds A–H...A–H...A–H have been observed. The isomerism of the structure of molecular complexes, that is the two minima of the potential energy of the relative orientation of the partners AH and B, has been more effectively studied. For example, in addition to the T-shaped complex $HCN.CO_2$ with an N...C bond, the less stable complex NCH...OCO has been observed (see the paper by Klots and co-workers[128] and references therein).

In an analysis of accurate spectral data on interatomic distances, Legon and Millen[129] revealed the "course" of the isotopic effect in the H-bond. The replacement of H by D decreases the zero-point amplitudes of hydrogen, both tranverse and longitudinal; the first increases, and the second decreases, the strength of the H-bond (as in the excitation of the vibrations ν_B and ν_S). With increase in the strength of the H-bond, the first contribution, which changes in the same sense as the "flexibility" of the H-bond, decreases, whereas the second, which changes in the same sense as the anharmonicity of ν_S, increases. Thus the overall isotopic effect may change sign: the deuterium bond is stronger than the proton bond for weak H-bonds, but is weaker in the case of strong H-bonds.

The new far infrared laser spectroscopy has demonstrated its promising possibilities in the interpretation of the complex rotational–tunnel spectrum of the water dimer.[130] As a result of the observation of the ν_B vibrations, it is also applicable in principle to cyclic non-dipolar (so that there is no rotational spectrum) associates—dimers and multimers $(AH)_n$.

Enantioselective effects in coordination compounds

A A Kurganov, T M Ponomareva, V A Davankov
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The information that has appeared during the last 15 years relating to enantioselectivity in the formation and reactions of kinetically inert and kinetically labile complexes is classified in the present review. Attention is mainly given to chiral discrimination of ligands that are exchanged in the internal or external coordination spheres of the complexes. The occurrence of enantioselective effects has also been recorded in reactions of coordination compounds that occur without ligand exchange, in particular, in photochemical processes. The variety of forms in which enantioselectivity is displayed is shown and methods for studying it are described.

The bibliography includes 223 references.

I. Introduction

Enantioselective effects may be encountered in very different regions of chemistry and biochemistry. These are the enantioselective effect of enzymes on racemic substrates, the enantioselective polymerisation of chiral monomers, photochemical processes involving circularly polarised light, etc. The variety of areas in which the reactions of enantiomers have been studied has resulted in the fact that up to the present time no single stereochemical terminology on selective and specific processes has developed. This literature review contains material that is selected in accordance with that definition of enantioselectivity which we gave in our first review[2] devoted to this subject—processes in which one out of the two enantiomeres present in a system is mainly involved are enantioselective. This type of discrimination can naturally only occur in a reaction with a particular chiral reagent (discriminator, selector), so in the general case enantioselectivity is the difference in the reaction of two enantiomeres with some third chiral structure.[1,2]

II. Enantioselective effects that accompany ligand exchange in the internal coordination sphere of kinetically inert complexes

Enantioselective processes that accompany ligand exchange in the internal coordination sphere of kinetically inert complexes were some of the first to be found in coordination chemistry. The most intensive studies of these processes were carried out at the end of the 1960's and the beginning of the 1970's. Enantioselectivity in kinetically inert systems may be both kinetic and thermodynamic in nature and in many cases it is no easy task to separate the contributions of these effects. It is assumed that a state of equilibrium between possible isomers of an inert complex is catalysed by the addition of active carbon, and this method is frequently used to achieve "thermodynamic" enantioselectivity.

Tatechata[3] studied the formation of $[Co(phen)_2(S\text{-aa})]^{2+}$ complexes (phen = phenanthroline, aa = amino-acid) from racemic Δ,Λ-*cis*-$[Co(phen)_2Cl_2]^+$ and *S*-amino acids (Ala, Leu, Ile, Val, and Phe were studied). The resulting diastereomeric complexes were separated by chromatography on Sephadex. The ratio of their Δ- and Λ-isomers was determined. The Λ-isomer was mainly formed in the systems studied, and the enantioselectivity increases significantly with an increase in branching of the α-substituent of the amino acid. Having studied the ^1H NMR spectra of the complexes, Tatechata[3] established that the amino acid in $[Co(phen)_2(S\text{-aa})]^{2+}$ has an equatorial configuration of the α-alkyl substituent. Enantioselectivity occurs as a result of the different degree of nonbonded interactions between the α-alkyl group of the amino acid and the aromatic ligands in Δ- and Λ-structures.

In a series of studies Vagg and Williams[4–11] studied similar reactions for racemic ruthenium complexes Δ,Λ-$[Ru(phen)_2Cl_2]$ or Δ,Λ-$[Ru(bipy)_2Cl_2]$, where bipy = bipyridyl, and since the reaction was carried out using excess *S*-amino acid, no enantioselectivity was found. However, the authors subsequently determined the equilibrium constants for isomerisation of the form:

$$\Delta\text{-}[Ru(am)_2(S\text{-aa})]^+ \rightleftarrows \Lambda\text{-}[Ru(am)_2(S\text{-aa})]^+,$$

where am = bipy or phen. The constants proved to be different from unity. The Λ-diastereomer is more stable for *S*-Phe, *S*-Tyr, *S*-His, and *S*-Pro.[5] At first glance these results do not have any bearing on enantioselectivity. But it follows from them that if the authors had used an insufficient quantity of *S*-amino acid, the Λ-isomer of the initial racemic complex would have mainly undergone reaction with *S*-Trp, *S*-Phe, *S*-Tyr, *S*-His, and *S*-Pro in reaching thermodynamic equilibrium. The reverse pattern would have occurred with *S*-Glu, *S*-Ala, and *S*-Ser.

In a series of studies by Yoshikawa et al.[12–17] the enantioselectivity and enantiospecificity of processes involving the formation of cobalt tetramine complexes was investigated. The coordination of tetramines is stereospecific and the *cis*-β-isomer is

mainly formed, its absolute configuration being clearly (100% enantiospecificity) determined by the optical configuration of the tetramine. For those tetramines studied—3(*S*),8(*S*)-Me_2-trien, 5(*R*)-Me-trien, 2(*S*),10(*S*)-Me_2-trien, 3(*S*),9(*S*)-Me_2-trien, and 1(*R*),2(*R*)-baetchxn, where trien = 1,4,7-triazaheptane, baetchxn = *N*,*N*′-bis(β-aminoethyl)diaminocyclohexane—the optical configuration of the cobalt complex was found to be Λ.[13,14] When this complex coordinates an amino acid molecule on to the two remaining free coordination sites to form $[Co(am)(aa)]^{2+}$, the coordination is again stereospecific with the Λ-β_2-structure mainly formed.

When the amino acid has an *N*-alkyl substituent (*N*-Me-Ala was the most widely studied), with such an amino acid fragment there will be two asymmetric centres in the complex—the carbon atom with a configuration that is determined by the configuration of the amino acid and the nitrogen atom which becomes asymmetric on coordinating. For most of the systems studied coordination of the nitrogen atom of an *R*-amino acid is not enantiospecific and the corresponding diastereomers are in equilibrium (which is rapidly established even at pH 7) in equal quantities. Only in the case of 3(*S*),8(*S*)-Me_2-trien and *N*-Me-Ala is there a ratio of 3:1 for diastereomers with *R*- and *S*-configurations of the N atoms. On the other hand, in complexes with *S*-amino acids the coordination of the N atom is 100% enantiospecific and only the *R*-diastereomer is formed. It was also shown that the ratio of diastereomers (on the nitrogen atom) is independent of the pH of the medium since equilibrium is reached even in neutral solution.[16]

At the same time, racemisation of the asymmetric carbon centre of the amino acid residue occurs in alkaline solution, resulting in the equilibrium:

$$\Lambda\text{-}\beta_2\text{-}[Co(am)(S\text{-}aa)]^{2+} \rightleftarrows \Delta\text{-}\beta_2\text{-}[Co(am)(R\text{-}aa)]^{2+},$$

where *R* and *S* denote the configuration of the C atom of the amino acid. Yamaguchi et al.[17] determined the ratio of the respective diastereomers in the equilibrium solution. These results, just as the results for the Ru complexes reported above, characterise not only the enantiospecificity of the complex formation process but also the enantioselectivity of the reaction:

$$\Lambda\text{-}\beta_2\text{-}[Co(am)]^{3+} + R,S\text{-aa} \rightleftarrows \Lambda\text{-}\beta_2\text{-}[Co(am)(R\text{- or }S\text{-aa})]^{2+}.$$

The enantioselectivity of this reaction depends both on the type of amine and on the structure of the amino acid. The introduction of an *N*-alkyl substituent has a particularly marked influence as does the ability of the α-alkyl substituent of the amino acid to form hydrogen bonds with the nitrogen atoms of the tetramine. The authors consider that the reason for enantioselectivity occurring lies in the difference between nonbonded interactions of both an interligand and intraligand type in the diastereomers. Conformational calculations were carried out in order to determine the most stable conformations of some complexes.[15] According to these calculations, $\{Co[2(S),10(S)\text{-}Me_2\text{-}tet]_2(R\text{-}Ala)\}^{2+}$, where tet = 1,4,7,10-tetraazadecane, is no different in energy from $\{Co[2(S),10(S)\text{-}Me_2\text{-}tet](S\text{-}Ala)\}^{2+}$, but $[Co(S,S\text{-}pyht)(S\text{-}Ala)]^{2+}$, where pyht = 1,7-bis(2-pyrrolidyl)-2,6-diazaheptane, is 3.15 kJ mol^{-1} more stable than $[Co(S,S\text{-}pyht)(R\text{-}Ala)]^{+}$. The latter value is quite close to the difference between the energies of the diastereomers (3.95 kJ mol^{-1}) found experimentally. At the same time, a value of 1.72 kJ mol^{-1} in favour of the diastereomer with (*S*)-Ala was found experimentally for the first system.

Yamaguchi et al.[16] subsequently carried out a more detailed conformational analysis of $[Co(am)(R\text{- or }S\text{-}N\text{-Me-Ala})]^{2+}$ complexes that took into account the contribution from the asymmetric nitrogen atom, and they obtained values for the conformational energy that agreed quite well with the experimental values. This is an indication of the correctness of the chosen model, from which it follows that the main contribution to enantioselectivity in this system is made up by distortions of the torsion and bond angles resulting from nonbonded interligand interactions. The system studied by Yoshikawa et al.[12–17] displays quite a small difference in conformational strain energies for two comparable diastereomers.

In a similar manner Brubaker and Massura,[18] by minimising the energy of nonbonded interactions in cobalt complexes with *N*,*N*′-bis(2-picolyl)-1,2-(*S*)-propylenediamine and alanine enantiomers, found that the difference in conformational strain energies between the two diastereomers was 2.5–3.5 kJ mol^{-1}, and they managed to detect both diastereomeric forms of the complex in an equilibrium solution.

The search for highly selective systems constitutes one of the areas of research on the stereochemistry of coordination compounds. A group of Japanese research workers led by Fujii[19–26] has had considerable success in this field. The authors studied heteroligand complexes of cobalt with Schiff bases and amino acids such as [Co(SB)(aa)], where SB = bis(salicylideneamino)ethylene (sal_2en) and its methyl derivative (Me-sal_2en) or bis(2-hydroxynaphthylideneamino)ethylene ($bsal_2en$). These Schiff bases coordinate stereospecifically with a Co atom to form exclusively the *cis*-β_2-structure.[19] Subsequent reaction of $[Co(sal_2en)]^{+}$ or $[Co(Me\text{-}sal_2en)]^{+}$ complexes with an *S*-amino acid (the reaction is carried out until thermodynamic equilibrium is reached) results in the formation of two diastereomers in unequal proportions; the ratio varies from 1.5:1 for *S*-Ala to 17:1 for *S*-Trp in favour of the $(-)_{435}$-diastereomer.[20] Correctly assuming that if racemic amino acid and optically active complex were reacted separation of the racemate could be achieved, Fujii et al.[21,22] used the enantiospecific coordinating ligand (1*S*,2*S*)-*N*,*N*′-1,2-cyclohexane-bis(salicylideneamine) (sal_2chxn), which forms complexes exclusively with a Λ-β_2-structure, in this reaction. In this case they achieved the following degree of enantiomeric enrichment remaining in the excess amino acid: Ala 6–8% (*R*), Leu 6–8% (*R*), Met 6–8% (*R*), Ser 10–12% (*R*), Thr 27–30% (*R*), Asp 16–18% (*R*), Glu 6–8% (*R*), Phe 39–41% (*R*), Trp 41–43% (*R*), Pro 48–50% (*S*). The results obtained agree quite well with the data from the determination of thermodynamic enantioselectivity in the same complexes in dimethylformamide:water (1:4) solution,[23] where the structure containing the *S*-enantiomer of the amino acid (Ala, Val, Leu, Phe, Trp were studied) proved to be the most stable. Thus, the Λ-complex preferentially contained an *S*-amino acid. Only proline, whose *R*-enantiomer proved more active, constituted an exception.

In this connection the [Co(Me-sal_2en)(*S*-Pro)] system was studied in greater detail.[24] It was found that when starting from *S*-proline and $[Co(Me\text{-}sal_2en)]^{+}$ the less stable diastereomer, which has a negative rotation at 435 nm, is initially formed, but subsequently it is slowly converted to the $(+)_{435}$-diastereomer. The rate constant of isomerisation *k* is equal to 7.95×10^{-5} s^{-1},[24] and according to the ^1H NMR spectra, only one isomer is present in the final solution. A similar transformation was subsequently also found for [Co(Me-sal_2en)(*S*-Hyp)] and [Co(Me-sal_2en)(*S*-*a*-Hyp)]. The degree of kinetic enantioselectivity, determined from the ratio of diastereomers $(-)_{435}$:$(+)_{435}$ at the initial moment in time, was lower in these complexes (56% for *S*-Hyp and 23% for *S*-*a*-Hyp) than for proline (87%).[25] However, in this case, just as for proline, a gradual conversion to the more stable $(+)_{435}$-diastereomer occurs.

Fujii et al.[26] subsequently succeeded in finding a system in which kinetic enantioselectivity occurs for other amino acids, in particular for valine and isoleucine. $[Co(bsal_2en)]^+$ complexes had this property. A considerable effect from the solvent on the ratio of diastereomeric structures in solution was reported.

The *N*-alkyl substituent in the amino acid residue of the complex has a very considerable effect on the degree of enantioselectivity. Thus, if the complex $[Co(Me\text{-}sal_2en)]^+$ is reacted not with *S*-alanine (ratio $\Lambda/\Delta \approx 2$) but with its *N*-methyl derivative, the content of Λ-isomer in the equilibrium mixture is as high as 93% while for the *N*-benzyl derivative it is 100%.[19] Correspondingly, if Λ-*cis*-β_2[Co(*S*,*S*-sal$_2$chxn)]$^+$ is used, racemic *N*-benzylalanine reacts with almost 100% enantioselectivity, leaving the *R*-enantiomer unreacted. The ratio of the resulting complexes for the system [Co(Me-sal$_2$en)(*R*- or *S*-*N*-Bzl-Ala)] was used to establish the following relative stability of diastereomeric complexes (configuration of the complex, configuration of the N atom in the amino acid molecule, and configuration of the amino acid are given): $\Lambda(S,S) = 19.5$; $\Delta(R,S) = 11.3$; $\Delta(S,S) = 8.2$; $\Lambda(R,S) = 0$ kJ mol^{-1}. This corresponds to the following ratio of $\Delta(R,S):\Delta(S,S)$ diastereomers at equilibrium of 96.5 : 3.5.[11] For comparison we can indicate that for the {Co[3(*S*),8(*S*)-Me$_2$-trien](*N*-Me-Ala)}$^{2+}$ system reported above the three complexes $\Lambda(R,S)$, $\Delta(S,S)$ and $\Delta(R,S)$ are in equilibrium in the ratio 60 : 20 : 20, which corresponds to a considerably lower selectivity for the system.

The high enantioselectivity for formation of complexes based on quadrivalent Schiff bases was also confirmed by Okawa,[27] who synthesised complexes of cobalt with Schiff bases obtained from 1,2-diaminopropane or *trans*-1,2-diaminocyclohexane and 1(*S*)-menthyloxy-3-benzeneacetone. If a Schiff base obtained from a racemic diamine is reacted, there is the sole formation of the Λ-*cis*-β_1-structure of the complex, containing only *R*-propylidenediamine or *S*-cyclohexanediamine residues.

The enantioselectivity found in complexes of cobalt with trimethylene-bis(pyrrolidine-2-carboxylic acid) is just as high.[28] This ligand coordinates enantiospecifically and stereospecifically, giving an asymmetric Λ-structure. Subsequent reaction of this complex with *R*,*S*-proline or *R*,*S*-pipecolinic acid results in the formation of a heteroligand complex that contains only the *R*-enantiomers of the amino acids.

The majority of the studies described above had octahedral complexes of trivalent cobalt as the subject of their research; these complexes were and remain a favourite topic in stereochemical studies. At the same time other kinetically inert complexes, and particularly other coordination polyhedra, in relation to enantioselectivity remain almost unstudied. There is no doubt that the study by Payne and Stephan[29,30] on square planar platinum complexes proved very interesting in this respect. Complexes with this type of stereochemistry were regarded as unfavourable subjects for the study of enantioselectivity. Since the ligands in these structures are situated at a considerably greater distance from each other compared to octahedral complexes, the occurrence of interligand interactions — the basis of enantioselectivity — seemed improbable. However, this study disproved these predictions. Platinum complexes that contained a chiral diphosphine ligand, methyl group, and chlorine atom reacted with a racemic monoamine or monophosphine to give diastereomers in a ratio which quite frequently differed from 1 : 1, which was an indication of the enantioselective course of the reaction.

Equally, Shinoda et al.[31] found that for the reaction of *trans*-{Pt(Cl$_2$)(SR$_2$)[(*R*,*S*)-Val-OMe]} with *R*- or *S*-phenylethylamine there were quite noticeable differences in the equilibrium constants, which indicate the preferential replacement by phenylethylamine of the amino acid ligand belonging to a configurational series opposite to that of the amine itself.

Studies on enantioselectivity in reactions of organometallic compounds should also be mentioned. Although research into the preparation of diastereomeric organometallic compounds was started a long time ago (see, for example, the study by Brunner[32] and the references in it), the question of the ratio of concentrations of the resulting diastereomers or the ratio of their rates of formation has generally not been raised. In the studies of Kane-Maguire et al.[33–35] it was shown that $[Fe(CO)_3(1\text{-}5\eta\text{-}2\text{-}MeOC_6H_6)]^+$ reacts with optically active phosphines[33,34] or phenylethylamine,[35] exhibiting both kinetic and thermodynamic enantioselectivity. Pearson and Yoon[36] reported that the reaction of iron dienyl complexes of the type $(\eta^4\text{-COD})Fe(CO)_2[P(OEt)_3]$ with optically active enolates stabilised with sulphoximine is enantioselective (about 50% enrichment) and may be used to obtain an organometallic derivative in an optically active form. They noted a considerable effect of the nature of the enolate cation on the degree of enantioselectivity (Li exhibits a considerably lower enantioselectivity than K).[36] A system in which the enantioselectivity is close to 100% is described in a study by Tsyryapkin et al.[37] The reaction of racemic $[Mn(CO)_3(\eta^5\text{-}1\text{-}N\text{-}Me_2\text{-}2\text{-}CHO\text{-}C_5H_3)]$ with optically active dipeptides in the presence of Cu^{2+} ions takes place in such a manner that only the $(-)_{435}$-enantiomer of the complex forms a Schiff base, while the $(+)_{435}$-isomer remains unreacted and can be isolated by extraction from the reaction mixture. Subsequent study of this reaction showed that the enantioselectivity depends to a considerable degree on the structure of the dipeptide.[47] Thus for Gly-(*S*)-Ala the ratio of diastereomeric complexes is 41 : 1 but for (*S*)-Ala-Gly or (*S*)-Val-Gly it is close to the statistical average.

It was found quite unexpectedly that organometallic compounds can act as substrates for enzyme reactions.[39] Although the enantioselectivity of the hydrolysis of (2-ethoxycarbonylbuta-1,3-diene)iron tricarbonyl with pig liver esterase was not so high (an optical purity of about 85% for the acid isolated), with a subsequent single-stage crystallisation a product with an optical purity of >98% could be obtained.

III. Enantioselective effects that accompany ligand exchange in the internal coordination sphere of kinetically labile complexes

In contrast to kinetically inert complexes with an octahedral structure, kinetically labile complexes did not originally attract a great deal of attention from research workers. The two main reasons for this situation may be stated here. Firstly, the majority of kinetically labile complexes have a square planar or tetrahedral structure of the coordination polyhedron which were not considered conducive for the display of enantiomeric effects. Secondly, in contrast to kinetically inert complexes, where each diastereomer can be isolated and characterised in a pure state, with kinetically labile complexes the researcher is compelled to work with an equilibrium mixture of all possible forms, whose individual properties can only be obtained by calculation. This naturally complicates the investigation.

The increased interest in this class of coordination compounds is due to the development of ligand-exchange chromatography,[1] which is based on the use of enantioselective effects in labile systems.

Even in the initial studies carried out by Davankov et al.[2] relating to the simulation of processes in ligand-exchange chromatography, considerable enantioselective effects were found in square planar complexes of Cu^{2+} with bidentate *N*-alkyl-α-amino acid ligands.[2] These investigations were subsequently extended in studies by other scientists.

Ritsma[40] studied bis-complexes of bivalent Co, Ni, Cu, and Zn with *N*-(*o*-hydroxybenzyl)alanine. From his results it is clear that the addition of a second ligand (chiral amino acid) to the metal is enantioselective. In the case of Co and Ni the formation of structures that contained ligands of the same optical configuration proved more favourable. Ritsma accounts for the occurrence of enantioselectivity by the fact that Co and Ni ions form octahedral complexes. On the other hand, in Cu complexes (square planar configuration) or Zn (tetrahedral configuration) there was no enantioselectivity. The difference between the stability constants of log 0.3 reflects only a statistical preference for the *meso* structure compared with an equal-paired one.

Ritsma subsequently studied[41] a further series of tridentate amino acid ligands: histidine, α-*N*-methylhistidine, α-*N*,*N*-dimethylhistidine, α-*N*-benzylhistidine, aspartic acid, glutamic acid, and their complexes with Co(II), Ni(II), Cu(II), and Zn(II) ions. In this case enantioselectivity was found not only for octahedral Co(II) and Ni(II) complexes but also for some Cu(II) and Zn(II) complexes. Moreover, as detailed studies of copper complexes showed,[40] enantioselectivity depends to a considerable extent on whether the amino group of histidine is protonated or not; protonation causes a change in enantioselectivity so that the formation of an equal-paired structure is preferred.

These results were subsequently confirmed by Pettit et al.[42] In a potentiometric study of the stability of complexes of Co(II), Zn(II), Ni(II), Pb(II), and VO(II) with histidine in unprotonated complexes, enantioselectivity was only found for Co, Ni and Zn, but in monoprotonated complexes it also occurred for Cu.

The study of histidines was extended by Pettit[43] to imidazolyl-substituted derivatives. In the ternary complexes M(*N*-imidazolyl-substituted histidine)(*R*- or *S*-histidine), the formation of M(*R*)(*S'*) complexes was more favourable for Ni and Zn. For Cu there was no enantioselectivity in the unprotonated complex while in the monoprotonated complex formation of an M(*R*)(*R'*) structure was more favourable.

However, in studies on ternary complexes containing histidine (or its *N*-substituted derivative) and bidentate amino acid ligands, results were obtained that differed from those described above. In this case selectivity occurred as a rule in unprotonated complexes but in protonated complexes it was absent.[44–46] Moreover, substituents in the imidazole ring affected the degree of enantioselectivity much less than did substituents on the α-amino group. An even more unexpected result was that there was no enantioselectivity in the analogous Ni(II) complexes.[45] It was also not found in heteroligand complexes of copper with histidine when the second amino acid ligand was threonine, serine, proline, or methionine.[46]

In order to elucidate the mechanism of enantioselectivity, Pettit et al.[45,47,48] undertook a potentiometric study of ternary complexes of bidentate amino acids. In most of the systems studied the enantioselectivity was insignificant or absent but for the system Cu–proline–tryptophan the Cu(*S*)(*S'*) structure proved more stable than the Cu(*R*)(*R'*) complex by a factor of log 0.26.[45]

For complexes of Cu with serine and threonine there is very little difference between the stability constants of the diastereomeric structures but, on the other hand, there is a distinct difference in the enthalpy of formation of these structures, as determined by calorimetry.[47] The Cu(*R*)(*R'*) structure was preferred. However, its enthalpy advantage is completely balanced by the entropy contribution, so the free energies of formation of *meso* and equal-paired structures become the same. A similar ratio of enthalpy and entropy contributions in the formation of *meso* and equal-paired structures of the complexes was also found in the system Cu-*N*-benzylproline.[49] But there was not a complete balance of the contributions in this system and as a result of the predominance of the entropy contribution, the formation of a *meso* structure was preferred. At the same time, in a complex of Ni(II) with methionine both the enthalpy and entropy contributions favour the formation of a *meso* structure; it proves to be 2.72 kJ mol^{-1} more stable than the equal-paired structure.[48]

With an improvement in the process for calculating the stability constants of complexes and methods for studying equilibrium systems, research workers have repeatedly directed their attention to complexes of copper(II) with bifunctional α-amino acid ligands, trying to find enantioselectivity in this most simple system. Thus, Olin et al.[50–52] again studied the formation of complexes with optically active and racemic ligands for the following α-amino acids: valine,[50] proline, serine, threonine, tryosine,[51] and aspartic acid.[52] In the majority of the systems, according to the findings of earlier studies,[2] enantioselectivity was not found, but for valine and tyrosine complexes it was possible to detect slight enantioselectivity. In the case of valine the equal-paired structure was preferred (log β_2^{RR} = 14.698, log β_2^{SS} = 14.699, log β_2^{RS} = 14.690), while in the case of tyrosine the meso structure was preferred (log β_2^{RR} = 14.355, log β_2^{RS} = 14.360). However, the differences occurring in this case probably lie within the limits of experimental error for determination of the constants.

Enantioselectivity was recorded with much greater reliability in a study of heteroligand complexes of proline with a number of other bidentate amino acid ligands,[53] where formation of a Cu(*S*)(*S'*) structure proved to be more favourable. As was mentioned above,[45] enantioselectivity of the same sign was also found in a complex of copper(II) with proline and tryptophan, so that this effect can be regarded as typical in proline complexes. From this point of view, and this was stressed by Olin et al.,[53] it is surprising that there is no enantioselectivity in the homoligand bis-complex of proline with Cu(II).

Sakurai et al.[54–56] tried to detect enantioselectivity in copper complexes that contained amino acids with functional groups carrying different electrical charges or forming hydrogen bonds between themselves. It was suggested that in one of the diastereomeric structures of the complex, interactions between the functional groups will occur more readily than in the other. The systems copper(II)–(aspartic acid or glutamic acid)–(lysine, ornithine, or asparagine),[54] copper(II)–(histidine)–(asparagine, homoserine, glutamine, citrulline, serine, threonine, alanine, or valine)[55,56] were studied, but enantioselectivity was not found at all. The resolution of the amino acid enantiomers that occurs on crystallisation of the ternary complexes[57–59] is probably due to the enantioselectivity of the process for crystallising diastereomeric salts, which has been known since the time of Pasteur.

It should be mentioned that in other studies[60,61] enantioselectivity was in fact found in a system of ternary complexes containing histidine and an amino acid ligand. For diaminocarbonyl ligands the formation of complexes containing ligands of a single

configurational series was more favourable,[60] while for a Zn(histidine)(threonine) complex the Zn(*S*-His)(*R*-Thr) form was more stable.[61]

Angelici et al.[62] studied enantioselectivity in complexes of Co(II), Ni(II), Cu(II), and Zn(II) with β-(2-pyridyl)-α-alanine and β-(6-methyl-2-pyridyl)-α-alanine, regarding them as analogues of the histidine ligand. They found that for Co(II), Ni(II), and Zn(II) the formation of *meso* structures was more favourable (difference in stability constants of the diastereomers reaches almost log 1), while for Cu, as in the case of histidine, there is no enantioselectivity. The authors also showed that introduction of a methyl substituent into the pyridine part of the ligand molecule reduces the difference in stability between the diastereomeric forms of the complexes. They attribute this effect to the reduction in coordinating ability of the 6-methyl-substituted pyridine compared to the unsubstituted ligand.

No appreciable selectivity was found either in the formation of heteroligand complexes of copper(II) with *N*-carboxymethyl-β-(2-pyridyl)-*S*-α-alanine and valine. On the other hand, in ternary complexes of nickel with the pyridyl ligand, noticeable differences in the stability of diastereomers occurred for a whole series of amino acids (ratio of log K_2^{RS} to log K_2^{SS} was 0.25:1 for Ala, 0.21:1 for Ser, 0.56:1 for Val, and 0.26:1 for Phe).[63] The different behaviour of the copper and nickel complexes was attributed to the different structure of the coordination polyhedron in these metals — square planar in Cu(II) and octahedral in Ni(II).

Enantioselective formation of complexes often has an effect on the course of processes that take place in coordination compounds. Kitagawa et al.[64] described nickel complexes with 1,2-bis[2(*S*)-2-aminomethyl-1-pyrrolidinyl]ethane and its *N*-methyl-derivative that had the ability to catalyse enantioselectively the hydrolysis of α-amino acid methyl esters. At the same time these complexes were able to coordinate enantioselectively amino acid ligands, where in the case of the unsubstituted ligand *R*-enantiomers of alanine and valine were more strongly bonded while in the case of the *N*-methyl derivative it was the *S*-enantiomers of these amino acids and also proline that were more strongly bonded.[64,65] Kitagawa et al.[64,65] noted that there is a direct correlation between the enantioselectivity of the amino acid ligand coordination and the enantioselectivity for hydrolysis of their methyl esters. A similar mechanism for enantioselectivity also occurred for a copper complex of 2-[hexadecyl-*N*,*N*-(2-hydroxypropyl)aminomethyl]pyridine.[66] Micelles formed by this complex were used as a catalyst for the hydrolysis of *p*-nitrophenyl esters of amino acids. The authors maintain that by using micelles they were able to achieve a more than tenfold difference in the rates of hydrolysis of the enantiomers.

In a number of studies[1,67–86,90–95] investigation of enantioselective effects was carried out directly in conjunction with ligand-exchange chromatography. The authors tried to establish a relationship between the degree of enantioselectivity in forming model complexes in solution and the exit order of enantiomers in ligand-exchange chromatography of corresponding racemates on a chiral sorbent. Such studies were first carried out by Davankov et al.[1] in the case of copper complexes of *N*-benzylproline which simulated the coordination compounds formed in the sorbent phase that was obtained from a chloromethylated polystyrene matrix and proline. Subsequently Kurganov et al.[67–73] studied a large number of homo- and hetero-ligand coordination compounds of copper with α-amino acid,[67–70] 1,2-diamine,[71,72] and 1,3-dicarbonyl[73] types of ligands and demonstrated that enantioselectivity occurs in a number of systems. This included the detection of enantioselectivity for the first time in complexes containing diamine ligands.

Considerable attention was given in the studies of Kurganov et al.[67–83] to the mechanism for the occurrence of enantioselectivity. With this purpose the circular dichroism spectra of these coordination systems were studied in detail,[67,73–80] the molecular structures of a number of model complexes were established,[81,82] and a conformational analysis of complexes of copper with alanine and its *N*-methyl derivative was carried out.[83] It follows from conformational calculations[83] that in equilibrium solution as methyl derivatives are introduced on to the nitrogen atom in the ligand molecule the proportion of complexes with a *trans*-structure of the chelate bonding increases and the proportion of *cis*-structures decreases; so for *N*,*N*-dimethylalanine the latter can be ignored. At the same time the difference in conformational energy between the respective diastereomeric forms of the complexes increases in favour of the structure that contains ligands of a single configurational series. These results are in good agreement with the data of crystallographic studies in which both *trans*- and *cis*-structures were found for unsubstituted ligands (amino acids or diamines) but for *N*-alkyl derivatives all of the structures studied were of the *trans* type.[81,82] At the same time, calculated results should be supplemented with data on the entropy component of free energy since, as was mentioned above, the enthalpy (one of the components of which is the conformational energy) and entropy often provide opposing contributions to the total enantioselective effect.

Similar calculations were carried out by Simeon et al.[84–86] for a wide range of conformers of copper(II) complexes with *N*,*N*-dimethylvaline or *N*,*N*-dimethylleucine (only the *trans*-structure of the chelate bonding was considered). According to their results each chelate ring (for example, *N*,*N*-dimethylvaline) has six local minima of conformational energy, one of which lies considerably apart ($\approx$10 kJ mol^{-1}) from all the others (this conformation is similar to that used in calculations on *N*,*N*-dimethylalanine complexes[83]). If the chelate rings are considered to be independent, a copper bis-complex of this ligand can exist in the form of 21 conformers, from which only three display noticeable enantioselectivity, all three containing the above-mentioned minimum-energy conformation at least for one of the chelate rings. The maximum enantioselectivity occurs for conformers in which both rings are in this favourable conformation. However, while for a complex containing *R*,*S*-ligands 98% of the conformers belong to this type, in complexes with *R*,*R*-ligands only 70% of the complexes have such a conformation since the conformational range is substantially greater in them than in complexes with *R*,*S*-ligands. This slightly reduces the enantioselectivity for the preferred formation of a *meso* structure.

From a detailed analysis of the structure of complexes and equilibria occurring in solution, it was later possible for Davankov et al.[87] to formulate a number of general rules for enantioselectivity to occur in square planar complexes with bidentate organic ligands. At the same time there was shown to be no clear correlation between the enantioselectivity of complex formation in solution and the enantioselectivity for separation of enantiomers by ligand-exchange chromatography in related systems. The reason for this proved to be that interactions between the complexes and the achiral stationary chromatographic phase play an active role in determining the enantioselectivity of chromatographic separation.[88] This follows from such an obvious example as the reversal in sign of enantioselectivity of the chromatographic system containing the same

chiral resolving agent and enantiomers being separated by simply changing the type of achiral stationary phase.[88] Moreover, it transpired that chromatographic separation of enantiomers is only possible when the enantioselectivity for the formation of complexes with a chiral selector in solution and on the surface of the stationary phase are different in magnitude (or even better, different in sign).[89]

In more recent studies[90–95] it was suggested that there must be a correlation between the enantioselectivity of formation of model complexes in solution and the enantioselectivity of a chromatographic system. Thus, Tsuchida et al.[90] compared the enantioselectivity of complex formation in the system Cu(II)–(*N*-benzyl-*S*-leucine)–(alanine, valine, or leucine) with the enantiomeric separation of these amino acids on a chiral sorbent obtained by the reaction of *S*-leucine with a chloromethylated copolymer of styrene and divinylbenzene. French research workers[91–95] examined systems of complexes that simulated sorbents, obtained by the reaction of *S*-proline with chloromethylpolystyrene[91,92] or polyacrylamide[93,94] and *S*-phenylalanine with chlorosulphonated polystyrene.[95] In a number of cases qualitative agreement was obtained between the exit order of the enantiomers from the chromatographic column and the enantioselectivity of complex formation in model systems. In the cases where it was absent the authors suspected that the models used were inadequate. In actual fact a model cannot be adequate if it does not transmit the essential adsorptive interactions between the diastereomeric complexes and the achiral surface or matrix of the sorbent.[88,89]

Enantioselectivity in labile complexes with other types of ligands has been studied much less than for amino acid ligands. Pettit and Swash[96] studied the enantioselectivity of complex formation between $[VO]^{2+}$ and tartaric acid ($tartH_2$). They found quite a large number of polynuclear structures in this system, from which a noticeable difference in the stability complexes with racemic and optically active ligands was only found for $[VO]_2(tart)_2(OH)_4$. The structure containing two ligands with opposing optical configurations is more stable.

The same type of relationship of the stabilities of diastereomeric structures of complexes was found for coordination compounds of Cu(II) with tartaric acid.[97] In this case the complex Cu(*l*-tart)(*d*-tart) is approximately twice as stable as the Cu(*l*-tart)$_2$ complex. While enantioselectivity is insignificant for hydroxo complexes present in the system, equal-paired structures are more stable for polynuclear structures with the composition $Cu_2(tart)_2$, the difference in the stability constants being so great (4×10^8 and 0.2×10^8) in an equilibrium solution of a racemic ligand, complexes with the composition Cu_2(*l*-tart)(*d*-tart) are virtually absent (less than 1%).

Petit-Ramel et al.[98] found enantioselectivity in the formation of heteroligand complexes of copper(II) with *N,N'*-dimethyltartramide and mandelic acid. In this case the complex containing *d*-tartaric acid amide and *l*-mandelic acid proved to be more stable (log β_{111} = 17.78). The stability constant of the complex containing *d*-tartaric acid amide and *d*-mandelic acid was lower by a factor of log 0.72.

The reasons for enantioselectivity to occur in these systems, which have a large number of various polynuclear forms, were examined by Tapscott.[99] He wrote a review[100] of the studies on complexes of tartaric acid, in which there is a section devoted to enantioselectivity and a discussion on the thermodynamics of the disproportionation of the complexes $(VO)_2$(*l*-tart)$_2(OH)_4$ and $(VO)_2$(*d*-tart)$_2(OH)_4$ to $(VO)_2$(*l*-tart)(*d*-tart)$(OH)_4$.[101] The enthalpy of this reaction is equal to 1.46 kcal mol^{-1}, which is an indication of the greater stability of the *meso* structure, with a content of not less than 96% in the equilibrium solution, compared to the equal-paired form.

The enantioselectivity of formation of gadolinium and dysprosium complexes with the tartaric acid analogue—α-hydroxysuccinic acid—was studied.[102] The stability constant of the complex with an optically active ligand was less than the stability constant of the complex with racemic hydroxysuccinic acid. Enantioselectivity occurs here in the formation of tris- as well as bis-complexes.

In contrast to α-hydroxysuccinic acid, *O*-phosphoserine did not show any noticeable enantioselectivity in complex formation with Co(II), Ni(II), or Cu(II), but for Zn(II) the equal-paired structure proved more stable than the *meso* structure (by a factor of log 0.28).[103] Enantioselectivity was found[104] in the coordination of histidine with the complex triaqua-tribenzo[*b,f,j*][1.5.9]triazacyclodecylnickel(II). The respective constants for formation of ternary complexes for *S*-His and *R*-His were 7.26 and 7.42. By using this difference in the stability of the heteroligand complexes, Erno and Jordan[104] were able to separate the initial homoligand complex into optical isomers and use it subsequently for the resolution of racemates of a number of other amino acids. However, in the latter case successful resolution is only achieved when two or three recrystallisations of the heteroligand complexes are used, and therefore the question of enantioselectivity occurring in them cannot be regarded as conclusive.

IV. Enantioselective effects in kinetically inert and kinetically labile coordination compounds that accompany outer-sphere ligand exchange

Enantioselective effects of outer-sphere complex formation are known in the chemistry of coordination compounds as the Pfeiffer effect (PE).[105–107] The latter first observed the following phenomenon: there is a change in the angle of rotation of (+)-α-bromocamphor-π-sulphonic acid when it is added to a solution of a racemic $Zn(phen)_3$ complex.[108] With the development of chiro-optical methods for studying PE, circular dichroism spectroscopy started to be used instead of optical rotation measurement.

The first explanation for PE was given by Dwyer,[109] who proposed that in placing a racemic compound in an optically active medium, the equilibrium between the enantiomeric forms is displaced in favour of one of them. He noted at the same time that associates (outer-sphere coordinate compounds) also contribute to PE, those involving enantiomers of the complex and an optically active component of the solution. The resulting associates are no longer enantiomeric but diastereomeric and hence they can have an unequal stability and occur in solution in unequal quantities. Moreover, their molar chiro-optical properties also cannot have the same absolute value.

A further reason for PE was disclosed by Mason,[110] who showed that electronic transitions not only for racemic complexes (i.e., chiral by nature) but also for achiral compounds can be optically active from the effect of a chiral medium. This effect was found by him in the case of the complex $[Co(NH_3)_6]^{3+}$ in a solution of tartaric acid. The extensive occurrence of this phenomenon was subsequently demonstrated.[111–114]

By correlating the results of different authors, Schipper[107,115] proposed two main mechanisms for the occurrence of PE:

associative and nonassociative (inductive). The latter, in essence, is similar to the chiral induction mechanism of Mason. The associative mechanism, according to Schipper, involves three types of equilibria:

$$\Delta\text{-antipode} + S\text{-inductor} \rightleftarrows \Delta\text{-antipode}.S\text{-inductor} \quad (1a)$$
$$\Lambda\text{-antipode} + S\text{-inductor} \rightleftarrows \Lambda\text{-antipode}.S\text{-inductor} \quad (1b)$$
$$\Delta\text{-antipode}.S\text{-inductor} \rightleftarrows \Lambda\text{-antipode}.S\text{-inductor} \quad (2)$$
$$\Delta\text{-antipode} \rightleftarrows \Lambda\text{-antipode} \quad (3)$$

The first of these equilibria represents the formation of diastereomeric associates, while the second and third represent a displacement of the equilibria between associates or enantiomers. All of these equilibria occur simultaneously:

$$\begin{array}{ccc} \Delta + S & \overset{(1a)}{\rightleftarrows} & \Delta\cdot S \\ {\scriptstyle(3)}\downarrow\uparrow & & \downarrow\uparrow{\scriptstyle(3)} \\ \Lambda + S & \overset{(1b)}{\rightleftarrows} & \Lambda\cdot S\,. \end{array}$$

The following equilibrium constants relate to these processes:

$$K^{1a} = \frac{[(\Delta\cdot S)]}{[(\Delta)]\,[(S)]},\quad K^{1b} = \frac{[(\Lambda\cdot S)]}{[(\Lambda)]\,[(S)]},$$
$$K^{2} = \frac{[(\Lambda\cdot S)]}{[(\Delta\cdot S)]},\quad K^{3} = \frac{[\Delta]}{[\Lambda]}.$$

In the case of kinetically labile complexes the equilibria are established rapidly and the observed PE is the total result of all these processes. For kinetically inert complexes the situation is complicated by the slowness in establishing equilibrium and the occurrence of additional kinetic enantioselective effects. On reaching equilibrium, the relationship $K^{1b}/K^{1a} = K^3/K^2$ will be fulfilled for all types of coordination compounds. Thus, PE can be characterised either by the difference in the stability constants of the resulting diastereomeric adducts or by the difference of the epimerisation constant of the resulting adduct from unity (the racemisation constant of the enantiomers). The latter case, according to Dwyer,[109] indicates the shift in chiral equilibrium between enantiomers in an optically active medium.

The occurrence of PE is usually monitored from the change in chiro-optical properties of the system, namely, from the change in angle of rotation or solution ellipticity of the chiral inductor in the presence of a coordination compound. In general, in accordance with the scheme given above, the chiro-optical property of an equilibrium solution can be represented in the following manner:[116]

$$\alpha = \alpha_S[S] + \alpha_\Delta([\Delta] - [\Lambda]) + \alpha_{\Delta\cdot S}[\Delta\cdot S] + \alpha_{\Lambda\cdot S}[\Lambda\cdot S], \quad (4)$$

where α_S, α_Δ, $\alpha_{\Delta\cdot S}$, and $\alpha_{\Lambda\cdot S}$ are the molar characteristics of the chiro-optical properties of the inductor, complex, and adducts respectively.

By analysing equation (4), Ogino and Kumagai[116] came to the conclusion that PE can occur even when there is no redistribution in the concentrations of enantiomers (i.e., $K^{1a} = K^{1b}$) or the chiro-optical properties of the diastereomeric associates appear to be enantiomeric ($\alpha_{\Delta\cdot S} = -\alpha_{\Lambda\cdot S}$). Usually these values differ from each other and the observed PE constitutes the change in chiro-optical properties of the solution both from the change in concentrations of the optically active components already in solution and from the appearance of new ones.

Mason et al.[117] studied PE in a system of racemic complexes $M_3[Cr(ox)_3]$ (ox = oxalate) in optically active esters of α-hydroxy-acids and found that the complex undergoes "antiracemisation" to the extent of 70% whatever the type of M and the configuration of the ester. The effect is completely eliminated by the addition of an equivalent of a crown ether to the solution. Miyoshi et al.[118,119] interpreted PE in a similar manner for $[Co(ox)_2(phen)]^-$ [118] or $[Cr(ox)_3]^{3-}$ and $[Co(phen)_3]^{3+}$ [119] complexes in solutions of quinine, quinidine, cinchonidine, or their derivatives. The same authors studied PE in the case of $[Cr(ox)_2(phen)]^-$ and $[Cr(ox)_2(dipy)]^-$ complexes in the presence of *N*(1)-methyl and 9-acetyl derivatives of the same alkaloids.[120] They showed that the magnitude of the shift of the chiral equilibrium mainly depends on the configuration of the C(8) and C(9) atoms of the alkaloid and that it is greater for acetyl derivatives than for unsubstituted alkaloids. Out of the complexes studied the greatest shift was achieved in $[Co(ox)_2(phen)]^-$ in the presence of 9-acetoxyquinidine (28.3% of enrichment with the Λ-isomer), 9-acetoxyquinine (22.4% of enrichment with the Δ-isomer), and *N*(1)-methyl-9-acetoxyquinine (23.8% of enrichment with the Δ-isomer). The rate constants of racemisation of the Δ- and Λ-isomers of $[Co(ox)_2(phen)]^-$ were also determined in the presence of the same alkaloids, and it was shown that an accumulating isomer in this system had a lower rate of racemisation. Miyoshi et al.[121] demonstrated the possibility of using coordination compounds as a chiral inductor and examined in detail PE for $[Co(ox)_3]^{3-}$ in the presence of optically active *cis*-[M-diamine)$_2$(X)(Y)] complexes, where M = Cr or Co; diamine = ethylenediamine (en) or diethylenetriamine (tr); X, Y = Cl^-, NH_3, NO_2^-, $C_2O_4^{2-}$, and acac. In order to confirm the possibility of a shift in the equilibrium between Δ- and Λ-enantiomers of $[Co(ox)_3]^{3-}$, the authors determined the rate of their racemisation in the presence of $[Co(en)_2(NO_2)_2]$Br enantiomers. Since the rate of racemisation in the Δ−Δ-system proved to be somewhat lower than in the Δ−Λ-system, the authors assumed that in a solution of Δ,Λ-$[Co(ox)_3]^{3-}$ when Δ-$[Co(en)_2(NO_2)_2]$Br is added, Δ-$[Co(ox)_3]^{3+}$ will accumulate. It is evident however that these conclusions are not completely correct. Firstly, while the oxalate complex undergoes racemisation, the chiral inductor will also racemise. Moreover, in many cases equilibrium is established in the system more rapidly than racemisation of $[Co(ox)_3]^{3-}$ takes place even in the presence of the optically active [M(diamine)$_2$(X)(Y)], which is an indication that it is not racemisation that is the rate-determining stage for PE.

A whole series of studies by Japanese authors[122–133] is devoted to the effect of different factors (the ionic strength of the solution, the presence of the organic solvent, the type of optically active inductor) on the magnitude of PE. In several studies[125,126,134–138] data on the structure of the associates formed in solution are given. According to these data, various interactions — ionic, hydrophobic, van der Waals — can cause the formation of adducts.[131] Even when the same charges occur on a complex and inductor it does not exclude the possibility of their association.

In the majority of cases the formation of associates occurs through hydrogen bonding. This conclusion is supported by the results of studying the structure of associates by both indirect methods[125–127,139] and the direct findings of X-ray diffraction analysis.[140–143]

Bosnitch and Watts[144] calculated the thermodynamic parameters of the shift in chiral equilibrium for a $Ni(phen)_3$ complex in (−)-2,3-butanediol: $\Delta H = -119$ cal mol^{-1} and $\Delta S = -0.28$ cal K^{-1} mol^{-1}. They also determined the rate constants of racemisation of (+)- and (−)-$Ni(phen)_3$ in this solvent and detected a difference in the rates of racemisation of the enantiomers which was in good agreement with the magnitude of the shift of the chiral equilibrium in the system (+)-$Ni(phen)_3$ − (−)-2,3-butanediol.

Mayer[145] had previously reported some results for the system (+)-$Ni(phen)_3$ − *L*-Glu that were not in such good agreement; the time of half-racemisation of the complex in this system was 14 h

while the PE equilibrium was reached after only 25 min. In order to overcome this contradiction, Mayer[145] proposed a new mechanism for PE—the mechanism of asymmetric modulation. Gillard et al.[146] suggested that the possibility of hydration of the phenanthroline or dipyridyl ligands (it is complexes of these ligands which are most widely used for studying PE), which results in the formation of new asymmetric sites, should be taken into account.

These studies indicate that in a number of cases PE can include specific processes inherent in individual systems, but these processes should not be regarded as general principles of the PE mechanism, especially as all the contradictions mentioned above can readily be eliminated if the enantioselectivity of association is taken into account.

Barton et al.[147] explain the phenomenon of PE in deoxyribonucleic acid (DNA) with $[Zn(phen)_3]^{2+}$ from these points of view, while Bartery et al.[148] use the same explanation for the change in peroxidase activity of an enzyme in the presence of Fe^{3+} chelates. It was subsequently shown[149] that enantioselective association of DNA also takes place with the $[Ru(phen)_3]^{2+}$ complex, with the right-hand spiral of DNA containing mainly the Δ-isomer of the complex. Yamagishi[150] confirmed these observations in the case of other tris-chelate complexes of transition metals.

It is interesting to note that if a $[Ru(phen)_2Cl_2]$ complex is used instead of $[Ru(phen)_3]^{2+}$ and hence there is a change from outer-sphere complex formation to inner-sphere (Cl ions are replaced), the Λ-structure of $[Ru(phen)_2Cl_2]$ will mainly be contained in the DNA spiral,[151] with one $[Ru(phen)_2]^{2+}$ species for every 11 pairs of nucleic bases. Thus, the enantioselectivity of inner- and outer-sphere coordination in these very similar systems proved to be directly opposite. A review was published by Barton[152] on the studies of enantioselective coordination of DNA with transition metal complexes, and the mechanism of the interaction of DNA with ruthenium complexes is discussed in detail in another study.[153]

Hemmes and Lee[154] studied PE for a complex of $[Zn(phen)_3]^{2+}$ with adenosine monophosphate and related compounds. They found quite considerable optical activity brought into this system, and they related it to the formation of associates with the following composition: 1 molecule of $[Zn(phen)_3]^{2+}$ to 2 molecules of adenosine monophosphate. The strength of these associates is mainly achieved through electrostatic interactions.

Association processes have also been studied in a fairly detailed manner for kinetically inert complexes.[136,155–167] In a number of systems thermodynamic enantioselectivity has been reliably detected. Formation constants of associates were not determined for some complexes but it has been clearly established by indirect methods[168,169] that they differ. In other cases the difference between the constants is within the limits of experimental error or absent altogether,[170,171] and hence PE is solely due in this case to the difference in chiro-optical properties of the diastereomeric associates.

Attempts have been made over a long period of time to establish a correlation between the absolute configuration of a chiral compound and the sign of PE occurring for it.[106,121,172–176] Definite progress was made in this direction but, as is noted by Miyoshi et al.,[177] it is first of all necessary to make an accurate assignment of the transition in the circular dichroism spectrum on which the correlation is carried out, and this is not always possible. Moreover, the occurrence of PE is due to a whole number of processes, the relative importance of which can vary significantly from system to system. Moreover, the suggestion put forward by Kirschner and Ahmad[176] that the observed PE reflects the spectroscopic characteristics of that enantiomer of the complex with which the solution is enriched gives rise to doubt.

Brittain et al.[178–187] studied the induced optical activity of tris-complexes of Eu(III) and Tb(III) with pyridine-2,6-dicarboxylic acid or 4,4,4-trifluoro-1-(2-thienyl)butane-1,3-diol in the presence of amino acids,[178,179] optically active chromium complexes,[180] amino alcohols,[181,182] ascorbic acid,[183] hydroxyphenyl derivatives of amino acids,[184] *N*-substituted amino acids,[185,186] and sugars.[187] Thus, the study of PE was extended to lanthanide complexes. The results obtained in these studies[178–187] are of considerable significance for the determination of the optical purity of organic compounds using a chiral shift reagent. In fact, in this case the formation of an outer-sphere complex (and perhaps an inner-sphere one) also takes place, and since an optically active lanthanide complex and a racemic (or enantiomerically enriched) organic ligand take part in reaction, the reaction can be enantioselective. Therefore the intensity of the signals from the two diastereomeric associates can depend, in addition to other factors, on the enantioselectivity of this process. Although NMR is extensively used to determine optical purity (see, for example, two studies[188,189] and subsequent reports[190–194]), its use for studying the enantioselectivity of complex formation has not been widely applied so far (see the study of Krasutskii et al.[195] and the references in it).

A very special case was reported in 1978 by Garvey and Pope.[196] The authors found PE in the heteropolyanions $[P_2Mo_{18}O_{62}]^{6-}$ and α-$[P_2W_{18}O_{62}]^{6-}$ in the presence of *l*-brucine. Another similar system—$[MnMo_9O_{32}]^{6-}$—was later found by Nomija et al.[197] Since the structure of a heteropolyanion rules out the possibility of its racemisation, PE occurs here solely as a result of the difference in the association constants and the differences in the chiro-optical properties of the adducts [equilibria (2) and (3) in the scheme given above do not occur].

In conclusion we should mention the study of Shigematsu et al.,[198] in which the formation of an axial adduct between a trifluoroacetyl-*d*-camphor copper(II) complex and phenylethylamine was studied. The formation constant of the adduct with the *d*-amine was approximately 2.5 times higher than with the *l*-amine. Formally this system can be classed as a complex with inner-sphere ligand exchange, since direct binding between the amine and the metal atom occurs in the adduct, and also as an outer-sphere complex, since the axial ligands are bonded to the copper atom much more weakly than the ligands of the main coordination sphere.

V. Enantioselective effects in the reactions of coordination compounds that occur without ligand exchange

A typical example of a potentially enantioselective reaction that takes place without involving a chiral chemical compound is the action of circularly polarised light on complexes (similar reactions are known for racemic organic compounds).[199] The essence of this effect is that enantiomers absorb light energy to a different degree when they are irradiated with right-handed and left-handed circularly polarised light.[200,201] This can lead to an unequal degree of photodestruction or other photochemical processes and hence to an accumulation in solution of that enantiomer which absorbs light energy to a lesser extent. Of course, for this effect to occur it is essential that racemisation of the complex without irradiation takes

place very slowly or not at all. Enantioselective photolysis was demonstrated experimentally in the case of complexes of Cr(III) with acetylacetone or its derivatives,[201–206] oxalic acid,[207,208] and phenanthroline,[209] in which the fundamental rate constant of racemisation has a value of the order of 10^{-6} s^{-1}. In all cases the observed enantiomeric enrichment did not exceed 5%, which is an indication of the small degree of enantioselectivity of such processes.

Approximately the same degree of enantiomeric enrichment also occurred in systems where linearly polarised light was used rather than circularly polarised light, but irradiation was carried out in an optically active medium.[209] The difference in the absorption of light in this case was due to the formation of diastereomeric associates. Yoneda et al.[210] studied these processes in greater detail in $[Cr(ox)_3]^{3-}$, $[Cr(ox)_2(phen)]^-$, $[Cr(ox)(phen)_2]^+$, and $[Cr(phen)_3]^{3+}$ complexes in the presence of *d*-cinchonine or *l*-cinchonidine. They established that a solution on irradiation is enriched with the same enantiomer of the complex which accumulates as a result of dark PE.

Less conclusive results were obtained by Norden[211] by irradiation of a solution of Cr(III) in the presence of racemic tartaric acid with circularly polarised light. In this solution a large number of isomeric forms of complexes can be formed and it is not clear towards which isomers the equilibrium is shifted on irradiation. Norden[211] suggests that the occurrence of optical activity in solution is mainly due to the isomerisation

$$\Lambda\text{-Cr}(R\text{-tart})_3 \rightarrow \Delta\text{-Cr}(R\text{-tart})_3$$
and
$$\Delta\text{-Cr}(S\text{-tart})_3 \rightarrow \Lambda\text{-Cr}(S\text{-tart})_3.$$

The question of enantioselectivity occurring in electron-transfer reactions between complexes also proved to be controversial. It was reported[212] that if the racemic complex $[Cr(phen)_3]^{2+}$ is oxidised by Λ-$(+)_D$-$[Co(phen)_3]^{3+}$, 92% Δ-$(-)_D$-$[Cr(phen)_3]^{3+}$ and 8% Λ-$(+)_D$-$[Cr(phen)_3]^{3+}$ is formed. However, Kane-Maguire et al.,[213] having checked these results, could not detect any noticeable optical activity in the resulting $[Cr(phen)_3]^{3+}$. She then studied a further 13 different systems in which electron transfer occurs and in which enantioselectivity could be expected to occur, but her endeavours were unsuccessful. She concluded from these results that enantioselectivity is not present in outer-sphere redox processes.

Geselowitz and Taube,[214] having examined the results of previous studies,[213] came to the conclusion that the required ratio of the rates of oxidation to racemisation was not fulfilled, so enantioselectivity could not be detected. Having chosen as their research topic the reaction between Δ,Λ-$[Co(edta)]^-$ and Δ-$[Os(bipy)_3]^{3+}$, they demonstrated that this reaction leads to the formation of $[Co(edta)]^-$ that is 3% enriched with the Δ-isomer. Similarly, when Λ-$[Os(bipy)_3]^{3+}$ was used, the same excess of Λ-$[Co(edta)]^-$ was obtained. Subsequently, these and a number of other electron-transfer reactions were studied in detail by Lappin et al.[215–219] They confirmed that enantioselectivity occurred in these processes and noted the important role of the conformation of the ligands[215] and the structure of the complex[219] for enantioselectivity to take place. They also showed that there was a correlation between the enantioselectivity for formation of outer-sphere associates between oxidising agent and reducing agent and the enantioselectivity of electron-transfer.[216,217] The important role of the solvent in these processes was studied by Geselowitz et al.[220]

In studying energy transfer (from emission spectra) between terbium and europium ions, Brittain[221] found that complexes of terbium with racemic aspartic acid transfer their energy to a europium ion more effectively than complexes with optically active aspartic acid. It is worthy of note that all attempts to find any difference in the properties of complexes of terbium with *R*- or *S*- and *R,S*-aspartic acids by other methods (potentiometric titration, spectrophotometry) were unsuccessful.

Enantioselectivity was shown to occur in processes involving electrochemical oxidation/reduction of complexes when this process is carried out using an optically active electrolyte. Thus, the reduction of $Co(acac)_3$ in the presence of trimethyl-(–)-menthylammonium results in optical activity in the unreduced complex.[222,223] The enantioselectivity of this process was small, but Ohkubo et al.[222,223] were confident of increasing it through the choice of a suitable supporting electrolyte.

The photochemistry of azines

Ya N Malkin, V A Kuz'min
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The features of the luminescence spectra and photochemistry of heterocyclic amines, such as derivatives of pyridine, quinoline, acridine, and diazines, in liquid and solid solutions are examined. The relationship between the composition of the lowest electronically excited states and the luminescence and photochemical properties is analysed. Particular attention is given to the nature of the photochemically active, electronically excited state.

The bibliography includes 106 references.

I. Introduction

At the present time the theoretical treatment of the mechanisms of photolytic processes in complex organic molecules and the reactivity of excited states are based on the findings of photophysics obtained by studying the luminescence spectroscopic properties of these systems. Progress in the photophysics of complex molecules (the relationship between the spectroscopic properties and structure,[1–4] the effect of the medium, the theory of radiationless transfers[5–10]) has considerably outstripped the advances in theoretical photochemistry. This circumstance is to a considerable extent due to the absence of data on the multiplicity and nature of the orbitals of the photochemically active, electronically excited state; a very limited number of photochemical reactions have been characterised through a reliable value of the quantum yield. In the present review the data on the reactivity of six-membered azines have been correlated on the basis of theories on the fundamental photochemical processes.

II. Features of the luminescence spectra

1. Pyridine, quinoline, and isoquinoline

The composition of the lowest electronically excited states and luminescence properties of six-membered *N*-heterocyclic compounds have been examined in monographs.[5,9] These compounds, including pyridine, quinoline, isoquinoline, and acridine, differ formally from aromatic hydrocarbons in that they have an $-N=$ atom instead of a methylene group. In this case the π-system remains unchanged and the absorption spectra of such compounds have much in common with the spectra of the hydrocarbon analogues of *N*-heterocycles since in both cases they result to a considerable extent from $\pi \rightarrow \pi^*$ transitions. These $\pi \rightarrow \pi^*$ transitions have the same polarisation as the transitions that give rise to the absorption and fluoroscence spectra of aromatic hydrocarbons.[5]

In the absorption spectra of pyridine the $\pi \rightarrow \pi^*$ bands (λ_{max} = 255 and 195 nm, ε_{max} = 1800 and 7500 litres mol^{-1} cm^{-1}) are more intense than the corresponding bands for benzene. This is because the electronegative nitrogen atom disturbs the symmetry of the π orbitals, so that while there is a complete similarity of the $\pi \rightarrow \pi^*$ transitions in benzene and pyridine the latter are more probable[6] (Table 1).

Table 1. Spectroscopic properties of azines.[15,16]

Note. φ_{ISC} and φ_f are the quantum yields for intersystem crossing and fluorescence; [a] gas, normal conditions; [b] in benzene; [c] in a butanol : isopentane (3 : 7) mixture at 77 K; [d] in hexane; [e] the luminescence properties are given in more detail in Table 10; unmarked values are given for solutions in cyclohexane.

By studying the electronic spectra of pyridine, pyrazine, and pyrimidine in compressed gases and comparing the π-electron systems of heterocycles and benzene it was possible to deduce that the π-electron systems of pyridine in the $^1B_{2u}$ and $^1B_{1u}$ π,π*-states

(notation adopted by analogy with benzene) and also those of pyrazine and pyrimidine in the $^1B_{1u}$ state resemble the corresponding system in benzene. In the transition of diazines to an excited $^1B_{2u}$ state, their π-electron systems are considerably different from that of benzene.[11–13] At the same time the excitation of pyridine, which is accompanied by the appearance of a band due to a $^1B_{1u}$ transition, is considerably different from the analogous excitation of benzene (the ^1B band of benzene corresponds to the transition to a $^1E_{1u}$ state, so comparisons cannot be made between these molecules in this excited state). In addition, pyrazine completely resembles benzene in its excitation to a $^1B_{2u}$ state.[14]

Apart from π,π* bands, in the spectra of pyridine and quinoline derivatives there are bands due to $n \rightarrow \pi^*$ transitions, which are directed perpendicular to the plane of the molecule. The occurrence of these transitions only slightly alters the absorption spectra of the molecules but has a very marked effect on the luminescence properties, which differ considerably from the properties of their hydrocarbon analogues.[5]

Zelikina et al.[14] were the first to record directly structural n,π^* bands in the spectra of solutions of pyridine, pyrazine, and pyrimidine in compressed krypton, xenon, and CF_4 (120–200 K). In the case of pyridine the $n \rightarrow \pi^*$ is superimposed on the long-wavelength section of a more intense $\pi \rightarrow \pi^*$ band. The vibronic structure of the n,π^*-band is completely eliminated even in hexane at room temperature,[14] i.e., intramolecular interactions can only be minimised in compressed gases. All these n,π^* bands undergo a bathochromic shift when there is a change from rarefied vapour to solutions in Kr and He.[14–17]

The luminescence properties of azines are determined by the relative configuration of the lowest electronically excited states of n,π- and π,π^*-type (Fig. 1). Heterocycles luminesce very weakly, whereas the corresponding aromatic hydrocarbons exhibit marked fluorescence and phosphorescence.[5] Pyridine hardly fluoresces at all and does not phosphoresce, quinoline does not fluoresce in non-polar solvents but fluoresces in polar solvents (π,π^*-type fluorescence), while acridine exhibits weak fluorescence in all aliphatic solvents but in alcohols the fluorescence increases markedly (see Table 2). Only for quinoline and isoquinoline has π,π^*-type phosphorescence been recorded.

In one monograph[5] the features of the luminescence spectra of monoazines are examined in a somewhat simplified manner, only in relation to the structure and relative configuration of the lowest electronically excited states and without taking into account the interaction between them, even though this interaction has a decisive effect on radiationless deactivation processes.[9] Thus, it is assumed that for all monoazines $T(\pi,\pi^*)$ is the lowest state and in this case only π,π^*-phosphorescence can occur. As the size of the π-system increases, the energy of the $S(\pi,\pi^*)$ state decreases more rapidly than that of $S(n,\pi^*)$, so that even in quinoline in the vapour phase and in hydrocarbon solvents the energies of the $S(\pi,\pi^*)$ and $S(n,\pi^*)$ states coincide. In all these amines with a single nitrogen atom (apart from pyridine) the n,π^* band is not at longer wavelength, and *N*-heterocycles in which the π,π^* band in the absorption spectrum occurs at shorter wavelength than in acridine must exhibit π,π^*-phosphorescence (Fig. 1).

In acid media and polar solvents (especially when intramolecular hydrogen bonds are formed with the nitrogen atom of the heterocycle), those molecules in which the energy of the $T(n,\pi^*)$ state is higher than that of the $S(\pi,\pi^*)$ states (quinoline, azaphenanthrene, acridine, and benzacridine)[5] start to fluoresce (Table 2).

The fluorescence of pyridine, quinoline, isoquinoline, and acridine is exceptionally weak or absent altogether in aprotic solvents but quite considerable in protic solvents,[9,15] and it is assumed that even this weak fluorescence in aprotic solvents is due to impurities.[9] However, the decrease in quantum yield of fluorescence in aprotic solvents is not due to an increase in intersystem crossing; for

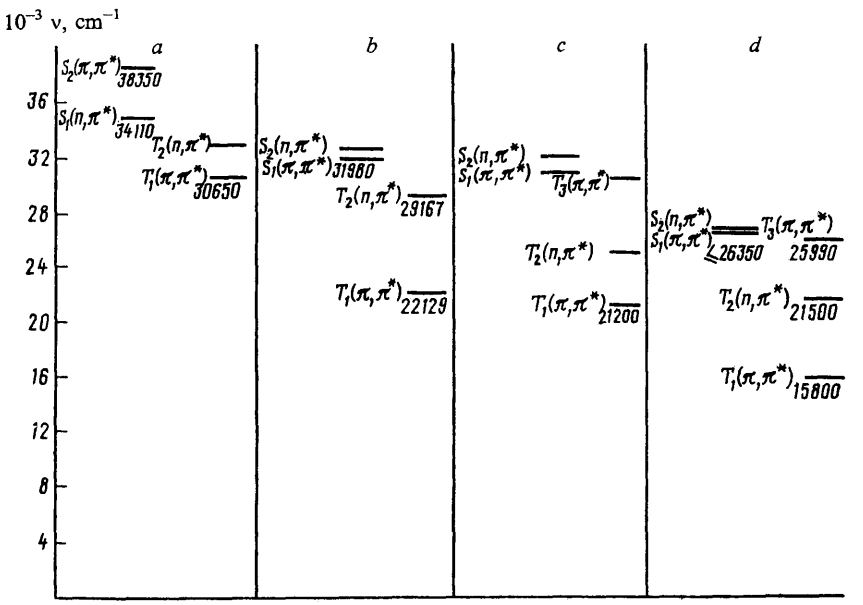

Figure 1. Distribution of the lowest energy levels of monoazines in non-polar solvents:[18–20] *a*, pyridine; *b*, quinoline; *c*, isoquinoline; *d*, acridine.

quinoline and isoquinoline the yields in the triplet state are equal to ~0.2 and 0.3 respectively.[9] Therefore the absence of fluorescence in these compounds in aprotic solvents is related to an acceleration of the $S_1 \rightarrow S_0$ internal conversion. This increase in internal conversion is due to a vibrational interaction between the closely situated $S(n,\pi^*)$ and $S(\pi,\pi^*)$ levels or, particularly in the case of quinoline and isoquinoline, to a perturbation (or even conversion) of the state as a result of movement along the coordinate corresponding to an extraplanar "scissor" vibration (in other words, as a result of a Jahn–Teller pseudoeffect). This perturbation (or inversion) must lead to a considerable increase not only in the rate of $S_1 \rightarrow S_0$ conversion but also $S_1 \rightarrow T_1$ intersystem crossing (experimentally this is exhibited by the lack of dependence of the quantum yield in the triplet states of quinoline and isoquinoline on the solvent[9]).

Thus, a vibrational interaction between the singlet n,π^* and π,π^* states of virtually all monoazines results in an extremely rapid radiationless deactivation of the S_1 state. The rate of radiationless deactivation in the gas phase increases sharply on excitation of the extraplanar scissor vibration of the lowest excited state.[26,27]

The main contribution to internal conversion of the thermalised S_1 state is provided by the highest vibrational sublevels of the S_1 state. In a deuteriated compound this effect is even more important since the frequency of the scissor vibration decreases, resulting in a reverse isotope effect in internal conversion.

On going from aprotic solvents to protic ones the π,π^* bands undergo a bathochromic shift while the n,π^* bands experience a hypsochromic shift. Consequently, if the lowest singlet state in the heterocyclic amine is a π,π^* state [or if the $S_1(n,\pi^*)$ levels are situated only just below it], the increase in the distance between the S_1 and S_2 levels results in a sharp decrease in the rate of internal conversion.[28]

Confirmation of the decisive role of a vibrational interaction between the n,π^* and π,π^* states in the luminescence of monazines (the "proximity effect")[9] is provided by the temperature dependence of the quantum yield of fluorescence. The quantum yield of fluorescence for isoquinoline in ethanol decreases markedly with an increase in temperature.[9,29] In this case the quantum yield of intersystem crossing (ISC) is virtually independent of temperature (~0.2 and ~0.3 at 298 and 77 K respectively). As the temperature increases the hydrogen bonds between isoquinoline and ethanol are weakened, resulting in a convergence of the $S(\pi,\pi^*)$ and $S(n,\pi^*)$ states and an intensification of the vibrational interaction, i.e., on heating the rates of $S_1 \rightarrow S_0$ and $S_1 \rightarrow T_1$ conversions increase simultaneously. As we shall see below, the "proximity effect" in one form or another determines the luminescence properties of all aromatic azines.

The kinetics of the decay of the triplet state of pyridine in the vapour phase are non-exponential. This is due to the existence of two closely situated triplet states that have different lifetimes. A model has been put forward in which it is assumed that there is a strong vibrational interaction between the almost degenerate $T(\pi,\pi^*)$ and $T(n,\pi^*)$ states of pyridine, which results in the appearance of a double minimum on the potential surface of the T_1 state[30,31] in the direction of the extraplanar "scissor" vibration. In this case the thermally relaxed T_2 state of pyridine is non-planar while the activated state is planar, and the rate constants for $T_1 \rightarrow S_0$ relaxation of these two states differ, amounting to less than 10^5 and 5×10^6 s^{-1} respectively.

A study of the hyperfine splitting at zero field of pyridine and its derivatives[32] has confirmed that the $T_1 \rightarrow S_0$ transition in pyridine is forbidden (this is evident from the small intensity of the O–O band). The occurrence of this transition is due to a vibrational interaction of the lowest triplet state with the closest $^3E(\pi,\pi^*)$ state and its spin-orbit interaction with $\sigma\pi^*$ and $\pi\sigma^*$ singlet states. In neutral molecules the vibrational interaction of the singlet $S(\pi,\pi^*)$ states with $T(n,\pi^*)$ states is apparently not strong enough to affect

Note. τ_{fl} is the lifetime of fluorescence; E_a is the energy of activation obtained from the temperature dependence of φ_{fl}; φ_m^S, φ_{rad}^S, φ_m^T, and φ_{rad}^T are the quantum yields for photoreduction of acridine from singlet and triplet states by a molecular and radical mechanism respectively.

the vibrational structure of the hyperfine splitting parameters at zero field. Phosphorescence of the pyridinium cation occurs from the $^3A_1(\pi,\pi^*)$ state (originating from "removal" of the n,π states) and has much in common with the phosphorescence of benzene. Thus, although the symmetry of pyridinium (C_{2v}) is lower than the symmetry of benzene, replacement of carbon by nitrogen leads to only a slight perturbation of the spin-orbit interaction in the benzene ring.

2. Acridine

The pattern of distribution for the lowest electronically excited states of acridine has been quite reliably established (Fig. 2). Previously the dependence of the quantum yield of the fluorescence of acridine on the solvent was interpreted as the result of a change in the nature of the S_1 state—π,π^* in protic solvents and n,π^* in aprotic solvents.[28,33] The lifetime of the S_1 state of acridine is equal to 50 ± 6 ps in hexane and 350 ps in ethanol.[34] However, after the detection of acridine fluorescence in a matrix of n-octane at 77 K and in benzene at room temperature,[35] it was accurately established that even in these solvents the lowest level corresponds to the $S_1(\pi,\pi^*)$ state.

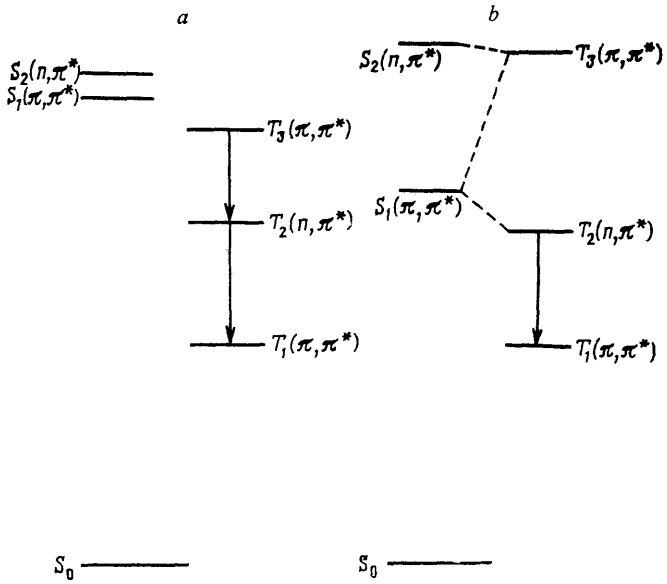

Figure 2. Distribution of the lowest energy levels of the electronically excited states of acridine: *a*, in benzene; *b*, in water at pH > 7.

Acridine undergoes photoreduction in solvents that can readily eliminate a hydrogen atom, and its lowest electronically excited state varies in different solvents (Fig. 2).[17] It was found that the φ_{ISC} of acridine decreases as the temperature increases in reactive solvents (methyl methacrylate and polymethyl methacrylate) and does not depend on the temperature in benzene (in which there is no photoreduction). In the opinion of Kasama and Kikuchi,[17] in water ISC takes place from the $S_2(n,\pi^*)$ state, which is thermally populated as a result of the following sequence of processes: $S_1(\pi,\pi^*) \rightleftarrows (\Delta E)S_2(n,\pi^*) \rightarrow T_3(\pi,\pi^*) \rightarrow T_1(\pi,\pi^*)$ (ΔE is the difference in energy between the S_1 and S_2 states). In benzene ΔE is very small and ISC takes place very rapidly, while in water ΔE = 1900 cm^{-1} and internal conversion can thus compete with ISC.[36] Schmidt et al.[36] determined the values of ΔE for acridine in different solvents; but it was mistakenly assumed by them that the lowest state of acridine is the $S_1(n,\pi^*)$ state (see Table 2).[37]

The fact that the sum of φ_R + φ_{ISC} + φ_{PR}† for acridine in solvents that are capable of eliminating a hydrogen atom is less than the sum of φ_R + φ_{ISC} in inert solvents, suggests that acridine is deactivated by removal of hydrogen and subsequent recombination.

In the radiationaless deactivation of the S_1 state of acridine an important role is played by the $T_3(\pi,\pi^*)$ state,[32] whose energy is equal to 26050 cm^{-1} in all solvents[38] and does not depend on the polarity of the latter.[17,37]

The magnitude of the energy gap between the electronically excited state of acridine depends also on the presence of substituents in the molecule and the annelation of the benzene rings (Table 2).[17] In all the acridine derivatives there are two routes for ISC to occur, with the rate of the process in one of them dependent on temperature and in the other not dependent on temperature. For all the acridines (except for 9-aminoacridine) the rate of the process: $S_1(\pi,\pi^*) \rightleftarrows (\Delta E)S_2(n,\pi^*) \rightarrow T_3(\pi,\pi^*)$ is dependent on temperature and the process: $S_1(\pi,\pi^*) \rightarrow T_2(n,\pi^*)$ is independent of temperature.[39]

In the case of 9-aminoacridine the energy gap is large, $\Delta E(T_3-S_1)$ = 4360 cm^{-1}, so participation of the T_3 state in the deactivation of the $S_1(\pi,\pi^*)$ state can be ignored (Table 2). The electron-donating NH_2 group gives rise to a hypsochromic shift of the n,π^* bands and a bathochromic shift of the π,π^* bands in the absorption spectrum, so the $T_2(n,\pi^*)$ level of 9-aminoacridine is higher than $S_1(\pi,\pi^*)$ and the dependence on temperature is solely determined by the possible transition $S_1(\pi,\pi^*) \rightarrow T_2(n,\pi^*)$.

Up to the present time there is still much that is unclear in the photophysics of acridine. Thus, the energy of activation of the fluorescence process of acridine in hexane and ethanol does not depend on the nature of the solvent, which cannot be explained by limiting the study to just the "proximity effect."[42]

3. Diazines

The lowest excited states of pyrazine, pyrimidine, and pyridazine are of an n,π^*-type.[5] The gas-phase absorption spectra exhibit a well resolved vibrational structure in the region of the n,π^* transition (Fig. 3).

The lowest T_1 state of pyrazine and pyrimidine is the $T_1(n,\pi^*)$ state. When methyl substituents are introduced in the molecule, the $T(\pi,\pi^*)$ band experiences a bathochromic shift but the $T(n,\pi^*)$ band undergoes a hypsochromic shift, so the $T(\pi,\pi^*)-T(n,\pi^*)$ energy gap in methylated diazines is much less than in the initial unsubstituted compounds.[9] As the width of the gap decreases the quantum yield and lifetime of n,π^*-phosphorescence decrease considerably.[9] The change in the value of φ_R for these compounds on methylation is solely due to the increase in probability of the radiationless transition $T_1(n,\pi^*) \rightarrow S_0$ (Table 3).

The dependence of the quantum yield of fluorescence on the excitation energy for pyrazine and pyrimidine vapour (Figs. 4 and 5) suggests[39] that while the rate constant k_{ISC} in the region of the $S_1 \leftarrow S_0$ and $S_2 \leftarrow S_0$ absorption bands is constant, the rate

† φ_R is the quantum yield of photoreduction.[40,41]

constant for internal conversion k_{IC} ($S_1 \rightarrow S_0$) increases sharply (to 10^{11} s^{-1}) for light with energy above 34 000 cm^{-1}. Thus, in the case of pyrazine, as for pyridine, at frequencies above 34 000 cm^{-1} a route for rapid radiationless deactivation occurs (having the same origins).

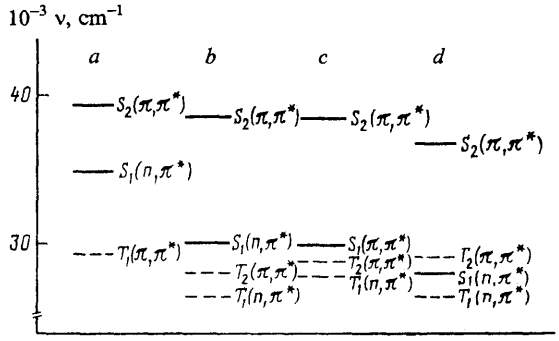

Figure 3. Distribution of the lowest energy levels of diazines: *a*, pyridine; *b*, pyrazine; *c*, pyrimidine; *d*, pyridazine.

Table 3. Quantum yields for intersystem crossing, fluorescence, and radiationless deactivation in the gas phase at a pressure of 1.0 mm Hg azine + 100 mmHg SF_6 (from the results of Yamazaki et al.).[38,40]

Compound	Transition	ν_{0-0}, cm^{-1}	φ_{fl}	φ_{ISC}	$k_{IC} \times 10^{-11}$, s^{-1}
Pyridine	$S_1(n,\pi^*) \leftarrow S_0$	34 769	$5.9 \cdot 10^{-5}$	0.30	0.17
	$S_2(\pi,\pi^*) \leftarrow S_0$	38 350	$2.4 \cdot 10^{-6}$	0.0067	7.68
Pyrazine	$S_1(n,\pi^*) \leftarrow S_0$	30 875	$1.3 \cdot 10^{-3}$	1.0	0.001
	$S_2(\pi,\pi^*) \leftarrow S_0$	37 840	$0.9 \cdot 10^{-4}$	0.13	5.25
Pyrimidine	$S_1(n,\pi^*) \leftarrow S_0$	31 072	$15 \cdot 10^{-3}$	1.0	0.001
	$S_2(\pi,\pi^*) \leftarrow S_0$	40 310	$0.4 \cdot 10^{-4}$	0.08	2.63

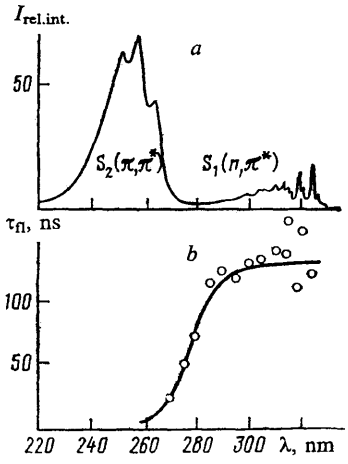

Figure 4. Absorption spectrum of pyrazine (*a*) and dependence of the lifetime of fluorescence (*b*) on the wavelength of excitation at a pyrazine pressure of 1 mmHg in the presence of SF_6.[39,40]

In contrast to pyrazine, k_{ISC} for pyrimidine increases with an increase in excitation energy near the S_1 band, which leads to an even more marked decrease in τ_{fl} and φ_{fl} (Figs. 4 and 5). The mechanism of this type of deactivation is possibly due to the acceleration of internal conversion as a result of photoisomerisation[43] (a similar mechanism has been proposed for benzene).

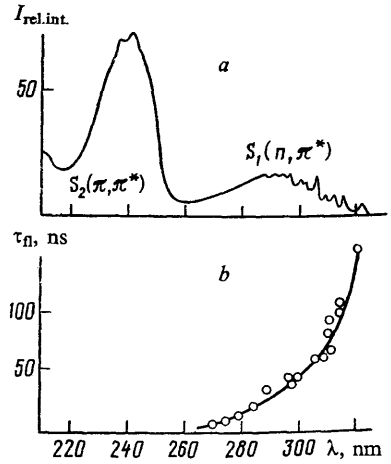

Figure 5. Absorption spectrum of pyrimidine (*a*) and dependence of the lifetime of fluorescence (*b*) on the wavelength of excitation[39,40].

The T_1 state of pyridine has been identified from the results of energy transfer studies;[44-47] only subsequently was the phosphorescence of pyridine itself detected.[44,45] The energy of this state has been estimated as 30 650 ± 800 cm^{-1},[48] and the lifetime for phosphorescence of pyridine vapour is several microseconds. The phosphorescence of pyridine derivatives—lutidines, cyanopyridines, and aminopyridines—in a condensed state is discussed by Motten and Kwiram.[32,49]

4. Phenazine

Phenazine may be regarded as pyrazine with annelated benzene rings. The absorption and emission spectra of phenazine have been studied in detail in solution and monocrystals at 77 and 4.2 K.[10,50] The relative configuration of the lowest electronically excited states $S_1(n,\pi^*)$, $S_2(\pi,\pi^*)$, and $T_1(\pi,\pi^*)$ has been established (Fig. 6).[51-53]

Fluorescence occurs for phenazine itself. It is of π,π^*-type in alcohols and n,π^*-type in hexane (Tables 4 and 5).

Struve et al.[42] used picosecond laser photolysis to record the $T-T$ absorption spectrum of phenazine in isooctane and methanol and demonstrate the existence of two different routes for population of the lowest $T_1(\pi,\pi^*)$ state of phenazine by excitation of the singlet $S_3(^1L_b)$ state: $S_3 \rightarrow S(n,\pi^*) \rightarrow T_1(\pi,\pi^*)$ and $S_3 \rightarrow T_2(n,\pi^*) \rightarrow T_1(\pi,\pi^*)$.

The introduction of F and Cl atoms into the β-position of phenazine leads to a successive increase in quantum yield of fluorescence. A subsequent change to Br and I reduces φ_{fl}, with a bathochromic shift of the fluorescence spectrum occurring. When a halogen is introduced into the α-position there is no fluorescence flashing and the fluorescence spectrum does not change (Table 4).[41]

In the opinion of Osipov et al.[52] πp_z-conjugation between the π-electron system and the halogen can result in this type of bathochromic shift of the π,π*-levels, so that inversion of the π,π* and lowest n,π^* level occurs. In the series F, Cl, Br, I the conditions for conjugation deteriorate since the 2-, 3-, 4- and 5-p_z electrons are involved.

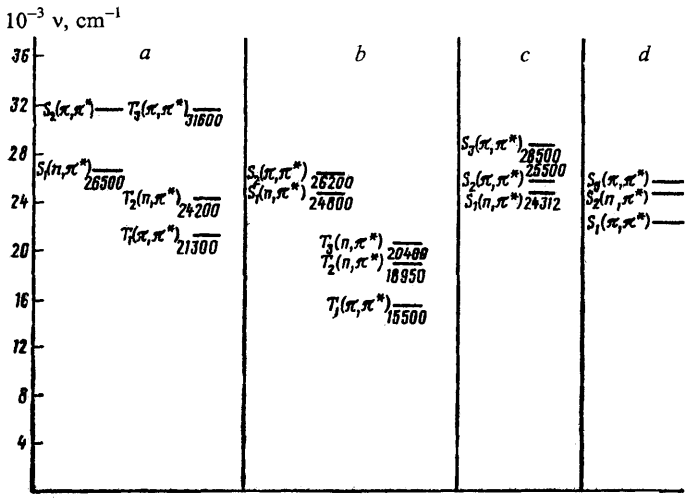

Figure 6. Distribution of the lowest energy levels of "anomalous" diazines.[92,96]

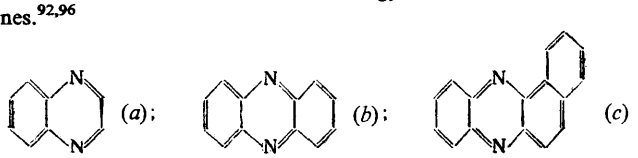

Table 4. Luminescence properties of phenazine derivatives in toluene at 20 °C.[41]

Compound	φ_n	τ_n, ns
Phenazine	$7\cdot10^{-4}$	0.06
1,2-Benzphenazine	0.012	0.2
1,2,3,4-Dibenzphenazine	0.10	0.18
1,2,3,4,5,6,7,8-Tetrabenzphenazine	0.16	1
1-Fluorophenazine	—	<2
1-Chlorophenazine	—	<2
2-Fluorophenazine	—	2
2-Chlorophenazine	—	3.5
2-Bromophenazine	—	5
2-Iodophenazine	—	5

An unusual effect involving the increase in quantum yield and lifetime of fluorescence of phenazine itself has been detected when toluene is replaced by methyl iodide as the solvent at 77 K.[52] This is apparently due to the formation of weak charge-transfer complexes between phenazine and methyl iodide in which the *n*-electrons of phenazine are partially bonded.

Annelation of the benzene rings causes a reduction in energy of the $S_2(\pi,\pi^*)$ state of phenazine, which leads to an increase in quantum yield and lifetime of fluorescence (Table 4). In this case inversion of the $S_1(n,\pi^*)$ and $S_2(\pi,\pi^*)$ levels does not occur, namely, for all the phenazines the $S_1(n,\pi^*)$ state is the lowest. However, the proximity of these levels suggests that there is a considerable temperature-dependent vibrational interaction between them. The temperature causes excitation of the vibrations linking the closely situated states and thus determining the features of the luminescence spectra of the molecules. Osipov et al.[41] attribute the two-component fluorescence of benzphenazine and dibenzphenazine to emission from the $S_2(\pi,\pi^*)$ and $S_1(n,\pi^*)$ states, i.e., for these molecules emission from the $S_2(\pi,\pi^*)$ state is more effective than from $S_1(n,\pi^*)$. Phenazine becomes a stronger base in its S_1 and T_1 states than in the ground state. Its mono- and di-protonated forms have been recorded (Table 5, see also Table 10 for comparison).

Table 5. Luminescence properties of phenazine (A), its monocation (AH^+), and dication (AH_2^{2+}).[53]

Compound	λ_{max}	λ_{0-0}	E_{T_1}, cm⁻¹	pK_{S_0}	pK_{T_1}	pK_{S_1}
A	21 000	23 500	15 475	1.24	4.0	6.0
AH^+	19 000	21 250	14 175	1.21	4.0	6.0
AH_2^{2+}	15 200	17 300	9 300	−4.30	5.7	4.1

Note. pK_{S_0}, pK_{S_1}, pK_{T_1} are the p*K* values in the ground, S_1 and T_1 states.

5. Aminopyridines

A class of pyridine derivatives such as aminopyridines has been studied in detail as have 7-azaindolines, which are very similar to them in structure.[54–63] A study of the features of the luminescence spectra and quantum-chemical calculations of the composition of the lowest electronically excited states of aminopyridines[55–58] showed that the amino group does not significantly perturb the energy levels of pyridine (Fig. 7). As in the case of pyridines, the features of the luminescence spectra of aminopyridine are determined to a considerable extent by the vibrational interaction between closely lying singlet n,π^* and π,π^* levels.[64,65] The effect of the amino group is to cause the distance between the lowest $S(n,\pi^*)$ and $S(\pi,\pi^*)$ levels to become even smaller, and in non-polar solvents inversion even occurs so that $S_1(\pi,\pi^*)$ becomes the lowest level.

According to calculations,[66] the $S_1(n,\pi^*)$ level of 2-aminopyridines is situated 0.72 eV below the $S_2(\pi,\pi^*)$ level. However, an analysis of the effect of the solvent on the luminescence properties of 2-aminopyridine and also a study of the vibrational and rotational structure of its spectra[57] show that even in non-polar solvents the lowest state is the excited $S_1(\pi,\pi^*)$ state, and the band at 298.0 nm corresponds to the $^1A_1 \leftarrow {}^1B_2$ transition in pyridine somewhat shifted by the effect of the amino group.

In non-polar solvents the distance between the levels increases and the efficiency of radiationless deactivation decreases, resulting in an increase in the yield of fluorescence, and there is a correlation between the strength of the oscillator of the $\pi \rightarrow \pi^*$ band and the quantum yield of fluorescence[55] (Table 6).

2-, 3-, and 4-Aminopyridines do not phosphoresce in non-polar solvents but phosphorescence occurs in polar solvents. According to Wolleben and Testa[57] this phenomenon is due to the increase in the rate of $S_1 \rightarrow T_1$ intersystem crossing, since in polar solvents the relative position of the $T(n,\pi^*)$ and $T(\pi,\pi^*)$ levels changes (Fig. 8).

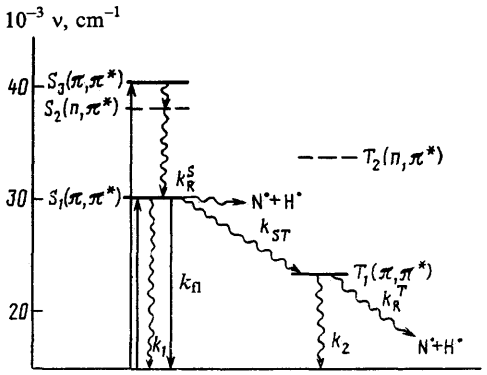

Figure 7. Distribution of the lowest energy levels of 5-methyl-7-azaindoline and rate constants for the fundamental processes taking place in it from the results of Dvornikov et al.:[59-62] $k_1 = 1.2 \times 10^8\ s^{-1}$; $k_2 = 2 \times 10^5\ s^{-1}$; $k_R^T = 8 \times 10^5\ s^{-1}$; $k_{fl} = 4 \times 10^7\ s^{-1}$; $k_{ISC} = 8 \times 10^7\ s^{-1}$; $k_R^S < 5 \times 10^6\ s^{-1}$; k_R^S and k_R^T are the rate constants of dissociation from the lowest singlet and triplet states respectively.

Table 6. Features of the luminescence spectra of 7-azaindolines and 2-aminopyridine.[55,57,59,60]

Compound	Solvent	λ_{abs}^{max}, nm	ε, $m^2 mol^{-1}$	λ_{fl}^{max}, nm	φ_{fl}	τ_0, ns	$k_{fl} \times 10^{-7}$, s^{-1}

4,6-Dichloro-7-azaindoline	"	312	—	370	0.0014	—	—

The relative position of the lowest n,π^* and π,π^* levels of 2-aminopyridine is highly dependent on the presence and nature of the substituent in the aromatic ring. The introduction of a methyl group into 2-aminopyridine (for example, the formation of 3-methyl-2-aminopyridine) leads to inversion of the lowest singlet n,π^* and π,π^* levels and to a reduction in width of the energy gap between them. Therefore the fluorescence of 3-methyl-2-aminopyridine occurs in non-polar solvents with the participation of the almost degenerate $S_1(\pi,\pi^*)$ and $S_2(n,\pi^*)$ states. At 77 K there is emission from S_2 while at room temperature it occurs from both states. The quantum yield of fluorescence is determined to a considerable extent by the strength of the oscillator of the long-wavelength π,π^* transition, with which the n,π^* transition is combined.[66] Calculations using the CNDO method showed[56] that as soon as the $S_1(\pi,\pi^*)$ state becomes the lowest state for 2-aminopyridine derivatives, this immediately leads to an increase in quantum yields of fluorescence in non-polar solvents. (Fig. 8).[67]

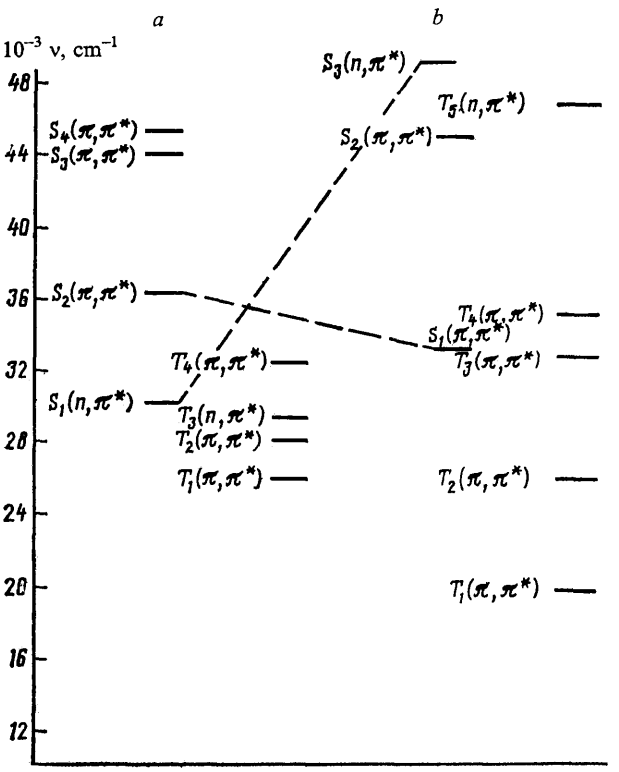

Figure 8. Distribution of the lowest energy levels of 2-aminopyridine (*a*) and its cation (protonated on the pyridine ring) (*b*).

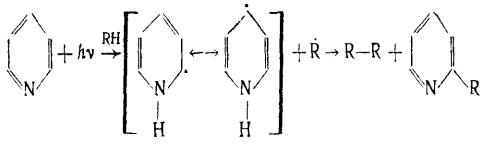
III. Photochemical properties

1. Pyridine, quinoline, acridine

As already mentioned above, pyridine is isoelectronic with benzene, but in pyridine there is a system of nitrogen n,π^* states which does not occur in aromatic compounds. Hence the photochemical reactions of pyridine can be divided into those which are similar to the photochemical conversions of benzene and those which are determined by the presence of the unshared electron pair of nitrogen.

Amongst processes of the first type are photoisomerisation (formation of benzvalene, Dewar pyridine), photosubstitution, and also photodissociation of halide-substituted pyridines. Processes of the second type are represented by hydrogen abstraction reactions

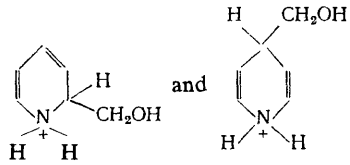
(photoreduction), processes related to the acid-base dissociation of pyridines in an excited state, and processes involving cleavage of ring bonds.



In the case of pyridine the photolytic processes that are typical of nitrogen-containing compounds occur via n,π^* excited states (as a rule the lowest in energy), while "benzene-type" reactions require excitation of the π-system.

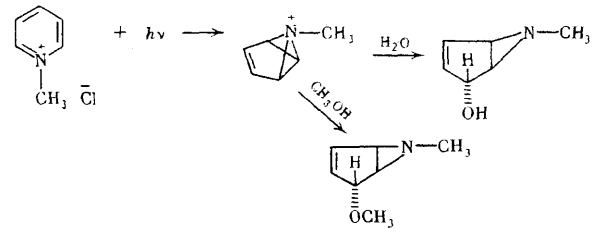
a) Acid-base properties of pyridine. According to CNDO calculations, the basicity of heterocyclic aromatic compounds in which the heteroatom is the basic site is considerably higher in the S_1 state that in the S_0 state.[62] The basicity of pyridine derivatives in the S_1 state is in fact higher than that in the S_0 state by a factor of 3–4, but the basicity of quinolines increases less (Table 7). Moreover, in protonation of the pyridine ring there is a marked increase in energy of the n,π^* transitions compared to the π,π^* transitions, since the proton interacts with the unshared electron pair on nitrogen. According to calculations,[56] when 2-aminopyridine is protonated the energy of the $S_1(n,\pi^*)$ state increases by 2.51 eV, as a result of which the vibrational interaction between the $S_1(n,\pi^*)$ and $S_2(\pi,\pi^*)$ states disappears and there is a sharp increase in the quantum yield of fluorescence in the cations. The increase in the basicity of bromine-substituted pyridine on going from the ground state to the S_1 and T_1 states is more related to the strong electron-donating properties of bromine as a result of the stronger conjugation of the p,π orbital of bromine with the π orbital of pyridine in these states[62] (Table 7).

Table 7. Acid-base properties of derivatives of pyridine and quinoline in aqueous and aqueous alcohol solutions.[62–64]



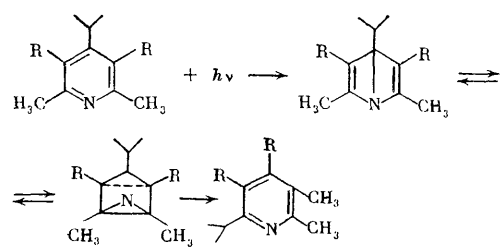
Compound	λ_{max}, cm^{-1}	pK_{S_0}	pK_{S_1}	pK_{T_1}
Pyridine	38 200	5.42	4.79	—
2-Bromopyridine	37 800	—	2.66	—
3-Bromopyridine	37 450	3.0	4.72	—
Quinoline	31 950	5.01	13.83	6.69
3-Bromoquinoline	31 050	3.07	13.14	5.38
6-Bromoquinoline	31 200	3.13	13.84	6.07
Isoquinoline	31 300	5.31	7.62	3.63
4-Bromoisoquinoline	30 900	3.32	6.05	3.49

On irradiation, pyridine is capable of removing a hydrogen atom even from cyclohexane. Irradiation of pyridine at 253.7 nm in cyclohexane (RH) results in the formation of dicyclochexyl (R–R), 2-, and 4-cyclohexylpyridines, and 2,5-dicyclohexylpyridine in the ratio 20 : 10 : 10 : 1.[16]

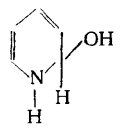


[According to our estimates the quantum yield in such a system does not exceed 2.3×10^{-4}, reaction takes place from the $S_1(n,\pi^*)$ state]. The resulting pyridine radicals can combine in the solvent cage to form dihydro-substituted compounds, recombination of which in turn leads to the formation of 2- and 4-substituted pyridines. In the presence of oxygen the yield of dicyclohexyl decreases by a factor of 10 and new products—cyclohexanol and cyclohexanone—are formed.

In a condensed state a large number of reactions involving introduction of substituents into the pyridine ring take place via the removal of a hydrogen atom by pyridine in an excited state. Thus, photoalkylation of pyridines in acid solution involves the removal of hydrogen by the nitrogen atom of a pyridine salt and the formation of the intermediates[26]



As a result of the recombination of these intermediates 2- and 4-methylpyridines, and 1-(2-pyridyl)-2-(4-pyridyl)ethane are formed. Another possible method for the photoconversion of pyridine in water and methanol is isomerisation with addition of the solvent.[16]

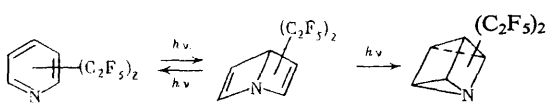


Pyridyl radicals could only be directly detected in an argon matrix. It was established that these radicals are photochemically active. On absorption of a second quantum they undergo ring-opening.[65]

The photoreduction of 3,5-dicarboxypyridines also takes place via the removal of hydrogen. Products from the photoreduction and addition of methanol (1,2- and 1,4-dihydropyridines with a hydroxymethyl group at the 2- and 4-positions) are formed in methanol. Removal of hydrogen by 3,5-dicarboxypyridines occurs in the $S_2(n,\pi^*)$ state and the resulting α-hydroxyalkyl radicals disproportionate. Malkin et al.[64] suggest that this reaction takes place via the S_2 state, since there is no correlation between the rate constants of fluorescence quenching and the photochemical reaction. In the excited $S_2(n,\pi^*)$ state of 3,5-dicarboxypyridines removal of hydrogen from the solvent as well as isomerisation to form the intermediate "Dewar pyridine" and prismane are possible. In this case photoreduction generally occurs more rapidly because of the large concentration of alcohol. However, the photoreduction of 4-isopropyl-3,5-dicarboxypyridine, whose isopropyl group gives rise to steric hindrance, does not occur, and instead of this isomerisation takes place

where R = COOH.

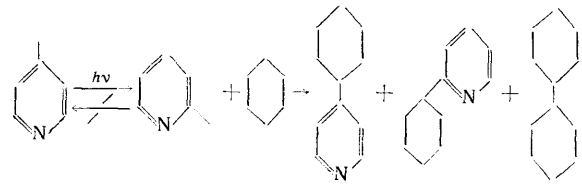
Pyridine decomposes very effectively on irradiation in aqueous solution;[65-67] the final product of photolysis are CO_2, ammonia, and water. The photolysis mechanism has so far not been precisely established, but it has been suggested[66-69] that on photoexcitation of the hydrogen-bonded complex that is formed between pyridine and water, radical addition of water takes place in the $S_1(n,\pi^*)$ state of pyridine at the 2- and 6-position to form the intermediate



which then decomposes to give the relatively stable 5-amino-2,4-pentadienal, which has been detected as an intermediate.[65,66,70,71] However, in the opinion of Wilzbach and Raush[66] 5-amino-2,4-pentadienal is formed in water by hydrolysis of "Dewar pyridine" (2-azabicyclo[2.2.0]hexa-2,5-diene). Thus, in all of the solvents pyridine initially gives "Dewar pyridine", which is either reduced to 2-azabicyclohex-5-ene or hydrolysed to the aldehyde.[66] Photolysis of pyridine is accelerated when the pH is lowered and suppressed in an alkaline medium.[65] In general the pyridine ring is much less stable towards light than the aromatic ring of aniline, which is confirmation of the important role of *n*-electrons during photolysis.

b) Photoisomerisation. The most characteristic photolytic reaction of pyridine itself and its derivatives is photoisomerisation to form "Dewar pyridine" and benzvalene.[39] Reverse rearomatisation of these unstable isomers leads to the formation of various substituted pyridines. Isomerisation occurs both in the gas phase and in solution.[72] The product from the photolytic irradiation of pyridine in butanol at −15 °C is "Dewar pyridine", whose lifetime is almost 2 min.[72]

When pyridine is irradiated with light in an argon matrix at 8 K there is the initial formation of "Dewar pyridine", which is subsequently reduced to HCN and cyclobutene and then decomposes right through to acetylene.[72] Similar reactions of pyridine to HCN and acetylene also occur in the gas phase.



It is assumed[39] that the reversible photoisomerisation of pyridine to benzvalene occurs on excitation to the $S_2(\pi,\pi^*)$ state and it is this reaction that is responsible for the efficient radiationless deactivation of the higher excited states of pyridine in the gas phase.

As in the case of benzene, replacement of hydrogen in pyridine by a perfluoroalkyl group contributes towards the isolation of the respective "Dewar pyridines" and azaprismane in high yield:[72]

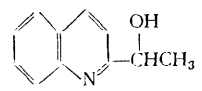
In contrast to perfluorobenzene, perfluoropyridine is light-stable. Photolytic irradiation of perchloropyridine results in cleavage of the C(3)−Cl bond, and the resulting radicals react with the solvent.[71,72]

Photolytic irradiation of 2-methylpyridine (2-picoline) in the gas phase gives 3- and 4-picolines. Irradiation of the different picoline and lutidine (dimethylpyridine) isomers results in the formation of other isomers, apparently via the formation of azaprismanes.[39,40] When 2- and 4-picolines and 3,4-lutidines are irradiated in cyclohexane, isomerisation and substitution occur,[39,73] while in the case of 2,3-, 2,4-, and 2,5-lutidines only substitution takes place:[73,74]

c) Photosubstitution. Halogen derivatives of pyridine undergo effective substitution of the halogen in water to form pyridines, the quantum yield being independent of the pH of solution. The reaction mechanism involves the heterolytic cleavage of the C−halogen bond (S_N1-type reaction) and reaction of the carbocation with water.

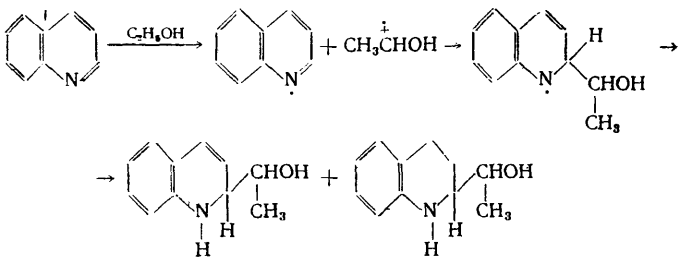
In the gas phase and also in heptane and methanol 2- and 3-bromopyridines when exposed to light form pyridine, while in water hydroxypyridine is formed.[71,75] In this case photosubstitution takes place via the S_1 state, in which pyridine is involved in a donor-acceptor reaction with water or other nucleophiles, resulting in substitution and induced deactivation. Substitution by hydrogen in non-aqueous solution is caused by homolytic dissociation of the C−halogen bond and removal of an H atom from the solvent by the respective radical.

The photoreduction of iodopyridine by sodium during matrix isolation leads to the formation of the respective pyridyl radicals[64] as a result of dissociative electron capture:



$$Na + PyX \xrightarrow{h\nu(\lambda > 500\ nm)} Na^+ + [PyX^-]^* \rightarrow Py + X^\cdot.$$

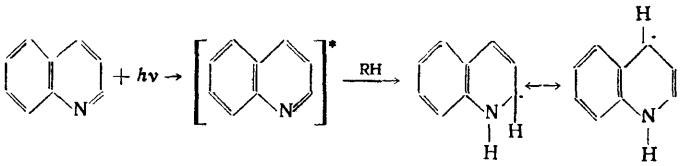
2-, 3-, and 4-pyridyl radicals have been detected. Pyridyl radicals can undergo further photochemical reactions related to cleavage of a CN bond in the aromatic ring; this frequently occurs in the direct photolysis of alkylpyridines.[64,70] The pyridyl radicals detected are σ-radicals, and the orbital which is occupied by the electron is to the extent of 70% a *p* orbital of the bond undergoing cleavage.[70]



In acid media (HCl in ethanol) quinolines undergo photoalkylation to form 2- and 4-ethylquinolines. In the opinion of Stermitz et al.[76] protonated quinoline in an excited state removes a hydrogen at the β-position of ethanol so that a hydrogen atom adds on to the amine nitrogen atom. The resulting radicals react with quinoline at the 2- and 4-positions and elimination of water and rearomatisation subsequently occur, leading to the formation of alkylation products with a quantum yield of 0.02.[76] In acid solutions of isopropanol the photoalkylation of quinoline does not occur. Under these conditions the reduced forms of quinoline dimers are formed in low yield.

Photolytic irradiation of isoquinoline in ethanol in the presence of HCl leads to the formation of 1-ethylquinoline, while in isopropanol (as in the case of quinoline) photoalkylation does not occur.

Photolytic irradiation of quinoline in ethanol in the absence of acid leads to the formation of 2-(1-hydroxyethyl)quinoline:



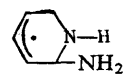
as well as traces of the 1,2,3,4-tetrahydroquinoline:

It is still not clear why substitution only occurs at the 2-position in the absence of acid.[76]

The photoalkylation of quinoline and isoquinoline in benzene also occurs in the presence of organic acids in an atmosphere of nitrogen. As in alcohols photoalkylation of quinoline occurs at the 2- and 4-positions while in isoquinoline it occurs at the 1-position. The mechanism of photoalkylation involves removal of a proton from the acid by quinoline in an excited state and formation of an exciplex. Decarboxylation of the exciplex leads to the formation of an ion pair, recombination of which gives products of reductive alkylation.[76,77]

When quinoline is irradiated in cyclohexane, 2-cyclohexylquinoline and 4-cyclohexylquinoline are formed, while in diethyl ether 2- and 4-(1-ethoxy)quinolines are formed.[67,78] Only 1-(1-ethoxy)isoquinoline is formed from isoquinoline in ether. The proposed mechanism involves the formation of unstable radicals:

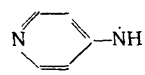
Photolytic irradiation of 2-cyanoquinoline in alcohols results in photosubstitution of the CN group by OR; the same process occurs in acid solutions but with a lower quantum yield (as mentioned above, quinoline undergoes photoalkylation).[79] Sensitisation experiments show that photosubstitution occurs in the $T_1(\pi,\pi^*)$ state.



Examples of electrophilic photosubstitution of pyridine and quinoline are almost unknown, possibly because electrophilic reagents are often efficient quenchers of excited states. Moreover, it is difficult to produce a high concentration of an electrophilic reagent that is needed to carry out the reaction with a short-lived triplet state.

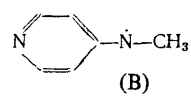
2. Aminopyridines and 7-azaindolines

The acid-base properties of aminopyridines and 7-azaindolines are virtually the same; the former and the latter are initially protonated on the pyridine ring (pK_a 5.8–7.1),[70,74,76] but a second protonation on the amino group occurs with difficulty. The absorption spectrum of the dication of 3-aminopyridine undergoes a hypsochromic shift relative to the monocation and neutral form (3800 cm^{-1} in water) while the fluorescence spectrum of the dication matches the fluorescence spectrum of the monocation. This is because adiabatic dissociation occurs in the S_1 state of the dication and fluorescence of the monoprotonated cation is observed.[66] This is a reflection of the general trend towards weakening of the basic properties of these heterocyclic amines in an excited state, as a result of which their cations dissociate adiabatically while neutral amines acquire the ability to fluoresce.[61,67] At the same time the acidity of the amino groups of all aromatic amines in an excited state increases, so both aminopyridines and 7-azaindolines undergo adiabatic dissociation by an acidic mechanism in the S_1 state on quenching of fluorescence with the OH^- ion.[60]



Protonation of the pyridine ring of 7-azaindolines in alcohols and water leads to a marked increase in the energy of $n \rightarrow \pi^*$ transitions compared with $^1\pi \rightarrow \pi^*$ transitions, since the proton interacts with the unshared electron pair of nitrogen in the pyridine ring. As was mentioned above, this is manifested in a sharp increase in the quantum yield of fluorescence of 7-azaindoline cations compared with the neutral compound (see Table 6). The increase in yield is due to "removal" of the $S(n,\pi^*)$ state and the absence of any possibility for intersystem crossing of the cations (Fig. 8).

When aminopyridines are irradiated, radicals of two types can be formed. It was proposed[58] that radicals that are formed by photolytic irradiation of 2-aminopyridine in cyclohexane should be regarded as of pyridyl type:



It is assumed that formation of the radical occurs in the $S_2(n,\pi^*)$ state of 2-aminopyridine by removal of a hydrogen atom from the solvent and that the NH bond is not cleaved (this conclusion was based on the absence of intermediates in the photolysis of 2-aminopyridine in methanol, ethanol, and acetonitrile).[58,68]

At the same time in the photolysis of 4-aminopyridine in isopropanol it is suggested[68] that there is cleavage of an NH bond and formation of an aminyl radical, whose absorption spectrum has a maximum at 440 nm:

It is thought that the NH bond of 4-*N*-methylaminopyridine is cleaved in isopropanol so that an aminyl radical is formed

(B)

The process takes place via an unidentified short-lived intermediate state. During photolysis in acetonitrile, the radical cation of 2-aminopyridine, whose absorption spectrum has a maximum at 500 nm, is formed in addition to (B).[57,58]

When the temperature is lowered the quantum yield for photodissociation of the NH bond decreases in all solvents and the triplet-triplet absorption of aminopyridines becomes appreciable[59,60] (this is the only case known to date of $T-T$ absorption in pyridine derivatives).

It was shown by pulsed photolysis that the photolytic irradiation of 2-aminopyridine and 7-azaindoline in all solvents leads to cleavage of an NH bond and formation of aminyl radicals, which then dimerise (Table 8).[59,60] The removal of a hydrogen atom from the solvent by aminopyridine in the $S_2(n,\pi^*)$ state as proposed by Wolleben and Testa[58] is unlikely and contradicts the results of Dvornikov et al.[59–62]

The luminescence spectroscopic and photochemical properties of aminopyridines and 7-azaindolines are very similar and this provides the basis for the assumption that on photolysis of 2-aminopyridines

cleavage of an NH bond occurs and aminyl radicals are formed from the T_1 state. The similarity of the spectra of the resulting radicals to the spectra of other aminyl radicals may serve as confirmation of this.[57,63]

The lifetime of the T_1 state of 7-azaindoline in heptane at room temperature is 1 μs and such a short lifetime is also characteristic of the T_1 state of *o*-aminopyridines.[61–63] The $T-T$ absorption spectrum could only be recorded at −155 °C, the rate constant for deactivation of the T_1 state being 381 s^{-1}.[55,56]

The quantum yield of fluorescence of 7-azaindolines does not depend on the wavelength of excitation,[67] which is also confirmation that photodissociation occurs from the T_1 state of 7-azaindolines (and not from higher excited states as in the case of amines and indoles).

Table 8. Extinction coefficients of aminyl radicals and quantum yields for photodissociation of the N–H bond of 7-azaindolines in benzene.[59–61]

Compound	ε_{rad}, mol^{-1} cm^{-1}	φ_{rad}
4,6-Dimethyl-AI*	480	0.36
4,6-Dichloro-AI	480	0.22
4-Methyl-AI	457	0.24

*AI = 7-azaindoline.

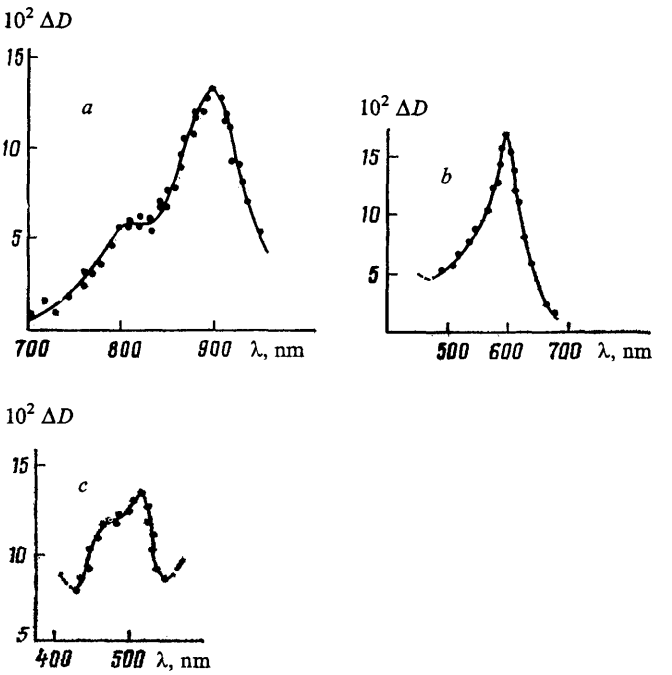
3. Acridine

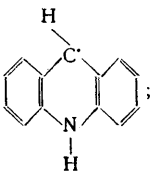
The most characteristic photolytic reaction of acridines is their reduction to acridanes, which occurs with varying efficiency in all solvents. The reduction takes place via both the $T_1(\pi,\pi^*)$ and $T_2(n,\pi^*)$ states.[80] The quantum yields of the photoreduction of acridine in different solvents are given in Table 2.

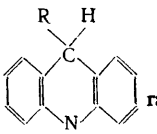
The photoreduction of acridine in non-polar solvents always takes place partly by a molecular mechanism and partly by a radical mechanism.[79–82] The radical mechanism involves the removal of a hydrogen atom by acridine in an excited state from the solvent to form acridine radicals, the destruction of which leads to the formation of acridane and dihydroacridane.[81,82] The molecular mechanism involves the successive or parallel reduction of acridine at two positions [N and C(9)], but is it not clear whether photoreduction occurs as a result of a one step process or via the formation of a short-lived intermediate.[81] A study of the photoreduction of acridines in binary mixtures showed[81] that the molecular and radical mechanisms occur independently of each other from different excited states of acridine.

In aqueous solution the photoexcitation of acridine results in its photoionisation, which occurs by a mechanism involving two quanta of energy. It follows from experiments on the effect of KI on the yield of solvated electrons that photoionisation mainly occurs via the S_1 state of acridine.[82] The reaction of a hydrated electron e^- with a neutral molecule of acridine results in the formation of a neutral *C*-centred radical while the acridine radical cation (formed at the same time as e^-) is deprotonated to give an *N*-centred radical (Fig. 9).

The photochemistry of acridane (9,10-dihydroacridine) is closely related to the photochemistry of acridine. The photolytic irradiation of acridane and acridine in ethanol at 93 K and room temperature results in the formation of a radical cation (maxima in the absorption spectra at 638 and 358 nm), an *N*-radical (364 and 351 nm), and a *C*-radical (520 nm).[84] All these species are formed by a two-quantum mechanism from the T_1 state of acridane.[84]







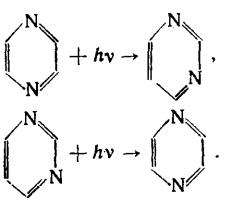


Figure 9. Absorption spectra of short-lived intermediates in the photolysis of acridine in ethanol: *a*, the acridine radical cation; *b*, the  radical; *c*, the  radical.

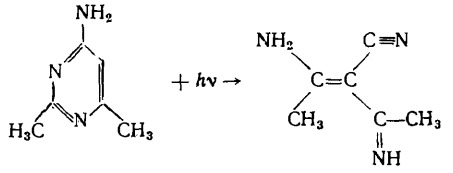
4. Diazines

Diazines undergo photoisomerisation in the vapour phase:[85]

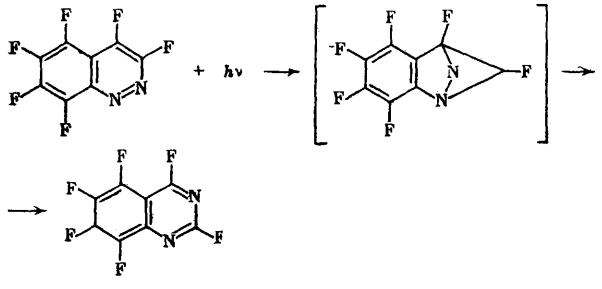
The quantum yield for formation of an isomer increases with an increase in energy of excitation—by a factor of 100 for light at 253.7 nm (S_2 band) compared with light at 313 nm (S_1 band) (Table 9). Isomer formation competes with the deactivation of



vibrationally excited molecules through collisions. The isomerisation of pyrimidine and pyrazine can be sensitised with mercury[85] but not with benzene, i.e., for photoisomerisation to occur a sufficiently high lying triplet state is required (Table 9).

Table 9. Quantum yields for photoisomerisation of diazines.[85]

Initial compound	Compound formed	φ_1^*	φ_2^{**}
Pyrimidine	Pyrazine	$(1.7\pm0.1)\cdot10^{-3}$	$(3.8\pm0.4)\cdot10^{-2}$
4,6-Dimethylpyrimidine	2,5-Dimethylpyrazine	$(4.6\pm0.4)\cdot10^{-3}$	$(3.6\pm0.4)\cdot10^{-2}$
5-Methylpyrimidine	2-Methylpyrazine	$(7\pm0.7)\cdot10^{-3}$	$(5.2\pm0.5)\cdot10^{-2}$
Pyrazine	Pyrimidine	$(7\pm0.7)\cdot10^{-3}$	$(2.8\pm0.2)\cdot10^{-2}$
2,5-Dimethylpyrazine	2,5-Dimethylpyrimidine	$(3\pm0.3)\cdot10^{-3}$	$(1.4\pm0.15)\cdot10^{-2}$
"	4,6-Dimethylpyrimidine	$(1.5\pm0.15)\cdot10^{-3}$	$(7\pm0.7)\cdot10^{-3}$



* φ_1 is the quantum yield for direct photolysis with light of wavelength 254 nm. ** φ_2 is the quantum yield for photolysis sensitised with mercury.

Perfluoropyridazine and perfluoropyrimidine are stable on irradiation at λ = 253.7 nm.[72] Ring-opening of 2,6-dimethyl-4-aminopyrimidine in aqueous alkaline solutions occurs via the formation of a "Dewar" intermediate:

The reaction product is a stable nitrile. Pyridazine undergoes photoisomerisation in the vapour phase to a mixture of pyrimidine and pyrazine, while perfluoropyridazine is converted to perfluoropyrazine, which in turn can isomerise to perfluoropyrimidine.[86] Similar reactions also occur for other fluoropyridazines and perchloropyridazine, which is converted at 77K via its $S(n,\pi^*)$ state.[72,86]

Diazines with condensed benzene rings do not undergo photoisomerisation. The only known exception to this is perfluorocinnoline, which photoisomerises to perfluoroquinazoline:

It was shown using kinetic EPR spectroscopy that pyrazine, 2,3-pyridipyrazine, and 9,10-diazaphenanthrene can remove a hydrogen atom from isopropanol when they are in the $T_1(n,\pi^*)$ state, while quinoxaline, phthalazine, phenazine, and acridine can remove an H atom when they are in the $T(\pi,\pi^*)$ state.[78]

5. Diazines with anomalous photochemical properties

As a result of the vibrational interaction between the closely situated $S_1(n,\pi^*)$ and $S_2(\pi,\pi^*)$ levels in azines and diazines, efficient internal conversion occurs as a rule, and these compounds do not fluoresce. When hydrogen bonds are formed, the energy of the n,π^* state increases and the quantum yield of fluorescence increases. In the majority of cases the addition of a proton also increases the intensity of fluorescence of *N*-heterocyclic compounds.[87–89]

Compounds containing a pyrazine ring (known as anomalous diazines) stand out from amongst the large number of diazines.[90] The anomalous nature of their behaviour lies in the large increase in their basicity in the S_1 and T_1 states. Moreover, in contrast to the other mono- and di-azines, the quantum yield of fluorescence and phosphorescence of the mono- and di-cations of anomalous diazines is very low (Table 10).

Table 10. Features of the luminescence spectra of diazines.[89–98]

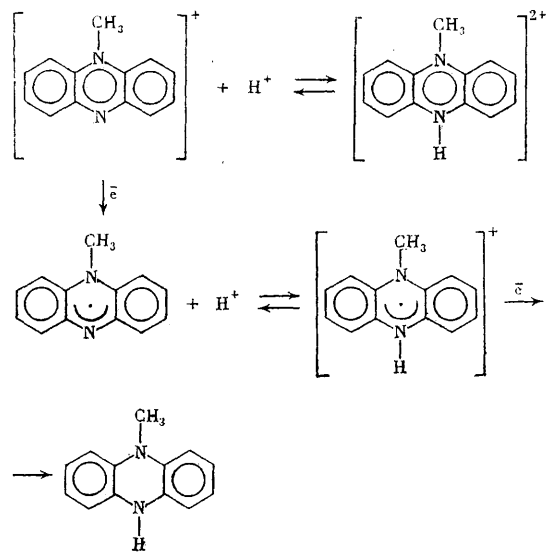
Thus, for example, pyrazine itself is protonated in frozen solutions of H_2SO_4, and phosphorescence of its neutral (A) and mono- and di-protonated forms (AH^+ and AH_2^{2+} respectively) occurs with maxima at 26 700, 21 600, and 24 100 cm^{-1}. In the opinion of Shinada[88] and Grabowska and Pakula,[89] while in free pyrazine phosphorescence occurs from the $T_1(n,\pi^*)$ state, in AH^+ and AH_2^{2+} it takes place from the $T_1(\pi,\pi^*)(^3L_b)$ state. The electron density on the nitrogen atom of pyrazine increases with π,π^*-excitation and decreases with n,π^*-excitation (compared to the ground state). Thus, pyrazine, which is an extremely weak base in the ground state, increases its basicity in the T_1 state.[89]

In the opinion of Grabowska and Pakula,[89] all of the anomalies of pyrazine derivatives are related to the fact that the pyrazine ring in an excited state adopts a bent conformation, and the hybridisation of the N atom changes from sp^2 to sp^3. The basicity of 1,2-benz-

phenazine, like an anomalous diazine, increases substantially on excitation. Relaxation of the excited state of the 1,2-benzphenazine monocation results in the occurrence of this type of bent structure, in which the $S(\pi,\pi^*)$ state is very effectively mixed with the $S(n,\pi^*)$ and $S(\sigma,\pi^*)$ states (much more effectively than in a planar molecule). On excitation the cation of 1,2-benzphenazine is folded like a butterfly about the N–N axis, with quantum calculations showing that protonation occurs on the N(10) atom.[99] This bent structure containing two sp^3-hybridised N atoms is only formed by a pyrazine ring and not by a pyrimidine ring (this follows from an examination of molecular models[90]). On excitation there is a substantial increase in electron density in the pyrazine ring. In the S_1 state of doubly protonated 1,2-benzphenazine it is as if an additional electron has appeared, and in the case of 1,4-diazatriphenylene as if there is an increase of 1,4 electrons,[92] which results in an increase in basicity (Table 10).

A consequence of this increase in basicity is the fluorescence quenching of benzphenazine by a proton at the almost diffusion-controlled rate of 3×10^9 litres mol^{-1} s^{-1} to form a non-fluorescing dication.[100] An extremely rare phenonenon characterises the benzphenazine monocation—a dependence of the emissive deactivation constant of the S_1 state on temperature. This also reflects the change in geometry of the molecule on excitation.[100]

In other diazines that do not contain a pyrazine ring (5,12-diazatriphenylene, 1,7-diazaphenanthrene) and in all monoazines there is no such increase in electron density on excitation.



For the other (non anomalous) bicyclic diazines an absence of fluorescence from the free molecules ($\varphi_f \approx 10^{-3}$) is typical (Table 10), namely, in all these molecules only internal conversion competes with intersystem crossing. It was demonstrated using the method of optically detected magnetic resonance that for quinoxaline the lowest state is $T_1(\pi,\pi^*)$ and the intersystem degradation $T_1(\pi,\pi^*) \rightsquigarrow S_0$ occurs as a result of a strong vibrational interaction with the ground state involving the z-orbital component of spin-orbit coupling.[54] In contrast to all the remaining bicyclic diazines, the lowest triplet state of phthalazine is a mixed $T(n,\pi^*)-T(\pi,\pi^*)$ state and not a pure π,π^* state.[101,102]

Phthalazine is reduced in isopropanol to form 1,2-dihydrophthalazine and its dimer 1*H*,1′*H*,2*H*,2′*H*-1,1-diphthalazine.[103] Photoreduction occurs through the removal of an H atom from isopropanol by phthalazine in the S_1 state to form 1,2-dihydrophthalazine with a quantum yield of 0.013. At the same time phthalazine undergoes dimerisation in the T_2 state with a quantum yield of 0.040. The photoalkylation of phthalazine occurs in alcohols on treatment with acids.[103]

6. Phenazine

During photolysis in the absence of oxygen, phenazine (in the same way as acridine) undergoes photoreduction to dihydrophenazine. In the presence of oxygen there is complete recovery of the initial phenazine. The quantum yield of the overall reduction of phenazine in toluene is 10^{-3} and in tetrahydrofuran the yield is 6×10^{-2}. A molecular complex between phenazine and dihydrophenazine which is in equilibrium with the initial reactants has been detected.[104] From an analysis of the dependence of the quantum yield of photoreduction on the concentration of tetrahydrofuran it was possible to conclude that the two lowest $T_1(\pi,\pi^*)$ and $T_2(n,\pi^*)$ states of phenazine participate in this process.[104,105] The decrease in quantum yield of photoreduction in the presence of eosin, which is accompanied by a triplet-triplet absorption of phenazine, indicates that photoreduction occurs at least partly via the $T_1(\pi,\pi^*)$ state. This is also confirmed by the sensitisation of photoreduction with diacetyl and the quenching of this process with oxygen. The rate constants for removal of an H atom from tetrahydrofuran by phenazine in the $T_2(n,\pi^*)$ and $T_1(\pi,\pi^*)$ states are equal to 1.5×10^7 and 4×10^3 litres mol^{-1} s^{-1} respectively. The quantum yields for photoreduction of phenazine in methanol, ethanol, and isopropanol on exposure to light at 365 nm are 0.023, 0.037 and 0.050 respectively.[104]

It was established by EPR spectroscopy and spectrophotometry that during photoalkylation of phenazine the methylphenazinium cation undergoes photoreduction in isopropanol on irradiation at 405 nm to form the stable methylphenazinyl radical and its radical cation. This radical exhibits a characteristic fluorescence with a maximum at 14 200 cm^{-1} and lifetime of 5.1 ns. In addition, the methylphenazinium cation undergoes dealkylation to free phenazine and the radical cation is later reduced to dihydrophenazine.[106] The ratio of the processes involving dealkylation and reduction to the radical depends on the steric properties of the alcohols (solvents). Dealkylation does not occur in isopropanol, while in methanol and ethanol the efficiency of both processes is comparable. The pK values of alkylated phenazines and their radicals have been determined:[106]

---o0o---

The presence of an unshared electron pair that does not participate in conjugation in six-membered azines leads to a fundamental difference between the features of the luminescence spectra and photochemistry of azines and those of the aromatic amines examined by us previously.[83] For heterolytic amines photoreduction and cleavage of bonds in the ring are typical. In almost all azines there is a vibrational interaction to a given extent, resulting in a mixing of the closely situated n,π^* and π,π^* states (the proximity effect), which generally increases the probability of radiationless deactivation of the excited states. Therefore the formation of hydrogen bonds and protonation, which assists the destabilisation of the n,π^* states and "removes" this type of vibrational interaction, always substantially alter the luminescence properties, leading as a rule to an increase in the quantum yield of fluorescence.

Heterocyclic amines, like aromatic amines have quite a low ionisation potential and participate in photoionisation and photooxidation, but on the other hand they have a set of properties characteristic of aromatic compounds (the capacity for photosubstitution, photoisomerisation, etc.). The ability of the NH bond to undergo dissociation is also common to all classes of amines.

Recent trends in the theory of the deamination of aliphatic and alicyclic amines

A V Manuilov, V A Barkhash
The Lenin Komsomol Novosibirsk State University
Novosibirsk Institute of Organic Chemistry, Siberian Branch of the USSR Academy of Sciences

ABSTRACT. The different theories that account for the stereochemical characteristics of the deamination of aliphatic and alicyclic amines compared to solvolysis of the corresponding sulphonates and halides are examined. There is a discussion on the recent hypothesis concerning the relative increase of electron demand for the participation of neighbouring groups and bonds in deamination compared to solvolysis, making it possible to predict the direction of skeletal rearrangements in reactions involving elimination of nitrogen and to carry out deliberately such rearrangements when they do not occur in reactions with classical leaving groups. Questions concerning the applicability of the extended Hammond postulate and the Curtin–Hammett principle to reactions that involve decomposition of alkyldiazonium ions are discussed.

The bibliography includes 73 references.

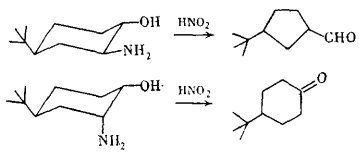
I. Introduction

During the past thirty years hundreds of articles devoted to a comparative study of deamination and solvolysis have been published. There have been a number of reviews in which this question has received special attention.[1–6] The present review, without claiming to be complete, makes an attempt to interpret the results reported earlier in terms of a new hypothesis that has recently been developed concerning the relative electron demand for participation of neighbouring groups and bonds in S_N1-decomposition of aliphatic and alicyclic diazonium ions.[7,8]

The steady interest in what appears at first glance to be a special problem is maintained not only by the contradictions existing to date in the interpretation of the experimental results but also by the close link with the basic concept of carbocations and the debate about nonclassical ions as well as with such fundamental theories as the Hammond postulate and the Curtin–Hammett principle. The above-mentioned hypothesis interprets the application of these postulates to aliphatic deamination in a new way. Moreover, for a long time the theoretical aspect of the problem has relegated the synthetic possibilities of deamination to second place. Meanwhile, the "driving force" of the rearrangements in such reactions is much higher than in traditional solvolysis and it would be tempting to learn how to regulate this process.

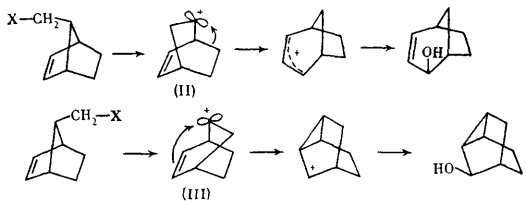
It may be assumed that the synthetic use of deamination has been held in check not so much by the widespread notion of the supposed low selectivity of reactions involving the elimination of nitrogen as by the long absence of an adequate theory that has predictive force in relation to stereochemistry and the composition of the products of such reactions in alicyclic compounds and particularly in aliphatic compounds. In the 1950's the concept of "hot" ions was put forward by a number of authors. This hypothesis, which qualitatively accounts for the "unconventional" rearrangements during deamination, has been followed in various forms in many publications. Various factors have been identified as the source of excess energy. Thus, the high stability of the nitrogen molecule must assist the large exothermicity of the reaction. In turn, it is possible with this hypothesis to conclude that there is "chemical activation" of the carbocations as reaction products. It was suggested that there is non-optimal solvation of the carbocations during rapid decomposition of a diazonium ion. Abnormal charge localisation in relation to the non-optimal geometry of the carbocation has also been proposed, as for example in one of the precursors of all "hot" ions—the hypothetical nonconjugated allyl cation (I):[9]

(I)



On the strength of this, the terms "localised", "free", and "open" carbocations have appeared in the literature together with the term "hot". These terms signify at the same time the classical nature of carbocations from deamination (as opposed to nonclassical cations from solvolysis) as well as the excess energy contained in them. There has been a lively discussion of the concept of "hot" ions in the literature, while, at any rate, for a long time two factors do not seem to have been in doubt—the classical nature of carbocations from deamination and the absence of any S_N2 activity in this reaction.

The ease in forming molecular nitrogen and the probable low energy of activation related to this led to the idea of a "compression" of the energy scale. This hypothesis, which belongs to Huisgen,[10] does not require the concept of a "hot" ion since the reduction in the difference in energies of activation between the competing routes for forming carbocations—processes involving

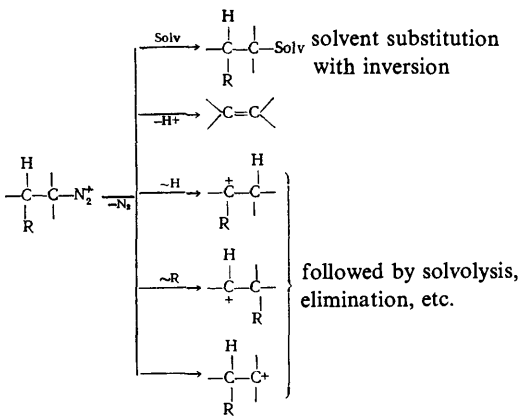


neighbouring groups and bonds (k_Δ) and with assistance from the solvent (k_s)—favours a reduction in selectivity in the choice of routes for forming carbocations as compared to traditional solvolysis. It is easy to see that by using these concepts it is impossible to predict the stereochemical result of a reaction.

It soon became clear that one of the main problems with the idea of "hot" ions is its failure to account for the differences in product composition that occur in the deamination of cyclic diastereomeric amines. For example, if in Scheme 1 the sole intermediate species is the 2-hydroxy-5-t-butylcyclohexyl cation, the reason for such a marked difference in the results of the reaction[11] remains unclear.

Scheme 1

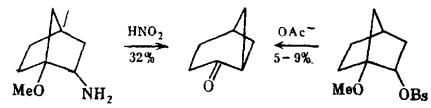
It was shown that this type of structural selectivity is characteristic of deamination[12] to an even greater degree than solvolysis:[13–15]



X = ONs, NH_2.

As a result, opinions that were developed from earlier ideas began to be formed. For example, the so-called "memory effect" is actually an extension of concepts such as the "localised" allyl cation to alicyclic ions. Structures (II) and (III) depict such "twist" cations.

However, it is not difficult to see that such a selective interaction of the cation site with a particular bond resembles anchimeric assistance. Streitwieser came closest to this standpoint when he put forward a familiar scheme of reaction pathways of the diazonium ion (Scheme 2).[16,17] However, he did not regard the synchronous shift of the periplanar group as a factor that assisted decomposition of the diazonium ion. In his opinion the shifts of the hydrogen atoms and alkyl groups cannot be regarded as participation in the sense that the neighbouring group can "push" the departing nitrogen but this process should more accurately be regarded as the neighbouring periplanar group being "pulled" by the departing nitrogen[16] or positively charged region which develops on the α-carbon atom.[17]



Scheme 2

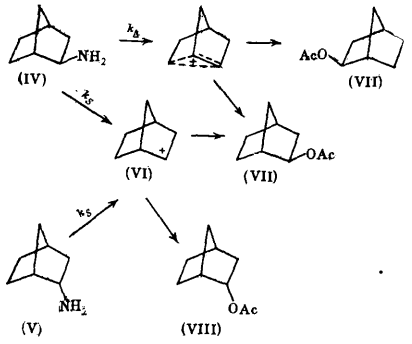
The view of Streitwieser, which was developed as an alternative to the concept of "hot" ions, was criticised (see two reviews[6,18]). It is held that the scheme of Streitwieser was disproved by Collins, who demonstrated that the shift of a neighbouring group to a cation site in a number of cases occurs after the nitrogen has left the molecule (discussed in detail in Section III). In the long run Streitwieser's view was relegated to second place and for a long time was not regarded as promising. The concept of conformational control and "counterion control" became prominent (discussed in Section IV).

With the exception of the "hot" ion concept, all the remaining views are in agreement that during deamination the group that is periplanar to the nitrogen being eliminated mainly migrates. This is important in so far as it can predict the expected direction of skeletal rearrangement in relation to the configuration or conformational composition of the diazonium ion.

However, the above-mentioned concepts are insufficient because they do not shed any light on the causes of the observed rearrangements. While the concept of "hot" ions contradicts many facts and is inaccurate, it remains unclear what exactly causes the neighbouring periplanar bond to migrate during deamination. The same bond is much less prone to rearrangement in solvolysis of the analogous sulphonate:[19,20]

Facts such as these have been increasingly accumulating in the literature (see Section II), but approaches to the solution of this problem have only recently come to light—during a discussion about nonclassical carbocations, in particular, the 2-norbornyl cation.[7] The interest in deamination within the scope of this problem arises in particular because decomposition of diazonium ions was thought for a long time to be the most reliable method of generating classical ions with a "short" lifetime. However paradoxical this may be, it was the use of deamination as a model reaction for studying the property of classical cations that in the long run made it possible for serious contradictions to be revealed. The solution of these led to formulation of the hypothesis that during deamination, when compared to solvolysis, the electron demand for neighbouring group participation as a most important factor determining the stereochemistry in reactions involving elimination of nitrogen is maintained[7] or even increased.[8]

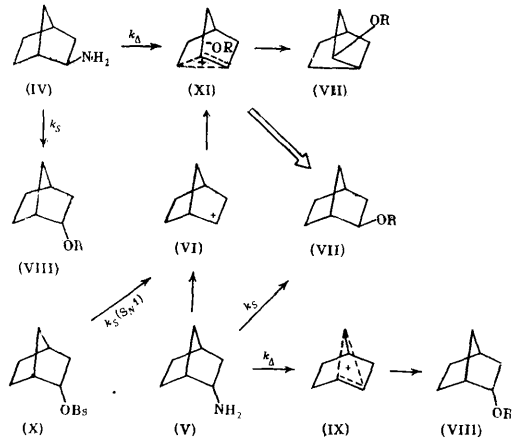
II. Theory of the increase in electron demand for participation in S_N1-deamination compared to S_N1-solvolysis



In the debate about the structure of the 2-nornbornyl cation ideas about the mechanism for deamination of epimeric 2-norbornylamines have undergone fundamental changes during the last 25 years. They can be illustrated by three studies, each of which constitutes a particular stage in the solution of the problem.

Initially Corey et al.,[21] by studying the deamination of optically active epimeric 2-norbornylamines (IV) and (V) with sodium nitrite in acetic acid, analysed the combined mixture of acetates, obtained

after reduction and acylation of the initial reaction mixtures, which contained not only acetates but also alcohols. This method of analysis, which was typical of the early studies in this area, led the authors to the mistaken conclusion that there was an approximately equal ratio of *exo*- to *endo*-products, retention of optical activity for the reactions of both amines, and hence a common intermediate—the classical cation (VI).



Berson et al.[22] subsequently studied in greater detail the composition of the acetate fractions that were isolated from the initial reaction mixtures, and they came to the conclusion that the assumption by Corey of a common intermediate for all products was incorrect since the degree of racemisation for *exo*-product (VII) and *endo*-product (VIII) was not the same. The values obtained for the acetate fractions were more in line with the reactions occurring according to Scheme 3. The relatively low ratios of *exo*- to *endo*-products [(VII):(VIII) ranging from 19:1 to 45:1] and the partial retention of optical activity suggest at first glance that there is a reduced degree of σ-participation in deamination compared to solvolysis, where this ratio is ~300:1 and racemisation occurs.[23]

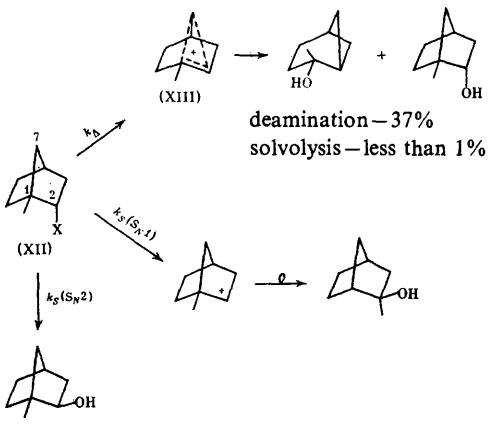
Scheme 3

Finally, Kirmse et al.[7] recently once again carried out a similar study using a wide range of media. By varying the polarity of the medium it was possible to establish that different routes—k_Δ and k_s (the latter was of two types: S_N1 and S_N2)—were competing in the decomposition of diazonium ions (Scheme 4).

Scheme 4

The formation of *endo*-alcohols (or esters) (VIII) increases for the *exo*-amine (IV) and decreases for the *endo*-amine (V) as the polarity of the medium is reduced. This is an indication that the *endo*-products (VIII) are formed from the epimeric amines by different reaction routes. The *endo*-products (VIII) are probably formed from *exo*-amine (IV) by an S_N2-type of route k_s, but they are formed from *endo*-amine (V) by the k_Δ route since an S_N1 mechanism is preferred when there is an increase in polarity of the medium. According to Kirmse and Siegfried[7] the classical cation (VI) can be excluded for the reason that in an aqueous medium which is favourable for an S_N1 mechanism there is the highest proportion of *endo*-attack on the chiral intermediate by the nucleophile. This intermediate may be the nonclassical carbocation (IX), which is formed as a result of participation of the C(1)–C(7) bond.

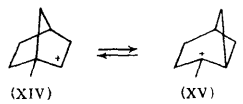
The question arises: what is the reason for this participation, which does not occur in solvolysis of the analogous sulphonate? Kirmse suggests that the k_Δ process usually has the lowest energy barrier and therefore frequently occurs in solvolysis. If the k_Δ route is accompanied by an increase in steric strain in the ring, as in the case of ion (IX), the k_s process becomes energetically more favourable and it is the only one to take place in solvolysis of the corresponding *endo*-brosylate (X). However, *endo*-amine (V), which reacts when there is "compression" of the energy scale, proves to be capable of reacting by the less favourable k_Δ route. Although Kirmse and Siegfried[7] consider that this situation is an exception to the general rule, it should be recognised that the conclusion made by them can be formulated as a hypothesis about the increase (if only in certain cases) in the degree of σ-participation in deamination compared to solvolysis. However, the authors only note that the study they carried out does not support the idea of a classical 2-norbornyl cation as the precursor of *endo*-2-norbornyl products.



For the deamination reactions of *exo*-amine (IV), Kirmse and Siegfried[7] concluded that the reactions occur by the k_Δ route via the nonclassical carbocation (XI), which is incorporated in an asymmetric ion pair, resulting in a preferred *exo*-attack by the nucleophile on the site of nitrogen elimination. However, it is noted here[7] that from the data obtained it is not possible to make a definite choice between the nonclassical carbocation structure (XI) and a rapid equilibrium involving "*exo*-selective" classical cations.

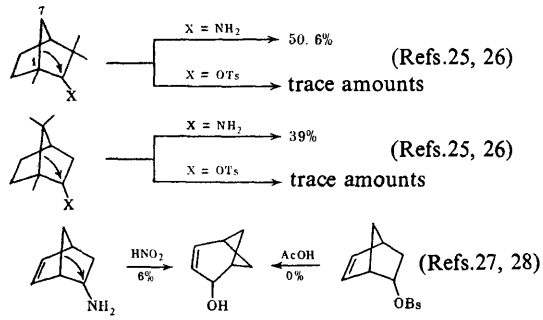
The alternative stated above is typical of the debate about the structure of the 2-norbornyl cation and we are convinced that it is predetermined by the choice of model compound, since 2-substituted norbornanes have a number of basic disadvantages in this capacity. The most important of them are: the Wagner–Meerwein rearrangement on elimination of 2-*exo*- as well as 2-*endo*-substituents in many cases only occurs with displacement of the C(1)–C(6) bond, resulting in the initial norbornane system; the directions of attack by the nucleophile coincide for the nonclassical 2-norbornyl cation (for stereoelectronic reasons) and for the classical 2-norbornyl cation (for steric reasons); the classical cation readily changes to the nonclassical; finally, a quantitative determination of the degree of epimeric purity of the initial compounds appears quite difficult.[1,8]

However, the introduction of very simple substituents (for example, methyl groups) into the skeleton of the same norbornane makes the model more convenient. A comparison of the results of deamination and solvolysis of 1-methyl-2-*endo*-substituted norbornanes with structure (XII), as a result of the 1,2-shifts of the C(1)–C(7) bond that occur (Scheme 5), clearly indicates a considerable σ-participation of this bond in deamination (water) but not



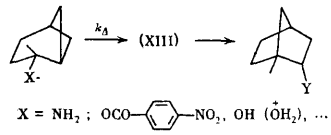
in solvolysis (aqueous acetone)†.[24]

Scheme 5



X = NH_2; *p*-$OSO_2C_6H_4$–...–...Me, –Br, –NO_2

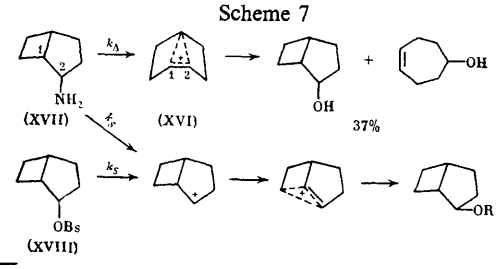
The important role of the nonclassical carbocation (XIII) in this deamination reaction follows from the direction of attack by the nucleophile on the *endo* side and also from the very low probability of an "imitation" of cation (XIII) by rapid inter-conversion of two completely different ions — the secondary (XIV) and tertiary (XV):



The case studied by Kirmse et al.[24] is also classed as an exception to the rule. However, 1,2-shifts of the C(1)–C(7) bond are not rare for deamination, but they hardly ever occur in solvolysis of norbornyl derivatives. Solvolysis leads to a displacement of the C(1)–C(6) bond without dependence on the configuration of the leaving group. In deamination, on the other hand, there is a clear dependence of the direction of the skeletal shift on the configuration of the leaving group, which suggests the idea of an increase in demand for the participation of neighbouring periplanar bonds in the elimination of nitrogen. A certain amount of conjecture about the change in demand for participation when going from solvolysis to deamination of compounds with a bicyclo[2.2.1]heptane skeleton gives Scheme 6,‡ which depicts a number of similar examples in outline.

Scheme 6

It should be mentioned that the reverse rearrangement of the norpinane skeleton to norbornane occurs with the same ease in both solvolysis and deamination; in this case every indication is that participation of the C(1)–C(7) bond occurs:[29]

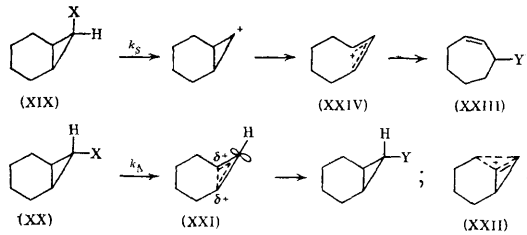


A number of problems may arise here. For example, why should the compression of the energy scale during deamination and the lack of this during solvolysis occur only in rearrangements of the type "norbornane–norpinane" and not in the reverse rearrangement or in rearrangements of *exo*-amines and sulphonates in the norbornane series. Then, if the examples of rearrangements of the type "norbornane–norpinane" given above are the exception, what should be considered the rule?

In the meantime these questions can be eliminated if it is assumed that during deamination there is an increased demand for the participation of the neighbouring periplanar band in any structures. In fact, the relative increase in the proportion of k_Δ in deamination is exhibited not only in models with a bicyclo[2.2.1]heptane skeleton.

For example, the "σ-route" to the nonclassical cation (XVI) can occur in deamination of amine (XVII) but not in solvolysis of the analogous brosylate (XVIII)[30] (Scheme 7). Kirmse et al.[30] also account for this phenomenon as an exception to the general rule. The bridging ion (XVI) is sterically unfavourable and is formed during deamination only as a result of "compression" of the energy scale together with products from the more "favourable" k_s process. In the case of solvolysis, where the k_Δ and k_s processes differ in energy much more considerably, it is only the k_s route, which is more favourable for this structure, that occurs.

Scheme 7



† Unfortunately, a comparison of solvolysis and deamination in the same solvents is seldom to be found in the literature. However, in our opinion, the significant differences that occur on going from solvolysis to deamination cannot solely be due to medium effects.[8]

‡ See also Scheme 5 and the reactions at the end of Section 1. The corresponding *exo*-epimers react almost exclusively with a shift of the C(1)–C(6) bond in both reactions.

It may be assumed, however, that the reason for the formation of the clearly sterically hindered carbocation (XVI) is the strong demand for participation in deamination and not "compression" of the energy scale. The latter may be illustrated by the following example.

The *endo*-tosylate (XIX), in which participation of the neighbouring carbon-carbon bonds is impossible because of the skeletal structure, reacts more rapidly than the *exo*-isomer (XX),[31] although in the latter participation of a C–C bond is probable, judging by the selectivity of nucleophilic attack (Scheme 8)§.

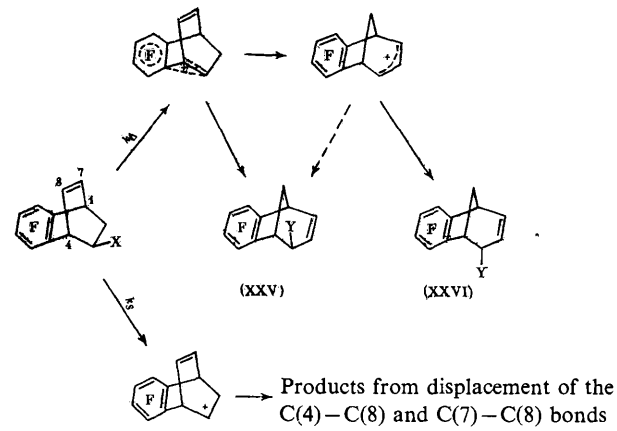
Scheme 8

X = NH_2; OTs, Cl, ... Y = OH, Br, OMe, OAc.

Thus, for this skeleton the barrier for the k_Δ process is definitely higher than the barrier for k_s, which, following the logic of Kirmse, unites this case with the previous one (Scheme 7). However, both solvolysis[31] and deamination[32] of compounds with the skeleton of (XIX) and (XX) give the same results for each of the epimers. Meanwhile, "compression" of the energy scale ought to lead to the formation of a considerable proportion of product (XXIII) in deamination of amine (XX), which in actual fact does not occur. The impression is created that participation of the neighbouring bonds assist to the same extent the "difficult" elimination of both the sulphonate group and nitrogen and starts to occur much earlier than the moment when the developing cation site may be stabilised by the formation of the allylic system (XXIV).

It is necessary to develop a more detailed hypothesis about the relative increase in demand for participation in deamination and substantiate the possible reasons for such an increase. Manuilov and Barkhash[8] made a comparative study of solvolysis and deamination of model sulphonates with tetrafluorobenzobicyclo[2.2.2]octadiene and tetrafluorobenzobicyclo[2.2.2]octene skeletal structures and obtained quantitative data that characterised the contribution of the k_Δ process in each reaction (one of the examples is shown in Scheme 9).

The following rules were established:



1. The preferred direction of the skeletal shift in both reactions is determined by the configuration (*exo*- or *endo*-) of the group being eliminated.

2. Selectivity in the choice of the direction of rearrangement and nucleophilic attack increases as the solvating power of the medium towards cations decreases (in the series DMSO > MeOH > AcOH). In this case the stereoselectivity of nucleophilic attack (ratio of *exo* to *endo* products) is substantially higher for deamination.

§Sliwinski et al.[31] propose the nonclassical structure (XXI). In our opinion the nonclassical carbocation (XXII) is more probable. In any case it is significant that the *exo*-isomers (XX) react by the k_Δ route while the *endo*-isomers (XIX) react by the k_s route in both reactions.

3. Comparison of the mixtures of acetates from deamination with solvolysis products generally indicates a relative decrease in the contribution of the k_Δ process in the case of deamination (agrees with Berson's results on acetate products from deamination[22]).

Scheme 9

medium—AcOH; *exo*/*endo* = (XXV)/(XXVI);
X = NH_2, Y = OH: $k_\Delta = 86 \pm 5\%$, *exo*/*endo* = (79%)/(2%)
X = OTs, Y = OAc: $k_\Delta = 89 \pm 6\%$, *exo*/*endo* = (51%)/(32%).

4. The alcohol fractions of the deamination products show a reverse trend. The relative contribution of the k_Δ process in deamination generally does not decrease or even increases compared to solvolysis (contradicts Berson's results but is in agreement with Kirmse's results[7,24,30]).

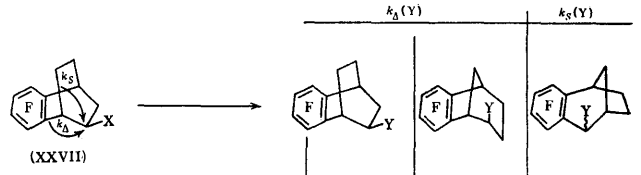
5. Nucleophiles have a greater tendency to attack the site of nitrogen elimination in deamination reactions, which may be due to the formation of an asymmetric ion pair (agrees with the conclusions of Kirmse and Siegfried[7]).

The rules established are interrelated and do not contradict each other as may appear at first glance. It is likely that with an S_N1 mechanism for the same model there cannot occur a relative decrease in the contribution of k_Δ in the case of the acetate products from deamination and at the same time an increase in contribution of this process for alcohol products. It is probable that the acetates are formed to a considerable extent by an S_N2 mechanism, so comparison of demand for participation should be carried out only "within" the S_N1 routes of solvolysis and deamination, this condition being more consistent with the alcohol fraction for the latter reaction.

In order to explain the rules propounded above from a single standpoint, it must be assumed that the observed increase in the share of the k_Δ process and the stereoselectivity of nucleophilic attack in deamination results from the increase in demand for participation in the S_N1 process of nitrogen elimination compared to a similar elimination of sulphonate or other group. The main reason for this may be a less favourable solvation of the transition state and carbocation (more precisely, cation site) in the more rapid process of decomposition of the diazonium ion. The idea of a less favourable solvation within the intimate ion pair is not inconsistent since at the moment that it is formed within the solvation cage the counterions

are separated by a nitrogen molecule (Scheme 10, compare with three studies[18,33,34]).

Scheme 10



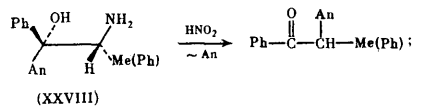
$$2HNO_2 \rightleftarrows N_2O_3 \xrightleftharpoons{Solv-OH} Solv-ONO + HNO_2;$$

$$R-NH_2 + Solv-ONO \rightarrow R-\overset{+}{N}H_2-N=O\ldots Solv-O^- \rightarrow$$

$$\xrightarrow{\sim H^+} R-\overset{+}{N}H=N-OH\ldots Solv-O^- \xrightarrow[-N_2]{\sim H^+} R^+\ldots N_2\ldots H_2O\ldots Solv-O^-.$$

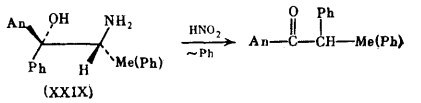
The formation of a cation site in deamination as against solvolysis is comparable, if not to gas-phase conditions, at least to substantially less nucleophilic conditions, namely, it corresponds to a considerable reduction in the solvating ability of the medium. In this case deamination in AcOH, for example, should give the same stereochemical result as solvolysis does in a much more ionising and less nucleophilic medium such as CF_3COOH. This actually occurs (Scheme 11). In this case, as was to be expected, the reactions of the model compounds (XXVII) demonstrate the relative increase in contribution of k_Δ on going from solvolysis to deamination in the same medium ($\sim$49% k_Δ in acetolysis compared to 82% k_Δ in deamination in AcOH).[8]

Scheme 11



(XXVII)

	k_Δ(Y)	k_s(Y)
(Ref.8) X=NH_2 in AcOH, k_Δ=82±1%:	59%(OH)	22%(OH)	14%(OH)
(Ref.35) X=OTs in CF_3COOH, k_Δ=75±4%	45% ($OCOCF_3$)	25% ($OCOCF_3$)	21% ($OCOCF_3$)
(Ref.35) X=OTs in AcOH, k_Δ=49±6%	19%(OAc)	15%(OAc)	37%(OAc)



The special conditions for elimination of nitrogen probably have the result that the electrons of the neighbouring periplanar bond ("internal nucleophile") gain an advantage in attack on the cation site over any other nucleophile. In this case the demand for participation may be so great that the determining role is played not by the migrating ability of the participating group but its optimal orientation relative to the developing cation site, namely, a periplanar position in relation to the C–N bond in a given conformation or configuration.

This property of diazonium ions is widely known since it "violates" the Curtin–Hammett principle in the case of pinacolic deamination (Scheme 12).[36,37]

Scheme 12

(XXVIII)

(XXIX)

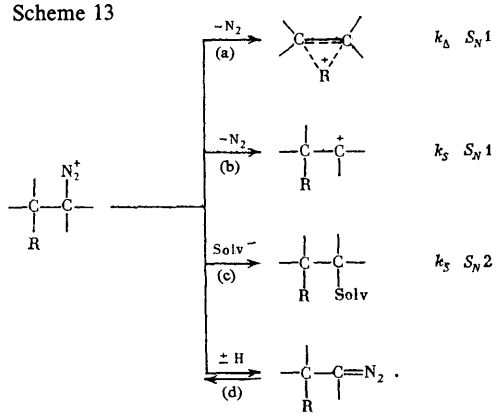
An = *p*-$MeOC_6H_4$.

In solvolysis the ratio of products formed from the different conformations of the substrate does not depend on the relative populations of the conformations and is determined solely by the free energies of the transition states leading to these products. In deamination this rule does not apply. Thus, diastereomer (XXVIII) reacts with preferred migration of anisyl while migration of phenyl is typical for diastereomer (XXIX). As Kirmse notes,[2] the nucleophilicity of the aryl group is not a factor that regulates the choice of migrant (the migrating ability of anisyl is higher in reactions with neighbouring-group participation). The ratio of products is determined by conformational control—from the most stable conformer with a *gauche*-orientation of OH and NH_2 groups stabilised by intramolecular hydrogen bonding.

This definition of conformational control in deamination is typical. In our view the electronic and conformational factors are incorrectly contrasted here, which on the whole is typical for many publications¶. It is more accurate to say that electronic factors assist the exhibition of conformational control. Among the former the demand of the cation site prevails over the nucleophilicity of the migrant. The concept of conformational control in deamination acquires a logical basis from such a statement.

If it is assumed that anchimeric assistance compensates the insufficient solvation of the cation site in decomposition of a diazonium ion, the retardation of 1,2-shifts at the stage of the nonclassical ion becomes clear. It is advantageous for a poorly solvated carbocation to preserve a nonclassical delocalisation and, moreover, the lifetime of an intimate ion pair within the solvation cage (see Scheme 10) may be relatively short. This corresponds to an increase in the ratio of *exo*- to *endo*-products in the reaction mixtures. The lack of symmetry of the intimate ion pair results in preferred attack on the site of nitrogen elimination.[7,8]

This explanation does not contradict the fact that in the acetate fractions of deamination products there is sometimes a relative increase in the share of the k_s process compared to solvolysis. In our opinion this occurs not because of a suppression of the k_Δ process for some reason "within" an S_N1 mechanism for forming acetates but is related to the increase in the relative role of an S_N2-type of k_s process that is typical for charged nucleophiles, including the acetate anion†. Thus, the theory of the increase in demand for participation in deamination compared to solvolysis applies only to S_N1 routes of both reactions.



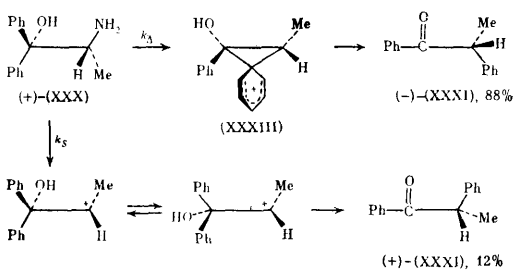
The theory advanced above can be summarised with the help of Scheme 13. The ratio of contributions of the competing routes (a)–(c) depends on the structure of the aliphatic part of the diazonium ion, the nucleophile, and the solvent. However, compared to solvolysis, the increase in demand for participation in deamination must always lead to a more effective shift of the neighbouring bond under conditions where the analogous sulphonates are often only able to react by an S_N2 mechanism. Hence the observed "reduction in selectivity" on going from solvolysis to deamination. On the other hand, the increase in electron demand makes it possible in deamination reactions to observe the shift of groups and bonds

¶ For example, in relation to the reactions of diastereomers (XXVIII) and (XXIX) Morrison and Boyd mention that the course of the reaction is determined more by conformational factors than electronic.[38] A similar but more expanded view is given by Bundel' et al.,[39] who assume that since the energy required for cleavage of the C–N bond is not great and lies within the conformational barriers, in the decomposition of the diazonium ion the determining factor for the choice of a particular conversion route is the initial confor-mation, in contrast to solvolytic reactions where the main role in this choice is played by the neighbouring group.

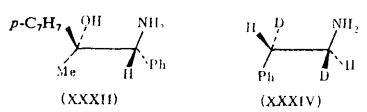
† For S_N2 processes in the decomposition of diazonium ions, see the studies of Kirmse[5] and Collins[6] and the references in them.

that do not migrate in solvolytic reactions. Hence, using this approach it is possible to explain satisfactorily not only the increased tendency towards rearrangements in deamination reactions, which is a well-known fact, but also to carry out rearrangements intentionally in those cases where the conformational composition (or configuration) of the initial amine is reliably known.

Scheme 13



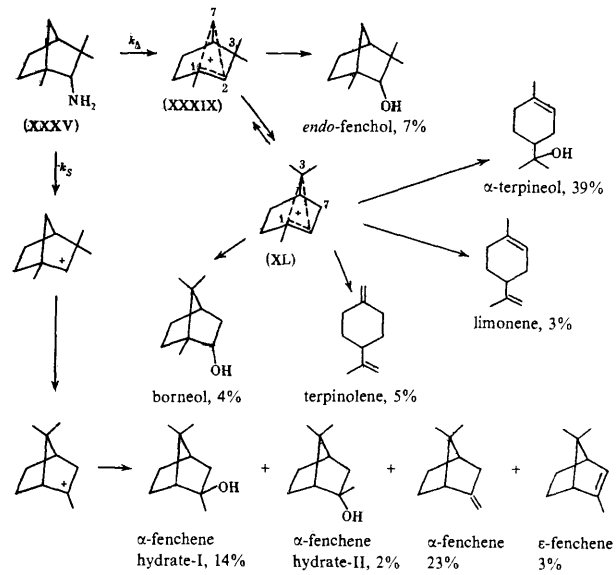
III. A critical examination of the literature data on a comparative study of deamination and solvolysis



In accordance with Schemes 2 and 13 the diazonium ion is the "branching point" in the competing pathways of deamination. As was mentioned above, Collins published a number of studies (see his review[18]) in which the scheme of Streitwieser is criticised. It is therefore necessary to examine the arguments of Collins in relation to the new Scheme 13.

In deamination of the optically active amine (+)-(XXX) in acetic acid, an appreciable quantity of product (+)-(XXXI) is obtained, being formed as a result of migration of a phenyl group to the cation site obviously after the nitrogen has left the molecule (Scheme 14).[40–42]

Scheme 14

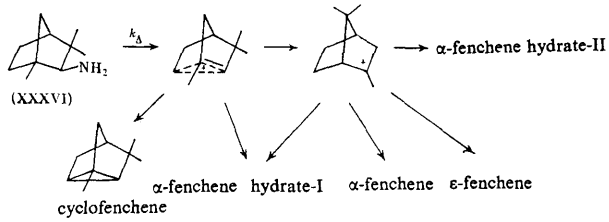


Retention of configuration is even more substantial (58%) compared to inversion in the case of the deamination of amine (XXXII) in the same medium.[42]

In the opinion of Collins these results contradict the postulate of Streitwieser that the diazonium ion prior to the carbocation serves as a branching point of the competing reactions, since the displacement of the neighbouring group occurs after the change in conformational state of the carbocation. In actual fact there is no contradiction with Scheme 13, as the formation of product (+)-(XXXI) corresponds to route k_s(b). However, at least a proportion of compound (−)-(XXXI) may be obtained by route k_Δ(a) via the phenonium ion (XXXIII) (Scheme 14). If the amino group is situated on a benzyl carbon atom rather than a secondary carbon atom, the k_s(b) process successfully competes with the k_Δ process. This specific example cannot, of course, be extended to deamination as a whole as Collins has done, assuming that "migration of hydrogen or aryl... in most cases occurs after decomposition of the diazonium ion."[18] For example, it is not surprising that in the reaction of the optically active amine (XXXIV), which has an amino group on a primary carbon atom, only processes k_Δ and k_s(c) compete.[43,44]

The view of Collins is disproved most convincingly in those cases where comparative data on deamination and solvolysis are available. Since the increase in demand for participation on going from solvolysis to deamination occurs in $S_\Delta 1$ routes of these reactions, model compounds that mainly give rearranged products are of particular interest. The reactions of model tosylates and amines of fenchane and bornane fully satisfy this requirement.[25,26] It is worth considering these results of Hückel et al. in greater detail on the basis of Scheme 13, when it is borne in mind that previously they were of interest to Collins from the point of view of deamination only occurring via classical ions.[42] The latter approach is not able to explain certain facts that can readily be accommodated by the assumption that processes k_Δ and k_s occur at the same time, as is shown in Scheme 15 for deamination of *endo*-fenchylamine (XXXV)‡.

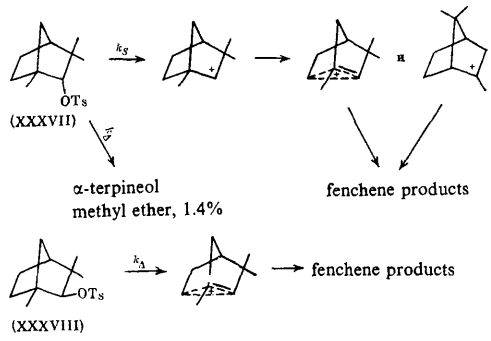
Scheme 15



In fact, deamination of *endo*-amine (XXXV) gives in total more than half of the products from displacement of the C(1)−C(7) bond whereas the *exo*-amine (XXXVI) rearranges almost exclusively with

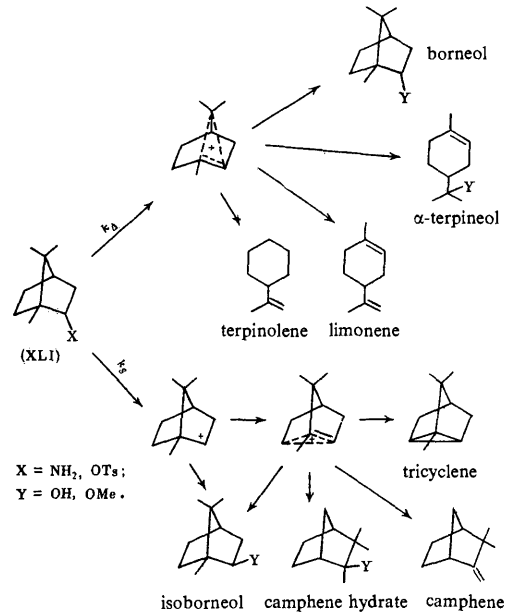
‡ Here and subsequently in Schemes 15–18, products with a content of less than 1% of the reaction mixtures are not given.

migration of the C(1)–C(6) bond (Scheme 16).



Scheme 16

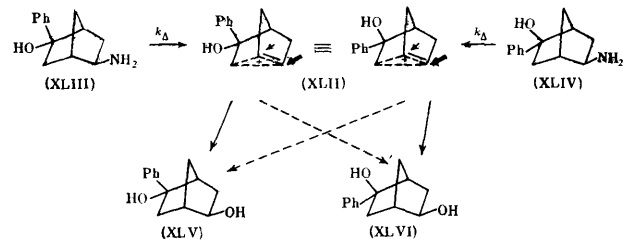
At the same time, in the solvolysis of the epimeric fenchyl tosylates (XXXVII) and (XXXVIII) such a dependence of the direction of skeletal displacement on the configuration of the leaving group does not occur (Scheme 17). This indicates that deamination of amine (XXXV) occurs to a considerable extent via the k_Δ route involving the C(1)–C(7) bond whereas in solvolysis of the analogous tosylate (XXXVII) there is virtually no participation of this bond. On the basis of Scheme 15 the results of deamination via the k_Δ route conform completely with the stereoelectronic requirements of the nonclassical carbocations (XXXIX) and (XL). This idea, in contrast to the view of Collins, can be used to explain the absence of *exo*-fenchol in the mixture while the yield of *endo*-fenchol is 7%. Similarly, it must be assumed from the isolation of borneol in the absence of isoborneol (the *exo*-epimer) in the mixture that nonclassical carbocation (XXXIX) isomerises to nonclassical carbocation (XL). The interconversion of these carbocations is postulated in the decomposition of the corresponding sulphonyl hydrazones (see the review of Ando[3]).



A quantitative determination of the relative contribution of the k_Δ and k_s processes in deamination and solvolysis can be made from Schemes 15–17. The ratio of k_Δ to k_s for the deamination of *endo*-fenchylamine (XXXV) is 1.4:1 in water and zero (in AcOH) or close to this value (in MeOH) for solvolysis reactions of *endo*-fenchyl tosylate (XXXVII). It should be emphasised that the k_Δ and k_s processes are compared exclusively on the basis of the S_Ni mechanism.

Scheme 17

The latter condition is not completely fulfilled for the model bornane compounds (XLI) (Scheme 18). It may be assumed, however, that the contribution of the S_N2-type mechanism k_s(c) is small, on taking into account the small content of inverted bornane products in the resulting mixtures. Assignment of the yields of products from the k_Δ and k_s routes in accordance with Scheme 18 leads to the following ratios of k_Δ to k_s: ~0.7:1 for deamination in water and ~0.005:1 for methanolysis of the tosylate (for quantitative data on the product content, see the studies of Hückel et al.[25,26]).



Scheme 18

In a number of alicyclic compounds one of the main arguments of Collins et al. in favour of the intermediate formation of a classical cation is as follows: the nonclassical carbocation (XLII) cannot be a common intermediate species in the reaction of amines (XLIII) and (XLIV) since each of them forms products (XLV) and (XLVI) in different ratios (2.3:1 and 1:1.7 respectively).[18,42] In the opinion of Collins, this fact suggests an equilibrium of classical cations which has not been reached, since solvolysis of the analogous sulphonates with formation of an intermediate nonclassical ion gives the same ratio of products (XLV) and (XLVI).[42]

It should be stated that the above-mentioned tendency of the regioselectivity of nucleophilic attack in deamination[7,8] to change can readily be used to explain this result with the concept of nonclassical ions. In the deamination of amines (XLIII) and (XLIV) the same nonclassical carbocation (XLII) is probably formed, being bonded in different ion pairs, in each case the nucleophile attacks the site of nitrogen elimination with a certain preference. In this connection the predominance of product (XLV) in the deamination of amine (XLIII) becomes clear, as does the predominance of product (XLVI) in the deamination of (XLIV). This is shown in Scheme 19.

Scheme 19

In the studies reviewed, Collins et al. include products whose content in the mixture is extremely small (for example, 0.114% and 0.039%) in their discussion of the mechanism, while the reaction mixtures from deamination are analysed without separating the

alcohol and acetate products.[42] The example given has been discussed since it is a good illustration of the experimental difficulties in the comparative study of solvolysis and deamination, particularly in models of norbornane compounds. An analysis of the experimental data and choice of routes for forming deamination products is often very troublesome not only because of the variety of products obtained but also as a result of possible competing reactions that take place by S_N1 and S_N2 mechanisms.[45] Berson indicates the difficulty of obtaining reproducible results.[22] There are features that are quite often ignored such as the need for a quantitative determination of the epimeric purity of the initial amines and sulphonates, the possibility of the diazonium ion epimerising via a diazoalkane, the occurrence of "internal re-entry" (trapping, Ed. of translation) of the leaving group in solvolysis, the influence of micellar effects in deamination, and the effect of temperature differences when conducting the reactions.[8] These complications to some extent help to answer the question as to why the substantial contribution of processes with anchimeric assistance in deamination often escapes the attention of research workers. Some of these factors are considered below in greater detail.

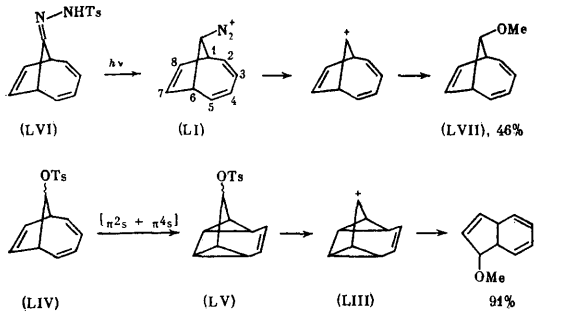
Thus, in Berson's study[22] discussed above, an analysis of a mixture of only some acetate products of deamination leads to the conclusion that there is a reduction in the degree of σ-participation compared to solvolysis, not in a "pure" S_N1 process but in a combination of S_N1 and S_N2 reaction routes.

Internal re-entry of a sulphonate group can only affect the comparability of results in certain cases. For many purposes titrimetric rate constants (k_t) rather than polarimetric rate constants (k_α) (for optically active sulphonates) can be used, since the error introduced is small; in solvents such as water and trifluoroacetic acid the ratio of the constants $k_\alpha : k_t$ is $\sim 1:1$, in methanol it is 1.2:1, and in aqueous acetone 1.4:1.[46] However, in ethanol (2.94:1) and acetic acid (3.46:1) the difference between k_α and k_t should probably be taken into account. On the whole this factor may result in a "thermodynamic" stereochemistry of the solvolysis products, which quite often imitates the stereochemistry of the k_Δ process. At the same time deamination, which is devoid of internal re-entry of leaving nitrogen, gives a purely "kinetic" product stereochemistry, which as a rule corresponds to competing k_Δ and k_s processes.

A factor such as micellar effects in deamination should be taken into account in a comparative study of the two reactions. It may be concluded from the literature data that the formation of micelles of diazonium ions is typical for relatively stable primary diazonium ions.[47] In this case the change in the stereochemistry of nucleophilic attack on reaching a critical micellar concentration occurs only for superweak nucleophiles such as perchlorate, fluoroborate, tosylate, and camphor sulphonate anions;§ such effects do not occur in "micellar" deamination in the presence of Cl^-, Br^-, and AcO^- anions.[50] In checking the reproducibility of the results it is useful to vary the concentration of the initial amine. Thus, in one study[47] micellar effects of primary diazonium ions occurred when the concentration was changed approximately by a factor of three.

The effect of temperature changes on the comparability of the results of solvolysis and deamination should also be considered. Usually deamination is carried out at temperatures close to room temperature while solvolysis occurs at an appreciable rate at higher temperatures, and the difference can reach 100 °C or more. In this connection the results of direct measurement of the rate constants of the k_Δ and k_s processes in the acetolysis of β-arylethyl tosylates at different temperatures[51] are of interest. The ratio of k_Δ/k_s for the model tosylates (XLVII)–(XLIX) changes symbatically (nonlinearly) with temperature, the increase in temperature always involving a more rapid increase in k_Δ (Fig. 1). For the acetolysis of 2-phenylethyl tosylate (XLVII) extrapolation of the linear dependence of log (k_Δ/k_s) on $1/T$ to room temperature gives a lower value of the ratio of k_Δ/k_s ($\sim 0.6:1$) compared to that calculated for the deamination of 2-phenylethylamine (L) in AcOH at room temperature ($\sim 0.8:1$).[52] Despite the proximity of the extrapolation made by us, it can be qualitatively maintained from this result that the increase in the contribution of the k_Δ process in deamination compared to solvolysis does not result from the different temperature conditions for carrying out the reactions. On the other hand, the higher temperature of solvolysis levels out the differences in the ratios of k_Δ/k_s due to the properties of the leaving groups. This is probably related to a deterioration in solvation conditions of carbocations when the temperature is increased. It cannot be excluded that the S_N2-type k_s(c) processes in solvolysis are suppressed, since this mechanism requires a strict orientation of the nucleophile. Thus, the phenomenon of "temperature levelling" indirectly confirms the concept that the increase in demand for participation may be due to insufficient external solvation. It follows from the results discussed that this property of nitrogen as a leaving group may remain unnoticed in a comparative study of solvolysis and deamination if the temperature conditions for conducting the reactions differ sufficiently strongly.

IV. The Hammond postulate and Curtin–Hammett principle applied to a comparative study of deamination and solvolysis



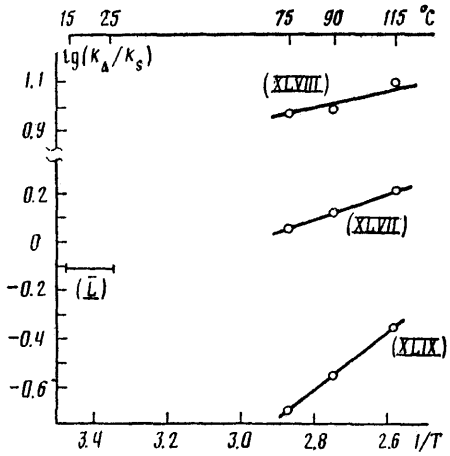
As a result of the widespread propagation of ideas about the obviously classical nature of carbocations in deamination reactions there have been attempts to use such reactions as a model for a typical process that has an "early" transition state. Extracts from many studies, including comparatively recent ones, can be quoted. For example: "deamination ... occurs with formation of an energy-rich diazonium ion, which makes the transition state of its decomposition 'early', i.e., without any change in nuclear coordinates (vertical ionisation). As a result of this, deamination may produce cations with an undistorted geometry that are not formed in solvolysis; the latter lead directly to more stable bridged forms."[3]

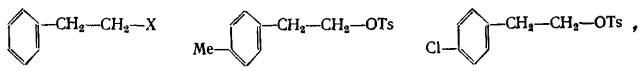
Another example is: "...solvolysis and deamination give a fundamentally different result. Solvolysis with its 'late' transition state on the reaction coordinate assists the transposition of the atomic nuclei in such a manner that the route is attained with the minimum of energy. On the other hand, deamination, which starts with an energy-rich diazonium ion passes through its transition state 'earlier' and without any significant distortion of the positions of the nuclei."[53] At first glance, the latter conclusion follows on logically from the stereochemical result shown in Scheme 20. The essential difference between solvolysis and deamination of compounds with the same skeleton is identified by Kirmse as the significant example

§ For example, this important phenomenon as well as the possibility of reactions occurring by an S_N2 mechanism has not been taken into account in studies[48,49] on the deamination of alkylamines in the presence of superweak nucleophiles.

of the formation of a "free carbocation" during decomposition of a diazonium ion.[5]

Scheme 20





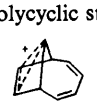


Figure 1. Dependence of the ratio of log (k_Δ/k_s) on temperature in the solvolysis of tosylates (XLVII)–(XLIX) from the data of Jones and Coce[51] and the ratio of log (k_Δ/k_s), calculated from the results of Coce,[52] in the deamination of amine (L) at room temperature; the ratio of k_Δ/k_s was obtained with the following assumptions: 1-phenylethanol (yield 18%) is formed by route $k_s(S_Ni)$; the proportion of k_Δ in the formation of 2-phenylethanol (yield 82%) is approximately equal to double the percentage of migration of the label: $k_\Delta/k_s \sim 44/(38 + 18)$;

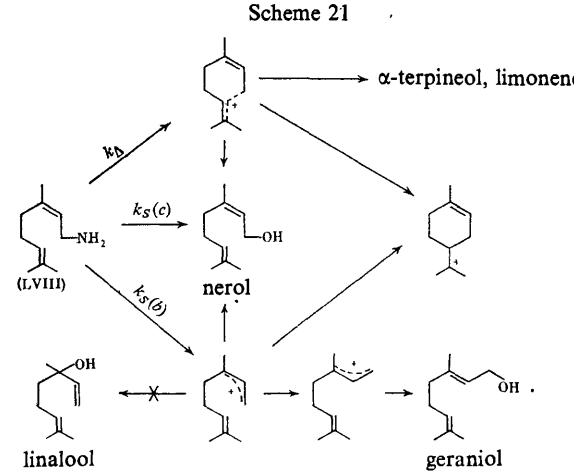
(XLVII) X = OTs, (L) X = NH_2. (XLVIII) (XLIX)

Meanwhile, an essentially different interpretation of Kirmse's results[53] is possible. The diazonium ion (LI) decomposes by the k_Δ route with anchimeric assistance from the C(7)–C(8) bond, giving the nonclassical carbocation (LII), whereas solvolysis occurs via the classical cation (LIII) (k_s), which is stabilised through the formation of a polycyclic structure.[8]

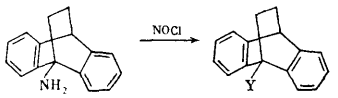


(LII)

In fact, from the equal rates of solvolysis of epimeric tosylates (LIV) and the lack of dependence of the composition of the reaction mixture on the configuration of the sulphonate group and the nature of the solvent, Kirmse and Voigt[53] correctly assume that the rate-limiting stage of solvolysis is formation of the intermediate tosylates (LV). However, no account was later taken of the essential characteristic that the formation of a similar polycyclic structure during the photochemical reaction of tosyl hydrazone (LVI) is prevented by orbital symmetry. An intramolecular Diels–Alder reaction in the rigid bicyclo[4.2.1]nona-2,4,7-triene system permits only a supra-suprasurface cycloaddition involving six electrons [$\pi 2_s + \pi 4_s$], which is photochemically forbidden. Consequently, stabilisation of the cation site during photochemical deamination cannot occur in the same way as in thermal solvolysis, and it probably occurs by intramolecular participation of the C(7)–C(8) bond to form ion (LII), which is suggested by the formation of only one of the two possible epimeric products (LVII).

The study by Bunton et al.[54] concerning a comparative deamination of nerylamine (LVIII) and solvolysis of the phosphate and chloride with the same skeleton is a similar example. The application of Scheme 13 from Section II to nerylamine gives Scheme 21, in which the k_Δ and k_s routes cannot be separated quantitatively. Nevertheless, Bunton et al.,[54] by indicating the relatively lower yield of cyclisation products in deamination, conclude that π-participation is considerable in the formation of the transition state for neryl chloride and neryl phosphate whereas elimination of nitrogen from the diazonium ion does not require neighbouring-group assistance.

The following features of this deamination reaction should be mentioned. Firstly, the total yield of identified products is low but the relative proportion of cyclisation products is almost the same as in solvolysis. Secondly, in deamination there is virtually no linalool formed, which again supports the idea of a change in regioselectivity in this reaction and also indirectly suggests a lower contribution of the k_s(b) process, since solvolysis gives 20–25% linalool against 9–14% geraniol in deamination. However, on the whole, a conclusion about the quantitative ratio of the k_Δ to k_s processes cannot be made using this model compound, as is evident from Scheme 21. Nevertheless, the results discussed by Bunton et al.[54] are used to illustrate the applicability of the Hammond postulate.



Scheme 21

The account of the different versions of the theory of an "early" transition state in deamination could be continued. However, the material presented in the previous sections suggests the reverse:

participation probably starts at the early stages of nitrogen elimination and the transition state is thus structurally similar to the final nonclassical carbocation. How can this conclusion be made to fit the generally accepted idea about the high exothermicity of this fundamental stage?

In fact, the exothermicity of nitrogen elimination from a diazonium ion is not in doubt in the majority of cases. Nitrogen is known to be eliminated with ease even from bridgehead positions. For example, amine (LIX) undergoes 47% reaction after 15 s at −70 °C, which is virtually impossible for traditional leaving groups ($\Delta\Delta F \geqslant 20$ kcal mol^{-1}).[55]

(LIX)

Y = Cl, OEt.

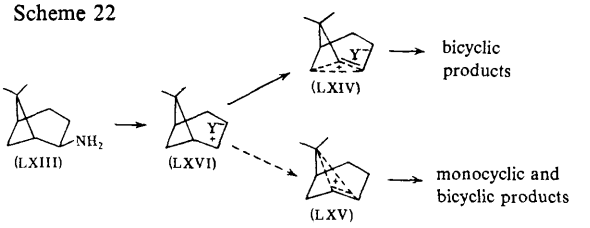
There have been various determinations of the height of the activation barrier and the heat of reaction for decomposition of an alkyldiazonium ion. Corey et al.[21] determined the heat of reaction from the sum of the ionisation potential of the sec-alkyl radical (8 eV), the energy of homolytic dissociation of the $C-N_2^+$ bond (4 eV), and the first ionisation potential of the nitrogen molecule (−15.6 eV). The value of −3.6 eV per mol obtained for ΔH is 83 kcal, which is quite unsuitable even for an approximate determination of the height of the activation barrier. This barrier is probably not as small as may be suggested from general considerations.

Direct kinetic measurements for stable diazonium ions give values in the region 10−20 kcal mol^{-1}. Thus, the energy of activation for elimination of nitrogen from diazonium ion (LX) is 19 ± 4 kcal mol^{-1}.

$$(CF_3)_2CN_2 + FSO_3H \xrightarrow{-70\ ^\circ C} \underset{(LX)}{(CF_3)_2CHN_2^+} + OSO_2F^-.$$

The very fact of the direct detection of diazonium ions (LXI)[57] and (LXII)[58] suggests that there is a perceptible activation barrier for their decomposition.

$$\underset{(LXI)}{CF_3CH_2N_2^+}\ OSO_2F^-, \quad \underset{(LXII)}{CH_3N_2^+}\ OSO_2F^-.$$



It should be mentioned here that the structure of ions (LX)−(LXII) and the conditions under which they occur (the medium) are not conducive for the elimination of nitrogen by a "pure" S_N1 route, namely, without any external or internal assistance.

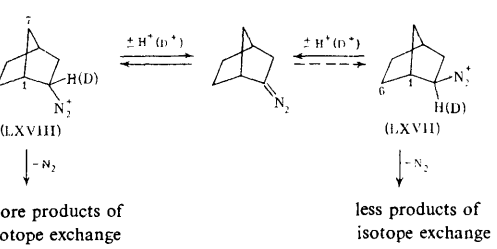
A calculation using the MNDO method that was carried out for methyldiazonium and ethyldiazonium ions showed that S_N2 reactions of these ions with different nucleophiles are exothermic processes with a heat of reaction ranging from −16.5 kcal mol^{-1} (reaction of the ethyldiazonium ion with water) to −64.9 kcal mol^{-1} (reaction of the methyldiazonium ion with imidazole). However, decomposition of these same ions by an S_N1 mechanism occurs endothermically (ΔH ranging from +13.9 to +45.8 kcal mol^{-1}), and even when solvation effects are taken into account such endothermicity for the process largely excludes an S_N1 decomposition of ion (LXII).[59]

These results again support the conclusion that nitrogen has no tendency to undergo elimination without external (S_N2) or internal (k_Δ) assistance. The high exothermicity and the low barrier in processes with such assistance together with the reverse situation for the S_N1 route for formation of a classical cation make deamination an "anomalous" process in relation to the extended Hammond postulate.

At first glance the contradiction that arises can be removed by rejecting the idea of anchimeric assistance as such. There is a view that the carbocation is formed without any participation and the cation site is then stabilised by a displacement of the neighbouring group. Thus, in the opinion of Collins, the intermediate carbocations in deamination reactions are classical ions and the subsequent stereoselectivity of the skeletal shifts and nucleophilic attack in an S_N1 reaction are determined by the position of the counterion.[42,60–63] Whittaker has expressed a similar view, according to which participation does nevertheless occur but not in the transition state for formation of a carbocation but at the subsequent stages (Scheme 22).[4,64]

Scheme 22

(LXIII) (LXVI) (LXIV) (LXV)



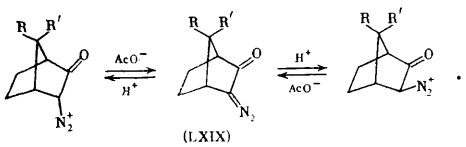
Deamination of amine (LXIII) in AcOH gives only products derived by further reactions of ion (LXIV). In water small quantities of products formed from ion (LXV) occur.

Whittaker proposes that the classical cation (LXVI) is formed at the first stage, the counterion in the intimate ion pair being positioned on the same side as the departing nitrogen. In this case delocalisation of the σ-bond is only possible on the opposite side. In water, separation of the ion pair can partly forestall this type of delocalisation, resulting in the competitive formation of ion (LXV).[4]

Nevertheless, if there is reason to suppose that in this case, as in all the other cases, ions of the type (LXVI) and (LXIV) are formed in parallel rather than successively, this conforms to the general Scheme 13. This is suggested in particular by results that can be used to determine the relative barriers of the decomposition of epimeric diazonium ions.

In the decomposition of the diazonium ions (LXVII) and (LXVIII) in aprotic media, route (d) in the general Scheme 13 starts to play a significant role (Scheme 23). It is worth noting that under these conditions significant deuterium exchange only occurs in the case of the *endo*-substrate (LXVIII).[65]

Scheme 23



(LXVIII) (LXVII)

Hence there is a higher barrier for elimination of nitrogen for the *endo*-diazonium ion (LXVIII) than for the *exo*-diazonium ion (LXVII). Bearing in mind that participation of the C(1)−C(6) bond is much more effective than participation of the C(1)−C(7) bond, it is doubtful that the difference in the barriers should be assigned to the variable orientation of the counterion. It is more

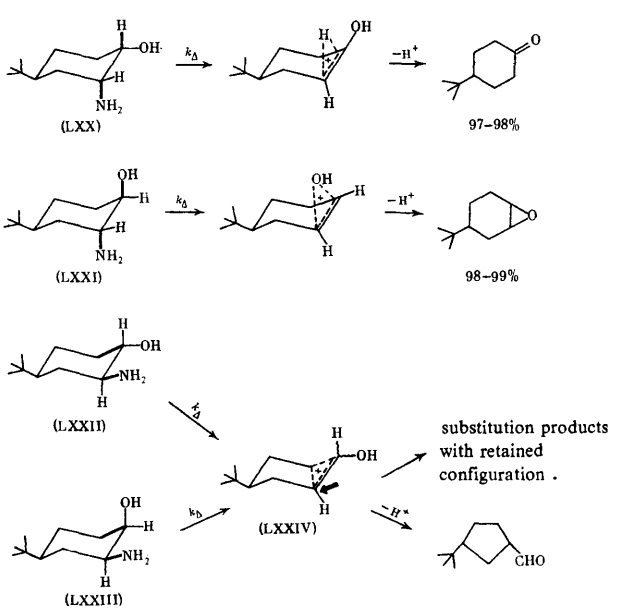
likely due to participation of the C(1)–C(6) bond in the transition state for elimination of nitrogen from the *exo*-diazonium ion (LXVII).

Fairly recently this proposal received further experimental confirmation in a study of the acid-catalysed decomposition of diazoketones (Scheme 24).[66]

Scheme 24

(LXIX)

	k_{H^+}, mol^{-1} s^{-1}	
	exo	*endo*
R = H, R′ = iso-Pr	7.4	0.47
R = H, R′ = t-Bu	0.28	0.06
R = iso-Pr, R′ = H	55	0.8
R = t-Bu, R′ = H	80	1.2
R = H, R′ = H	—	—



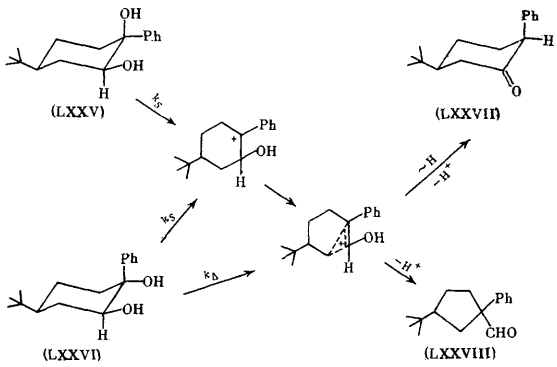
It can be seen from the results in Scheme 24 that the rate constants of reaction for the *exo*- and *endo*-epimers differ by a factor of 10–100. There is reason to suppose that in the presence of acetate anion, elimination of nitrogen in the protonation of diazoketone, is, at least in part, the rate-limiting stage.[66] This is due to the competing deprotonation of the diazonium ions. In a medium without acetate anion added the rate-limiting stage is protonation of diazoketone (but it probably has a similar rate to the nitrogen elimination stage). The enthalpy of activation of this reaction for diazoketone (LXIX), R = H, R′ = iso-Pr, in aqueous acid is 13.7 kcal mol^{-1}, which may be similar to the enthalpy of nitrogen elimination. The entropy of activation (–8.4 e.u.) increases the barrier by a further 2.3 kcal mol^{-1} under normal conditions¶.[66]

The many illustrations of the extended Hammond postulate in the case of deamination are based on an estimate of the energy of activation for decomposition of the diazonium ion in the region of 3 to 5 kcal mol^{-1} that was made by Streitwieser from general considerations.[16,17] The findings reported above confirm that this barrier usually does not exceed 10–15 kcal mol^{-1} when the process is accompanied by internal or external assistance. Thus, the contradiction between the concept of the increase in demand for participation in deamination developed here and the extended Hammond postulate is retained. It may be assumed that in an exothermic reaction with assistance (which in turn gives rise to exothermicity), the "early" substrate-like transition state contains a partial displacement of the neighbouring group in so far as even when the diazonium ion exists there can arise a "low-electron, multicentred" delocalisation involving the electrons of the neighbouring periplanar bond, which is accompanied by a partial rehybridisation of the carbon atom bonded to the charged nitrogen. This specific precarbocation stage of nonclassical delocalisation in the diazonium ion does not contradict the existing facts. It may be confirmed or disproved using quantum-chemical methods, but these results have so far not appeared in the literature.

In our opinion, regardless of whether it is possible at the present time to resolve the contradiction between the Hammond postulate and the hypothesis developed here, the predictive potentialities of the latter should be utilised. It is useful to give as an example the solution of the problem relating to the reactions of diastereomeric cyclohexylamines whose conformations are stabilised by the introduction of bulky alkyl substituents.

Thus, in terms of the general Scheme 13, deamination of the diastereomeric amines (LXX)–(LXXIII) is given by Scheme 25, in which the determining factor is participation of one of the periplanar neighbouring bonds. Moreover, by using Scheme 25 it is possible to answer the question raised previously, but up to now not having received a satisfactory explanation (see the reviews of Kirmse[2] and Moss[11] and the references in them), namely: why do axial cyclohexylamines of the type (LXX) and (LXXI) give many elimination products and only a few equatorial (inverted) products while equatorial amines of the type (LXXII) and (LXXIII) mainly form substitution products with retained configuration and few elimination products?

Scheme 25



It can be seen from Scheme 25 that in the typical axial amine (LXX) participation of the C–H bond must be less effective than participation of the C–C bond of the ring in any equatorial epimer. The latter, for its part, gives nonclassical cations of the type (LXXIV), whose stereoelectronic requirements assist the formation of substitution products with retained configuration.

¶If it is assumed that the kinetic parameters for protonation of diazoketones are similar to those for the nitrogen elimination stage, the results of Kronis et al.[66] do not support the idea of the entropy factor, when there is a low enthalpy of activation, having a decisive effect in deamination.[4,67,68] According to this hypothesis the entropy factor inhibits the formation of a nonclassical carbocation as a more ordered species under conditions where the solvate shell has little effect on the degree of ordering of the transition stage. It is evident from the activation parameters stated above that the entropy contribution is not decisive.

In the meantime the lesser requirement for ordering of the solvation shell from a nonclassical cation compared to a classical cation[69] may in fact make the nonclassical cation "entropy-preferred". Thus, according to the results of two studies,[70,71] diazoalkane (LXIX), R = R′ = H, after being protonated decomposes with σ-participation.

As expected, glycols (LXXV) and (LXXVI), which are analogous in structure to the amino alcohols (LXX)–(LXXIII), do not react stereospecifically. The products—(LXXVII) and (LXXVIII)—are formed in the ratio 9 : 1 whatever the configuration of the leaving group[2,72] (Scheme 26).

Scheme 26

In this case it is worth comparing the reactions of aliphatic and alicyclic substrates. Thus, the example shown in Scheme 25 is similar to the pinacolic deamination discussed earlier (Scheme 12). In both cases the result contradicts the Curtin–Hammett principle in that the ratio of products formed from the different conformations (or diastereomers) of the substrate depends on the relative populations of the conformations (or on the configuration of the leaving group).

There is reason to suppose that the above-mentioned "violations" of the extended Hammond postulate and Curtin–Hammett principle in deamination have a common origin which should be looked for under the specific conditions of ionisation of the substrate. These conditions, which have been discussed in detail in the preceding sections, lead to the formation from different conformers (diastereomers) of different carbocations (as a rule, nonclassical) that tend not to undergo interconversions. As has already been mentioned, one of the causes may be a specific precarbocation ionisation stage which involves a partly "nonclassical" diazonium ion. Under these conditions formation of carbocations from diazonium ions is kinetically controlled and the stereospecificity is not disturbed.

In solvolysis, where anchimeric assistance in the S_N1 process plays a lesser role but internal re-entry plays an important part†, the composition of the intermediates is to a greater degree thermodynamically controlled. The Curtin–Hammett principle is fulfilled precisely in the "thermodynamic" region of nucleophilic substitution, which is accessible to only a limited degree for nitrogen elimination reactions (see, for example, Scheme 14). However, this fact makes deamination a convenient method for carrying out uncommon (such as the Dem'yanov rearrangement) and directed skeletal rearrangements.

† There is no information about internal re-entry of nitrogen in the decomposition of a diazonium ion in aliphatic compounds. It may be judged that this is a very insignificant process from the results on the insertion of nitrogen into the reactive phenyl cation; at 300 atm 2.46 ± 0.4% external nitrogen is inserted.[73]

On the other hand, decomposition of a diazonium ion is a single-stage fundamental process and it conforms to the Hammond postulate. In this sense the diazonium ion must also be partially stabilised through nonclassical delocalisation.

Having summarised the results of the critical examination of the literature conducted above, we consider it desirable to note the following fundamental characteristics of deamination reactions as compared to solvolysis.

1. The formation of a charged diazonium ion species at a precarbocation stage helps to develop a greater degree of anchimeric assistance in deamination as compared to traditional solvolysis. By using deamination it is possible to carry out purposefully rearrangements which are impossible or difficult in other reactions. In this case the group periplanar to the leaving nitrogen is always displaced. In a number of cases replacement of a separating sulphonate group by nitrogen is equivalent to conducting solvolysis in a much more ionising and less nucleophilic solvent.

2. The direction of nucleophilic attack in S_N1-deamination should be expected to correspond to the stereoelectronic requirements of the nonclassical carbocation in which participation of the neighbouring periplanar group develops. Regioselectivity must be taken into account; substitution occurs primarily on the site of nitrogen elimination.

3. In a comparative study of deamination and solvolysis, particular factors that affect the comparability of the stereochemical results of the two reactions must be taken into account:

a) the possibility of partial epimerisation of a diazonium ion via a diazoalkane;

b) internal re-entry of the leaving group in solvolysis;

c) micellar effects in deamination;

d) the difference in the temperature conditions for carrying out the reactions;

e) the necessity of making a separate analysis of deamination products that belong to different classes of compounds.

4. The observed variance of the stereochemistry of deamination products with the extended Hammond postulate and Curtin–Hammett principle probably has a common origin and can be accounted for in a similar way. The concept of nonclassical delocalisation of the positive charge in a diazonium ion itself may serve as one of the explanations.

Structural features and reactivity of tetrahalomethanes

B V Timokhin
Irkutsk State University

ABSTRACT. It is shown from an analysis of data on the structure and properties of tetrahalomethanes CX_4, where X = Cl, Br, I, that their chemical behaviour in many respects depends on the energy accessibility of the lowest unoccupied molecular orbital, which is the antibonding analogue of a bonding orbital of σ-type. This characteristic is responsible for, on the one hand, the occurrence of intramolecular interactions between halogen atoms and, on the other hand, their electrophilic properties in reactions with electron donors.

I. Introduction

The problem of nucleophilic substitution in alkyl halides is one of the most frequently studied in theoretical organic chemistry. Up to the present time the structural factors that determine the reactivity of the substrate and nucleophile are generally apparent, the stereochemical characteristics of these processes are clear, and there exists the possibility of controlling a reaction using the solvent.[1,2] However, it has been observed for a long time that as the degree of halogenation of CH_nX_{4-n} molecules increases, the rate of reaction of bimolecular nucleophilic substitution usually decreases despite the increase in electron-withdrawing action of the substituents. Tetrahalomethane molecules, which are the limiting case of this type of α-substitution, react very sluggishly with nucleophiles. The reactions only take place under much more severe conditions and their results are ambiguous.[3] The nature of this type of α-effect is not at all clear up to the present time. Different explanations of this phenomenon have been put forward both in terms of the valence bond approach[4] and the molecular orbital approach.[5–7]

In recent times tetrahalomethanes, principally carbon tetrachloride and carbon tetrabromide, have started to be used effectively in different syntheses, especially those involving phosphorus-containing nucleophiles,[8] to give products whose formation cannot be accounted for on the basis of substitution reactions on the carbon atom.

Recently the concept of so-called "X-philic reactions" was developed.[9] It accounts for this and other similar reactions that take place by attacking a peripheral site rather than the central carbon atom on the basis of the theory of the perturbation of molecular orbitals. Ligand transfer to the nucleophile results from such reactions. By solving this problem in a general form and not solely for halogen-containing substrates, the authors who developed this concept did not set themselves the task of trying to find the structural causes through which a tetrahalomethane becomes the source of a "positive" halogen. Moreover, being clearly aware of the possibility of an alternative to the mechanism of an X-philic reaction, they confined their study solely to a theoretical approach. Meanwhile, there is a variety of information on the use of carbon tetrahalides in different chemical reactions related to halogenation of a nucleophile, in which the existence of radical intermediates have been recorded. The lack of correspondence that occurs, in our opinion, can be resolved by establishing the structural features and reactivity of polyhalomethanes from the available information, which, despite its considerable volume, has not been correlated to date. What has been stated above, together with the possibility of the future use of the conclusions obtained to interpret similar reactions of tetrahalides of other elements such as phosphorus,[10] constituted the reason for writing this review.

II. Structural features of polyhalomethanes

The properties of polyhalomethanes are determined in many respects by the highest occupied and lowest unoccupied molecular orbitals (HOMO and LUMO).

According to nonempirical calculations the electronic configuration of tetrahalomethanes can be represented by the following MO sequence:[11,12]

$$(1a_1)^2\,(1t_2)^6\,(2a_1)^2\,(2t_2)^6\,(1e)^4\,(3t_2)^6\,(1t_1)^6\,(3a_1)^0\,(4t_2)^0.$$

The orbitals with e, $3t_2$, and t_1 symmetry are classed as π-type group orbitals formed from the p_z and p_y atomic orbitals (AO) of the unshared electron pairs (UEP) of the halogen atom. The $3a_1$ and $4t_2$ orbitals are classed as antibonding analogues of the $2a_1$ and $2t_2$ σ-type bonding orbitals.

Localisation of the upper occupied levels and their composition have been demonstrated by X-ray and photoelectron spectra, a detailed discussion of which is conducted in a recently published monograph.[13] In this case the first ionisation potential (IP) of halomethanes can be related to the HOMO energy, and the energy of the LUMO can be obtained by comparing these values and the energies of the $p \rightarrow \sigma^*$ transitions in UV spectra,[14,15] which generally correspond to the difference in energy between HOMO and LUMO.

In contrast to alkyl fluorides CH_nF_{4-n}, in which the energy levels of the UEP of the fluorine atoms lie below the bonding energy levels of the σ bonds, which are most apparent in the far UV region,[15] their analogues with heavier halogen atoms have certain characteristics.

Thus, the first IP in these derivatives correspond to the UEP of the halogen. It is clear that on increasing the degree of halogenation and also on replacing Cl by Br, the magnitudes of the first IP decrease (Table 1), which is probably due to a decrease in orbital energy of the ligand atoms on changing from Cl to Br and a decrease in effective charge on the carbon atom.[13]

Table 1. First ionisation potentials (IP, eV) and energies of the $p \rightarrow \sigma^*$ transition (E, eV) for halomethanes.[13,14]

Compound	F		Cl		Br		I	
	IP	E	IP	E	IP	E	IP	E
CH_3X	13.1	—	11.29	7.3	10.54	6.20	9.54	4.77
CH_2X_2	11.29	—	11.10	7.29	10.61	5.64	9.52	—
CHX_3	14.28	—	11.48	7.09	10.47	5.10	9.21	—
CX_4	16.30	—	11.69	7.08	10.39	4.90	9.10	3.20

When the energies of the $p \rightarrow \sigma^*$ transitions in the UV spectra of alkyl halides CH_nX_{4-n}, X = Cl, Br, I, n = 0–3 are examined and compared with the ionisation potentials, it can be seen that the energy gap between the HOMO and LUMO in this series of compounds decreases since the energy of the LUMO successively decreases on replacing chlorine with bromine and iodine and by increasing the degree of halogenation of methane.[16] These changes in the HOMO and LUMO should apparently assist both intra- and intermolecular interactions which depend on the energy of the frontier orbitals. For example, as the degree of halogenation of methane increases, the electron affinity should increase.[17] This conclusion is supported by the decrease in the values of the half-wave potential of polarographic reduction on increasing the number of bromine atoms in a methane molecule,[18] since it is known that its value is proportional to the energy of the LUMO.[19] This is also convincingly shown by the spectroscopic data of dissociative attachment of electrons to halomethane molecules.[20–23] The results obtained by different authors suggest that when an electron interacts with a halomethane molecule it is placed in its σ^* orbital with t_2 symmetry to form a temporary anionic state. This is very unstable and decomposes almost immediately. A quantum-chemical calculation with a CNDO/2 approximation on an *sp* and *spd* basis was used to analyse the different ways for the decomposition of such CX_4^- intermediates when X = Cl, Br, I:[24]

$$CX_4^- \rightarrow CX_4 + e^-, \quad CX_4^- \rightarrow CX_3^- + X^\cdot, \quad CX_4^- \rightarrow CX_3^\cdot + X^-.$$

It transpired that the route leading to a halogen anion and trihalomethane radical has the least energy. Consequently, this route is predominant in the dissociative attachment of an electron. In this case the maximum yield of halogen will occur at the absorption energy of the electron. It is possible thus to determine the electron affinity in CH_nX_{4-n} molecules, which increases as the number of halogen atoms increases and on going from chloromethanes to their bromine analogues,[22,23] which accords with the direction of change in energy of the LUMO in these molecules.

The steric structure of halomethanes with a varying degree of substitution has been studied in detail in both the gas phase and crystalline state. Extensive tables of data on interatomic distances are available in a monograph[25] and booklets.[26,27] Data obtained by the same or comparable methods are given in Table 2.

Table 2. Carbon–halogen bond lengths in CH_nX_{4-n} molecules, Å.[25–27]

Compound	F		Cl		Br		I	
	g	c	g	c	g	c	g	c
CH_3X	1.383	—	1.781	1.805	1.939	1.863	2.133	2.134
CH_2X_2	1.357	—	1.767	1.768	1.925	1.91	—	2.12
CHX_3	1.332	—	1.758	1.750	1.930	—	2.12	2.18
CX_4	1.319	—	1.767	1.751	1.942	—	2.18	—

Note: g—gas phase; c—crystalline state.

Despite the fact that the absolute values of the C–X interatomic distances obtained for the different phase states are not the same, their patterns of change with a successive build-up of halogen atoms as well as when changing the nature of the halogen atom are clearly visible. On the one hand, there is an evident tendency of the C–X bond length to decrease with an increase in the number of halogen atoms in halomethanes in the case of the relatively compact fluorine and chlorine atoms. This can be followed most clearly in fluoromethanes. This would appear to result from the increase in effective electronegativity of the carbon-centred fragment, so that there is a reduction in polarity of the bond and as a result a reduction of the interatomic distance.[28] This is also indicated by the decrease in dipole moment of the C–X bond as the degree of halogenation of methane increases[29] and also by the occurrence of the shortest recorded carbon–halogen bond in the case of tetrahedral chlorides and bromides in chloro- and bromotrinitromethanes (1.712 and 1.885 Å respectively).[25]

On the other hand, on going to the more diffuse, bulky bromine and iodine atoms a tendency for the C–X bond to lengthen becomes apparent. This effect may be due to the steric interactions of the neighbouring halogen atoms, which is suggested, for instance, by the unusual intramolecular distances of X...X in the dihalomethanes CH_2Br_2 and CH_2I_2 [30,31] and in CCl_4.[32] In these molecules they are noticeably less than the sum of the van der Waals radii of the halogen atoms. It is also thought that these interactions reduce the energy of dissociation of the C–X bond, where X = Cl, Br, I, as the methane is halogenated, which does not occur for fluorination. It is possible that for this reason the valence force constants of this bond are reduced.[34]

It appears that the interactions of the geminal halogen atoms also have an effect on the enthalpy of formation of halomethanes. It has been observed that when there is a build-up of halogen atoms, this function increases nonlinearly.[37]

Another interesting feature of these alkyl halides CH_nX_{4-n}, X = Cl, Br, I, is the effect of the decrease in halogen–halogen intermolecular distances in the crystalline state.[30,31] It is thought

that this occurs as a result of charge transfer from a halogen atom to the σ^* orbital of a C–X bond in neighbouring molecules. This results in a decrease in the magnitude of halogen-halogen intermolecular contacts and consequently to underestimated values of the van der Waals radii.[38,39] It is therefore thought that the very concept of a radius for halogens is only significant when applied to contacts with atoms that do not have unshared electron pairs.

Table 3. Dissociation energy of the C–X bond in halomethanes CH_nX_{4-n}.[35,36]

Compound	Dissociation energy, kcal mol^{-1}			
	F	Cl	Br	I
CH_3X	112	83.6	69.7±1	54
CH_2X_2	114.5	81±3	62.7±5	45.5
CHX_3	128±5	77.2±5	56.7±5	37
CX_4	92.0±4	73.3±2	49.7±5	28.5

It cannot be excluded that this intermolecular charge transfer has an effect on the length of the C–X bond in tetrahalomethanes that is determined in the crystalline state. It should also be mentioned that a similar but solely intramolecular interaction is quite likely to occur between geminal halogen atoms, making it possible for them to converge to distances less than the sum of the van der Waals radii.

Table 4. Dipole moments of CH_nX_{4-n} molecules (μ), the C–X bond (μ_{C-X}), and the charges on the halogen atom (q_X).[40–42]

Compound	F			Cl			Br		
	μ, D	μ_{C-X}, D	q_X, e	μ, D	μ_{C-X}, D	q_X, e	μ, D	μ_{C-X}, D	q_X, e
CH_3X	1.87	—	0.2083	1.861	1.59	0.0850	1.86	1.52	0.0237
CH_2X_2	1.96	—	0.1983	1.57	1.05	0.0738	1.42	1.03	0.0176
CHX_3	1.62	—	0.1967	1.01	0.55	0.0659	0.99	0.54	0.0190
CH_4	0	—	0.1980	0	0.08	0.0664	0	0.05	0.0208

An increase in the effective electronegativity of the CR_3 fragment in an R_3C-X molecule on increasing the degree of methane halogenation should lead to a reduction in negative charge on the halogen atom through its transfer to the bond. A consequence of this should be a reduction in dipole moment of the C–X bond, as has been mentioned above. In fact, a comparison of the dipole moment of halomethane molecules (the dipole moments are determined in the gas phase in order to exclude intermolecular interactions) with the value of the group dipole moment of the C–X bond [40,41] and the magnitude of the charge on the halogen atom (obtained by calculation using the modified CNDO/2 method[42]) supports this conclusion (Table 4).

The electric polarisability of the molecules may serve as a qualitative measure of the mobility of the electrons and hence may also reflect the intramolecular interactions. In this case the anisotropy of bond polarisability calculated from the molecular anisotropy and the Kerr constants serves as a specific test for such effects.[43,44] For example, in a determination of the ellipsoids of polarisability for molecules of the type CH_2X_2, X = Cl, Br, I, for all three axes and when comparing the results with monohalogen derivatives, it was concluded that the significant experimental deviations from additivity in dihalomethanes are due to the interaction of the neighbouring C–X bonds through space.[45] Since the values of polarisability of the valence MOs decrease with an increase in the number of halogen atoms,[46] it may be assumed that the main contribution to polarisability is provided by the UEP of the halogen atom.

Table 5. Chemical shifts (δ, ppm) of ^1H, ^{13}C, ^{19}F, and ^{35}Cl atoms in halomethane molecules.

Compound	F			Cl			Br		I	
	δ^1H	$\delta^{13}C$	$\delta^{19}F$	δ^1H	$\delta^{13}C$	$\delta^{35}Cl$	δ^1H	$\delta^{13}C$	δ^1H	$\delta^{13}C$
CH_3X	7.1	75.5	271.9	7.1	25.1	40	7.3	10.2	7.6	−23.5
CH_2X_2	8.8	112.2	143.4	9.9	54.2	230	10.1	21.6	9.8	−61.1
CHX_3	10.3	118.8	78.6	11.8	77.7	410	12.4	12.3	6.5	−139.7
CX_4	—	119.9	63.3	—	96.7	560	—	−28.5	—	−229.1

Note. Chemical shifts of the ^1H atoms were measured relative to methane,[47] ^{13}C atoms relative to tetramethylsilane,[48,53] ^{19}F atoms relative to fluorotrichloromethane,[49] and ^{35}Cl atoms relative to an aqueous solution of sodium chloride.[50]

Haloalkanes have been studied repeatedly using radiospectroscopic methods and almost always the relationship between the changes in the spectroscopic characteristics of the indicator atom and the number of halogen atoms on the carbon atom has been investigated. As a rule a build-up of electronegative geminal substituents on carbon in halomethanes results in nonadditive effects which distort the dependences of the spectroscopic properties of these compounds on the structure. The chemical shifts in the spectra of halomethanes in relation to the number and nature of the halogen atoms can be given as such an example (Table 5).

It is clear from Table 5 that with an increase in the number of halogens the ^1H chemical shift is displaced downfield. This type of deshielding conforms to the increased electronegativity of the halomethyl residue and is likely to correspond to a reduction in electron density on the hydrogen atoms. However, it is noticeable that the contribution of a halogen in shielding the proton is not additive, as is indicated, for example, by the unsatisfactory value of the ^1H chemical shift in haloforms using Shoolery constants.[51]

A study of intramolecular interactions in halomethanes using ^{13}C NMR spectroscopy has been undertaken by different authors.[48,52–55]

By treating the chemical shifts of the ^{13}C nuclei in these compounds as the sum of mono-, di-, and tri-atomic increments that take into account interactions along the C–X bond as well as those through space,[48,52] it was possible to make quite an accurate prediction of their value. However, in considering this approach limited, Dostovalova et al.[54] gave greater consideration to the reasons for the nonoadditivity of the changes in this spectroscopic parameter and made an attempt to represent it through the bond increments $\Delta\delta_{C-X}$.[55] These values occur as the ratio of the difference between the chemical shifts of the halohydrocarbon in question and unsubstituted methane to the degree of substitution. The nonlinear change in these values is due to nonbonded interactions between the geminal halogen atoms, which lead to a distortion of their electron shell and consequently to an alteration in the charge on the C–X bond. The nature of such nonbonded interactions is probably similar to that which has been put forward to explain the changes in chemical shifts of ^{13}C and ^{19}F atoms in a number of substituted fluorochloromethanes.[56] In this case overlap of the UEP orbitals of the halogen with the virtual orbitals of the neighbouring carbon–halogen bond is thought to be most likely. This approach is confirmed by quantum-chemical calculations with the CNDO/2 approximation and by the good correlation of the ^{13}C chemical shift with the charge on this atom.

In the opinion of Cheremischin and Schastnev,[57] another reason for the nonadditive changes in chemical shifts of carbon that increase as the number of substituents in halomethanes increases is the occurrence of spin-orbit interaction. It has been observed that this effect is small for chloro derivatives but is substantial for the bromine- and iodine-containing analogues.

NMR spectroscopy of halogen nuclei has, with the exception of fluorine, not been used much for the study of halomethanes.[50,58] This is mainly because of the limitations arising as a result of broadening of the resonance line. Thus, for example, in the ^{35}Cl NMR spectrum of CCl_4 its width is equal to 15 kHz. Nevertheless it can be seen that the stepwise change from methyl chloride to carbon tetrachloride leads to deshielding of the nucleus of the chlorine atom.[50] The linear relationship between the chemical shifts of the ^{35}Cl and ^{19}F atoms indicates that there is a uniform structural effect on the shielding of both nuclei.[58]

An interpretation of the spectroscopic data of nuclear quadrupole resonance (NQR) of the nuclei of halogen atoms using the Townes–Dailey approximation can be used to determine the spatial distribution of electron density around these nuclei, and it has therefore been widely used to study organohalogen compounds, in particular halomethanes.[59]

It can be observed here that as the number of halogen atoms in the methane molecule increases, the NQR frequencies increase, which is interpreted as a consequence of the decrease in ionic nature of the C–X bond. However, it can be seen that the change in frequency is nonadditive.[60]

Introduction of substituents that are electron-donating relative to the halogen into the CX_4 molecule reduces the frequency of ^{35}Cl NQR, while electron-withdrawing substituents increase it. However, the change in frequencies in this case is determined by the inductive effect only to a first approximation. For example, for RCH_2Cl derivatives in which substituent R has unshared electron pairs (X = RO, F, Cl, Br) there are appreciable deviations from a linear dependence, which is due to conjugation of $p \rightarrow \sigma^*$-type.[61,62]

Thus, a study of intramolecular interactions in polyhalomethanes using radiospectroscopic methods shows that the change in spectroscopic characteristics is subject to the effect of the geminal halogen atoms, which in all probability is due to overlap of the orbitals of the unshared electron pairs of the halogen with the low-energy antibonding orbital of the neighbouring C–X bond. This effect is likely to determine the overall specific nature of intramolecular interactions in tetrahalomethanes. The energy availability of the antibonding orbitals of the C–X bond enables CX_4 molecules (X = Cl, Br, I) to exhibit electrophilic properties which give rise to reactions with certain types of charged and neutral nucleophiles as well as with free radicals.

III. Reactions of tetrahalomethanes with free radicals

It was noted earlier that when the number of halogen atoms on carbon is increased, the capacity of halomethanes for dissociative attachment of an electron increases. In this case temporary anionic states are formed, readily decomposing in the case of tetrahalides to a trihalomethyl radical and a halogen anion. Acceptance of an electron into an antibonding orbital accounts for the instability of the intermediate, which, however, decreases with an increase in the number of halogen atoms. This is indicated by a quantum-chemical calculation using the MINDO/3 approximation.[63]

Free radicals, as real electron carriers, should also in principle cause a similar dissociation of a halomethane. In fact, elimination reactions of a halogen from polyhalomethanes by the action of free radicals are well known. It has been shown by a large number of experiments that the energy of activation of the chain-transfer reaction

$$R^{\cdot} + CH_nX_{4-n} \rightarrow RX + \dot{C}H_nX_{3-n}$$

decreases as the number of halogen atoms in polyhalomethanes is increased, and when chlorine is replaced by bromine and then by iodine.[64] It should be emphasised here that such reactions are not typical for fluoromethanes.

Studies of a model chain-transfer reaction in the polymerisation of alkenes showed that in the reaction of the hydrocarbon radicals $(CH_3)_2C^{\cdot}R$, where R = PhO, MeCOO, PhS, Ph, with CBr_4, CCl_3Br, and CCl_4, there is electron transfer from the radical to the polyhalomethane. In this case the rate of reaction decreases in the series $CBr_4 > CCl_3Br > CCl_4$.[65]

Free-radical donor properties relative to tetrahalomethanes have been found in the case of the formation of adducts between 2,2,6,6-tetramethylpiperidine *N*-oxide and carbon tetrachloride.[66] At the same time paramagnetic shifts were detected in the ^1H NMR spectra of chlorine-containing molecules without α-hydrogen atoms in the presence of stable nitroxyl radicals. An analysis of the concentration dependence of these shifts showed that in this case weak complexes are formed between the components.[67] Morishima et al.[68,69] also found a downfield shift of the resonance signal in the ^1H and ^{13}C NMR spectra in the reaction of halomethanes with di(t-butyl)nitroxyl. They relate this phenomenon to the formation of short-lived complexes. The linear dependence between the observed contact shift and the half-wave potential of polarographic reduction of halomethanes serves as evidence of the donor-acceptor nature of these interactions involving a σ^*-type LUMO of the halomethanes. This is suggested by the appearance of a new absorption band in the region 310–370 nm in a solution of the same stable radical in carbon tetrachloride. It is thought that for carbon halides containing hydrogen, a complex is formed through hydrogen bonding,[70] while for tetrahalides the acceptance of electron density may only occur via the antibonding orbital of the C–X bond.

IV. Reactions with charged nucleophiles

During the last fifteen years attempts have been made to obtain carbon compounds with a coordination number greater than four. The highest expectations in this area relate to stabilisation of this unusual state by electron-withdrawing substituents. Hence the pentahalocarbonate anion CX_5^- has attracted a considerable amount of attention from research workers. The most promising method of obtaining this is the reaction of carbon tetrachloride or tetrabromide with phosphonium or tetraorganylammonium halides[71] as halide anion donors. Thus, it was possible to obtain complex compounds, but when they were studied by IR and Raman spectroscopy and X-ray diffraction analysis it was shown[72] that in the crystalline state carbon is not pentacoordinate in these compounds. In this case there is the formation of a complex ion in which a halogen anion is surrounded by four tetrahalomethane molecules with coordination via the halogen atoms (the three-membered fragment C—X—X is linear).

The formation of complex compounds with a $Br_3C-Br..Br^-$ fragment can be accounted for using the following two models. On the one hand, it is possible to form a donor-acceptor complex whose existence is achieved through charge transfer from the halogen anion to an antibonding orbital of the C—X bond or using a vacant 3*d* orbital of the halogen in the carbon halide. On the other hand, it may be assumed that because of the high polarisability of the CX_4 molecule, an electrostatic interaction of the type ion—induced dipole can occur.

An analysis of the X-ray diffraction data showed that the X...X distance in these complexes is considerably less than the sum of the van der Waals radii.[72] It was found for complexes of $R_4N^+Hal^-$ (R = Me, Et; Hal = Cl, Br, I) with CX_4 (X = Cl, Br, I) that the X...X distance increases (for a given halomethane) as a function of the halogen anion in the series $Cl^- < Br^- < I^-$, and it increases as a function of the acceptor molecule (for a given anion) in the series $CCl_4 < CBr_4 < CI_4$. The data obtained provide a basis for classing these complexes as donor-acceptor types. In the opinion of Creighton and Thomas,[72] the acceptor orbital in these complexes is a σ^*-type LUMO.

Recently a nonempirical calculation of the structure and stability of pentahalocarbonate anions CX_5^- (X = F, Cl, Br, I) was carried out. The formation energies of the three most probable structures were compared in this case. One of them has D_{3h} symmetry and two have C_{3v} symmetry. They differ in that the incoming anion coordinates either on the side or the top of the CX_4 tetrahedron.[73] It transpired that a pentahalocarbonate anion with a trigonal bipyramidal structure is unstable for any type of halogen. When the symmetry is reduced to C_{3v} the result is that such structures for X = F, whatever the approach of the incoming anion, are energetically unfavourable and the anion is unstable both in the gas phase and crystalline state. However, for X = Cl, Br, I, the coordination of the incoming anion to the halogen atom situated at the top of the tetrahedron always requires 25—45 kJ mol^{-1} less energy than when approach is made to the side, namely, to the carbon atom. In other words, according to the nonempirical quantum-chemical calculation, attack by the halogen anion on to the tetrahalomethane molecule occurs via a halogen atom, which is in complete agreement with the findings of X-ray structural analysis as given above.

The reaction of organometallic compounds (OMCs) with tetrahalomethanes has been studied for quite a long time and a considerable amount of information relating to this has been collected to date.[74] Information about the mechanisms of such reactions can be found in a monograph.[75]

Among OMCs of Group I metals, organolithium compounds are of the greatest interest. At very low temperatures (−115 to −100 °C) and in media with a high solvating capacity, such as in tetrahydrofuran or its mixtures with ether, a reaction that gives an organic halide and trichloromethyllithium readily occurs:[76—78]

$$R—Li + CHalCl_3 \rightarrow R—Hal + CCl_3Li,$$

R = Me, Et, n-Bu, Ph; Hal = Cl, Br, I.

However, when the temperature is increased, the reaction is different. It is frequently used as a source of dihalocarbenes. Thus, when ICF_3 [79] or CBr_2F_2 [80] is reacted with alkyllithium, difluorocarbene is formed and it is stabilised by alkene cyclopropanation. Reaction of methyl- and butyl-lithium under similar conditions with different tetrahalomethanes in the presence of cyclohexene gives dihalonorcarane in about 90% yield.[77] The change in the outcome of the reaction at an increased temperature is usually related to the ease of α-elimination of lithium halide from trihalomethyllithium. In fact, trichloromethyllithium which is obtained at a low temperature decomposes by 50% over a period of 30 min even at −65 °C according to the scheme

$$CCl_3Li \rightarrow LiCl + :CCl_2.$$

It should be mentioned here that there is no sign of a Wurtz type of condensation in these reactions.[74]

Among OMCs of Group II elements, organomagnesium compounds should first of all be mentioned. As a rule Grignard reagents react with CX_4 in different ways, in the case of alkylmagnesium halides forming complex mixtures of alkanes and olefins. However, it is thought that at low temperatures the reaction takes place via the formation of an organic halide and a trihalomethyl derivative of the metal.[81,82]

Comparatively recently a more detailed study of the reactions of organomagnesium compounds with tetrahalomethanes was made.[83—85] In this case chemically induced polarisation of ^1H nuclei was detected for the reaction between t-butylmagnesium chloride and carbon tetrachloride in bromotrichloromethane. Savin et al.[84] propose that the outcome of the reaction can be represented by a scheme that assumes single-electron transfer at the first stage:

$$(CH_3)_3CMgCl + CX_4 \rightarrow [(CH_3)_3\dot{C}MgCl^+ + C\dot{X}_4^-] \rightarrow (CH_3)_3\dot{C} + \dot{C}X_3 + MgClX.$$

The resulting radical pair disproportionates in two ways:

$$(CH_3)_3\dot{C} + \dot{C}X_3 \begin{cases} \rightarrow HCX_3 + (CH_3)_2C{=}CH_2 \\ \rightarrow (CH_3)_3CX + :CX_2 \end{cases}$$

as indicated by the ^1H polarisation phase in t-butyl chloride. In this case the high yield of products from the further reaction of dihalocarbene indicates that the reaction mainly occurs by the second route.

However, in the opinion of Davies et al.,[86] while the reaction of CCl_4 with EtMgBr occurs by a radical route (as is indicated by the formation of ethane and ethylene), the reaction of phenylmagnesium bromide, although giving 1,1-dihalonorcarane in the presence of cyclohexene, follows a heterolytic route via trichloromethylmagnesium bromide, which acts as a carbenoid. Thus, there is no common view about the mechanism of the

reactions of organic compounds of the most active metals of Groups I and II with halomethanes, but there is evidence to support radical processes which occur through the acceptance of electrons by tetrahalomethane.

A considerable number of reports on these types of reactions of carbon tetrahalides with OMCs relate to organomercury compounds. It is observed that in contrast to organolithium and organomagnesium compounds they generally react at higher temperatures. Thus, Ph_2Hg starts to react with CCl_4 at 200 °C, as a result of which phenylmercuric chloride, benzene, benzotrichloride, and hexachloroethane are formed.[87]

It is assumed that the initial stage of the reaction of organomercury compounds with CX_4 is dissociation of the OMC to radicals.[88–90] The free-radical pathway for the process has been confirmed by the inhibitor method.

Photolysis of organomercury compounds, which gives free radicals, assists the reaction, and in this situation it occurs even at room temperature.

Organic peroxides also have an initiating effect on the reaction between organomercury compounds and tetrahalomethanes.[91] A mechanism that includes a single-electron transfer stage has been proposed for reactions involving peroxides:[92]

$$\begin{matrix} R{-}Hg{-}OR \\ + \\ Cl{-}CCl_3 \end{matrix} \rightarrow \left[\begin{matrix} R{-}Hg^{+}\ \dot{O}R \\ Cl^{-}\ \dot{C}Cl_3 \end{matrix} \right] \rightarrow RHgCl + RO^{\cdot} + {}^{\cdot}CCl_3.$$

It is thought in this case that the catalytic effect of the peroxide consists essentially of forming a complex with the OMC, in which an additional polarisation of the carbon–metal bond occurs and hence the reactivity of the OMC towards the tetrahalomethane is increased. Strongly solvating media (dioxan, pyridine, hexamethylphosphotriamide) appear to have a similar effect.[93]

Tetrahalomethanes, in particular CCl_4, exhibit their electrophilic properties not only in the case of reactions with OMCs but also with other carbanion sources. These can be strong CH-acids which generate a carbanion *in situ* on treatment with different bases. The main course of the reactions, as in the case of OMCs, is halogenation of the carbanion. However, dimerisation can quite often be an alternative reaction.

Thus, by treatment with CCl_4 and lithium diisopropylamide or with alkali in alcohols it is possible to halogenate diarylmethanes,[94] ketones,[95,96] sulphones,[97,98] and saturated and unsaturated ethers.[99] Apart from CCl_4, CBr_4 or CCl_3Br can also act as halogenating agents.[99] It is interesting to note that in the latter case α-bromination of the carbanion mainly occurs, which is an indication of the greater ease of transfer of the bromine atom.

Phase-transfer catalysis is particularly promising for the halogenation of CH-acids with tetrahalomethanes. In the system concentrated alkali–triethylbenzylammonium chloride, halogenation of phenylacetylene,[100] 2-phenylalkyl nitriles,[101] and arylbenzyl ketones,[102] readily occurs. Dimerisation is possible as a side-reaction:[103]

$$PhCH_2CN + CCl_4 \rightarrow PhC(CN)=C(CN)Ph,$$
$$Ph_2CHCN + CCl_4 \rightarrow Ph_2C(CN)-C(CN)Ph_2.$$

It is assumed that halogenation of the carbanion occurs through the formation of a radical–radical anion pair as a result of discrete electron transfer,[96,99] for example:

$$\ominus\!\cdot\!\cdot\!\cdot\!\overset{O}{\overset{\|}{C}}H_2{-}C{-}OR \xrightarrow{CBr_4} \left[\ominus\!\cdot\!\cdot\!\cdot\!\overset{O}{\overset{\|}{C}}H_2{-}C{-}OR\ \ \dot{C}Br_4^{-} \right] \rightarrow \overset{O}{\overset{\|}{Br}}CH_2{-}C{-}OR + \ominus CBr_3.$$

It should be noted that a similar approach to the reactions of carbanions with alkyl halides has generally been actively discussed recently.[104]

V. Reactions with electron-neutral nucleophiles

The electrophilic properties of carbon tetrahalides are exhibited in the formation of complexes with different *n*- and π-donors. However, in this case also the coordination site is not carbon but a peripheral halogen atom. It is to be expected that this route is taken in the self-association of CX_4 molecules (X = Cl, Br, I),[105] which disappears on addition of cyclohexane,[106] if it is assumed that such an association occurs through the interaction of the UEP of the halogen atom (as an *n*-donor) with the antibonding orbital of the C–X bond of neighbouring molecules as occurs in intermolecular X...X contacts in these compounds in the crystalline state.[38,39]

Interactions of a similar type apparently occur on mixing carbon tetrachloride with ethers, which act in this case as *n*-donors.[107]

It is well known that the π-electron properties of aromatic hydrocarbons have an effect on their ability to form complexes with various electron acceptors, including tetrahalomethanes. Thus, it has been known for quite some time that carbon tetrachloride and tetrabromide form crystalline complexes with benzene,[108,109] toluene,[109] and polymethylated benzenes.[110] X-Ray diffraction analysis of the complex between CBr_4 and *p*-xylene showed that in a crystal molecule of the partners alternate in small chains, in which each halide molecule is bonded to two molecules of aromatic compound via bromine atoms. In this case the distance between the bromine atom and the centre of the plane of the hydrocarbon ring is less than the sum of the van der Waals radii.[112] When the halogen nuclei were studied by NQR it was not possible to come to any conclusion about the nature of the bonding in these complexes,[113] but the data of IR spectroscopy suggest that in hydrocarbon–tetrahalomethane mixtures, complexes of composition 1:1 are apparently formed by charge transfer.[114,115] The changes in the Raman spectra of a solution of CCl_4 in benzene and mesitylene are interpreted as resulting from charge transfer from the π-donor to the chlorine atom.[116] It is thought in this case that an electron can be accepted either via the σ* orbital of the carbon–halogen bond[113] or via vacant 3*d* orbitals of the halogen atom.[116,117]

Reactions of tetrahalomethanes with neutral nucleophiles such as tricoordinate nitrogen or phosphorus compounds occupy a special place in terms of the quantity of information as well as the chemical effects. It is therefore worth examining them in greater detail.

The instability of solutions of amines in carbon tetrachloride was observed some time ago.[118–120] On standing in glass vessels, a precipitate is rapidly deposited from this mixture and chloroform is formed. It is thought that the cause of this instability is the formation of a charge-transfer complex between the reactants. The existence of such complexes has been confirmed by UV spectroscopy for the systems $NH_3{\cdot}CCl_4$, $NH_3{\cdot}CBr_4$,[121] $Et_3N{\cdot}CCl_4$, $Et_3N{\cdot}CBr_3Cl$,[120] and $Bu_3N{\cdot}CCl_4$.[122] Recently crystalline complexes of carbon tetrabromide with diazabicyclo[2.2.2]octane (DABCO) and quinuclidine were successfully isolated and studied using X-ray diffraction analysis.[123] It was shown that the molecular structure of the complex between CBr_4 and DABCO is in the form of sinuoidal chains in which the diamine is coordinated with the halogen atoms of two tetrahalide molecules, while quinuclidine forms discrete donor–acceptor pairs.

Since the formation of complexes in these cases, in the opinion of the authors, assumes that there is an interaction between the UEP of the donor and the σ^* orbital of the C–X bond, this transition to some extent neutralises the bonding due to the two electrons situated in the σ orbital. Therefore, on irradiation in the near-UV region dissociation of the complex can occur,[124] resulting in the formation of radical-ion pairs

$$\left[\equiv N\cdot CBr_4\right] \xrightarrow{h\nu} \left[\equiv \dot{N}^{+}\, \dot{C}Br_4^{-}\right],$$

whose reactions account for the photochemical instability of the solutions of amines and tetrahalomethanes. Thus, on irradiation of $RNH_2\cdot CCl_4$ with visible light at $\lambda = 2537$ Å in the absence of oxygen, $R\dot{N}H_3\ Cl^-$, $CHCl_3$, C_2Cl_6, $R'CH=NR$, and NH_3 are formed, with a quantum yield ranging from 1 to 100.[122] The formation of these compounds results from the following series of reactions:

$$RNH_2\cdot CCl_4 \xrightarrow{h\nu} R\dot{N}H_2\ Cl^- + \dot{C}Cl_3,$$
$$R\dot{N}H_2\ Cl^- + RNH_2 \rightarrow R\dot{N}H_3\ \dot{C}l^- + R\dot{N}H,$$
$$\dot{C}Cl_3 + RNH_2 \rightarrow CHCl_3 + R\dot{N}H\ (\text{or}\quad R'\dot{C}HNH_2),$$
$$R\dot{N}H\ (R'\dot{C}HNH_2) + RNH_2 \rightarrow R'CH=NH + R\dot{N}H_3\ Cl^-,$$
$$R'CH=NH + RNH_2 \rightarrow R'CH=NR + NH_3,$$
$$2\dot{C}Cl_3 \rightarrow C_2Cl_6.$$

When the reaction is carried out in the presence of oxygen, the molar ratio of the reaction products varies and, moreover, *N,N'*-dialkylureas are formed, apparently by the reaction of the amine with phosgene that occurs as a result of the radical oxidation of CCl_4.

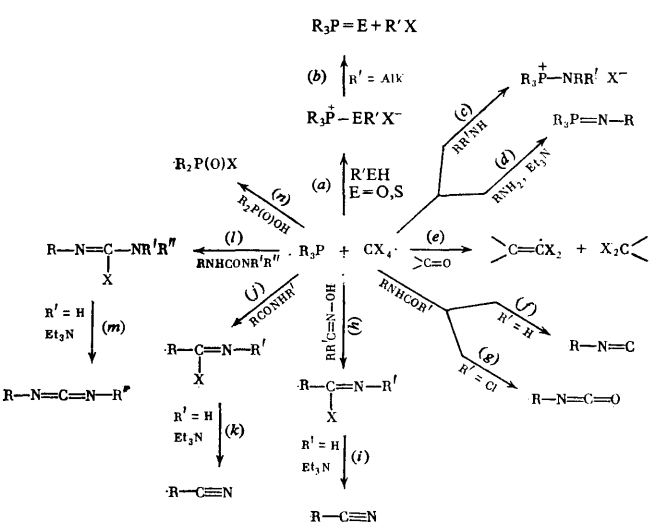
Recently the radical nature of the photochemical reaction of amines with carbon tetrachloride has been confirmed by the occurrence of the effect of chemically induced polarisation of the ^1H nuclei.[125]

The reaction with tetrahalomethanes in the dark and in the absence of oxygen can be initiated with Cu(I), Cu(II), Fe(II), and Fe(III) salts.[126] It is thought that in this case the reaction is radical in nature. In addition, the reaction mixture stimulates the addition of CCl_4 to olefins.[127]

The reactions of tetrahalomethanes, in particular CCl_4, with tricoordinate phosphorous derivatives have become quite widespread in recent times. The greatest attention of research workers has been given to the system Ph_3P-CCl_4, which is a mild selective reagent. This system has been applied most widely in the halogenation of alcohols with a very variable structure and also in reactions that accompany the dehydration and formation of the P–N bond.[128–130]

From the ideas about the electronic structure of tetrahalomethanes and their reactions with both charged and neutral nucleophiles, it is to be expected that the initial stage of the reaction involving the Ph_3P-CCl_4 system should be electron transfer from the phosphorus atom to the σ^* orbital of the C–Cl bond. But while in the case of the amine–tetrahalomethane system homolytic decomposition follows the transfer of electrons, in the case of tertiary phosphines there is heterolysis of the intermediate complex.[129] Nevertheless, it should be noted that on exposure of solutions of Ph_3P in carbon tetrachloride to light, photochemically induced homolytic reactions occur concurrently, as chemically induced polarisation of the ^{31}P nucleus occurs.[131]

Thus, a scheme involving nucleophilic attack by the phosphorus atom on a halogen atom in the tetrahalomethane has been proposed by many authors for reactions that take place in the absence of light and radical initiators:



$$R_2(R'_2CH)\,P^{+\delta}\ldots X\ldots \overset{-\delta}{C}X_3 \rightarrow [R_2(R'_2CH)\,P{-}X]^+\ CX_3^- \rightarrow$$
$$\xrightarrow{(1)} R_2(R'_2CH)\,\overset{+}{P}{-}CX_3\ X^-$$
$$\xrightarrow{(2)} R_2P{=}CR'_2 + HCX_3$$
$$\qquad\qquad |$$
$$\qquad\qquad X$$

The resulting dipolar associate is converted to an ion pair with a trihalomethide anion, which, depending on the structure of the phosphorus-containing residue, is converted either to the corresponding phosphonium salt[132] or (when there is an active hydrogen on the α-carbon atom) to haloform and a *P*-halogen ylide by deprotonation.[130] The latter is stimulated on the one hand by an increased CH-acidity and on the other hand by steric shielding of the phosphorus atom. It is observed here that the reactivity of the tetrahalomethane increases on going from CCl_4 to CBr_4 and then CI_4.

Reactions of CX_4 with tertiary phosphines that take place by route (*1*) are not complete when the trihalomethyltriorganylphosphonium halide is formed. In the presence of excess phosphine these very active compounds react further:

$$R_3\overset{+}{P}CX_3\ X^- + R_3P \longrightarrow R_3P{=}CX_2 + R_3PX_2 \longrightarrow \left[R_3P{-}CX_2{-}PR_3\right]^{++} 2X^- \xrightarrow{R_3P}$$
$$\longrightarrow \left[R_3P{=}C(X){-}PR_3\right]^{+}\ X^- + R_3PX_2\,.$$

It is assumed that the formation of triorganylhalophosphonium trihalomethide $R_3P^+Hal\ CHal_3^-$ at an intermediate stage of the reaction permits a considerable number of reactions involving tertiary phosphines and tetrahalomethanes to take place.[129]

The system tertiary phosphine–tetrahalomethane–hydrogen donor has been used successfully to obtain quasiphosphonium salts from phenols or thiophenols (*a*) and also alkyl halides from alcohols (*b*). By introducing secondary amines into the reaction it is

possible to obtain aminophosphonium salts (*c*). Phosphinic acids can readily be converted to their acid halides (*n*). For the purposes of organic synthesis an R_3P-CCl_4 mixture can be used for the preparation of chloroformamidines from trisubstituted ureas (*l*) or imidoyl halides from *N*-substituted carboxamides (*j*) and ketoximes (*h*). When carbamoyl halides are used it is possible to obtain isocyanates (*g*).

If the compound that acts as a hydrogen donor contains two active hydrogen atoms, conducting the reaction in the presence of triethylamine as a halogen halide acceptor has the result that dehydrohalogenation takes place by a route different from route (*c*) [reactions (*d*), (*f*), (*i*), (*k*), and (*m*)].

The use of the binary system R_3P-CX_4 to obtain 1,1-dihaloalkenes from aldehydes and ketones has been reported. Dihaloalkenes are probably obtained from an intermediate triorganylhalomethylenephosphorane as the result of a Wittig reaction (*e*).

The use of the system R_3P-CX_4 for halogenation of the hydroxyl group has been described in great detail.[128,129] However, during the time that has passed since these reviews were written, a large quantity of additional information has been published.

A considerable number of studies have been devoted to establishing the mechanism of this reaction. It has been shown conclusively that the reaction takes place via an intermediate alkoxyphosphonium salt, which then undergoes an S_N2 substitution.[133,134]

$$Ph_3P + CCl_4 \rightarrow Ph_3\overset{+}{P}-Cl\ CCl_3^- \xrightarrow{ROH} Ph_3\overset{+}{P}-OR\ Cl^- + HCCl_3,$$
$$Ph_3\overset{+}{P}-OR\ Cl^- \rightarrow Ph_3P{=}O + RCl.$$

Sometimes this salt can be separated as a stable hexafluorophosphorate.[135]

In recent times interest has mainly been directed towards using this sytem Ph_3P-CCl_4 for the halogenation of polyols.[136-140] It is observed that the reaction is selective, namely, only a primary hydroxyl group undergoes transformation. However, intramolecular cyclodehydration to an α-oxide can occur as a subsequent stage.[138,139]

There is continued interest in the use of systems containing CX_4 and diphenylphosphinated polymers for the halogenation of alcohols, giving higher yields of products than the binary system Ph_3P-CX_4.[141,142]

The system Ph_3P-CCl_4 has been used to obtain cyclic and acyclic 1,2-dichloroalkanes from α-oxides[143] and for the synthesis of 1,1-dichloroalkenes from the corresponding carbonyl compounds.[144,145]

In addition to the widely used carbon tetrachloride, other symmetric tetrahalomethanes have started to be used for halogenation of the OH group. It is observed in this case that CBr_4 and CI_4 react more readily than their chlorine analogue,[140,146-148] while in the case of CF_2Cl_2 only a chlorine atom participates in the reaction.[149]

The system CBr_4-PPh_3 has been quite widely used for the selective halogenation of primary hydroxyl groups in sugars and nucleosides.[140,146-147] It can be used to dehydrate amides, aldoximes, and ureas to the corresponding nitriles and carbodiimides after a shorter period of time and at a lower temperature than in the case of Ph_3P-CCl_4,[150] and there is a much greater ease in forming the ylide $Ph_3P{=}CBr_2$, which then either undergoes alkylation by alkyl halides to the corresponding phosphonium salts[151] or gives dibromoolefins by the Wittig reaction.[152,153] The quantitative polycondensation of *p*-aminobenzoic acid is achieved using the system CBr_4-PPh_3.[154]

The bromine atom in $BrCCl_3$ is attacked very readily by tertiary phosphines. This is suggested by the formation of only $Ph_3P{=}CCl_2$ [155,156] and also the preparation of bromophosphazo compounds from phosphinous acid anilides.[157]

The fluorine atom in fluorine-containing tetrahalomethanes CF_nX_{4-n} (X = Cl, Br, I; $n = 1-3$) is never attacked by tertiary phosphines. In all cases transfer of the more polarisable halogen occurs. This is suggested by the formation of $Ph_3P{=}CFX$ in the reaction of Ph_3P with CFX_nY_{3-n}, where X and Y = Cl, Br, I,[158] and by the trifluoromethylation of silicon chlorides R_nSiCl_{4-n} with the binary system $(Et_2N)_3P-CF_3Br$.[159]

$$(Et_2N)_3P + CF_3Br \rightarrow (Et_2N)_3\overset{+}{P}-Br\ CF_3^- \xrightarrow[-(Et_2N)_3PBrCl]{Me_3SiCl} Me_3SiCF_3.$$

It is thus possible to replace one or two chlorine atoms on silicon in organylchlorosilanes with the trifluoromethyl group. Similarly trifluoromethyl P(III) derivatives are formed if a tricoordinate phosphorus halide is introduced into the reaction as the third component.[160]

The stability of the C–F bond in tetrahalomethanes is confirmed by the formation of 1,1-difluoroolefins in the reaction of carbonyl compounds with a mixture of $(Me_2N)_3P-CF_2Br_2$ [161] or 1,1-difluorocyclopropanes as a result of the reaction of this system with disubstituted alkenes.[162]

1,1-Diiodoalkenes are formed in good yield when the binary system CI_4-Ph_3P is treated with aldehydes.[163]

The reaction of white phosphorus P_4 with CCl_4 may also be regarded as a process that involves reactions between tricoordinate phosphorus derivatives and tetrahalomethanes. Treatment of this reaction mixture with alcohols or phenols leads to the formation of phosphite esters[164,165] and treatment with thiols gives their thio analogues.[166]

Reactions of esters of tricoordinate phosphorus acids with tetrahalomethanes also play an important role in synthetic organophosphorus chemistry:

$$\rangle P-OR + CX_4 \rightarrow \rangle P\begin{matrix}O\\ \diagdown CX_3\end{matrix} + RX.$$

Those reactions with carbon tetrachloride are the most common. It reacts with phosphite,[128,167,168] phosphonite,[130,169,170] and phosphinite[171-174] esters and also with phosphorus acid ether amides.[175,176]

As a rule P(III) acid esters react with CBr_4 more readily than with CCl_4.[128,130] Among the other tetrahalomethanes that take part in reactions with phosphinites, mention should be made of $CBrCl_3$,[177,178] $CFBr_3$, and CF_2Br_2.[179]

As far as the mechanism of these reactions is concerned, at the present time the idea is becoming established that in the absence of radical initiators, in the dark, and when there is steric hindrance at the phosphorus atom, a heterolytic reaction takes place by means of attack by the phosphorus-containing nucleophile on a halogen atom:

$$\rangle P-OR + X-CX_3 \rightarrow RO-\overset{+}{P}\begin{matrix}\diagup X\ CX_3^-\\ \diagdown\end{matrix} \rightarrow$$
$$\rightarrow RO-\overset{+}{P}\begin{matrix}\diagup CX_3\ X^-\\ \diagdown\end{matrix} \rightarrow \rangle P\begin{matrix}-CX_3\\ \| O\end{matrix} + R-X.$$

This relates to the reactions of $(RO)_3P$,[180] $RP(OR)_2$,[130,169] $(Me_2N)_2POR$,[176] R_2POR,[171,173] and $(R_2N)_2PSR$.[181]

It has been observed that the reactivity of P(III) acid esters towards CCl_4 varies in accordance with the following series:[176,182]

$$iso\text{-}PrO)_3P > (EtO)_3P > (MeO)_3P > (EtO)_2POPh > EtOP(OPh)_2 \gg P(OPh)_3.$$

This sequence matches the increase in the half-wave potential of the anodic oxidation of P(III) acid esters,[183] which is proportional to the HOMO energy. Thus, it may be assumed that these processes between CX_4 and tricoordinate phosphorus acid esters correspond to a donor-acceptor interaction between P(III) compounds and tetrahalomethanes and in this respect there is a perfect similarity between them and the reactions of tertiary phospines depicted above.

—o0o—

The analysis carried out on the structural features and reactivity of carbon tetrahalides indicates that, in contrast to the widely known chemical inertness of CF_4, its analogues exhibit a large number of reactions on treatment with electron donors. These properties of CX_4 molecules, where X = Cl, Br, and I, are apparently due to the energy accessibility of σ-type antibonding molecular orbitals of the C–X bonds, which accounts for the coordination of the reactants on a peripheral halogen atom rather than on the carbon atom, resulting eventually in halogen transfer.

It cannot be excluded that similar reactions occur in the case of tetrahalides of other elements.

High speed autowave reaction regimes in low-temperature solid state chemistry

V V Barelko, I M Barkalov, V I Gol'danskii, A M Zanin, D P Kiryukhin
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The results of studies on new phenomena of the travelling wave type in low-temperature solid state chemistry, observed in a wide variety of solid-state chemical reactions at the temperatures of liquid nitrogen or helium, are surveyed. The processes investigated are characterised by anomalously high rates of reaction for the temperature range indicated, comparable to the rates of the fastest high-temperature combustion reactions in classical chemistry. A mechanism is proposed with an autocatalytic mechanochemical step which permits a qualitative explanation of all the characteristic features observed in the phenomenon. It is suggested that the mechanism indicated occurs widely in space chemistry and in the processes involved in the chemical evolution of the universe.

I. Introduction

Quite recently, at the beginning of the 1970s, the very possibility of a chemical reaction in the solid state near the absolute zero of temperature appeared doubtful (electron transfer reactions[1] in the solid state at low temperatures are not considered in this review). An event which made it necessary to revise the existing ideas was the discovery of the phenomenon of the low-temperature limit of the rate of a chemical reaction in relation to the radiation-initiated polymerisation of formaldehyde;[2] the existence of this phenomenon was subsequently established in a number of other chain and non-chain reactions (see Gol'danskii et al.[3] and the references therein). It was discovered that there exist systems in which a reaction occurs even at the temperature of liquid helium at a low but entirely measurable rate, which is independent of temperature. In order to account for the phenomenon of the low-temperature limit in cryochemical reactions, the concept of molecular tunnelling was put forward. It was subsequently developed taking into account low-temperature intermolecular interactions (see Gol'danskii and co-workers[3–7] and the references therein).

A fundamentally new factor in the introduction of the concept of the tunnel mechanism into the kinetics of low-temperature radiation-initiated chain reactions in the solid state was the assumption of the energy equilibrium in the reacting solid-phase system. However, the universality of the proposed kinetic models for the processes indicated, wholly based on the classical ideas of equilibrium Arrhenius kinetics, was never regarded as axiomatic, particularly since the subject under consideration consisted of various chemical reactions stimulated by ionising radiation supplied from the outside, i.e. under conditions where temperature ceases to be the only parameter characterising the energy state of the system.

The appearance of alternative mechanisms, according to which the leading role in low-temperature solid-phase reactions was attributed to non-equilibrium states, was entirely natural. As early as 1960, Semenov[8] proposed a mechanism involving energy chains in order to describe the radiation-stimulated solid-phase polymerisation. According to this mechanism, the energy evolved in each elementary step during the growth of the polymer chain ensures the overcoming of the activation barrier in the next step of this kind. The polymer chain can grow via this mechanism at the rate of propagation of the exciton ($\sim 10^6$ mm s^{-1}). This exciton chain model has been examined theoretically in detail.[9] The important conclusion was reached that very high rates of a solid-phase reaction really occur even at very low temperatures as a result of the chain transfer of energy via the frozen matrix.

A combined mechanism, assuming the operation of the tunnel mechanism in the reaction initiation stage, postulating the subsequent very rapid development of a chain process as a result of the recovery of the energy of the reaction steps, has been described.[10]

Together with this chain-tunnel mechanism, mention should be made of yet another combined mechanism. This is the chain-thermal mechanism proposed and developed[11–13] in order to interpret the limiting phenomena in the accumulation of radicals during the irradiation of frozen specimens of different organic substances.

Here however we should like to draw attention not to the difference between the equilibrium tunnel mechanism and the mechanisms of the non-equilibrium type but to the simplifying assumption, from which all these approaches have originated, and which must be abandoned in many instances. This topic will be dealt with later in the review.

The point is that in the models investigated the solid matrix itself was regarded in essence from a single standpoint, namely as a kind of ideal defect-free system in mechanical equilibrium. In other

words, in the analysis of the phenomena the fact that the systems investigated are characterised by a significant mechanoenergetic disequilibrium was rejected. This quality of the specimens actually studied was a consequence of both the conditions in their preparation and of the effect of fluxed of ionising radiation. It is known that the initial spatial disposition of the molecules is significantly distorted in the irradiated solid, the phase state of the solid is modified, homogeneity is affected, the internal stresses field is greatly altered, and the strength characteristics are appreciably reduced. The transition in the experiments to the post-effect conditions does not eliminate the problem of the role of the mechanical disequilibrium of the specimen in the solid-phase reaction because the specimen remains a significantly non-equilibrium object even after the γ-ray energy flux has been switched off because of the retardation at low temperatures of all kinds of relaxation processes. Apart from the factors quoted, the chemical reaction itself, which has been initiated in the solid matrix, must be a source of intensification of distortions in the lattice i.e. of further accumulation in the latter of mechanical potential energy

The considerations described above served as a starting point in the formulation of tasks in a series of studies[14–24] The factor which stimulated the consideration of the mechanochemical aspect of the radiation cryochemistry of the solid state was the observation[14] of initiation of the reaction by a local break in irradiated specimens stabilised by a low temperature.

The principal questions can be briefly formulated in the following way. Can one liberate the potential energy accumulated in the mechanically non-equilibrium matrix of the frozen specimen of the reactants by its brittle breakdown. Will the stored mechanical energy be transformed into chemical energy and will a chemical reaction occur under these conditions?

The possibility of a positive answer to these questions was supported by the general postulates of the theory of the strength of a solid, from which it followed that the mechanical energy of the elastic deformation at the instant when the break occurs is concentrated in the region directly adjoining the surface being formed. It is known[25] that this energy transformation process is accompanied by a significant change in the physicochemical properties of the substances on the freshly formed surface compared with the bulk-phase properties: the brittle breakdown is coupled with phenomena such as electron and ion emission, luminescence, the formation of radicals, and a sharp acceleration of transport processes on the cleavage planes. In other words, it appeared likely that the transition of the process from the homogeneous regime to a significantly heterogeneous regime via the brittle breakdown of the specimen involves a non-equilibrium mechanism of energy transfer to active centres previously "frozen" in the three-dimensional matrix and induces thereby a chemical reaction at low temperatures. To the foregoing, one should add that in the traditional mechanochemical processes, a notable role was always attributed to brittle breakdown (although it did occur under the conditions of forced dispersion of the specimen) (see Lyakhov and Boldyrev[26] and the references therein).

We may note yet another factor which has stimulated a revision of the existing ideas. In previous studies, both the kinetic models themselves, describing the solid-phase radiation-chemical reactions, and the experimental methods were based on the assumption that the system is uniform and that the chemical reaction is homogeneous. This stage was entirely natural because, with the aid of calorimetric and spectroscopic methods using an integrated signal, it was difficult to discover and investigate the characteristic features of non-uniform chemical reaction regimes. We may note that doubts about the admissibility of the application of zero-dimensional kinetic models in the radiation chemistry of the solid state have always existed, because it is well known that an irradiated specimen is never homogeneous (highly active regions, tracks and spurs, arise during radiolysis and the stabilising radicals and ions are distributed non-uniformly throughout the space within the body). Apart from the neglect of the inhomogeneity factor in the development of the process throughout the specimen, the homogeneous approach was also restricted by the fact that it did not make it possible to go outside the framework or linear (or almost linear) kinetic models and hindered the discovery of the features of significantly non-linear mechanisms—mechanisms with feedback. Nevertheless, their existence in complex chemical systems such as a reactive solid had to be regarded as extremely likely. In particular, the existence of feedback between the mechanical state of the system and its chemical activity is extremely probable. These considerations also stimulated the study of the role in the solid-phase processes investigated of all kinds of artificially introduced or spontaneously arising local perturbations.

The selected approach justified itself, the initial postulates proved to be legitimate, and the investigations led to the discovery of highly intense autowave regimes in low-temperature solid-phase reactions. The principal results of this first stage of these studies have been surveyed in a previous review.[27] In order to maintain a logical consistency, certain fundamental conclusions arising from previous studies were introduced into the present review, which is devoted to the analysis of the state of the problem of autowaves in cryochemistry of the solid state at a new stage of its investigation.

II. Objects of study

The objects of study[27] were systems in which a spontaneous development of reaction chains is impossible in the solid state at radiolysis temperatures of 77 and 4.2 K. In the course of the γ-irradiation of these solid-phase systems at the nitrogen and helium temperatures, non-chain radiation-chemical reactions take place and lead to the formation of energy-rich active centres which are chemically stable in the temperature range indicated. Various classes of reactions have been investigated: chlorination of hydrocarbons, chlorination and hydrobromination of alkenes, polymerisation, etc. The characteristic features of solid-phase reactions were investigated in the first stage in the following systems: (1) a vitreous solution of chlorine in butyl chloride (molar ratio 1:3, glass point $T_g \simeq 100$ K);[28] (2) a vitreous solution of chlorine in methylcyclohexane (ratio 1:3, $T_g \simeq 93$ K);[14] (3) the crystalline complex $C_2H_4.HBr$ (T_m† = 110 K);[29,30] (4) a vitreous solution of SO_2 in 2-methylbuta-1,3-diene (ratio 1:1, $T_g \simeq 110$ K).[17]

III. Activating role of brittle breakdown in the reaction excitation stage

In order to achieve the brittle breakdown of the specimen, the method involving the induction of thermoelastic stresses by selecting a rate of change of the specimen temperature sufficient to induce cracking was applied initially. The rate of change of temperature was recorded and the thermal signals accompanying the breakdown

† Melting point (Ed. of translation).

were observed with the aid of a differential scanning calorimeter (for a more detailed description of the method, see Barkalov et al.[31]).

When the specimens are heated slowly from 4.2 to 77 K, which does not lead to cracking, the calorimeter does not reveal any thermal effects (Figs. 1*a* and 1*b*, continuous lines). Rapid heating induces the cracking of the specimen and the accompanying thermal effect is recorded by the calorimeter (Figs. 1*c* and 1*d*, continuous lines). After selecting a rate of change of temperature such that the specimen cracks, similar experiments were carried out but this time with specimens treated with a definite dose of ^{60}Co radiation (in order to create stabilised active centres in the system). During slow heating of the irradiated specimen, unaccompanied by its cracking, the system remained chemically inert, i.e. thermal effects were not recorded (Figs. 1*a* and 1*b*, dashed lines). At a high heating rate, a chemical reaction was initiated at the instant of the brittle breakdown of the specimen (Figs. 1*c* and 1*d*, dashed lines).

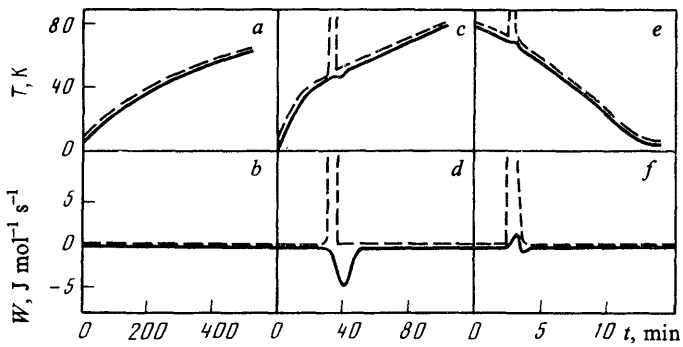

Figure 1. Time variation of the temperature of a vitreous solution of chlorine in methylcyclohexane (*a*, *c*, *d*) and of the accompanying thermal effects (*b*, *d*, *f*): continuous—non-irradiated specimen; dashed lines—specimens irradiated with ^{60}Co γ-rays at 77 K at a dose of 27 kGy.

The brittle breakdown of the specimen and the accompanying chemical reaction were achieved also on rapid cooling. Figs. 1*e* and 1*f* present data obtained on fairly rapid cooling of the specimen inducing the cracking of the solid matrix. Evidently the cracking of the irradiated specimen was accompanied by a chemical reaction (there was no reaction in the non-irradiated specimen).

In order to demonstrate the decisive role of the formation of cracks as a factor initiating the chemical reaction, a direct experiment was formulated involving a non-thermal disruption of the solid mixture of reactants. The cracking was achieved at a constant thermostat temperature of 4.2 K by rotating a thin metallic rod frozen into the specimen. At the instant of the introduction of such perturbation into the matrix containing the stabilised active centres, a rapid, one might say "explosive", chemical reaction occurred. Despite the local initiating, the reaction spread throughout the cell—the dark colour induced by the γ-radiolysis vanished.

The results described above permitted two fundamentally important conclusions: (1) in the systems investigated, brittle breakdown induces an abrupt solid-phase chemical reaction and (2) the development of the process initiated by the cracking of the specimen is self-accelerating and involves the entire specimen. Consequently the formation of the primary crack plays the role of an initiating device incorporating a positive feedback mechanism, which ensures a self-maintaining process regime. In order to elucidate this mechanism, experiments were formulated in order to investigate the dynamics of the reactions developing in this system in response to the perturbation introduced.

The observed features of the dynamics of the development of an abrupt reaction demonstrated convincingly that the classical thermal feedback mechanism is not decisive in the given instance. The establishment of the leading role of the surface formed on disruption of the matrix made it possible to formulate the following hypothetical non-thermal mechanism of the self-activation of the system investigated: the chemical reaction arising on the cleavage planes and in the adjoining regions generates in its turn breaks in continuity in the regions of the solid matrix not involved in the reaction (for example, as a consequence of the appearance during the reaction of temperature or density gradients, which create stresses disrupting the specimen). This model, which can be classified as of the branched-chain type, describes qualitatively a number of experimentally observed facts, namely: (1) the critical phenomena involving the appearance and spontaneous self-accelerating development of a reaction accompanied by intense dispersion of the solid matrix comprising the reactants; (2) the initiation of a similar explosive process by creating in the initial instant an initiating network of cracks by the mechanical or thermal disruption of the specimen (in the absence of such perturbations, the rate of reaction is immeasurably small); (3) the degeneracy of critical phenomena (see the bibliography in the paper of Barelko et al.[27]).

IV. Autowave reaction regimes

It is known that a fundamental feature of the systems described by non-linear branched-chain models is autowave phenomena characteristic of such systems. The autowave reaction regimes should arise in sufficiently large specimens in response to a locally introduced perturbation.

On the other hand, in the first experiments[16] it proved possible to initiate the spontaneous propagation of the reaction wave by means of a local perturbation (by creating a local cleavage plane in the specimen as a result of mechanical action or by supplying a thermal pulse disrupting a limited region in the solid matrix). The characteristic results obtained in experiments with a cylindrical specimen of a frozen mixture of reactants 0.5–1.0 cm in diameter and 5–20 cm long are presented below. Since the reaction was accompanied by a change in the colour of the specimen, the velocity of the fronts was measured successfully using the possibilities of cine-techniques. The cinegrams show clearly how the front, propagated parallel to itself along the axis of the cell at a constant rate of 1–2 cm s^{-2}, is formed on local mechanical breakdown.

In order to investigate the structure of the wave front (its temperature profile), a series of thermographic experiments on the autowave process were carried out. The rate was determined from the time taken by the waves to traverse the distance between two thermocouples frozen into the specimen.[16–18]

Fig. 2 presents the characteristic profiles of the travelling temperature waves (in terms of time and spatial scans) for initial temperatures of 77 K (*a*) and 4.2 K (*b*). The form of the profile does not undergo qualitative changes when the thermostat

temperature is altered. The process consists of the following stages: *AB*—inert heating (at 77 K, this stage was not recorded, i.e. was almost isothermal); *BC*—abrupt start and explosive course of reaction (characteristic break at point *B*); *CD*—cooling stage. The *BC* stage is rapid. The oscillograph scan of this zone of the running wave front shows that at 77 K (Fig. 2*a*) the duration of the given stage is ~0.1 s, i.e. at a wave velocity $U \simeq 20$ mm s^{-1} the zone width is $\delta \simeq 0.2$ cm, while at 4.2 K (Fig. 2*b*) the duration of the stage is ~0.3 s and the width is $\delta \simeq 0.3$ cm (wave velocity $U \simeq 10$ mm s^{-1}).

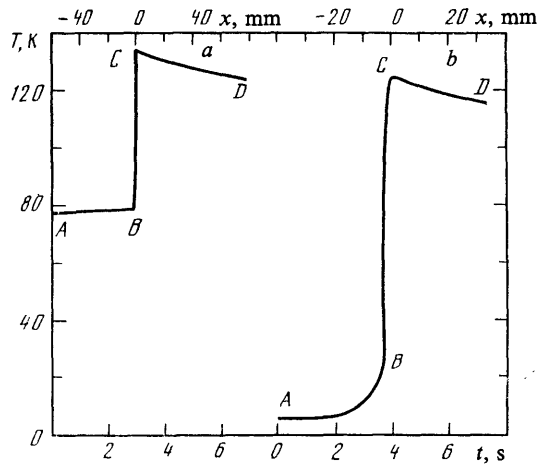

Figure 2. Time and spatial scans of the characteristic temperature profiles of the $C_4H_9Cl + Cl_2$ reaction propagation waves at 77 K (*a*) and 4.2 K (*b*): *a*, $U = 20$ mm s^{-1}; *b*, $U = 10$ mm s^{-1}. Preliminary irradiation dose 27 kGy.

In the structure of the travelling front of a low-temperature reaction presented, it is possible to see clearly features which are completely atypical for classical thermal self-propagation processes: (1) the stage of the inert pre-explosion heating is weakly expressed or is altogether absent; (2) the reaction starts and stops abruptly (characteristic breaks at points *B* and *C*), the reaction at point *B* starting at temperatures significantly lower than the temperature of the onset of the thermally activated reaction ($T_g \simeq 100$ K); (3) the dynamic picture of the development of the process in the spontaneous layer-by-layer initiation of the reaction by the travelling wave is identical with the picture of the forced initiation of the reaction by impact heating; (4) the rate of propagation of the wave changes only slightly on reducing the temperature from 77 to 4.2 K despite the marked alteration of the heat evolution.

The next important step in the elucidation of the role of the thermal factor in the mechanism of the phenomena investigated involved the study of the influence of the size of the specimen on the characteristics of the autowave process.[20] Can the self-maintaining wave regime of the reaction be precluded by intensifying the heat evolution as a result of the reduction of the diameter of the cylindrical tube with the frozen mixture of reactants?

When the experiments with travelling waves were carried out in capillaries 0.5–1.0 mm in diameter (which corresponds to an increase in the parameter characterising the intensity of heat evolution by more than an order of magnitude), it was established[20–22] that there is no degeneracy of the autowave process under these conditions in any of the systems considered. Furthermore, it was discovered that the characteristic rates of autopropagation of the reaction do not undergo any appreciable changes under these conditions.

In the course of development of the relevant research, a series of experiments were performed with thin film specimens of the reactants.[22,27] The experiments were carried out with films frozen onto a flat support and immersed in liquid nitrogen, i.e. under conditions where there was no shield between the surface of the film and the bath of the cooling agent. When the films were punctured or scratched, an autowave process was excited. The use of such objects made it possible to achieve quasi-isothermal process conditions and to promote thereby the manifestation of the isothermal mechanism mentioned above, consisting of the layer-by-layer self-dispersion of the specimen as a result of the difference between the densities of the initial reactants and the final reaction products. Under these conditions, the autowave was not only not suppressed but actually became even more pronounced.

V. Theory of autowave processes in solid-phase cryochemical reactions

The experimental results made it possible to formulate in greater detail the hypothesis concerning the mechanochemical nature of the self-activation of the solid-phase reaction and to construct a tentative qualitative picture of the development of the autoclave process in a chemical interaction in the systems under consideration. The occurrence of the process can be represented as the movement in the solid specimen of a narrow zone extensively intersected by a dense network of freshly formed cracks. The chemical reaction arises in precisely this zone on the surface of the cracks (or near them) and creates in its turn conditions for the continuation of the breakdown in the neighbouring layer of the solid matrix. Such layer-by-layer dispersion of the specimen is induced by the propagating field of the stress, which can be generated, as already stated, either by the difference between the densities of the initial reactants and of the final products (isothermal mechanism) or by the appearance in the specimen of steep temperature gradients as a result of the exothermicity of the reaction (a non-isothermal mechanism). Naturally, these two factors can also operate simultaneously. The non-isothermal mechanism has been analysed[18] in relation to massive cylindrical specimens in which, as shown above, significant heating can take place due to the reaction and the role of thermal stresses in the dispersion steps should be very notable.

The model considered[18] was constructed on the basis of the following assumptions. It is assumed that the specimen is infinite in size and no account is taken of the heat exchange with the surrounding medium, i.e. it is assumed that the characteristic time for the evolution of the heat of reaction is much shorter than the characteristic time for the removal of heat. These conditions constitute the basis for the analysis within the framework of a one-dimensional model. According to the hypothesis, the initiation of the reaction in the given section of the specimen occurs when a stress exceeding the tensile strength of the solid matrix is generated. Since one is dealing with thermal stresses and the region of elastic deformation and brittle breakdown is considered, it follows that, in relation to the given physical model, the stresses can be replaced by temperature gradients assuming that there is an unambiguous

correspondence between them (Fig. 3). Such change of variables greatly simplifies the model and makes it possible to exclude from consideration mechanical equations and to reduce the analysis to only one heat balance equation in which, instead of the limiting brittle breakdown stress, a critical value of the temperature gradient is introduced as the parameter.

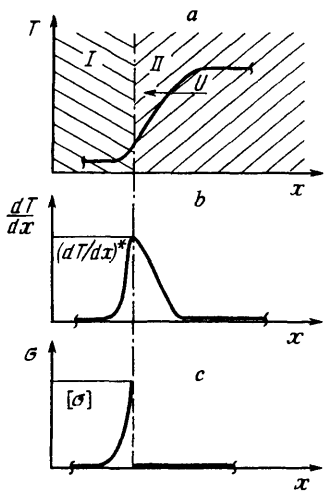

Figure 3. Characteristic form of the temperature profile (*a*), the temperature gradient (*b*) and the stresses field (*c*) in the running wave front: (I) zone of the specimen not involved in the reaction; (II) zone of the specimens dispersed as a result of the reaction.

Taking into account the assumptions made, the equation describing the autowave process assumes at first sight a form analogous to the fundamental equation of the theory of combustion:[32]

$$\lambda \frac{d^2T}{dx^2} - Uc\rho \frac{dT}{dx} + Q = 0, \qquad (1)$$

where T is the temperature, x the coordinate, λ the thermal conductivity, c and ρ are respectively the heat capacity and density of the solid mixture of reactants, Q is the rate of evolution of the heat of reaction, and U is the rate of propagation of the thermal wave front.

However, there are fundamental differences between the process under consideration and combustion, which are reflected in the character of the dependence of Q on the variable: Q is a function not of temperature but of its derivative with respect to the coordinate. We express Q as a function varying abruptly from 0 to Q^* at $dT/dx = (dT/dx)^*$, this value remaining unaltered throughout a specific time interval τ. Physically, this implies that the heat evolution in the reaction starts only in response to the brittle breakdown of the specimen under the influence of thermal stresses attaining the ultimate strength of the material. The use of the quantity τ as the parameter of the reaction time reflects both features of the hypothesis being developed, according to which the period when the chemical reactivity is maintained in the course of the formation of a crack is limited by the operation of a deactivation process (for example, as a consequence of the recombination of active species on the surface of the break). When applied to the stationary model considered here, described by Eqn. (1), the parameter τ contains information about the reaction zone (the dispersion zone) in the running front whose size is $U\tau$. At each point within this zone, the reaction takes place at a rate Q^*, while outside its limits its rate is $Q = 0$.

The boundary conditions are formulated in the following form:

$$T|_{x=-\infty} = T_0, \; T|_{x=+\infty} = T_0 + Q\tau/c\rho \equiv T_{max},$$

where T_0 is the initial temperature of the specimen and T_{max} the maximum temperature of the adiabatic heating of the specimen. The model is assumed to be quasi-homogeneous, i.e. it is postulated that the characteristic size of the grain formed in the dispersion zone is much smaller than the width of the temperature wave front.

Eqn. (1), where the heat source is represented by a function of the type indicated, can be integrated in an analytical form when account is taken of the boundary conditions presented above and has a solution in the form of a running wave. We shall concentrate attention on the analysis of the dependence of the rate of propagation of the reaction wave on the parameters. This dependence assumes the following form:

$$g(u) \equiv \{1 - \exp(-u^2)\}u^{-1} = G, \qquad (2)$$

where $u = U(\tau/a)^{0.5}$ is the dimensionless velocity of the travelling wave (the parameter to be determined), $G = (dT/dx)^*(a\tau)^{0.5}/(T_{max} - T_0)$ is the specified dimensionless critical temperature gradient, and $a = \lambda/c\rho$ is the thermal diffusivity.

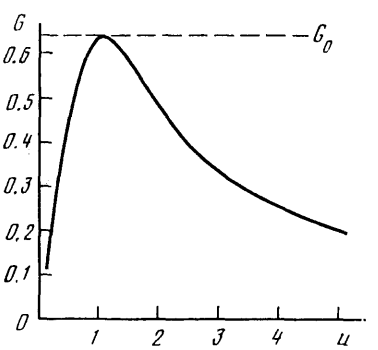

Figure 4. Dependence of the critical temperature gradient on the rate of propagation of the reaction wave.

Fig. 4 shows that an autowave solution of Eqn. (2) exists only for $G < G_0 \simeq 0.64$. Physically, this implies that, in the system described by the given model, the autowave regime in the propagation of the reaction in the solid mixture of reactants becomes impossible when the material of the specimen is strengthened to a definite extent, when the heat and rate of reaction are reduced, and also when the thermal diffusivity of the system is increased.

An important feature of Eqn. (1) is the non-unique nature of its solution. In the region $G < G_0$, two values of the stationary velocity of the running wave correspond to one value of the parameter g. We shall compare the characteristics of both regimes of the wave process. To simplify the treatment, we shall go over to the region $G \ll G_0$ in which Eqn. (2) is soluble for u. The expression for u, corresponding to the regime with a low velocity (the "slow" wave regime), has the form

$$u = a(dT/dx)^*/(T_{max} - T_0) \text{ or } u = a(dT/dx)^*/(Q^*\tau/c\rho), \quad (3)$$

while the expression corresponding to a high velocity (the "fast" wave regime) is

$$u = (T_{max} - T_0)/(dT/dx)^*\tau \text{ or } u = (Q^*/c\rho)/(dT/dx)^* \quad (4)$$

When the process takes place in the "slow" wave regime, it is possible to see features which reflect the similarity of this process, despite the differences in its physical nature, to the classical combustion process: the velocity of the wave depends on the thermal diffusivity in the same way as in the propagation of a flame; the position of the reaction zone in the wave front is the same as in combustion, i.e. it is located near the point of the maximum temperature T_{max} [the critical gradient $(dT/dx)^*$, for which the reaction is initiated, is in fact located near T_{max}]; most of the temperature profile of the front corresponds to the inert heating of the specimen (the zone referred to as the "Michelson" zone in the theory of combustion).

The characteristics of the process in the "fast" wave regime are significantly different. The most striking feature is the absence from Eqn. (4) of the dependence of the rate on the thermal diffusivity. The physical explanation of this result, which is unexpected for a problem with conductive heat transfer, is associated with the characteristic features of the structure of the "fast" wave front. In this case, the temperature profile of the wave front is much steeper than in the low velocity regime and the coordinate of the onset of reaction is located in the leading part of the front near T_0. This in fact explains the disappearance of the influence of the parameter a on the wave process, because the temperature gradients are high and close to the critical value even in the unheated part of the front. In terms of qualitative features, the "fast" wave regime is close to that observed experimentally.

In order to test the agreement between the experimentally observed phenomenon and the phenomenon considered in theoretical terms, it is of fundamental importance to attempt to realise experimentally the "slow" wave regime.

It was initiated (in conformity with theory) not by pulsed heating but by slow heating of the initiation zone. In special experiments,[18,22] the specimen was placed in a cryostat in boiling nitrogen vapour. Under these conditions, it was possible to observe, together with the "fast" wave (whose velocity did not differ from that described previously), also a "slow" wave (Fig. 5). Evidently the velocity of the "slow" wave is approximately an order of magnitude less than that of the "fast" wave, which agrees with data calculated by Eqns. (3) and (4).

It is noteworthy that the practical achievement of the "slow" wave involved certain difficulties. Initiation by slow local heating did not induce the appearance of a slowly propagated wave in each experiment. The "fast" wave was frequently initiated. Cases were observed where the "slow" wave generated was converted into the "fast" wave during its movement. This result is a consequence of the instability of the "slow" wave regime.

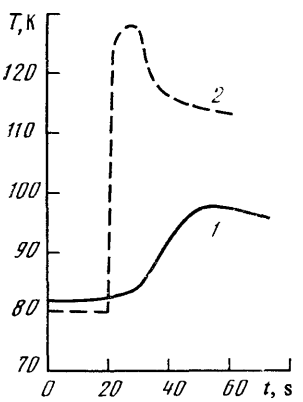

Figure 5. Time scan of the temperature profiles of the $C_4H_9Cl + Cl_2$ reaction propagation waves on slow (curve *1*) and rapid (curve *2*) heating; *1*, $U = 1$ mm s^{-1}; *2*, $U = 12$ mm s^{-1}.[18]

VI. Autowave reactions under the conditions of uniform compression and the role of mechanical stress dynamics

It follows from the above analysis that the effect of various factors on the strength characteristics of a solid mixture of reactants can serve as an instrument for testing the ideas being developed. For this purpose, studies were made of the influence of high pressures on the dynamic characteristics of autowave reactions[19] and also of the role of the rate of application of a stress and of the regimes in the cracking of the specimen on the excitation of reaction by a mechanical influence.[33]

In conformity with the theoretical prediction,[18] an increase in the pressure applied to the specimen reduced the velocity of the reaction wave front. The decrease in velocity at a pressure of 6×10^8 Pa proved to be very considerable—approximately by a factor of 2.5–3 compared with the rate of the process in the non-compressed specimen. Thus the increase in the homogeneity and structural order in the matrix under the influence of pressure, leading to its strengthening and hindering the formation of cracks, slows down the dispersion-reaction travelling wave, which is associated, according to Eqn. (4), with the increase in the critical value of the temperature gradient $(dT/dx)^*$ leading to the brittle breakdown of the specimen.

Experiments undertaken to investigate the role of the dynamics of the application of a mechanical stress, which determine the brittle or plastic character of the breakdown, were performed with film specimens 50–100 μm thick prepared from a chlorine–butyl chloride mixture. Impact by a striker (regime involving the rapid application of a stress, pressure $\sim 10^8$ Pa, duration of impact ~ 0.1 s) leads to the appearance of a network of cracks. Such treatment of

an irradiated film, inducing brittle breakdown, also induces an autowave.

On local impact by a striker in the regime involving a slow application of a stress to a film subjected to the same dose of γ-radiation, a chemical reaction is not initiated although an appreciable trace remains on the film in the form of a plastically deformed imprint having the shape of the cross-section of the striker.

Thus neither a significant plastic deformation (both on uniform compression and on local shearing) of the solid reaction systems investigated nor their transition to a highly stressed state under the influence of a static load are factors responsible for the critical phenomena and autowave processes observed in the reactions of these systems. A series of experiments[19,33] provided new important evidence for the decisive role of brittle breakdown in the mechanism of the phenomena under consideration (for further details, see Barelko et al.[27]).

VII. Expansion of the range of systems investigated (new types of autowave process)

Studies have demonstrated the wide occurrence of autowave phenomena in cryochemical reactions of solids and the identity of their physical mechanisms in a wide range of chemical systems. This justified the hypothesis that autowave reaction regimes can prove useful for the creation of new non-traditional chemical technologies. In the autowave processes described above, the principal technological problems (activation of the chemical system, supply of energy, and mixing of the reactants) are solved by combined procedures involving the use of the energy of the chemical reaction. The high rates of the chemical reaction occurring at low temperatures in the autowave regime are also extremely attractive. All this has stimulated the search for new objects of study.

1. Waves in acetaldehyde

In the light of the foregoing, the study of the post-polymerisation of γ-radiolysed solid acetaldehyde was extremely interesting. The kinetics of this reaction had been studied previously by an integral calorimetric method.[34] However, the development of ideas about autowave processes made it necessary to return to the analysis of the characteristics of the given reaction at a new qualitative level. This system is of special interest in connection with two factors. Firstly, the observation of the autowave regime in the polymerisation of acetaldehyde would provide the first example of a cryochemical wave in a one-component system. Secondly, the above reaction is characterised by a heat change smaller almost by an order of magnitude than in the systems studied previously. This created a basis for a more detailed specification of ideas concerning the role of the isothermal and non-isothermal mechanisms and about their interaction in an autowave process.

The propagation of the polymerisation front in solid radiolysed acetaldehyde at the relatively high temperatures 117–147 K (close to the melting point of the monomer which is 150 K) had been observed long before our investigations and had been recorded by thermographic measurements and cinefilming.[35]

This phenomenon was interpreted[35] within the framework of the classical thermal mechanism of combustion. Having restricted their treatment to one thermal conductivity equation and having made a number of assumptions, the authors obtained an extremely short time for the addition of one monomer unit to the polymer chain ($\sim 10^{-8}$ s). Subsequently, the kinetics of this reaction were studied in detail by the calorimetric method in the slow scanning regime with respect to temperature and directly in the field of the specimen.[34] The time required for the addition of one monomer was only $10^{-1}-10^{-2}$ s. The problem of the legitimacy of the application by Psheshezhetskii and Tupikov of the theory of combustion to the description of the layer-by-layer propagation of the polymerisation front naturally arose in this connection.

The principal ideas concerning the mechanochemical feedback in an autowave process were confirmed in the study of this system. An autowave polymerisation regime occurred in polycrystalline acetaldehyde already at 4.2–77 K and its principal characteristics were investigated.[36] The polymerisation wave in crystalline acetaldehyde was observed in massive (cylindrical) and thin-film specimens in both nitrogen (77 K) and helium (4.2 K) baths. The wave was excited in response to the local brittle breakdown of frozen aldehyde.

When the autowave passed through the specimen in the helium bath, the maximum temperature in the front did not exceed ~130 K, i.e. was significantly lower than the melting point of the monomer (150 K). Consequently this system provides an example of an autowave process occurring exclusively in the solid phase. This is in fact why conditions were created for the analysis of the changes in the structure and phase state of the polycrystalline specimen induced by the passage of the mechanochemical cryowave through it. According to the ideas being developed, the chemical reaction front consists of a mechanical dispersion zone moving in the solid reactant. Examination of the cinegrams recording the passage of the wave established that behind the front the initially opaque polycrystalline specimen is fully clarified. It could be assumed that this clarification is associated with the amorphisation of the specimen.

This hypothesis was tested by calorimetric analysis which made it possible to determine the ratio of the amorphous and vitreous phases in the solid matrix from the change in the heat of fusion. In order to carry out such analysis, the acetaldehyde specimen was transferred to a bath of liquid nitrogen after an autowave had passed through it in liquid helium and was then sliced into several parts along the height of the cylinder. Each part was placed in a calorimeter at 77 K and the calorimetric heating curve was recorded for it. It was found that, after the passage of the wave, the specimen contained no crystalline phase along its height (only a heat capacity jump accompanying devitrification was detected in the calorimetric experiments and a signal corresponding to the heat of fusion was absent). On the other hand, when the process was carried out not in the autowave regime but in the regime involving the slow heating of the entire specimen in the calorimeter (without the brittle breakdown initiating the autowave), the unreacted monomer retained its crystallinity. Thus the passage of the mechanochemical wave through the polycrystalline specimen results in its amorphisation, for which two factors are responsible: the formation as a result of the reaction of an amorphous polymer and the mechanical dispersion of the specimen in the front.

The rate of propagation of the autowave depends on the dose of the preliminary γ-irradiation. As in the system studied previously,[27] there is a critical dose necessary for the attainment of the autowave regime. The size of this dose increases with decrease in the thermostat temperature (Fig. 6). It could be postulated that the increase in the rate of propagation of the wave with increasing dose is caused by the increase in the concentration of stabilised active centres accumulated in the system during the preliminary radiolysis. However, the increase in the concentration of paramagnetic centres

(radical-ions and radicals) during the radiolysis at 77 K of polycrystalline acetaldehyde takes place linearly only up to a dose of ~50 kGy and then slows down. After the attainment of ~700 kGy, the accumulation of centres ceases altogether. On the other hand, the rate of propagation of the wave in this range continues to increase in proportion to the dose.

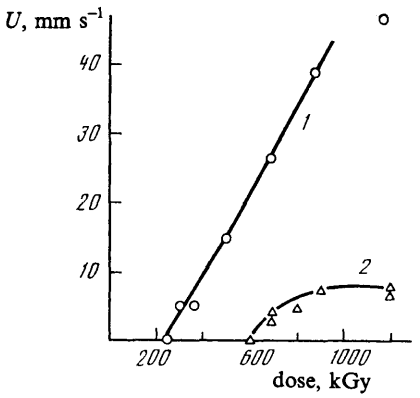

Figure 6. Dependence of the rate of propagation of the polymerisation wave front in polycrystalline acetaldehyde on the preliminary irradiation dose at 77 K (curve *1*) and 4.2 K (curve *2*).[36]

It is known that, in the low-temperature radiolysis of acetaldehyde in a matrix, its decomposition products appear—methane and carbon monoxide, which are in the condensed state at 77 K. When the polymerisation wave passes through the system, these radiolysis products are gasified (the boiling points of CH_4 and CO are respectively 111 and 81 K), which can facilitate the brittle breakdown of the specimen and can accelerate the movement of the running reaction front.

The problem of achieving the wave process in the vitreous acetaldehyde matrix is of great interest. Even on rapid cooling, pure acetaldehyde cannot be converted into the vitreous state[34] and its polymerisation in the vitreous state had not therefore been studied previously. Kichigina et al.[37] investigated a vitreous solid solution of acetaldehyde in butyl chloride (BC), in which local brittle breakdown induced an autowave polymerisation regime. It was found that the critical dose of the preliminary γ-irradiation, above which the autowave propagation of the process in the vitreous solution can be attained, is only 60 kGy, while in crystalline acetaldehyde it exceeds 300 kGy.

Convincing evidence has also been obtained for the occurrence of polymerisation in this system via a cationic mechanism. On the other hand, in previous studies,[27] autowave regimes had been observed only in systems in which characteristic reactions are radical processes.

2. Autowaves of the detonation type

Experimental data indicating the explosive character of the reaction occurring in condensates of atomic magnesium with halogenohydrocarbons (the formation of organomagnesium compounds) and the polymerisation of cyclopentadiene with $TiCl_4$, initiated a 77 K by the impact of a metallic needle, have been published.[38,39] The authors of the above studies did not, however, investigate the dynamics of these processes and the characteristics of their development in time and space. The idea arose naturally that the above studies[38,39] were concerned with yet another type of autowave cryochemical reactions occurring under qualitatively new conditions and not requiring a preliminary activation of the solid matrix by γ-radiation. Furthermore, Kabanov et al.[39] drew attention to the wave character of the polymerisation process in a film and even estimated the velocity of the front (~200 mm s^{-1}).

We observed similar phenomena in experiments with non-irradiated thin-film ethylene + chlorine, propene + chlorine, and vinyl chloride + chlorine cocondensates.[23] It was possible to establish that the chlorination of these hydrocarbons at 77 K takes place not in the form of a homogeneous explosion but in an autowave regime and the film is pricked or scratched and is characterised by extremely intense dispersion in the front of the self-propagating reaction, which is indicated, in particular, by the "recoil" of finely dispersed fragments of the reacting matrix accompanying the wave. The second of the above factors as well as the high velocity of the front (tens of centimetres and even metres per second) give grounds for agreement with the authors,[39] who believe that yet another variety of a low-temperature wave, mechanochemical in nature and close in its essential physical features to detonation phenomena (admittedly with features of degeneracy—presonic velocities), may exist in a solid.

This problem is complex and requires the development of fundamentally new theoretical and experimental approaches to the elucidation of the mechanisms of the chemical reaction energy transfer in low-temperature detonation processes in solid systems.

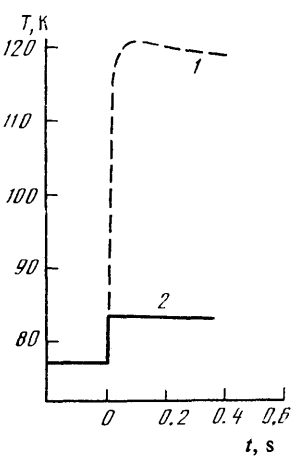

Figure 7. Temperature profiles of the reaction wave in radiolysed (curve *1*) and photolysed (curve *2*) $C_4H_9Cl + Cl_2$ specimens. The initial concentration of radicals was in both cases 2×10^{18} g^{-1}:[40] *1*, $U = 10$ mm s^{-1}; *2*, $U = 400$ mm s^{-1}.

Here one is dealing not with the usual mechanism of the excitation of the detonation wave, known in the classical theory of explosion, but with an unusual type of detonation which may be called gas-free detonation.

3. Autowaves in photoactivated systems

There exists yet another and apparently very wide and varied, as regards manifestations, class of solid systems which react at low temperatures in accordance with the travelling wave laws. Here we have in mind experiments on the local mechanical initiation of a reaction in photoactivated solid matrices.[40] It has been found that preliminary treatment of previously investigated solid systems, for example $C_4H_9Cl + Cl_2$, at 77 K not by γ-radiation but by light also leads to the accumulation in the matrix of potential energy, which can be used for the subsequent initiation of a specific chemical reaction with the aid of local mechanical breakdown. Under these conditions, the process occurs, as in the case of γ-irradiation, in the form of a layer-by-layer dispersion running wave accompanied by a chemical reaction. Furthermore, in the first experiments designed to investigate autowave reaction regimes in photolysed matrices, new features were discovered in addition to the usual features characteristic of the self-propagation of reactions in a solid at low temperatures.

We shall compare the principal characteristics of reaction autowaves in radiolysed and photolysed $C_4H_9Cl + Cl_2$ systems at 77 K (Fig. 7). In the front of a wave propagated in a photolysed specimen, there is no pre-explosive heat exchange, as in the radiolysed system. However, the remaining characteristics of the wave processes differ appreciably. Indeed the rate of propagation of the front in the photolysed system is significantly higher ($\sim$400 mm s^{-1}) than in a radiolysed system ($\sim$10 mm s^{-1}) for identical concentrations of the stabilised alkyl radicals.

The temperature profiles of the front also differ greatly: the maximum temperature in the radiolysed system is 121 K, while in the photolysed system it is only 83 K, i.e. in the latter case the superheating in the reaction zone relative to the thermostat reaches only $\sim$6 K. These differences are probably associated with the difference between the mechanisms of the chemical reactions occurring on mechanical breakdown. For the same initial concentrations of the alkyl radicals, the initial rate of reaction in the radiolysed system is slower than in the photolysed system, because some of the chlorine atoms propagating the chain are captured by Cl^- ions, which are not formed on photolysis.[41]

The problem of the vibrational instability of the movement of the cryoreaction front, demonstrated in relation to the pulsating character of the cryowave in the methylcyclohexane + chlorine system, has been formulated.[20] The hypothetical mechanism of this phenomenon was based on the fact that in the radiolysed system the zone corresponding to dispersion induced by the chemical reaction moves ahead abruptly (at rates of the order of the velocity of sound) to a depth comparable to the characteristic fragmentation grain size. The chemical reaction begins in this disrupted layer and a new jump of the reaction zone in space occurs only after the attainment of a critical density or temperature gradient. Since the rate of the chemical reaction in the breakdown zone of the photolysed system is higher, the necessary conditions for the next jump of the reaction zone are attained faster than in the radiolysed system, which in fact increases the average velocity of the wave.

One can also postulate that photolysis results in a more significant decrease than in the radiolysis by γ-rays, in the strength of the system and in the accumulation of metastable states in the latter, as a result of which the characteristic front velocities increase. One cannot rule out the possibility that the higher rates of the process in photolysed systems are also caused by the involvement of mechanisms of the detonation type.

4. The role of radicals and ions in solid-phase processes

We shall deal with yet another apparently very important aspect of the problem under consideration, which was considered by Barelko et al.[42] It is known that significant changes occurring in the lattice of the solid under the influence of the flux of radiation are not associated solely with the formation of stabilised radicals and ions. Appreciable energy changes occur in the matrix also as a result of its deformation and loosening. The deformation energy retained within the bulk of the solid can reach high values comparable to the solid–liquid and sometimes also solid–gas phase transition energies. One can apparently assume that in the irradiated solid there is a continuous spectrum of states whose energy band extends from the zero value (equilibrium state corresponding to an ideal crystal) to the energy corresponding to a free atom or fragment all the bonds of which with the lattice have been ruptured.

Thus one cannot rule out the possible activating role of this accumulated energy in the chemical process. Indeed, in the autowave reaction regimes described above, a pronounced non-linear relation was observed between the potential chemical reactivity (velocity of the wave) and the concentration of the stabilised active centres of the radical type. The most striking result of this kind was obtained in a study of the dependence of the rates of the layer-by-layer propagation of the polymerisation wave in solid acetaldehyde on the concentration of the radicals stabilised on radiolysis.[37] For doses in excess of the critical value ($\sim$300 kGy), local excitation initiates the reaction wave, whose velocity depends linearly on the dose throughout the experimental range (Fig. 8*a*). On the other hand, measurement of the EPR signal of the specimen indicates a significant deviation of the concentration of the radicals from the linear law even for doses of $\sim$50 kGy (this can be seen particularly convincingly in Fig. 8*b*). Consequently the potential chemical reactivity of the irradiated solid matrix, whose quantitative measure is the velocity of the autowave, is not determined solely by the concentration of the stabilised radicals.

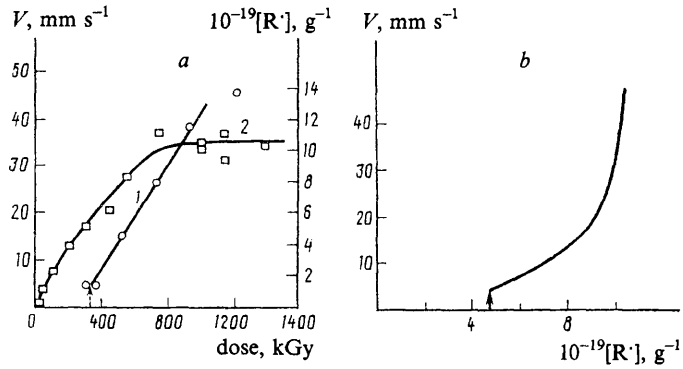

Figure 8. Dependence of the velocity of the polymerisation wave front (curve *1*) and of the rate of accumulation of radicals (curve *2*) in crystalline acetaldehyde on the γ-irradiation dose at 77 K (*a*) and the dependence of the velocity of the wave on the radical concentration (*b*) obtained from curves *1* and *2*.[37]

Direct experimental evidence has been obtained[43] for the amorphisation of crystalline methanol during its radiolysis. Direct calorimetric measurements during the heating of the specimen radiolysed at 77 K made it possible to detect heat evolution

associated with the crystallisation of the amorphised methanol. Calculation showed that the energy stored on irradiation, whose carrier is the metastable amorphous phase formed, exceeds appreciably the part of the energy accumulated in the radical and ionic states.

VIII. Conclusion

In conclusion of the description of the relevant data, it is important to define the place occupied by the phenomena considered here in the general series of different self-propagating chemical processes. For this purpose, we shall attempt to classify the chemical systems characterised by autowave phenomena. Without going into details, we shall differentiate in terms of phenomenological features two large groups to which virtually any of the systems of this kind known at present can be assigned: (1) processes of the type of combustion (the factor determining the existence of the running wave regime in this case is thermal non-linearity) and (2) processes of the branched-chain type (the so-called "chain combustion" associated with kinetic non-linearity of an autocatalytic character). Evidently the mechanism of the self-activation of a frozen reactive system, which determines the characteristic features of the wave processes investigated, is in essence close to the branched-chain mechanism.

The concept of the branched-chain mechanism in solid state chemistry is itself by no means new and has been discussed in the literature for many decades.[44,45] It is constructed on the basis of the claim that the active centres ("nuclei") of the reaction are all kinds of defects distributed in the solid matrix of the reactants and progressively multiplying in it when acted upon by the influences induced in the solid by the reaction itself. The operation of this mechanism has been examined in greatest detail and most convincingly in a large series of investigations[46–50] of the thermal decomposition of ammonium perchlorate at temperatures of about 500 K.

The authors of these studies, who observed the changes in the structure of a decomposing crystalline specimen, established that (1) the reaction of the solid reactant takes place within the framework of the strong influence on the process by the mechanical stresses induced by the decomposition reaction and consists of stages involving the formation and growth of the reaction "nuclei", their multiplication, the increase in their density, and their coalescence and (2) that, on coalescence of the separately developing reaction zones, a single reaction front may be formed and can move within the specimen in the form of a cloud of multiplying nuclei at low but quite definite velocities (of the order of 10^{-4} mm s^{-1}).

Critical phenomena, which are known to constitute a necessary feature of branched-chain and autowave processes, were not observed in the above studies.[46–50] This is most probably due to the retention in the perchlorate decomposition reaction of the leading role by the thermal mechanism. This is in fact indicated by the pronounced exponential dependence of the overall rate of decomposition of the salt (as well as of the velocity of the front) on temperature: on cooling, the reaction rapidly slows down and ceases almost completely already at 460–470 K. One should add that the perchlorate decomposition reaction is not strictly a solid-phase reaction, because it is accompanied by a change in the phase state. The authors[46–50] in fact see in this feature (in the formation of gaseous decomposition products) the cause of the mechanical deformation of the solid reactant matrix and of the development in the latter of defects activating the reaction.

Several years ago, the concept examined above was extended to low-temperature solid state chemistry.[51] The authors[51] used the idea of the self-activation of the matrix due to the feedback between the chemical reaction and the stressed state of the frozen specimen comprising the reactants to explain and describe the so-called "explosion on cooling" which they observed in the photolysed $CH_3C_6H_{11} + Cl_2$ system. The model proposed[51–53] is unfortunately not entirely concrete, because it operates with an abstract quantity called by the author the "excess free energy of internal stresses". No methods were proposed in the above studies for its measurement or for the estimation of its numerical values. Nor is the relation between this characteristic and the defectiveness of the solid matrix discussed. Furthermore, in order to achieve the feedback, the authors had to introduce into the model the feed balance equation, although their claims are based on non-thermal ideas about the mechanism of the self-activation of the reactants at low temperatures. Nevertheless, the essential features of their ideas[51–53] can be formulated by the following phenomenological postulate: the mechanical energy accumulating in the matrix promotes directly the acceleration of the chemical solid-phase reaction by the corresponding reduction of its activation barrier. In other words, in contrast to the molecular tunnelling mechanism,[4] the proposed model of low-temperature reactions in a solid is constructed wholly within the framework of the classical Arrhenius kinetics supplemented merely by certain elements of the kinetic theory of mechanical strength.[54]

We shall attempt to estimate the reality of this model. For this purpose, we turn to the results of our studies of cryochemical solid-phase reactions carried out under the conditions of the artificial transition of the specimen to a highly stressed state (see Section VI). To make the system concrete, we shall deal with the same hydrocarbon chlorination reaction which was investigated in the above studies[51–53] but with preliminary activation by γ-irradiation and not by light. It has been established experimentally that application of a mechanical stress to the specimen under the conditions of uniform compression up to pressures $P = 6 - 10^8$ Pa not only does not promote the reaction but actually hinders it: the reaction does not occur in a matrix in a highly stressed state, while the rate of the autowave process in the compressed specimen is appreciably reduced. Estimation of the specific energy introduced into the specimen yields $\Delta U = P^2/E \simeq 6-12$ kJ mol^{-1}, where E is the modulus of elasticity amounting to $(3-6) \times 10^9$ Pa, according to Benderskii et al.,[55] at low temperatures for this vitreous systems investigated. This value of $\Delta\mu$ is fully comparable to the activation energies for the test reactions measured previously[28] (~ 20 kJ mol^{-1}) and it should seemingly reduce significantly the activation barrier and accelerate and not inhibit the reaction. Naturally, the above considerations are far from sufficient to reject the concept developed by Benderskii and co-workers.[51–53] However, they throw doubt on the very idea that the mechanical energy of the deformed solid matrix can participate directly in its chemical activation.

Having concentrated in their investigations on the study of critical effects, Benderskii and co-workers[51–53] confined themselves to considering uniform quasi-homogeneous models in the zero-dimensional approximation. Problems concerning the extent to which the onset of the reaction in the specimen is synchronous and the mechanisms of the transfer of the excitation of the chemical reactivity within the bulk of the reacting solid, which are of fundamental importance, were only touched upon in the above

studies,[51–53] while the question of the existence of autowave regimes remained almost fully outside the framework of these investigations.‡

The ideas which we have developed concerning the nature of autowave highly intense regimes in a cryochemical reaction are constructed on the basis of a mechanism, which can be called, by analogy with the mechanism already mentioned,[8] an "energy chain". It follows from the data presented in this review that this analogy is entirely justified because the proposed mechanism involves a chain of stages, closed by negative feedback and accompanied by the transformation of the energy of the chemical reaction in time and space. Indeed, it is suggested that during the reaction part of the energy evolved accumulates in the solid matrix in the form of an elastic deformation, i.e. the unreacted part of the specimen passes in this stage to a mechanically non-equilibrium and in a certain sense "excited" state; the potential energy of this metastable state is then transformed into chemical energy. However, the transformation is not direct but occurs only through the brittle breakdown stage in which conditions are created for the chemical reaction, occurring on freshly cleaved surfaces or near them where the energy has been concentrated. This mechanism in fact determines the self-maintaining regime in the reaction of a solid specimen excited by layer-by-layer autodispersion. Ideas postulating the branched-chain character of the process are reflected by the pattern of the continually branching and migrating network of cracks in the reacting matrix.

The operation of this mechanism of the recovery of the energy of the chemical reaction, leading to the self-activation of the solid matrix, is especially favoured by low and ultra-low temperatures. Under these conditions, where the dissipation of the energy stored in the mechanically non-equilibrium matrix is retarded (as a consequence of the limiting constraint on the molecular mobility and the virtually complete loss of plasticity), there is in fact the possibility of an extremely large accumulation of energy in the lattice. The liberation of this energy on mechanical breakdown ensures the subsequent development of the self-maintaining reaction of the reactants.

In the study of solid-phase chemical reactions under the conditions of high pressures combined with shear forces, an "ultrahigh" molecular mobility was observed.[56] In order to interpret such chemical processes, the authors[56] had to postulate the existence of diffusion coefficients exceeding by 10–15 orders of magnitude the usual values. It is to be expected that the autowave ideas, based on allowance for the self-dispersion of the reacting matrix, will prove useful for the explanation of these surprising phenomena.

The postulates being developed must be resorted to also in order to account for the processes involving the "cold" evolution of matter in the universe. In particular, one can imagine a process in which compounds such as ammonia and methane are formed from a frozen mixture of the elements. Such compounds have been detected in appreciable amounts in the solid state on the cold planets of the solar system. The diurnal changes in temperature and the thermal stresses arising under these conditions in the solid coating of the planet might have served as the instrument for continuous mechanism breakdown leading to the chemical bonding of the components which were additionally activated by solar radiation. The next stage of evolution, in which solid ammonia and hydrocarbons, dispersed in the "solar mill", are converted into the simplest amines, also appears likely. It is to be expected that a direct experimental test of the chain of cryosyntheses described here will be an important step in the understanding of many secrets of space chemistry.

The importance of the results of studies on autowave phenomena examined in this review may go beyond the framework of the low-temperature field alone. It may be that the exceptionally high rates of reaction frequently observed experimentally in systems of different chemical nature are in fact associated with the autodispersion of a solid reactant matrix—a process which transfers the chemical reaction from the bulk phase to the highly reactive cleavage surface. These rates may be comparable to or exceed greatly the rates of the corresponding processes in liquid media and special attention should therefore be devoted to the non-thermal, non-equilibrium mechanisms of the activation of a solid matrix due to the inclusion in the chemical process of the energy accumulated by the lattice. A specific example illustrating this general consideration is provided by a study[57] in which the self-activating role of the dispersion of the particles of a refractory component was considered in the formation of intermetallic compounds from powders in a completely different temperature range. In this system, the dispersion of the solid component is referred to as the wetting of the particles by the liquid reaction products (a kind of mechanochemical autocatalysis).

The problem of the legitimacy of the quasi-uniform ideas, very widely used in solid-phase cryochemical kinetics, which rule out from consideration matter and energy transfer processes within the bulk of a solid matrix, was touched upon in the Introduction. The ideas described in this review concerning the autowave dynamics of reactions of solid reactants, the sensitivity of the process to local perturbations, and the non-uniformity of the development of the reaction in the specimen intensify doubts about the applicability of the above classical approach to the kinetics of solid-phase reactions. Under conditions where non-linear mechanisms operate, which are particularly characteristic of solid state chemistry, a spatially uniform course of the process is extremely unlikely. As a result of this, the integral signal due to the chemical reaction (and this signal has in fact been recorded in the vast majority of studies on the kinetics of solid-phase reactions) represents a superposition of signals arising from different points within the specimens and differing both as regards rate and phase. Evidently such a signal cannot carry reliable information about the true process kinetics and the attempt to correlate it with theoretical kinetic models described by a system of ordinary different equations would be simply erroneous.

‡ In addition to the above considerations, we should like to draw attention to an important methodological factor which might have escaped the attention of Benderskii and co-workers.[51–53] This concerns the influence of the material of the cells on the conditions in the initiation of the photochemical reaction. When experiments are carried out in γ-irradiated or photolysed systems, cooling of the specimen can, as already stated above, induce a rapid reaction. However, a decisive factor was not cooling as such but the rate of decrease of temperature. By reducing the rate of cooling, it was easy to maintain the specimen in a fully inert state down to 4.2 K. However, this is characteristic only of Pyrex bulbs. Another picture is observed when quartz bulbs are used. The strict reproducibility of "explosion on cooling"[51–53] might have been associated with the exclusive use of quartz cells in the experiments. The coefficients of the thermal deformation of this material differs greatly (in contrast to that of ordinary glass) from that of the reactants, as a result of which the inevitable peeling of the substance from the walls of the bulb on cooling (i.e. fracture) induced the "explosion" described by Benderskii and co-workers.[51–53]

We shall now turn, as an example, to the case of "polychronic" kinetics well known in solid-phase radiation chemistry.[58] In order to explain the phenomenon of the "kinetic arrest of the reaction", actually recorded with the aid of integral methods, a spectrum of kinetic constants is introduced. Its presence is attributed to the non-uniformity with respect to energy states of the active centres distributed in the matrix. The autowave approach makes it possible to explain the experimental phenomenon without resorting to a polychronic kinetic scheme: it is easy to image that separate reaction waves arise on local perturbations during the process and are propagated frontally throughout the specimen, being arrested at some kind of non-uniformities of the matrix or its macrodefects. Another situation, where the chemical process simply cannot develop uniformly because of spatial instability and the reaction is accompanied by the formation of the so-called "dissipative domain structures",[59] is also entirely realistic.§ Thus in each specific case, quasi-uniform models and in particular "polychronic" kinetic models require special experimental justification, which rules out the influence of autowave phenomena on the dynamics of the development of the reaction.

The ideas about the activating role of self-disruption may prove useful in a number of related fields of study dealing with solids.

This may in fact be a clue to the high sensitivity of many explosive substances to friction and impact. Hitherto the general theory of the sensitivity of explosive substances to mechanical influences has been constructed solely on the basis of thermal ideas, according to which the mechanical energy introduced into the specimen must be transformed initially into thermal energy to create a hot spot, and only then can it excite explosion via a "centre of origin" mechanism. It appears likely that the initiation of an explosive reaction is caused not by the conversion of mechanical energy into thermal energy but by the appearance in the specimen of chemically high reactive cleavage planes arising on friction or impact.¶

The processes involving the transition of a solid from a metastable, amorphous state to a polycrystalline state, which have been vigorously investigated (especially in recent years) (see Shklovskii[64] and the references therein) are autowave in character and outwardly resemble the solid-phase cryochemical reactions considered in this review. In this class of processes, one cannot rule out the operation of the same autodispersion mechanism, facilitating the phase transformation as a result of its transfer from the bulk phase to the fracture surface. Indeed, both classes of processes resemble one another as regards their essential physical features and are associated with the rearrangement of the solid matrix. Both are exothermic and differ only in the magnitude of the thermal effect. Furthermore, one should add that the cracking and dispersion of the specimens, which can be observed even with the naked eye, are extremely typical for wave processes involving the decomposition of amorphous states.†

Yet another field, seemingly very remote from solid state chemistry, is that concerned with the puncturing of transparent media by a flux of radiant energy with a high power (radiant breakdown).[66] As regards their character, these processes can also be classified as autowave processes. The current theory describing these processes, is close in its essential features to the theory of combustion. The difference consists solely in the transition from the exponential temperature variation of the intensity of the chemical heat evolution in the case of combustion to the exponential absorption of radiant energy by the solid medium in the optical breakdown. Analysis of the literature on the optical strength of glasses suggested the idea that the mechanism of the autoacceleration which we have developed in relation to chemical reactions in a solid can be resorted to also in order to describe the dynamics of the radiant disruption of glasses. Using these ideas, the picture illustrating the disruption of the specimen by a light flux can be represented as follows. The light-absorbing submicron impurities, always present in glasses, are heated by the radiant flux. The temperature attained under these conditions presents no risk to the material because of the intense conductive removal of heat from a given small centre and the heated zone, around the impurity particle, is just as small as the absorbing centre itself. However, owing to the high curvature of the spherical centre of such size, the temperature gradients generated are very high. This factor in fact influences the strength of the material and leads to cleavage and the peeling of the particles from the matrix. The non-equilibrium states on the cleavage plane arising at the instant of fracture begin to absorb energy vigorously, which leads to the heating of a fresh surface and then to the cracking of the next layer of the irradiated transparent medium. The cracking at the impurity can be initiated in this way with subsequent wave propagation of the disruption under the conditions of the layer-by-layer dispersion of the specimen. This process can be described theoretically with the aid of a phenomenological model completely identical with the model examined in the present review. The information published[66] about two regimes in the cracking of glasses, occurring as a function of the initial excitation conditions, is qualitatively predicted by the model indicated. The considerations described here concerning the mechanism of the optical breakdown of transparent media are apparently convincing, as shown, in particular, by their use of specialists in the given field.[67]

In conclusion of the review of studies on the phenomena involving the running waves of cryochemical reactions in a solid and of the analysis of the mechanisms controlling these processes, we may note that the studies which have been carried out are mainly phenomenological in character. Naturally, the next task is the solution of a whole series of fundamentally important problems associated with the elementary stages of the process. The main ones are the elucidation of the nature of the active states arising on the cleavage planes, their lifetimes, the establishment of the mechanism of the intensification of transport processes on fresh fracture

§ Similar phenomenon have been observed in heterogeneous catalysis,[60-62] in the field close to solid state chemistry.

¶ V V Boldyrev drew our attention to the fact that similar ideas concerning the nature of the sensitivity of explosives to friction and impact were put forward more than 30 years ago by Ubbelohde.[63] However, owing to the lack at that time of adequate physical justification, this concept was not developed further and was in essence forgotten.

† Yet another possible application of the ideas about self-maintaining phase transitions in a solid, formulated in a brief communication by American geophysicists, is extremely interesting.[65] They put forward a hypothesis according to which the phase transformations in terrestrial rocks as a result of the operation in them of an autocatalytic self-disruption mechanism are the main cause of earthquakes and other catastrophic geotectonic processes.

surfaces, the search for electrical signals associated with the emission of charged particles during the cracking process, and also the search for signals of the type of triboluminescence arising from the front of the dispersion (chemical reaction) running wave.

The structure and properties of complexes simulating molecular recognition

O A Raevskii
Institute of Physiologically Active Compounds, USSR Academy of Sciences, Chernogolovka

ABSTRACT. The main trends in the evolution of the concept of molecular recognition are examined. The possibility of using thermodynamic parameters for a quantitative characterisation of recognition and the effect of their relationships on the degree of recognition are analysed. Complexes, containing one or more hydrogen bonds, between macrocyclic compounds and metal ions, alkyl and alkylammonium derivatives, and various anions are characterised in detail as model compounds. The problem of competitive complexation in an aqueous medium is discussed. The role of computer-aided simulation of molecular recognition in applied studies relating to the design of biologically active compounds is assessed. The suitability of such a combination of experimental and theoretical studies, in which the models for molecular recognition could be constantly improved, is noted.

I. Introduction

The phenomenon of molecular recognition may be regarded as fundamental for many biological processes—in the functioning of the immune system, the formation of substrate–enzyme and hormone–receptor complexes, the transmission of nerve impulses, and in the sense of taste and smell, etc.[1] Identification of the mechanism and nature of the interactions between the molecules in such systems is not only a fundamentally important scientific development but also should assist in the creation of a firm basis for resolving the extremely urgent applied tasks of obtaining specific biologically active compounds with pesticidal and pharmacological action.[2–4] It is obvious therefore that research workers have given very considerable attention to the problem of molecular recognition; the exponential rise in the number of publications on this topic in recent decades is an indication of this.

A considerable contribution to this scientific development has been made by the following Nobel prize-winners: E Fischer (the complementarity principle of substrate–receptor complexes), P Ehrlich (the "lock and key" mechanism in the action of the immune system), C Landsteiner (the specificity of serological reactions), L Pauling (establishment of the cooperation effect of weak forces, including van der Waals forces, electrostatic interactions, and hydrogen bonding between complementary structures), F H C Crick and J D Watson (the molecular structure of desoxyribonucleic acid), K Pedersen, J M Lehn, D Cram (the synthesis, structure, and properties of macromolecular polydentate ligands that can act as "hosts").

In the present review the task is to analyse the current trends in the development of the theory and experiment concerning the simulation of molecular recognition. The examination of material is carried out according to the order of complexity of the systems (from systems of several low molecular-weight compounds to complexes of ions and low molecular-weight compounds with synthetic macromolecular receptors and then natural molecular receptors). This type of presentation of the material is helpful for an assessment and analysis of the relative contributions of different noncovalent interactions to molecular recognition. It should be emphasised here that the degree of molecular recognition of chemical compounds increases by an order on going from a selective donor–acceptor interaction or hydrogen bonding of molecules, containing one electron-donor and one acceptor site, to selective complexation of metal ions with polydentate ligands, then to selective catalytic reactions, and finally to enzyme reactions.

The very large number of articles that have been devoted to molecular recognition make it necessary to leave out whole aspects of this topic from the present publication. However, the detailed reviews and books that have been published in recent years on the conformational analysis of macromolecules,[5–7] quantum-chemical calculations of biological systems,[8–10] and protein engineering[11] compensate for these omissions to a considerable extent. The classes of complexes reviewed have also been limited. Since the main focus of attention in this review is the nature of the noncovalent interactions in substrate–receptor systems, there is a detailed analysis of H-complexes, complexes of polydentate macrocyclic ligands, and mixed ternary complexes involving transition metal ions and aminocarboxylic and aminophosphonic acids.

II. Thermodynamics of molecular recognition

In considering the binding of a physiologically active compound A to a receptor R, the resulting concentration of complex AR can be given by the relationship†

$$[AR] = \frac{K_A [A] R_T}{1 + K_A [A]},$$

† R H Davies *Int. J. Quantum. Chem., Quantum Biol. Symp.*, 1987, (14) 221.

where K_A is the binding constant and R_T is the total number of molecules of receptor. The observed response E of the system to the introduction of compound A into it is a given function of the concentration of complex AR. In this case two possible relationships linking the binding [AR] with the observed response can occur. Thus, if the response is given by the equation

$$E = \frac{K_E\,[\mathrm{AR}]}{1 + K_E\,[\mathrm{AR}]},$$

where K_E is a given factor, when

$$E = \frac{K_A\,[\mathrm{A}]\,\tau}{1 + (\tau + 1)\,K_A\,[\mathrm{A}]},$$

where $\tau = K_E R_T$, or

$$E = \varepsilon\,\frac{K_A'\,[\mathrm{A}]}{1 + K_A'\,[\mathrm{A}]},$$

where $\varepsilon = \tau/(\tau + 1)$ and $K_A' = (\tau + 1)K_A$. Thus the three parameters—the binding constant K_A, the factor K_E, and the total number of molecules of receptor R_T—determine the recognitive and effector functions of a physiologically active compound A in its effect on a receptor.

The thermodynamic criteria of molecular recognition during competitive complexation in multicomponent solutions have been clearly stated in two articles.[12,13] A recognizer A_0 must bind with molecules of a particular type B_0, namely, with the correct effector, in a solution that contains N types of molecules (B_0, B_1, $B_2 \ldots B_{N-1}$) at a random series of concentrations. The probability of all the false recognitions can be denoted as P_f. Thus, the degree of recognition can be characterised by the number N of possible effectors amongst which A_0 correctly recognises B_0 and by the probability P_f of a false recognition.

For the simplest example—complexation between A_0 and B_i in the ratio 1 : 1—we obtain

$$\mathrm{A_0} + \mathrm{B}_i = \mathrm{A_0B}_i,$$
$$[\mathrm{A_0B}_i]/[\mathrm{A_0}]\,[\mathrm{B}_i] = K_{0i} = \exp\,(-\Delta G_{0i}/RT),$$
$$i = 0,\ 1,\ 2,\ \ldots\ N-1.$$

The probability in this case of a false recognition is equal to:

$$P_f = \frac{\sum_{i=1}^{N-1} [\mathrm{A_0B}_i]}{[\mathrm{A_0B_0}] + \sum_{i=1}^{N-1} [\mathrm{A_0B}_i]} = \frac{\sum_{i=1}^{N-1} [\mathrm{B}_i]\,K_{0i}}{[\mathrm{B_0}]\,K_{00} + \sum_{i=1}^{N-1} [\mathrm{B}_i]\,K_{0i}}$$

Hence there will be a greater degree of recognition the higher the ratio of the binding constant for correct recognition to that for false recognitions, namely, the greater the difference in free energies ($\Delta\Delta G$) which represents the difference between the concentrations of A_0B_0 and A_0B_i. The degree of recognition decreases, and hence the value of P_f increases, if the total number of molecules B_i, and B_0 in particular, is comparable to or less than the number of molecules of recogniser A_0. If the number of molecules A_0 exceeds the total number of molecules B_i and all constants K_{0i} are of a single order, virtually all of the molecules B_i will be bound in complexes A_0B_i and P_f will reach a value equal to unity.

Thus, highly specific recognition requires a large value of $\Delta\Delta G$, characterising the clearly defined capacity of the recogniser A_0 to interact with the correct (B_0) as opposed to false (B_i) effector.

It is evident from the description above that in order to develop quantitative models of molecular recognition, it is necessary to have information about the interactive capacity of very diverse electron-donating and electron-withdrawing sites. In this case the thermodynamic representation of complexation as a whole requires a determination not only of the difference in free energies but also that of the enthalpy (ΔH) and also entropy (ΔS), given by

$$\Delta G = \Delta H - T\Delta S.$$

Four possible combinations of ΔH and ΔS values, resulting in different bonding of the molecules in complexes, have been selected by Raevskii.[14]

1. There is a positive change in enthalpy and negative change of entropy on formation of a complex. In this case at all temperatures and absolute values of ΔH and ΔS the equilibrium will be displaced towards the initial compounds and complexation will not occur.

2. The change is enthalpy and entropy are positive. In this situation the final result of the reaction for complexation is determined by the ratio of the absolute values of ΔH and $T\Delta S$. There will be perceptible binding when $|T\Delta S| \gg |\Delta H|$.

3. The change in enthalpy and entropy are negative. In this case perceptible binding will occur when $|\Delta H| \gg |T\Delta S|$.

4. The change in enthalpy is negative and the change in entropy is positive. In this case for all ratios of the absolute values of ΔH and ΔS there is a maximum quantity of complex (in comparision with the first three examples).

These four possible combinations of the values of ΔH and ΔS do occur in molecular recognition processes. Highly specific recognition will occur when there are maximum absolute negative values of the difference between the enthalpy change of the recogniser interaction with the correct effector and that of its interaction with false effectors ($\Delta\Delta H$) and when there are maximum positive values of the difference in entropy change for these interactions ($\Delta\Delta S$).

It should be noted that in the vast number of publications on the thermodynamics of molecular recognition, the change in entropy is either neglected[15] or considered to be proportional to the enthalpy change, which is determined experimentally or from the change in calculated energy.[16] However, in a number of cases a significant contribution of the entropy factor to binding has been established. This relates in particular to the hydrophobic interaction which plays a significant role in biological systems. A clear example of the predominant contribution of entropy to the free energy is given by Hobza et al.[17] The significant influence of the relationship between ΔH and ΔS on the binding of ligands with receptors is convincingly shown in the study of Weiland et al.[18] It is clear from these results (Table 1) that the binding of agonists with an adrenergic receptor of turkey erythrocytes takes place with a large negative entropy, while antagonists display a relatively low enthalpy but an entropy that favours complexation. This in the complexation of *L*-adrenaline and practolol with this receptor with the same values of ΔG, binding occurs in the first case mainly because of a negative enthalpy while in the second case it occurs as a result of a positive entropy.

It is clear from these examples that a more fundamental understanding of the nature of molecular recognition is only possible when the entropy change is taken into account. Theoretical approaches to a calculation of entropy change are described in a review.[9] It is noted in this publication that for real biological systems the best method of determining the entropy change is to carry out calculations using molecular dynamics or the Monte Carlo method. However, considering the rather complex nature and high cost of such calculations, simple empirical approaches to a

determination of the changes in the thermodynamic properties of complexation should not be disregarded. Thus, a correlation between the difference in free energy and the number of covalent and ionic interactions has been reported,[19] and the difference in free energy has been calculated using a simple additive scheme.[20] In such approaches the noncovalent interactions have been divided into a number of components: hydrophobic, van der Waals, hydrogen bonding, dipole–dipole, ion–dipole, ionic, intensified ionic interactions, charge transfer, etc.[21] In order to assess the importance of the contributions of these components to the overall thermodynamic properties of specific interactions, a study of model systems in which one of the types of interaction is the predominant one is of particular importance. It is for this reason that in the present review a considerable amount of space is given to simple complexes with hydrogen bonding, complexes of macrocyclic ligands, and mixed complexes. It appears that a detailed study of such systems should favour a more precise simulation of substrate–receptor complexes.

Table 1. Thermodynamic properties of the binding of ligands with the β-adrenergic receptor of turkey erythrocytes at 310 K.

Ligands	ΔG, kcal mol^{-1}	ΔH, kcal mol^{-1}	ΔS, kcal mol^{-1} K^{-1}
Agonists:			
L-isoprenaline	−9.39	−13.39	−12.9
L-noradrenaline	−7.91	−18.86	−35.3
L-adrenaline	−7.50	−12.75	−16.9
Partial agonists:			
soterenol	−8.23	−7.84	+1.26
metaproterenol	−6.78	−10.83	−13.06
terbutaline	−6.19	−4.13	+6.65
Antagonists:			
L-propranolol	−12.51	−3.85	+27.9
pindolol	−11.85	−5.08	+21.8
zinterol	−9.13	−3.06	+19.6
metoprolol	−8.36	−0.66	+24.8
sotalol	−8.21	−2.15	+19.5
practolol	−7.46	+3.93	+36.7

III. Complexes with hydrogen bonding

1. Complexes with a single H-bond

The exceptional role of hydrogen bonding in the formation of specific substrate–receptor complexes has been quite well covered in the literature.[22–32] There is a large number of studies that contain information on an experimental determination of the thermodynamic properties of H-complexes. However, calculation methods are of greatest value for the simulation of molecular recognition, making possible an assessment of interactions in hypothetical complexes. Two approaches—quantum-chemical and empirical—can be selected here in relation to the calculation of the energy of an H-bond. At the present time quantum-chemical calculations are only applicable to small H-complexes[33–35] and this is a serious obstacle preventing their widespread application. For this reason in current methods of calculating H-complexes there is a predominance of empirical approaches—additive,[36–38] multiplicative,[39–42] and additive-multiplicative.[43,44] By using a multiplicative approach in the form of a "coefficient rule"[39] it was possible in two studies[45,46] to develop a single scale of hydrogen bonding, which led to the possibility of a quantitative comparison of electron-donating and electron-withdrawing capacities of different active sites.[47–49] The practical application of a single scale of electron-donating and electron-withdrawing coefficients in order to predict the enthalpy values of the hydrogen bonding of various molecules is only made possible by the development of a relatively simple system for calculating their values. In studies by Martynov and Raevskii[50–52] equations that relate the values of these factors with constants representing the electronic effect of the substituents form the basis of such a system. The algorithm of a programmed calculation of the values of electron-donating and electron-withdrawing factors has been reported.[53]

It should be emphasised that only the enthalpies of hydrogen bonding are discussed in the publications reviewed.[33–53] At the same time, as has already been stressed in the previous section, a knowledge of both the enthalpy and entropy change is needed for the thermodynamic treatment of complexation. At the present time, even though calculations of the change in entropy on formation of an H-bond have been carried out (see, for example, the study of Carsky and Urban[54]) they are complex and for that reason are not to be found very often in the literature. From this point of view there is interest in extending a simple multiplicative approach, as proposed[55] in a discussion of the experimental data on the complexation of electron-withdrawing phenols with various electron-donating compounds, to the problem of calculating the change in entropy.

The applicability of a multiplicative approach to the calculation of thermodynamic properties of hydrogen bonding of very diverse electron-donating and electron-withdrawing compounds has been specially tested.[56] In this study[56] data on the thermodynamic properties of 174 systems was analysed, 27 compounds acted as electron donors (dioxan, tetrahydrofuran, acetone, dimethylformamide, benzaldehyde, cyclohexanone, various sulphoxides, sulphodioxides, phosphoryl compounds, pyridine, acetonitrile, thiophosphoryl and selenophosphoryl derivatives), while 23 compounds acted as electron acceptors (substituted phenols, alcohols, carboxylic acids, and their halogen-substituted derivatives, amines, nitroamines, chloroform). By using this collection of data for determination of the values of electron-donating (E_j) and electron-withdrawing (E_i) factors, 174 nonlinear equations of the form:

$$\Delta H_{ij} = \Delta H_{11} E_i E_j,$$

were drawn up, where the values E_i of twenty-two acceptors (for phenol it is assumed that $E_i = -1.00$) and the values E_j of twenty-six donors (for diethyl ether $E_j = 1.00$) acted as unknown quantities. The solution of these equations led to a determination of the $E_i(E_j)$ values of all the compounds used in this study. It transpired that the electron-donating and electron-withdrawing capacity of the compounds varied over a wide range (E_i from −0.25 to −1.70 and E_j from 0.70 to 1.70) and were considerably dependent on the nature of the substituents at the active site. In this case the ranges of the $E_i(E_j)$ values for the different forms of active sites showed considerable overlap, which provides the opportunity for developing compounds that are capable of forming the required complexes from examples of different classes. A clear picture of the convergence of the experimental values of enthalpy and those calculated from $E_i(E_j)$ values is given by Fig. 1*a*. When

represented mathematically the correlation between ΔH_{calc} and ΔH_{exp} appears as the following:

$$\Delta H_{calc} = (-0.23 \pm 0.65) + (0.99 \pm 0.03)\Delta H_{exp},\ \text{kJ mol}^{-1}$$

$$(n = 174;\ R = 0.98;\ SD = 1.82;\ F = 5307)$$

Comparison of the data from particular systems showed that only in one out of 174 cases did the discrepancy between the experimental and calculated values of ΔH exceed 5.0 kJ mol^{-1}. In 18 systems the discrepancy was 3.0–4.5 kJ mol^{-1}. In the remaining 155 systems the calculated values were no different from the experimental values within the limits of experimental error. Thus the multiplicative principle for calculating the enthalpy of a hydrogen bond was borne out by studying a wide variety of electron-donating and electron-withdrawing compounds. It should also be emphasised that since the range of enthalpy change in the systems studied was 5.0–65.0 kJ mol^{-1}, the coefficient rule represents weak, medium, and strong H-complexes to the same extent.

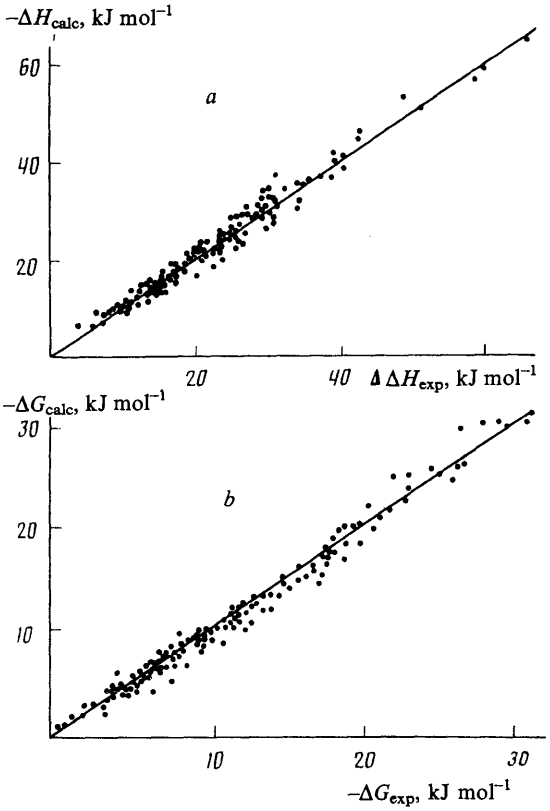

Figure 1. Graphical correlation of the experimental values and those calculated by an empirical multiplicative scheme for the enthalpy (*a*) and free energies (*b*) of H-complexes.[56]

In the same study[56] the coefficient rule was extended for the first time to free energy. For this the following equation was used:

$$\Delta G_{ij} = \Delta G_{11} C_i C_j,$$

where C_i and C_j are electron-withdrawing and electron-donating free-energy factors and ΔG_{11} is the free energy for complexation between phenol and diethyl ether in CCl_4 at 298 K. Formulation of 174 nonlinear equations of this type led to the derivation of the $C_i(C_j)$ values, which made it possible to calculate values of ΔG with an error no greater than the experimental error (Fig. 1*b*).

$$\Delta G_{calc} = (0.006 \pm 0.27) + (1.01 \pm 0.02)\Delta G_{exp}\ \text{kJ mol}^{-1}$$

$$(n = 174,\ R = 0.99,\ SD = 0.96,\ F = 8733).$$

Thus, by using the coefficient rule on the basis of the multiplicative principle it was possible to carry out accurate calculations of the thermodynamic parameters of hydrogen bonding. In order to demonstrate this, the experimental values of the difference in enthalpy and free energy and those calculated from the coefficient rule are given in Table 2 together with the binding constants for certain systems not included in the collection of data from which the values of the factors were calculated.

Table 2. Experimental and calculated values of the thermodynamic parameters of some H-complexes (solvent—CCl_4, 298 K, 1:1 complexes).[56]

Electron acceptor	Electron donor	ΔH, kJ mol^{-1}		ΔG, kJ mol^{-1}		log K, litres	
		exp.	calc.	exp.	calc.	exp.	calc.

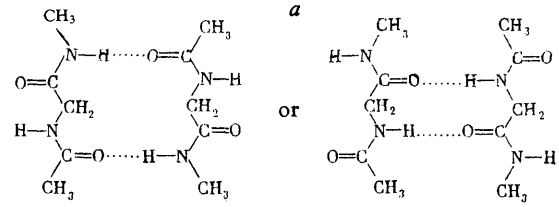
		14.2	15.6	3.19	4.99	0.56	0.88

Apart from the collection of data used in this study[56] there is quite a considerable amount of information in the literature on the thermodynamic properties of hydrogen bonding of a wide variety of compounds. However, these data are incomplete and therefore for the time being cannot be used for a systematic analysis of electron-donating and electron-withdrawing functions of the active sites. Nevertheless, it may be assumed that the growing scientific interest in a quantitative measurement of intermolecular interaction and the improvement in measuring techniques and mathematical simulation will lead in the near future to a considerable expansion of experimental data that can be used to develop accurate calculation methods of the thermodynamic properties of hydrogen bonding.

It should be emphasised that the random collision of molecules is too "unreliable" a process for specificity to be exhibited.[57] It is necessary to define the direction of interaction. Hence a determination of the steric configuration of the interacting atoms in the molecular complexes is of considerable importance. The study of Murray-Rust and Glusker[58] is worthy of special mention here in relation to H-complexes. In this study, in order to determine the directivity of H-bonds involving sp^2- and sp^3-hybridised orbitals of

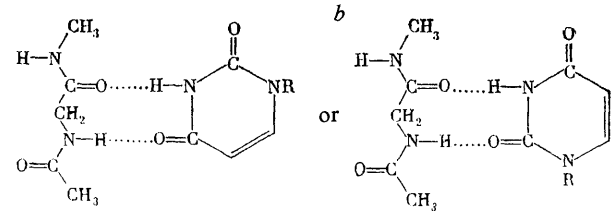
oxygen atoms, a systematic analysis of the structural data on several thousand of such compounds available on the Cambridge crystallographic data bank was carried out. Fairly strict requirements [effective localisation of the atoms, a small *R*-factor (less than 0.1), etc.] were applied to the selected data. In this case it was assumed that an intermolecular H-bond occurs when the distances between two electron-donating sites (one of which contains a hydrogen atom capable of forming a hydrogen bond) are less than 3.0 Å. Classification of the structural data on H-complexes of various cyclic ethers and ketones, epoxide compounds, acyclic ethers, ketones, esters, and other oxygen-containing compounds made it clear that hydrogen bonding occurs in all cases occurs preferentially in certain directions and that probably the most important factor is that zones of increased electron density from the unshared electron pairs (UEPs) are distributed along these directions. Thus, for ethers and epoxides hydrogen bonding occurs in a plane orthogonal to the plane of C–O–C, whereas for ketones and esters it occurs in the plane of CC(=O)Y, where Y = C, O. Murray-Rust and Glusker[58] concluded from this that the directivity of proton-donating groups towards UEPs is a characteristic feature of H-complexes.



2. Complexes with several H-bonds

A study of the interaction of molecules, each of which contains several sites capable of forming H-bonds, is of particular importance in relation to molecular recognition. It is in these cases that there is a theoretical possibility for complexes with very large values of binding constants to occur both as a result of the summation of the enthalpies from each H-bond and as a result of the change in entropy in the conformational reorganisation of the interacting molecules providing the most convenient relative orientation of the atoms participating in the formation of H-bonds. Unfortunately, while there is quite an extensive amount of data on the thermodynamics, structure, and physicochemical properties of complexes with a single H-bond, the literature information on complexes with several H-bonds is very sparse. It is therefore useful to analyse the data from the few studies devoted to an experimental physicochemical investigation of such complexes.

A detailed study of the thermodynamics of the complexation of compounds, each containing two active sites, was carried out by Hopman.[59] In this study the thermodynamic parameters for autoassociation of 1-isobutyl-6-methyluracil (IBMU), γ-butyrolactam (BL), δ-valerolactam (VL), and ε-caprolactam (CL) were determined using UV-spectrophotometric titration, and their interaction with 2-aminopyridine (AP) and 2-aminopyrimidine (APM) was studied. Table 3 summarises the results obtained, which lead to the conclusions that: 1) while autoassociates of IBMU are least in strength, complexes of IBMU with AP and APM have a substantial value of the free energy difference because of the lower absolute value of the negative change in entropy in the series of compounds studied; 2) while the strength of complexes of BL with AP and APM are virtually the same, the free energy difference of the latter is twice as large as the former; 3) replacing the solvent (cyclohexane by benzene) has little effect on the enthalpy values of the reactions of both homo- and hetero-association (however, the free energy is markedly reduced). The results given above indicate with certainty that in the case of the hydrogen bonding of several sites a significant role is played by the steric structure of the interacting molecules. Unfortunately, the method selected in this study[59] can shed hardly any light in relation to this (as regards details about the effect of structure on complexation).



In one article[60] IR spectroscopy, which is more informative for determining structure, was used to study similar systems. In this case complexation between acetylglycine *N*-methylamide (AGMA) and 1-cyclohexyluracil (CHU) was studied. From the enthalpy value determined for homoassociation of AGMA and also the observed pattern of change in intensities of the bands with temperature and concentration, Carmona and Garcia-Ramos[60] were able to deduce that the homoassociates are dimers formed from each other:

a

The following structure was proposed for the heteroassociates:

b

It is noted here that since the ΔH values of heteroassociation do not constitute twice the value of ΔH for a single bond of this type, this suggests that steric hindrance has a considerable effect on complexation.

Table 3. Thermodynamic parameters for complexation of some compounds with two sites capable of forming hydrogen bonds (solvent — cyclohexane).[59]

In another article[61] the possibility of forming simultaneously two H-bonds of the type NH...N and/or N–H...O is examined. 2-Aminopyridine and 2-pyridone were taken as research compounds.

In this study calculations on the energy of formation of H-complexes using the CNDO/2 method were carried out together with the collection of experimental data on the thermodynamic parameters of complexation. It was established that the enthalpy of dimerisation of 2-aminopyridine is approximately twice as high as the usual values of the enthlapy of complexation for compounds that each contain one nitrogen site and one-H-bond. Thus, formation of an eight-membered ring with four nitrogen atoms is very favourable in this case in terms of enthalpy. The enthalpy value for the formation of a 2-aminopyridine-2-pyridone complex was approximately half the sum of the energies of formation of 2-aminopyridine and 2-pyridone dimers. This is clearly a reflection of the multiplicative principle for electron-donating and electron-withdrawing functions as described in the previous section.

There are other publications in the literature related to a study of complexes with two H-bonds.[62–68] Unfortunately, there is no detailed information in these publications about the molecular structure of the complexes. This makes it very difficult to interpret the results and does not offer any idea about the nature and directivity of the H-bonds.

The progress in organic synthesis has had a considerable influence on studies relating to simulation of molecular recognition. As an example, reference may be made here to the studies of Rebek et al.[69,70] In these studies the problem was to synthesise a compound which would interact in a complementary manner with diamines and would thus serve as a model for the respective receptor. A model receptor containing two carbonyl groups and an acridine nitrogen atom was synthesised as this type of compound. A very polar environment of the hydrophobic skeleton of the molecules, which assists transport of this compound through biological membranes, should be regarded as a characteristic of its structure. The complex of this model receptor with purine has three H-bonds and very much resembles complementary biological systems. Thus, it is known that purine and pyrimidine derivatives, forming part of the polymeric molecule, DNA, act as monomer units in the storage of genetic information.

It is known that in the system of H-bonds that occur in DNA, the bases of one of the chains are joined to the bases of the other chain in a very specific manner, forming two H-bonds in a thymidine–adenine pair and three H-bonds in a cytosine–guanine pair. With regard to the problem of molecular recognition, particular attention should be given to studies relating to a determination of the stability of complexes of the different pairs of bases. The available literature data on the enthalpy of interaction of such bases[22,71,72] is given in Table 4. This material suggests that the guanine–cytosine complex which occurs in DNA is very much more stable than all of the others. As a reflection of this, using very simple calculations that took into account the strength of H-bonds, Pauling and Pauling[15] established that the probability of the wrong nucleotide entering a chain was approximately one in ten million.

It should be mentioned that at the present time there are many publications relating to a determination of the role of hydrogen bonding in substrate–receptor complexes. However, the use of this material for a discussion of the role of hydrogen bonding alone is complicated because of the occurrence of other types of interaction. Nevertheless, such studies provided a better understanding of the complex processes (the mechanism of the action of α-chymotrypsin,[73] proton transfer along hydrogen-bonded residues formed by hydroxyl groups in the side-chains of amino acids,[74–76] etc.).

It should also be noted that in the simulation of substrate–receptor complexes it is not possible to take into account hydration of the molecules that can affect both the interactive ability of the active sites and the conformational state of the partners. During the last ten years a great deal of attention has been given to this problem.[77–84] However, at the present time there is still much that remains unclear about the nature of the interaction of water molecules even with very simple organic compounds.

Table 4. ΔH values for homo- and hetero-association reactions of certain bases.[22,71,72]

IV. Synthetic macrocyclic biomimetics

The confirmation of the cyclic structure of valinomycin and the determination in the mid-1960's of the mechanism of this and other antibiotics led to the possible idea of synthesising macromolecules that are capable of selectivity binding metals that play an important part in biological processes and of transporting them through biological membranes. In 1967 Pedersen[85] reported the synthesis and complexing properties of such compounds. The first publications of Pedersen literally started an avalanche in the development of studies on the synthesis and use of these compounds both in fundamental chemical and biological studies and in a wide variety of applied fields.[86] Many thousands of the widest variety of ligands that can be classed as crown compounds have been synthesised to date. These are mainly coronands (containing classical crown ethers with oxygen, nitrogen, sulphur, and phosphorus atoms), cryptands (bicyclic polydentate ligands), podands (open-ring crown compounds), podand-coronands, oxocrowns, spherands, etc.[87] In the present section the complexing ability of such polydentate sytems towards a wide variety of ions and molecules will be discussed very briefly.

1. H-Complexes of macrocyclic compounds

18-Crown-6 is the most frequently used electron-donating compound for such complexes. In particular, its complexes with 4-nitroaniline,[88] 3-nitroaniline,[89] urea,[90] thiourea,[91] 4-nitro-1,2-benzdiamine,[92] and 2,4-dinitrophenylhydrazine[93] have been reported and studied.

Complexes of macrocycles involving the hydrogen atoms of methyl groups are of particular interest. Thus, Rogers and Green[94] reported the results of X-ray diffraction analysis of a complex between 18-crown-6 and nitromethane. This complex consists of a single crown ether molecule and two nitromethane molecules. In this case one nitromethane molecule is positioned above and the other molecule is positioned below the plane of the macrocycle, and each hydrogen atom of both methyl groups of the two nitromethane

molecules is connected by weak hydrogen bonds to one of the six oxygen atoms. The existence of H-bonds has also been established spectroscopically for this complex. A characteristic H-bond vibration has been detected in the far-infrared region.[95] Complex formation of this type has also been established for 18-crown-6 with the hydrogen atoms of the methyl groups of dimethylacetylene dicarboxylate,[96] bis(dimethyl) sulphone,[97] and dimethyl sulphate.[98] Complexes of other macrocyclic compounds with methyl and methylene groups have also been reported.[99,100] It appears that complexes of this type have still not been studied sufficiently. At the same time, the importance of noncovalent interactions of the type C–H...X in biological systems may be very considerable, since in substrate–receptor complexes there are many CH groups adjacent to electronegative substituents and having appreciable electron-withdrawing properties on account of this.

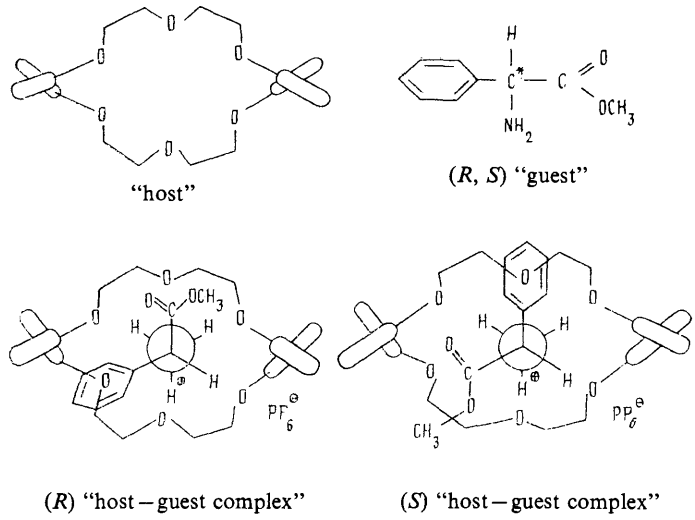
2. Complex formation with alkyloammonium cations

The interaction of macrocycles with ammonia and alkyl-ammonium compounds, in the same way as complexation between macrocycles and methyl groups, may be classed as "tetrahedral" recognition.[101] However, in this case, in addition to H-bonds, $N^+...O^{\delta-}$ electrostatic interactions also occur. The ratio between these two forms of interaction is 0.75:0.25.[102] In this case the strength and stability of the H-bonds depends to a considerable extent on the steric structure of the complexes. A group situated in the polar part of the molecule can affect the nature of complexation. The interaction of such groups with macrocyclic ligands can either destabilise the complex or increase its stability through hydrophobic and dipole–dipole interactions, H-bond formation, etc.

Complexes of the ammonium ion may be regarded as the simplest examples of this type of tetrahedral recognition. This ion forms complexes of medium stability with a large number of macrocyclic polyethers and cryptands. In the case of using a cryptand with four nitrogen atoms and six oxygen atoms as a ligand, an exceptionally stable complex is formed as a result of the considerable structural and energy complementarity.[103,104] As a result of such strong binding of NH_4^+ in a complex the pK_a value increases by six units. In the opinion of Lehn,[101] such effects of a change in pK_a values also exist in the active areas of enzyme molecules.

The effect of substituents in the amine group on the stability of complexes may be assessed from the results of Izatt et al.[105] It was shown that a substantial change in the nature of the substituents in NH_3Alk has little effect on the stability constants of its complexes with 18-crown-6. The effect of the structure of the macrocyclic ligand on the stability of complexes with a t-butylammonium cation has been studied in detail.[106] It was found that there was a considerable effect from the nature of the anion, the size of the ring, and the type of functional groups in the ring on the stability of the complexes. How strongly these structural features can affect the stability of such complexes is suggested by data on the discrimination of enantiomers of racemic salts by chiral macrocyclic ligands.

The concept of "chiral recognition" in the chemistry of macrocyclic compounds was developed by Cram et al.[107] using the analogy of the stereospecificity exhibited by high molecular residues in their interaction with low molecular substrates. In order for recognition of a chiral "guest" to be made possible, the "host" ligand must satisfy at least two conditions: 1) to have a cavity suitable for complexation; and 2) to have the conditions for energetically more stable interactions with only one of the two enantiomeric "guest" molecules to occur. A schematic representation of an example of "chiral" recognition is given in Fig. 2. The enantiomeric resolution achieved for the racemate of an ammonium salt[108] was obtained because in the (*R*) "host–guest" complex four strong noncovalent interactions in the cavity of the macrocycle occur whereas in the (*S*) "host–guest" complex there is no such steric correspondence.



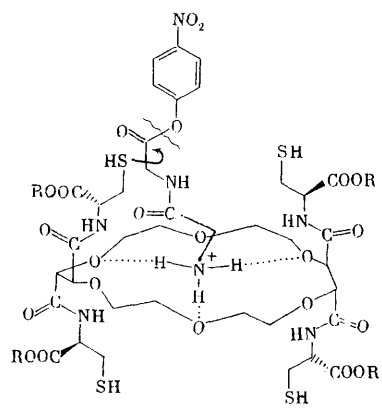


Figure 2. Schematic representation of an example of "chiral" recognition.[10]

In the simulation of enzyme systems, the process of cleavage of an ester bond, which occurs widely in metabolism, is often discussed. In the case of macrocyclic compounds it was possible to carry out this process using a tetra-*L*-cystinyl derivative which bound *p*-nitrophenyl esters of amino acids and peptides; *p*-nitrophenol was obtained as a result:[109]

In this case precise "chiral" recognition occurred between enantiomeric dipeptide esters. Many similar examples of the simulation of biological systems have been reported to date.[101,110,111] They have very considerable value for an understanding of the mechanisms of complex biochemical processes.

3. Complex formation with metal ions

The property of crown ethers that has been studied in the greatest detail is the "spherical" recognition of ions of alkali and alkaline earth metals. At the present time this topic is covered by a very large number of publications, which cannot be examined in detail within the scope of a short review. Therefore only the most prominent examples of a physicochemical study of such systems are given here. The X-ray studies of complexes of macrocycles with metal ions will be selected primarily (see several reviews[112–115]).

Let us consider 1:1 complexes between calcium and macrocycles as an example. The structure of a complex between calcium thiocyanate and 18-crown-6 has briefly been reported.[116] According to these findings, a coordination number of 8, which is typical for calcium, occurs for the metal in this complex, and the metal ion is situated inside the cavity of the macrocycle and lies at approximately the same distance from all six oxygen atoms of the macrocycle. The complex molecule has D_{3d} symmetry.

Quite a different situation has been identified in the complex of calcium nitrate with the same ligand.[117] In this case the complex molecule has C_2 symmetry. The calcium atom is also situated inside the cavity of the macrocycle. The nitrate groups act as bidentate ligands. The dihedral angles in two pairs of COCCOC residues have a *trans-gauche-trans*-conformation while in the third pair there is approximately a *trans-gauche-gauche*-conformation, with the dihedral angle in the CCOC fragment deviating by 37° from that which is usual for a *gauche*-conformation.

On the whole, the available data provide a basis for the conclusion that the conformational state of macrocyclic ligands in complexes is determined by the nature, not only of the cation, but also the anion.[118] This question has been studied in greater detail in the case of X-ray and spectroscopic analysis of benzo-15-crown-5 and its complexes with different calcium salts.[119] It was shown that the nature of the bonding between the electron-donating sites of the macrocycle and the calcium ion is determined by the combined interactions between the cation, anion, and macrocyclic ligand and electronically neutral molecules of water or solvent. This conclusion has been fully confirmed[120,121] with respect to the complexation of other macrocycles with calcium. Thus, in the established molecular structure of the complex between calcium and benzo-12-crown-4 that was isolated from acetonitrile solution, containing this ligand and calcium isocyanate as well as water of crystallisation,[120] the coordination sphere of calcium is formed by the four oxygen atoms of the macrocycle, the two nitrogen atoms of the isocyanate groups, an oxygen atom from one water molecule, and the nitrogen atom of a single acetonitrile molecule. In the case of the complex between calcium thiocyanate and dibenzo-24-crown-8,[121] the immediate environment of calcium is made up by four oxygen atoms of the macrocycle (two ether and two anisole), two nitrogen atoms of anionic isothiocyanate groups, and an oxygen atom of a coordinated water molecule. The four other oxygen atoms of the macrocycle do not participate in coordination. It appears that these types of calcium complexes of macrocycles can be regarded as models of bioorganic complexes.[122] It is possible to conclude from a number of publications[123–130] that there is evidence for competitive occupation of the coordination sphere during complexation of other metals with macrocyclic ligands. However, it should be noted in this case that a metal–ligand composition of not only 1:1 but also 1:2,[131] 2:1 [132,133] and 2:2 [134] is typical for such complexes.

Data on the thermodynamic properties of complexation of macrocyclic ligands with metal salts in solution are of considerable value in relation to molecular recognition. Considerable attention was given to this problem in the 1970's and 1980's. Several detailed reviews[135] and also the study of Buschmann‡ should be mentioned first of all. Of the original studies, mention may be made of the publication of Solov'ev at al.,[140] in which the thermodynamic properties of the complexes of two crown ethers (benzo-12-crown-4 and benzo-15-crown-5) with thiocyanate salts of lithium, sodium, potassium, calcium, and ammonia were obtained and analysed. It was established that in complexation between benzo-12-crown-4 and lithium and sodium, cation–ligand complexes occur with a composition of both 1:1 and 1:2. In the case of benzo-15-crown-5, 1:2 complexes are not formed for these salts. In complexation involving benzo-15-crown-5, the enthalpy of interaction with sodium, potassium, and calcium increases by 25% compared to benzo-12-crown-4, which may be regarded as evidence for the participation of an additional electron-donating site in complexation with benzo-15-crown-5. The entropy data are also very interesting. Thus, in complexes of lithium with benzo-12-crown-4 and benzo-15-crown-5 with composition 1:1, the enthalpy of interaction is virtually the same. At the same time, the value of the stability constant for the complex with benzo-15-crown-5 is higher by a factor of three. The small negative value of the entropy is thought to be the cause of this phenomenon. It is worth noting that in the case of the 1:2 complex between calcium and benzo-15-crown-5, the entropy change is even positive, resulting in a significant value of the stability constant even though there is a small enthalpy.

It is possible to assess how the structure of macrocyclic compounds affects their ability to bind metal ions from the data of Table 5.[141] It can be seen from Table 5 that the maximum binding results when there is a correspondence between the size of the cavity of the macrocycle and the diameter of the cation (complexation between potassium and 18-crown-6 and between caesium and

21-crown-7). Data on an acyclic analogue — pentaglyme — and a natural ionophore — valinomycin[142] — are also given in Table 5. Comparison of these data shows that binding with macrocyclic ligands has a considerable advantage over binding with open ligands. The very high selectivity of the natural ionophore towards the potassium ion compared to the sodium ion attracts attention.

The discovery of the complexing ability of macrocyclic ligands towards alkali and alkaline earth metal was the basis for research into synthetic ionophores. Extensive studies, including a number cited here,[143–150] which led to both a better understanding of ion transport processes through biological membranes and the preparation of compounds of practical importance, have been carried out in this area up to the present time.

4. Complex formation with anions

In contrast to the coordination chemistry of cations and particularly metal ions, complexation involving anions has not been studied in sufficient detail. This situation is evidently at variance with the important role that is played by anions in chemistry and biology. That is obviously why interest in research in this area has increased markedly in recent years.[151,152]

Charged ammonium and electronically neutral residues containing strong electron-withdrawing atoms can act as atomic groups capable of binding anions. However, particularly stable and selective anionic complexes are obtained when macrocyclic molecules are used as receptors. In these cases the anionic substrate can enter the cavity of the receptor and can be stabilised in this position through different types of interactions. The structure of such complexes is analysed in detail in a study by Lehn et al.[153] A cryptand (BT) with six secondary and two tertiary amine nitrogen atoms and three ether oxygen atoms was used as the receptor. In the formation of a complex between this ligand and a fluoride ion, the latter occupies an asymmetrical position inside the cavity, probably because of the small size of the anion, and it coordinates tetrahedrally with four protonated nitrogen atoms (two from one chain and one each from two other chains). In the case of complexes with chlorine and bromine ions, the anions are positioned almost exactly on the axis joining the tertiary amine nitrogen atoms and are equidistant from them. In this case the anions are coordinated octahedrally with the six protonated secondary amine atoms through hydrogen bonds of the type NH...X. In the azide complex the N_3^- ion lies on the N...N axis, the two terminal atoms are at a distance of 3.24 and 3.21 Å from the tertiary amine nitrogen atoms of the ligand. In this case the terminal nitrogen atoms of the N_3^- ion form hydrogen bonds of virtually the same length (2.96 ± 0.04 Å) with the protonated secondary amine groups. These coordinate bonds form two tetrahedra. In both the free ligand and the three complexes studied an *endo,endo*-conformation occurs for the macrocyclic skeleton, with the tertiary nitrogen atoms turned towards the cavity.

Complex formation of this macrocyclic ligand with chloride, bromide, iodide, and azide anions, as well as with a number of organic and inorganic anions has been studied in solution by means of potentiometric titration (Table 6). It was established that stable complexes are formed with substrates that have the highest charge density such as the small-sized fluoride anion and polyphosphate ions. However, it follows from the literature data that when other polyammonium macrocycles are used as receptors, the binding of adenosine monophosphate (AMP^{2-}), adenosine diphosphate (ADP^{3-}), and adenosine triphosphate (ATP^{4-}) can be even more effective.[154]

The synthesis of the so-called co-receptors, which can bind either polyfunctional substrates or two or more small substrates at the same time[155] should be regarded as an important area of the chemistry of molecular receptors. Thus, polyammonium macrocycles that can effectively bind dicarboxylate anions have been obtained.[156] In this case there was a well-defined selectivity for formation of a complex between these macrocycles and dicarboxylates in whose molecules the coordination sites are separated by a different number of methylene bonds.

The significant change in ratio of the different free and bonded molecules when the solvent is varied for complexation of polyammonium macrocycles with anions is worthy of note. This evidently occurs as a result of the differing ability of partially and fully protonated structures to bind anions.

It should be mentioned in conclusion to this section that apart from the macrocyclic compounds described above, which are used as models of biological complexes related to the transport of substances and enzyme processes, synthetic porphyrins and nonporphyrinic tetraazomacrocyclic ligands have been widely used. The use of macrocyclic compounds as models of molecular recognition has also been described in reviews.[148,157–159]

Table 6. Stability constants of complexes of the two protonated forms of the macrocyclic BT ligand ($BT\text{-}6H^+$) and ($BT\text{-}5H^+$).[153]

Anion	log *K*, litres mol^{-1}		Anion	log *K*, litres mol^{-1}	
	BT-6H+	BT-5H+		BT-6H+	BT-5H+
F^-	4.10	3.20	$CH_2(CO_2)_2^{2-}$	3.10	2.00

$(CO_2)_2^{2-}$	4.95	3.35	—	—	—

V. Simulation of equilibria in aqueous solution

When the role of molecular recognition in specific biological processes is considered, the effect of the aqueous medium on the nature of complexation must also be taken into account. In a physiological medium a large number of chemical equilibria occur, in which hydrogen and metal ions and many biologically active compounds such as amino acids, peptides, proteins, carboxylic acids, organic phosphates, nucleic acids, and others participate. In this case there is competition between hydrogen and metals for the ligands. It should be emphasised here that even in a three-component system (one bivalent metal M^{2+} and two different bidentate ligands A and B) the formation of various species such as MA, MA_2, MB, MB_2, MAB is possible. In relation to molecular recognition there is particular interest in mixed complexes MAB. The probability of formation of the latter is twice as high compared to MA_2 and MB_2 complexes. Moreover, electrostatic and steric

interactions and hydrogen bonding,§ which is favourable for stable complexation, can occur in such mixed complexes.

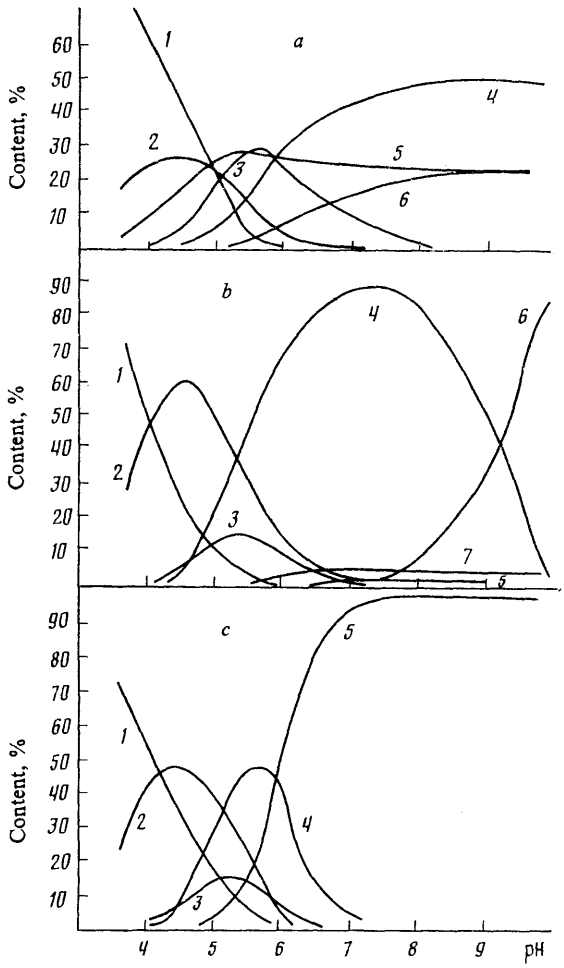

Figure 3. Graphical representation of the dependence of the composition of the following reaction systems: *a*, α-methylphenylaminophosphonic acid (MPAP) + *L*-phenylalanine (PA); the curves correspond to the change in Cu content (in %) in solution of: copper ion (curve *1*), Cu(PA) (curve *2*), Cu(MPAP) (curve *3*), Cu(PA)(MPAP) (curve *4*), $Cu(PA)_2$ (curve *5*), $Cu(MPAP)_2$ (curve *6*); *b*, MPAP + *L*-tyrosine (Tyr); the curves correspond to the change in Cu content (in %) in solution of: copper ion (curve *1*), Cu(TyrH) (curve *2*), Cu(MPAP) (curve *3*), Cu(TyrH)(MPAP) (curve *4*), $Cu(MPAP)_2$ (curve *5*), Cu(Tyr)(MPAP) (curve *6*), $Cu(Tyr)_2$ (curve *7*); *c*, MPAP + *L*-dihydroxyphenylalanine (Dopa); the curves correspond to the change in Cu content (in %) in solution of: copper ion (curve *1*), Cu(Dopa-H) (curve *2*), Cu(MPAP) (curve *3*), Cu(Dopa)(MPAP) (curve *4*), Cu(Dopa)(MPAP) (curve *5*); the content of $Cu(MPAP)_2$ and $Cu(Dopa)_2$ was less than 3%.

§ V V Lukachina *Ligand–ligandnoe Vzaimodeistvie i Ustoichivost' Raznoligandnykh Kompleksov* (Ligand–ligand Interaction and the Stability of Heteroligand Complexes), Naukova Dumka, Kiev, 1988, p. 181.

Another important characteristic of complexation in an aqueous medium is the change in the number of different complex species when the medium is varied. This results from the possible interaction of ligands with hydrogen ions when there is a change in their electron-donating properties. Since the pH values of the medium differ considerably in different parts of the organism, a study of such systems is particularly important for an understanding of molecular recognition under natural conditions.

The structure and stability of mixed complexes have been discussed in detail in three reviews.[160–162] Data on the composition of complex species in systems containing copper and two amino acids are displayed in the form of graphs in Fig. 3. A study is made on four types of system, in which one of the amino acids, namely, α-methylphenylaminophosphonic acid (MPAP), is present in all four cases, while the second varies, leading to substantial changes in the stability of the resulting complexes.[163] In the system MPAP–PA–Cu (Fig. 3*a*) a mixed complex is formed in quantities not exceeding its statistical proportion, while in the system MPAP–Dopa–Cu (Fig. 3*c*) it is evidently in excess of all other complexes. There has been a growing emphasis on studying such systems in recent years aimed at a better understanding of the complexation processes in a physiological medium and the potential practical application of the selective nature of bonding.[164–172]

To what extent competitive complexation can affect the composition and distribution of complex species in a physiological medium can be assessed from the results of calculation of a model plasma in the absence of EDPA and when this ligand is added.[160] It follows from the results in Table 7 that the addition of EDTA leads to its complete binding of zinc and copper, has a considerable effect on the type of calcium complexes, and in actual fact has no effect on the distribution of magnesium. The calculations carried out clearly demonstate that because of such a complex action on the plasma,

Table 7. Distribution of complexes in a plasma model.[160]

Type of species		Content, %		Type of species		Content, %	
metal	ligand	without EDTA	with EDTA	metal	ligand	without EDTA	with EDTA
Ca	Globulin	24.0	15.0	Zn	Histidine, cysteine	3.4	—
Ca	Albumin	16.0	13.0				
Ca	Bicarbonate	7.6	4.3	Zn	Cysteine, histidine	2.1	—
Ca	Citrate	2.4	2.0				
Ca	Phosphate	0.8	0.5	Zn (free)		4.7	0.0
Ca (free)		49.0	28.0	Zn	EDTA	—	99.99
Ca	EDTA	—	38.0	Mg	Bicarbonate	12.0	12.0
Zn	Cysteine, histidine	19.0	0.0	Mg	Phosphate	4.3	4.2
				Mg	Citrate	2.4	3.0
Zn	$(Cysteine)_2$	16.0	0.0	Mg	Lactate	0.6	0.6
Zn	$(Histidine)_2$	13.0	0.0	Mg (free)		80.0	78.0
Zn	Albumin	13.0	0.0	Mg	EDTA	—	1.5
Zn	Glycine, histidine	6.2	—	Cu	Histidine, cysteine	44.0	0.7
Zn	Histidine	3.6	—	Cu	Histidine, cysteine	38.0	0.6
Zn	Citrate	3.6	—				
				Cu	$(Histidine)_2$	16.0	0.3
				Cu	EDTA	—	98.3
				Other species		0.3	

Note. Metals and EDTA were at the following concentrations (in moles): $[Ca] = 2.5 \times 10^{-3}$, $[Mg] = 1.1 \times 10^{-3}$, $[Zn] = 46 \times 10^{-6}$, $[Cu] = 1.1 \times 10^{-6}$, $[EDTA] = 1.0 \times 10^{-3}$.

the use of EDTA as a pharmacological compound that assists the binding of free calcium can have very unfavourable results. It seems that such calculations should become an essential element of studies that precede the pharmacological insertion of ligands which effectively bind biometals.

In examining complex equilibrium systems in solution, we should not omit the progress made in programming[179] using the Newton method,[174] Simplex method,[175] Monte Carlo method,[176] and others.

VI. Computer-aided molecular simulation

The general principles of this method have been presented in sufficient detail in several studies.[177-184] Within the scope of this review it should be noted that the most important feature of any molecular computer model is its energy. In principle, quantum mechanics can provide a basis for the calculation of the molecular energies of biologically active compounds.[8-10,184,185] However, the complexity of the research subjects makes it necessary in practice to use various approximations with the calculation of force field parameters based on experimental data. Vibrational spectra are used to determine the force constants. Information on the bond lengths and bond angles obtained from X-ray diffraction analysis, gas electron diffraction, neutron diffraction, and microwave spectroscopy is used for a determination of the geometric parameters. The parameters of the interactions between nonbonded atoms are often determined from thermodynamic data (heats of mixing, evaporation, etc.).

In the computer-aided molecular simulation of a specific compound using systems that comprise a minicomputer, computer graphics, and also a data bank of structural and physicochemical properties, the design of the initial structure is carried out at the first stage. Then calculations are carried out, leading to an optimisation of the molecular geometry and a determination of the possible electronic and steric structure of the molecule and its energy properties. In this case, since the molecules of biologically active compounds usually contain several axes of internal rotation and hence have many stable conformations that are similar in energy, special routines of systematic scanning of such conformations are used.

A significant contribution to a more fundamental understanding of the structure of molecules under real conditions is provided by the computer-aided simulation of the dynamic properties of chemical systems based on the Monte Carlo method[8,186,187] and that of molecular dynamics,[188-191] which make it possible, in principle, to calculate also the entropy.[192,193]

Computer-aided simulation of molecular recognition can be carried out using calculations on the competitive interaction of several ligands (L_I, $L_{II} \ldots L_N$) with a receptor (R). If the entropy contribution to this process is neglected, by analogy with the study of Fruhbeis et al.[184] we can write:

$$\Delta E(L_I) = E(RL_I) - E(R) - E(L_I),$$
$$\Delta E(L_{II}) = E(RL_{II}) - E(R) - E(L_{II}),$$
$$\ldots\ldots\ldots\ldots\ldots\ldots$$
$$\Delta E(L_N) = E(RL_N) - E(R) - E(L_N).$$

A negative ΔE value is necessary for the formation of a complex, and for highly selective binding of L_I with the receptor, the following condition must be fulfilled:

$$|\Delta E(L_I)| \gg |\Delta E(L_{II})|, \ \ldots \ |\Delta E(L_N)|.$$

Thus, in order to assess the recognition between molecules L and R, it is necessary to have information on the steric structure and energetics not only of the molecules themselves but also for the corresponding complexes. According to Humphries,[194] three aspects need to be considered in the scanning of stable conformations of a complex: the relative orientation of L to R, the optimum conformations of L in contact with R, and the optimum conformations of R in contact with L. All these questions have now been successfully resolved using computer docking of molecules.[182,184,195,196] This is assisted by quite a well developed contemporary mathematical facility for molecular computer graphics, which makes it possible to carry out numerous manipulations on the display screen: to represent the molecules as a combination of bonds (Dreiding models) or as overlapping spheres of atoms. The image can be rotated, fragmented, superimposed, put in perspective, etc.[197,198]

It is very important to emphasise that the methodological developments in computer-aided molecular design as described above have been applied very quickly to the development of biologically active compounds. There are a number of review articles on this topic.[2,19,199-202] As an example we can examine a recent publication,[203] in which the computer analysis of basic structures for interaction with papain and carbonic anhydrase was carried out. The X-ray diffraction data on these enzymes were taken from the study of Bernstein et al.[204] Compounds selected from the widely used Cambridge databank of X-ray diffraction data were investigated as interaction partners. Docking of the active sites of the pairs of molecules was carried out using a programmed procedure described by Kuntz et al.[205] Amongst the identified compounds whose active sites were effectively docked with papain were: 3-iodophenyl hippurate (IPH) (a known substrate of this enzyme), a derivative of trimethoxybenzamide (TMB), and three macrocyclic compounds—2,6-pyridine-24-crown-8 (PC8), 10,10-ethylene-bis(1,4,7-trioxa-10-azocyclododecane) (TACD), and 2,2-bis(4,4-benzophenono(2,6)naphthalenophane) (BPN). The calculated energies of these ligands and their complexes with papain are given in Table 8. The results in Table 8 are an indication of the high stability of these complexes.

Table 8. Energies of complexation of a number of compounds with papain (calculated value of the free energy of papain is equal to 266.2 kJ mol^{-1}).[203]

Ligand	E_L, kJ mol^{-1}	E_C, kJ mol^{-1}	E_I, kJ mol^{-1}
PC8	22.5	−2784.0	−141.3
TACD	60.2	−2712.7	−117.7
TBA	145.6	−2555.1	−135.6
BPN	82.2	−2696.0	−113.0
IPH	24.7	−2741.2	−100.7

Note. For ligand notation, see text; E_L—energy of free ligand; E_C—energy of complex; E_I—energy of interaction.

In recent years studies of computer-aided methods for the simulation of molecular recognition have been increasingly extended to a determination of the relationships between the structure of

compounds and the biological activity which they exhibit. In particular, simulation has been carried out for the inhibition of dihydrofolate reductase,[206,207] and elastase,[208] the binding of DNA,[209] adrenergic and muscarinic receptor systems,[210,211] the complexation of ligands with a serotonin receptor[212] and cytochrome,[213] the mimetics of α-chymotrypsin,[214] the inhibition of photosynthesis,[215] the reactions of ribonucleic acid with synthetase[216] and different drugs with tubulin.[217]

The simulation of bioorganic complexes in an aqueous medium may be regarded as a close approximation to reality. Thus, the results of studies on the effect of hydration on ionic permeability processes have been correlated.[218] In these studies complexes of valinomycin, nonactin, and dialkyl-substituted dibenzo-18-crown-6 with potassium[219–221] and antibiotic X 537 A with serotonin, dopamine, noradrenaline, and adrenaline[222] have been investigated. The ionic channels formed in a lipid membrane by gramicidin A [223] and amphotrycin B [224] have also been simulated.

— o0o —

In view of the progress made in the 1980's in the fine organic synthesis of model compounds, physicochemical techniques, mathematical methods for analysis of the properties of complex equilibrium systems, and computer-aided molecular design it is possible to agree with the view that "we are starting to recognise the molecular parameters which control the reactions of ligands with macromolecules".[2] However, in order that the concept of molecular recognition should become a firm principle in the directed search for compounds with given properties, further development of fundamental studies in many areas is necessary. This primarily concerns studies to determine the thermodynamic properties of H-complexes in different solvents in order to identify the principles concerning the effect of the medium on complexation. The extremely sparse amount of information at present on the detailed molecular structure and thermodynamics of complexes with several H-bonds should also be mentioned.

Determination of the role of the entropy factor in the binding of substrate–receptor complexes is of particular importance for a more fundamental understanding of molecular recognition. At the present time the entropy effect is neglected in the vast majority of studies. However, there are findings which suggest that a decisive role is actually played by this factor, for example, in the complexation of different ligands with similar enthalpy values. Hence, the usefulness of experimental studies to determine the entropy as well as calculations, particularly those using the Monte Carlo method and molecular dynamics, is evident.

In the final section of this review the growing contribution of computer-aided molecular simulation to the study of molecular recognition was noted. For all the evident merits of this method, it should not be forgotten that it is based on fairly incomplete knowledge of the nature of intra- and inter-molecular interactions. On this basis it seems reasonable to combine the different types of studies so that the models of molecular recognition can be constantly improved through the application of accurate new experiments as well as theoretical developments.

Reactions involving the heterolytic cleavage of carbon–element σ-bonds by Grignard reagents

Yu N Polivin, R A Karakhanov, V N Postnov
Gubkin Moscow Institute of Petroleum and Gas
Lomonosov State University

ABSTRACT. The reactions involving the heterolysis of the C–O, C–C, C–N, C–S, C–Cl, etc. bonds by organomagnesium compounds are examined and the nature of this interesting phenomenon is analysed. On the basis of the analysis of the characteristic features of the cleavage under discussion, it is shown that the heterolysis of the carbon–element bond is, firstly, a general reaction for all classes of organic compounds (provided that two conditions are observed: the substrate molecule must fragment into two stable species—a carbonium ion and an anion—and the strength of the Lewis acid properties should be adequate for the occurrence of the above reaction) and, secondly, the heterolysis of the carbon–element bond is one of the independent pathways in the reactions of the Grignard reagents.

The bibliography includes 158 references.

I. Introduction

For more than 85 years investigators have been studying extensively Grignard reagents in organic synthesis, especially in nucleophilic addition and substitution reactions. This is apparently why, for historical reasons, chemists concentrated attention on the nucleophilic properties of organomagnesium compounds and regarded these reagents as typical nucleophiles. The Lewis acid properties of Grignard reagents were hardly taken into account in assessing their reactivity. Nevertheless, the initial coordination of the RMgX (R_2Mg, MgX_2, $R_2Mg.MgX_2$) molecules via the free electron pair of the most nucleophilic heteroatom of the substrate has been frequently included in the mechanisms of the reactions of Grignard reagents with various compounds.

It has been shown that, on the one hand, this intensifies the deficiency of the electron density on the reactive carbon (element) atom, which is as a rule linked to the heteroatom via a σ- and π-bond. On the other hand, the coordination considered increases the nucleophilicity of the reagent cryptobase.

Thus the coordination (i.e. Lewis acid) properties of the reagent merely assist in a more striking manifestation of the nucleophilic properties. The reactions proceeding via this mechanism (and this happens in most cases) have been referred to as "normal". Those which do not fit into the framework of the above mechanism have been called the "anomalous" (including reduction and enolisation reactions).

The segregation of processes in which the Lewis acid properties of RMgX merely supplement the nucleophilic properties greatly simplifies the understanding of the nature of this reagent but does not therefore provide a complete and correct idea about its reactivity.

The dual nature of the Grignard reagent consists in the fact that, in reactions with molecules whose skeleton is extremely sensitive to the action of weak Lewis acids, the initial coordination of RMgX (R_2Mg, $MgX_2.R_2Mg$, etc.) already leads to pronounced and irreversible changes in the molecular skeleton and to the appearance of new reaction centres not provided for by the mechanism of the "normal" nucleophilic addition. In such cases, the Lewis acid properties of organomagnesium compounds determine the structure and yield of the reaction products. The application of the term "anomalous" to these reactions is illegitimate.

This review deals with reactions in which the structure of the products is determined precisely by the Lewis acid properties of RMgX.

II. The structure and reactivity of Grignard reagents

1. The structure of RMgX

In a review published in 1980, Ashby[1] traced the development of ideas about the structure of organomagnesium compounds in solutions in organic solvents. He proposed a model described by the following scheme:

$$\ldots \rightleftarrows \text{trimer} \rightleftarrows \text{dimer} \rightleftarrows 2RMgX \rightleftarrows R_2Mg + MgX_2 \rightleftarrows \text{dimer} \rightleftarrows \text{trimer} \rightleftarrows \ldots \quad (1)$$

The above scheme takes into account the possibility of the establishment in solution of the Schlenk equilibrium and the formation of dimers, trimers, and more complex associated species. In view of their insignificant amount, ionic species have not been included in this scheme.

The Schlenk equilibrium for isobutylmagnesium bromide[2] and t-butylmagnesium bromide[3] in solution in tetrahydrofuran (THF) was investigated by ^1H NMR spectroscopy and that of dicyclopentadienylmagnesium was studied by ^{25}Mg NMR spectroscopy.[4] It was shown that the equilibrium depends greatly on the reagent concentration and to a lesser extent on temperature.

In a later study[5] the existence of the Schlenk equilibrium in solution was questioned. According to the authors,[5] the following equilibria occur in solution in THF:

$$4[RMgX(THF)_n] \rightleftarrows 2[MgR_2(THF)_2] + [MgCl_4]^{-2} + [Mg(THF)_6]^{+2}, \quad (2)$$

$$4[RMgX(THF)_n] \rightleftarrows [(THF)_nMg(\mu\text{-}Cl)_2MgR_2] + [RMg(\mu\text{-}Cl)_2MgR(THF)_3]. \quad (3)$$

The above scheme, extended also to other solvents and other halogen atoms, was proposed on the basis of indirect data. Thus $[NBu_4]_2MgCl_4$ and $[(THF)_4Mg(\mu\text{-}Cl)_2FeCl_2]$ have been isolated from a solution of a Grignard reagent. According to Sobota and Duda,[5] $MgCl_2$ is too reactive to exist in solution in a free state. On this basis, the existence of the Schlenk equilibrium is in fact rejected.

The evidence presented by Sobota and Duda[5] is apparently inadequate and too controversial to question the existence of the Schlenk equilibrium, but it is necessary to take into account Eqns. (2) and (3) in considering the structure of RMgX in solution.

In the study of equilibria involved in Scheme (1), it has been noted[6,7] that the equilibrium depends on many factors — the nature of the organic group, the halogen, the temperature, the concentration of the organomagnesium compound investigated, and the solvent. The influence of the solvent, or more precisely of its solvating capacity, on the equilibrium plays a decisive role under these conditions.

The solvating capacity of the solvent is a complex function of the coordination properties of the heteroatom involving the lone electron pairs of the solvent and the steric hindrance of the coordination of its molecules to the substrates.[8] For this reason, the solvating capacities of solvents can be compared only when their basic properties are referred to the Lewis acid properties of a specific substrate.

The quantity serving as a measure of the solvating capacity of the solvent relative to a given Lewis acid can be estimated from ^1H NMR spectra.[9,10] The strength of strong Lewis acids relative to a given base can be estimated similarly.[11]

Another approach to the quantitative allowance for the effect of steric and basic properties of the solvent on its solvating capacity has been proposed by Tuulmets and co-workers.[12–14] They introduced the function B^* — the effective basicity characterising the solvating capacity of the solvent relative to a given Lewis acid (organomagnesium compound):

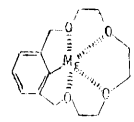
$$B^* = B(B_0/B + \varphi^* + E_s^{0'}).$$

The quantities B and $E_s^{0'}$ — characteristics of the basic and steric properties of solvent molecules — have been tabulated. The values of the effective acidity index φ^* of the reference substrate can be calculated from the following correlation equation:

$$\varphi^* = 10.1 + 2.4\,E_s^{0'} + 0.6\,\Sigma\sigma^*. \quad (4)$$

where $E_s^{0'}$ are the isosteric constants of the substrate molecules and $\Sigma\sigma^*$ is the sum of the inductive constants of the cryptobase and the halogen of RMgX. These have been tabulated. B_0 is a constant.

Thus the quantity B^* characterises the effectiveness of the interaction of the selected reference substrate with the solvent, the decisive role being attributed, according to the author,[12] to steric hindrance of coordination.



It follows from Eqn. (4) that the quantity φ^* serves as an estimate of the effectiveness of the interaction of the Lewis acid with the molecules of the given solvent and the effective acidity indices were therefore used by the author[12] to determine the position of the Schlenk equilibrium:

$$K_{Schl} = -\gamma(2\varphi^*_{RMgX} - \varphi^*_{R_2Mg} - \varphi^*_{MgX_2}), \quad (5)$$

where γ is a characteristic of the base, entering as a proportionality coefficient between the left- and right-hand sides of Eqn. (5).

The structural transitions defined by Eqn. (1) and occurring in solvents can be understood more readily by determining the driving force of the processes described — the coordinative unsaturation of the RMgX molecule. This is manifested primarily by the formation of complexes by organomagnesium compounds (Table 1).

Table 1. Composition of the complexes formed by RMgX.

Ligand (L)	Composition of the complex RMgX : L	Refs.
Ph^-	$[Li(TMEDA)^*]_2Mg_2Ph_6$	[15]

		[22]

* TMED = tetramethylethylenediamine.

The magnesium in Grignard reagents can have different coordination numbers in crystals and in solution but in a solvent a coordination number of four is most characteristic of these compounds.[23]

In the absence of the solvent (either at high concentrations or in the case of weak interactions with the solvent molecules), the hypothetical RMgX molecule is then coordinatively unsaturated. The coordination saturation of asymmetric organomagnesium compounds is attained in this instance as a result of the creation of halogen bridges[24] or alkyl(aryl) bridges.[25] Symmetrical organomagnesium compounds form polymer chains in the solid state[26] while in solution they give rise to self-association species formed via alkyl(aryl) groups.[2,27]

The solvent molecules competing with the halogen atoms and the atoms of the organic group for coordination sites at the magnesium atom hinder the formation of self-associated species, and the greater the solvating capacity of the solvent the more intense is this competition. This is why highly basic solvents not only decompose

the conglomerates RMgX (X = Br, I) at low reagent concentrations as far as monomeric species but they also solvate effectively the symmetrical molecules of organometallic compounds, displacing the Schlenk equilibrium to the right. This claim is confirmed by the weaker effect of solvation on the rate of exchange of organic groups in symmetrical Grignard reagents compared with the asymmetric reagents.[9]

Certain halogen bridges (X = F, Cl) are so strong that a highly solvating solvent cannot disrupt them and the molecules of the organomagnesium are associated even at high dilution.[1] On the other hand, in the presence of a highly electron-accepting substituent in the skeleton of the cryptobase, for example, fluorine atoms (R = C_6F_5), certain Grignard reagents behave even in weakly basic solvents as if they were placed in highly basic solvents. This is reflected not only by the absence of association but also by a rightward shift of the Schlenk equilibrium.[28]

Since the substrates used in reactions with Grignard reagents have lone electron pairs in the heteroatoms, they are all Lewis bases. When these substrates are introduced into a RMgX solution, they begin to compete with solvent molecules for coordination sites at the magnesium atom. The ability of Lewis bases to complete with solvent molecules and the strength of the Lewis acid properties of RMgX determine in many respects the reactivity of the organomagnesium compound.

2. The reactivity of RMgX

The reactions of organomagnesium compounds with various substrates are difficult to study because even in the simplest case (at high dilution and for X = Cl, Br, or I) there exist in solution at least three, in conformity with the Schlenk equilibrium, species with different reactivities.

It has been found that in many instances symmetrical organomagnesium compounds are more reactive than asymmetric compounds,[29,30] while the opposite behaviour was noted in other cases.[31]

The reactivities of monomeric and polymeric forms are in its turn also different, as shown by a number of workers.[32,33]

When the amount of Grignard reagent is equivalent or deficient, the primary products of the addition reagent—magnesium enolates or alkoxides—can themselves function as competing reactants.[34,35] The competitive reactions are suppressed by a large excess of the Grignard reagent.

Thus the reactivity of organomagnesium compounds is equal to the sum of the reactivities of all the magnesium-containing species present in solution.

(a) Nucleophilic, basic, and reducing properties of RMgX. It has been suggested[36] that the entire wide variety of reactions of organomagnesium compounds proceeding via the polar mechanism be divided arbitrarily into two main types in terms of the effect of solvation on their course, for example:

$$R_2C{=}O + R'MgX \rightarrow R_2R'C{-}OH \text{ addition—first type;}$$

$$RMgX + R'X \rightarrow R{-}R' + MgX_2 \text{ substitution—second type.}$$

The reactions of the first type are inhibited and those of the second type are promoted with increase in the solvating capacity of the solvent.[37] Intense solvation polarises the Mg—C bond, enhancing the electron-donating properties of the α-carbon atom of the cryptobase of the organomagnesium compound, on the one hand, and blocks the coordination sites at the magnesium atom, on the other.[37]

In the reactions of the first type, the nucleophilic attack on the cryptobase R^- is preceded by the coordination of the Grignard reagent to the carbonyl compound with formation of a complex. The existence of such complexes has been confirmed spectroscopically.[38,39] It is believed that this stage enhances the electrophilic properties of the attacked carbon atom.[40]

Weakly basic substrates, for exzmple $C_2F_5CH{=}O$, cannot displace solvent molecules and give rise to reactions of an intermediate type occurring without preliminary coordination.[41]

In reactions of the second type, the coordination of RMgX to the substrate does not play a decisive role and Grignard reagents behave like typical nucleophiles.[42]

We believe that there exists a further type of reactions of organomagnesium compounds proceeding via a polar mechanism. The substrate cleavage (isomerisation) reactions under the influence of RMgX belong to this type. These reactions proceed as a rule in weakly basic solvents, highly basic solvent retarding or fully inhibiting them. Not only the primary coordination of RMgX but also the Lewis acid strength of the reagent are important for reactions of the third type.

In our view, highly solvating solvents weaken the acid properties of organomagnesium compounds. This fact is important because, whilst causing an overall retardation of addition reactions, intense solvation makes their occurrence possible. Under the conditions of intense solvation, cleavage (isomerisation) reactions are as a rule inhibited.

Since reactions of the third type take place via a carbonium-like state (or via the intermediate formation of a carbonium ion, the solvation (stabilisation) of these states plays an important role in the above reactions. Therefore, if the solvating capacities of the solvents do not differ greatly, cleavage (isomerisation) reactions can take place in solvents with a higher solvating capacity as a result of the solvation stabilisation of carbonium-like transition states.

In order to understand the structures and yields of the products of the reactions of RMgX with various substrates, we shall now turn to conclusions reached for reactions of ketones with RMgX.[42–44] In the first place, in the presence of a large excess of RMgX magnesium alkoxides and enolates compete weakly with the Grignard reagent in addition, enolisation, and reduction reactions. Consequently, ketones react with RMgX via three main pathways.

The influence of structural differences in these three reactions is susceptible to quantitative interpretation. The partial rate constants for the reactions of ketones having the general formula $RCOCH_3$ with RMgX can be calculated from the following equations:

$$\lg(K_{add}/K_0) = \rho^*\sigma^* + \delta E_s^0 + h\Delta n, \quad \text{(Ref.42)}$$

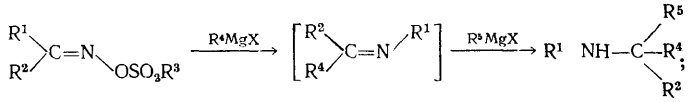
$$\lg(K_{red}/K_0) = \rho^*\sigma^* + \delta E_s^0, \quad \text{(Ref.43)}$$

$$\lg(K_{enol}/K_0) = \delta\Sigma E_s^0. \quad \text{(Ref.44)}$$

The influence of the inductive effect of the group R on the addition constant (K_{add}) and the reductive constant (K_{red}) is taken into account by the first term in the equations (σ^* are the Taft inductive constants of the substituents). The steric hindrance in the addition and reduction reactions is described by the term δE_s^0 (the steric constant of the substrate group R) and enolisation (the enolisation constant K_{enol}) is described by the term $\delta\Sigma E^0$ (the steric constants of the substituents at the α-carbon atom of the ketone).

The third term ($h\Delta n$) in the equation describing the kinetics of the addition reaction takes into account the influence of the C–H and C–C σ-bonds in the α-positions. Among the wide variety of factors influencing the rates of parallel reactions, steric factors are believed to play a decisive role.[42–44]

The study of the kinetics of the reactions of ketones with RMgX enabled the authors[42–44] to conclude that, for the three reactions analysed, the transition state has a structure close to that of the initial compounds, i.e. the ketone and RMgX, and in this sense they can be regarded as related. One cannot therefore differentiate one of them (addition) as the only "correct" or "normal" reaction of RMgX with carbonyl compounds.

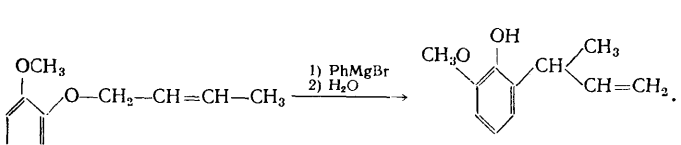


The partial rate constants for parallel reactions are greatly influenced by the basicity of the solvent, whose increase as a rule entails a decrease in the above quantities.[45]

Later studies[46,47] of the interaction of ketones with Grignard reagents confirmed the validity of the conclusions reached by Khyrak et al.[45]

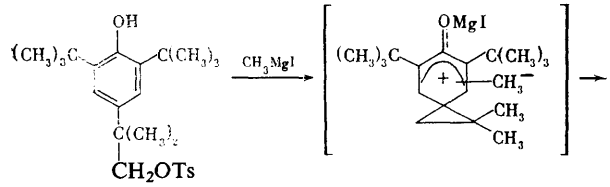
Thus the reactions of organomagnesium compounds with ketones (and other carbonyl compounds) proceed via at least three independent pathways examined above. The yield of the products in each pathway is not related to the structures of the ketone and the Grignard reagent. This feature is reflected in the partial rate constants.

Many reactions of organomagnesium compounds involving major internal rearrangements of the substrate have now been discovered. These reactions are not characteristic of organolithium compounds and cannot be understood from the standpoint of reactions of the second type (nucleophilic substitution). These reactions are determined by the Lewis acid properties of RMgX.



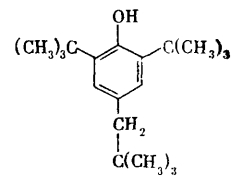
(b) The Lewis acid properties of organomagnesium compounds. Before discussing specific reactions involving the heterolysis of C–element σ-bonds, we should like to quote a number of examples of the behaviour of the Grignard reagent as a typical electrophile. The Beckmann rearrangement of oxime sulphonates has been discovered.[48] It takes place on treatment with organomagnesium compounds:

$R^4MgX = CH_3MgI$, n-$C_4H_9C{\equiv}CMgBr$.



The imines formed are converted under the influence of the excess R_5MgX into secondary amines. Neither the nature of the organic group nor that of the halogen influences significantly the rearrangement.

Another example illustrating strikingly the Lewis acid properties of a Grignard reagent may be the Claisen rearrangement of the ether shown below under the influence of phenylmagnesium bromide:[49]



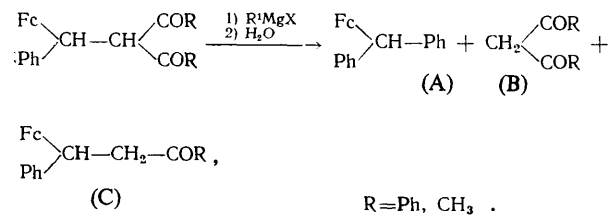
23%

It is believed that phenyl tosylate also undergoes a rearrangement on treatment with a Grignard reagent and it is assumed that the latter proceeds via a pyrocyclic complex:

Ts = *n*-$CH_3C_6H_4SO_2$–

The question of the existence of the complex is apparently controversial but presumably a carbonium-like transition state may be formed on treatment with RMgX.

Thus organomagnesium compounds, acting on certain substrates as Lewis acids, can induce profound changes in their molecular skeleton.



The data described below are devoted to the analysis of the characteristics of the structures of the substrate and the reagent necessary for the fragmentation of σ-bonds under the influence of the Grignard reagent.

III. Reactions involving the heterolysis of carbon–element α-bonds by Grignard reagents

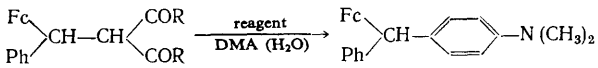
1. C–C heterolysis

σ-C–C heterolysis on treatment with RMgX is not by itself a very interesting reaction, since in the given instance a very strong bond is usually readily fragmented. The authors of the present review studied this reaction in detail in relation to β-dicarbonyl compounds and discovered its principal characteristic features which made it possible to regard σ-C–C heterolysis as a special case of the more general fragmentation of the C–element σ-bond by organomagnesium compounds and other Lewis acids. We therefore decided to begin the consideration of the problem indicated in the heading of this Section with the cleavage of a C–C σ-bond.

The interesting reaction involving the fragmentation of a C–C σ-bond in ferrocene-containing β-diketones by Grignard reagents was discovered in 1980 (Table 2):[51,52]

(A) (B) (C)

R=Ph, CH_3 .



Together with the C–C cleavage products, traces of the ketone cleavage products were detected. The difference between the yields of the σ-C–C fragmentation products has been explained[51,52] by the difference between the nucleophilic properties of the Grignard reagents.

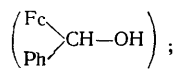


Table 2. The yields of the products of the reactions of RMgX with β-diketones.

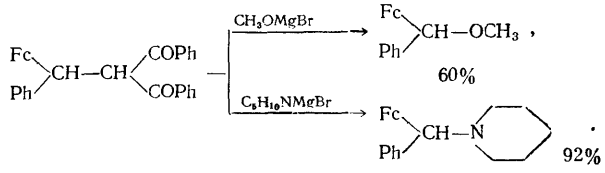
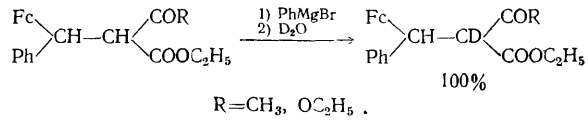
R	Reagent	Yield of products, %			Refs.
		(A)	(B)	(C)	
CH_3	PhMgBr	35	см.*	см.*	[51]
CH_3	CH_3MgI	17	см.*	см.*	[52]
Ph	PhMgBr	60	74	insignificant	[53]

*Not isolated.

In another study,[53] the same workers showed that ferrocene-containing β-diketones are cleaved at a C–C σ-bond by strong Lewis acids: $MgBr_2$, $ZnCl_2$, $SnCl_4$, as well as trifluoroacetic acid:

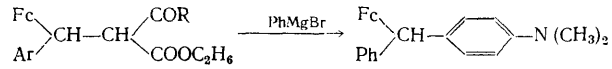




; DMA = dimethylaniline .

According to the authors[52,53] the nature of the cleavage by RMgX and by strong Lewis acids is different.

The nature of the interaction of α-monosubstituted β-dicarbonyl compounds with Grignard reagents was studied in detail by the present authors.[54] In the first place, we established that the Lewis acid properties of RMgX are in fact responsible for the σ–C–C fragmentation. This conclusion follows from the following observations: firstly, an increase in the solvating capacity of the solvent led to a sharp increase in the yield of the product of the fragmentation considered, as far as its complete disappearance from the reaction mixture in the presence of crown-ethers, and, secondly, in contrast to lithium piperidide and alcoholic alkali, dibenzoyl-(ferrocenylphenylmethyl)methane is cleaved by piperidylmagnesium bromide and methoxymagnesium bromide:[55]



It has also been established that this reaction depends on the structure of the β-dicarbonyl component of the substrate. In contrast to β-diketones, a β-ketoester and diester are not cleaved by phenylmagnesium bromide at a C–C σ-bond. In this case, the enolisation of the β-dicarbonyl compound takes place quantitatively:

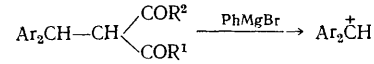
;

R=CH_3, OC_2H_5 .

The σ-C–C fragmentation depends in many respects on the stability of the carbonium ion, which can be formed by the α-substituent. *p*-Dimethylaminophenylferrocyenylmethylmalonic and acetoacetic esters are cleaved at a C–C σ-bond:[56]

;

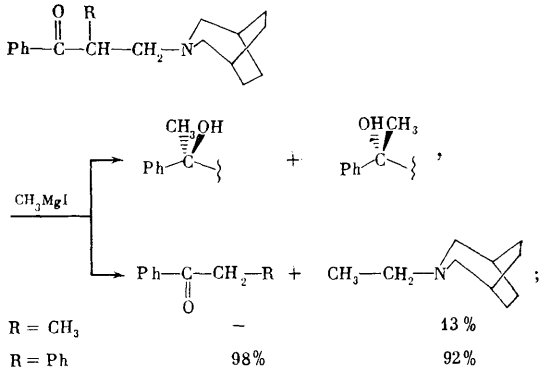
Ar=*n*-$(CH_3)_2NC_6H_4$



R=CH_3 (83%),
R=OC_2H_5 (7%).

On the other hand, as a result of a decrease in the stability of the carbonium ion formed by the α-substituent, dibenzoyl-(ferrocenylmethyl)methane is not fragmented by phenylmagnesium bromide:[57]

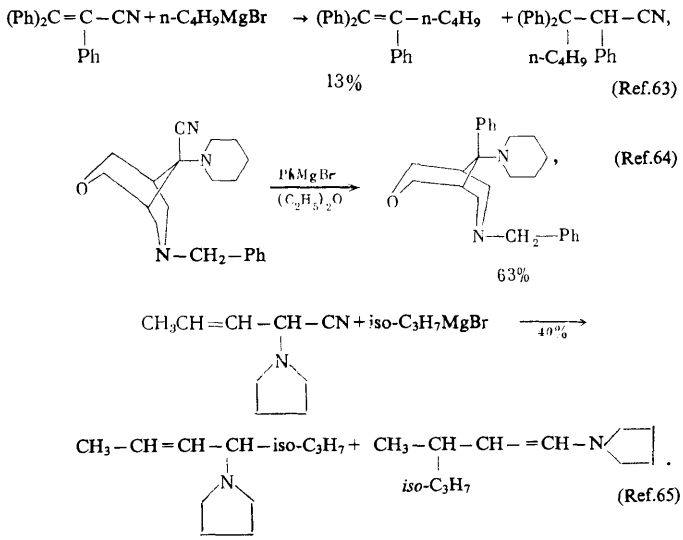
Thus we reached the following conclusions: the course of the σ-C–C cleavage reaction is determined by the stability of the carbonium ion formed by the α-substituent of the substrate and also by the stability of the carbanion formed by the unsubstituted β-dicarbonyl compound, the role of the Lewis acid properties of the organomagnesium compound being decisive.[57,59] The σ-C–C fragmentation reaction should therefore be characteristic also of compounds without the ferrocenyl fragment and also not only of β-dicarbonyl compounds.



The reaction under discussion has been observed, for example, with derivatives of bis(*p*-dimethylaminophenyl)methyl series:[60]

R^1=R^2=CH_3, Ph, OC_2H_5;
R^1=CH_3, R^2=OC_2H_5.

The occurrence of fragmentation was inferred from the appearance of the λ_{max} = 611 nm band characteristic of bis(*p*-dimethylaminophenyl)methyl carbonium ion.[61]



It has been established[62] that the σ-C−C fragmentation reaction also takes place with certain monocarbonyl compounds:

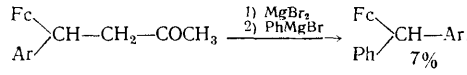
R = CH_3	–	13 %
R = Ph	98%	92%

This "anomalous" reaction, in the view of Angiolini et al.,[62] is accompanied by the "normal" nucleophilic addition reaction.

The σ-C−C cleavage reaction has been observed[63–65] for nitrile derivatives:

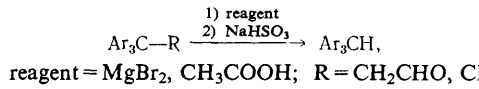
(Ref.63)

(Ref.64)



(Ref.65)

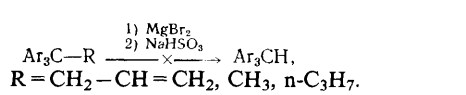
In all the studies examined above, the σ-C−C cleavage reaction is accompanied by addition to the nitrile group[64,65] (1,2-addition) and to alkene double bond (1,4-addition).[63]



Thus the σ-C−C fragmentation of organic compounds by Grignard reagents is one of the possible reaction pathways, provided that (1) the substrate molecules can be imagined to be cleaved into a stable carbonium ion and a carbanion (the stability of the fragment is correlated with the values of pK_{R^+} and pK_a for the carbonium ion formed by the α-substituent and the carbanion derived from the unsubstituted β-dicarbonyl compound respectively) and (2) the strength of the Lewis acids RMgX must be sufficient for the fragmentation of the substrate molecule.

The σ-C−C dissociation reactions are obscured by parallel reactions involving addition to the carbonyl group and enolisation. This apparently leads to a complex dependence of the yield of the σ-C−C cleavage products on the Lewis acidity of the organomagnesium compounds expressed in terms of φ*.[12]

This obstacle can be avoided using strong Lewis acids or protic acids. Thus, although monocarbonyl compounds are not fragmented by a Grignard reagent, they are cleaved at a C−C σ-bond by magnesium bromide etherate:[54]



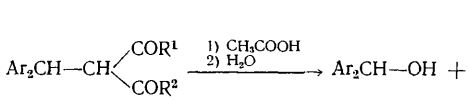
Aldehydes, nitro-compounds, and the nitrile oxides of the tris(*p*-dimethylaminophenyl)methyl series undergo σ-C−C fragmentation:[66–68]

Although the authors[66–68] do not explain the observed phenomenon, it can be understood in terms of the values of pK_{R^+} and pK_a. The relation between these quantities, estimated in terms of pK_a and pK_{R^+}, can be demonstrated by the following example. Despite the high thermodynamic stability of $Ar_3\overset{+}{C}H$, compounds forming unstable carbanions are not cleaved:[66]

The primary coordination of the reagent and the substrate is extremely important for the σ-C−C fragmentation reaction. This postulate is well illustrated by the following example:[68]

On formation of two stable ions, the possibility of the protonation of the olefinic double bond by acetic acid appears, which leads to the σ-C−C fragmentation of tris(*p*-dimethylaminophenyl)methylallyl:[68]

The ready fragmentation of β-dicarbonyl compounds of the bis(*p*-dimethylaminophenyl)methyl series at a C−C σ-bond by acetic acid, discovered in 1909 by Fosse,[698] also becomes entirely explicable:



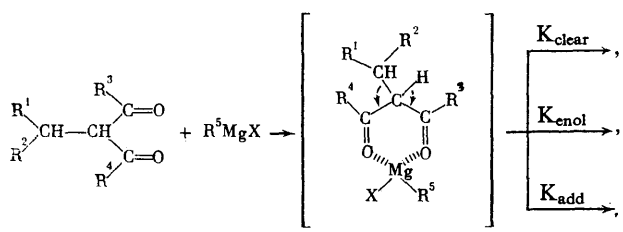


Table 3. The yields of the products of the cleavage of ethers.

No.	Substrate	Reagent	Yield of products, %		Refs.
			(D), (D′)	(E), (E′)	
1	Ph–CH=CH–CH_2–O–$(CH_2)_2$Ph	n-C_6H_{13}MgBr	Ph, n-C_6H_{13} >CH–CH=CH_2 15	Ph$(CH_2)_2$OH 23	[76]

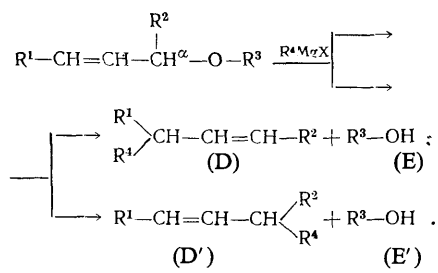
The following mechanism has been proposed for the σ-C–C fragmentation of β-dicarbonyl compounds (different classes of organic compounds) by Grignard reagents (and other Lewis acids):[54]

In the first stage of the reaction, the β-dicarbonyl compounds is coordinated to the Grignard reagent (chelate formation).[70] It is well known that the coordination of Lewis acids, especially of the Mg^{2+} ion,[71] labilises the proton in the α-position relative to the carbonyl group.[72] When the molecule contains an α-substituent capable of giving rise to a stable carbonium ion, the α-substituent begins to compete with the proton as regards lability, i.e. the σ-C–C cleavage and enolisation reactions complete, whereupon the coordination of the reagent enhances also the electrophilic properties of the carbonyl groups.



Thus coordination (chelate formation[73,74]) of the Grignard reagent leads to polarisation (in extreme cases to ionisation) of the C–C, C–H, and C=O bonds, which are in any case already polarised.[75] In the second stage, the three cryptobasic centres formed are attacked with different effectiveness. The ratio of the products via the three pathways — σ-C–C cleavage, enolisation, and addition of the carbonyl group — depends on the ratio of the partial constants K_{cleav} (cleavage) K_{enol}, and K_{add}.

The characteristics noted for the σ-C–C fragmentation of β-dicarbonyl and monocarbonyl compounds hold also for other classes of organic compounds.

2. C–O Heterolysis

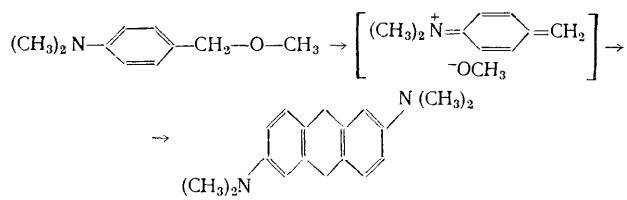
(a) The cleavage of ethers. A number of ethers undergo heterolysis at a C–O σ-bond on treatment with Grignard reagents. This reaction is observed only for a particular structure of organic compounds of this class.

Vinyl and allyl ethers undergo cleavage at a C–O σ-bond. The observed reaction can be represented schematically in the following manner in relation to αβ-unsaturated ethers:

Data on the σ-C–C heterolysis of unsaturated ethers are compiled in Table 3.

By analogy with ketones, it is believed,[77,78] that a complex of the Grignard reagent with the ether is formed initially and then rearranges with formation of the products of the given reaction. Hill et al.[77] believe that the coordination of the RMgX molecule to that of the ether increases the electron density deficiency on the α-carbon atom with subsequent attack on the latter by the cryptobase (1,2-addition). The 1,4-adducts are consistent with the mechanism involving a six-membered transition state.[77]

On the other hand, the authors themselves[76,78] noted that the model with the six-membered state is not universally applicable to the given reaction, since it does not explain the composition of the products of the reaction of RMgX with ethers having bulky substituents in the 2- or 4-position (Table 3, example 4).



We may note that the molecules of unsaturated ethers, presented in Table 3, can be cleaved into two fragments: the stable allylcarbonium ion and the alkoxide (enolate) anion.

The presence of the carbonium ion in the transition state explains satsifactorily the presence in the reaction mixture of the products of the Claisen isomerisation of the enol ether. The presence in the molecule of a group which can be readily eliminated makes possible the cleavage at a C–O σ-bond of the tosylate derived from a sterically hindered enol (see above).

As in σ-C–C heterolysis, the coordination of RMgX to the oxygen atom of the ether leads to intense polarisation (ionisation) of a C–C σ-bond and attack by the nucleophilic completes the heterolysis.

The data presented in Table 4 may serve as evidence in support of the occurrence of the reaction investigated via an ionic mechanism.

The existence of immonium structures in the transition state has been postulated.[79] According to these workers, this explains the presence of condensed systems in the reaction mixture:

The immonium ion was formed not under the influence of RMgX, but, as follows from the mechanism proposed by the authors,[79] resulted from σ–σ conjugation.

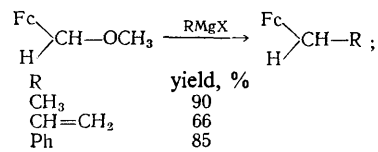


Table 4. Yields of the products of the cleavage of ethers.

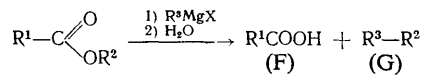
No.	Substrate	Reagent	Yield of product, %	Refs.
1	Ar–CH_2–O–CH_3	PhMgBr	Ar–CH_2–Ph 84	[79]
2		**n-C_3H_7MgBr**	 43	[80]
3	$(CH_3O)_2CH$–$N(CH_3)_2$	PhMgBr	$(Ph)_2CH$–$N(CH_3)_2$ 89	[81]
4	PhO–$CH(OC_2H_5)_2$	**n-C_4H_9MgBr**	**n-$C_4H_9CH(OC_2H_5)_2$** 90	[82]
5	CH_3O–CH_2NR_2	$(CH_3)_3SiCH_2MgCl$	$(CH_3)_3SiCH_2$–CH_2NR_2 70	[83]
6	PhOCH$(OC_2H_5)_2$	CH_2=CH–CH_2MgBr	CH_2=CH–CH_2–$CH(OC_2H_5)_2$ 70	[84]
7	$(PhO)_2CHOC_2H_5$	**n-C_4H_9MgBr**	$(C_4H_9)_2CHOC_2H_5$ 74	[85]
8	(PhO)$CH(OC_2H_5)_2$	**n-C_4H_9MgBr**	**n-$C_4H_9CH(OC_2H_5)_2$** 80	[86]
9	$CH_3OCH_2N[Si(CH_3)_3]_2$	CH_3MgBr	$CH_3CH_2N[Si(CH_3)_3]_2$ 89	[87]

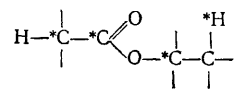
The C–O σ-bond in the ethers listed in Table 4 is so labile that, in contrast to the compounds listed in Table 3, the σ-C–O heterolysis by organomagnesium compounds in THF of ethers, which are cleaved in diethyl ether or diethyl ether–benzene mixtures, takes place with high yields.

In all the examples listed in Table 4, the C–O σ-bond is cleaved selectively — on the side of the most stable immonium cation. On the other hand, when the molecule contains carbonium ions of comparable stability, cleavage takes place on the side of the more stable anion (Table 4, examples 4 and 6–8).

There is nothing surprising about the fact that the ethers containing the ferrocenyl group — a powerful stabiliser of the α-carbonium ion — undergo σ-C–O heterolysis by organomagnesium compounds:[88]



R	yield, %
CH_3	90
$CH=CH_2$	66
Ph	85

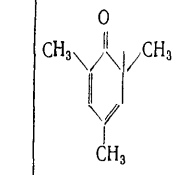


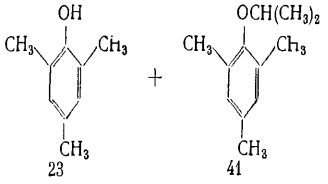
In this case, the σ-bond under consideration is highly polarised (ionised) and coordination of RMgX leads to σ-C–O fragmentation in the presence of a leaving group which is effectively eliminated.

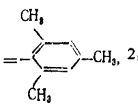
Thus ethers are selectively cleaved at a C–O σ-bond, the latter being fragmented on the side where stable carbonium ions and alkoxides are formed.

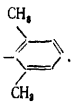
(b) The cleavage of esters. A number of esters undergo σ-C–O fragmentation on treatment with RMgX:

At least three parallel reactions take place simultaneously due to the existence of the following four reaction centres:[89]









All the possible reaction pathways operate after the formation of the coordination complex of RMgX and the substrates as a result of its rearrangement.[90] The reaction with a six-membered transition state has been postulated[91,92] as anomalous for σ-C–O heterolysis. In a later study,[93] the mechanism with a six-membered transition state was questioned and an ionic reaction mechanism was put forward for the reaction with the following characteristic features: (1) the alkyl substituent linked to the oxygen atom is capable of giving rise to a stable carbonium ion; (2) among the ethoxycarbonyl groups, the "normal" addition to the carbonyl group is hindered and is therefore retarded.

Table 5 presents a compilation of data on the σ-C–O heterolysis of esters.

The postulates of Arnold and Searles[93] are applicable in cases 2, 3, 6, and 7 (Table 5), while in other instances they fail to account for the occurrence of σ-C–O heterolysis. Indeed, in examples 1, 4, 5, 8, and 9, the ethoxycarbonyl group is not blocked to nucleophilic attack by the cryptobase, but the cleavage under consideration does not occur.

Table 5. The yields of the products of the cleavage of esters.

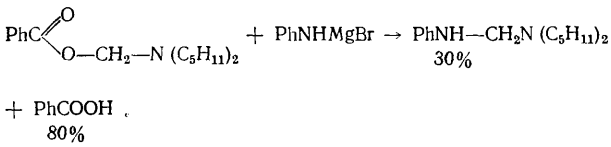
Mes =  , [2] Not isolated. [3]* Dur =  .

The occurrence of cleavage in case 5 is inexplicable from the standpoint of these two postulates. Firstly, the carbonyl group of the ester is fairly active in nucleophilic addition reactions and, secondly, the dimesityl carbonium ion is apparently unstable.[98] It is sufficient to note that, according to the data of Fieser and Heymann,[98] neither diphenylmethyl acetate nor fluorenyl acetate are cleaved by phenylmagnesium bromide at the C–O σ-bond.

In the given instance, the stability of the leaving group assumes an important role in our view: $K_a = 1.75 \times 10^{-5}$ for CH_3COOH and $K_a = 6.5 \times 10^{-5}$ for PhCOOH. Incidentally, one cannot rule out also an important contribution by the *I* effect of the methyl group to the stability of the dimesityl carbonium ion.

It is important to note that both in the original studies[89–99] and in the monographs referring to these investigations, in the interpretation of the σ-C–O cleavage of esters by RMgX the authors invoke the Lewis acid properties of magnesium bromide etherate:[100]

The examination of the structure of RMgX in the earlier part of the review showed that even at high dilutions the content of MgX_2, formed in accordance with the Schlenk equilibrium in ethereal solutions and in other weakly solvating solvents, where the heterolysis under consideration takes place, is extremely insignificant. The formation of magnesium halides as a result of the reaction analogous to the Wurtz reaction, occurring simultaneously with the formation of asymmetric and symmetrical organomagnesium compounds, is unlikely.[101]

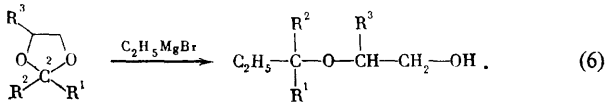


Under the experimental conditions (ethereal solution, $c > 0.01$ M), polyassociated species always exist and the MgX_2 formed therefore forms part of the composition of these macromolecular formations, its acid properties being weakened under these conditions.

In the case of organomagnesium compounds with branched alkyl groups (Table 4, example 4), a reduction reaction is observed together with the nucleophilic substitution reaction. In our view this is associated with the fact that, on coordination to the ester molecule via the C—O σ-bond, RMgX is highly polarised to such an extent that attack on the new electrophilic centre becomes possible not only by R^- but also by the hydride ion.

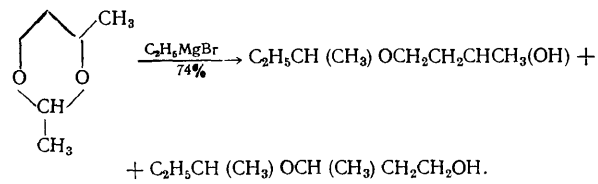
The presence of 1,2- and 1,4-adducts derived from allyl esters can be readily accounted for from the standpoint of a carbonium-like transition state, while the mechanism with a six-membered transition state and a synchronous redistribution of electrons does not explain it—for example in case 7 in Table 5.

Thus the σ-C—O cleavage reaction can be observed or not observed for esters with a bulky substituent R^1, i.e. the steric hindrance to nucleophilic addition via the carbonyl group generated by this substituent is not obligatory or of decisive importance for the reaction considered. On the other hand, the σ-C—O heterolysis may be expected if the substituent R^2 is capable of forming stable carbonium ions. The influence of the structure of R^3 on the cleavage considered is expressed by the fact that, together with the cleavage products (G) (in the scheme above), one may expect also the reduction products (H-R_2) in the case of branches groups R_3, and is also reflected by the contribution resulting from the Lewis acidity, expressed, for example, in terms of φ * (see above).



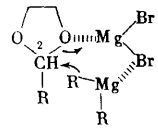
The nucleophilicity of the Grignard reagent is apparently unimportant for the heterolysis reaction, since esters are cleaved by various organomagnesium compounds. The cleavage of esters by RNHMgX has been described:[102,103]

The C—O fragmentation involving ethers and R_2NMgX takes place similarly.[104]



Thus the heterolysis examined above is analogous to the reaction involving ethers and is determined by the stability of the carboxylate ions and carbonium ions which can be formed by the substituent R^2. The role of the Lewis acid properties of RMgX is then decisive.

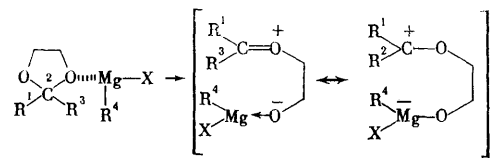
(c) The cleavage of 1,3-dioxolans. Cyclic ketals and acetals undergo the σ-C—O heterolysis on treatment with organomagnesium compounds. This reaction proceeds as a rule under more severe conditions than those examined above—in boiling benzene or toluene:[105]



(6)

Dioxolans forming six-membered rings are cleaved under still more severe conditions than the five-membered compounds. This is believed[105] to be associated with the smaller strain in six-membered rings:

Data on the σ-C—O heterolysis of 1,3-dioxolans are compiled in Table 6.



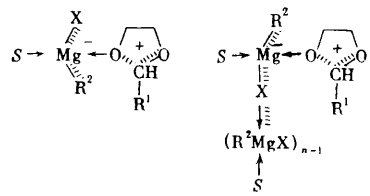
The mechanism of σ-C—O heterolysis involving a six-membered transition state was postulated in almost all the studied presented in Table 6:

It has been suggested[106–110] that the driving force of the σ-C—O heterolytic process is the polarisation of the cleaved C—O bond by magnesium bromide etherate. The cleavage process is regarded as a concerted circular electron transfer. According to the authors,[106–110] this mechanism is confirmed by the isolation of the complexes of 1,3-dioxolans with MgX_2 (2,4-dimethyl-1,3-dioxolan : MgX_2 = 1.65 : 1).

In their assessment of the influence of substituents in the 2-position on the ease of opening of the dioxolan ring, Trofimov et al.[108] noted the parallel variation of the yield of the products of σ-C—O heterolysis and the electron-donating capacity of the substituents (for example, the unsubstituted dioxolan is not cleaved by RMgX). However, the observed variation has not been explained.[106–110]

Blomberg et al.[111] explained the influence of the substituents in the 2-position in the dioxolan molecule by the fact that the mesomeric form of the transition state includes the C(2)-carbonium ions, which is stabilised by electron-donating substituents.

In a later study,[114] it was suggested that the interaction of a series of dioxolans with Grignard reagents results in the formation of an oxocarbonium transition state and that the driving force of the process is the Lewis acid properties of all the organomagnesium conglomerates present in solution: the RMgX monomers at a low concentration and the $(RMgX)_n$ polymers at a high concentration:



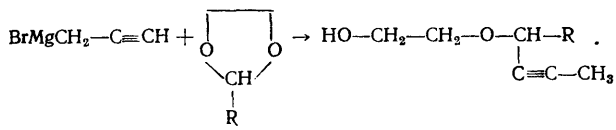


Table 6. The yields of the products of the cleavage of dioxolans via reaction (6).

No.	R^1	R^2	R^3	Reagent	Yield of product, %	Refs.
1	CH_3	H	H	$CH_2=CH-C\equiv CMgBr$	$CH_2=CH-C\equiv C-CH(CH_3)-O-(CH_2)_2OH$ 58	[106]

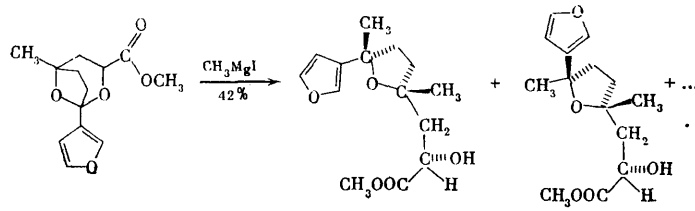
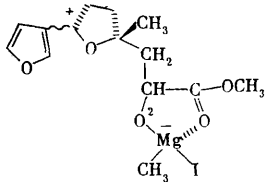
8	H	CH_3	CH_3	$(CH_3)_2CHMgBr$	$(CH_3)_2CH-CH(CH_3)-O-CH(CH_3)-CH_2OH$ 71	[113]

In a study[115] of the σ-C–O cleavage of a dioxolan by a Grignard reagent, the formation of the final reaction product was attributed to the nucleophilic properties of RMgX and its structure was attributed to the migration of the triple bond under the influence of the base and temperature:



We believe that, firstly, in the given case σ-C–O heterolysis takes place and, secondly, that the above workers[115] indicate an erroneous structure of the reagent.

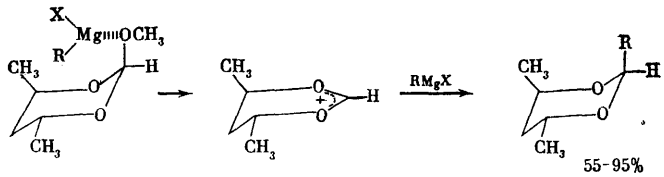
In view of the greater basicity of a carbanion with an sp^3-hybridised carbon atom than that of a carbanion with an *sp*-hybridised carbon atom,[116] the structure of the reagent can be represented by the formula $CH_3-C\equiv CMgBr$.



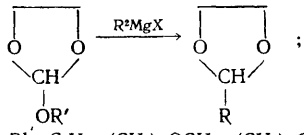
The following equilibrium may be established in solution:

$$CH_3C\equiv CMgBr \rightleftarrows BrMgCH_2-C\equiv CH.$$

Abell and Mass-Westropp[117] observed the heterolytic cleavage of the C–O σ-bond in dioxolan:



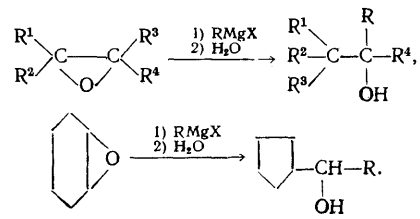
The selectivity of the reaction, reflected in the products, can be explained according to the authors[117] by the chelation reaction of the methoxycarbonyl group, via the O(2) atom, with methylmagnesium iodide and the subsequent formation of an oxocarbonium ion:



A competing reaction involving nucleophilic addition to the carbonyl group takes place simultaneously. The relation between the stabilities of the two fragments produced as a result of the breakup of the dioxolan molecule after coordination was not investigated in the above study.

The stereospecific synthesis of 1,3-dioxolans with an axial substituent at the C(2) atom has been described:[118]

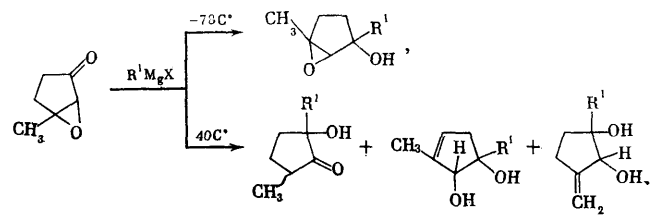
This character of the reaction is determined, according to the authors,[118] by the need for a stereoelectronic factor in the formation and subsequent reaction of the oxocarbonium ion. It has been shown[119] that at high temperatures cyclic ortho-esters are cleaved by Grignard reagents also in a highly basic solvent—tetrahydrofuran



$R^1 = C_2H_5$, $(CH_2)_2OCH_3$, $(CH_2)_2O(CH_2)_2OCH_3$.

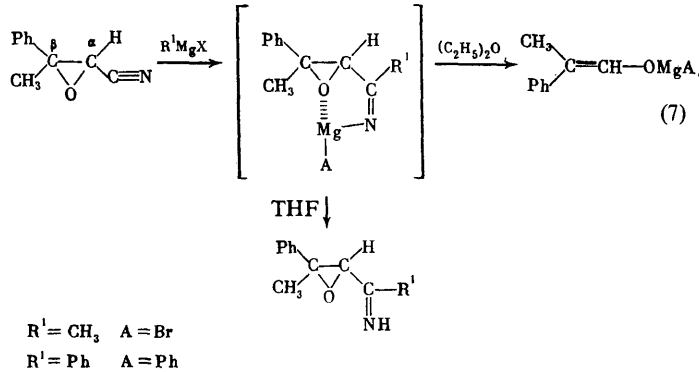
The driving force of the above process is believed[119] to be the coordination of MgX_2 to the oxygen atom linked directly to the C(2) atom. An increase in the number of oxygen atoms in the substituent R leads to a fall in the yield of the product of σ-C—O heterolysis owing to the saturation of the coordination sites of magnesium by the oxygen atoms of the substituent R^1 remote from the C(2) atom (i.e. owing to the weakening of the Lewis acid properties of the Grignard reagent).

Thus the σ-C—O heterolysis of 1,3-dioxolans by RMgX is one of the examples of the fragmentation of substrates by a Lewis acid. This reaction proceeds if a stable carbonium ion can be generated in the dioxolan molecule under the influence of RMgX. An alkoxide ion is invariably the leaving group. The acceleration of the heterolysis by the introduction of electron-donating substituents in the 2-position occurs, in our view, as a result of the stabilisation of the carbonium ion in the transition state. The introduction of alkoxy-substituents, i.e. effective leaving groups, into the 2-position in cyclic ortho-esters leads to the formation of 1,3-dioxolans.



The marked dependence on the solvating capacity of the solvent and the uncharacteristic course of the σ-C—O heterolysis of organolithium compounds show that the Lewis acid properties of RMgX in the reaction under discussion are responsible for the possibility of the occurrence of the σ-C—O heterolysis of dioxolans.

(d) Isomerisation of epoxides. Organomagnesium compounds induce the isomerisation of epoxides similarly to the Lewis acids MgX_2:[120–125]

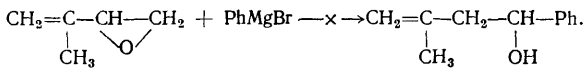


The above isomerisation reaction is accompanied, according to the authors,[122–125] by the simultaneous "normal" nucleophilic opening of the ring. The isomerisation of epoxides by organomagnesium compounds is fully inhibited in highly basic solvents.

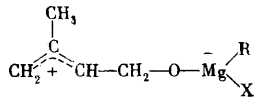
It is sometimes possible to isolate the epoxide isomerisation products themselves. An α-hydroxyketone has been identified[126,127] in the reaction mixture produced by the interaction of α-epoxycyclopentanones with RMgX:

The above scheme shows that the products of the reaction are determined by the temperature of the reaction mixture. An increase in temperature enhances the acid properties, i.e. leads to isomerisation.

The species inducing the isomerisation of certain epoxides are alkyl(aryl)magnesium imines:[128–130]



(7)



$R^1 = CH_3$ A = Br
$R^1 = Ph$ A = Ph

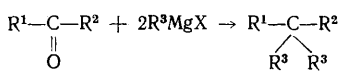
Scheme (7) shows that the acid properties of magnesium-containing conglomerates are responsible for the possibility of isomerisation.

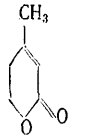
The cleavage of isopropenyloxiran by phenylmagnesium bromide has been investigated,[131] but the epoxide isomerisation products were not detected in the reaction mixture:

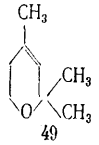
In our view, in the given instance a carbonium-like state with a primary carbon atom is not produced because of the higher stability of a carbonium-like transition state with a secondary carbon atom stabilised by $\pi-\pi$ conjugation:

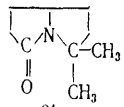
We believe that isomerisation proceeds because the epoxide molecule can be cleaved into two stable oppositely charged fragments within the molecule, which rapidly and irreversibly isomerise to ketones or aldehydes. The carbonyl compounds formed combined with an RMgX molecule and are converted into carbinols.

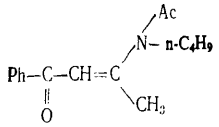
(e) The cleavage of carbinols and alkoxides. After introduction with RMgX in weakly solvating solvents, many ketones form the products of the "anomalous" reaction: after the "normal" addition to the carbonyl group, the magnesium alkoxide formed reacts with another RMgX molecule and is cleaved at the C–O σ-bond[132–137] (Table 7):

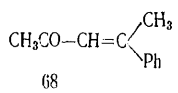












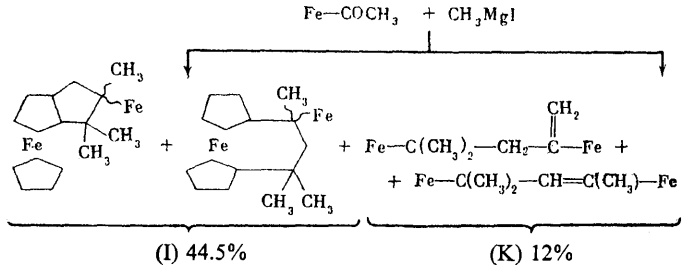


Table 7. The yields of the products of the cleavage of carbinols and alkoxides.

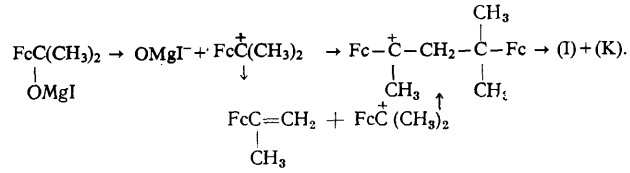
Substrate	Reagent	Yield of product, %	Refs.
	CH_3MgI	 49	[132]
	CH_3MgBr	 21	[133]
	CH_3MgI	 68	[134]
	RMgX		[135]
$FcC(CH_3)_2OH$	CH_3MgI	$FcC(CH_3)_2$ 14	[136,137]



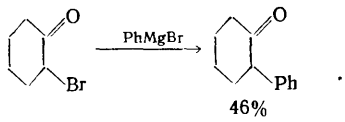
All the substrates listed in Table 7 contain in the α-position relative to the carbonyl carbon atom potential stabilisers of the α-carbonium ion—nitrogen and oxygen atoms and the ferrocenyl group. On the other hand, the oxygen ion stabilised by the MgX^+ counterion is converted into a readily eliminated group and thus the lability of the C–O σ-bond in such alkoxides becomes understandable.

The isolation of products of the intramolecular homo- and heteroannular alkylation of the ferrocenyl substituent and also of ferrocene-containing alkenes from the reaction mixture produced by the interaction of acetylferrocene and methylmagnesium iodide supports the view that the reactions of the organic compounds of the classes considered proceed via a stage in which a carbonium ion (a carbonium-like transition state) is formed:

(I) 44.5% (K) 12%

It is believed[136,137] that the reactions discussed above proceed via the C–O σ-bond ionisation stage with formation of the dimethylferrocenylcarbonium ion:

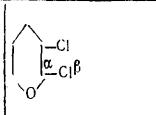
3. The cleavage of the C–Cl bond

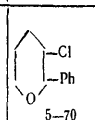


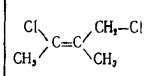
Certain chlorine-containing compounds undergo heterolysis at the C–Cl σ-bond by Grignard reagents. Table 8 presents examples of such reactions.

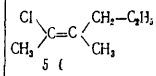
It is striking that all the cleaved compounds can give rise to a stable carbonium ion and a stable anion and that, in the presence of two chlorine atoms in the substrate molecule (two readily eliminated groups) (Table 8, examples 1 and 6), the $C^{\alpha}-Cl^{\beta}$ σ-bond is cleaved (Table 8, example 1).

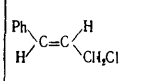
Arbuzov et al.[138] noted that the stereochemical results of the interaction of 2,3-dichlorotetrahydropyran with RMgX can be explained by the intermediate formation of an oxocarbonium ion.

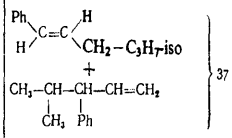


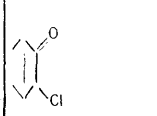


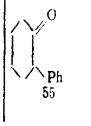












It has been noted[142] that the substitution of the chlorine atom in (*Z*)-3-chloro-1-phenylpropene takes place only in ether; in THF, the products of the C–Cl heterolysis—(*Z*)-4-methyl-1-phenylpent-1-ene and (*Z*)-4-methyl-3-phenylpent-1-ene—are not formed. Although this fact was not explained,[142] we believe that in the given instance the weakening of the Lewis acid properties of RMgX in THF prevents the fragmentation of the chlorine-containing alkene.

Grignard reagents also cleave bromine-containing compounds. The cleavage of the C–Br σ-bond has been described:[140]

Apparently iodine- and fluorine-containing compounds can also be cleaved by RMgX.

Table 8. The yields of the products of the cleavage of chlorine-containing compounds.

No.	Substrate	Reagent	Yield of product, %	Refs.
1		PhMgBr	 5–70	[138–140]
2		C_4H_9MgBr	 5 (	[141]
3		iso-C_3H_7MgB	 37	[142]
4	$CH_3CH{=}C(Cl){-}CH_2Cl$	CH_3MgI	$CH_3{-}CH{=}C(Cl){-}CH_2 + CH_3{-}CH(CH_3){-}C(Cl){=}CH_2$ 50 18	[143]

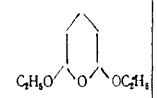
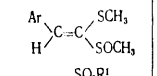
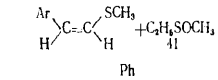
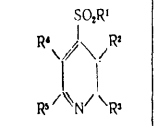
6		PhMgBr	 55	[145]

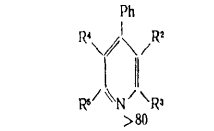
4. The cleavage of compounds of different classes

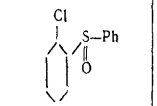


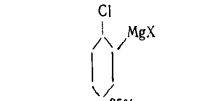


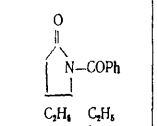


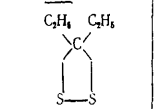


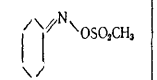


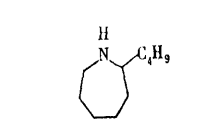


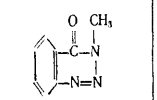


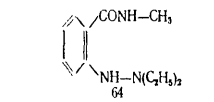












Isolated examples involving the heterolysis of a carbon–element σ-bond by organomagnesium compounds derived from organic compounds of different classes can be found in the literature. Examination of examples 1–7 (Table 9) shows that these are related reactions, since the yield of the products indicated in Table 9 depends on the solvating capacity of the solvent and also on the stability of the fragments of the molecules of the initial compound into which they can cleave heterolytically by RMgX at the carbon–element bond.

Examples 8–10 (Table 9) show that the heterolysis of the carbon–element σ-bond examined in the present review is a special aspect of a wide range of reactions involving the cleavage of element–element bonds by Grignard reagents.

IV. Conclusion

In conclusion of the review, it is essential to note that the heterolysis of a carbon–element σ-bond is hardly likely to be very important for organic synthesis, in the first place because well tried synthetic methods for the preparation of stable carbonium ions or carbanions already exist. Using the latter as the starting materials, it is possible to obtain fairly readily the required products without resorting to the cleavage by RMgX of substrates comprising the species under consideration [a carbonium ion (and its counterion) and the carbanion (and its counterion)].

Table 9. Yields of the products of the cleavage of different class of organic compounds.

No.	Substrate	Reagent	Yield of product, %	Refs.
1		PhMgBr	$Ph{-}CH(OC_2H_5){-}(CH_2)_3{-}CH(OH){-}Ph$ 100	[146]
2	$R{-}S{-}C{\equiv}N$	R^1MgX	$R{-}S{-}R^1$ >40	[147]
3		C_2H_5MgBr	 41	[148]
4		PhMgBr	 >80	[149]
5		PhMgBr	 85%	[150]
6	$(CH_3)_2N{-}CH(SCH_3)_2$	PhMgBr	$(CH_3)_2N{-}CH(Ph)_2$ 30	[151]
7		$n\text{-}C_6H_{13}MgBr$	$n\text{-}C_6H_{13}CO(CH_2)_3NH{-}COPh$	[152]
8		CH_3MgI	$(C_2H_5)_2C(CH_2SCH_3)SH$ 86	[153]
9		C_4H_9MgI	 57	[154]
10		C_2H_5MgI	 64	[155]

However, the possibility of the heterolysis of a carbon–element (element–element) σ-bond by organomagnesium compounds must always be taken into account for compounds which can fragment into stable charged species.[156–158]

Thus reactions in which carbon–element bonds are apparently cleaved have been described in the literature, although the authors of the communications quoted did not describe the identification of the following compounds [the products of the heterolytic reactions (8)–(10) respectively]:

$(C_2H_5)_2N—CH_2C\equiv C—CH_2—N(C_2H_5)_2$, $(CH_3)_2N—CH_2CH_3$, $PhCH(OCH_3)Ph$.

$$(C_2H_5)_2N—CH_2—C\equiv CMgI + ClSi(CH_3)_3 \rightarrow (C_2H_5)_2N—CH_2—C\equiv C—Si(CH_3)_3 \text{ (Ref.156).} \quad (8)$$

$$(CH_3)_2N—CH_2—CH(Ph)—CO—CH_3 + CH_3MgI \rightarrow \rightarrow (CH_3)_2N—CH_2CH(Ph)—C(CH_3)_2 \text{ (Ref.157)} \quad (9)$$
$$\quad\quad\quad

Reactions of phosphorus(III) chlorides with carbonyl compounds

M B Gazizov, R A Khairullin, V V Moskva
Kirov Kazan Institute of Chemical Engineering

ABSTRACT. The composition of the products of the interaction of phosphorus(III) chlorides with carbonyl compounds and the pathways leading to their formation are analysed as a function of the structure of the initial reactants and the experimental conditions. The catalytic role in the primary processes of the admixture of hydrogen chloride in phosphorus(III) chlorides is discussed. The influence of the functional group in substituted aldehydes and ketones and of the third reactant on the course of the reactions and on the nature of the final product is demonstrated.

The bibliography includes 231 references.

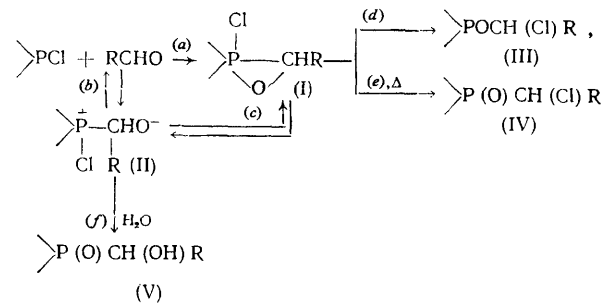
I. Introduction



The reactions of phosphorus(III) chlorides with carbonyl compounds have already been discussed in reviews,[1,2] but the later of the two was published 20 years ago. Since then considerable advances have been made in the study of these reactions and a large amount of new scientific data, which have significantly altered many of our ideas about these reactions, has accumulated. The structure of the products of the interaction of phosphorus(III) chlorides with carbonyl compounds and the pathways leading to their formation depend very significantly on whether the reaction is carried out in the presence of a third reactant or in its absence. In the present review, attention is concentrated on the survey of literature data published during the last 20 years. The endeavour to demonstrate the evolution of views on the reactions considered led us to include in the review also certain studies from an early period.

II. Reactions of phosphorus(III) chlorides with carbonyl compounds in the absence of a third reactant

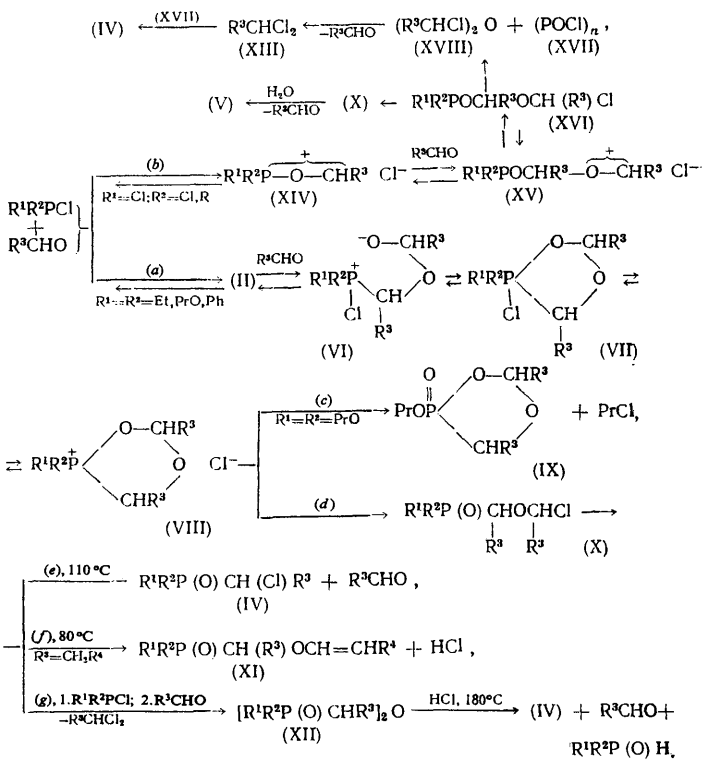
1. Aldehydes

More than 100 years ago, Fossek[3] established for the first time that phosphorus trichloride interacts vigorously with aldehydes to form thick oily adducts. Michaelis[4] attributed to them the structure of cylcophosphorane (I) (Scheme 1, pathway *a*), i.e. he postulated that the interaction proceeds with an increase in the coordination number of phosphorus. Conant[5] initially fully supported Michaelis's scheme but on the basis of kinetic studies he assumed the initial formation of a dipolar product (II) (pathway *b*)[6] capable of being converted into the phosphorane (I) (pathway *c*).

Scheme 1

Page,[7] Kabachnik,[1] and Atherton et al.[8] held a different view on the nature of the primary process. They assumed that phosphorus(III) chloride is an electrophile and that the coordination number of the phosphorus atom does not change in the primary process.

$$\text{PCl} + \text{RCHO} \rightarrow \underset{\text{(III)}}{\text{POCH (Cl) R}}.$$

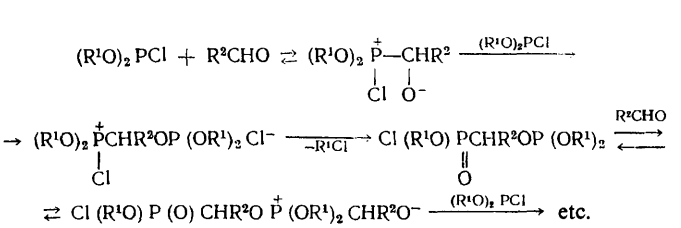


Pudovik and Khairullin[2] maintained the view that phosphorus(III) chlorides behave as nucleophiles in the primary step of the interaction and, taking into account new data,[1,7,8] supplemented the Michaelis–Conant mechanism by introducing into it the new pathways *d* and *e*. If the product of the direct interaction of phosphorus(III) chloride with an aldehyde is pyrolysed (pathway *e*) or is treated with water (pathway *f*), then stable α-chloroalkyl derivatives [compounds (IV)] and α-hydroxyalkyl derivatives [compounds (V)] of phosphorus(IV) are formed.[1,2,9–15]

On the basis of the structures of compounds (IV) and (V), the investigators assumed that only one aldehyde molecule is consumed in the formation of the product in the reaction of phosphorus(III)

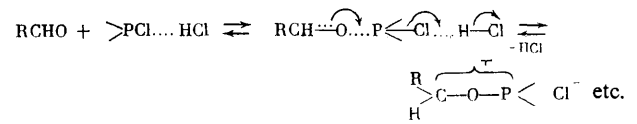
chloride with aldehydes. However, since the 1970's, studies have been published indicating the consumption of two aldehyde molecules per P–Cl bond.[16–21] From the character of the effect of the nature of the substituents in phosphorus(III) chlorides and aldehydes on the rate of reaction, it was concluded that PCl_3 and $RPCl_2$ exhibit electrophilic[16–19,22–24] reactivity, while R^1R^2PCl and $(R^1O)(R^2O)PCl$ exhibit nucleophilic activity.[16,17,20] Thus the interaction of secondary chlorophosphines with benzaldehydes affords the salts (VIII), which are then converted via the Arbuzov reaction into compounds (X) (Scheme 2, pathways *a* and *d*),[24] while the interaction of chlorodiphenylphosphine with aliphatic polyfluoroaldehydes gives rise to the stable phosphoranes (VII).[20] The phosphorane (VII) with $R^1 = R^2 = PrO$ is stabilised as a result of the elimination of propyl chloride with retention of the 1,4,2-dioxaphospholan ring (IX) (pathways *a* and *c*). The formation of compounds (VII) and (VIII) can probably be represented in the following way: as a result of the nucleophilic attack by the lone pair of phosphorus(III) on the carbon atom of the carbonyl group, the dipolar ion (II) is formed and combines with a second aldehyde molecule, being converted into a new dipolar ion (VI). The latter is sterically more favourable for the formation of the phosphorane structure (VII) compared with the ion (II).

At 80 °C, compound (X) is dehydrochlorinated to the product (XI) (pathway *f*),[18] while at 110 °C it splits off an aldehyde molecule and is converted into the familiar compound (IV) (pathway *e*).[23] The phosphine oxide (X) also readily reacts with chlorodiphenylphosphine and an aldehyde, affording the alkylidine chloride (XIII) and the ether (XII) (pathway *g*). The pyrolysis of the latter in the presence of HCl leads, as in the case of the product (X), to compound (IV).[16]



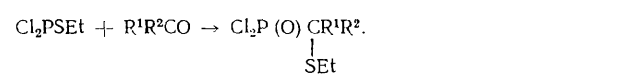
Scheme 2

In the case of phosphorus(III) chlorides exhibiting electrophilic properties, the primary products apparently arise from the exchange of chlorine atoms at the phosphorus(III) for a new group[16] and are formed as a result of the nucleophilic attack by the oxygen atom of the carbonyl group on the phosphorus(III) atom, which leads to the ion pair (XIV) (pathway *b*). The cation (XIV), whose stability is enhanced by the delocalisation of the charge, combines with the next aldehyde molecule, affording the new ion pair (XV). Compounds (XV) and (XVI) are converted into the product (X) via a stage involving the formation of a quasi-phosphonium salt of type (VIII). Compound (X) readily gives rise to the α-hydroxyalkyl derivative (V) of phosphorus(IV) on treatment with water and can also react chemically via pathways *e* and *f*.[18]



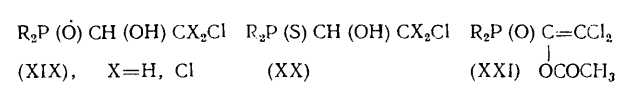
In later studies,[22,23] the isolation of compounds (XIII) and (XVIII) after the reaction of PCl_3 with benzaldehyde led to the hypothesis that the phosphorus-containing product (XVII) is formed and reacts with benzylidene chloride (XIII) via the mechanism of the Arbuzov reaction. The structure of compound (XVII) was not demonstrated rigorously and it is also difficult to postulate the interaction of a compound having a P(III)–Cl bond with a weak electrophile such as benzylidene chloride. It has still not been elucidated from what intermediate are the ethers (XVIII) formed directly under mild conditions. However, it is entirely possible that it is a compound containing one or several 1-(1′-chloroalkoxy)-alkoxy-groups at the phosphorus atom. One should also note that, in the interaction of formaldehyde (paraformaldehyde) with phosphorus(III) chloride, the formation of organophosphorus compounds with $POCH_2OCH_2Cl$ and $P(O)CH_2OCH_2Cl$ structural fragments has not so far been confirmed experimentally, although the detection or isolation of the ether (XVIII, $R^3 = H$) after this reaction has been frequently reported.[9,25–27]

The manifestation by dialkyl phosphorochloridites of both nucleophilic and electrophilic properties at different stages of the reaction with aldehydes has been assumed in some investigations:[27,28]



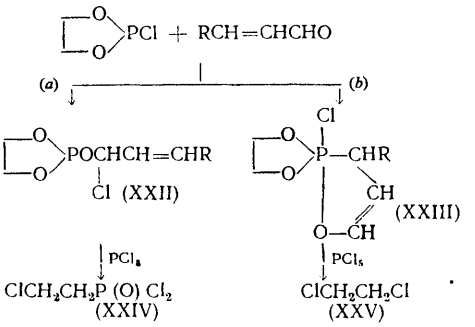
The demonstration of the catalytic effect of the HCl impurity in phosphorus(III) chlorides on the course of the reactions considered is extremely important.[29,30] It was found that phosphorus(III) chloride freed from the HCl impurity by treatment with alkyl vinyl ethers (AVE) does not interact with an aldehyde at 20 °C. The process begins only after the introduction of HCl into the reaction mixture. The catalytic effect of the HCl impurity had been detected previously in the reaction of phosphorus(III) chlorides with alkene oxides,[31,32] carboxylic acids,[33] and acetals.[34,35] The catalytic role of the HCl impurity in phosphorus(III) chlorides in exchange reactions is also emphasised in a recent review.[36] The catalytic role of HCl in the interaction of aldehydes with phosphorus(III) chlorides can be

reflected by a mechanism analogous to that of the reactions of the latter with alkene oxides and acetals:



The nature of the phosphorus(III) chloride can alter radically the mode of its interaction with carbonyl compounds. It has been shown recently that ethyl phosphorodichloridothioate reacts with benzaldehyde and acetone via the P–S bond and not with participation of the P–Cl bond.[37,38]

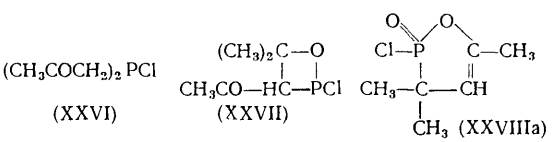
The interaction of phosphorus(III) chlorides with aldehydes containing functional groups as substituents has also been investigated. Thus mercurated acetaldehyde reacts with phosphorus(III) chlorides to form *O*-derivatives, i.e. the reaction takes place with transfer of the reaction centre.[39]



It has been suggested that secondary chlorophosphines exhibit nucleophilic reactivity in their reactions with α-chloroaldehydes and that an adduct having the betaine structure (II) is formed.[2,40,41] In order to obtain the individual compounds (XIX)–(XXI), the R_2PCl + $X_2ClCCHO$ reaction mixture is treated with proton-donating compounds or acetic anhydride.

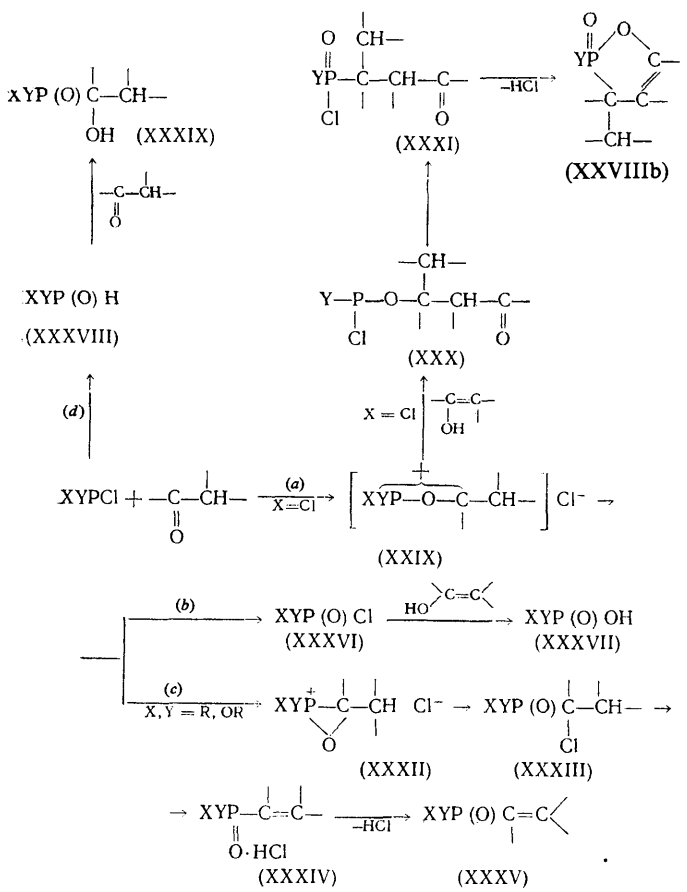
However, one should note that the possibility of the initial interaction of various secondary chlorophosphines with chloroaldehydes has not been confirmed experimentally, while the products (XIX)–(XXI) can be formed as a result of the initial hydrolysis of the chlorophosphines to the corresponding acid and the addition of the latter to the carbonyl group of the aldehyde. A structure analogous to that that of compound (III) has been attributed[42] to the product of the interaction of chloral with 2-chloro-1,3,2-dioxaphospholan, but adequate evidence for this has not been adduced.

2-Chloro-1,3,2-dioxaphospholan reacts vigorously with acroleine and crotonaldehyde to form oligomers (Scheme 3).[43] On the basis of the structure of the products (XXIV) and (XXV) obtained after treating the oligomers with phosphorus pentachloride, the authors concluded that the 1,2-addition of the chloride to the carbonyl group with dissociation of a P–Cl bond mainly takes place, i.e. a chlorine atom at the phosphorus(III) atom is exchanged for a new group [pathway *a*, compound (XXII)]. The partial 1,4-addition of the phosphorus atom to the conjugated system without the rupture of a P–Cl bond and with increase in the coordination number of phosphorus from 3 to 5 has also been postulated [pathway *b*, compound (XXIII)].



Scheme 3

It seems to us that the interaction of phosphorus(III) chlorides with unsaturated aldehydes has still been studied inadequately and that more far reaching studies are necessary to establish the real reaction mechanism.

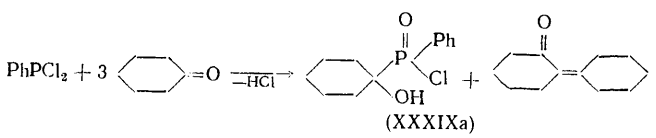


2. Ketones

In the past century, Michaelis[1,2] already established that in the presence of aluminium trichloride PCl_3 and $RPCl_2$ condense with acetone in proportions of 1 : 2. The acyclic structure (XXVI) was attributed initially to the reaction product, which has come to be called "the Michaelis chloride" in the literature. Later the cyclic structure (XXVII) was assigned to it. Much later, in the study of the reactions of phosphorus(III) chlorides with unsaturated ketones, it was possible to show that the product has the structure of 2-chloro-2-oxo-1,2-oxaphospholene (XXVIIIa).[44]

During the last 15 years, it has been found that aliphatic and aliphatic-aromatic ketones react with phosphorus(III) chlorides also in the absence of $AlCl_3$ but on heating. The products of the reactions of PCl_3 and phosphorus(III) dichlorides are derivatives of 1,2-oxaphospholene (XXVIIIb) (Scheme 4, pathway *a*).[13,45–50]

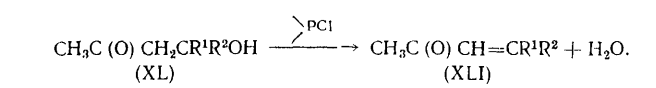
Scheme 4



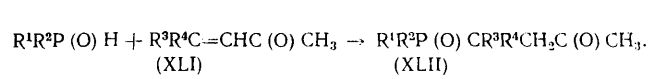
The authors suggest that the primary process is the exchange of a chlorine atom at the electrophilic phosphorus(III) atom (Scheme 4, pathway *a*). The ion pair (XXIX) reacts with the enolic form of the ketone, affording a γ-ketoester chloride of phosphorus or phosphonous acid (XXX), which isomerises to the phosphorus(IV) derivative (XXXI) capable of cyclisation, with elimination of HCl, to the final product (XXVIIIb). If cyclohexanone is used as the ketone, then a polycyclic compound is formed and this too is a substituted 1,2-oxaphospholene.[51]

The formation of the intermediate compound (XXXI) was confirmed by IR spectroscopy and NMR. In the studies indicated, the question of the pathways leading to the transition (XXX) → (XXXI) was not discussed. It is entirely possible that compound (III) decomposes into partial phosphorus acid chloride and an unsaturated ketone, which interact, affording the product (XXXI). HCl probably favours such decomposition.

Chlorodiethyl- and chloroethylphenyl-phosphines and phosphorochlorodites react with ketones,[50–53] including cyclic ketones,[53–56] in proportions of 1:1 to form α-chloroalkyl derivatives of phosphorus(IV) (XXXIII) (Scheme 4, pathways *a* and *c*), which split off HCl on heating or on treatment with a base and are converted into the unsaturated compounds (XXXIV) and (XXXV). It has been noted[53–57] that, in the interaction of secondary chlorophosphines with cyclohexanone, it was possible to detect by NMR the intermediate (XXXII) and to convert it into the more stable tetraphenylborate derivative. In the case of secondary chlorophosphines, the initial nucleophilic attack by the oxygen atom of the carbonyl group on the phosphorus(III) atoms has also been postulated. This entails the formation of the exchange product (XXIX), which is rapidly converted into compound (XXXII). However, one should note that, as for the reactions with aldehydes, there is a possibility that the secondary chlorophosphines may manifest nucleophilic properties, i.e. compound (XXXII) may be formed from the dipolar ion (II).

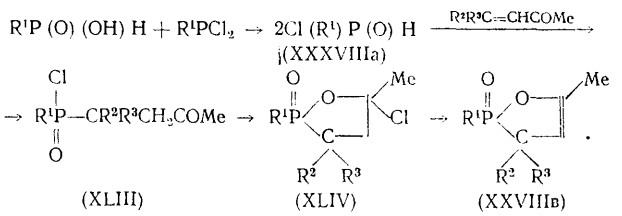


In contrast to other phosphorus(III) chlorides, chlorodiphenylphosphine reacts with acetone via pathway *b* (Scheme 4). When acted upon by the enolic form of the ketone, the acid chloride (XXXVI) is converted into the acid (XXXVII).[57] It reacts with cyclohexanone in an even more complex manner—via the three pathways *b*, *c*, and *d*—and compounds (XXXIII), (XXXVII), and (XXXIX) are isolated from the reaction mixture. The interaction of dichlorophenylphosphine with cyclohexanone also proceeds via pathway *d*. In this reaction, the initial reactants are consumed in proportions of 1:3.[58]



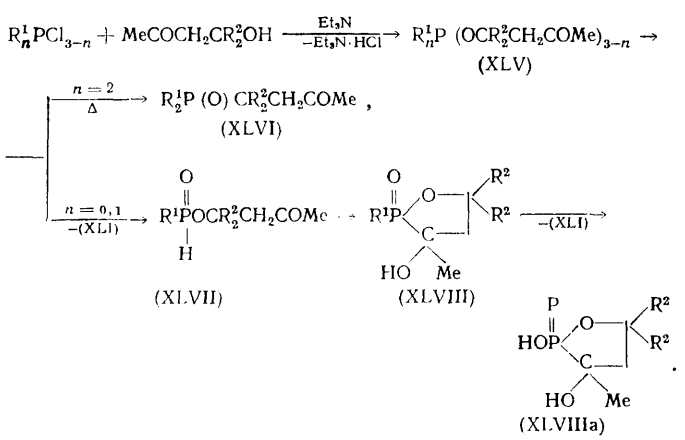
The reactions of cyclopentanone with dichlorophosphines and of cyclohexanone with phenyl phosphorodichloridite and dichloro-*p*-fluorophenylphosphine proceed via pathway *c* and the reaction products are cyclopentenyl and cyclohexenyl derivatives of phosphorus(IV) (XXXV).[13,59,60]

The reactions of phosphorus(III) chlorides with ketones having a second functional group have also been studied. For example, they interact in a fairly complex way with the hydroxyketones (XL). The structure of the final reaction product depends significantly both on the experimental conditions and on the nature of the substituents in the initial reactants. Whether or not triethylamine is present in the reaction mixture is an important factor.



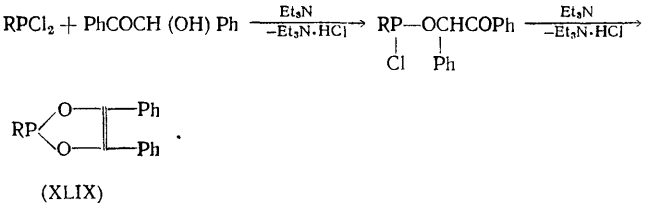
In the absence of a base, all the phosphorus(III) chlorides induce the rapid catalytic decomposition of β-ketoalcohols into αβ-unsaturated ketones (XLI) and water.[61–69]

Further reactions, leading to the final products, are therefore treated within the framework of reactions of unsaturated ketones with phosphorus(III) chlorides in the presence of water. The latter hydrolyses the phosphorus(III) chlorides to the corresponding acids XYPHO (XXXVIII) (X = Y = R, RO, Ar; X = OH, Y = R, RO, Ar; X = Y = OH). Acetic acid acts similarly on phosphorus(III) chlorides,[69,70] but the process is reversible. The acids (XXXVIII) exhibit different reactivities in relation to ketones (XLI); phosphinous acids add to the double bond, forming tertiary phosphine oxides (XLII), while the remaining acids are fairly inert under the conditions of the reaction considered.



Dialkylphosphorous acids can be isolated in a pure form. Alkylphosphorous, phosphonous, and phosphorous acids react readily with phosphorus(III) chlorides, forming chemically extremely reactive partial acid chlorides (XXXVIIIa). The interaction of the latter with ketones (XLI) leads to Δ^4-1,2-oxaphospholenes (XXVIIIc). The formation of the intermediates (XLIII) and (XLIV) was demonstrated not only by spectroscopic methods but also by isolating them, for certain substituents R^1, R^2, and R^3, in a pure form. The claim that the 1,2-oxaphospholene systems are formed as a result of intermolecular and intramolecular nucleophilic substitution at the phosphorus(III) atom[71] in the reactions considered is controversial.

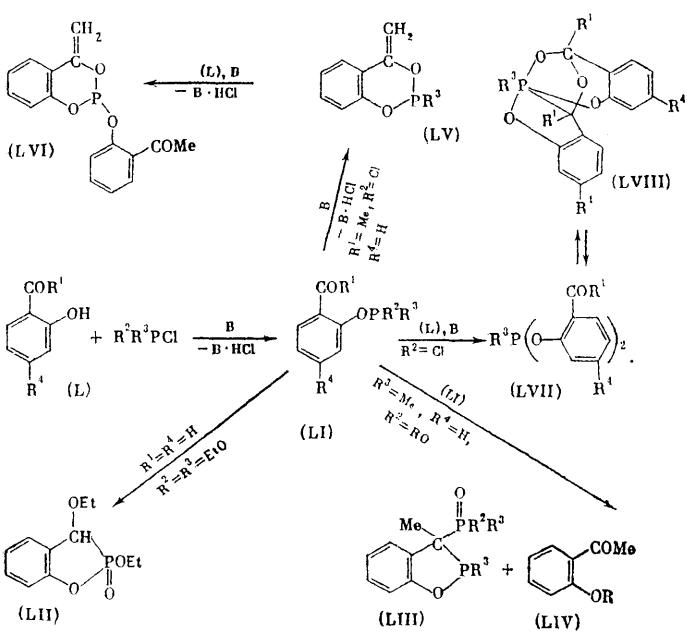
(XLIII) (XLIV) (XXVIIIв)



Without exaggeration, one can now claim that the idea of the chemists of the Kazan School that β-ketoalcohols undergo catalytic decomposition to an unsaturated ketone and water and that the phosphorus(III) chloride interacts initially with water and not with the carbonyl compounds, as well as the idea that the partial acid chlorides (XXXVIIIa) are formed as intermediates were fully confirmed in subsequent studies[70] and constitute a major contribution to the theory of the reactions of phosphorus(III) chlorides with all aldehydes and ketones in the presence of proton-donating compounds, whose investigation was initiated more than a century ago.

In the presence of triethylamine, the character of the reaction of phosphorus(III) chlorides with hydroxyketones is completely different: the primary process involves the hydroxy-group without altering the coordination number of the phosphorus atom.[69,72–78] If the exchange products (XLV) contain only one γ-ketoalkoxy-group, then on heating they rearrange to the phosphorus(IV) derivatives (XLVI);[73,77] if there are two such groups, then an unsaturated ketone is split off and the acid (XLVII) cyclises to the oxaphospholan (XLVIII).[69,72–76,79] If there are three such groups, then yet another ketone (XLI) molecule is eliminated[69] and the oxaphospholanol (XLVIIIa) is formed:

(XLVII) (XLVIII) (XLVIIIa)



The products of the reactions of benzoin with phosphorus(III) di- and tri-chlorides are unsaturated phosphorus(III) derivatives (XLIX) formed as a result of the primary exchange and subsequent cyclisation.[80,81]

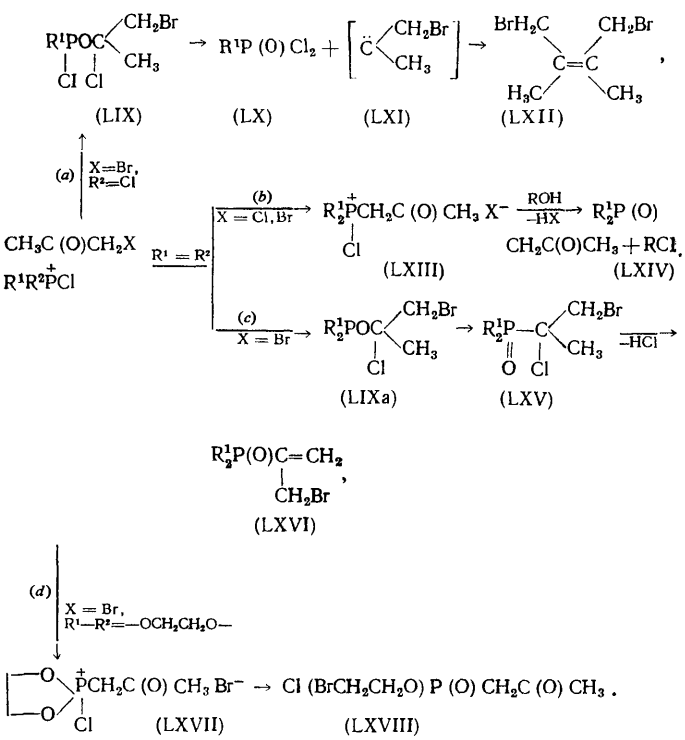
(XLIX)

Phosphorus(III) chlorides interact in a very complex manner with *o*-carbonylphenols (L). The subsequent reactions of the primary products (LI) depend on the nature of the groups R^1, R^2, R^3, and R^4 and the experimental conditions. The products are the most stable in the case of phosphorus(III) monochlorides.[82,83] However, when R^1 = H, heterocyclisation proceeds readily as a result of the attack by the lone pair the phosphorus(III) atom on the carbon atom of the carbonyl group and compound (LII) is formed (Scheme 5).[84]

Scheme 5

Compounds (LIII) and (LIV) are the products of the slow interaction of two (LI, R^1 = Me) molecules. In the presence of a base (B), compound (LI, R^2 = Cl) is converted into the products (LV) and (LVII) as a result of intramolecular (R^3 = RO, Cl)[82,83,85] or intermolecular (R^3 = alkyl, aryl)[82,85–88] nucleophilic substitution. When R^3 = Cl, the product (LV) can enter into an exchange reaction with formation of compound (LVI).[85] Compounds (LVII)

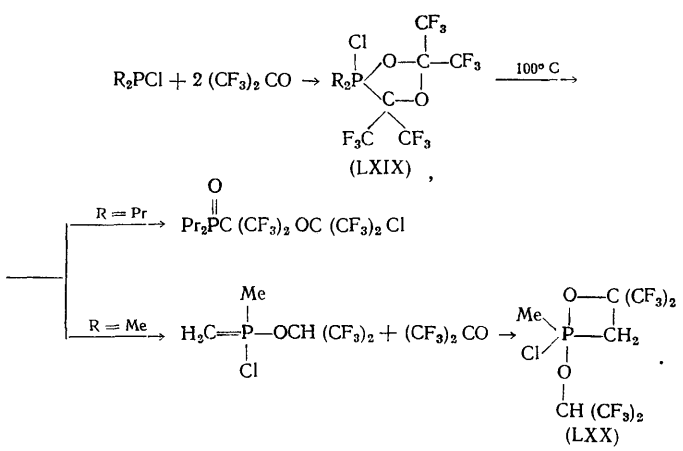
are entirely stable if R^4 is the sterically bulky 2,4,5,6-tetramethylphenyl group or if the electrophilicity of the carbonyl group is reduced (R^1 = OMe).[86] In the absence of these factors, compounds (LVII) are converted into the cyclic phosphoranes (LVIII) as a result of oxidative cyclisation.[85–88] When R^1 = 2,4-$Me_2C_6H_3$ and R^4 = OMe, the phosphorane (LVIII) is in equilibrium with the phosphonous form.[86]



The interaction of salicylaldehyde with PCl_3 under severe conditions (high temperatures) leads to 2,3-dichloro-2-oxo-4,5-benzo-1,2-oxaphospholan.[89,90]

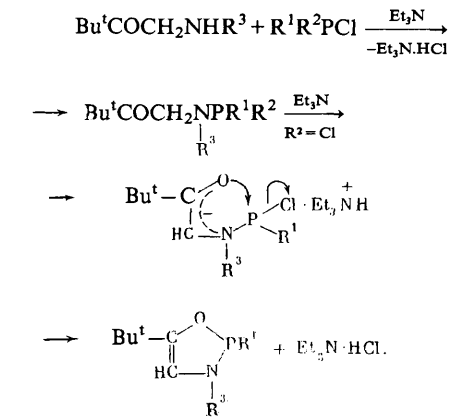
Metal derivatives of ketones react readily with phosphorus(III) chlorides. Thus the latter react with α-mercurated ketones with transfer of the reaction centre and the formation of unsaturated esters.[91]

The influence of the nature of the substituents at the phosphorus(III) on the mode of interaction can be traced in relation to the reactions of phosphorus(III) chlorides with trialkylstannylacetone:[91] PCl_3 and the secondary chlorophosphines react without transfer of the reaction centre, phosphorochloridites and phosphorodichloridites react with transfer of the reaction centre, while phosphonous ester chlorides afford a mixture of *O*- and *C*-phosphorylated products.

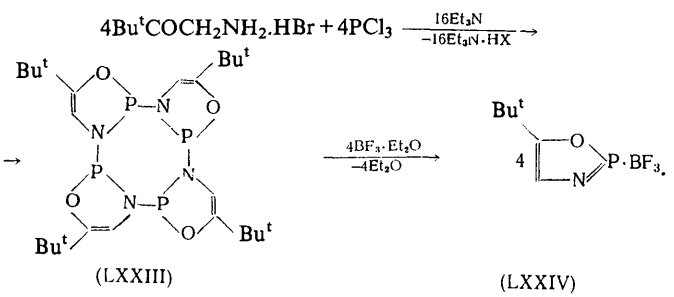


Depending on the nature of the substituents at the phosphorus(III) atom, phosphorus(III) chlorides can interact with α-monohalogenoketones both at the α-carbon atom and at the carbonyl group.[92–95] The reaction of phosphorus(III) dichlorides with bromoacetone results in the formation of phosphorus(IV) dichlorides (LX) and the dibromoalkene (LXII) (Scheme 6).[92] It has been suggested that phosphorus(III) dichlorides exhibit electrophilic properties and that initially a chlorine atom at the phosphorus(III) atom is substituted by a new group [pathway *a*, compound (LIX)]. Compound (LIX) then decomposes at the C–O bond with formation of the dichloride (LX) and the carbene (LXI), which dimerises to the alkene (LXII). Secondary chlorophosphines react with α-halogenoketones via two pathways:[93–95] in the first pathway, phosphorus(III) combines with halogenoacetone (nucleophilic properties) to form the phosphonium salt (LXIII), which can be isolated in a pure form[94] or can be converted into the phosphine oxide (LXIV) on treatment with alcohols,[93,95] water, or acetaldehyde[95] (pathway *b*); in the other pathway, a chlorine atom at the phosphorus(III) atom is substituted by a new group (electrophilic properties) with formation of the intermediate (LIXa), which subsequently isomerises to the phosphorus(IV) derivative (LXV); the latter is dehydrochlorinated, affording the product (LXVI) (Scheme 6, pathway *c*). 2-Chloro-1,3,2-dioxaphospholan (R^1–R^2 = $-OCH_2CH_2O-$) exhibits nucleophilic properties, combining with bromoacetone and affording the quasi-phosphonium salt (LXVII), which is converted into the product (LXVIII) via the Arbuzov reaction.[93]

Scheme 6

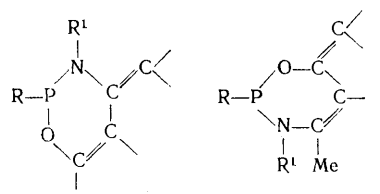


Hexafluoroacetone reacts with secondary chlorophosphines similarly to polyfluoroaldehydes[20] in proportions of 2:1 to form the phosphorane (LXIX) with the 1,2,4-dioxaphospholan ring.[96–98]



Compound (LXIX, R = Pr) undergoes the Arbuzov reaction[96] at 100 °C, while the corresponding compound with R = Me is converted into the cyclic compound (LXX). It is suggested that the reaction proceeds via the intermediate formation of an ylide.[98]

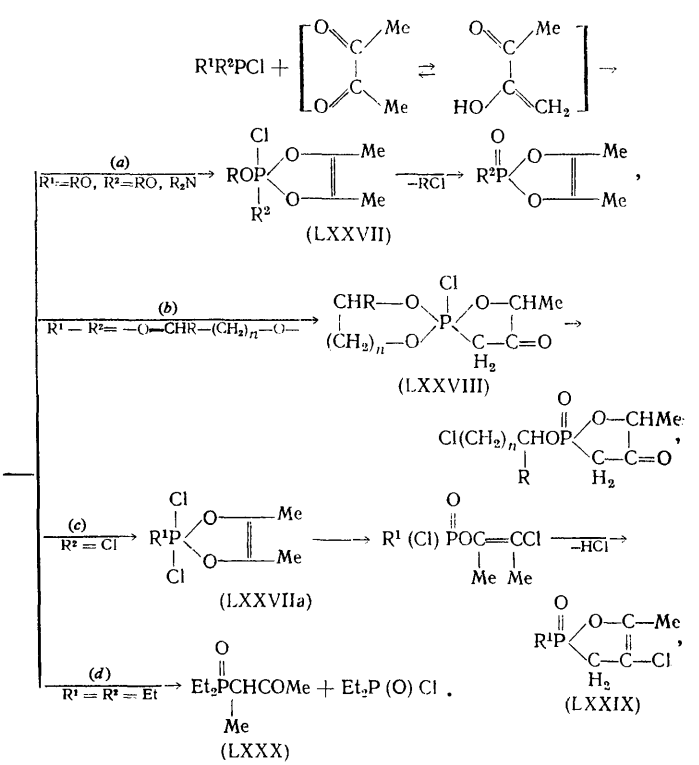
α-(*N*-Alkyl)aminoketones interact with phosphorus(III) chlorides with dissociation of an N–H bond. When there is a chlorine atom at the phosphorus(III) atom, the exchange products (LXXI) readily undergo intermolecular cyclisation to the product (LXXII).[99–104]



The salt of the unsubstituted aminoketone reacts with PCl_3 to produce the complex polycyclic compound (LXXIII) which is converted into a product with a two-coordinated phosphorus atom (LXXIV) on treatment with boron trifluoride etherate. Compound (LXXIV) was identified as a complex with BF_3.[105]

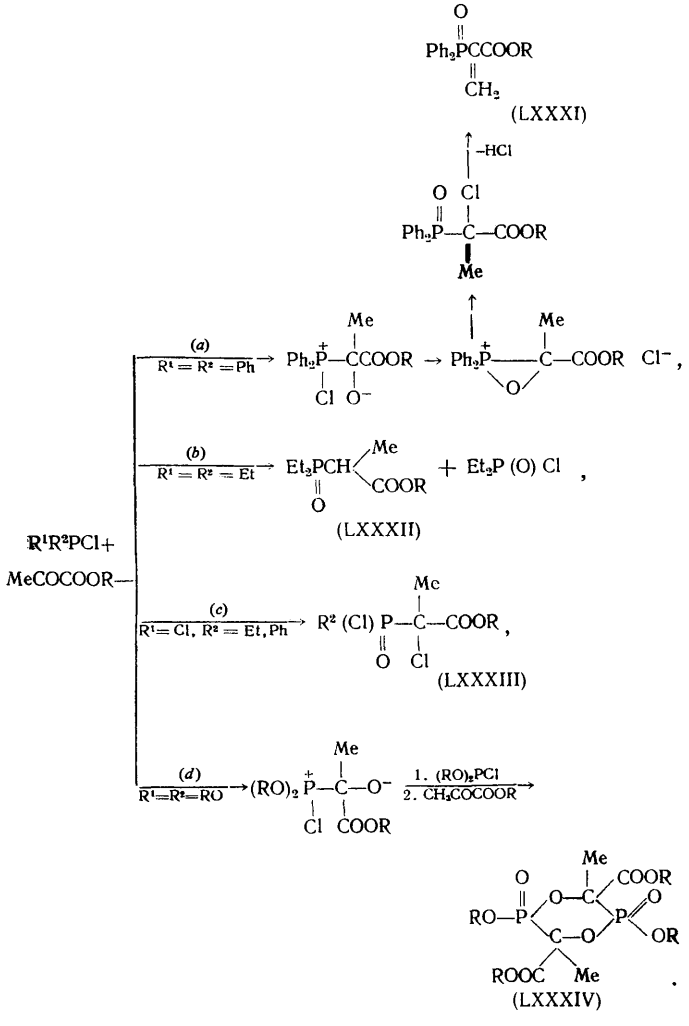
(LXXIII) (LXXIV)

The reactions of phosphorus(III) dichlorides with *N*-monosubstituted enaminoketones lead to 1,3,2-oxazaphosphorinanes with a diene system of C=C bonds [compounds (LXXV)], their exocyclic C=C bond adjoining the nitrogen atom.[106] Their product with the exocyclic C=C bond at the oxygen atom [compound (LXXVI)] has not been detected.



(LXXV) (LXXVI)

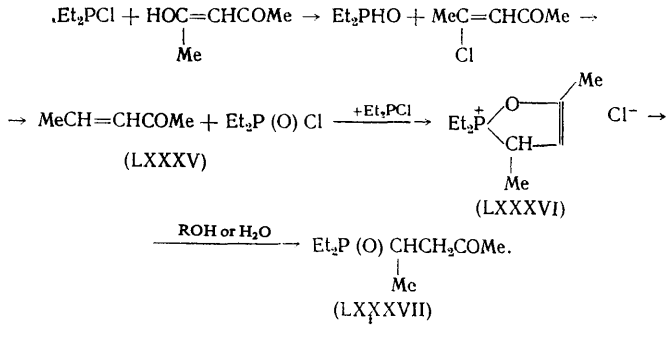
Although phosphorus(III) chlorides react with saturated aminoketones[99–104] and the nitrogen analogues of acetylacetone and acetoacetic ester[107] exclusively at the nitrogen atom, the conclusion that the enaminoketones are initially phosphorylated at the O or N atom must be reached with much caution, since there is a possibility of prototropic interactions between the primary exchange products and also compounds (LXXV) and (LXXVI).



The reactions of phosphorus(III) chlorides with α- and β-dicarbonyl compounds (diacetyl, acetylacetone, and pyruvic and acetoacetic esters) have been investigated. Diacetyl reacts exothermically with all phosphorus(III) chlorides. The structure of the reaction product depends on the nature of the substituents at the phosphorus(III) atoms. It is believed that acyclic phosphoromonochloridites react with the ketone form of diacetyl (Scheme 7, pathway *a*),[108–111] while cyclic phosphorochloridites react with the enolic form (Scheme 7, pathway *b*).[112] The adducts (XXVII) and (XXVIII) are converted into phosphorus(IV) derivatives via the mechanism of the second stage of the Arbuzov reaction. The formation of the phosphorane (XXVII) has been confirmed by ^{31}P NMR.[111] The adduct (XXVIIa) formed in the first stage of the reactions of dichlorophosphines is subsequently converted into the 1,2-oxaphospholene (XXIX), i.e. the reaction proceeds with formation of a new P–C bond (Scheme 7, pathway *c*).[113,114] The reaction of chlorodiethylphosphine with diacetyl produced the tertiary phosphine oxide (XXX) and the chloride of diethylphosphinic acid (Scheme 7, pathway *d*).[115] The authors assumed the possibility of the involvement in the reaction of the enolic form of diacetyl and the formation of diethylphosphinous acid as an intermediate. Although it follows from mechanisms *a*, *b*, and *c* that the phosphorus atom exhibits biphilic properties, there is no unanimous view in the literature about the character of the primary step of the interaction. Whereas the role of phosphoromonochloridites in the primary step of the reaction remains unelucidated,[108–111] the role of nucleophiles is attributed to the more electrophilic primary dichlorophosphines.[113,114] At the same time, the possibility of a donor–acceptor interaction of the oxygen atom of diacetyl with the phosphorus(III) atom of chlorodiethylphosphine[115] (electrophilic properties)—the most nucleophilic of phosphorus(III) chlorides—has been postulated. It follows from the data presented that the role of the phosphorus(III) chloride in the primary step of the interaction has not been clearly defined and that additional studies are necessary in order to throw light on this problem.

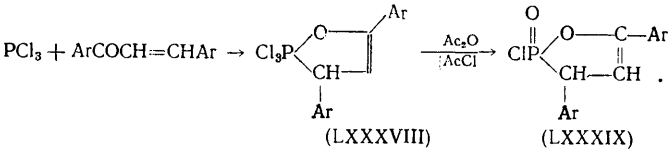
Scheme 7

According to literature data, pyruvate esters react, in contrast to diacetyl, with phosphorus(III) chlorides exclusively in the ketone form and the structure of the reaction products depends significantly on the nature of the substituents at the phosphorus(III) atom. Thus the product of the reaction of chlorodiphenylphosphine (Scheme 8, pathway *a*) is the unsaturated phosphine oxide (LXXXI),[116] while the product of the reaction of chlorodiethylphosphine (Scheme 8, pathway *b*) is the unsaturated phosphine oxide (LXXXII).[115–117]



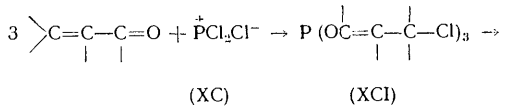
Scheme 8

The reaction of pyruvate esters with primary dichlorophosphines (Scheme 8, pathway *c*) gives rise to the chlorides of phosphinic acids (LXXXIII) with functional-group substituents,[116,118] while their reaction with dialkyl phosphorochloridites (Scheme 8, pathway *d*) affords 2,5-dialkoxy-3,6-dialkoxy-carbonyl-3,6-dimethyl-2,5-dioxo-1,4-dioxa-2,5-diphosphorinanes (LXXXIV).[119]



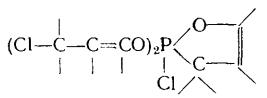
It is believed that in the reactions described, chlorodiphenylphosphine exhibits nucleophilic reactivity,[116] while dialkyl phosphorochloridites exhibit nucleophilic reactivity in the first stage and electrophilic reactivity in the second.[119]

The interaction of chlorodiethylphosphine with acetylacetone in the absence of a base is completed by the formation of the chloride of diethylphosphinic acid and the phosphonium salt (LXXXVI), which is converted into the tertiary phosphine oxide (LXXVII) on treatment with alcohols or water.[57,115] The authors believe that the reaction proceeds with participation of the enolic form of the β-diketone via the intermediate formation of diethylphosphinous acid and the unsaturated ketone (LXXXV). The product of the reaction of the latter with the initial phosphine is the salt (LXXXVI).



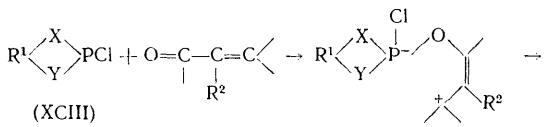
A similar scheme has been postulated also for the reaction of chlorodiethylphosphine with acetoacetic ester.[115]

The study of the reactions of phosphorus(III) chlorides with ketones containing an alkylidene group as a second substituent was initiated by Conant as early as 1917.[1,2] He suggested that the reaction proceeds via the 1,4-addition of phosphorus(III) to the ends of the conjugated system with formation of the phosphorane (LXXXVIII),[120] which is converted into the oxaphospholene derivative of phosphorus(IV) (LXXXIX) on treatment with acetic anhydride.

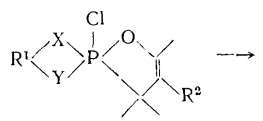


Later Drake and marvel[44] established that the 1,4-addition of PCl_3 to alkyl- and aryl-substituted unsaturated ketones is a general feature although in the study of more complex systems such universality was questioned.[121,122]

In view of the difficulty of alkylating PCl_3 and the results of his own studies of the interaction of this chloride with five- and six-membered cyclic unsaturated ketones, Kabachnik[1] criticised the 1,4-addition mechanism proposed by Conant. He suggested instead a mechanism involving the 1,4-addition of the charged $P^+Cl_2Cl^-$ fragments to the ends of the conjugated system of the ketone, which results in the formation of the γ-chlorinated unsaturated phosphite ester (XCI). The latter is converted via the mechanism of the first stage of the Arbuzov reaction into compound (XCII) with the 1,2-oxaphospholene ring.

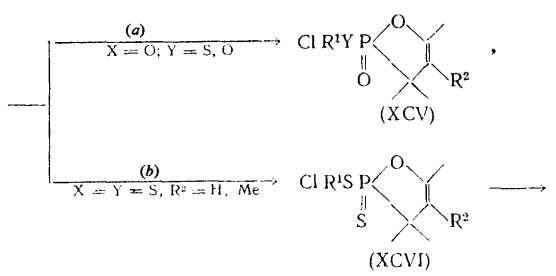


(XC) (XCI)

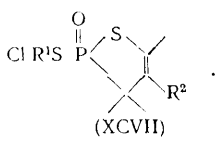


(XCII)

Thus, as for unsubstituted aldehydes, the nucleophilic substitution of a chlorine atom at the electrophilic phosphorus(III) by a new group is postulated. The interaction of PCl_3 with complex ketones such as 4-cholest-3-ynone and 10-methyl-2-oxo-$\Delta^{1,9}$-octalin has been interpreted similarly.[123] However, the manifestation of biphilic properties by phosphorus(III) and its 1,4-addition to the end of the conjugated system of the unsaturated ketones are generally acknowledged.[2,43,124–129]

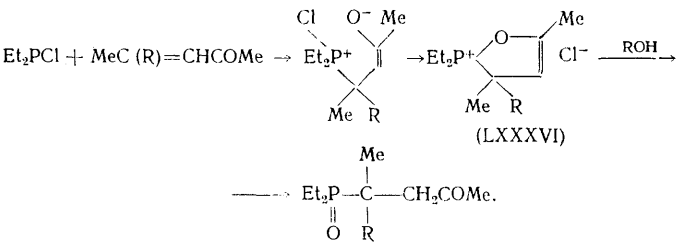


The reactions of unsaturated ketones with cyclic phosphorus(III) halides (XCIII) have been studied in detail. It has been suggested that cyclic phosphorus(III) chloride exhibit electrophilic reactivity in the primary step of the interaction.[128]



(XCIII)

(XCIV)

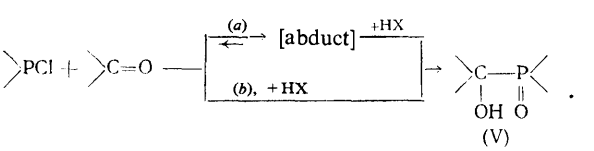


(XCV) (XCVI)

(XCVII)

The 1,4-adduct (XCIV) is stable when R^1 = arylene,[128] whereas in the case where R^1 = alkylene the adduct (XCIV) is converted into compounds (XCV) and (XCVI) via the mechanism of the second stage of the Arbuzov reaction.[2,43,124,125] When R^2 = H, compound (XCVI) isomerises to compound (XCVII) via Pishchimuka's mechanism.[126]

Important results were obtained in a study of the interaction of chlorodiethylphosphine with unsaturated ketones.[57] In this case, the 1,4-adduct was isolated in a pure form and some of its reactions were investigated. On the basis of the chemical shift of the phosphorus atom (126–128 p.p.m.), the structure of the quasi-phosphonium salt (LXXXVI) was attributed to it. Furthermore, chlorodiethylphosphine proved to be more reactive than phosphorus trichloride and phosphorus(III) dichlorides, whence it it possible to conclude that it manifests nucleophilic properties in the primary step of the interaction.

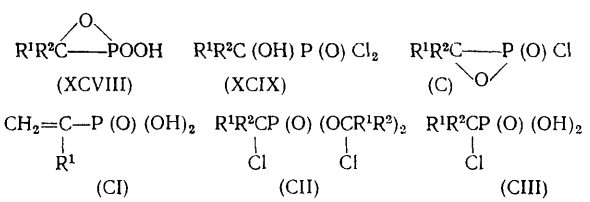


(LXXXVI)

The data described above show that during the last 15–20 years important information has been obtained about the reactions of phosphorus(III) chlorides with carbonyl compounds in the absence of a third reactant: the involvement in the role of the catalyst of the HCl impurity in the phosphorus(III) chloride and the consumption of two aldehyde molecules, in some cases also ketone molecules, for each P–Cl bond were established and new pathways in the reactions of ketones were discovered.

III. The reactions of phosphorus(III) chlorides with carbonyl compounds in the presence of a third reactant

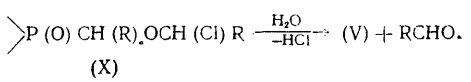
The reactions of phosphorus(III) chlorides with carbonyl compounds in the presence of hydrolysing agents (water, acetic acid, and acetic anhydride with subsequent treatment of the reaction mixture with water) leads to 1-hydroxyalkylphosphonic and 1-hydroxyalkylphosphinic acid (V).[1,2] Under these conditions, it is possible to obtain initially the product of the addition of the phosphorus(III) chloride to the carbonyl compound and it can then be treated by the hydrolysing agent[6,130–132] (pathway *a*) or the initial reactants can be mixed in the presence of water, acetic acid, or acetic anhydride[132] (pathway *b*).



(V)

Approximately 15 years ago, it was assumed that whatever the pathway (*a* or *b*) followed in the synthesis, the mechanism of the formation of compounds (V) is the same: the interaction of the phosphorus(III) chloride with the carbonyl compound leads initially to an adduct, which is then acted upon by the hydrolysing agent.

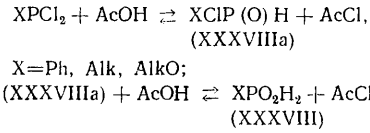
However, the mechanisms of the interaction of these reactants via pathways *a* and *b* are fundamentally different.



We shall deal briefly with the evolution of views on the reaction of phosphorus(III) chlorides with carbonyl compounds involving the subsequent employment of hydrolysing agents (pathway *a*). According to Michaelis, the adduct (I) hydrolyses directly to the acid (V) (see Scheme 1).[4] Conant assumes the intermediate formation of phosphonic acid (XCVIII).[130,131,133] Careful kinetic studies led him to the conclusion that the hydrolysable reactants interact with the dipolar adduct (II).[6] When acetic acid is employed, the acid chlorides (XCIX) and (C) are formed initially and are converted into the acid (V) on treatment with water. The reaction with ketones is complicated by the formation of the unsaturated acids (CI).[130,132] The mechanism of the interaction of phosphorus(III) chlorides with unsaturated ketones is treated similarly.[6,120,130,131,133]

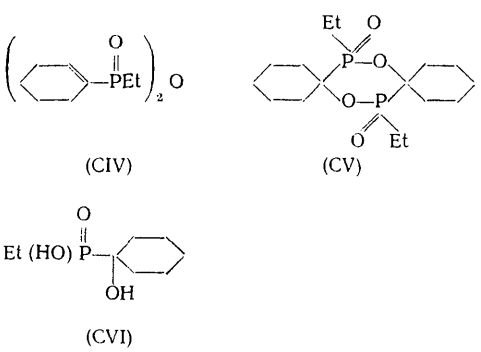
(XCVIII) (XCIX) (C) (CI) (CII) (CIII)

According to the ideas of Page[7] and Kabachnik,[1] the primary product (III) containing phosphorus(III) isomerises to compound (CII), which subsequently hydrolyses to the acids (CIII) and (CV). In later investigations, Kabachnik[90,134] rejected the possibility of the transition (CIII) → (V) under mild conditions.



At the present time, the views described above on the reaction pathway *a* are apparently of only historical value. In reality, 1-(1-chloroalkoxy)alkyl derivatives of phosphorus(IV) (X) are formed initially and are subsequently hydrolysed to the acid (V).

(X)

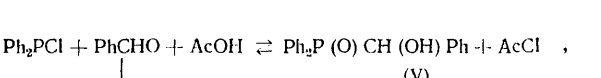


Ketones, which are less reactive than aldehydes, react sluggishly with phosphorus(III) chlorides under mild conditions: in the course of 20–40 h at room temperature.[56,57] Therefore, even if the hydrolysing agent is added to the mixture of phosphorus(III) chloride and the ketone several hours after they have been mixed, pathway *a* hardly makes a decisive contribution to the overall reaction mechanism. Furthermore, in contrast to aldehydes, the interaction of phosphorus(III) chlorides with ketones leads to the formation of different organophosphorus compounds depending on the structure of the ketones: (XXXIII), (XXXV), (XXXVII), and (XXXIX) (Scheme 4), which are entirely stable in relation to hydrolysing agents. On the other hand, in the presence of the latter, the reaction is very rapid (pathway *b*) with formation of compounds (XXXIX) in high yields. Hence it follows that in the case of ketones the adducts (I) and (II) and compound (CII) are not the direct objects of the action of hydrolysing agents.

Mainly as a result of the work of Soviet chemists, it can now be regarded as demonstrated that pathway *b* involves the primary interaction of phosphorus(III) chlorides with the hydrolysing agent and the intermediate formation of hydrophosphoryl compounds (XXXVIII) [in particular, the extremely reactive partial chlorides of phosphonous and phosphorous acids (XXXVIIIa)].[59,61–64,69,70,135–150] When carboxylic acids are used as hydrolysing agents,[70,142] the phosphorus(III) chloride is initially converted into the partial acid chloride (XXXVIIIa), which is capable of hydrolysing further to the acid (XXXVIII). The latter interacts both with the initial phosphorus(III) chloride and with the acyl chloride to form compound (XXXVIIIa). When water is used, the reactions are irreversible.

(XXXVIIIa) (XXXVIII)

Carbonyl compounds constitute a kind of trap for active hydrophosphoryl compounds, especially the partial acid chlorides (XXXVIIIa). Cyclohexanone proved to be the most successful carbonyl compound, which made it possible to isolate the product (XXXIXa) in a pure form as a result of its direct interaction with compound (XXXVIIIa, X = Ph).[58,59,139,140] When Ph is replaced by Et in compound (XXXIXa), its stability falls and after the removal of the solvent only the organophosphorus compounds (CIV)–(CVI) are produced.[140,145]



(CIV) (CV) (CVI)

It has been shown recently that compounds (XXXIX) change after a time, being converted into the acid (CIII) containing a 1-chloroalkyl group.[151–153]

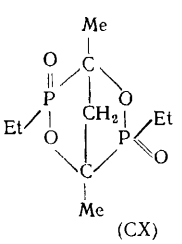
(XXXIX) (CIII)

There are also literature data showing that even compounds without a labile P–Cl bond may be modified, for example, compound (V). Thus Miller and Stewart,[154] who repeated Conant's experiments on the interaction of chlorodiphenylphosphine with benzaldehyde in the presence of acetic acid, established that the expected product (V) is initially formed rapidly (5 min) but after three days the final reaction product is not compound (V) but the acetate (CVII) and the diphosphorylated ester (XII):

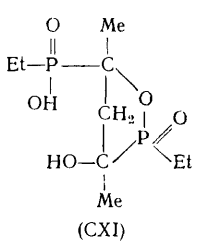
(V) (CVII) (XII)

The substance characterised by Conant as compound (V)[135] turned out to be the ester (XII).

The reaction of aryldichlorophosphines with ketones in the presence of monothioacetic acid takes place in a somewhat unusual manner:[155] instead of the expected 1-hydroxyalkylphosphinomonothioic acids, 1-mercaptoalkylphosphinic acids (CVIII) are obtained. Since the coordination number of phosphorus remains unaltered in the initial stage of the reaction, the following reaction mechanism has been proposed:

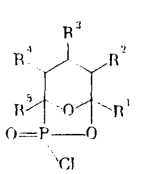


$$PhPCl_2 + CH_3COSH \xrightarrow{HCl} PhP(Cl)SCOCH_3 \xrightarrow{R^1R^2C=O} \rightarrow R^1R^2C(Cl)P(O)(SCOCH_3)Ph \xrightarrow{H_2O} R^1R^2C(SH)P(O)(OH)Ph.$$
(CVIII)

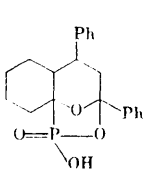


The interaction of phosphorus(III) chlorides with aldehydes and ketones in the presence of mercaptans is a new convenient method of synthesis of α-alkylthioalkylphosphonates and the corresponding phosphinates (CIX).[156]

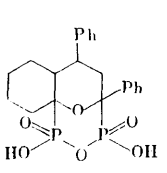
$$R^1R^2PCl + R^3R^4C=O + R^5SH \xrightarrow{-HCl} R^1R^2P(O)CR^3R^4(SR^5).$$
(CIX)



The reactions of phosphorus(III) chlorides with unsaturated ketones in the presence of hydrolysing agents also includes a stage involving the formation of hydrophosphoryl compounds (XXXVIII).[69,157] If hydrogen sulphide is used instead of acetic acid or water, products with the thiophosphoryl group are obtained.[158]



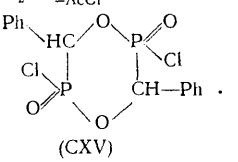
The reactions of diketones with phosphorus(III) chlorides in the presence of acetic acid have also been investigated.[159–163] The reaction of chloroethylphosphine and actylacetone leads to the formation of the bicyclic diphosphorus compound (CX), which hydrolyses very readily to the monocyclic derivative of 2-oxa-1,2-oxaphospholan (CXI).[159]



(CX)

(CXI)

Monophosphorylated [compounds (CXII) and (CXIII)] and diphosphorylated [compound (CXIV)] derivatives of tetrahydropyran are formed from PCl_5 and 1,5-diketones:[160–163]



(CXII)

(CXIII)

(CXIV)

A hydrolysing agent, can also be used in the synthesis of polyfunctional organophosphorus compounds from a phosphorus(III) chloride, a carbonyl compound, and a dialkylamine[164,165] or the amides of carboxylic and carbonic acids.[166–176] It is suggested that the reactions proceed via a stage involving the formation of hydrophosphoryl compounds.[172]

New data have also been obtained in the study of the reactions of phosphorus(III) chlorides with aldehydes in the presence of acetic anhydride.[8,177] The authors were able to isolate the cyclic product (CXV), which is assumed to be a precursor of compound (V), obtained by the hydrolysis of the adduct of the aldehyde with the phosphorus(III) chloride. A mechanism including the initial interaction of PCl_3 with the aldehyde was postulated initially:[8]

$$PhCHO + PCl_3 \rightleftarrows PhCH(Cl)OPCl_2 \xrightarrow[-AcCl]{Ac_2O} \rightarrow PhCH(OCOCH_3)P(O)Cl_2 \xrightarrow{-AcCl}$$

(CXV)

This mechanism is incorrect, because, as shown above (see Section II), not one but two aldehyde molecules should be consumed per P–Cl bond.[16–18,22–24] It was later established that aldehydes react initially with acetic anhydride to form the diacetate (CXVI), PCl_3 functioning as the process catalyst.[177,178] The subsequent reaction of the diacetate with PCl_3 leads to compound (CXV). It was obtained by unambiguous synthesis from compound (CXVI) and PCl_3 and also from compounds (XVII) and (CXVII):

$$PhCHO + Ac_2O \xrightarrow{PCl_3} \underset{(CXVI)}{PhCH(OAc)_2} \xrightarrow{PCl_3} \underset{(CXVII)}{PhCH(OAc)Cl} + AcOPCl_2 \rightarrow$$
$$\rightarrow \underset{(XVII)}{(POCl)_n} + AcCl + (CXVII) \rightarrow (CXV).$$

However, not everything is clear in this mechanism. The structure of the product (XVII) has not been established and it has not been shown what are the essential features of the catalysis and whether or not compound (XVII) does really react on treatment with compound (CXVII) in accordance with the mechanism of the Arbuzov reaction (since α-chloroalkyl carboxylate esters are weak electrophiles). The mechanism of the interaction of phosphorus(III) chlorides with ketones, including unsaturated ketones, in the presence of acetic anhydride has not been finally elucidated, although in the case of unsaturated ketones we have an important general method of synthesis of compounds with the 1,2-oxaphospholene ring[2,179–183] and the latter can be used to synthesise ketoalkyl esters of phosphorus acids.[2,184–187]

The procedure in which the reactions of phosphorus(III) chlorides with carbonyl compounds are carried out in the presence of phosphorus(III) acid esters proved to be fruitful.[40] Such reactions were first achieved by Birum.[188] Organic compounds containing several phosphorus atoms different coordination numbers have been obtained by this procedure. It is believed that the phosphorus(III) acid ester initially adds to the carbon atom of the carbonyl group with formation of the dipolar ion (CXVIII),[40] whose interaction with the phosphorus(III) chloride leads to the polyfunctional compounds (CXIX):

$$(3-n)\ R^1R^2POR^3 + (3-n)\ R^4R^5C{=}O \rightarrow (3-n)\ R^1R^2\overset{+}{P}(OR^3)-\underset{R^5}{\overset{R^4}{C}}-O^- \xrightarrow{+R^6_nPCl_{(3-n)}} \rightarrow$$

(CXVIII)

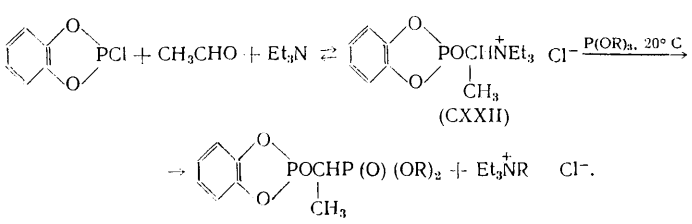
$$\rightarrow R^6_nP\,[OCR^4R^5P\,(O)\,R^1R^2]_{3-n} + (3-n)\ R^3Cl.$$

(CXIX)

In recent years, these reactions were used to obtain acetals containing two phosphorus atoms with different coordination numbers[189,190] and the monophosphorylated [compound (CXX)] and diphosphorylated [compound (CXXI)] alkyl phosphorodichloridites:[191,192]

$$R^1CHO + P\,(OR^2)_3 + PCl_3 \rightarrow (R^2O)_2\,P\,(O)\,CHR^1OPCl_2 + R^2Cl,$$

(CXX)



$$(R^1O)_2\,P\,(O)\,COCH_3 + P\,(OR^2)_3 + PCl_3 \rightarrow (R^1O)_2P(O)-\underset{O{=}P\,(OR^2)_2}{\overset{O\quad CH_3}{\overset{\|\quad|}{C}}}-OPCl_2 + R^2Cl.$$

(CXXI)

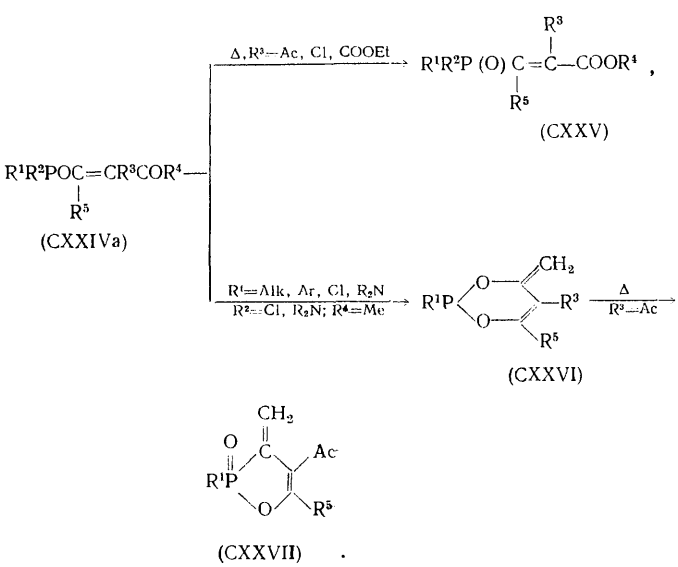
The replacement of trialkyl phosphites in this process by their thioanalogues alters fundamentally the character of the reaction:[193]

$$(R^1S)_3\,P + R^2R^3C{=}O + PCl_3 \rightarrow Cl_2P\,(O)\,\underset{SR^1}{CR^2R^3}.$$

Fairly numerous studies have been devoted to the reactions of phosphorus(III) chlorides with carbonyl compounds in the presence of triethylamine in order to synthesise unsaturated organophosphorus compounds. The synthesis of vinyl esters of phosphorus(III) acids by the reaction of *o*-phenylene and ethylene phosphorochloridites with acetaldehyde in the presence of triethylamine was reported as early as 1957.[194] The salt (CXXII) is formed initially in these reactions, its vacuum heat treatment affording the vinyl ester. However, further study of this reaction showed that, under conditions described in the above study,[194] the salt (CXXII) decomposes into the initial compounds, *o*-phenylene phosphorochloridite being isolated in a satisfactory yield. In the presence of trialkyl phosphite, the salt (CXXII) decomposes under mild conditions with formation of compounds (CXXIII) containing two phosphorus atoms:[29]

(CXXII)

(CXXIII)



It has been established that electron-accepting substituents at the phosphorus(III) atom and the α-carbon atom of the ketone favour reactions involving the formation of a wide variety of unsaturated organophosphorus compounds (CXXIV):[81,82,91,100,195–224]

$$R_nPCl_{3-n} + (3-n)\ O{=}CCHYZ \xrightarrow[-(3-n)Et_3N\cdot HCl]{(3-n)Et_3N} R_nP\,(OC{=}CYZ)_{3-n}.$$

(CXXIV)

Base catalysis apparently operates in this instance and the intermediates are triethylammonium enolates. This has been confirmed indirectly by the interaction of both phosphorus(III) and phosphorus(IV) chlorides with ketones exhibiting an enhanced CH acidity under comparable conditions. For comparison, one should note that, depending on the structure of the ketone and the nature of the substituents at the phosphorus(III) atom and the solvent, sodium enolates give rise not only to unsaturated compounds but also to *C*-phosphorylated derivatives as well as *OC*-diphosphorus compounds.[225–228]

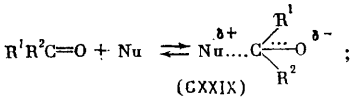
In the case of β-dicarbonyl compounds, the substitution products (CXXVIa) can be isolated in a pure form,[82,210–219,222] while in the presence of a base many of them are converted into the cyclic derivatives (CXXVI).[80,206–212,215,216] On heating, compounds (CXXIVa) and (CXXVI, R^3 = Ac) undergo the vinyl phosphite–vinyl phosphonate rearrangement with formation of compounds (CXXV) and (CXXVII):[214,215,218,223]

(CXXV)

(CXXIVa)

(CXXVI)

(CXXVII)

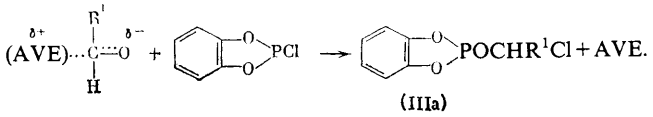


In the case of thiocyanatoacetone, the substitution product (CXXIVb) cyclises to 1,3,2-oxathiaphospholene (CXXVIII) with elimination of propionitrile:[209]

$$(EtO)_2\,POC{=}CHSCN \rightarrow \underset{O}{\overset{S}{\square}}P\,(O)\,OEt + EtCN.$$

(CXXIVb) (CXXVIII)

Important results have been obtained using as the third reactant an alkyl vinyl ether (AVE), which is a weaker nucleophile than trialkyl phosphites and triethylamine. The latter activate the carbonyl compound and enter unchanged into the composition of the final products (CXXII) and (CXXIII), forming a new C–E bond (E = P, N).[188,194] In contrast to them, alkyl vinyl ethers



activate only the carbonyl group in aldehydes, without forming a new C–C bond and do not enter into the composition of the reaction product.[29,30,229] The fact that all the nucleophiles enumerated block the carbon atom of the carbonyl group as a result of the formation of the donor–acceptor complex (CXXIX) and hence also the carbonium ion centre in the intermediate adduct (XIV) is also an important feature. This is apparently in fact the cause of the consumption of only one molecule of the carbonyl compound per P–Cl bond in the presence of these nucleophiles.

(CXXIX)

Nu = $P(OR)_3$, Et_3N, AVE.

Only by creating special conditions has it been possible to achieve the synthesis of one of the representatives of the primary adducts of phosphorus(III) chlorides with aldehydes (IIIa),[29,30,229–231] the possibility of the formation of which had been predicted at an early stage by Page[7] and then by Kabachnik[1] and Atherton.[8]

(IIIa)

In the absence of an alkyl vinyl ether, the product (IIIa) decomposes slowly into the initial compounds, the latter forming an adduct in proportions of 1 : 2.

IV. Conclusion

The main conclusion arising from the data described is that, in the case of PCl_3 and phosphorus(III) dichlorides, the primary process in the interaction with carbonyl compounds can be characterised as catalytic nucleophilic substitution at the electrophilic phosphorus(III) atom, the admixture of HCl in the phosphorus(III) chlorides playing the role of the catalyst under these conditions. In various secondary processes, the coordination number of phosphorus rises to 4. Depending on the nature of the carbonyl compound, the roles of both a nucleophile and an electrophile are attributed to secondary chlorophosphines and phosphorochloridites. However, additional studies are required for a more correct solution of this problem.

Ketones are less reactive than aldehydes, but their reactions with phosphorus(III) chlorides are more varied. More far reaching studies are required to establish the true nature of the processes leading to specific compounds. In the presence of a secondary functional group in the ketone, the more reactive group reacts with the phosphorus(III) chloride and subsequently the primary product participates in various intramolecular and intermolecular interactions with formation of important polyfunctional organophosphorus compounds. The reactions of phosphorus(III) chlorides with aldehydes and ketones in the presence of hydrolysing agents are characterised by the conversion of phosphorus(III) chlorides into hydrophosphoryl compounds and the addition of the latter to the carbonyl group. Tertiary amines, trialkyl phosphites, and alkyl vinyl ethers, used as the third reactant, do not increase the coordination number of the phosphorus atom linked initially to the chlorine atom. Depending on the structure of the carbonyl compound, base or nucleophilic catalysis operates. An alkyl vinyl ether makes it possible to synthesise the primary products of the interaction of phosphorus(III) chlorides with aldehydes in proportions of 1 : 1. The question of the synthesis of intermediates with phosphorus(III) and two aldehyde fragments per P–Cl bonds still remains open.

A satisfactory answer cannot be found in the literature for all the questions raised. In view of both the theoretical importance of these reactions and their importance in the development of preparative syntheses of organophosphorus compounds with functional group substituents, there has been an increasing growth of interest in these processes. The present review surveys the advances in the development of this field and is also designed to draw the attention of investigators to a number of problems which are still unsolved.

The azinyl–azinylidene tautomerism of azinylmethanes and general problems of the tautomerism of azines

V V Lapachev, O P Petrenko, V P Mamaev (deceased)
Novosibirsk Institute of Organic Chemistry, Siberian Division of the USSR Academy of Sciences

ABSTRACT. The results of studies on the tautomerism of azinylmethanes are surveyed. The terminology, the structure of the tautomeric forms, the thermodynamics and mechanisms of their interconversion, the dependence of the equilibrium on structure factors and the character of the medium, and certain general characteristic features of tautomeric equilibria of the azinyl–azinylidene type are discussed.

The bibliography includes 127 references.

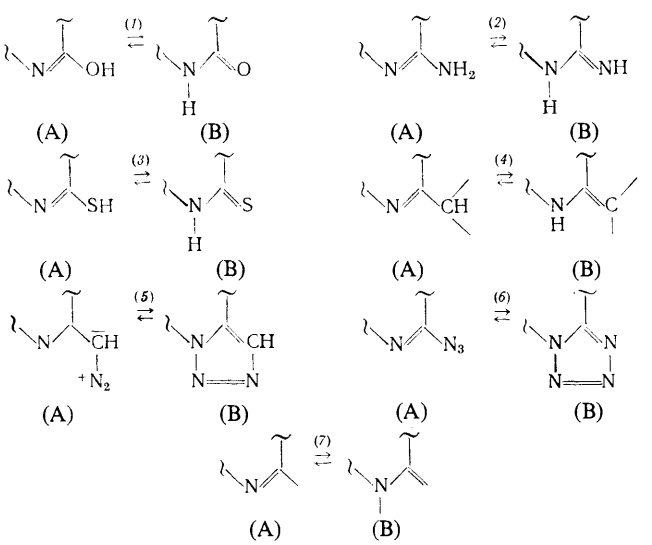
I. Introduction

The tautomerism of organic compounds is an important branch of organic chemistry with an interesting history and tradition, the interest in which has been sustained also in recent years.[1–3] It is possible to differentiate three main problems which have stimulated the interest in tautomerism.

1. The dependence of the structure and physical properties of the compounds on their tautomeric composition
2. The inter-relation between tautomerism and reactivity.
3. The search for and construction of tautomeric molecules with properties of practical importance (photochromic systems, models of enzyme active centres, rearranging molecules).

Since prototropism is as a rule associated with the heteroatomic groups OH, NH, SH, etc., it is not surprising that tautomeric equilibria are encountered particularly frequently in heterocyclic compounds. The structure and physical and chemical properties of the latter are frequently difficult to understand if their tautomeric characteristics have not been elucidated. It is not fortuitous that virtually every chapter in modern monographs on the chemistry of heterocyclic compounds (see, for example, Barton and Ollis[4]), devoted to a particular class of heterocyclic compounds, includes also a section on tautomerism. The tautomerism of azine derivatives† (Scheme 1), whose fundamental character has been emphasised in an extensive monograph[3] in connection with the study of the structure of DNA, is especially important. The tautomerism of azines has also been discussed in connection with the problem of enzyme catalysis,[6] in the study of the reactivity on internal factors and medium effects,[7] etc.



Scheme 1 presents the principal types of tautomeric equilibria observed in the series of azine derivatives as a function of the character of the exocyclic fragment undergoing tautomerism. Among equilibria of types (*1*)–(*6*), the tautomerisms of hydroxyazines [equilibrium (*1*)] and aminoazines [equilibrium (*2*)] have been most completely studied, which is to a significant extent due to their biochemical importance. An important difference of the tautomeric equilibria of azinylmethanes consists in the fact that the rate of dissociation of the CH bond is significantly lower than those of the OH, NH, or SH bonds. This increases the lifetime of the tautomers and makes it possible to use the NMR method effectively. Its application to equilibria (*1*)–(*3*) is hindered by the proton exchange, which is rapid on the NMR time scale. Thus, apart from their independent interest, azinylmethane derivatives can also serve as key models for the search for and formulation of general characteristics of the tautomerism of the azinyl–azinylidene type: (A) ⇄ (B).

The tautomerism of substituted methylazines[4] has not so far been the subject of a special review. Admittedly there exists a monograph[3] in which the literature up to 1975 is presented, but the very character of the monograph precluded a detailed treatment of the analysis of such tautomeric molecules. Furthermore, during the

† There is some uncertainty as to which compounds should be classified as azines. If a formal standpoint and nomenclature are adopted as a basis, then the group of azines will include, together with diazines, triazines, and tetrazines, also, for example, thiazines but not pyridine (see, for example, the Chemical Encyclopaedic Dictionary).[5] On the other hand, from a non-formal point of view, pyridine is in many respects closer to diazines and triazines than are oxazines or thiazines. Bearing in mind the chemical similarity, there is a genuine need for differentiating the group of six-membered heteroatomic compounds—benzene analogues where one of several –CH= groups have been replaced by a nitrogen atom –N=. It would be useful to adopt firmly the term "azines" for this particular group of compounds. We may note that in a recent fundamental publication[4] the section on azines included pyridine and its analogues but did not deal with nitrogen-containing cyclic compounds with oxygen, sulphur, etc.

last ten years numerous important data on the tautomerism of substituted methylazines have been published. The present review deals with studies on the prototropic tautomerism of azinylmethanes (up to 1988) as well as certain general features characteristic of both the tautomerism of azinylmethanes and and azinyl-azinylidene tautomerism as a whole. We endeavoured to restrict the treatment to derivatives based on the aromatic ring of azines or their condensed benzo-analogues. We shall not discuss in detail in this review the relation between tautomerism and reactivity, although important studies in this field have been published recently.[7,8] Nevertheless, it is essential to emphasise the methodological relation between the study of tautomeric and chemical properties in relation to a class of potentially tautomeric compounds such as azinylmethanes, hydroxyazines, etc. A series of studies have been published[9] on tautomerism and dual reactivity, where it was shown that the phenomenon of dual reactivity is extremely general and is by no means always caused by tautomerism. This conclusion concerning the dual reactivity of tautomeric molecules is frequently treated too broadly and is applied to their reactivity as a whole. Nevertheless, if the class of compounds considered from the standpoint of chemical behaviour exhibits also a tautomeric property, its far-reaching characterisation is impossible without considering such properties. Just as the study of the structure of a chemical compound precedes a complete understanding of its chemical properties, so does the study of the tautomeric structure constitute a necessary basis (stage) for the understanding of the reactivity of compounds exhibiting tautomeric properties.[1]

Scheme 1

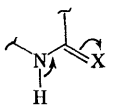
For tautomers whose stabilities are close, the relation between the composition of the reaction products in the tautomeric equilibrium is determined by the familiar Curtin–Hammett principle.[2,10] For slow (relative to the reaction rates) tautomeric interconversions, the composition of the product is predetermined by the tautomeric equilibrium constant K_T. For "fast" reactions, no direct relation between the structure of the tautomers and the composition of the reaction products may be observed. Nevertheless, in these cases too it is necessary to understand the tautomeric characteristics if only to be able to elucidate which of the tautomeric forms is responsible for the formation of the products.

It is likewise noteworthy that the range of energies corresponding to the contents of the tautomers being compared is very narrow ($\Delta G \simeq 0-5$ kcal mol^{-1}) and the chemist frequently deals with potentially tautomeric compounds existing almost wholly in one form or another. Although in this case one may speak of the absence of tautomerism, nevertheless the study of such systems is undoubtedly essential in the investigation of tautomerism from general standpoints. The specific properties of individual tautomers whose reactivities, generally speaking, differ radically can be most fully manifested under these conditions. In the case of a marked difference between the chemical properties of the tautomers, the specific fixation or displacement of the equilibrium to one side or another (for example with the aid of methylation, by means of structural factors, medium effects, complex formation, and irradiation) can be one of the ways of regulating the reactivity of compounds.

Thus the knowledge of the tautomeric properties of compounds not only helps to explain and predict their chemical properties but also provides a possibility for regulating them.

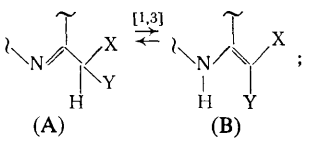
The main types of tautomeric interconversions (*1*)–(*6*) in series of azines (Scheme 1) can be combined on the basis of the characteristic rearrangement of bonds [equilibrium (*7*)]. The two principal features of this rearrangement are the change in the hybridisation of the nitrogen atom from the "pyridine" type to the "pyrrole" type ("amide" type) and the change in the multiplicity of the exocyclic bond involved in the tautomeric transformation.

In the classification of equilibria of types (*1*)–(*6*), one usually adopts as a basis the structure of the exocyclic group, for example, the "hydroxy–oxo" tautomerism of hydroxyazines (1), the thiol–tautomerism of mercaptoazines (2), etc. In those cases where it is necessary to differentiate the general features of a family of equilibria, it is also logical to base the treatment on the structural characteristics of the azine component of the molecule, treating it as a substituent in relation to the exocyclic fragment. Using the IUPAC nomenclature for naming the azine groups, we shall if necessary refer henceforth to equilibria of type (A) ⇄ (B) as pyridyl–pyridylidene and pyrimidyl–pyrimidylidene tautomerisms or in the general case the azinyl–azinylidene tautomerism (which can be shortened to azinyl–ylidene or azaheteroaryl–ylidene tautomerism). The names proposed above can be applied not only to the sigmatropic tautomerism[11] of type (*1*)–(*4*), associated with the migration of a proton, but also to the tautomerism of the electrocyclic type [equilibria (*5*) and (*6*)], where the topology of the change in the bonds also satisfies the conditions mentioned above. Within this family, it is useful to employ the general classification of tautomeric processes.[11] Almost all the processes examined below are [1,*j*]sigmatropic rearrangements where it is possible to identify an atom or group whose position is altered ("migrant") and the remainder of the molecule ("skeleton").[12]



For heterocyclic molecules, synchronous or multistage processes with participation of two (or more) migrating groups are common.[2,3,13] The term "diotropic transformations" proposed previously[14] appears inadequate in this instance, because it is firmly related to the type of mechanism of the interconversion. Potentially tautomeric molecular systems with two and more migrating groups can be more conveniently classified as di-(tri-, etc.)sigmatropic systems, while the corresponding type of equilibria, where the different forms differ by the positions of two migrating groups, can be referred to as disigmatropic equilibria.[15]

In view of the lack of firm boundaries between the phenomena of tautomerism and isomerism, there should exist some consistency in

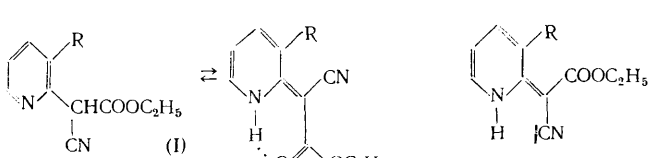


the terminology employed. Thus, taking into account the analogy of the pairs of terms "isomerism"—"isomerisation" and "tautomerism"—"tautomerisation" (the latter expression will be used to designate the tautomeric rearrangement (A) ⇄ (B) (but not the equilibrium).

II. The [1,3]sigmatropic tautomerism of azinylmethanes

The tautomeric equilibrium of unsubstituted azinylmethanes (A) ⇄ (B) is fully displaced to form (A). Judging from experimental data, the relative capacity of substituted azines for transition to form (B) increases in the series of exocyclic groups CH < NH < OH, which apparently reflects the stabilisation which arises when the endocyclic NH group is conjugated with the C=C, C=N, and C=O fragments respectively:[16]

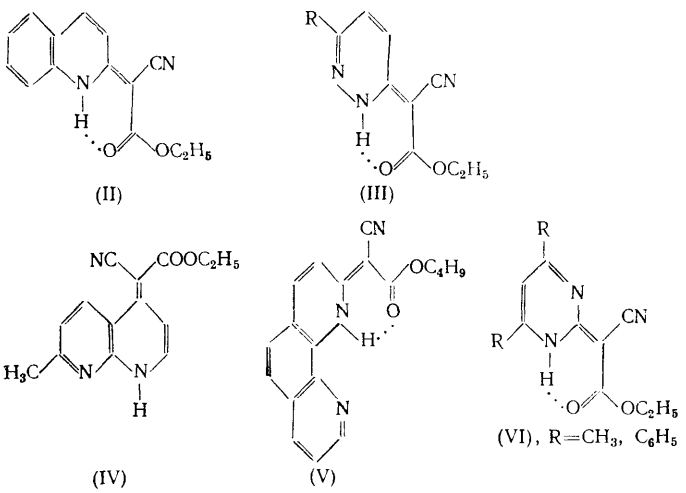
As in the case of aminoazines,[17,18] the appearance of the ylidene tautomer in the series of azinylmethanes is promoted by electron-accepting substituents in the exocyclic fragment:[16,19]



(A) (B)

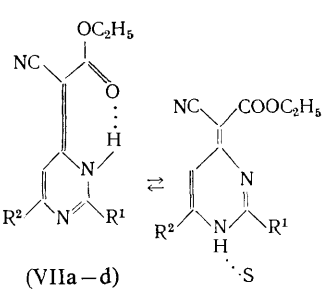
X = Y = CN, NO_2, COOR, SO_2R, $C_6H_4NO_2$.

Type (4) tautomerism was apparently first mentioned by Chichibabin in 1918.[20] A little later he succeeded in observing tautomeric forms of types (A) and (B) for dinitrobenzylpyridine.[21] During the same years, tautomerism was observed in the series of pyridylmethanes[22] and quinolinylmethanes,[23,24] whose study was subsequently continued.[25]



In the series of substituted CH-azines, the tautomerism of azinylcyanoacetic esters has been studied in fair detail. Thus, according to ^{1}H NMR spectroscopic data obtained in $CDCl_3$,[26] pyridyl-2-cyanoacetic ester (I, RH) is in the ylidene form (B) (δ_{NH} = 14.1 p.p.m.). For the analogous 3-methyl derivative, it has been suggested[27] on the basis of ^{1}H NMR spectra that the non-chelate ylidene tautomer (B′) (R = CH_3) is formed. It may be that, in view of the low rate of the tautomeric interconversion, form (B′) was observed by the authors[27] under non-equilibrium conditions. The formation of thermodynamically stable non-chelate tautomers requires special conditions, for example, basic solvents, which stabilise the form of type (B′) as a result of the formation of an intermolecular hydrogen bond (HB).

(A) (I) (B) (B′)

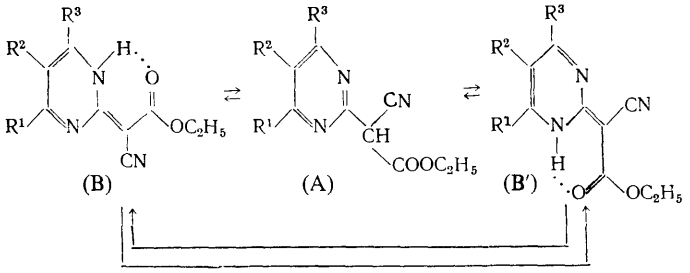


Thus the use of dimethyl sulphoxide (DMSO) as the solvent led to the formation of significant amounts of non-chelate ylidene forms in the case of substituted pyrimidinyl-2-cyanoacetic esters.[28]

Quinolinylcyanoacetic ester (II) [29,30] and the analogous pyridazine (III),[30] pyrazine,[31] naphthyridine (IV),[32] and phenanthroline (V) [29] derivatives, obtained by the reaction of the corresponding *N*-oxides or halogeno-derivatives with cyanoacetic ester, exist in the ylidene tautomeric form. The latter predominates also for pyrimidinyl-cyanoacetic ester (VI), whose structure was examined by Zagulyaeva and Mamaev[33] and was later proved by UV spectroscopy.[34]

(II) (III) (IV) (V) (VI), R=CH_3, C_6H_5

In the case of cyanoacetic derivatives of di- or tri-azines, several types of ylidene tautomers can be produced. Thus, 4-pyrimidinyl-cyanoacetic esters (VII) can form ylidene tautomers with the *ortho*- and *para*-quinonoid disposition of the double bonds in the heterocycle. Both tautomers of 2-methylpyrimidinyl-4-cyanoacetic ester (VIIb) were isolated in a pure state (solid phase).[35] It was shown that in solvents of low polarity the *ortho*-quinonoid tautomer is more stable; the formation of the *para*-quinonoid tautomer is promoted by polar media and solvents forming hydrogen bonds.[36,37]

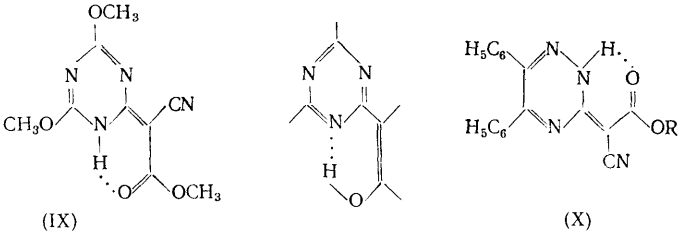


(VIIa–d)

(VIIa): $R^1 = R^2 = H$;
(VIIb): $R^1 = CH_3$, $R^2 = H$;
(VIIc): $R^1 = CF_3$, $R^2 = H$;
(VIId): $R^1 = H$, $R^2 = C_6H_5$.

The stabilisation of the *para*-quinonoid tautomer by polar solvents was also observed for the unsubstituted 4-pyrimidinyl-cyanoacetic ester (VIIa) and its trifluoromethyl analogue (VIIc). The steric hindrance in 6-phenyl-4-cyanoacetic ester (VIId) prevents the formation of the *para*-quinonoid tautomer either in DMSO, or in hexamethylphosphoramide (HMPA), or in the crystalline state.[35]

Two types of ylidene tautomers (B) and (B′) have been detected for pyrimidinyl-2-cyanoacetic esters (VIII) substituted asymmetrically in the pyrimidine ring. Analysis of the spin–spin coupling of the ring protons in the ^{1}H NMR spectrum made it possible to distinguish reliably these forms and to determine the ratios of the forms (A), (B), and (B′).[28] For example, 2% of the tautomer (A),

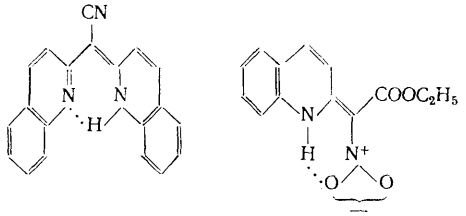


70% of the tautomer (B), and 28% of the tautomer (B′) were detected for the pyrimidinylcyanoacetic ester (VIIId) in $CDCl_3$.[28] The occurrence of the degenerate tautomeric transformations of the type (B) ⇄ (B′) ($R^1 = R^3 = H$) was established by a pulse mode double resonance ^1H NMR study using transfer of a saturation label.[28,38]

(B) (A) (B′)

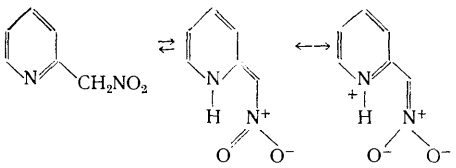
(VIIIa): $R^1 = R^2 = R^3 = H$; (VIIIb): $R^1 = R^3 = H$, $R^2 = OCH_3$; (VIIIc): $R^1 = R^3 = H$, $R^2 = N(CH_3)_2$; (VIIId): $R^1 = C_6H_5$, $R^2 = R^3 = H$.

Among 1,3,5-triazine derivatives, the tautomerism of the dimethoxy-derivative (IX) was studied in greatest detail.[39] It exists in $CDCl_3$ predominantly in the ylidene tautomeric form. Traces of the aromatic form (A) of this compound were detected by IR spectroscopy (the change to a hexane solution entails an increase in the content of this tautomer[38]). It has been assumed[39] that the enolic tautomer of compound (IX), involving an enolised ester group, exists. However, from ^{14}N NMR data, it has been shown[28,40] that an appreciable amount of the enolic tautomer is not formed in cases of this kind. The signal of the NH group observed in the ^{14}N NMR spectrum (−260 p.p.m. relative to CH_3NO_2) is typical for nitrogen of the amide type;[41] on the other hand, in the case of enolisation, a downfield shift of the signal should have been observed (−100 p.p.m.). 1,2,4-Triazinylcyanoacetic ester (X) also exists in the ylidene tautomeric form.[42]



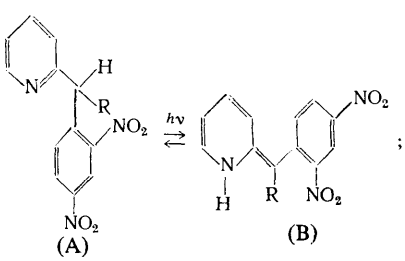
(IX) (X)

^{14}N NMR	−260 p.p.m. (exp.)	−100 p.p.m. (expected value)



Thus, the ylidene tautomer of cyanoacetic acid derivatives of unsubstituted azines is as a rule more stable than the aromatic tautomer. The aromatic tautomers have been detected in trace amounts only for pyrimidinyl-2-cyanoacetic and pyrazinyl-2-cyanoacetic esters.[28,31] The presence of a cyclic substituent affects appreciably the position of the tautomeric equlibrium and in many cases the content of forms (A) and (B) may prove to be comparable, as happens, for example, for 5-methoxy- or 5-dimethylamino-pyrimidinyl-2-cyanoacetic esters (VIIIb, c).[28]

In the series of azines, the structure of malonodinitrile derivatives has also been studied. Regardless of the nature of the heterocycle, malonodinitrile derivatives exist in the ylidene tautomeric form.[19,27,29–31,33,34,43–46] The lower electron-accepting capacity of the COOR group compared with the nitrile group is responsible for the lower tendency of azinylmalonic ester to be converted into the ylidene form. The aromatic tautomer of azinylmalonic esters is usually more stable.[34,47–49] However, in certain cases, for example for pyridinyl-4-malonic and pyridazinyl-3-malonic esters, the contents of the tautomers (A) and (B) were comparable.[50] The azinyl−azinylidene tautomeric equilibrium occurs for bisquinolinylmethanes of type (XI)[51,52] and derivatives of nitroacetic ester (XII).[30]

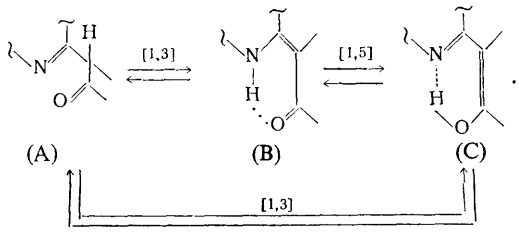


(XI) (XII)

The substituted azinylmethanes examined above contain two electron-accepting substituents at the CH fragment, but the presence of only one acceptor is sometimes sufficient for the occurrence of an equilibrium of type (A) ⇄ (B). Thus, in the nitration of a large series of methylazines, it has been observed that the nitromethylazines (XIII) obtained in this process are capable of the (A) ⇄ (B) tautomerism.[53] (It is noteworthy that the representation of the ylidene tautomer in the above study by another resonance formula does not alter the essential features of the situation. It is essential not to confuse resonance representations of the same ylidene tautomer with the tautomeric equilibrium itself.)

(A) (B) (XIII)

The ylidene tautomers of certain azinylmethanes are kinetically stable and can be formed, in particular, under the influence of UV irradiation. Among such compounds, derivatives of *o*-nitrobenzyl type are best known.[54] After the irradiation of compound (XIV), the appearance of a coloured ylidene form is observed. It undergoes thermal tautomerisation to the starting material.[55] With increase in the electron-accepting capacity of the substituent at the CH fragment, the equilibrium (A) ⇄ (B) occurs even in the ground state. Thus for compound (XV) in $CDCl_3$ such equilibrium was established by ^1H NMR and UV spectroscopic methods.[56]



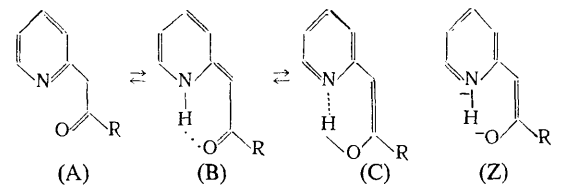
(A) (B)

(XIV): R = H; (XV): R = $COOCH_3$.

In this case too, irradiation increases the fraction of the tautomer (B), i. e. one may speak of an example of a photosensitive equilibrium of the azinyl–azinylidene type.[56] (A detailed discussion of the photoinduced tautomerisation of the azinyl–azinylidene type is outside the framework of the present review.)

III. Intrachelate [1,5]sigmatropic tautomerism of substituted methylazines

The compounds examined above are characterised by a low tendency towards a tautomeric rearrangement of the substituents in the exocyclic group. More favourable possibilities for tautomerism in the side chain are provided by acyl groups, which constitute the basis of the most frequently encountered tautomeric equilibria of the keto–enol type. The structure and tautomerism of acylmethylazines (including the simplest representative 2-acetonylpyridine) have been the subject of a prolonged controversy.[57]



The tautomeric transitions (A) ⇄ (B) and (A) ⇄ (C) are instances of [1,3]sigmatropic tautomerism.[11] Intermolecular proton transfer is characteristic of such processes, while an intramolecular mechanism is unlikely because of symmetry requirements.[58] Since the rate of proton migration between the heteroatom and the carbon atom is usually low,[59] the study of such equilibria by NMR does not present appreciable difficulties in most cases. The intrachelate tautomeric (B) ⇄ (C) transition, an example of the [1,5]sigmatropic tautomerism, occurs, on the other hand, by an intramolecular mechanism characterised by a high rate and the NMR spectra show average signals due to both forms—(B) and (C).[60]

Vigorous investigation of the character of the potential energy surface (PES) for the [1,5]transfer of a proton, carried out in relation to the enolic form of malonodialdehyde (XVI) by both experimental and theoretical methods,[61] showed that the two-well PES profile corresponds to this type of equilibrium (Fig. 1). Since even in this favourable case the one-well potential does not occur, its existence for asymmetric chelates of types (B) and (C) appears unlikely.[62]

A reliable demonstration of the occurrence of the tautomers (B) and (C) (two-well potential) is provided by the spectroscopic identification of both tautomers with the aid of some kind of "rapid" method (IR, UV, and photoelectron spectroscopy, etc.). It is essential to note that formulae with equalised bonds are used not so much to designate a one-well potential surface for this compound but to state the uncertainty in the position of the proton (OH or NH form) (Fig. 1).[63]

Another uncertainty arising when the intrachelate tautomerism is discussed is frequently associated with the fact that in some studies the possibility of the formation of a "zwitter-ionic" tautomer is discussed. Thus, for the pyridine derivatives (XVII), the authors[64] consider also the tautomeric form (Z) together with forms (A), (B), and (C). However, it is easy to see that the formulae (B) and (Z) are merely different resonance designations of the same tautomer.

(XVII): R = CH_3 (a), C_2H_5 (b), C_3H_7 (c), iso-C_3H_7 (d), CF_3 (e), C_6H_5 (f), t-C_4H_9 (g).

In many early studies, the authors considered only two tautomeric forms for compounds of the pyridine series (XVII): the keto-form (A) and the enolic form (C). The possibility of the formation of the ylidene tautomer (B) in the equilibrium mixture was not then discussed.[65,66] For example, the picolinylketones (XVIIa–e)[65] and derivatives of phenylacylpyridine (XVIIf),[66] whose structures had been determined by IR, UV, and ^1H NMR spectroscopic methods, were examined from these standpoints. It was found that the tautomeric composition of the picolinylketones (XVIIa–e) is not correlated with the polarity constants of the substituent R, but there is a satisfactory correlation with the constants E_s reflecting the steric requirements of the substituents.[65] Evidently the neglect of the possibility of the formation of the ylidene tautomer (B) lowers the reliability of the conclusions reached. The tautomerism of the simplest representative of acylmethylazines—2-acetonylpyridine (XVIIa)—has been investigated[67] and the authors took into account all three possible tautomers. Information about the positions of both the "slow" tautomeric equilibria (A) ⇄ (B) and (A) ⇄ (C) and of the "fast" tautomeric equilibrium (B) ⇄ (C) has been obtained with the aid of ^1H NMR. Mondelli and Merlini[67] based their treatment on the fact that allylic interaction of the protons of the methylidyne and methyl groups (J_{CH/CH_3} = 1–2 Hz) should occur in the enolic tautomer (C) of acetonylazines. In the ylidene tautomer, the interaction of these protons takes place across a single bond and is significantly weaker; the corresponding spin–spin coupling constant is assumed to be zero. J_{CH/CH_3} = 0.65–0.75 Hz for acetonylpyridine, which indicates, according to the authors,[67] the predominance of the enolic form in the equilibrium (B) ⇄ (C). It is thought that, as a consequence of the weakness of the spin–spin

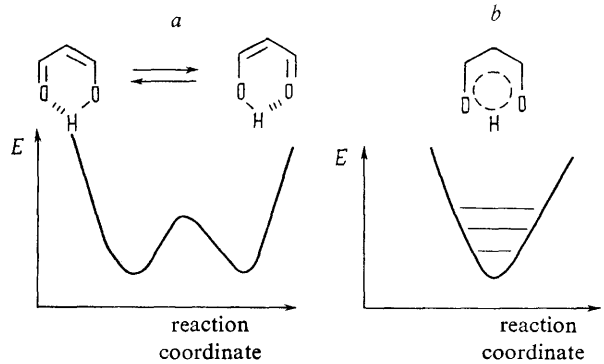


Figure 1. The character of the potential energy surface for two-well (*a*) and one-well (*b*) profiles.

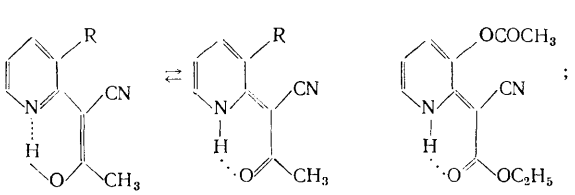


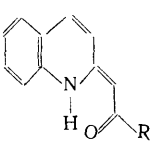
coupling and also because of the lack of rigour of the zeroth approximation for J_{CH/CH_3} in the case of the ylidene form, it is in many cases difficult to use the above criterion, especially for quantitative estimates.

Using ^1H NMR spectroscopy, Klose and Uhlemann[64] examined the tautomerism of ^{15}N-labelled picolinylketone derivatives (XVIId, g). Since $^{15}N-H$ spin–spin coupling was not observed, the ylidene form was rejected. In reality, a small amount of this form is produced,[68] but the observation of the corresponding small splitting apparently requires a more sensitive apparatus. Nevertheless, the possibilities of the above method are very great because, by virtue of the weak dependence of $J_{^{15}N-H}$ on the structure, in most cases there is no need to synthesis model compounds. The magnitude of the splitting for the tautomer (B) is close to 90 Hz, while for the enolic form it is apparently zero,[69] which ensures the quantitative estimation of K_T.

New possibilities arise in connection with the use of high-field instruments and special pulse trains (INEPT) for increasing the sensitivity and the measurement of ^{15}N NMR spectra on the basis of the natural abundance of the isotope. The possibilities of the broad-band version of the INEPT procedure for the measurement of $J_{^{15}N-H}$ have been demonstrated recently in the study of the tautomeric acylmethylazines of the pyridine, pyrimidine, and quinoline series.[70]

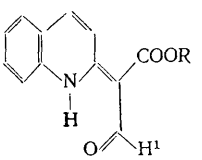
In contrast to earlier data,[64,72] Cassity et al.[71] state that the equilibrium (A) ⇄ (B) occurs for a series of picolinylketones (XVIIa, d, f, g). It may be that[57] this claim is a result of the careless reading of the communication[67] to which the authors refer in order to confirm their conclusions. The contradictory nature of the data on the structures of simple acylmethylazines was pointed out as early as 1982 in a study[57] of the tautomeric equilibrium of t-butyl 2-picolinyl ketone (XVIIg) and its quinoline analogue in 25 solvents. The value of the above study[57] is somewhat reduced because the position of the "fast" equilibrium (B) ⇄ (C) was not investigated and it was assumed (referring to the study of Mondelli and Merlini[67]) that only the (A) ⇄ (C) equilibrium obtains for the pyridine analogue and only the (A) ⇄ (B) equilibrium obtains for the quinoline analogue. This approach can lead to inaccurate conclusions. Thus the examination of the spectral characteristics of acylmethylazines in various solvents has shown[73] that the third tautomer occurs also for the above ketones.

The tautomerism of 2-cyanoacetonylpyridine (XVIII) has been discussed.[74] On the basis of ^1H NMR, IR, and UV spectroscopic data, the authors[74] postulate that the enolic tautomer (C) predominates in chloroform, cyclohexane, and basic aqueous media, while the tautomer (B) predominates in methanol and in acid media.



(C) ⇄ (B); (XX)

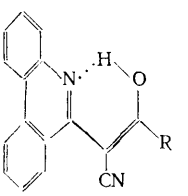
(XVIII): R = H; (XIX): R = $OCOCH_3$.



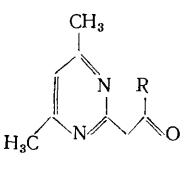
More reliable data, obtained by the joint application of the ^{17}O and ^{14}N NMR methods[75] showed that the equilibrium (B) ⇄ (C) occurs in $CHCl_3$ with the ylidene form predominating. A shift of the equilibrium towards the ylidene tautomer may be expected also for substituted cyanoacetonylpyridine (XIX), although the authors[76] give preference to the other chelate form (C). The ylidene structure of compound (XIX) is supported by the identity of the UV spectrum of compound (XIX) with that of its close analogue (XX), for which the formation of an enolic form of type (C) is uncharacteristic owing to the low tendency of the ester group to enolise. The significant difference between the chemical shifts of the chelate proton for compounds (XIX) and (XX) (δ = 17 and 14 p.p.m.), observed by Stein et al.,[76] may be caused by the difference between the strengths of the hydrogen bonds in the ylidene forms of these compounds.

Contradictory data on the structures of condensed acylmethylazines have been quoted in the literature. Thus the enolic structure has been attributed[77] to phenacylquinoline (XXI) and to acetonylquinoline (XXII). However, other workers[67] have adduced evidence in support of the ylidene form, in agreement with the data of Yamazaki et al.[78] Nevertheless, in the assignment of the signals in the ^1H NMR spectra of 2-phenacylquinoline (XXI), Hay and Wolfe[79] used the enolic form as a basis.

(XXI): R = C_6H_5;
(XXII): R = CH_3.

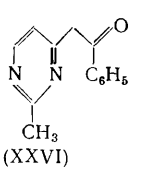


(XXI), (XXII)



(XXIII)

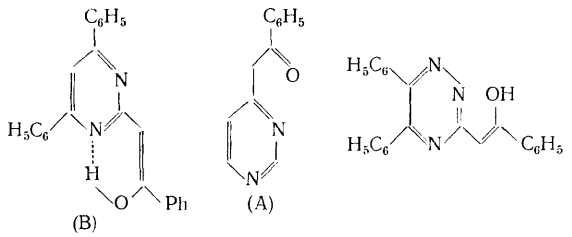
In view of the absence of the characteristic splitting of the signals due to the protons of the methyl and methylene groups and also as a result of comparing the UV spectra of acetonylcholines and model compounds, it has been concluded[67] that the two forms (A) and (B) of 2-acetonylquinoline (XXII) are in equilibrium. The study of a series of acylmethylquinolines and of the formyl derivative (XXIII)[78,80] led to the preference being given to form (B) among the chelate tautomers. The conclusion that the formyl(quinolinyl)acetic ester (XXIII) has the ylidene structure can be reached in view of the absence of spin–spin coupling of $H^{(1)}$ and the proton of the hydroxy-group, which would have occurred in the case of the enolic tautomer.[80]



The structure of the phenanthridine derivatives (XXIV, R = CH_3, C_6H_5) has been examined in a study[81] where preference was given to the enolic form on the basis of the proton chemical shift (16.8 p.p.m.). This conclusion is inconsistent with the usually observed effect of the electron-accepting substituent and of annelation (in both cases the ylidene tautomer is stabilised) and requires additional confirmation.

(XXIV)

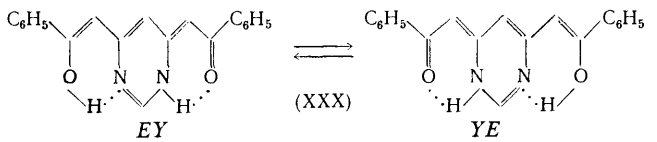
(XXV)



(XXVI)

In the series of diazines, studies have been made of the tautomerism of substituted acetonylpyrimidines (XXV) and phenacylpyrimidines (XXVI)[82–84] and also of 2- and 4-trichloro- and 2- and 4-trifluoro-acetonylpyrimidines.[85]

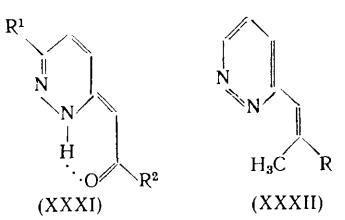
On the basis of ^1H NMR spectroscopic data for compounds (XXV) and (XXVI), it has been stated[82,84] that the tautomers (A) and (B) or (C) are present in the mixture, but the choice between the enolic and ylidene tautomer was not made. The tautomerism of



2-phenacyl-4,6-diphenylpyrimidine (XXVII) has been investigated by ^{1}H NMR and UV spectroscopy.[83] The absorption in the UV spectrum of the tautomeric forms (A), (B), and (C) was modelled by the absorption of the corresponding *C*, *O*-, and *N*-methyl derivatives. The absence of the ylidene tautomer (B) from the equilibrium was demonstrated; the ratio of the forms (A) and (C) is 1:2 (in $CHCl_3$) according to ^{1}H NMR data.[83]

(B) (XXVII) (A) (XXVIII) (XXIX)

Judging from the ^{14}N and ^{17}O NMR data, 4-phenacylpyrimidine (XXVIII) contains comparable amounts of the tautomers (B) and (C) [from ^{1}H NMR data, the fraction of form (A) in $CHCl_3$ is 20%].[86] The synthesis of a series of substituted acylmethylated pyrimidines, quinazolines, and pyrazines has been described,[87] but the tautomerism of these compounds has not been studied. The occurrence of the keto–enol equilibrium has been noted for phenacyl-1,3,5-triazine (XXIX) (with reference to ^{1}H NMR data).[42] However, these results do not permit a reliable exclusion of the presence of the ylidene tautomer.

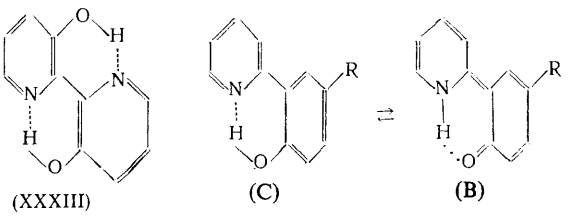


The tautomerism of 4,6-diphenacylpyrimidine (XXX) is more complex.[15] Using ^{17}O NMR and by observing the tautomerisation dynamics using ^{1}H NMR in $CHCl_3$, it has been possible to establish the presence of five tautomers (*KK*, *KE*, *KY*, *EE*, and *EY*, where *K*, *E*, and *Y* are indices denoting the keto-, enol-, and ylidene fragments in the 4- and 6-positions).

EY (XXX) *YE*

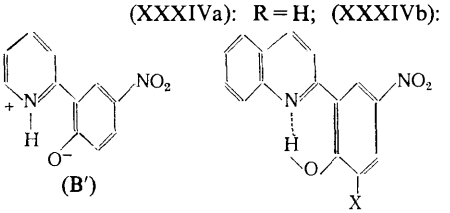
It is of interest to note that the [1,5]–[1,5]disigmatropic EY ⇄ YE equilibrium is an example of tautomerism of the cyclodismutation type, previously deduced within the framework of the formal classification of tautomeric systems.[11]

Among the chelate forms of acylmethylpyridazines (XXXI), preference has been given[88] to the NH form. The main evidence in support of this was obtained by comparing the ^{1}H NMR spectra in $CDCl_3$ with the spectra of model compounds (XXXII) (relative to the enolic form).



(XXXI) (XXXII)

However, the OH group in compound (XXXI) would be a stronger donor than the CH_3 group in compound (XXXII) as a result of which models of the type (XXXII) may prove to be relatively unsuitable. In particular, reliable ^{14}N and ^{17}O NMR data for phenacylpyridazine, which was considered by Ohsawa et al.,[88] have shown that the contents of the two chelate tautomers in $CHCl_3$ are comparable.[86]



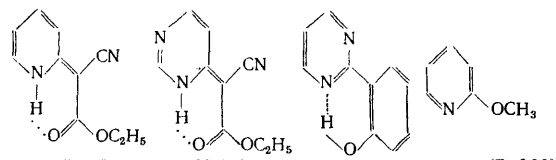
o-Hydroxyphenylazines and their condensed analogues are an interesting group of compounds capable of undergoing intrachelate tautomerism of the [1,5]sigmatropic type. The photoinduced tautomerisation of these compounds has been studied in detail in the series of *o*-hydroxyphenyl- and hydroxynaphthyl-azines,[89] including the procedure using laser flash photolysis with picosecond resolution.[90–92] Disigmatropic [1,5]–[1,5]tautomerisation has been observed for the bipyridyl analogue (XXXIII).[93] *o*-Hydroxyphenylazines are effective photostabilisers of polymers[94,95] and the characteristic features of their tautomerisation can have a significant effect on their properties. The tautomerism of these compounds in the ground state is therefore of special interest. In particular, it is of interest to discover the structural limits of the stability of the aromatic tautomeric form (to which total stabilising properties are attributed) as well as factors favouring the formation of the ylidene tautomeric form.

The first hypotheses concerning the occurrence of the ylidene form (B) were put forward as early as 1918 in a study of *o*-hydroxyphenylpyridine (XXXIVa).[20] Later it was suggested,[96] from IR spectra, that the *p*-nitrophenyl derivative (XXXIVb) has the zwitterionic structure (which is easily seen to constitute another resonance representation of the ylidene tautomer).

(XXXIII) (C) (B)

(XXXIVa): R = H; (XXXIVb): R = NO_2.

(B′) (XXXIVb)

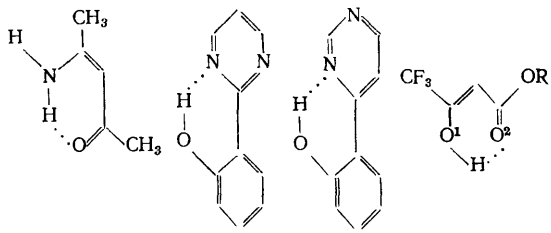


(XXXVa): X = H
(XXXVb): X = NO_2.

It has been shown with the aid of ^{17}O NMR and UV spectroscopic methods[97] that the ylidene tautomers of hydroxyphenylpyridine (XXXIVa) and of its nitro-analogue (XXXIVb) are not observed in $CHCl_3$. However, the ylidene tautomer of the nitrophenylquinoline (XXXVa) is present in small amounts while the content of this tautomer of the dinitro-derivative (XXXVb) becomes dominant.

The studies of the tautomerism of acylmethylazines examines above contain a large number of contradictory examples, sometimes involving mutually exclusive conclusions about the structures of the same compounds. This is caused primarily by the difficulties arising in the study of fast intrachelate equilibria by traditional methods. Reliable information about an intrachelate equilibrium of the type (B) ⇄ (C) can be obtained by observing the NMR spectra of the nitrogen and oxygen atoms which are involved directly in the tautomeric transformation. In contrast to the H and C atoms, the

hybridisation of the N and O atoms in the tautomeric transition changes, as a result of which the differences between the chemical shifts of the indicator nuclei should be extremely large (hundreds of p.p.m.).



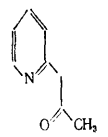
It has been suggested[68,86] that a combination of the ^{14}N and ^{17}O NMR methods be used to establish the position of the intrachelate tautomeric equilibrium of the type (B) ⇄ (C). The ratio of the (B) and (C) tautomers is estimated from the positions of the nitrogen and/or oxygen signals relative to the signals of model compounds. The corresponding azinylidenecyanoacetic esters were used to estimate the chemical shifts of the nitrogen atom in the ylidene form. The position of the ^{14}N NMR signal for the enolic forms was modelled with the aid of *o*-hydroxyphenylazines, for which the enolic structure of the chelate tautomer has been established reliably.[98]

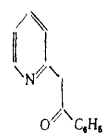
Compound 

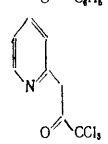
$\delta(^{14}N)$, p.p.m. -215 ± 5 -230 ± 3 -130 ± 5 -110 (Ref.99)

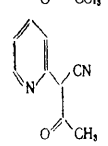
The ^{14}N NMR signal of the NH form (B) is fairly narrow ($\Delta_{1/2} \simeq 200$ Hz) in contrast to the signal of form (A) ($\Delta_{1/2}$ up to 800 Hz).[99] The ^{14}N NMR spectroscopy is therefore effective when the ylidene form predominates in the equilibrium (B) ⇄ (C).

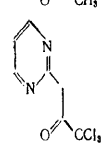
2-Aminopent-2-enone, in which the carbonyl group is incorporated in the enaminocarbonyl fragment involved in the hydrogen bond, as in the ylidene form, was used to model the ^{17}O NMR shifts of the ylidene tautomer (B). In selecting a model for the ^{17}O NMR of the enolic tautomer (C), it was important to take into account the conjugation of the OH group with the heteroaromatic ring through the double bond and also the intramolecular hydrogen bonds. These requirements are satisfied in many respects by *o*-hydroxyphenylazines [$\delta(^{17}O) \simeq 94-97$ p.p.m.] and the enolic forms of β-ketoesters.[98] Comparison of the chemical shifts of hydroxyphenylazines and β-ketoester enols showed[98] the position of the OH signal of the unmodified enolic fragment depends comparatively little on the form of the proton-accepting component of the chelate ring (the carbonyl group in β-ketoazines and the azine fragments in *o*-hydroxyphenylzines).

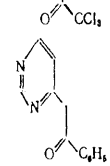


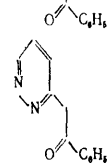


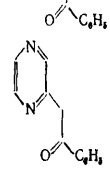












Compound 

$\delta(^{17}O)$, p.p.m. 419 96 94 O^1 96, O^2 315

The accuracy of the determination of the contents of the (B) and (C) tautomers by the ^{14}N and ^{17}O NMR methods has been analysed.[68]

The ^{14}N and ^{17}O NMR spectroscopic data in Table 1 agree fairly satisfactorily, which makes it possible to establish reliably the structure of acylmethylazines and to resolve the contradictions existing in the literature. Thus the chemical shifts found for acetonylpyridine and phenacylpyridine indicate the virtually complete displacement of the equilibrium (B) ⇄ (C) to the enolic tautomer (C). The ^{17}O NMR data, which are more accurate when the enolic tautomer predominates, show that, together with forms (A) and (C), the ylidene tautomer is also present albeit in small amounts. The accumulation of electron-accepting substituents in the exocyclic group favours the ylidene tautomer to a greater extent. Isotypical derivatives of azines exhibit different tendencies towards conversion into the ylidene tautomeric form (B), whose fraction in the intrachelate equilibrium (B) ⇄ (C) is a maximum for 4-pyrimidine and 3-pyridazine derivatives. The high sensitivity of the intrachelate tautomeric equilibrium to the effect of the

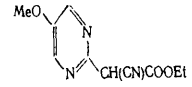
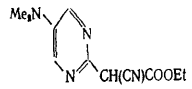
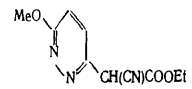
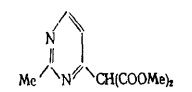
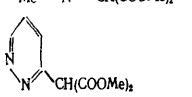
substituent at the carbonyl group is striking. Thus transition from acetonylpyridine (XVIIa) to its trichloromethyl analogue reverses the ratio of forms (B) and (C).







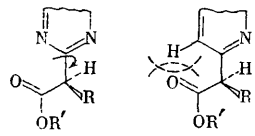




^{14}N and ^{17}O NMR methods have been used to investigate the tautomerism of acylmethylpyrazines and their annelated analogues.[100] Compared with pyridine derivatives, acylmethylpyrazines exhibit a smaller tendency towards transition to the ylidene form, which remains unstable even in the case of trifluoroacetonylpyrazine. As for other acylmethylazines, annelation greatly stabilises the NH tautomer

The above data demonstrate the great potential possibilities for the joint employment of the $^{15,14}N$ and ^{17}O NMR methods in the study of the tautomerism of heterocyclic compounds.

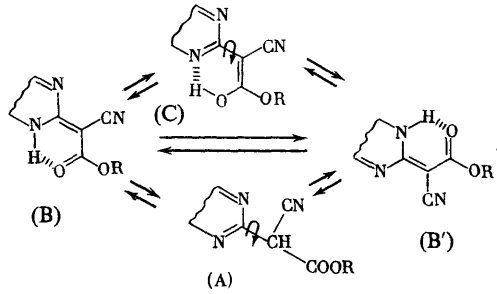
IV. Thermodynamics, kinetics, and mechanism of the tautomeric interconversions of azinylmethanes



The temperature dependence of the equilibrium and the thermodynamic parameters ΔH and ΔS for pyrimidine and pyridazine derivatives[101] are listed in Table 2. The tautomeric equilibrium (A) ⇄ (B) proved extremely sensitive to changes in temperature. An extremely high ΔS has been observed for compounds (VIIIb, c), which is uncharacteristic of prototropic equilibria as a whole. For example, ΔS for the keto–enol equilibria involving benzoylacetic esters or for the tautomerism of 2-hydroxypyridine varies in the range from 8 to 16 J mol^{-1} K^{-1}.[102,103] The values of 60–70 J mol^{-1} K^{-1} found by Petrenko et al.[101] agree with the entropies in the azido-tetrazole tautomeric equilibrium,[101,104] which, however, is not of the prototropic type.

Table 2. Thermodynamic parameters of the tautomeric equilibrium.[101]

Compound	Structural formula	ΔH, kJ mol^{-1}	$-\Delta S$, J mol^{-1} K^{-1}
(VIIIb)		21.1±0.2	62±1
(VIIIc)		23.2±0.2	71±1
(XXXVI)		7.9±0.6	47±2
(XXXVII)		12.2±0.6	38±2
(XXXVIII)		4.7±0.8	24±2.5

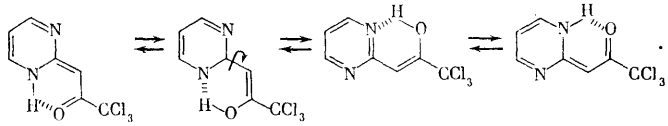


The unfavourable entropy change on transition to the ylidene tautomer in the case of pyrimidinylcyanoacetic esters (VIIIb, c) is evidently associated with the loss of freedom of rotation about the exocyclic C–C bond in the ylidene tautomer.

Scheme 2

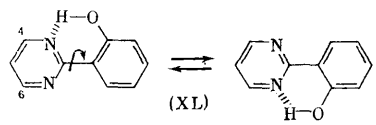
When the C–H fragment, which is more bulky than the N atom, is present in the β-position [compound (XXXVI), Table 2], the rotation in the tautomer (A) becomes hindered (Scheme 2), which reduces the difference between the entropies of the tautomers (A) and (B).[105] The further decrease in ΔS for the malonic esters (XXXVII) and (XXXVIII) (Table 2) is associated with still greater hindrance to the rotation of the more bulky exocyclic group.[101]

The kinetic characteristics of the tautomeric transformations of azinylmethanes were obtained in a study of the tautomerism of pyrimidinyl- and pyridazinyl-malonic esters[50] as well as phenylacylquinolines.[106] In both studies, it was concluded that the tautomerisation mechanism is of the ionic-dissociative type and is close to that which is well known for keto–enol tautomeric systems. This mechanism is supported by the following experimental data: the occurrence of acid–base catalysis, the dependence of the rate of tautomerisation on the concentration of the tautomeric compound (autocatalysis), and the ready deuterium exchange of the acid protons of the NH and CH groups.[106,107] In the ionic-dissociative mechanism, the dissociation (or formation) of a C–H bond is the rate-limiting stage; this has been confirmed in a study[107] of the tautomeric equilibrium involving pyrimidinylcyanoacetic ester (VIIIb) by the kinetic isotope effect (k_H/k_D = 3.5).



The mechanism of the annular tautomerism of the type (B) ⇄ (B′) has been studied.[38,39] The merging of the signals of the methoxy-groups in the ^1H NMR spectrum of 4,6-dimethoxy-1,3,5-triazinyl-2-cyanoacetic ester (IX) was observed on passing from $CDCl_3$ to DMSO and dimethylformamide (DMF)[39] and the authors suggest that this merging is caused by a rapid intramolecular reaction proceeding via the intermediate enolic form. However, later UV spectroscopic data[38] obtained in various solvents indicate a pronounced (if not complete) ionisation of compound (IX) in DMSO and DMF. Thus the changes observed in the ^1H NMR spectrum[39] can be altogether unrelated to tautomerism. The mechanism of the annular tautomerism has been investigated[38] in relation to the pyrimidinyl-2-cyanoacetic ester (VIIIa), which is less acid and is scarcely ionised in DMSO or DMF.

Evidently the [1,3]sigmatropic tautomerisation examined above can involve with equal probability both the N(1)H and the N(3)H group. Hence it follows that, in the presence of even traces of form



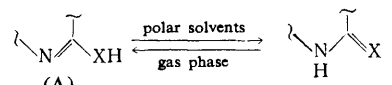
(A), the interconversion of forms (B) and (B′) via the tautomer (A) is one of the routes of [1,5]tautomerisation. The mechanism with participation of the aromatic tautomer (A) should differ from the other possible mechanisms of the (B) ⇄ (B′) process (for example, via the formation of the enolic form of the anion) by the presence of a kinetic isotope effect, which has in fact been detected[38] in the study of the kinetics of the degenerate tautomeric transformation of compound (VIIIa) with the aid of the pulse version of the method involving the transfer of a magnetic saturation label.[108] It is believed that the mechanism with participation of form (A) is not ruled out also in the case of the triazinylcyanoacetic ester (IX) mentioned above, particularly bearing in mind that appreciable amounts of the aromatic tautomer of this compound in hexane have been detected.[38]

Evidently the probability of an intramolecular mechanism of the tautomeric type (B) ⇄ (B′) transformation via the enolic tautomer increases if the side group contains the readily enolisable carbonyl group. Such a mechanism apparently actually operates for 2-trichloroacetonylpyrimidine (XXXIX):[86]

(B) (C) (C′) (B′)

Although comparable amounts of the ylidene form are present in the equilibrium with the enolic form of compound (XXXIX),[86] the C(4) and C(6) signals in the ^{13}C NMR spectrum have been averaged as a consequence of the rapid (B) ⇄ (B′) exchange even at room temperature. Since the (B) ⇄ (C) stage is extremely fast,[60,61] the following question arises: can the barrier to the rotation in the enolic form, associated with the rupture of a fairly strong hydrogen bond, be so low that averaging at this temperature is ensured? The study of the temperature spectra of the model compound (XL) showed that this type of rotation does indeed have a low barrier. Thus the separation of the C(4) and C(6) signals in the ^{13}C NMR spectrum arises only when the solution of compound (XL) in $CHCl_3$ is cooled to −50 to −60 °C.[86]

(XL)

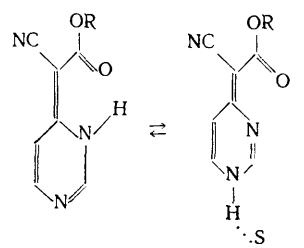


Thus the mechanism of the degenerate tautomeric transformation (B) ⇄ (B′) for substituted azinylmethanes can change depending on the nature of the substituents in the side group.

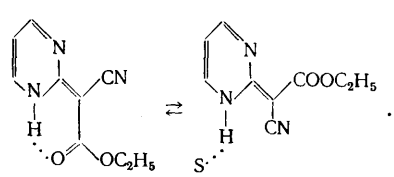
V. The influence of the solvent and structural factors on the tautomerism of azinylmethanes and general characteristics of tautomeric equilibria of the azinyl–azinylidene type

1. The influence of the solvent

Vigorous studies in recent years have shown that the solvent can have a decisive effect on tautomeric equilibria of the azinyl–azinylidene type. The change to solvents of low polarity and the gas phase greatly destabilises the ylidene form, which has been repeatedly demonstrated for hydroxyazines.[109–110] The existence of reliable experimental data made compounds of this series a favourite model for testing the most modern computational schemes for medium effects based on quantum-chemical calculations and the Monte Carlo method.[111,112]



Theoretical estimation of the effect of solvent polarity for azinylmethane derivatives[113] within the framework of the method of solvatons[114] permitted the elucidation of the principal trend: a non-polar solvent and the gas phase favour the aromatic form (A), while a polar solvent shifts the equilibrium towards the ylidene tautomer (B):

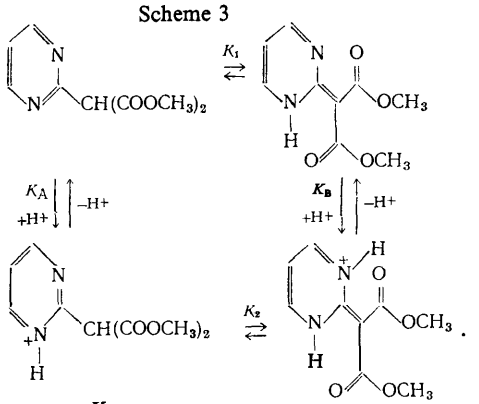


(A) (B)

X = O, NR, CR^1R^2.

Numerous experimental data obtained in the study of the tautomeric equilibria of azinylmethanes in various solvents agree well with this prediction.[113] This behaviour is apparently associated with the specific rearrangement of the electronic structure of the heterocycle on passing to the ylidene form. Judging from quantum-chemical calculations,[113] a marked alternation of the electron density in the ring is characteristic of this form, which, on the basis of the Born approximation,[115] favours solvation by polar solvents. It has been suggested[113] that bulky substituents at a CH fragment, which do not undergo changes in structure on tautomerisation, can abolish the tendency mentioned above. It may be that the low sensitivity of the tautomerism of derivatives of malonic and dinitrophenylacetic esters to the character of the solvent is in fact associated with this factor.[113]

In many cases the change of solvent induces the appearance of a new tautomeric form. This situation is characteristic of derivatives of 4-pyrimidinylmethane, for which the use of polar or specifically solvating solvents leads to the appearance of the ylidene tautomer with the *para*-quinonoid disposition of the double bonds.[35–37] Judging from quantum-chemical calculations[36] and experimental data,[116] this feature is characteristic also of other 4-substituted pyrimidines, for example 4-hydroxypyrimidines.[116] On the other hand, in the case of 2-pyrimidinylcyanoacetic ester (VIIIa), the addition of a highly basic solvent (DMSO, HMPA) apparently leads to the dissociation of the intramolecular hydrogen bond and the appearance of non-chelate tautomers of the ylidene type:[117]



(VIII a)

For highly acidic compounds [for example, 2-trifluoromethyl-4-pyrimidinylcyanoacetic ester (VIIc)], dissolution in DMSO (or HMPA) is accompanied by appreciable and sometimes even complete ionisation.[37] This can be readily established by comparing the UV spectrum of this compound in DMSO with the spectrum of the corresponding sodium salt. Nevertheless, the possibility of ionisation in solutions is frequently not taken into account, which can lead to erroneous conclusions.[38,39] Hydroxylated solvents (alcohols, acetic acid) stabilise the ylidene tautomer both as a result of solvent polarity and as a result of specific solvation.[113]

The effect of protonated solvents (CF_3COOH), which has been investigated in relation to azinylmalonic and azinylcyanoacetic esters,[117,118] is very strong. It has been suggested[117] that, by virtue of the conjugation of the C=N fragment with the electron-donating NH group, form (B) is apparently more basic ($K_B > K_A$). According to Eqn. (1), this means that protonation shifts the tautomeric equilibrium towards the ylidene form. The most striking example is provided by the equilibrium of derivatives of 2-pyrimidinylmalonic esters,[117] which exist in form (A) and do not exhibit tautomeric properties in neutral solvents of the type of $CHCl_3$. On the other hand, in the presence of trifluoroacetic acid, whose acidity ensures the monoprotonation of pyrimidine derivatives, the equilibrium shifts towards the ylidene tautomeric form (B).[117]

Scheme 3

$$K_2 = K_1 \frac{K_B}{K_A} \qquad (1)$$

The reverse shift—towards the protonated form (A)—is observed under these conditions for pyridyl- and quinolinyl-cyanoacetic esters, which has been confirmed by UV and NMR spectroscopic data.[30,118]

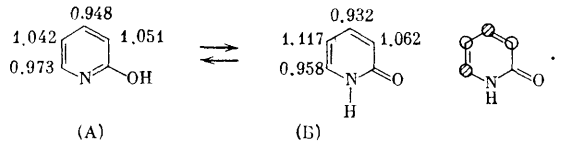
The high sensitivity of the tautomeric equilibrium to solvation effects is characteristic also of the intrachelate tautomerism of the [1,5]sigmatropic type. It has been found for *o*-hydroxyphenylazines[97] and acylmethylazines[73,100] that, as in the case of tautomeric equilibria of the [1,3]sigmatropic type, polar solvents stabilise the ylidene form.

Comparison of the results presented above the effect of the solvent on the tautomerism of azinylmethanes with data on the tautomerism of hydroxy- and amino-azines[3] suggests that prototropic equilibria of the azinyl-azinylidene type as a rule obey a universal rule: a decrease in solvent polarity or transition to the gas phase destabilises the tautomer of the ylidene type. On the other hand, if account is taken also of data for the effect of the solvent on non-prototropic equilibria of the azinyl—azinylidene type (for example, the tautomerism of azidoazines where polar solvents favour the tautomer of the ylidene type—the tetrazole form[119]), then the above tendency is seen to be very general for the entire family of tautomeric equilibria of the azinyl—azinyldene type. There is no doubt that such generality is caused by the similarity of the topologies of the bonds of the corresponding tautomers (see Scheme 1) [Scheme 3?], which is independent of the type of substituent.

2. The influence of structural factors on the tautomeric equilibrium

The combination of a large number of different tautomeric systems into the family of tautomeric equilibria of the azinyl—azinylidene type[86] is not purely formal. Although the type of exocyclic fragment introduces its characteristic features, nevertheless it is clear that the topological similarity in the (A) ⇄ (B) bond rearrangement predetermines the existence of certain general features of the tautomerism of the azaheteroaryl—azaheteroarylidene type. This follows from the profound relation between the topology of the molecules and their electronic structure, which has been discovered in recent years.[120] Bearing in mind the importance of tautomerism of the azinyl—azinylidene type and the existence of extensive experimental data, the search for such features is of very great current interest. Evidently the dynamic characteristics of the tautomerism (mechanism, kinetics) will vary markedly as a function of the type of the azine component and the nature of the exocyclic fragment. On the other hand, general features may be expected primarily as regards the thermodynamic characteristics and their dependence on various factors. The medium effects, the characteristics of the influence of which were examined above, and the effects of structural changes must be regarded as the most important factors. Among the latter, one can differentiate the influence of the type of heterocyclic nucleus and of the substituents in the heterocycle and in the side fragment as well as the influence of annelation.

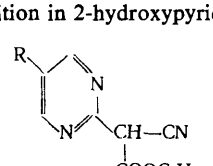
Despite the extensive experimental data on the tautomerism of substituted azines, the number of systematic data concerning the effect of structural factors is small. Since such studies are extremely laborious, the following approach to the study of the effect of structural factors is useful:[86,121–124] for a topologically similar group of tautomeric systems, the electronic structures of the tautomers (the redistribution of charges and bond orders in the tautomeric transition and the change in frontal orbitals) are analysed. Using the formalism of the molecular orbital perturbation method (MOP), the principal trends and the characteristic features of the effect of structural factors on the position of the tautomeric equilibrium can be discovered. Taking into account the resulting prediction, a specific experimental test is carried out in order to formulate finally the manifested features or trends.



Examination of the frontal MO of the tautomers in the series of hydroxy-, amino-, and methyl-azines[122] made it possible to note the isolobal analogy[125] for isotypical tautomers: the forms and energies of the corresponding frontal MO are similar. Since the interaction of substituents with isolobal fragments is qualitatively similar, one may expect similar trends in the "response" of various equilibria of the type (A) ⇄ (B) to identical structural perturbations.

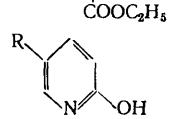
The effects of the heteroatom and the substituent can be estimated conveniently qualitatively with the aid of "difference charts", which reflect the relative changes in key electronic, energy, or orbital characteristics in the transition (A) ⇄ (B). Employing the usual approximations of the MOP method, it has been found that,[86,121–124] in order to estimate the effect of the heteroatom and the inductive and mesomeric effects of the substituents, it is

necessary to use the charts of the differences between the charges, energies, and the squares of the coefficients of the frontal MO. Although the calculations which have been performed correspond to the gas phase, allowance for the polarity of the medium within the framework of the Germer model[114] demonstrated the low sensitivity of the difference charts to the solvent.[122–124]



In the analysis of the inductive effect of the substituent within the framework of the MOP method, one considers the change in the π-electron density on the atom at which the substituent is introduced.[126] According to non-empirical calculations (using the STO-3G basis set),[123] the transition from form (A) to form (B) in the case of 2-hydroxypyridine leads to an increase of the π-electron density in the 3- and 5-positions and to its decrease in the 4- and 6-positions in the heterocycle. These changes are presented in Scheme 4 as graphical difference charts on which the shaded positions correspond to a positive sign of Δq and the open positions correspond to a negative sign.

Scheme 4



Accordingly, the fraction of the tautomer (A) should increase following the introduction of an electron-accepting substituent in the shaded positions in the heterocycle or of an electron-donating substituent in the unshaded positions. This prediction has been largely confirmed experimentally for substitution in the α-position (relative to the heteroatom), where electron-accepting inductive substituents stabilise form (A), while electron-donating substituents destabilise it.[3,122] The trifluoromethyl group has precisely this effect on the equilibrium in the series of substituted hydroxy- and methyl-azines.[3,123] Nevertheless, the effect of substituents does not reduce to electron-donating substituents favouring the pyridine form and electron-accepting substituents favouring the aromatic form. For example, the introduction of the methyl group in the 5-position in 2-pyrimidinylcyanoacetic ester (VIIIa) leads to a shift of the tautomeric equilibrium towards the aromatic tautomer, as predicted by the charge difference charts.[123]

Comparison of the charge difference charts[123] shows that their topology for mono- and di-azines remains constant regardless of the type of exocyclic tautomerising fragment and the nature of the heterocycle. One may therefore expect that the character of the *I* effect of substituents in the series of tautomeric equilibria of the azinyl–azinylidene type is to a significant extent universal. Indeed, according to the available experimental data,[123] the effect of the methyl group on the tautomerism of 2-hydroxypyridine is similar to its effect on the position of the tautomeric equilibrium involving pyrimidinylmethanes: the introduction of the methyl group in the 5-position in 2-hydroxypyridine stabilises the aromatic tautomer.

R	K_T (hexane)

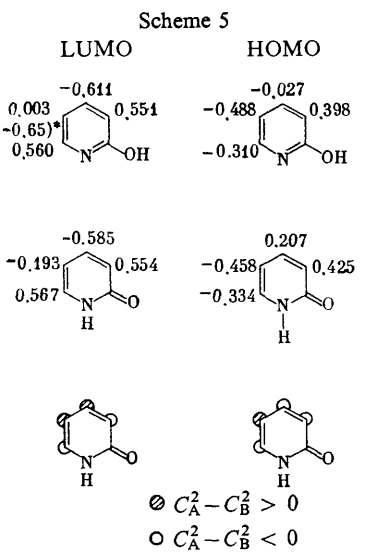
CH_3	3.6



R	pK_T (water)
H	3.0
CH_3	2.6

$K_T = [A]/[B]$

Ultimately, comparison of the charge difference charts with the experimental data made it possible[123] to formulate the main trend in the inductive effect of substituents—the introduction of electron-donating substituents in the *meta*-position relative to the exocyclic tautomerising fragment shifts the equilibrium towards the ylidene form, while its introduction in the *ortho*- and *para*-positions shifts the equilibrium towards the aromatic tautomer. Electron-accepting substituents have the opposite inductive effect.[123]

It is of interest that, for substituents of the mesomeric type, such reversal of the effect on transition from electron-donating to electron-accepting substituents may not in fact be observed, which can be seen from a comparison of the charts for the difference between the squares of the coefficients of the frontier MO (Scheme 5). Thus the introduction of mesomeric substituents of both electron-donating and electron-accepting types in the *para*-position relative to the tautomerising fragment should shift the equilibrium towards the aromatic tautomer because for this position the difference between the squares of the coefficients of both frontier MO is greater in form (A) than in form (B).

Scheme 5

*Coefficient of a neighbouring unoccupied MO

Experimental data agree with this conclusion. For example, the introduction of the electron-donating $N(CH_3)_2$ group, the electron-accepting p-$NO_2C_6H_4$ group, and the "neutral" C_6H_5 group in the 5-position of 2-pyrimidinylcyanoacetic ester (VIIIa) increases the fraction of the aromatic tautomer (Table 3). A similar behaviour

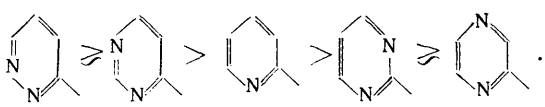


Table 3. Tautomeric equilibrium constants for 5-substituted 2-pyrimidinylcyanoacetic esters (VIII).[122]

has been observed also for cyanoacetic esters of the pyridazine series[127] and also for hydroxy-azines, which has been noted by Petrenko and Lapachev.[122] The latter implies that, in the case of mesomeric substituents, the character of the effect of the substituent in azines with different exocyclic tautomerising fragments is the same.[122]

It follows from the charts of the differences between the squares of the coefficients[122] and the π-electron densities[123] that identical effects of the substituent (as a result of the mesomeric and inductive contributions) on the position of the tautomeric equilibrium should be encountered fairly rarely. Bearing in mind the character of the approximations of the simple MOP method, direct comparison of the contributions of the inductive and mesomeric effects on the basis of difference charts is scarcely possible. At the same time, joint examination of the experimental data and difference charts frequently makes it possible to discover which effect predominates.[122]

In order to understand and predict the tautomeric properties in the series of different azines, it is important to estimate the tendency of each type of azine to rearrange to the ylidene form. Analysis using difference charts and experimental tests have shown[124] that isotypical azine derivatives are fairly clearly differentiated as regards their tendency to undergo a transition to the ylidene tautomeric form. Thus it has been shown that the transition from the pyridine tautomeric compound to the analogous 2-pyrimidine or 2-pyrazine derivative promotes a shift of tautomeric equilibrium towards the aromatic tautomer, while transitions to 4-pyrimidine and 3-pyridazine derivatives promote the transition to the ylidene tautomer.[124] Thus the series of relative tendencies by isotypical azine compounds to undergo a transition to the ylidene tautomeric form is as follows:

Analysis of the distribution of electron density on the nitrogen atoms and in the bonds, the search for isolobal analogy, and inspection of difference charts for tautomeric pairs have made it possible to discover the basis of this similarity, which is observed among tautomeric equilibria of the azinyl–azinylidene type. Despite the multiplicity of approximations, which make it necessary to treat with caution the predictions obtained, the simplicity and clarity of the method make it promising for the construction of a general approach to the study of equilibria of the azinyl–azinylidene type and also of other types of tautomeric equilibria differentiated on the grounds of their topological relationship.

- - - o 0 o - - -

The data examined show that tautomeric interconversions occur very widely in the series of substituted azinylmethanes. Apart from their independent importance, tautomeric azinylmethanes are very convenient models for the determination of the general characteristics of the tautomerism of the azinyl–azinylidene type, which is the most important type of tautomerism in the series of azines.

The MOP method proved to be effective for the discovery and prediction of features of this kind. Its use makes it possible to examine from a general standpoint the dependence of the tautomeric equilibrium of the azinyl–azinylidene type on structural factors. A similar methodology (the differentiation of a family of tautomeric equilibria on the basis of topological criteria, analysis of the similarity of the electronic structures of the tautomers, the use of the MOP method for the interpretation of experimental data, and the prediction and determination of the characteristic features) can be applied also to other classes of tautomeric equilibria.

Tautomeric azinylmethanes constitute one of the examples of molecules with a similar behaviour, which exist in different forms depending on the structure, medium, temperature, or irradiation. There is no doubt that interest in "flexible" molecules of this kind with extensive structural possibilities will continue to grow in the future, especially in connection with the construction of biochemically important molecules and their analogues, as well as compounds with more complex functions for applied purposes. The experience gained in the study of the tautomerism of heterocycles will then also prove essential.

Neutral acyclic analogues of crown-ethers and cryptands and their complex-forming properties

T E Kron, E N Tsvetkov
Karpov Physicochemical Institute, Moscow
Institute of Physiologically Active Substances, USSR Academy of Sciences, Chernogolovka

ABSTRACT. **The review deals with neutral podands (acrylic analogues of crown ethers) of various types, their structures, their complex-forming properties, and their practical applications. Phosphorus-containing and analogous organoelement podands are not included in the review.**

The bibliography incorporates 241 references.

I. Introduction

The term "podands" appeared in the chemical literature comparatively recently — towards the end of the 1970s.[1,2] It embraces various types of acyclic polyether complex-forming agents. The name comes from the Greek word "podos" — foot. In the podand molecule, there is one or several "feet" formed by polyether chains with various end groups. According to the number of such feet, podands are divided into mono-, di-, tri-, and poly-podands. Compounds of this type can be investigated long before the appearance of the term "podands" itself. Thus the simplest representatives of monopodands [diethyl ethers of oligo(ethylene glycols — glymes] became well known in the 1950s–1960s as solvents solvating alkali and certain other metal cations.[3,4] Polyether acyclic antibiotics (nigericin, monensin, etc.), containing tetrahydrofuran and tetrahydropyran rings in the chain, which were discovered and vigorously investigated in the 1950s–1970s, belong to the same type of complex-forming agents.[5] These compounds effect the transport of alkali metals through artificial and biological membranes. In the complex formation reaction, the molecules of acyclic antibiotics twist round a cation and form a pseudoring stabilised by the intramolecular interaction of the end groups.

The specific synthesis of podands as a special class of ligands began to develop mainly after Pedersen's discovery in 1967 of the complex-forming properties of crown ethers.[6] Oligo- and poly-(ethylene glycols) and glymes began to be regarded as open-chain analogues of crown ethers. Polydentate acyclic complex-forming agents of a new type were created on their basis[1] and found extensive application as solvents. Despite certain advances, this field nevertheless remained of secondary importance compared with the much more thoroughly developed and popular field of macrocyclic complex-forming agents.[7,8] However, in recent years open-chain analogues of crown-ethers have attracted increasing attention because of their availability, fairly high effectiveness, and the possibility of regulating on a wide scale their complex-forming properties by altering their structure. Their properties as phase-transfer catalysts,[9–12] extractants,[13,14] and as components of ion-selective electrodes[15] are being investigated. The growing interest in this new class of complex-forming agents is reflected by review articles[1,16,17] on this topic.

The present review differs from those already published by a much more complete coverage of literature (up to 1988), an attempt at the analysis of the dependence of the complex-forming capacity of podands on their structure, and a discussion of the applied aspects of the problem.

II. Neutral acyclic unbranched ligands — monopodands

1. Introduction

The specific solvation of alkali and alkaline earth metal cations by ethylene glycol ethers and their oligomers (glymes) is well known.[3,4] The use of these compounds as solvents for organic anionic reactions is in fact based on this phenomenon. Diglyme, which is in essence a fragment of the 18-crown-6 ether molecule, has come to be widely used. Following the discovery of crown-ethers in the second half of the 1960s, chemists again turn their attention to oligo(ethylene glycols) and glymes as cheaper analogues and began to investigate vigorously their complex-forming properties relative to those of crown-ethers.[18–21]

The principal method of synthesis of monopodands having the general formula $RO(CH_2CH_2O)_nR$ with various end groups is the Williamson reaction between the corresponding dihalides and hydroxyl-containing compounds in the presence of a base.[1]

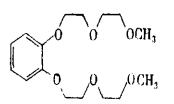
Individual oligo- and poly-(ethylene-glycols) are obtained as a rule[22] by the reaction of the monoalkoxide of the lowest oligo-(ethylene glycol) with the dihalide of the corresponding oligo(ethylene glycol) using alkali metals or their hydroxides as metallating agents. The alkoxide of the lowest glycols was synthesised using sodium hydroxide, distilling away the water formed as a result of the reaction.[23] The yields of poly(ethylene glycols) do not then exceed 60%.

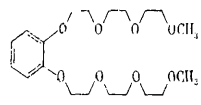
Ethers of oligo(poly)(ethylene glycol) were obtained by alkylating the corresponding alkali metal glycosides with a 1.5–3.0-fold excess of the alkyl halide at 50–90 °C in a solvent or in its absence. They

are freed from salts by filtration or with the aid of ion-exchange resins.[24]

The formation constants of the complexes of podands with metal cations are determined by NMR, IR, and UV spectroscopy, calorimetry, conductimetry, potentiometry, and extraction methods.

2. Oligo(poly)(ethylene glycols) and glymes





The formation of complexes by poly(ethylene glycols) (in which the number of units is $n = 1-8$) with alkaline and alkaline earth metal cations in aprotic solvents has been observed by the NMR method.[25] The formation constants of the complexes of glymes with alkali metal picrates in toluene were measured spectrophotometrically and were compared with data for crown-ethers.[26]

Oligo- and poly-(ethylene glycols) exhibit a fairly strong capacity for ion–dipole interaction with alkali and alkaline earth metal cations in methanol, which is a polar proton-donating solvent.[27–35] The interaction is in general determined by the ionic radius of the cation and the number of glycol units. The relatively strong interaction with large cations is due to the flexibility of the glycol molecule, which is able to assume the energetically favourable *trans*, *gauche*, *trans*-conformation.[36,37] The weak interaction with lithium and sodium cations has been explained[30] by the vigorous solvation of the latter by methanol. However, there exist conductimetric data[38] according to which glycols with $n = 2-4$ form fairly stable complexes with lithium picrate in isopropyl alcohol. Their composition corresponds to metal:ligand = 1:2 and their stability constants are approximately the same ($\lg K_{st} \simeq 2.37-2.51$). It has been shown[39] that in an aprotic solvent (toluene) the lower glycols with $n = 2-4$ are also capable of dissolving alkali and alkaline earth metal mono-, di- and tri-nitrophenoxides. According to NMR data,[28,40] the optimum number of units in the oligo(ethylene glycol) is six in the interaction with sodium and calcium cations, seven in the interaction with potassium, rubidium, caesium, and strontium cations, and five–seven for the barium cation. Glymes having the same number of binding sites as a rule interact somewhat more weakly with sodium and calcium cations in methanol, whereas the monomethyl ethers of the corresponding glycols occupy an intermediate position[28,32] (Table 1). On the other hand, it has been shown for a large series of poly(ethylene glycols) and their mono- and di-methyl ethers by the potentiometric method that,[31,32] with increase in the length of the polyether chain, the stability of the complexes of these ligands with the sodium cations increases (Table 1). Neither maxima, nor the attainment of a plateau, nor a decrease in complex-forming capacity were observed under these conditions. The complex formation constants for poly(ethylene glycols) and their derivatives with molecular weights in the range 1000–14000 ($n = 24-319$) are closer to those for 15-crown-5- and 18-crown-6-ethers. The stability of the sodium complexes on poly(ethylene glycols) and their ethers with a lower molecular weight is lower by 2–3 orders of magnitude than the stability of the complexes of the above macrocyclic compounds.[32,41] The replacement of two methyl end groups by the $C_2H_5OCOCH_2CH_2$ groups has little effect on the complex formation constants. The replacement of the central ethylene glycol unit by the rigid catechol unit is hardly reflected in the complex-forming properties of glymes[27,42] (Table 1). Poly(ethylene glycols) with a 1,2-acenaphthene fragment[43] and glymes with a central ferrocene nucleus[44] are known.

The stability constants of the lanthanide complexes of tetraglyme in propylene carbonate have been determined potentiometrically.[45] The stability of these complexes ($\lg K_{st} = 5.05$) proved to be lower by 1.5 orders of magnitude than in the case of 15-crown-5-ether and higher by an order of magnitude than for the complex of 3-t-butylbenzo-15-crown-5-ethyl.

Not only association with metal cations in solutions but also the formation of crystalline complexes is characteristic of oligo(ethylene glycols) and their dimethyl ethers. Numerous studies have been devoted to the synthesis and crystal structures of the complexes of glymes with transition metal salts.[1] According to the principles of hard and soft acids and bases, the most stable complexes are formed with transition metal cations by analogues of glymes with nitrogen or sulphur atoms or their combinations.[46–54] Crystalline complexes of oligo(ethylene glycols) and their derivatives with lanthanide nitrates and perchlorates have been obtained.[55,56]

Table 1. The logarithms of the stability constants of complexes of poly(ethylene glycol) ligands $R^1O(CH_2CH_2)_nR^2$, certain other ligands, and macrocycles with alkali metal halides in methanol.

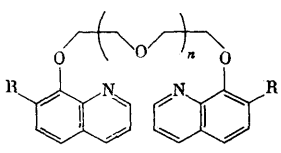
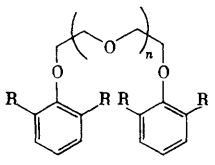
Crystalline complexes of glymes with alkali and alkaline earth metal cations could not be obtained for a long time.[6,57] However, numerous crystalline complexes of not only glymes but also glycols



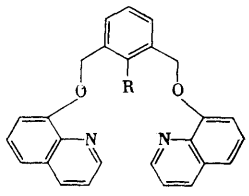
with alkali and alkaline earth metal salts are now known.[25,8–61] These complexes form stoichiometric complexes. They have been synthesised mainly from metal thiocyanates. The interaction of oligo(ethylene glycol) with cations is of the donor–acceptor type and resembles the formation of complexes by macrocyclic polyethers.[6] The structures of certain complexes of oligo(ethylene glycol) have been established by X-ray diffraction.[62–64]

Thus oligo(poly)(ethylene glycol) and their alkyl ethers exhibit complex-forming properties in relation to alkali, alkaline earth, transition, and other metal cations. However, in terms of their complex-forming capacities, these compounds are largely appreciably inferior to macrocyclic polyethers. Only poly(ethylene glycol) and their alkyl ethers with a high molecular weight approach crown-ethers as regards effectiveness.



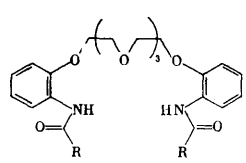
3. Monopodands with rigid end groups

As shown above, only poly(ethylene glycols) with a high molecular weight can to some extent compete with crown ethers (Table 1). According to the concept of end groups proposed by Vögtle,[65] the introduction of aromatic substituents carrying electron-donating centres at the ends of the oligo(ethylene glycol) chain greatly facilitates complex formation. The electron-donating centres of rigid end groups fix the metal cation in the complex formation reaction. The entire ligand molecule can then assume the conformation ensuring the coordination of the electron-donating centres incorporated in the oligo(ethylene glycol) chain. Vögtle and co-workers synthesised in the 1970s a wide variety of aromatic analogues of oligo(ethylene glycol)ethers with rigid groups at one or both ends of the polyether chain.[1] These studies in fact initiated a new stage in the development of podands. There was a transition from solvating solvents to solid complex-forming agents used as solvating additives.

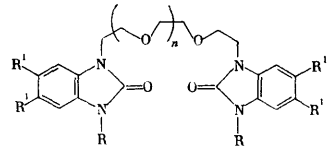


The first representatives of compounds of this type were bis(quinolinyl)oligo-ethers having 8-hydroxyquinoline residues at the ends of the oligo(ethylene glycol) chain structure (I).

(I), $n = 1 \div 6$
$R = H, CH_3$

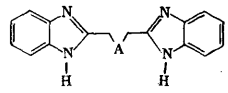


(II), $n = 1 \div 3$
(III), $n = 0 \div 2$



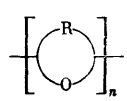
(IV), $R = H, OCH_3, NO_2$

The phenyl, *o*-hydroxy-, *o*-methoxy-, *o*-nitro-, and *o*-ethoxy-carbonyl-phenyl groups [compounds (II)] and the 2,6-dimethoxy-phenyl group [compound (III)] can be used as rigid end groups.[1,42] The flexible glycol units in ligand molecules can be replaced by rigid aromatic units [as in compound (IV)].[57]



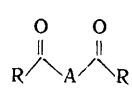
Monopodands with amidophenyl [compound (V)], benzimidazole [compounds (VI) and (VII)], and substituted thiadiazole end groups are known.[65–69] In order to create ligands capable of "becoming adjusted" to various ions, oligo(ethylene glycols) (V), in which R represents a polyether residue with the *o*-nitrophenyl group at the end, were synthesised.[70]

(V)



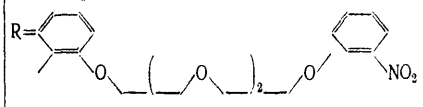
(VI)

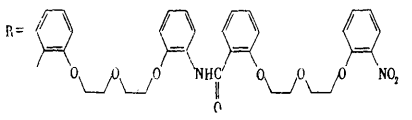
(VII)



(VI), $n = 0, 1$; $R = R^1 = H, CH_3$;
$R = CH_2CO_2C_2H_5$, $C(CH_3)=CH_2$; (VII),
$A = O, OCH_2CH_2O, S, CH_2SCH_2, 1,2\text{-}OC_6H_4O$.

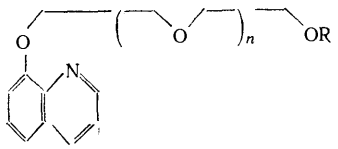
Podands of a special type were constructed exclusively from cyclooxaalkane segments.[71] Some of these ligands bind metal cations in the same way as crown-ethers, but, in contrast to the latter, they form complexes with a large set of cations.





The cation-binding properties of these ligands are manifested particularly clearly when the average length of the segment is sufficient ($n = 6$) and the cyclic units have the *threo*-configuration. Nevertheless, in an experiment on the transport of lithium and potassium picrates from an aqueous solution to chloroform, 18-crown-6 was more effective (63.74%) than the ligand and six tetrahydrofuran units (37.53%) (the amount of the transferred lithium and potassium salt respectively is indicated in brackets).

Ligands with ester groups [compound (VIII)] have been attained by treating alcohols, phenols, and oligo(ethylene glycols) with benzyl chloride, phenylacetyl chloride, or *o*-phenylenedioxydiacetyl chloride.[1,16,72–74]



(VIII), $A = (OCH_2CH_2)_nO$, $(n = 1 \div 5)$; CH_2OCH_2; $o\text{-}CH_2OC_6H_4OCH_2$;
$R = OC_4H_9$, $(OCH_2CH_2)_2OC_4H_9$, $2\text{-}R^1C_6H_4$ ($R^1 = H, OCH_3, NO_2$),
$3.5\text{-}(NO_2)_2C_6H_3$, $2.5\text{-}(CH_3)_2C_6H_3CH_2$

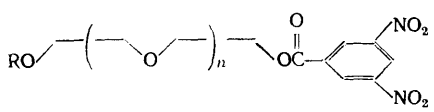
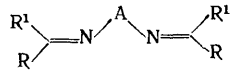
Note. A = spectrophotometry, B = NMR spectroscopy, and C = potentiometry.

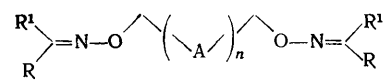


The asymmetric compounds (IX) and (X), containing a combination of different end groups, sometimes a combination of strongly and weakly electron-donating residues, have been synthesised.[42,65,75–79]

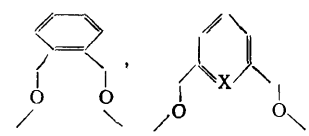
(IX), $n = 1-3$, R = H, CH_3, Ph, 2-CH_3O-4-$CH_3C(O)C_6H_3$, 2-$R^1C_6H_4$ ($R^1 = OCH_3$, CN); 1-naphthyl.



(X)



(XI), $n = 2-4$, R = Ph, 2-$CH_3OC_6H_4$, 4-$CH_3OC_6H_4$, 3,5-$(CH_3O)_2C_6H_3$, 1-naphthyl



The polyethers (XI), in which electron-donating and electron-accepting groups at the ends of the chains are combined, have been described.[80] The interaction of these compounds with metal cations entails an intramolecular charge transfer. The cationic selectivity of the ligands is inferred from the changes in the electronic spectra.

The open-chain multidentate Schiff bases (XII)—derivatives of diketones, diamines, and aromatic aldehydes—as well as ligands (XIII) in which oxime residues serve as the end groups have been synthesised in order to investigate the influence of the ligand structure on the complex formation reaction.[81,82]

(XII), A = $(CH_2)_n$ ($n = 2$, 3); 2,2'-bisphenylene; R = $CH_2C(O)CH_3$, $CH_2C(O)Ph$, 2-HOC_6H_4, 3-HOC_6H_4, 2-hydroxy-1-naphthylene, 2-pyridyl, 5-(α'-picolinyl), R' = H, CH_3.

(XIII), $n = 1 \div 3$, A = CH_2OCH_2, 

X = N, CH, Cl, $COCH_3$, CNO_2;
R = C (O) CH_3, 2-$R^1C_6H_4$ (R^1 = OH, OCH_3), 4-$CH_3OC_6H_4$, 2-R^1-5-$R^2C_6H_3$ (R^1 = H, OH, CH_3, R^2 = H, OCH_3, NO_2); R^1 = H, CH_3.

The reduction of the ligands (XII) having pyridyl or picolinyl groups at the ends led to the formation of the corresponding tetraamine ligands.[83]

The formation of complexes by certain monopodands in solution has been studied.[70,75,80,84–87] Table 2 lists the logarithms of the stability constants of the complexes of ligands with alkali and alkaline earth metal cations in organic solvents. Metal thiocyanates were used for compounds (I), (II), (IX), and (XIX) as well as nigericin and 18-crown-6. The formation of complexes by the ligands (V) with sodium perchlorate was studied. Lithium, magnesium, and calcium nitrates, sodium, potassium, and rubidium thiocyanates, and barium perchlorate were used for compounds (XIV).

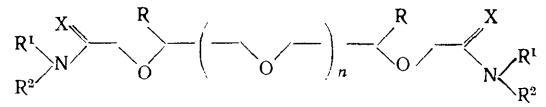
With increase in the strength of the electron-donating properties of the end groups of the ligand (I), (IIa, b), and (IX) with a tetra(ethylene glycol) chain, the stability of the complexes formed by them also increases, as shown by the stability constants. The diphenyl ether of tetra(ethylene glycol) (IIa) exhibits a very weak tendency towards the formation of complexes with alkali metal cations with the exception of potassium. The stability constant of the potassium complex is comparable to those for the ligands (IIb) and (IX). The author suggests that, since the π-electron interaction with the metal ion weakly stabilises the pseudoring, the size of the coordination sphere determines the most favourable conformation of the ethylene glycol chain. On replacement of one phenyl ring by the quinoline group [as in ligand (IX)], the stability constant increases, especially for the large rubidium and caesium cations. The selectivity with respect to potassium is then maintained but is less pronounced than in the case of the ligand (IIa). The introduction of the *o*-nitro-group into the phenyl substituent appreciably improves the complex-forming properties of the podand. The authors explain the preferential formation of complexes by the ligand (IIb) with large cations by the electrostatic repulsion of the *o*-nitrophenyl end groups. The compound with two quinoline end groups [compound (I)] exhibits the most effective complex-forming properties. The partial stacking interaction of the quinoline groups stabilises the pseudocyclic conformation of the complex.[88] Thus the additional electron-donating centres of the rigid end groups play an important role in the stabilisation of the complexes.

Crystalline complexes of monopodands with alkali, alkaline earth, and transition metal ions, lanthanide and actinide ions, and the ammonium cation have been obtained.[1,55,72,77] The complexes are formed as a rule with an exact stoichiometric composition even in the presence of a large excess of one of the components.

Crystalline complexes could not be obtained for analogues of compounds (I)–(III) in which the quinoline and *ortho*-methoxyphenyl end groups are linked by a hydrocarbon chain made up of 8 or 9 carbon atoms.[65,89,90] Crystalline complexes were not obtained for analogues of the ligands (II) with *meta*-methoxy-groups either.[89] Glycols with phenyl end groups [compounds (II)] form crystalline complexes only in the presence of at least five oxygen atoms in the chain.[65,75] Compounds with aromatic bridges, carrying substituents [compound (VII)] also do not afford solid complexes.[57,65]

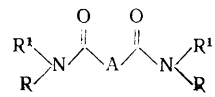
Open-chain multidentate Schiff bases with various rigid end groups [compounds (XII)] are capable of forming crystalline complexes with transition metal ions.[81,82]

Compounds (XIII) with hydroxyphenyl or methoxyphenyl end groups as well as ligands containing diacetyl monoxime units at the ends of the oligo(ethylene glycol) chain have the (*E*)-configuration and do not form crystalline complexes. Some of them can transfer sodium or potassium permanganate to an organic medium.[82]



Data on the structures of the complexes of monopodands with alkali and alkaline earth metal ions have been obtained by X-ray diffraction.[1,88,91–94] Podands, which are open-chain ligands, do not have a ready made cavity in which the metal cation could be accommodated. However, during the complex-formation process they form such a cavity in one way or another. The podand molecule can twist into a ring or a helix around the cation.

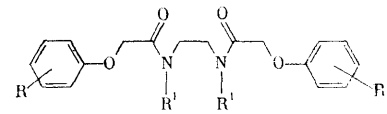
Podands form crystalline complexes with neutral molecules similar to the crown-ether complexes of the "guest–host" type.[17,95–97]



4. Membrane-active monopodands

The ability of podands to interact with metal cations is used in membrane processes. However, there is no direct relation between the effectiveness of the complex-forming agent and its membranotropic properties. Ligands which are effective complex-forming agents for alkali and alkaline earth metal cations are not always good agents for the transfer of ions through membranes. Ion transport can be achieved subject to the condition that the complex formation process is selective and dynamic. It has been shown that[98] there exists a range of optimum stability constants of complexes for the most effective transport of cations. Above and below this range, the rate of transport falls sharply. For a series of alkali and alkaline earth metal cations, ion transport is slight or is altogether absent if the logarithms of the complex formation constants in methanol are less than 3.5–4.0 units.

Open-chain ligands of the amide type with aromatic or hydrocarbon substituents and with a long chain at the nitrogen atom are selective agents transferring alkali and alkaline earth metal ions through liquid membranes [compounds (XIV) and (XV)].[15,16,86,99–105]

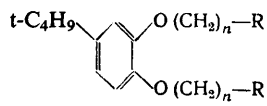


(XIV), $n = 0 \div 2$, X = O, S; $R = R^1 = R^2 = Alk$
$R^1 = (CH_2)_m CO_2Alk$ ($m = 1 \div 11$)

(XV), $A = CH_2OCH_2CH_2OCH_2$, CH_2OCH_2;
$R = CH_3$, $R^1 = C_7H_{15}$, $(CH_2)_5COOC_4H_9$;
$R = R^1 = Alk$, CH_2COOCH_3, Ph

Symmetrical ligands (XVI) containing amide and ether groups are known.[106]

(XVI), R = *o*-NO_2, *o*(*m*)-$NHCOCH_3$, R′ = H, CH_3.



The selectivity of such ionophores with respect to cations is determined mainly by the nature and number of coordination centres and the nature of the substituents at the nitrogen atoms. An increase in the polarity of the ligand molecule leads to the preferential formation of complexes with cations having small radii. The ethylene glycol ligands (XIV) with ω-ethoxycarbonyldecyl, ω-ethoxycarbonylundecyl, or phenyl substituents are selective ligands in relation to alkaline earth metal cations[15,17,86,104] (Tables 2 and 3). The introduction of higher alkyl groups such as hexyl, octyl, decyl, undecyl, and heptadecyl at the nitrogen atom leads to the

Table 3. Potentiometric selectivity coefficients ($K^{pot}_{M_i,M_j}$) of electrodes with liquid membranes containing neutral ligands.

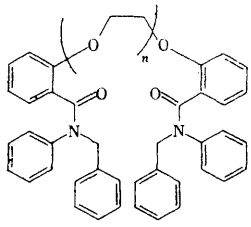
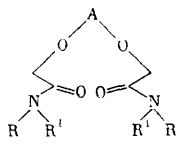
preferential interaction with the calcium cation.[99,106] With increase in lipophilicity, the ionophoric properties of these compounds vanish owing to the kinetically limited exchange reaction between the aqueous phase and the membrane. The dioxadithioamide (XIV) with butyl substituents at the nitrogen atom is a highly selective ionophore for the cadmium ion.[15] The potentiometric selectivity series for this ligand is Cd (1) > Li (1×10^{-3}) > K (8×10^{-4}) > Cs (3×10^{-4}) > Na (1×10^{-4}) = Rb (1×10^{-4}) > Ca (5×10^{-5}) = Ba (5×10^{-5}) > Mg (1.5×10^{-5}). It follows from the data presented that, with the aid of an ion-selective electrode containing a given ligand, it is possible to determine the content of cadmium ions in a mixture with other cations whose concentration is higher by 3–5 orders of magnitude. The *NNN*^{1}*N*^{1}-tetracyclohexyl-substituted diamide (XV) with A = CH_2OCH_2 exhibits selective properties in relation to the calcium ion in the presence of magnesium ions with a separation factor of 10^4.[100]

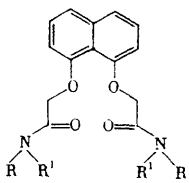


The acyclic polyethers (XVII) with sulphenyl groups are selective in relation to the calcium cation[102] (Table 3).

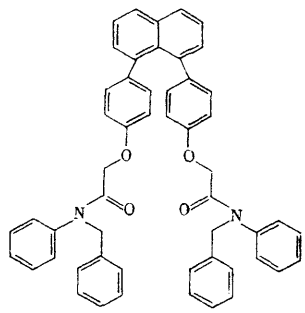


(XVII), R= S(O)C_6H_5, S(O)$CH_2C_6H_5$, S(O)C_8H_{17}-*n*

Ligands with rigid units between the amide end groups [compounds (XVIII)–(XXI)], exhibiting selectivity with respect to sodium in the joint presence of sodium and potassium ions

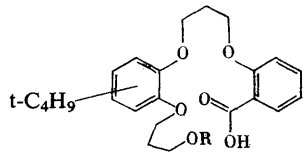


(separation factor of 20), have been obtained.[101,103,107]

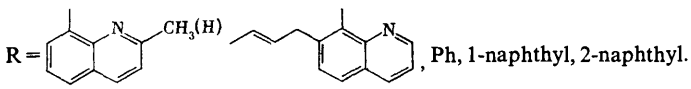


(XVIII)

(XIX)



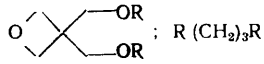
(XX)



(XXI)

(XVIII), $n = 0$, 1; (XIX), A = 1,2-phenylene, 2,2′-bisphenylene, or 2,3-naphthylene; R = cyclo-C_6H_{11} or Ph, $R^1 = (CH_2)_{11}CO_2C_2H_5$, cyclo-$C_6H_{11}$, or $CH_2C_6H_5$; (XX), $R = R^1$ = cyclo-C_6H_{11}; $R^1 = CH_2C_6H_5$.

Few acyclic ligands selective with respect to lithium ions relative to sodium ions are known.[15,108,109] The creation of lipophilic ionophores for lithium is difficult because the lithium ion has the smallest radius among alkali metals and exhibits a very high capacity for hydration. These ligands are mainly acid in character.



R = , Ph, 1-naphthyl, 2-naphthyl.

Ethylene and tri- and tetra-methylene derivatives have been obtained.[87,110] Ligands with two trimethylene units exhibit the highest selectivity with respect to lithium.

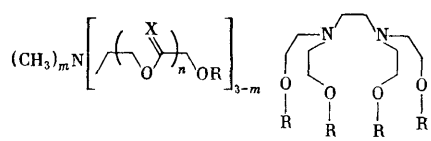
A series of ionophores with a high selectivity with respect to lithium were synthesised recently by the reaction of 3,3-bis(chloromethyl)oxetan or other dihalides with 8-quinolinols.[111]

; R $(CH_2)_3$R

R = 8-quinolinyl.

The selectivity coefficient with respect to lithium relative to sodium is 110 for oxetan with 8-hydroxyquinoline groups. This is the best of the known lithium transferring agents.

The parameters of the membrane electrodes in which neutral complex-forming agents are used are listed in Table 3. The selectivity of the complex formation reaction is influenced by the medium of the membrane. With increase in the polarity of the medium, the stability of the complexes falls.[87]



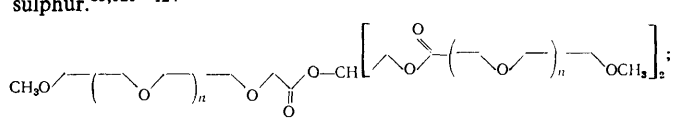
It has been shown by ^{13}C NMR spectroscopy[107,112] that in solution amide ligands of type (XIV) form complexes with ligand : metal = 1 : 1 and 2 : 1 compositions. The amide and ether oxygen atoms and in 1 : 1 complexes the carbonyl groups (as a rule) participate in coordination to the cation. Crystalline complexes with alkaline earth and transition metal salts are stabilised by water molecules.[103]

Monopodands with rigid end groups occupy an intermediate position between oligo(ethylene glycols), on the one hand, and glymes and crown-ethers, on the other, as regards their complex-forming properties. The simplest method of synthesis of monopodands, which does not require a high dilution or the use of a matrix method, and high yields of products are all advantages of the open-chain ligands over their cyclic analogues.

III. Oligo(poly)podands

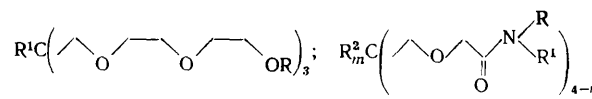
1. Acyclic analogues of cryptands

The high complex-forming capacity of bicyclic nitrogen-containing polyethers — cryptands[113] — stimulated the synthesis of their acyclic analogues,[66,114–119] which are open-chain ligands with several polyether chains diverging from the central nitrogen atom. Ligands of this type are combined under the general name oligo(poly)-podands.[2] The oligo(ethylene glycol) chains of these compounds have different end groups. Ligands based on ethanolamines with hydroxy-end groups are known. The alkyl groups in polypodands can be replaced by rigid phenyl, quinolinyl, and tropolone groups [compounds (XXII)–(XXV)].



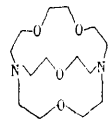
(XXII),(XXIII) (XXIV) (XXV)

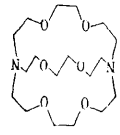
(XXII), $m = 1$, $n = 0$, $X = H_2$; (XXIII), $m = 0$, $n = 0-3$, $X = H_2$, O; (XXII)–(XXIV), R = H, Alk, Ph, 2-$R^1C_6H_4$ ($R^1 = CH_3$, OCH_3, NO_2); 2,6-$(CH_3O)_2C_6H_3$, 8-quinolinyl, 2-tropolonyl; (XXV), $n = 0$, 2, R = Alk, CH_2OCH_3, $CH_2(OCH_2CH_2)_2OC_4H_9$, R^1 = Alk.



Tri- and tetra-podands containing 4-aminomethylene-2,2′-bipyridyl groups as complex-forming fragments have been synthesised.[120]

The central nitrogen atom in compounds of type (XXII)–(XXV) can be replaced by carbon [compounds (XXVI)–(XXVIII)] or sulphur.[85,121–124]





(XXVI), $n = 2$, 3

(XXVII), R = H, Alk, R^1 = Alk (XXVIII), $m = 1$, 2, R = Alk, Ph, R^1 = Alk, R^2 = Alk

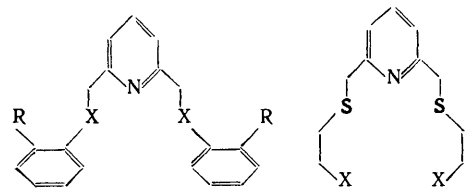
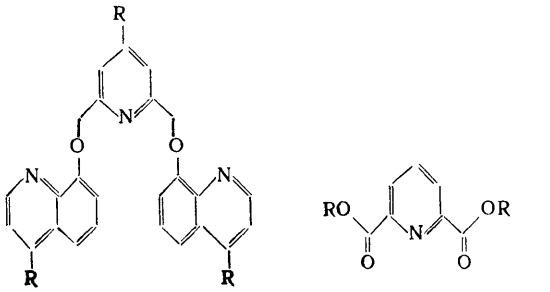
* Metal thiocyanates were used as the salts.

The stability constants of the complexes formed by open-chain cryptands with alkali metal, alkaline earth metal, and lanthanide cations have been determined by spectrophotometric[65,75] and potentiometric[115,125,126] methods. The most stable complexes are formed by these ligands with cations having large radii—sodium, potassium, strontium, and barium. The logarithm of the stability constant of the barium complex of the tripodand (XXIII, n = 1) with 8-hydroxyquinoline end groups is 4 units.[127] The end groups play an appreciable role in complex formation. Thus ligands with tropolone groups form more stable complexes than their analogues with quinolinyl groups (Table 4). For ligands with the same number of units in the oligo(ethylene glycol) chain, the stability of the complexes increases with enhancement of the electron-donating capacity of the end group in the sequence C_6H_5 < 2-$NO_2C_6H_4$ ⩽ CH_3 < 2-$CH_3OC_6H_4$ ⩽ 8-quinolinyl.[127] It is of interest that the tetrapodands (XXIV) form more stable complexes than the analogous dipodands (XXII) but less stable than the tripodands (XXIII). This is attributed to the steric hindrance which may be generated by the four bulky end groups.



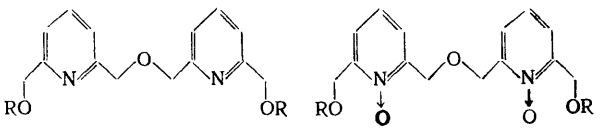
Comparison of the complex-forming properties (Table 4) of the tripodand (XXIII) and the tetraethylene glycol monopodand with quinolinyl end groups [compound (I)], having the same number of electron-donating atoms, shows that in the series of alkali metals this ligand is only slightly superior to the monopodand (I) only in the case of the sodium cation. As regards other di-, tri- and tetrapodands, they all form less stable complexes with alkali metal cations than the monopodand (I). This permits the conclusion that the simpler monopodands are also more effective for alkali metal cations. It is noteworthy that bicyclic nitrogen-containing ligands (cryptands) form very stable complexes with alkali and alkaline earth metal cations[125] but they are difficult to obtain.

In contrast to nitrogen-containing podands, the complex-forming properties of the carbon ligands are much weaker.[85,87] The logarithms of the stability constants of the complexes of the ligands (XXVI, n = 2) and (XXVII) with sodium perchlorate in pyridine are 2.0 and 1.3 respectively.



Numerous crystalline complexes with alkali, alkaline earth, transition, and other metal salts have been obtained for the open-chain cryptand analogues.[51,127–129] The tripodand (XXIII, n = 1), having methylquinolinyl groups, forms crystalline complexes with neutral molecules such as those of urea, 4-nitrophenylhydrazine, and water.[17,130]

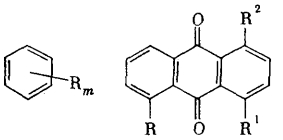
Compounds whose characteristic structural elements are central pyridine and pyridine oxide units constitute a separate group of acyclic multidentate ligands—dipodands. A general method of synthesis of compounds with one pyridine unit [compounds (XXX)–(XXXII)] consists in the interaction of 2,6-di(halogenomethyl)piperidine with phenols or thiols in the presence of a base.[57,84,114,131] Their oxidation with hydrogen peroxide can afford the corresponding *N*-oxides.[132]



Pyridine ligands with ester groups [compound (XXIII)] have been synthesised.[72] Compounds containing two pyridine or pyridine oxide units [compounds (XXXIV) and (XXXV)] are known.[132–134]

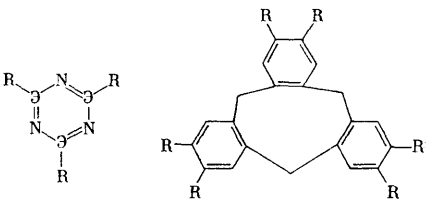
(XXX), X=O, S; R=H, Hal, NO_2, OAlk, CO_2Alk (XXXI), X=H, OH, NH_2

(XXXII), R=H, Cl CH_3O, $N(CH_3)_2$ (XXXIII), R=Alk, $CH_3OCH_2CH_2$, $ClCH_2CH_2$



(XXXIV) (XXXV)

(XXXIV), (XXXV), R=H, OH, OAc, 8-quinolinyl, 8-(2-methylquinolinyl), 2-$H_3COC_6H_4$, 2,6-$(CH_3O)_2C_6H_3$.

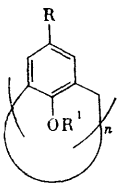


Representatives of compounds of this type form very readily crystalline complexes with alkali, alkaline earth, and heavy metal ions.[15,57,72,84] Ligands with pyridine oxide units exhibit a reduced complex-forming capacity in relation to alkali metal cations.[132] The introduction of pyridine units into the polyether chain imparts rigidity to the ligands, which greatly improves their selectivity in relation to alkali metal cations.[75,84] It is of interest that classical ligands for transition metal ions, such as bipyridyl, terpyridyl, and phenanthroline, form stable complexes with alkali and alkaline earth metal salts.[135,136] Ligands of the ester type (XXXIII) do not form complexes with heavy metals.[72] Certain compounds with pyridine and pyridine oxide units afford crystalline complexes with urea, thiourea, malodinitrile, and water.[132,137]

2. "Octopus-like" polypodands

The number of oligoether chains in polypodands can be increased by combining them with some kind of binding centre. Ligands with six and more multidentate chains whose electron-donating centres consist of oxygen, sulphur, selenium, and nitrogen atoms have been obtained in this way. The benzene ring [compound (XXXVI)] has been used as the binding fragment.[66,138–140] These ligands have been synthesised by treating hexa(bromomethyl)benzene in the presence of a base with the corresponding phenol, thiol, or selenol.

(XXXVI) (XXXVII)



(XXXVIII) (XXXIX)

(XXXVI), $R=CH_2X(CH_2CH_2O)_nAlk(Ph)$, X=O, S, Se, $n=0-3$, $m=2-6$;
(XXXVII), $R=R^1=O(CH_2CH_2O)_3CH_3$, $R^2=H$, $R=R^2=O(CH_2CH_2O)_3CH_3$, $R^1=H$;
(XXXVIII), E=C, P(V), $R=N[(CH_2CH_2O)_4Alk]_2$, $(OCH_2CH_2)_nOAlk$;
(XXXIX), $R=(OCH_2CH_2)_3Alk$.

Treatment of 1,5- or 1,8-dichloroanthraquinone with the monomethyl ether of triethylene glycol in the presence of sodium hydride led to the synthesis of podands[141] with the anthraquinone unit [compounds (XXXVII)].

Polyether chains may be present in triazine, or cyclophosphazene [compound (XXXVIII)] and cycloveratrylene [compound (XXXIX)] systems.[123,142] Oligoethylene glycol units can be combined in a matrix made up of cyclic oligomers obtained under the conditions of base catalysis.[143,144] Multidentate chains are introduced into these compounds instead of hydroxy-groups via the tosylates of the corresponding cellosolves.[145–148] Such macrocyclic compounds have been called spherands or calixarenes (XL).

(XL)

(XL), $n=4, 6, 8$; R = H, Alk; R^1 = Alk, $(CH_2CH_2O)_nAlk$.

Since the complex-forming capacity of these ligands is mainly determined by the structure of the side chains carrying electron-donating centres, they can be regarded as a variety of podands.

The complex-forming capacity of the ligands (XXXVI)–(XXXIX) decreases with decrease in the number of their binding sites. Compounds (XXXVI) with six short chains, terminating in thiophenyl or thiocycloalkyl groups, do not interact with metal ions but do form inclusion compounds with neutral organic molecules.[140,149] "Octopus-like" polypodands whose chains terminate in rigid electron-donating groups form crystalline complexes with derivatives of urea, pyridine, amides, nitriles, diglyme, and crown-ethers.[150] Trisubstituted benzenes do not give rise to inclusion compounds.[139] Crystalline complexes of calcium and barium thiocyanates with a trisubstituted benzene having amide groups have been isolated.[66]

Polypodands based on a cyclic oligomeric matrix — the spherands (XL) — exhibit complex-forming properties in relation to alkali metal cations. The formation of complexes by these compounds with lithium and sodium perchlorates and picrates has been observed by NMR spectroscopy.[151,152] The sodium complex of a calix[4]arene ($R^1 = CH_3$), in which the sodium ion interacts with all four oxygen atoms, has been isolated.[153] The high selectivity of spherands based on anisole with $n = 6$ in relation to lithium and sodium ions in the series of alkali metals has been demonstrated.[154] There exist data indicating a high extracting capacity of spherands with $n = 6$ and 2-methoxy-groups in aromatic rings in relation to guanidine.[147] However, the complex-forming capacity of these compounds is appreciably inferior to that of its analogues in which R^1 consists of ester or amide groups.[148,153,155–157]

Thus the increase in the number of binding sites in the ligands achieved by including additional oligoethylene glycol chains in the podand molecules constitutes yet another way of enhancing their complex-forming properties. The replacement of electron-donating ether oxygen atoms by other heteroatoms or groups with an enhanced nucleophilicity also makes it possible to improve the complex-forming capacity of podands. However, the increase in the complexity of the structure of such ligands makes them less available.

IV. Applications of neutral acyclic complex-forming agents

At the present time, the number of studies devoted to the practical use of podands is small but these compounds have considerable potential possibilities for applications in chemistry and technology. The most thoroughly investigated field in which podands are used is phase transfer catalysis, which constitutes a promising method for effecting chemical reactions.[9–12] Oligo- and poly-ethylene glycols accelerate the nucleophilic substitution reactions at a carbon atom between anions and water-insoluble neutral organic compounds in two-phase systems. Systems incorporating different potassium salts, carboxylic and sulphonic acid chlorides, and alkyl halides have been investigated[29,32,76,158–165] (Table 5). The effectiveness of oligo- and poly-ethylene glycols and their ethers increases with increase in concentration and in the molecular weight of the ligand. Polyethylene glycols with a molecular weight in excess of 400 can be used as phase transfer catalysts (Table 5) whose activity depends on the specific system. The increase in the rates of nucleophilic reactions in the presence of polyethylene glycols has been explained by the cooperative solvation of alkali metal cations by oxygen atoms leading to the activation of the anions.[166]

The use of monopodands based on catechol with quinolinyl end groups as phase transfer catalysts increases by a factor greater than 2–3 the yield of the product (Table 5). The application of "octopus-like" ligands (XXXVI) in reactions of alkyl halides with potassium cyanide increases the yield by a factor of 10.[167] Derivatives of 1,3,5-triazine (XXXVIII) proved to be effective catalysts in any anionic reactions.[123,142] The activity of these ligands increases with increase in the number of binding sites of the oligoethylene glycol chains and also in the length of the alkyl groups at their ends. The catalytic properties of triazine ligands resemble those of tetraalkylphosphonium salts. Comparison of the catalytic activities of crown-ethers, cryptands, glymes, and poly(ethylene glycols) showed that the cryptand 222 is the most effective. Decaglyme is not inferior to 18-crown-6-ether and tetrabutylammonium perchlorate, while the effectiveness of poly(ethylene glycol) (Carbowax-20M) is similar to that of dibenzo-18-crown-6 [163] (Table 6).

Table 5. Yields of products in certain nucleophilic substitution reactions using podands as phase transfer catalysts.

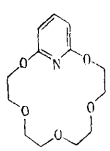
The catalytic activity of glymes with $n = 1-4$, 10, 21 in the aminolysis of esters[168] is higher than that of crown ethers with the same number of oxygen atoms (Table 6).



Poly(ethylene glycols) and their ethers can be used as phase transfer catalysts in *N*- and *S*-alkylation reactions.[169–172]

The tripodands (XXIII, $n = 1$, $m = 0$, $X = H_2$) constitute a new class of phase transfer catalyst in a solid–liquid system.[173]

An important field where podands can be used is extraction. Thus poly(ethylene glycols) containing more than 23 units exhibit strong extracting properties in relation to potassium, which are comparable to those of 18-crown-6[174,175] (Table 7). Poly(ethylene glycols) with molecular weights ranging from 400 to 4000 are more effective extractants for lead and strontium than dibenzo-18-crown-6

and dibenzo-24-crown-8 but are inferior to 18-crown-6.[176,177] Oligo(ethylene glycols) with nitrile end groups can be used to extract alkali metals from boracic water in the presence of a large excess of alkaline earth elements.[178] The sulphur-containing podand 1,12-di-2-thienyl-2,5,8,11-tetrathiadodecane extracts silver ions quantitatively from dilute aqueous solutions.[179] An asymmetric monopodand, at the ends of oligo(ethylene glycol) chain (n = 11) of which there are substituted aryl groups, extracts alkali and alkaline earth metal cations with formation of 1 : 1 complexes.[180]

Table 6. Catalytic activities of different catalysts.

Another possible application of podands is association with their ability to solubilise salts in solvents of low polarity. This makes it possible to carry out a whole series of reactions under homogeneous conditions in non-polar media. The nitrogen-containing tripodands (XXIII) transfer potassium permanganate and alkali metal picrates to the organic phase much more readily than dibenzo-18-crown-6.[118] In the presence of poly(ethylene glycols), it is possible to dissolve metallic potassium in benzene[181] and potassium permanganate in organic solvents[182] and alkenes can be oxidised by potassium permanganate.[160,161]

A series of applications of podands are associated with their membrane activity. Some of them can be used in cation-sensitive membrane electrodes specific to alkali and alkaline earth metal ions (Table 3). Thus the complex $Ba(BPh_4)_2$ with nonyl phenyl ether of poly(ethylene glycol) (n = 30) is used in a barium-sensitive electrode.[15] The neutral acyclic diamide [XIV, n = 0, X = O, R = CH_3, R^1 = $(CH_2)_{10}COOC_2H_5$] is used in a calcium-selective electrode.[5] Many polydentate ligands, such as the oxa-analogues of diamides of sebacic and azelaic acids (XIV), are known. They are selective transferring agents for lithium and sodium ions in the presence of protons and calcium, strontium, and barium ions.[15,17,86,99–101,104,108,183] A study of the membrane activity of tetraethylene glycol with quinoline end groups showed that this ligand transfers ammonium cations selectively through a liquid membrane in the presence of alkali metal ions.[184] The tripodand (XXIII, n = 1, X = H_2) exhibited effective and specific transport properties for silver ions.[119] Podands of the type of spherands (XL) can also be used in membranes.[144]

Table 7. The extracting capacities of certain ligands in relation to alkali metal salts in the H_2O-CH_2Cl system.[174,175]

The great variety of structures of the neutral acyclic polydentate ligands makes it possible to vary their selectivity with respect to cations within wide limits. The ability of podands to form complexes with neutral organic molecules can be of pharmacological interest, particularly in the case of urea. Furthermore, the availability of these compounds makes them promising complex-forming agents which can find applications in various branches of chemistry and the national economy.

- - - o 0 o - - -

During the preparation of the manuscript for the press, new studies on the synthesis of podands, on their complex-forming properties, and on their applications in organic synthesis were published. Thus these questions are discussed in a book.[185] New Schiff bases capable of combining in complexes transition and alkali or alkaline earth metal ions simultaneously have been synthesised.[186–188] Podands with imidazole units have been obtained and their transport properties in relation to alkali metals and ammonium cations have been investigated.[189–191] The synthesis

of chiral podands derived from carbohydrates[192–194] and from the 2,3:6,7-dibenzobicyclo[3.3.1]nona-2,6-diene fragment[195] are being developed. A chiral ligand coordinating the lithium cation has been put forward.[196] New tripodands of type (XXVII) are selective complex-forming agents in relation to cations with a small radius.[197] Monopodands with different end groups have been obtained by opening epoxide rings in the diglycidyl ethers of poly(ethylene glycols).[198] The synthesis of new sulphonamide podands,[199] compounds based on 1,4-benzoquinone,[200] cyclohexane,[201] and a phosphazene matrix,[202] and open-chain analogues of benzo-crown-ethers[203] have been described. A report has been published on the synthesis of a new class of branched polyethers—the so-called dendrimers and arboreols.[204] Dendrimers have a spherical steric oligomeric structure. Some of them (arboreols) contain a large number of terminal OH groups.

The study of the formation of complexes by oligo- and poly-(ethylene glycols) and their ethers with alkali metal and ammonium ions[205,206] and of tripodands having a central carbon atom with the Fe^{3+} and Ga^{3+} cations by various physicochemical methods is being continued.[207] The structures of complexes of tetraglyme with the oxonium cation,[208] of penta- and hexa-glymes with calcium, strontium, and barium thiocyanates,[209,210] and of triethylene glycol with lanthanide chlorides[211] have been established. The complex-forming properties of their sulphur-containing analogues are being investigated.[212,213] The interaction of amino-derivatives of oligo-(ethylene glycol) with alkaline earth and transition metal ions is being studied vigorously.[214–219] New data have been obtained on the behaviour in solution of polyamines with various end groups in the presence of transition and other metal cations.[220–223] Their complexes with the lanthanides[224] and rhenium(V)[225] have been synthesised and characterised.

The properties of podands of different types as phase transfer catalysts are being investigated. In the presence of poly(ethylene glycols) and their derivatives, nucleophilic substitution reactions,[226–228] oxidation reactions of cyclic ketones,[229] and the dissolution of metals[230] are accelerated and oxidation-reduction processes are promoted.[231] There are new examples of the use of ligands of type (XXXVIII)[232] and of calixarenes (XL) with oligoethylene chains in the formation reactions of ethers.[233]

The extracting properties of hydrophobic dialkyl ethers of oligo-(ethylene glycols)[234] and of their analogues with electron-donating S and N atoms[235–237] in relation to alkali and alkaline earth metal cations are being investigated in relation to the similar properties of macrocyclic ligands.

Podands which could be used as electrode-active components of membranes of ion-selective electrodes are being sought.[238–239]

A method of synthesis of solid complexes of organomagnesium compounds with tris(dioxa-3,6-heptyl)amine has been described.[240] The first photophysical study of complexes of podands, coronands, and cryptands in photoelectron transfer reactions has been noted.[241]

The use of microorganism cells immobilised in carrageenan for the synthesis of organic substances

T I Davidenko, G I Bondarenko
Bogatskii Physicochemical Institute, Academy of Sciences of the Ukrainian SSR, Odessa

ABSTRACT. The present state of the problem of the use of immobilised cells of microorganisms for the synthesis of organic substances is analysed. The physicochemical properties of carrageenan and the characteristic features of the immobilisation of microorganism cells in carrageenan are examined and a systematic account is given of the results of treating carrageenan and the immobilised preparations with stabilising reagents.

The bibliography includes 112 references.

CONTENTS

III. The use of microorganism cells immobilised in carrageenan for the synthesis of organic substances 302

I. Introduction

It is generally known that all biochemical reactions in nature and approximately 80% of industrial processes are effected by virtue of catalysis. Biocatalysts (especially the cells of microorganisms), which possess a high catalytic activity, specificity, and the ability to effect processes at the usual temperatures, have become the objects of close attention in recent years. The advances in the chemistry of steroids, where biocatalysts are widely used, clearly demonstrated their advantages over chemical reactions. However, the use of biocatalysts for the specific transformation of organic substances has been significantly restricted by the specific features of experiments involving them, by the fact that particular classes of compounds were studied, by their lability, by the difficulty of separating them from the reaction products, and in many cases by their low economic effectiveness because they are used only once.

The employment of biocatalysts developed extensively following the discovery of the possibility of immobilising them, as a result of which during the last 10–15 years they have been deliberately prepared in the form immobilised on a carrier or in a gel.[1–15] Special attention has been devoted to the creation of highly effective biocatalysts based on immobilised cells of microorganisms.

About 100 laboratory procedures for the use of immobilised microorganism cells in fine organic synthesis for the preparation of organic acids, solvents, methane, hydrogen, ethanol, enzymes, antibiotics, aminoacids, pantothenic acid, glutathione, and steroids and also for the purification of waste water are now known. Several of these processes have found practical application on an industrial scale: in the preparation of aspartic and malic acids, of lysine from caprolactam, and of leucine and ethanol.[16] A factory manufacturing phenylalanine with an annual output of 600 tonnes has been working in the USA since 1984, while in Japan not only aminoacids but also ethanol and acrylonitrile are produced with the aid of immobilised microorganism cells.

This can be explained by a whole series of advantages of the use of immobilised cells compared with the use of immobilised enzymes and ordinary cells.[17–19]

1. The lack of expenditure on the isolation and purification of enzymes.
2. The higher stability and activity compared with immobilised enzymes and free cells, since immobilisation protects the cells against external influences.
3. The reduction of expenditure on the isolation and purification of reaction products, since they are isolated from the biomass and the metabolic products of the microorganism.
4. The possibility of creating continuous automated manufacturing processes in which inhibition by both the substrate and by the reaction products is diminished.
5. The ability of polyenzyme systems to function for a long time and the regeneration of cofactors.
6. The possibility of reducing the volumes of the reactions effected by immobilised cells compared with free cells.
7. The improvement of the possibility of monitoring the reaction.
8. The likely significant diminution of the contamination of the environment.
9. A significant decrease in the cost of the reaction products.

However, despite the increasing number of publications on the immobilisation of microorganism cells, the results of this process and of the use of immobilised microorganism cells are unpredictable and are determined primarily by the ability of the cell to retain on immobilisation and in the immobilised state a specific activity and to operate stably in a specific process. They depend on a very large variety of factors. Virtually all the existing immobilisation methods have definite advantages and disadvantages. The commonest method involves incorporation in a gel. It ensures repeated use without the separation of the cells and repeated sowing of the medium, a high concentration of cells in the carrier, and the employment of highly productive reactors, but it is also distinguished by an increased resistance to mass transfer, because the substrates and products have to diffuse into the gel and out of the gel. The

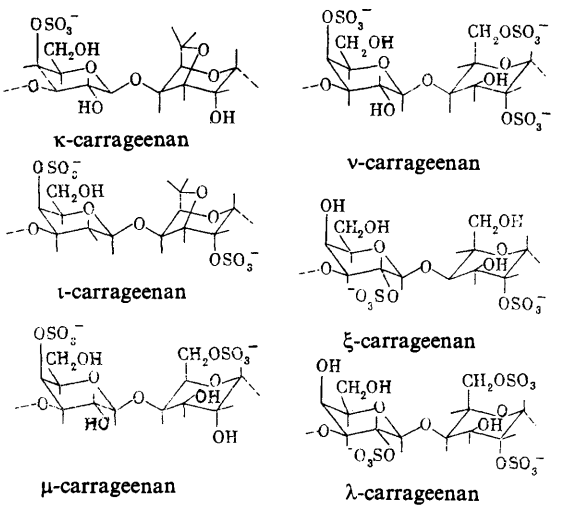
physicochemical parameters of the microenvironment (for example, the pH) in the carrier particles can differ significantly from the corresponding characteristics of the medium outside the particles. Microorganisms can elute from the particles in the course of the experiments. This method is also restricted by the need to use substrates with a low molecular weight. The growth of the microorganism cells and the formation of CO_2 frequently disrupt the gel.

For incorporation in a gel, the most suitable physicochemical properties are those of polyacrylamide gel,[4,20,21] polyurethane,[3] collagen,[6] agar,[7,8] gelatine,[9,10] cellulose,[22] alginates,[12,23] and carrageenan.[13–15]

The characteristic features of polyacrylamide gel are the difficulty of obtaining regular spherical particles and the low activity of the resulting preparations, usually owing to the toxic effect on the cell by the gel components: acrylamide, *NN'*-methylenebisacrylamide, and $K_2S_2O_8$. However, the effective mechanical properties and the possibility of regulating the gel network together with data on the multiplication of the cells in the gel have aroused an increased interest by investigators in the use of this gel.[1,16,24–26]

The advantage of agar consists in the rapid growth of new cells in the gel, but its disadvantage is its brittleness. The strength of the gel rapidly falls as cells grow and CO_2 is formed.[27]

The problem with calcium alginate is its instability in the presence of phosphate buffers and certain cations: Mg^{2+}, K^+.[28,29] The gel breaks down fully in 0.1 M K_2HPO_4/KH_2PO_4 solution after 15 min,[29] while phosphate is one of the principal nutrients of microbial cells.



So far there is no universal carrier for the immobilisation of microorganism cells nor is there a universal immobilisation method. However, analysis of data on immobilisation in carrageenan showed that its practical use is promising, since the Japanese research laboratory of the Tanabe Seiyaku Company reported the successful incorporation of more than 50 microorganisms in this gel.

In the present review, an attempt is made to survey and describe systematically the results of experimental studies which make it possible to justify the employment of carrageenan as an immobilisation matrix, as well as data on the use of microorganisms immobilised in carrageenan for the synthesis of organic substances.

II. Physicochemical properties of carrageenan and the characteristic features of the immobilisation of microorganism cells in carrageenan

Carrageenans are sulphate derivatives of polysaccharides obtained from the red seaweed *Phodophyceae* and *Ginartinaceae*.[30] The annual manufacture of carrageenans is on a scale not smaller than that of agar. The principal consumer of these polysaccharides is the food industry, where they are used as gel-forming agents for the preparation of confectionery, milk products, dough, and meat preserves.[17,30,31]

In contrast to agar, carrageenans include, apart from D-galactose, also 3,6-anhydro-α-D-galactose and a much larger amount (20–30%) of sulphate groups[32–34] (MW = 100 000–800 000). The limiting structures of carrageenans can be represented by the following formulae:

The real polysaccharides of the carrageenan group can be very close to one of the formulae represented in the scheme above, but they are usually molecular hybrids—combinations of two and more limiting structures. Only biopolymers characterised by the limiting "kappa" and "iota" structures are able to form gels. Their characteristic feature is the formation of thermoreversible gels under certain conditions. This distinguishes the polysaccharides of the carrageenan group from neutral gel-forming polysaccharides of the agarose group.

According to modern ideas, on extraction of carrageenans from seaweed, their ordered structure breaks down with formation in aqueous solutions of a disordered conformation, which is subsequently restored on formation of a gel and drying until solid. Intermolecular packed structures close to or identical to those *in vivo* are then formed.[35]

The specific nature of the ordered structure depends on the geometry of the covalent bonds between each residue of the primary structure.[36] Carrageenans are made up of six-membered (pyranose) rings having a geometry of the chair type[37] and connected by equatorial bonds. However, the bonds between the carbohydrate rings are not parallel, which leads to the formation of a "bend" and the ordered conformation is in this case helical.[35] X-Ray diffraction data and the temperature dependence of the optical rotation confirm the formation of a double helix for κ- and ι-carrageenans. Despite the existence of hypotheses which tend to explain the nature of intermolecular interactions inducing gel formation, at the present time this question has not been finally resolved. Studies designed to elucidate the causes of the increased stability of carrageenan gels have demonstrated the necessity for the optimum ratio of the length of blocks of the regular structure which are capable of association (and their optimum distribution along the polymer chain) to the length of sections with a masked regularity.[38] The gel formation inducing agents are metal ions—Ca^{2+}, K^+, and Rb^+ for ι-carrageenan and K^+ for κ-carrageenan (other ions exhibit a weaker effect). An X-ray diffraction study of the Ca^{2+} salt of ι-carrageenan showed that in this case the double helix is more extended than in agarose, as a result of which it has no central cavity in which bound water could be inserted. The factor stabilising the ordered structure is the hydrogen bond between the O(2) and O(6) residues of D-galactose in different chains. Since the only unsubstituted hydroxy-groups are present here, the double helix

of ι-carrageenan is structurally completely bound by hydrogen bonds, in contrast to κ-carrageenan. Bearing in mind the large distance between the chains, it is unlikely that the van der Waals forces play an important role in the formation of the helix. However, the ionic interaction is undoubtedly important, each Ca^{2+} ion being linked to two sulphate groups in different helices.[39]

On substitution of Ca^{2+} by univalent cations, a similar structure can be formed in κ-carrageenan, in which there is no second sulphate group. Direct spectroscopic proof of the interaction of K^+ with the sulphate groups of κ-carrageenan has been obtained from the IR spectra of the solutions.[35] Whereas under severe conditions the formation of the double helix in κ- and ι-carrageenans can be induced by ions which are bound non-specifically, under normal conditions cations of suitable size are necessary. The reason for such cationic specificity is evidently the conformational and configurational features of ι- and κ-carrageenans, although it has still not been fully explained.

The polysaccharides from the Black Sea phyllophora can also be classified as carrageenans, since their carbohydrate skeleton is made up of only β-D-galactose and 3,6-anhydro-α-D-galactose joined by alternating α(1) → (3) and β(1) → (4) bonds. The contents of suphate groups in the polysaccharides vary significantly as a function of the phyllophora species (from 17.8 to 27.2%). The different contents of 3,6-anhydro-α-D-glactose and different distributions of the sulphate groups along the carbohydrate skeleton are also characteristic of polysaccharides from different phyllophora species.[38,40] Carrageenans from different phyllophora species show significant differences in their structure and therefore also differ in their physicochemical properties.[41,42]

Table 1. Immobilisation of enzymes and microorganism cells in carrageenans.[48]

Enzymes and microogranisms	Enzyme activity[a]		Yield, %
	before immobilisation	after immobilisation	
Aminoacylase	20	10	50.0
Aspartase	650	300	46.2
Fumarase	360	260	61.5
E. coli (aspartase)	65000[b]	30400	46.8
B. ammoniagenes (fumarase)	9670[c]	5800[d]	60.0
S. phaeochromogenes (glucose isomerase)	7910	4280	54.1

[a] Enzyme: μmol h^{-1} (mg of protein)$^{-1}$; microbial cells: μmol h^{-1} (g of cells)$^{-1}$.
[b] After ultrasonic treatment.
[c] In the presence of bile extract.
[d] After treatment with bile extract.

Microorganism cells are immobilised in κ- and ι-carrageenans, κ-carrageenan being used most often.[13,14,17,18] In studies on the immobilisation of cells in the USSR, carrageenans are little used and Soviet carrageenans are hardly used at all.[43–47] This is incomprehensible, since this method is carried out under mild conditions, simple, and is susceptible to the development of an appropriate technology. The immobilisation of cells in carrageenans consists of virtually two stages: the preparation of a suspension of cells in the carrageenan solution and gel formation. If the stability of the gel is inadequate, the gel has to be stabilised.

It is noteworthy that microbial cells are mixed with the carrageenan solution at 40 °C, the cells of different microorganisms being stable in carrageenan at this temperature; the mixture formed is readily converted into a gel. The gel does not break down during the enzymic reaction, withstands variations in pH, and the size of the pores within the given gel is sufficiently small for enzymes and cells not to leave the gel matrix, while low-molecular-weight substrates and products readily pass through it. Both enzymes and whole cells with a high degree of retention of the initial activity (40–60%) can be immobilised by this method (Table 1).[27,48]

The possibility of immobilising various microorganisms in carrageenan has been demonstrated:[27] *Achromobacter aquatilis, A. liquidum, Aspergillus oryzae, A. niger, Bacillus megatherium, B. subtilis, B. succinium, Brevibacterium ammoniagenes, B. flavum, Corynebacterium glutamicum, Erwinia herbicola, Escherichia coli, Gluconobacter melanogenus, Lactobacillus bulgaris, Micrococcus ureae, Penicillium vinaceum, Proteus vulgaris, Pseudomonas aeruginosa, P. dacunhae, P. putidum, Sarcina lutea, Streptomyces griseus, S. phaeochoromogenes, Serratia marcescens.*

Table 2. Influence of the conditions in the formation of the κ-carrageenan gel on the strength of the latter.[48]

Gel formation conditions	Strength of gel
Cooling to 10 °C	+
Treatment with NH_4Cl	+++
Treatment with metal salts: LiCl, NaCl;	–
KCl, RbCl, CsCl;	++++
$MgCl_2$, $SrCl_2$, $MnCl_2$, $FeCl_2$, $BaCl_2$	
$CoCl_2$, $NiCl_2$, $CuCl_2$, $ZnCl_2$, $Pb(CH_3COO)_2$	++
Treatment with amines:	
Methylenediamine, ethylenediamine, p-phenylenediamine, δ-hydroxy-L-lysine, L-lysine hydroxamate, L-histidine hydroxamate *S*-2-aminoethyl-L-cysteine;	+++
hexamethylenediamine, octamethylenediamine, 4-guanidinobutylamine, histidine, DL-histidine hydrazide;	++++
L-ornithine, L-lysine, L-tryptophan hydroxamate	++
Treatment with organic solvents miscible with water: methanol, ethanol, acetone	++

Note. Gel strength: (+), load from 100 to 200 g cm^{-2}; (++), 200 to 500 g cm^{-2}; (+++), 500–1000 g cm^{-2}; (++++), 1000 to 1500 g cm^{-2}; (–), no gel formation.

In order to obtain more stable gels with incorporated *S. phaeochromogenes* cells, a study was made of the influence of the conditions for the formation of the carrageenan gel (Table 2) and in addition also of the influence of the anions of the potassium salts: CO_3^{2-}, SO_4^{2-}, $S_2O_8^{2-}$, PO_4^{3-}, $P_2O_7^{4-}$, $Al_2(SO_4)_4^{2-}$, $Fe(CN)_6^{3-}$, CH_3COO^-, and $^-OOC-COO^-$. Significant differences between the stabilities of

the gels were not found when different anions were used, whereas it follows from the data in Table 2 that more stable gels are formed on contact with KCl, RbCl, CsCl, hexamethylenediamine, octamethylenediamine, agmatine, histamine, and DL-histidine hydrazide. Unfortunately these data do not make it possible to understand the reason for such stabilisation of the gel, nor do they reflect the influence of the gel formation conditions on the retention of the initial activity of the microorganism cells. However, there is no doubt that the stability of the carrageenan gel can be regulated, which encouraged investigators in the search for a more technological solution for specific processes with participation of microorganism cells immobilised in carrageenan.

Thus treatment with stabilising reagents (hexamethylenediamine and glutaraldehyde) made it possible to increase the operational stability (half life) of *E. coli* cells (aspartase activity) in carrageenan from 50 days for untreated cells to 686 days,[48] in the case of *S. phaeochromogenes* (glucose isomerase activity) the increase was from 150 to 260 days, while treatment with gelatine and glutaraldehyde resulted in an increase to 532 days.[49]

Treatment of κ-carrageenan with amines, proposed by Takata et al.,[50] increased the operational stability of immobilised *Brevibacterium flavum* cells without reducing the initial activity.

Interesting results were obtained following the addition of polycationic polymers: the fumarase activity of *B. flavum* cells immobilised in κ-carrageenan in the presence of 0.15% of polyethyleneimine was distinguished by an increased stability to changes in external factors and temperature.[51]

Bearing in mind that the melting points of κ-carrageenan gels with immobilised *B. flavum* cells are higher by 20% in the presence of polyethyleneimine than without it, it has been suggested that there is an interaction between κ-carrageenan, polyethyleneimine and *B. flavum*.

An increase in the porosity of the carrageenan matrix was noted after the introduction into carrageenan of tripotassium phosphate,[52] which improved the diffusion of nutrient substances into the gel and the mechanical properties of the latter.

Treatment of carrageenan with epichlorohydrin and with alkylenepolyamide when *Aspergillus niger* and *Saccharomyces cerevisiae* are incorporated also leads to positive results.[53]

A new method for the stabilisation of microorganism cells immobilised in carrageenan, consisting in the treatment of the gels with polyacrylamide, is noteworthy. For this purpose, acrylamide, *NN'*-methylenebisacrylamide, and β-dimethylaminopropionitrile are allowed to diffuse into the carrageenan grains with subsequent polarisation.[54]

It has also been suggested that the cells be subjected to an activating treatment with NaCl solutions before being incorporated in carrageenan.[55]

Reliable physicochemical evidence which would account for the results of studies on the stabilisation of the carrageenan gel and for the increased operational stability of the immobilised cells as a result of the chemical modification of the gel has not so far been obtained. As a result of the large number of criteria which must be taken into account and the unpredictable behaviour of a specific enzyme activity on immobilisation, it is at present difficult to give preference to any stabilising procedure. The attempts to resort to the ζ-potential of the cells in order to select the immobilisation conditions have also not been convincing.[56] However, it is clear that the gel of the carrageenan matrix plays an important role in the stabilisation of the incorporated microorganism cells, while dissolved carrageenan has no stabilising effect.[31]

Numerous studies have demonstrated that cells can grow in a carrageenan gel at the same rate as the free cells, while in many instances their growth is better: in the stationary growth phase, the number of live yeast cells in the gel was ten times greater compared with the native cells.[57] Similar results have been obtained for *S. carlsbergensis*[58] and *E. coli*.[14] The growth is concentrated in the surface layer of the gel, as a result of which the diffusional effects are slight, oxygen and the nutrient medium are satisfactorily consumed, and there is no growth in the centres of the grains.

Since one of the main purposes of immobilisation is to obtain the maximum possible concentration of the cells in the carrier, the possibility of cell growth in the carrageenan matrix is used to activate them and to accumulate the biomass.[59]

The results achieved in the preparation of biocatalysts from microbial cells immobilised in κ-carrageenan made it possible to use them for a whole series of processes.[13,17,48,60–66]

III. The use of microorganism cells immobilised in carrageenan for the synthesis of organic substances

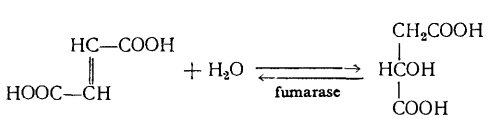
Synthesis of L-aspartic acid. In 1969, the Tanabe Seiyaku Company (Japan) achieved the separation of the racemates of DL-aminoacids on an industrial scale using immobilised aminoacylase.[67] This was the first case of the use of immobilised enzymes. Later an attempt was made to obtain L-aspartic acid using immobilised aspartase.[68] However, the low productivity of this process led to the use of cells of *E. coli* incorporated in a polyacrylamide gel,[21] which made it possible to obtain pure L-aspartic acid in 95% yield. Taking into account the partial inactivation of the aspartase activity of the cells, the polyacrylamide matrix was replaced by κ-carrageenan.[21] In order to increase the operational stability, the immobilised cells were treated with gluaraldehyde and hexamethylenediamine. If the productivity of the cells immobilised in polyacrylamide gel is adopted as 100%, then that of the cells incorporated in κ-carrageenan was 1500%, which made it possible to initiate in 1978 the industrial manufacture of L-aspartic acid. It is of interest to note that, despite the fact that the strength of the Japanese κ-carrageenan is 650 g cm^{-2} while that of the Soviet preparation is 170 g cm^{-2}, after use for 400 h the activity of the gels immobilised in κ-carrageenan was 43 mmol g^{-1}, while that of the cells immobilised in the Soviet carrageenan was 54 mmol g^{-1}.[45]

Synthesis of L-alanine. Alanine is a valuable aminoacid required for use in medicine and the food industry. Cells of *B. dacunhae* immobilised in carrageenan were used for its continuous preparation. They were treated with glutaraldehyde,[59,63,66] and incubated at pH 4.75 and 30 °C for 1 h in order to suppress the alanine racemase and proteolytic activities. The half-inactivation time of such catalysts exceeded 280 days.

L-Alanine can be obtained more efficiently from ammonium fumarate by using in the same reactor *E. coli* cells immobilised in κ-carrageenan, which exhibit aspartase activity, and *P. dacunhae* cells with L-aspartate β-decarboxylase activity, also immobilised in κ-carrageenan.[62,64,69]

Synthesis of glutamic acid. Cells of *Corynebacterium glutamicum* ATCC 13058, immobilised in κ-carrageenan worked stably for 30 days in a flow type fermenter with a productivity of 1.08 g of glutamate per litre per hour.[61]

Synthesis of L-arginine. The reactor with *Serratia marcescens* cells immobilised in κ-carrageenan made it possible to obtain 10 mg ml^{-1} of L-arginine at pH 6.5 for a long time.[70] When pure oxygen was passed through the reactor, the immobilised cells grew five times more vigorously than the free cells.



Synthesis of L-tryptophan. When *E. coli* cells with L-tryptophan synthetase activity were immobilised in polyacrylamide, alginate, and carrageenan gels, the highest activity (80% relative to the free cells) was observed for carrageenan.[71]

Synthesis of L-tyrosine. Comparison of the immobilised *Citrobacter freundii* cells with tyrosine phenol lyase activity immobilised in gelatine, agar, agar-agar, and κ-carrageenan gels indicated that the cells in κ-carrageenan were the most effective. The activity of 2–4% gels was 80% of the activity of the free cells.[72,73]

Synthesis of L-isoleucine. In order to manufacture L-isoleucine from D-threonine, a study was made of a system with growing *Serratia marcescens Ar130-1* cells immobilised in carrageenan. The reactor with the immobilised cells worked stably for 30 days with a productivity of 0.5 mg of L-isoleucine per gram of gel per hour.[14]

Synthesis of *N*-acetyl-L-methionine. *E. carotovora* cells immobilised in carrageenan cross-linked by glutaraldehyde and hexamethylenediamine catalysed the stereoselective hydrolysis of the amide of *N*-acetyl-*D*L-methionine with formation of *N*-acetyl-L-methionine and the retention of 61% of the initial activity. The optical purity was 100%.[74]

Synthesis of *L*-malic acid. In an attempt to improve the synthesis of L-malic acid, widely used in the pharmaceutical industry, from fumaric acid, the cells of *B. ammoniagenes* and *B. flavum* were immobilised in carrageenan.

If the productivity of *B. ammoniagenes* immobilised in polyacrylamide gel was adopted as 100%, then that of *B. flavum* incorporated in carrageenan was 897%.[48,75–77] It has been shown in a number of studies[51,78,79] that the thermal and operational stability of *B. flavum* cells increases sharply when they are immobilised in κ-carrageenan in the presence of polyethyleneimine and Chinese gallotannin: in the former case, the half-inactivation time for the biocatalyst increased by a factor greater than two,[79] while in the latter the increase was by a factor of 3.[78]

Manufacture of antibiotics. The cells of *Penicillium chrysogenum* immobilised in κ-carrageenan have been used to obtain penicillin *G*.[80] The cells of *Tolypocladium inflatum* synthesised cyclosporin *A*, which possesses immunodepressant properties and is used in organ transplantation.[81] The cells of *Penicillium urticae* have been used for the semicontinuous and continuous manufacture of the antibiotic patulin from glucose,[82–84] while the cells of *Xanthomonas citri*, immobilised in κ-carrageenan and treated with hexamethylenediamine and glutaraldehyde, were used to synthesise cephalexin.[85] The existence of two phases separated in time was established in the synthesis of penicillin *G* and cyclosporin *A*: cell growth (on incubation in a nutrient medium) and the formation of antibiotics.

The manufacture of ethanol. In view of the growth of the price of petroleum, there has been a growth of interest recently in the study of alcoholic fermentation by yeast immobilised in κ-carrageenan.[86–89] Problems concerning the increase in the number of cells in the gel and in the concentration of glucose and the stabilisation of gel grains with the immobilised cells have been investigated in detail.[57,58,90–92] Yeast cells immobilised in carrageenan grow more effectively than the free cells,[93] the productivity of immobilised growing cells of *Saccharomyces carlsbergensis* is three times higher than that of homogeneous cells,[58] and continuous formation of ethanol from molasses (more than 110 mg ml^{-1}) has been observed over a period of six months. The gel particles used for the manufacture of ethanol were strengthened with polyacrylamide,[54,94] by alkylenepolyamide,[53] and also by introducing tripotassium phosphate into carrageenan.[52] Metabolic inhibitors have also been introduced: dinitrophenol, azide, and arsenate.[95] Studies in which more productive microorganisms are sought are being continued.[8] When sugars were fermented by *Bacillus butacone* immobilised in carrageenan, a solution containing a butanol : acetone : ethanol = 8 : 1 : 1 mixture, which is promising for the manufacture of diesel fuel, was obtained.[96]

Synthesis of sugars. The continuous preparation of D-fructose from D-glucose has been achieved using *Streptomyces phaeochromogenes* cells immobilised in κ-carrageenan.[15] The glucose isomerase activity and the stability of the cells immobilised in carrageenan approached those for cells immobilised in polyacrylamide gel, their half-life in a column reactor amounting to 289 days.[31]

The cells of *Acetobacter* suboxydans, immobilised in a κ-carrageenan gel, produced L-sorbose in an amount of 0.2 mg per ml of the gel per hour in a stable process over a period of 15 days.[14]

The *Gluconobacter suboxydans* cells with a high alcohol dehydrogenase activity were immobilised by incorporation in a κ-carrageenan gel and were used for the biotransformation of D-arabitol into D-xylulose in 80% yield. They were activated by preliminary incubation in a nutrient medium containing D-glucose.[97]

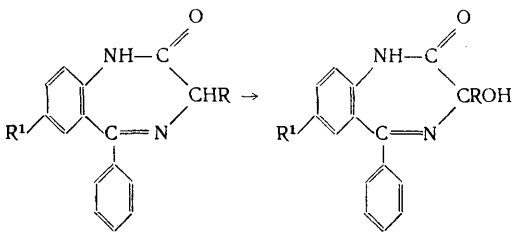
Synthesis of acetic acid. The cells of *Acetobacter aceti* immobilised in κ-carrageenan manufactured acetic acid in a stable process for a long time at a rate of 22.5 mg per ml of the gel per hour.[98,99] *Clostridium thermoaceticum* immobilised in κ-carrageenan has been used for the same purpose.[100]

Synthesis of citric acid. *Aspergillus niger* cells immobilised in 2% carrageenan in the presence of 1% NaCl and 1% ethylenediaminetetraacetic acid, with subsequent dispersion in a mineral oil at 40 °C and treatment with polyethyleneimine or alkylenepolyamide, were used. The yield of citric acid was 5.2–5.3 g per 20 ml of the reaction mixture in 31 days.[53,101]

Synthesis of steroids and alkaloids. Steroids were one of the first substrates transformed with the aid of immobilised cells.[102] There are few instances of the employment of carrageenan for the

immobilisation of microorganisms transforming steroids and alkaloids:[103,104] these include the incorporation of *Arthrobacter globiformis* cells, which possess 3-ketosteroid Δ'-dehydrogenase activity, and the cells of *Claviceps purpurea*, which effect the biosynthesis of pharmaceutically important alkaloids: xanthoclavine, agroclavine, elymoclavine, and ergometrine. Comparison of the results with data for immobilisation in polyacrylamide gel and calcium alginate enabled the authors to conclude that they are preferable to carrageenan in the synthesis of steroids.[1]

Synthesis of vitamin B_{12}. Comparative study of the synthesis of vitamin B_{12} by cells of *Propionibacterium shermanii, P. freundenreichii subsp. shermanii ATCC 13673, Propionibacterium sp. ar I AKU 1251,* and *N_3 AKU 1253,* and *Propionibacterium sp. IAM 1714* immobilised in κ-carrageenan, calcium alginate, agar, and urethane photopolymers indicated that the cells immobilised in the urethane photopolymer have an advantage.[105]



Synthesis of enzymes. The advantages of the manufacture of enzymes using immobilised cells consist in the possibility of maintaining a high concentration of cells and their rapid separation. However, the rate of diffusion of nutrients to the polymer matrix, especially of oxygen in aerobic cultures, significantly limits the growth and metabolic activity of the cells in the gel. When *Bacillus amyloliquefaciens* cells were incorporated in carrageenan, the respiratory activity and the rate of growth were suppressed to 1/2 and 1/6 respectively, but the formation of *L*-amylase was virtually similar to that by free cells.[106]

Synthesis of dihydroxyacetone. Dihydroxyacetone, which is used in the cosmetic and food industry, was synthesised from glycerol by *Gluconobacter melangenes* cells immoblised in κ-carrageenan.[107]

Synthesis of butane-2,3-diol. The cells of *Enterobacter aerogenes* immobilised in κ-carrageenan manufactured butane-2,3-diol stably over a period of ten days. On activation by incubation in a nutrient medium, the cells multiplied by a factor of 200.[108]

Reduction of nitro-compounds. The nitroreductase activity of *E. coli* cells immobilised in phyllophorin from the broad-jointed form of phyllophora and in carrageenan from spherical phyllophora is higher than that of cells immobilised in κ-carrageenan. The maximum retention of nitroreductase activity is then observed for the cells: carrageenan gel = 1:10 weight ratio. The study of the granulation conditions showed that the optimum granulation is in toluene at 0–4 °C. The gel grains with immobilised cells having a high nitroreductase activity are strengthened in 0.3–0.4 M KCl solutions. The study of the modification of the immobilised preparations by amines (ammonia, hexamethylenediamine, hydrazine hydrate, diethylamine, and triethylamine), glutaraldehyde, and titanium tetrachloride showed that the nitroreductase activity of the preparations treated with titanium tetrachloride is at the level of the unmodified preparations, while on treatment with diethylamine and triethylamine, it increases to 122 and 145% respectively. The reduction of nitro-derivatives of benzo-2,1,3-thiadiazoles and 1,4-benzodiazepin-2-ones as well as substituted nitrobenzenes with formation of the corresponding amines under column conditions has been achieved with the aid of the biocatalysts obtained.[109,110]

Synthesis of 3-hydroxy-1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones. It has been shown[111] that the transformation of 1,2-dihydro-3*H*-1,4-benzodiazepin-2-ones by actinomycetes immobilised in carrageenan results in the formation, in 65% yield relative to the activity of the free cells, of optically active (+)3-hydroxy-derivatives having a more pronounced activity in their antagonism to corazole and in potentiating hexenal sleep compared with the racemate.

The achievement of this process makes it possible to obtain the corresponding 3-hydroxy-derivatives in one stage instead of the six stages required in the chemical method of synthesis.

Purification of waste water. The cells of *Clostridium pasteurianum* and *Alcaligenes eutropis*, catalysing the reaction $HT + H_2O \rightleftarrows H_2 + HTO$, were immobilised in calcium alginate and κ-carrageenan in order to remove tritium from water contaminated by radioactive impurities (for example, from the cooling systems of atomic power stations).[112] In terms of its catalytic activity, 10 g of cells immobilised in carrageenan is equivalent to 1 g of a platinum catalyst, but, in contrast to the latter, the former catalysts are cheap, can be readily obtained in a large amount, and are active in the liquid phase.

The reduction of the acidity of materials for the production of wine. It has been shown that the cells of *Leuconostoc oenos* immobilised in carrageenan effect the 100% transformation of L-malic acid into L-lactic acid in the treatment designed to reduce the acidity of materials for wine making. Thus, summarising the data presented above, one may conclude that microorganism cells immobilised in carrageenan are likely to be useful in the synthesis of organic compounds.

—o0o—

In conclusion, the authors express the hope that this review will serve as a starting point for further study of the possibilities of using immobilised microorganism cells in organic synthesis, which will help create new biocatalysts for practical employment. Here attention should be concentrated on the study of Soviet produced carrageenan and its applicability in the immobilisation of cells. Evidently, more detailed investigation of the immobilisation and of the mechanism of gel formation will permit a deeper understanding of the nature of the intermolecular interactions in polysaccharide complexes and of the causes of the increased stability of microorganism cells immobilised in carrageenan and will help to develop more effective methods of synthesis of organic substances for the needs of industry, agriculture, and medicine.

Organic and molecular ferromagnetics: advances and problems

A L Buchachenko
Institute of Chemical Physics, USSR Academy of Sciences, Moscow

ABSTRACT. The possible ways of creating organic and molecular ferromagnetics are analysed and the principles of the molecular design of these magnetic substances are examined. Comparison of the theoretical predictions with the experimental results permits certain conclusions and predictions as to whether different ways of creating molecular ferromagnetics are realistic.

The bibliography includes 68 references.

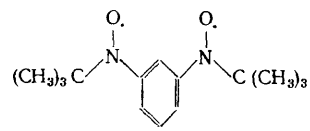
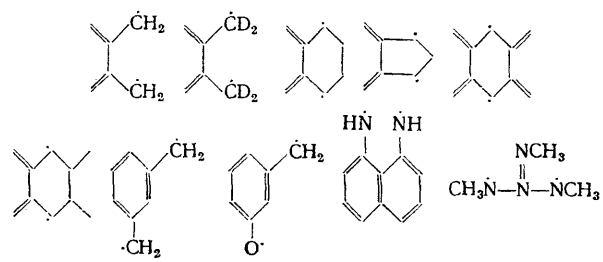
I. Introduction



All the known ferromagnetics are made up of metal atoms with unfilled *d* or *f* electron shells, i.e. on the basis of the spin magnetism of the inner *d* and *f* electrons. The question arises whether it is possible to create ferromagnetics on the basis of *s* and *p* electrons. Experiment shows that alkali and alkaline earth metals, in the atoms of which the spin is due to the outer *s* or *p* electrons, are non-magnetic. Organic radicals with outer *p* electrons also lose their paramagnetism at low temperatures and become non-magnetic. Solid oxygen is diamagnetic, although the oxygen molecule is paramagnetic. These phenomena have a common cause: for all the atoms with *d* and *f* electrons, the exchange interaction (i.e. that part of the Coulombic, electrostatic interaction of electrons which depends on their spin) is positive and arranges the electron spins on the neighbouring atoms in parallel (in a ferromagnetic manner); for atoms with *s* and *p* electrons, the interatomic (or intermolecular) exchange interaction is negative and gives rise to an antiparallel arrangement of the electron spins on the neighbouring atoms or molecules (in an antiferromagnetic manner).

The problem of "organic" ferromagnetism is how to obviate this difficulty and how to find ways and procedures whereby a ferromagnetic arrangement of electrons in organic paramagnetic molecules, i.e. in molecules with *s* or *p* unpaired electrons, can be achieved. An organic ferromagnetic is understood to be a magnetic material made up of purely organic paramagnetic molecules; this is a special albeit important case of a molecular ferromagnetic in which paramagnetic molecules may contain metal atoms (for example, organometallic molecules).

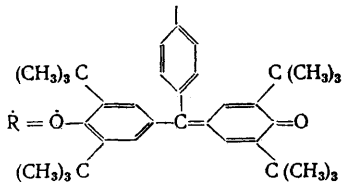
In order to create an organic or molecular ferromagnetic, two main conditions are essential. Firstly, a building material is needed, namely organic multispin paramagnetic molecules (high-spin molecules are best) with a high density of oriented spins in order to ensure an appreciable magnetisation. Secondly, a procedure is needed (and this is the main problem) for organising these molecules in the crystal or in an amorphous body in such a way that a ferromagnetic arrangement of the spins is achieved.



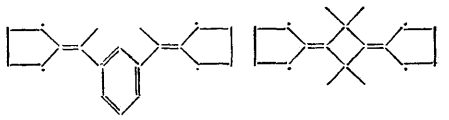
II. Multispin and high-spin molecules

The construction of high-spin molecules is the first part of the problem and here most progress has been achieved. Independently of organic ferromagnetics and long before their appearance, major advances were made in the chemistry and physics of stable organic radicals and an enormous number of such radicals with a wide variety of structures belonging to various chemical classes were synthesised.[1] Many stable biradicals were created on their basis, most of them being of the low-spin type ($S = 0$, singlet ground state). However, among them there are many high-spin species ($S = 1$, triplet ground state), for example:

as well as certain bisphenoxyls, bisverdazyls, etc. (for further details, see Buchachenko and Vasserman[1]).

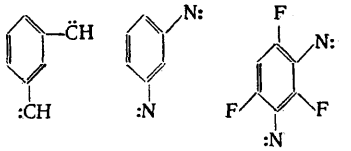


In connection with organoferromagnetics, interest in these biradicals was revived from new standpoints: the question arose how the unpaired electrons within the molecule interact, under what conditions is their exchange interaction positive and arranges the spin in a ferromagnetic manner (triplet ground state), and when is it negative (zero overall spin, singlet ground state). Many simplest biradicals of the type

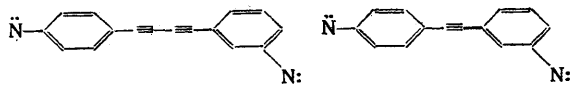


were synthesised (they were obtained at low temperatures mainly by the photolysis of the corresponding azo-compounds and other precursors). It has been demonstrated convincingly (by EPR) that

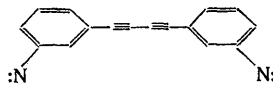
they all have the spin $S = 1$ and a triplet ground state and that the dipole interaction of their electrons amounts to $D \simeq 0.01-0.03$ cm^{-1}.[2,3] We may note that it has been frequently predicted quantum-chemically that these biradicals have singlet ground states and the idea actually arose that Hund's rule breaks down for such π-conjugated non-Kekulé structures. However, experiment confirmed the presence of the triplet state—in agreement with the simplest valence bond scheme.



High-spin molecules based on polyradicals, carbenes, and polycarbenes are also known. For example, the stable tetraphenoxyl $C\dot{R}_4$, i.e.



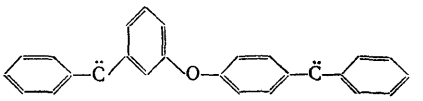
has a quintet ground state ($S = 2$, exchange interaction with $J \simeq 600$ MHz);[4] the tetraradicals



also have a quintet ground state ($S = 2$).[5] In the bicarbenes and binitrenes

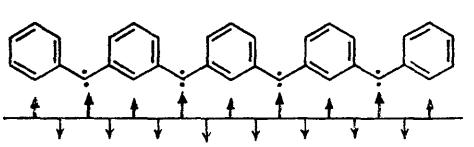
the exchange interaction of the electrons is positive and stabilises the high-spin (quintet) state.[3] In binitrenes, compounds with acetylenic and diacetylenic bridges of the *para—meta* type (one nitrogen atom is in the *para*-position and the other is in the *meta*-position relative to the substituent), i.e.

the high-spin state with $S = 2$ is also stabilised, but if the combination of the nitrenes is of the *meta—meta* type, i.e.



the low-spin singlet state (with $S = 0$) is stabilised.[6] (One can predict that a compound of the *para—para* type will also stabilise the singlet state.)

By combining carbene systems, it is likewise possible to obtain both high-spin and low-spin molecules. Thus the combination of two diphenylcarbenes (each of these fragments is in a high-spin triplet state) of the *para—para* type, i.e.

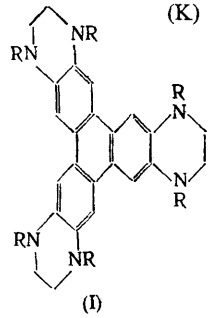


stabilises the low-spin singlet state ($S = 0$), i.e. the exchange interaction of the electrons arranges the electron spins within the molecule in an antiferromagnetic manner. A combination of the *meta—meta* type stabilises the low-spin state, but a combination of the *meta—para* type, i.e.

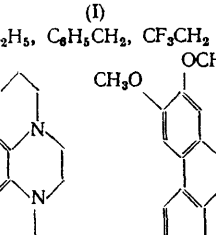
stabilises the high-spin ($S = 2$) quintet state of this dicarbene.[7]

We shall now turn to the problem when and under what conditions and in what systems is the exchange interaction positive and stabilises the high-spin electronic state of the molecule and when is it negative and even a molecule with a large number of unpaired electrons is in a low-spin state; in the former case, a ferromagnetic arrangement of all the spins in the molecule takes place, while in the latter case an antiferromagnetic arrangement obtains. It would seem that it is possible to count on an exact answer from the rigorous quantum chemistry of the molecule, but theory frequently falls out of step (we have seen an example above), the reason being that spin molecules are systems with open shells for which an exact calculation is unreliable (particularly when one is dealing with small differences between the energies of spin states). There is, however, a simple way of predicting the sign of the exchange interaction and the spin state based on a simple valence bond scheme and on the ideas of spin delocalisation and spin polarisation; as a result of delocalisation, the spin is distributed throughout the molecule and spin polarisation induces a negative spin density at certain points within the molecule, i.e. the local spin at these points is oriented against the total spin. (An example is provided by the allyl radical $\dot{C}H_2 - CH = CH_2$ in which the spin is distributed on the terminal carbon atoms and its density is positive—~0.45 on each; however, on the central atom the spin polarisation induces a negative spin density of about −0.01.) If the spin densities of both electrons in a two-spin system (for example in a π-electron biradical) alternate rigorously as regards sign (in other words, the two spins are separated by a negative spin density), a triplet state obtains, but if the distribution of spins in the molecule results in the appearance of direct spin contacts (i.e. there are no regions of negative spin density between them), the low-spin state is stabilised.

We shall demonstrate this rule in relation to the polycarbene synthesised by Iwamura and co-workers:[8,9]



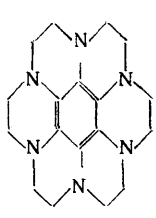
Five phenyl rings are linked by carbene fragments at the *meta*-positions. The signs of the spin densities are indicated below: the bold arrows denote positively oriented spins and the thin arrows denote negatively oriented spins. Evidently the signs of the local spins alternate rigorously: the contacts between positive spins are formed solely via atoms with negative spins. Clearly a high-spin state of this carbene should be achieved. Indeed the spin of this molecule is $S = 4$ and the ground state has the nonet multiplicity ($2S + 1 = 9$)[8] and all 8 unpaired electrons are arranged in a ferromagnetic manner.



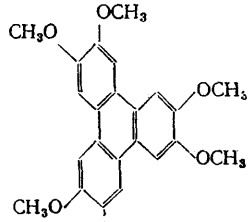
Using this rule, it is easy to demonstrate that the binitrenes or bicarbenes discussed above are high-spin species when they are combined via a *meta—para* junction but are low-spin species if the

combination of the nitrene or carbene groups is of the *meta—meta* or *para—para* type. These predictions agree with experiment. It is easy to extend these rules to any case of polyconjugated multispin systems and to predict when the multispin system will be in a high-spin state and when it will be in a low-spin state. In other words, it is possible to show when the multispin molecule will be "ferromagnetic" and when it will be antiferromagnetic (strictly speaking these concepts are macroscopic and refer to a crystal or an amorphous body, but we shall sometimes apply them also to molecules). These features and rules are useful in predicting the synthesis of high-spin molecules as potential precursors of organic ferromagnetics.

Among the high-spin molecules, charged species are known. Thus the cyclopentadienyl and pentachlorocyclodienyl cations are triplet species,[10,11] although their stability is low. On the other hand, the pentaphenylcyclopentadienyl cation has a singlet ground state.[12] Interest in organic ferromagnetics has stimulated the search for and the synthesis of stable high-spin cations. The hexachlorobenzene cation is known to be in a triplet state but is unstable.[13] Breslow and co-workers[14,15] synthesised aromatic hexazo-molecules of the type

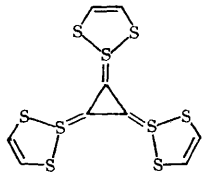


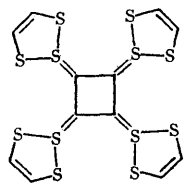
(K)



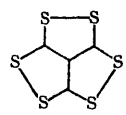
(I)

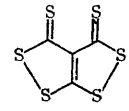
R=C_2H_5, $C_6H_5CH_2$, CF_3CH_2 etc.



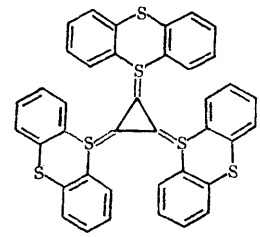


(II)

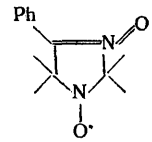


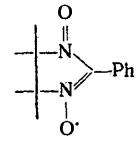


(III)



whose dications are stable triplet species. Compound (I, R = C_2H_5) has been designated[14,15] by the abbreviation HET (hexaethyltriphenylene) and compound (II) has been designated by HOC (we shall make use of these abbreviations below). Chiang et al.[16] synthesised hexamethoxytriphenylene (HMT) (III), whose dication is also a stable triplet species. Readily oxidised sulphur-containing molecules of the type

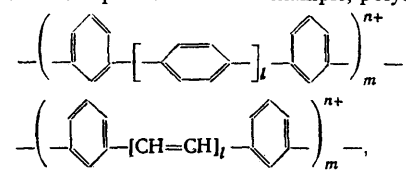




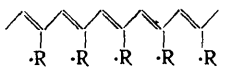
have been synthesised and it is expected (and the first confirmations have already been obtained) that their dications are high-spin triplet species, which may be suitable for the creation of organic ferromagnetics.[17,18]

Mixed organometallic high-spin complexes have already been synthesised. Thus in the complex $3Cu(hfacac)_2.2L$, where hfacac = perfluorinated acetylacetonate and L = nitroxyl, with two complex-forming groups, i.e.

the exchange interaction of the electrons of the metal ion and the ligand is positive (~ 12 cm^{-1}) and stabilises the high-spin state of the complex.[19]

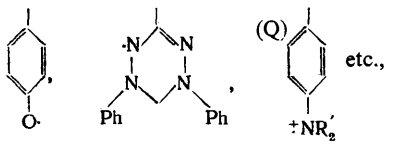


In the complex of the nitroxyl radical



with $Mn(hfacac)_2$, six Mn^{2+} ions and six ligand radicals form a ring with ferromagnetic intramolecular interaction of all the unpaired electrons; it stabilises the high-spin state of the complex with the total spin $S = 6(5/2) + 6(1/2) = 18$.[20,21] In the complex $[Cr_4S(O_2CCH_3)_8(H_2O)_4]_2.H_2O$, the Cr_4S cluster has a spin $S = 6$ in the ground state.[22] In the complexes $Mn_{12}O_{12}(O_2CCPh)_{16}(H_2O)_4$ and $Mn_{12}O_{12}(O_2CCH_3)_{16}(H_2O)_4$, the cluster nucleus contains the Mn_4^{4+} and Mn_8^{3+} ions with a positive exchange interaction, which stabilises the high-spin state of the cluster with a spin $S = 14$.[23]

Finally, macromolecules (linear or two-dimensional networks) with a high density of paramagnetic centres are multispin species with the largest number of spins. Spin-labelled polymers with a high concentration of paramagnetic labels—nitroxyl and verdazyl radicals (in the limit one paramagnetic fragment per monomer unit)—have been synthesised. These polymers and their magnetic properties are described below in Section V; organometallic multispin macromolecules and the magnetic properties of the corresponding polymers are discussed in Section VI.



For the purpose of synthesis, hypothetical structures have been proposed for linear multispin molecules in which a "ferromagnetic" exchange interaction of the spins and the stabilisation of the high-spin state are expected.[24–26] For example, polycations of the type

in which the blocks comprising poly-*p*-phenylenes or polyenes are joined via phenyl rings, should be high-spin species. The polyene macromolecules

where R are the radical fragments

should also be ferromagnetic (according to the predictions formulated above). On the basis of the same principle, it is possible to suggest a series of other "ferromagnetic" macromolecules for synthesis.

Mataga[27] was the first to propose the hypothetical structures of high-spin planar two-dimensional hydrocarbons made up of triplet diphenylcarbenes combined into a single conjugated system via the *meta*-positions in the phenyl rings (actually the polycarbene with a spin $S = 4$, examined above, is a fragment of such a structure and has been synthesised in accordance with Mataga's principle). Another two-dimensional structure, which he also proposed, is based on the triphenylmethyl radical as the main structural element; the interaction of unpaired electrons is effected via the *meta*-positions in the phenyl rings. Mataga regarded both systems as potential precursors of organic ferromagnetics.[27]

A number of interesting linear and two-dimensional conjugated systems have been proposed by Ovchinnikov;[24] they include a hypothetical boron-substituted graphite—a high-spin system which is a possible precursor of a ferromagnetic. The same worker proposed a general theory and formulated a simple rule which permits the prediction of the spin of such polyconjugated high-spin molecules. The experimental data concerning the construction of organic ferromagnetic polymers on the basis of multispin molecules will be examined below (see Section V).

III. The ideas and theoretical foundations of "organic" ferromagnetism

In organic spin molecules, the unpaired electrons populate the highest of the occupied molecular orbitals and are localised on the "surface" of electron shells. The exchange intermolecular interaction of unpaired electrons is therefore negative and antiferromagnetic, orienting the spins of neighbouring, even high-spin molecules in opposition to one another. The key problem in "organic" ferromagnetism is how to overcome this difficulty; the attainment of ferromagnetism through antiferromagnetic interactions—this is the paradoxical formulation of the problem.

Several ideas for the resolution of this paradox have been proposed and we shall now consider them. The first was formulated as early as 1963 by McConnel.[28]

As we have already seen above, two mechanisms are significant in the propagation of the spin in the molecule—spin delocalisation and spin polarisation. The interplay of these mechanisms make the distribution of the unpaired electrons in a spin molecule non-uniform not only in magnitude but also as regards sign: at certain points within the molecule, the spin density is negative, i.e. a local (partial) spin is oriented in opposition to the total spin of the unpaired electron. The regions of positive spin density in the molecule frequently alternate with regions of negative spin density. Suppose that in a crystal or glass the spin molecules can be organised in a remarkable manner such that the regions of positive spin density of one molecule are in contact with the regions of negative spin density of another and this order is retained throughout the given volume. It is readily seen that in such a system the negative intermolecular (interspin) exchange generates two spin subsystems: positive spin densities oriented on one side and negative spin densities oriented on the opposite side (as in a ferromagnetic). However, the positive spin densities are much greater than the negative spin densities and the overall spin corresponds to a ferromagnetic arrangement, the substance becoming an organic ferromagnetic.

We shall refer to this route to ferromagnetics as the McConnell mechanism and the regions of intermolecular contact in which the positive spin densities of one molecule are combined with the negative spin densities of another will be referred to as the McConnell islands. There is direct evidence for this mechanism—both theoretical and experimental. A calculation has been carried out for the allyl + methyl radical pair in terms of the geometry illustrated in Fig. 1.[29] In case *a*, the methyl radical approaches one of the terminal carbon atoms of the allyl radical (the π-electron spin density on these atoms is positive and amounts to ~0.49 on each), while in case *b* the methyl radical approaches the central atom (the spin density on this atom is negative, amounting to −0.01). The McConnell island arises only in case *b*—this is the region where the positive spin density of the methyl radical is in contact with the negative density of the central atom of the allyl radical.

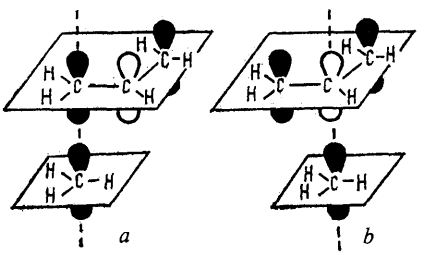


Figure 1. Schematic illustration of the disposition of the partners in the allyl + methyl radical pair: (*a*) the methyl group approaches the terminal carbon atom of the allyl group, where the spin density is positive; (*b*) the methyl group approaches the central atom of the allyl group with a negative spin density.[29]

Fig. 2 presents the dependence of the exchange interaction on the distance between the radicals. In case *a*, the exchange interaction is negative, there is a singlet ground state, and the orientation of the spins in the pair is antiferromagnetic. In case *b* (where there is a McConnell island), the exchange interaction is positive and stabilises the high-spin triplet state, while the orientation of the spins in the pair corresponds to ferromagnetism. The simplicity of the system for which the calculation has been made and the identity of the approximations used in the calculations in both versions, *a* and *b*, as well as the independence of the principal results of the method of calculation ensure the reliability of the result.

Another piece of evidence is experimental.[30]

Substituents (triplet phenylcarbenes) were introduced into the phenyl rings of paracyclophanes fixed in space by chemical—CH_2CH_2—bridges in different positions within the ring: pseudo-*ortho*- (Fig. 3*a*), pseudo-*meta*- (Fig. 3*b*), and pseudo-*para*- (Fig. 3*c*). It is readily seen that, when the unpaired π-electron migrates from the carbene to the phenyl ring of the cyclophane, the distribution of its spin density in the pseudo-*ortho*- and pseudo-*para*-structures creates McConnell islands—spin densities of one sign in one phenyl ring of cyclophane are located opposite the spin densities of the reverse sign in another ring. In the pseudo-*meta*-structure, there are no McConnell islands—spin densities of the same sign are in contact. In exact correspondence to this property, the arrangement of spins in the pseudo-*ortho*- and pseudo-*para*-structures is ferromagnetic (quintet ground state, $S = 2$), while in the pseudo-*meta*-structure it is antiferromagnetic (singlet ground state). These results were also reproduced for cyclophanes whose phenyl rings are fixed in space by—$CH_2CH_2CH_2$—bridges.[6]

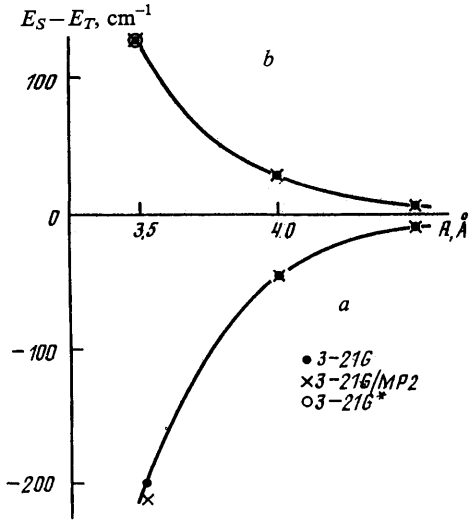

Figure 2. The exchange interaction (singlet–triplet splitting) in the allyl + methyl radical pair as a function of the distance R between the partners for the two types of their mutual approach (*a* and *b*). Circles—results of the calculation in terms of three different approximations; continuous lines—their exponential representations.[29]

These two simple and elegant proofs reliably justify the McConnell mechanism of the route to organic ferromagnetics.

The second idea was also put forward by McConnell in 1967[31] and referred to the possible ferromagnetism of a special class of compounds—the radical-ion salts of the type ...$D^+A^-D^+A^-D^+A^-$... constructed as quasi-one-dimensional spin chains of the donor radical-cations D^+ alternating rigorously with the acceptor radical-anions A^-. It was suggested that virtual excited states of the D^+A^- pair may exist, stabilising its high-spin triplet state and ensuring a ferromagnetic arrangement of the spins in the quasi-one-dimensional chain. An admixture of such excited states can arise as a result of the virtual forward charge transfer ($D^+ + A^- \rightarrow D^{2+} + A^{2-}$), the reverse charge transfer ($D^+ + A^- \rightarrow D^0 + A^0$), or a disproportionating charge transfer ($D^+ + D^+ \rightarrow D^{2+} + D^0$). If any one of the charge transfer states (D^{2+}, D^0, or A^{2-}, A^0) is singlet, the singlet spin state of the D^+A^- pair, to which corresponds an antiferromagnetic arrangement of the spins in the chain, is established. If even one of the species D^{2+}, D^0 or A^{2-}, A^0 is a high-spin triplet molecule (and this is its ground state), then the virtual charge transfer will stabilise the high-spin state of the D^+A^- pair and will give rise to a ferromagnetic arrangement of the spin chain.

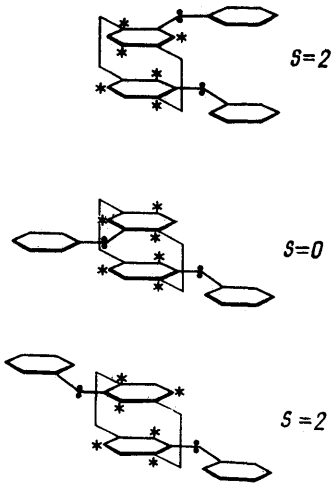

Figure 3. The structures of paracyclophane dicarbenes—pseudo-*ortho* ($S = 2$), pseudo-*meta* ($S = 0$), and pseudo-*para* ($S = 2$).[30]

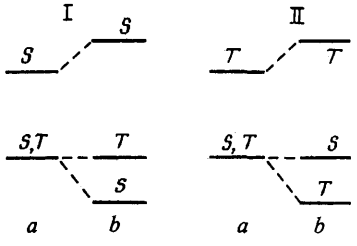

Figure 4. The energy levels of the D^+A^- pair without taking into account the virtual charge transfer (*a*) and the change in the energy levels when account is taken of the virtual charge transfer (*b*). Case I corresponds to the stabilisation of the singlet state of the pair and case II corresponds to the stabilisation of the triplet state.

The energy level schemes for these versions are illustrated in Fig. 4. The normal state of the D^+A^- pair is degenerate (the difference between the energies of the singlet S and the triplet T may be neglected), but the virtual charge transfer in the excited state of

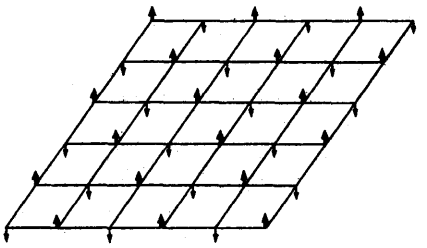
the pair reduces the energy of the singlet (if the transfer takes place with participation of the singlet state of one of the D^{2+}, A^{2-}, D^0, and A^0 species) and of the triplet (if even one of the D^{2+}, A^{2-}, D^0, and A^0 species has a high-spin triplet ground state). The schemes in Figs. 4*a* and 4*b* correspond to the first and second versions respectively. The reduction of energy as a result of the admixture of the excited state of the pair (virtual charge transfer) can be estimated in terms of the perturbation theory; it is a quantity of the order of magnitude of $t^2/\Delta E$, where ΔE is the excitation energy of the pair and t is the charge transfer integral.

This simple idea was specified in detail by Torrance et al.,[32] was expanded by Breslow and Le Page,[15] and was generalised by Miller and Epstein.[33]

In order to generate ferromagnetism by means of this mechanism, it is necessary that one of the partners (but not both) should have a degenerate and partly occupied molecular orbital; an appreciable charge transfer is needed, i.e. an appreciable admixture of the excited state of the D^+A^- pair, in order to stabilise its ferromagnetic and antiferromagnetic states; the molecules must be highly symmetrical without any structural or electronic defects (of the type of the Jahn–Teller effect), which remove the degeneracy already in the ground state.

There is no direct evidence for this mechanism of the generation of ferromagnetism, although most of the studies (both experimental and theoretical) have been devoted to the development of precisely this field. Highly symmetrical molecules, producing excellent readily crystallisable radical-ion salts, have been specially synthesised in conformity with this mechanism; furthermore, among them are there also those which produce doubly charged high-spin cations ideally corresponding to the conditions for charge transfer and the stabilisation of the ferromagnetic state [of the type $(HET)^{2+}$ and $(HOC)^{2+}$; see Section II]. However, ferromagnetics were never obtained (with the exception of metallocene salts—this will be discussed later in Section IV). Here one should recall that, regardless of the search for ferromagnetism, an enormous number of radical-ion salts (including organic superconductors) are known, but they all become antiferromagnetic at low temperatures (like other organic paramagnetic materials). One-dimensional spin chains are known to be unstable in such salts (Peierls instability): the chain breaks up into pairs with a strong interaction within the pair and a weak interaction between the pairs. This suppresses the virtual charge transfer (and yet ferromagnetism requires a collective charge transfer throughout the sequence of ions in the chain, since otherwise a complete arrangement of all the spins is not achieved). The Peierls instability is in fact the cause of the conversion of highly conducting radical-ion supports (organic metals) into dielectrics and can prevent the possible transition of the chain to the ferromagnetic state. Incidentally, the theory of spin waves in radical-ion chains has been thoroughly developed and predicts the antiferromagnetism of these chains (in agreement with experiment).

The third idea[34] is the cocrystallisation of low-spin and high-spin molecules (for example monoradicals and biradicals with spins of 1/2 and 1). If their chemical structures are almost identical, one may expect a regular alternation of the two types of molecules in the crystal. Negative intermolecular exchange arranges the spins of neighbouring species in opposition and generates two spin sublattices: the spins of molecules of one kind are oriented in one direction and those of molecules of the other kind are oriented in the opposite direction. The overall ferrimagnetic arrangement of the spins is illustrated schematically in the two-dimensional version in Fig. 5. This idea was confirmed experimentally in relation to organic metallic polymers (see Section VI); it gives rise to a simple route to the ferromagnetic arrangement of multispin molecules (at any rate it is now not more complex than the arrangement of the McConnell islands).



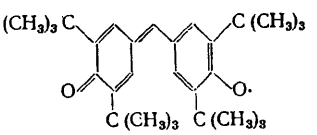


Figure 5. Two-dimensional ferrimagnetic spin lattice.

We shall now proceed to the analysis of experimental studies carried out in connection with the search for organic ferromagnetics.

IV. Molecular crystals

The magnetic properties of stable organic radicals of different classes and their relation with the structure of the crystals have been described systematically and surveyed.[35] Their common property is paramagnetism which obeys the Curie–Weiss temperature law with a negative Curie–Weiss point corresponding to the antiferromagnetic interaction of the spins. Indeed, at low temperatures the crystalline radicals become antiferromagnetics. Compression of the crystals does not alter the negative sign of the exchange interaction and merely enhances the antiferromagnetism, shifting the Curie–Weiss point to higher temperatures.[36]

There are several exceptions to this general rule, among which only two are trustworthy. This concerns a phenoxyl radical (the galvinoxyl) radical, i.e.

and its deuterio-analogue (the central CH group has been replaced by the CD group).[37,38] The high-temperature crystalline phase of the galvinoxyl ($T \geqslant 85$ K) is paramagnetic but shows signs of ferromagnetism (a positive Curie–Weiss temperature of 19 K).[38] Below 85 K, there is a phase transition and there is a new low-temperature phase, this time antiferromagnetic. In mixed crystals with the added phenolic precursor of galvinoxyl (its crystallisation is of the same type as that of its radical), the phase transition is suppressed and the higher the content of the phenol in the crystal the lower the temperature at which the high-temperature ferromagnetic phase is retained.[39–41]

In mixed crystals of galvinoxyl with its phenol, direct evidence was also obtained for the ferromagnetic interaction between the radicals in the high-temperature ferromagnetic phase. For high

dilutions with the phenol [low (1–10%) contents of the radical], EPR signals characteristic of triplet states (including forbidden transitions at $g = 4$) were observed in the mixed crystals.[41] It follows from the temperature variation of the intensity of these signals that there is a triplet ground state and the latter was referred to a radical pair with a positive, ferromagnetic interaction of the spins $J \simeq 1.5 \pm 0.7$ meV (approximately 30 cal mol^{-1}).

For high contents of the radical in the mixed crystals, triplets, quadruplets, etc., i.e. radical clusters, appear together with the isolated radical pairs. There is of course a distribution with respect to the sizes of these clusters, which is generated in the lattice by the insertion of phenol molecules between the radicals. It has actually been possible to estimate the sizes of the clusters.[41] Thus in a mixed crystal with ~20% of phenol the dependence of the magnetisation $M(H)$ on the magnetic field is described satisfactorily by the Brillouin function $B_J(x)$:

$$M(H) = M_S B_J(x), \text{ where } x = Jg\mu_B H/kT,$$

whence it was found that the average size of the ferromagnetic cluster corresponds to six radicals; its spin is $S = 3$ and it has a septet ground state ($2S + 1 = 7$).[40]

Thus the high-temperature phase of galvinoxyl is ferromagnetic not only as regards macroscopic features (positive Curie–Weiss temperature) but also as regards molecular features: the exchange interaction in the radical pairs and in the radical clusters is also positive and ferromagnetic, stabilising the high-spin states of the pairs and clusters. This means that the high-temperature phase of galvinoxyl can be regarded as the first organic ferromagnetic.

The low-temperature phase of this radical is antiferromagnetic—this follows also from the negative Curie–Weiss temperature and from EPR data. EPR signals corresponding to triplet states were also found in this phase, but it follows from the temperature variation of their intensity that these triplets are thermally excited and that there is a low-spin singlet ground state corresponding to the antiferromagnetism of this phase. The exchange interaction of the radicals in the antiferromagnetic phase is fairly intense (about 45 meV).[41]

The question arises of the cause of the anomalous ferromagnetism of galvinoxyl among radicals. The crystal structure of its high-temperature ferromagnetic phase is illustrated in Fig. 6.[42] The lattice is monoclinic and there are four molecules in the unit cell. The planar molecules are arranged in layers; one-dimensional chains of radicals are formed along the c axis of the crystal. They are "skewed" in such a way that opposite the $-CH=$ groups of one radical there are the phenyl rings and oxygen atoms of another radical at a very short distance. In other words, the regions with negative spin density (in galvinoxyl, this is the $-CH=$ group) are in contact with regions where the spin density is predominantly positive (oxygen atoms and phenyl rings). These are McConnell islands and are apparently the cause of the ferromagnetic arrangement of the spins[43] in the high-temperature phase of galvinoxyl.

Naturally, this is only a hypothesis, but it is difficult to find an alternative. It will be extremely important to establish the crystal structure of the low-temperature, antiferromagnetic phase of galvinoxyl. If it is such that there are no McConnell islands, this will be evidence in support of the proposed explanation of the ferromagnetism and even in support of the entire concept of McConnell islands.

We shall now deal with the search for other molecular ferromagnetics. As already mentioned (see Section II), polycarbene has a high-spin molecule but the hopes that after the accumulation of such molecules at sufficient concentrations signs of a ferromagnetic behaviour of the system would appear proved vain.[7]

When polycarbenes were generated in frozen glasses, in a host (benzophenone) single crystal in which the molecules of polyazide (a precursor of polycarbene) were incorporated, and also in polyazide crystals, the accumulation of polycarbenes was always accompanied by the appearance of signs of antiferromagnetic behavoiur (negative Curie–Weiss temperature.[8] This means that the intermolecular exchange interaction of even the high-spin molecules is antiferromagnetic (as in solid oxygen).

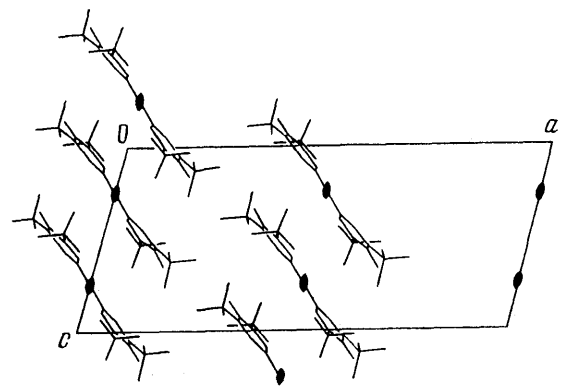

Figure 6. The crystal lattice of galvinoxyl.[42]

As already mentioned above, the search is directed principally towards the synthesis of radical-ion salts in which the conditions for the virtual charge transfer, stabilising the ferromagnetic arrangement of the spins, are achieved (see Section III). Among the large number of such salts of the type $D^{+\cdot}A^{-}$, where the donor D consists of HOC, HET, and HME molecules (see Section II), while the acceptor A consists of TCNQ, TCNE, $TCNQF_4$, and hexacyanotrimethylenecyclopropane molecules, no signs of ferromagnetism were observed; on the contrary, all the salts were clearly antiferromagnetic.[15,16,32] However, all the conditions satisfying McConnell's second idea are in fact brilliantly fulfilled in precisely these salts—they crystallise as ideally ordered alternating chains of cations and anions and the virtual charge transfer $D^{+\cdot} + A^{-\cdot} \rightarrow D^{2+} + A^{2-}$ gives rise to the doubly charged cation D^{2+} in the triplet, high-spin state (see Section II) and it should therefore stabilise the ferromagnetic state of these salts. Thus the idea of the virtual charge transfer as a means of ensuring the ferromagnetism of radical-ion salts has not so far been justified.

A remarkable exception to this series of failures is certain radical-ion salts of the decamethylferrocenium radical-cation $[Fe(C_5Me_5)_2]^{+\cdot}$ with the radical-anions $(TCNE)^{-\cdot}$, $(TCNQ)^{-\cdot}$, and $[C_4(CN)_6]^{-\cdot}$. They have been synthesised and investigated by Miller, Epstein, Reiff, and co-workers[44–49] and although they contain an iron atom, they should be regarded as true molecular ferromagnetics because their ferromagnetism is associated with the unpaired electron in the highest occupied molecular orbitals of the ferrocenium ion.

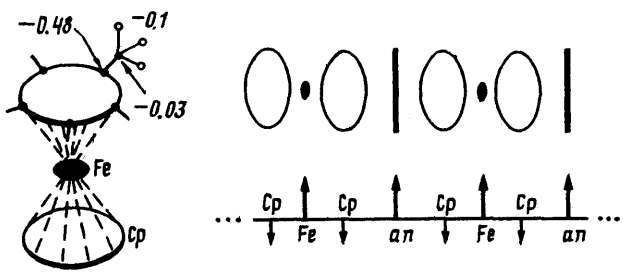
The above ferrocenium salts form ideal one-dimensional spin chains of alternating cations and anions. The ferromagnetic properties are manifested most strikingly by the salt

$[Fe(C_5Me_5)_2]^+(TCNE)^-$: the Curie–Weiss temperature is 30 K, the saturation magnetisation of the polycrystalline material at 2 K in magnetic fields $H > 300$ Oe is 11000 e.m.u. mol^{-1} (this is comparable to the magnetisation of metallic iron under normal conditions), and sextets characteristic of a ferromagnetic appear in the ^{57}Fe Mössbauer spectra near 9 K.[45] Spontaneous magnetisation ($m \simeq 2000$ e.m.u. mol^{-1}) appears in a zero magnetic field at $T < 4.5$ K. In a single crystal, when the magnetic field is oriented along the axis of the one-dimensional arrangement of cations and anions, the saturation magnetisation is 16000 e.m.u. mol^{-1}; this is greater by 36% than for metallic iron (when calculated per atom) and agrees with the theoretical magnetic saturation moment in the ferromagnetic arrangement of the spins of the cation ($S = 1/2$, $g = 4$) and the anion ($S = 1.2$, $g = 2$). There is also a hysteresis loop with a coercive force of 30 Oe at 4.2 K and 1000 Oe at 2.0 K.[47]

It follows from the temperature variation of the magnetic susceptibility χ, the magnetisation M, and the field dependence $M(H)$ that above 16 K the magnetic properties are best described by the one-dimensional Heisenberg exchange model with $J = 19$ cm^{-1}, while at $T < 16$ K the substance is closer to a three-dimensional ferromagnetic.

The magnetisation of the salt $[Fe(C_5Me_5)_2]^+(TCNQ)^-$ in fields $H < 1.6$ kOe is characteristic of an antiferromagnetic, but for $H > 1.6$ kOe it increases abruptly and rapidly attains saturation, which is characteristic of a ferromagnetic. This is a feature of a metamagnetic—a layered magnetic (of the type of $FeCl_2$) in which the intensity of the exchange interaction within the layer exceeds that of the exchange interaction between the layers. A number of inorganic metamagnetics are known but among organic substances this is the first example.

The creators of this class of organic ferromagnetics explain the origin of their ferromagnetism within the framework of the hypothesis of the virtual charge transfer (McConnell's second idea), although the first idea is in this instant much more reasonable.[43]



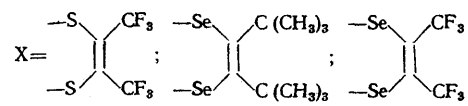


Figure 7. Schematic illustration of the spin distribution in the ferrocenium cation (on the left) and the arrangement of spins in a one-dimensional chain of a ferrocenium salt (on the right). Fe = iron atom; Cp = cyclopentadienyl ring; an = anion. The numerals denote the $^{13}C-H$ hyperfine interaction constants (in gauss).[50]

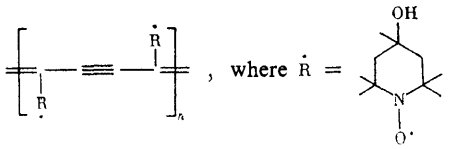
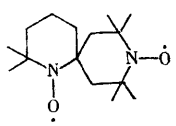
Fig. 7 illustrates schematically the arrangement of the radical-cations $[Fe(C_5Me_5)_2]^+$ and the radical-anions $(TCNQ)^-$ in a regular one-dimensional chain and, also schematically, the spin distribution in the radical-cation known from the contact paramagnetic NMR shifts for this radical-cation.[50] The π-electron spin density in the ring of the radical-cation is positive, while on the methyl groups along the perimeter of the ring the spin density is negative. McConnell islands can exist between the methyl groups of the ring of the radical-cation (negative spin density) and the CN groups of the radical-anion on which a positive spin density is localised. The McConnell islands are responsible for the alternating arrangement of the positive and negative spin densities illustrated in Fig. 7 and leading to the ferromagnetic arrangement of the spins and to ferromagnetism.

Within the framework of this concept, it is possible to explain the change in magnetic properties when the radical-anion or the metal ion is replaced in radical-ion salts of this type. Thus the salt $[Fe(C_5Me_5)_2]^+[C_4(CN)_6]^-$ is ferromagnetic, while the salt $[Fe(C_5H_5)_2]^+[C_4(CN)_6]^-$ is merely paramagnetic and shows no signs of ferromagnetic properties. It is known that the signs of the spin densities in the ligands C_5H_5 and C_5Me_5 are different and the replacement of the C_5Me_5 ligand by C_5H_5 therefore breaks up the McConnell islands, which entails the disappearance of ferromagnetism. The replacement of the $[C_4(CN)_6]^-$ paramagnetic radical-anion in the salts by the diamagnetic $[C_3(CN)_5]^-$ anion or of the paramagnetic radical-cation $[Fe(C_5Me_5)_2]^+$ by the diamagnetic cation $[Co(C_5Me_5)_2]^+$ also abolishes the McConnell islands and the substituted salts do not therefore show signs of ferromagnetism. In contrast to the ferromagnetic salt $[Fe(C_5Me_5)_2]^+[C_4(CN)_6]^-$, the salt $[Ni(C_5Me_5)_2]^+[C_4(CN)_6]^-$ is antiferromagnetic; the cause is similar because the signs of the spin densities in the C_5Me_5 ligand at the Fe and Ni ions are different (this is known from NMR[51]) and there are therefore no McConnell islands and no ferromagnetism in the nickel salt. We may note that all these substitutions should not affect the ferromagnetism if its origin were associated with the virtual charge transfer.

The first discoveries of molecular ferromagnetics among ferrocenium salts stimulated an extensive search for analogues. Thus radical-ion salts in which the anion is provided by the complex salt NiX_2, where



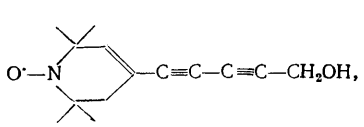
have been synthesised on the basis of $Fe(C_5Me_5)_2$. These molecules are packed in crystals in stacks with a remarkable two-dimensional architecture and the Curie–Weiss temperature is positive (about 1 K), which indicates weak signs of ferromagnetism but explicit ferromagnetics have not so far been found among these substances.[52]



V. Organic polymers

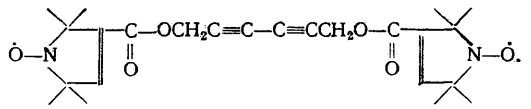
Ovchinnikov and co-workers[53,54] achieved impressive results in the preparation of ferromagnetic organic polymers. The thermal or photochemical polymerisation of the spin-labelled diacetylene $\dot{R}-C\equiv C-C\equiv C-\dot{R}$, where $\dot{R}$ is a nitroxyl radical, yielded a polymer in which 0.1–0.3% of the overall mass consisted of particles which could be separated magnetically and whose magnetisation reached ~ 1 G g^{-1}. The Curie point is 420–460 K and sometimes higher, i.e. the ferromagnetism persists up to anomalously high temperatures adjoining the limiting temperature of the chemical stability of the polymer. The crystal structure of the

initial diacetylene[55] prevents its topochemical polymerisation, typical for the majority of diacetylenes. However, one can assume that oligomeric blocks of the type



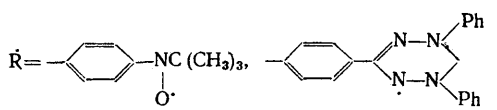
exist in the polymer. The two spin systems—one belongs to the principal polyene chain (in which the concentration of unpaired electrons is as usual high) and the other belongs to nitroxyl fragments—are independent, i.e. the exchange interaction between them is negligible. This follows from the fact that even in the initial monomer the paramagnetic fragments are independent (the EPR spectrum of the biradical consists of a triplet and is typical of a nitroxyl monoradical) and there is no exchange between the unpaired electrons through the π-system. Even in a biradical with the paramagnetic centres in close proximity, i.e.

the exchange energy is $J \ll 15$ Oe (i.e. $J \ll a$, where a represents the hyperfine electron–nuclear interaction involving the ^{14}N nucleus).[1] The low value of J is due to the barrier set up by the σ-bonds which separate the two π-electron systems.



The very weak exchange interaction of the two spin systems ($J \lesssim 10^{-7}$ eV) is inconsistent with the high-temperature ferromagnetism of the polymer (there is an energy deficiency by 7–8 orders of magnitude), which means that it is not the cause of the ferromagnetism. It may be that McConnell islands are present in the structure of Ovchinnikov's ferromagnetic polymer, but it would then be necessary to assume that structures with such islands are very rigid, are not disrupted by molecular motion, and persist even at 450–500 K, where the polymer itself already undergoes chemical degradation. This is naturally a large claim for which there is no proof. At any rate, the origin of the ferromagnetism of the spin-labelled polydiacetylene remains puzzling. The structure of the polymer is just as puzzling: it is insoluble and amorphous and the type of polymerisation and the chemical mechanism of the propagation of the polymer chain are unknown; it is only known that polymerisation entails the destruction of the paramagnetic centres of the nitroxyls (sometimes to an extent up to 80%), possibly as a result of addition to multiple bonds.[56] Polymerisation can be induced by the shear deformation of the monomer under high pressure conditions (1.2 GPa, 40° and 270° shifts), which affords a dark-brown powder (resembling that formed on thermal polymerisation), but it shows no signs of ferromagnetism.[55]

The polymerisation of another spin-labelled diacetylene has been reported:[57]



In contrast to the previous monomer, it is capable of topochemical polymerisation and its structure is much more definite. The polymer contains about 3% of a ferromagnetic fraction with a saturation magnetisation of 0.3 G cm^3 g^{-1}.[57]

Japanese workers[58] reproduced Ovchinnikov's polymer and in addition synthesised a polymer from another spin-labelled diacetylene:

Its magnetic properties are similar to those of Ovchinnikov's polymer (coercive force 300 G, saturation magnetisation ~0.2 e.m.u. g^{-1} at 30 K, residual magnetisation 2.5×10^{-2} e.m.u. g^{-1} (although the exchange interaction between the two spin systems—polyene and nitroxyl—is in this case still weaker (because the σ-bond barrier between these systems is much higher).[58]

Iwamura and Murata[6] synthesised spin-labelled polyacetylenes in another way—by the catalytic polymerisation of acetylenes CH≡ĊR, where

in the presence of the $WCl_6/SnPh_4$ catalyst. In the former case, the average number of monomer units in the macromolecule was 180, while in the latter case it was 210 and the fraction of radical spins preserved in the "living" units was 25–30%. The polymer was paramagnetic and showed no signs of ferromagnetism.[6]

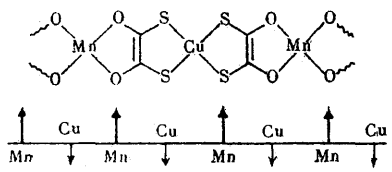
In flexible-chain polymers spin-labelled with nitroxyls [styrene–maleic anhydride copolymer, poly(glycidyl methacrylate), polyfulvene, etc.], a ferromagnetic fraction (3–5%) was also found.[59] The ferromagnetic grains "follow" the magnet. After the subsequent division in two, one of the halves attains ferromagnetism, while the other loses it. The destruction of nitroxyl radicals (by thermolysis or by treatment with acids) does not destroy the ferromagnetism, i.e. there is no direct relation between paramagnetism and ferromagnetism.

The magnetisation of the flexible-chain ferromagnetic polymers is 10^{-1}–10^{-2} G g^{-1} and the Curie point is at 350–400 K. Measurements have been made of the amounts of metal ions present as an impurity (10^{-1}–10^{-2}%) and it was shown[59] that the experimentally measured magnetisations do not as a rule exceed the magnetisations calculated on the assumption that the iron ion impurities are combined into clusters consisting predominantly of α-iron. However, one cannot conclude from this that the impurity iron ions are reduced to metallic iron which is responsible for the ferromagnetism. It may be that the metal ions arrange the paramagnetic fragments of macromolecules into ferromagnetic organometallic structures (as a result of an interaction of the metal–ligand type). A similar possibility was incidentally discussed as early as 1963 by Blyumenfel'd[60] in connection with the previously discovered ferromagnetism of DNA and other biopolymers. The ferromagnetism of organic structures is naturally induced by iron impurities, but one cannot reduce it to trivial ferromagnetic contaminations (inclusions); iron ions or clusters are linked to the main organic structure in such a way that together they generate a single ferromagnetic system.[60] It is likely that these ideas will now become again of current interest.

Weak ferromagnetism is frequently observed in degraded or carbonised polymers (including cellulose) and in polymers subjected to strong shear deformation at high pressures. It has a number of unusual features (non-reproducibility, irreversible disappearance in

time, etc.) and has therefore generated much scepticism. Its origin is obscure. It can be associated with the reduction of traces of metal ions by chemical reactions induced by degradation or mechanodegradation, but one cannot exclude (although this is unlikely) the possibility of the formaton of structural clusters with McConnell islands. At any rate, the question whether or not purely organic ferromagnetic polymers without ferromagnetic metal impurities can be created remains open.

We may note a further three cases of the observation of ferromagnetism in organic polymers. The pyrolysis of polyacrylonitrile at 350 °C is accompanied by the appearance of a weak ferromagnetism (the magnetisation is 0.3–0.5 G g^{-1}), while its heat treatment at high temperatures (up to 900 °C) affords a material (pyropane) with a magnetisation of 15 G g^{-1}.[61] It consists of amorphous graphite (~80%) and an aromatic polymer (10–12%) and contains a highly crystalline phase (8–10%), which can be separated magnetically and has a magnetisation of about 150 G g^{-1} and a density of 3 g cm^{-3} (we may recall that the magnetisation of metallic iron is 200–215 G g^{-1}). The iron content in pyropane is $(1-3)\times10^{-4}$% and that in the magnetic phase is 1×10^{-2}%, which is too negligible to permit the assumption that the ferromagnetism of pyropane is due to the impurity. The idea of an intermediate graphite–diamond system in which each second carbon atom in the graphite-like lattice plane has an unpaired electron has been proposed.[61] Such an idealised structure has a theoretical magnetisation of 230 G g^{-1} and a spin concentration of about 10^{23} cm^{-3}, which is completely unusual for organic structures.[61] It has been concluded that pyropane approaches this idealised graphite–diamond structure. However, later other data indicated that the content of iron in the magnetic phase of pyropane 8% instead of 10^{-2}%,[57] but even this is too low to account for the ferromagnetism of pyropane.



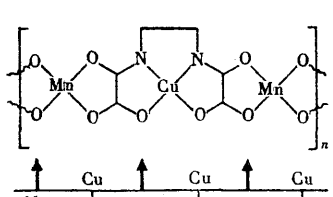
It has also been noted that, when pyropane is ground in a ball mill, its magnetisation increases with a simultaneous rise in the iron content[57] (the spheres in the ball mill were probably metallic, although this is not reported; however it is known that on treatment in a ball mill with steel or magnetite spheres, even wood filings become ferromagnetic).

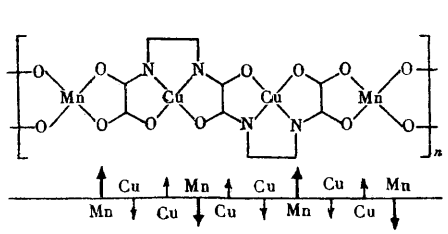
Torrance[32,62] reported that the reaction of symmetrical triaminobenzene with iodine in different solvents and even in the vapour phase results in the formation of a black, insoluble polymer of unknown structure, which sometimes contains up to 2% of a ferromagnetic fraction with a magnetisation of the order of 10^{-2} G g^{-1}. It vanishes irreversibly only at ~700 K; there is also a weak hysteresis loop.[62] The results are random and non-reproducible; the polymer contains traces of iron, but, according to the author's claim,[62] its amount is smaller by a factor of 15 than that required for the "impurity" explanation of the ferromagnetism.

Finally, Japanese workers[63] have reported the appearance of ferromagnetism (0.2–0.6 G g^{-1}) in resins based on condensed polynuclear aromatic compounds. There are two remarkable features of this ferromagnetism. Firstly, it arises only on UV irradiation of the resins, i.e. on generation of radicals, and, secondly, it appears only in resins based on *meta*-substituted aromatic compounds but is absent from polymers based on *p*-xylylenes. The possibility of "native" ferromagnetism as a result of the generation of McConnell islands on photolysis have been postulated. However, a trivial explanation cannot be ruled out either: although the authors claim that there were no metals in the resins, there is a possibility that traces of metal ions were reduced to ferromagnetic chemical forms under the influence of photochemical reactions.

VI. Organometallic polymers

This class of ferromagnetics is based on multispin organometallic macromolecules in which the spins belong to paramagnetic ions. The first example of macromolecules of this type is provided by the mixed bimetallic dithiooxalate polymeric complex of manganese and copper:[64]





The alternating copper and manganese ions are joined together by organic ligands in such a way that each copper atom is at the centre of a planar square made up of four sulphur atoms, while each manganese atom is at the centre of a plane made up of five oxygen atoms, two pairs of which belong to two dithiooxalate ligands and the fifth is the oxygen atom of an attached water molecule.

The isolated macromolecule has a planar zig-zag shape in which the exchange interaction of the metal ions via the organic ligand is negative and arranges the spins of the ions antiferromagnetically (as shown below, underneath the chemical formula of this macromolecule). However, since the spin of the Mn^{2+} ion ($S=5/2$) is greater than that of Cu^{2+} ($S = 1/2$), the spin chain proves to be ferrimagnetic, its magnetisation increasing with decrease in temperature (when the exchange energy J_{intra} is comparable to or exceeds kT).

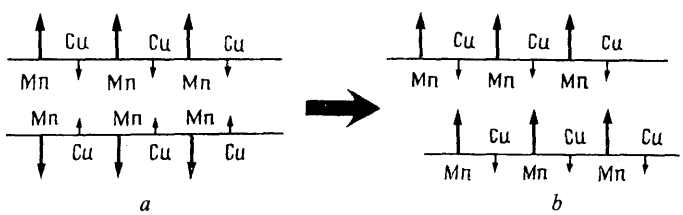
In the crystal, these high-spin macromolecules are arranged in parallel in stacks: an Mn^{2+} ion opposite another Mn^{2+} ion and a Cu^{2+} ion opposite another Cu^{2+} ion. The intermolecular exchange interaction arranges the spins of neighbouring ions in an antiparallel fashion, so that the overall high spin of one macromolecule is compensated by the spin of a neighbouring molecule. Therefore at T_c = 7.5 K, where $J_{inter} \simeq KT_c$, the polymer passes to the antiferromagnetic state.[64]

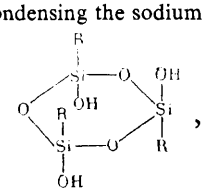
Kahn and co-workers[65,66] have made the greatest advances on the way to organometallic polymers. They synthesised bimetallic crystallising linear multispin macromolecules from the 1,3-propylenebisoxamate dianion:

The arrangement of spins in these macromolecules is indicated under the formulae. In both cases, the intermolecular exchange interaction between the ions is negative and arranges them

antiferromagnetically. In the first case, the macromolecule is of the high-spin type and ferrimagnetic (the overall spin of the Cu^{2+} ions does not compensate for the total spin of Mn^{2+}). However, in the crystal the intermolecular exchange interaction is negative and again the high spin of one macromolecule is compensated by the oppositely oriented spin of a neighbouring molecule, so that the crystal, made up of high-spin macromolecules, become antiferromagnetic overall at low temperatures. In the second case, the change in the sequence of ions in the chain can result in the complete compensation for the spins and the macromolecule is of the low-spin antiferromagnetic type.

The arrangement of the spins in a pair of neighbouring macromolecules with a regular alternation of Cu^{2+} and Mn^{2+} ions is illustrated in Fig. 8*a*; their compensation is evident. However, if one macromolecule is displaced relative to another by a distance equivalent to "half a ligand" (under these conditions the Cu^{2+} ions of one molecule are placed opposite the Mn^{2+} ions of another and conversely), then the arrangement of the spin changes sharply and becomes ferrimagnetic: the Mn^{2+} spins are oriented in one direction and the small Cu^{2+} spins are oriented in another (Fig. 8*b*). Such arrangement of spins had in fact been predicted previously (Fig. 5).





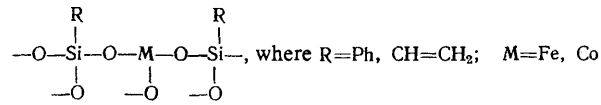


Figure 8. The transformation of the antiferromagnetic arrangement of the spins of two organometallic molecules into a ferrimagnetic arrangement by the "shift" of one macromolecule relative to the other.

The "half-ligand" shift of the macromolecule has been achieved experimentally[66] by replacing the $CH_2CH_2CH_2$ group connecting the nitrogen atoms in the ligand by the $CH_2CHOHCH_2$ group. The resulting organometallic polymer did indeed prove to be a low-temperature ferromagnetic with typical properties, including a hysteresis group.[66] The same workers obtained a similar ferromagnetic on the basis of another ligand—the oxamidobisbenzoate dianion.[67]

In essence, all these polymers are polymeric complexes of organic ions with organic ligands which were synthesised by methods of inorganic chemistry. Procedures are also being developed to produce ferromagnetics based on organometallic polymers with paramagnetic metal atoms bound covalently in the main polymer chain. A notable example is provided by polymetallosiloxanes,[68] which were obtained by condensing the sodium salt of cyclotrisiloxane, i.e.

, where R = Ph, CH=CH$_2$,

with metal salts ($FeCl_3$, $CoCl_2$, etc.) in anhydrous solvents. They contain the fragments

, where R=Ph, CH=CH$_2$; M=Fe, Co

with alternating—SiOM—and—SiOSi—bridges, as well as siloxane rings, open chains, and cross-linked structures. Polymer fractions with an M : Si ratio ranging from $10^{-3}-10^{-2}$ to 1.5 can be isolated by fractional precipitation. In the fractions with a high M : Si ratio, the—$MO(SiOSiO)_nM$—molecular fragments with high values of n are replaced by short fragments with $n = 1$ and even $n = 0$ (—MOM—).

In order to convert such paramagnetic polymers into ferromagnetics, it is necessary to achieve an exchange interaction between the metal atoms. There are various ways of doing this: by shortening the bridges between the atoms, making them "conducting" to the exchange interaction; by creating new additional bridges; and finally by removing the organic bridges altogether and joining together the paramagnetic atoms.[68] All these versions are being actively developed. The simplest is attained in the high-temperature pyrolysis of ferropolysiloxane. A considerable proportion of the organic component of the molecule is then removed and a ferromagnetic composite material with a magnetisation of 10—50 G g^{-1} is produced (depending on the metal content and the pyrolysis temperature). It contains iron silicide and carbide phases, amorphous silicon dioxide, and carbon, as well as 300—350 Å α-ion clusters.[68] As regards their dynamic properties, these high-temperature ferromagnetics belong to the rigid class: in the wavelength range 0.8—30 cm, their magnetic permeability is close to unity and the tangent of the magnetic loss angle is negligible. This aspect of the chemical construction of ferromagnetics is closely related to the modern materials science of metal-filled polymeric composites.

VII. Conclusion

The principal achievements of the science of organic ferromagnetics are the recognition and understanding of the physical principles of their construction and the chemical pathways leading to it; there exists reliable theoretical and experimental evidence showing that these procedures are realistic; finally, the first "genuine" organic ferromagnetics exist.

Problems and difficulties can be clearly seen; the main one is the problem of the molecular organisation of multispin and high-spin molecules in a "solid state" order such that a ferromagnetic arrangement of the spins is ensured. This problem is soluble (we have seen brilliant examples of such solutions), but requires serious intellectual efforts.

One must clearly recognise also the deficiencies of organic ferromagnetics as potential magnetic materials. They all arise from the fact that organic molecules contain a lot of "dead weight"—a ballast consisting of spinless groups and fragments which results in a low spin density, i.e. a small number of spins per unit volume of the substance. Thus metallic iron contains 4×10^{23} spins per cm^3 while their number in an organic ferromagnetic is smaller by 1—2 orders of magnitude. This gives rise, firstly, to low magnetisations (smaller by 1—3 orders of magnitude than in iron) and, secondly, to low exchange energies (because of the large interspin distances), resulting

in low temperatures of transition to the ferromagnetic state (in other words, "genuine" organic ferromagnetics should be as a rule low-temperature materials); thirdly, the dipole interaction of the spins is also weak and this hinders the formation of a domain structure and spontaneous magnetisation. Finally, one should bear in mind the chemical instability of organic materials, the "ageing" of magnetic materials based on them as a function of time, and the restricted operational usefulness of such materials under severe thermal conditions or in oxidising media. Organic ferromagnetics are hardly likely to have superior static magnetic properties compared with classical metallic ferromagnetics but they can possess unusual dynamic properties—magnetic and dielectric losses and their frequency dependence.

From technical standpoints, the polymeric organic ferromagnetics are naturally the most attractive, although there is no certainty that such polymers can exist in the absence of impurities or traces of metals.

The problem of ferromagnetic impurities and inclusions (especially for low magnetisations) is most acute for polymers. The problem is tricky for the following reasons. On the one hand, impurities are discouraging, creating the impression of a "non-genuine" ferromagnetic, and destroy the stimulus to scientific research. On the other hand, if impurities are incorporated in an organic structure and organise its paramagnetic component (spin labels, polyconjugated systems, etc.) into a ferromagnetic order, we have a success, an achievement. It is then necessary to learn how to control this process—how to introduce such impurities into such polymers and in a way ensuring the maximum "synergism" of the organic and inorganic components in the generation of ferromagnetic organo-metallic structures. Here there is only one procedure—quantitative comparison of impurities with magnetisation. The problem is not yet clear: in some cases the impurities are sufficient to ensure the observed ferromagnetism, whilst in others their content is insufficient by 1–2 orders of magnitude. However, the unreliability of the analyses for metallic impurities and the non-reproducibility of the results leave open this part of the problem of organic ferromagnetics (although it is entirely clear how it could be "closed").

At the present level of knowledge, mixed organometallic ferromagnetics merit most attention, although overall the entire field of organic ferromagnetics merits vigorous development. Nor can one ignore its useful forays into adjoining fields, in particular into the chemistry of multispin and high-spin molecules as the potential elementary basis of the future molecular electronics.

The conformational analysis of organoelemental and organometallic molecules

T V Timofeeva, Yu T Struchkov
Nesmeyanov Institute of Organoelemental Compounds, USSR Academy of Sciences, Moscow

ABSTRACT. The results obtained using the mechanical model of a molecule to calculate the conformation and conformational transformations of the molecules of organoelemental and organometallic compounds have been reviewed. The conformational characteristics of the molecules of hydrocarbons and their organoelemental analogues have been compared. The present state and future prospects of the use of the mechanical model in calculations for the molecules of π-complexes and metal clusters have been described.

The bibliography contains 134 references.

I. Introduction

Conformational analysis in the wider sense involves the study of the relative arrangement of the parts of a molecule and the possibility of a change in this arrangement, taking place without the rupture of chemical bonds, and also the search for the relationship between the reactivity of molecules and their conformation. This analysis includes an examination of both the geometric (bond lengths, valence and torsional angles, non-valence contacts) and the energetic (the relative energies of the conformers and isomers, the barriers to internal rotation, etc.) characteristics of the molecules. The conformers are studied by experimental methods and calculations, and the accessibility of the latter has increased considerably with the significant development of computer technology.

The principal experimental methods for studying the conformation of molecules at present are X-ray diffraction (XRD), neutron diffraction (for molecules in the crystalline state), NMR (for molecules in the liquid state), gas-phase electron diffraction (GED), and spectral methods (for molecules in the gaseous state). All these methods have their advantages and limitations, the most significant limitation being that the results of a study of the structure of molecules in one phase state (particularly for the conformation of non-rigid molecules) cannot be transferred to another phase state without additional analysis (most frequently by calculation).

The calculation methods for studying the conformation of molecules now include semi-empirical and non-empirical quantum-chemical methods, and also empirical methods which use the mechanical model of a molecule (MMM)†, based on the atom–atom approximation.

The possibility of examining a wide range of materials and the considerable saving of machine time (compared with quantum-chemical methods) has now enabled the MMM to occupy an important place among methods used to study molecular conformations. The MMM began to be used for simple organic molecules about 40 years ago,[1,2] and is now used extremely widely in organic and bio-organic chemistry.[3–6] The MMM has also been used for a fairly long time in coordination chemistry.[7,8] In these fields, the method, which has passed through a period of methodological construction and development, is used to solve specific chemical problems. The present paper reviews for the first time the available data on new fields of application of the MMM in the study of the conformational characteristics of organoelemental and organometallic molecules (in particular π-complexes), which have developed significantly only in recent years.

II. The mechanical model of a molecule

The mechanical model of a molecule is an empirical approximation based on the Born–Oppenheimer principle, which makes it possible to examine the motion of nuclei and electrons separately. In this model, the molecule is regarded as a system of interacting atoms, and the intramolecular and non-valence interactions are central in character. For each type of atom there are "ideal" values of the valence angles and bond lengths, deviations from which require the expenditure of energy. To reproduce the experimental values of the dihedral angles and the barriers to rotation about the bonds in the molecules, the model is usually supplemented by a so-called torsional component characterising the expenditure of energy due to the deviation from the optimum relative orientation of the fragments of the molecules joined by chemical bonds. Where necessary, the model also takes account of the energy of electrostatic interactions, hydrogen bonds, etc.

Thus the conformational energy of a molecule (representing the fraction of its total energy which depends on the conformation) can be written as

$$U_{conf} = U_{non\text{-}v} + U_{bd} + U_{ang} + U_{tors} + U_{el} + \ldots$$

† A number of equivalent names are used in the Soviet and other literature for calculations of this type, for example "molecular mechanics", "force-field calculations", etc.

Here, the energy of the non-valence interaction ($U_{non\text{-}v}$) is the sum of the paired interactions of all the atoms (atom–atom approximation), and is most frequently described by the Lennard–Jones ("6–12") or Buckingham ("6-exp") potentials:

$$U_{non\text{-}v} = -Cr^{-6} + Ar^{-12},$$
$$U_{non\text{-}v} = -Cr^{-6} + A\exp(-Br),$$

where r represents the interatomic distances, and A, B, and C are empirical constants, obtained, for example, from the virial coefficients and the equilibrium interatomic distances for the inert gases.

The terms U_{bd} and U_{ang} are the energies required to deform all the bonds and valence angles in the molecule from the ideal values (l_0 and θ_0), for which the mean-statistical values are often taken‡, to the actual values (l and θ). For the small deformations usually observed with change in the conformation, Hooke's law (the harmonic approximation) is applicable:

$$U_{bd} = 0.5K_l(l-l_0)^2,$$
$$U_{ang} = 0.5K_\theta(\theta-\theta_0)^2,$$

where K_l and K_θ are the force constants of the bonds and angles, obtained from the vibrational spectra of the simple molecules. The torsional energy (U_{tors}) is written as

$$U_{tors} = 0.5U_0(1+\cos n\varphi),$$

where U_0 is the torsional constant (inherent barrier), selected from experimental or quantum-chemical data on the barriers to internal rotation, φ the dihedral (torsional) angle for the kth bond, and n the multiplicity of the barrier to rotation.

The energy of the electrostatic interactions (U_{el}) is taken into account fairly infrequently, sometimes in the dipole–dipole or, more often, in the monopole approximation:

$$U_{el} = q_i q_j/\varepsilon r_{ij},$$

where q_i and q_j are the charges on the ith and jth atoms (obtained from a quantum-chemical calculation) situated at a distance r_{ij} from one another, and ε the dielectric constant (usually, $\varepsilon = 1$).

The geometry of an isolated (free) molecule corresponds to a conformational energy minimum. Thus the determination of the optimum molecular conformation involves the search for a minimum value of U_{conf}.

Depending on the form of representation of the coordinates of the atoms in the molecule (Cartesian or coordinates expressed in terms of the bond lengths and valence and torsional angles—the so-called "tree system"), different methods of minimising U_{conf} are used, and these have been described in detail.[3,4] In the general case, the problem of determining the optimum geometry of a molecule reduces to the search for a minimum of a function of $(3N-6)$ variables, where N is the number of atoms in the molecule. Fairly frequently, however, most of the geometric parameters of the molecule can be fixed, so that the problem is simplified, and reduces to scanning the values of U_{conf} over several variables (constructing the corresponding graphs and conformational maps). The search for the minimum of U_{conf} over all variables is naturally possible only for molecules in which the number of atoms is not too large, up to ~100, whereas when the number of parameters is restricted, it is possible to examine the conformation of very large molecules, for example proteins. The molecule is usually described in the Cartesian system of coordinates in the first case, and using the "tree system" in the second. Both of these methods of specifying the geometry and the corresponding methods for finding the minimum of U_{conf} have been used in a large number of computer programs. The first of these methods is employed, for example, in the widely used programs MM2 and MMP2 of Allinger and co-workers[4] and in Boyd's program MOLBD3,[9] and the second is used in the program ECEPP of Scheraga and co-workers[10] for calculating peptide structures.

The choice of parameters for conformational calculations will not be dealt with in detail. The most widely encountered method of finding the parameters—the constants in the expressions for the components of U_{conf}—is by variation for a series of simple compounds of the same type to achieve the best agreement between the calculated and experimental data (the geometric parameters of the molecules, the barriers to internal rotation, etc.) or corresponding data obtained in a non-empirical quantum-chemical calculation. Data on the specific sets of parameters proposed by different authors for groups of compounds of the same type will be given in the appropriate sections.

III. Conformational calculations for organoelemental molecules

The similarity in the structures of hydrocarbons and organoelemental compounds in which one or several C atoms have been replaced by the atoms of an element X = Si, Ge, Sn, Pb is fairly obvious (the tetrahedral coordination of the atoms C and X, the formation of ordinary σ-bonds, the absence of lone pairs of electrons). Conformationally, however, the molecules of hydrocarbons and their organoelemental analogues (linear and cyclic) may differ considerably. This led to the idea of using the MMM to calculate the conformations of these molecules to investigate the reasons for their similarities and differences.[11–13] Two large groups of compound forming acyclic and cyclic molecules will be considered as an example of how this problem was solved.

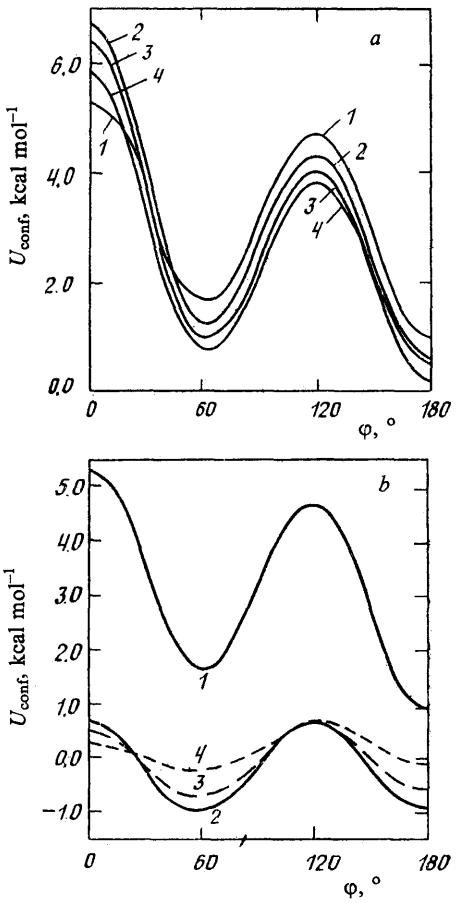
1. Acyclic organoelemental molecules

Parameters of the potentials have been proposed[11–13] for the calculations for organoelemental molecules (X = Si, Ge, Sn), and a number of calculations have been carried out for fairly simple molecules, to verify the suitability of the proposed parameters. Most of the calculations have been carried out for organosilicon molecules,[11,12] since they have been more fully characterised by physicochemical methods. The good agreement between the calculated and experimental data made it possible to use the proposed parameters with confidence for carrying out specific calculations.

The relative energetic advantage of the conformers and the barriers to conformational transformations have been examined[13] for various simple hydrocarbons and their organoelemental analogues in which one of the C atoms has been replaced by an X atom. In the compounds $MeHX_3$, Me_2XH_2, and Me_3XH, on going from X = Si to X = Ge and Sn, the barrier to rotation about the C–X bond decreases considerably, the values being 1.6 (X = Si), 1.2 (X = Ge), and 0.65 (X = Sn) kcal mol^{-1} respectively. This is attributed to the decrease in the contribution of the non-valence interactions to the magnitude of the barrier, as a result of the increase in the length

‡The mean-statistical values of the geometric parameters are calculated for the isolated molecules in the gas phase from GED data or for the molecules in the crystal from XRD data, collected in the Cambridge Structural Data Bank.

of the C–X bond, and to the simultaneous decrease in the torsional constant for this bond, which has the values 0.5, 0.38, and 0.22 kcal mol^{-1} for X = Si, Ge, and Sn respectively.



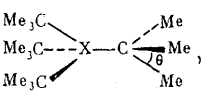


Figure 1. Dependence of U_{conf} on the angle of rotation about the central bond in the molecules $CH_3CH_2CH_2XH_3$ (*a*) and $CH_3CH_2XH_2CH_3$ (*b*), where X = C (*1*), Si (*2*), Ge (*3*), and Sn (*4*).[10]

The introduction of an organoelemental substituent on one of the C atoms has little influence on the magnitude of the barrier to rotation about the C–C bond. Thus for the molecules $CH_3CH_2XH_3$, these barriers have the values 3.78, 3.87, and 3.98 kcal mol^{-1} for X = Si, Ge, and Sn respectively.

A calculation made it possible to estimate[10] the ratio of the relative energies of the *gauche* (or crossed, φ = 60°) and *anti* (or *trans*, φ = 180°) conformations (rotation about the central bonds) for the molecules $MeCH_2CH_2XH_3$ and $MeCH_2XH_2Me$. In the first case (Fig. 1*a*), the introduction of the atom X into the terminal group does not change the conformation of the molecule relative to n-butane, and only leads to a slightly greater difference in the energies of the eclipsed and staggered conformations. This is understandable, since in this case the central bond does not change, and the terminal groups are "repelled" more strongly in the eclipsed conformation, since they are brought closer together by the increase in the length of the C–X and X–H bonds. In the second case, the *trans*- and *gauche*-conformers of $MeCH_2XH_2Me$ (unlike the corresponding conformers of n-butane) have similar energies (Fig. 1*b*). The explanation is that the increase in the length of the central bond in the molecule is associated with an increase in the contribution made to U_{conf} by the energy of attraction between the H atoms of the terminal methyl groups, favouring the approach of these groups, that is the energy of the *gauche*-conformation approaches that of the *trans*-conformation.

Mislow and co-workers[14–19] examined not only the relative advantage of the conformers and the values of the barriers to rotation but also the mechanism of internal rotation in molecules, in particular the mechanism of the rotation of several bulky substituents situated on one C or X central atom. Thus the rotation of the t-butyl groups in the $HSi(Bu\text{-}t)_3$ molecule was analysed.[19] Here, two mechanisms of internal rotation of the alkyl substituents are possible: independent and coupled, that is involving the simultaneous rotation of at least one other substituent. In the case being considered, only coupled rotation takes place. The rotation of the t-butyl groups can take place in two ways: all three t-butyl groups may be present simultaneously in the staggered (*S*) orientation (*SSS*, barrier to rotation 5.1 kcal mol^{-1}), or one of the groups may be present in the eclipsed (*E*) orientation, and the other two in the staggered orientation (*ESS*, barrier 6.8 kcal mol^{-1}). The fact that the magnitude of the second barrier is close to the experimental value obtained from NMR data, $\Delta G^{\neq}$ = 6.1 ± 0.3 kcal mol^{-1}, was taken as evidence that the actual mechanism of internal rotation is of the *ESS* type.

For two series of sterically crowded molecules $X[CMe_3]_4$ and $X[SiMe_3]_4$, where X = C, Si, Ge, Sn, and Pb, calculations have been carried out[18] to determine the geometric parameters of the molecules (there are no published experimental data for molecules of the first type) and to compare the energies of their conformers with *T* and S_4 symmetry. The results of the calculation for the molecules

where X = C, Si, Ge, Sn, Pb, are summarised in Fig. 2. Fig. 2 shows that the difference in the values of U_{conf} for the energetically more favourable (*T*) and less favourable (S_4) conformers (ΔU_{conf}) decreases with increase in the atomic number of the central atom. At the same time, the angle θ increases, and its value approaches the usual tetrahedral value. For the first member of the series (X = C), for which the steric crowding is greatest, the decrease in this angle is fairly large. The same trend in the change in the geometric and energetic parameters was detected in the series of molecules $X[SiMe_3]_4$.

A search for the most favourable conformations and an analysis of the routes of conformational rearrangements has also been carried out for aryl-substituted§ derivatives of methane and silane.[15,16] The most favourable conformations were found to be that with D_{2d} symmetry for the CPh_4 molecule, and that with S_4 symmetry for the $SiPh_4$ molecule.[15] It was pointed out[15] that this result was not obtained for these compounds in earlier calculations,[20] since the authors of these calculations did not vary all the geometric parameters, but only the values of the torsional angles round the C–Ph or Si–Ph bonds. For the molecules CR_4 and SiR_4, where R = *o*-tolyl or 2,6-xylyl, the S_4 conformers were found to be most

§The parameters of the potentials for conformational calculations for molecules containing an Si–Ar bond have been published.[15]

favourable.[15] A calculation to analyse the mechanism of internal rotation in molecules of this type showed[15] that the rotation of the substituents in this case, as in the case of the t-butyl derivative of silane, is not independent, and the route of the conformational transformation can be represented by the sequence of conformers shown in Fig. 3. Although the molecules with the *o*-tolyl substituents are less symmetrical, and a large number of conformational transformation routes are possible for these molecules, the most favourable mechanism of rotation for these molecules was found to be similar to that found for the Ph-derivatives. The calculated values of the barriers to the internal rotation of the substituents for the molecules of $SiPh_4$ and $Si(o\text{-}CH_3C_6H_4)_4$, 14.9 kcal mol^{-1} and 19.6 kcal mol^{-1} respectively, lie in the range of values of the activation energy of the topo-isomerisation process obtained experimentally from NMR data.

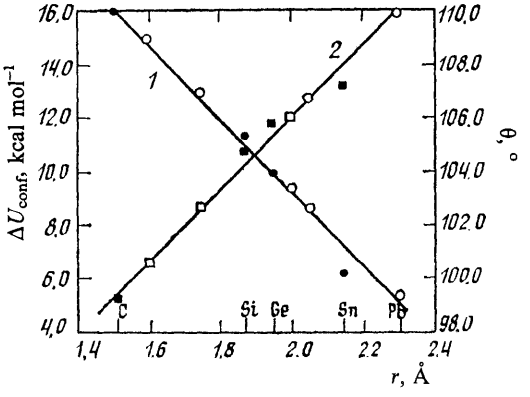

Figure 2. Dependences of the difference in the energies ΔU_{conf} (*1*) between the *T*- and S_4-conformers and of the angle θ (*2*) on the C–X bond length in $X(CMe_3)_4$ molecules, where X = C, Si, Ge, Sn, Pb;[18] the black points correspond to the actual structures, and the white points to model structures with intermediate values of the C–X bond lengths.

Stereo-isomerisation has been examined[14] for a large number of triaryl-substituted molecules. The authors cited used a simplified approach, in which the same parameters [as for the $HC(Mes)_3$ molecule] were used for the molecules $Z(Mes)_3$, where Z = B, CH, SiH, GeH, N, P, and As, and Mes = mesityl, and only the length of the Z–Mes bond was changed. The calculation of the routes for the simultaneous internal rotation of one, two, and three substituents (Fig. 4) showed that the simultaneous rotation of two aryl fragments is most favourable in this case. The calculated and experimental values of the barriers to rotation in these molecules are compared in Fig. 5. The calculation provides a qualitatively correct description of the change in the magnitude of the barrier with change in the Z–Mes bond length, but it does not reproduce the experimental values quantitatively. This last feature (the high values of the barriers) was attributed to the use of a simplified model, in which the lengths of the bonds formed by the central atom Z in the molecule were not varied.

Halogen-substituted alkylsilanes of the type $Si(CH_2Hal)_4$, $H_2Si(CHal_3)_2$, and $Hal_2Si(CHal_3)_2$, where Hal = F, Cl, Br, have been studied.[21,22] For the tetra-substituted molecules,[21] for all Hal, the conformation with D_{2d} symmetry is most favourable. The order of the relative advantage of the conformers is different for different halogens, however: $D_{2d} > C_s > C_2 > C_1 > S_4$ for F, $D_{2d} > C_4 > C_1$ for Cl, and $D_{2d} > S_4$ for Br. The conformation with C_2 symmetry is most favourable for the dialkyl-substituted molecules $H_2Si(CHal_3)_2$, and that with C_{2v} symmetry is most favourable for $Hal_2Si(CHal_3)_2$. The calculated barriers to the internal rotation of the substituents are 5.7, 14.5, and 14.8 kcal mol^{-1} for F, Cl, and Br respectively in the molecules $H_2Si(CHal_3)_2$, and 2.2, 8.2, and 8.5 kcal mol^{-1} respectively for $Hal_2Si(CHal_3)_2$.

Parameters making it possible to use the mechanical model of a molecule to carry out calculations for allylsilanes have been proposed.[23] The parameters were selected by fitting the results of calculations using the MMM to the results of non-empirical quantum-chemical calculations using different basis sets. The torsional potential of the rotation about the central bond in the fragment C=C–C–Si was found to be close to the usual value for rotation about a $C(sp^2)$–$C(sp^3)$ bond. The minimum energy

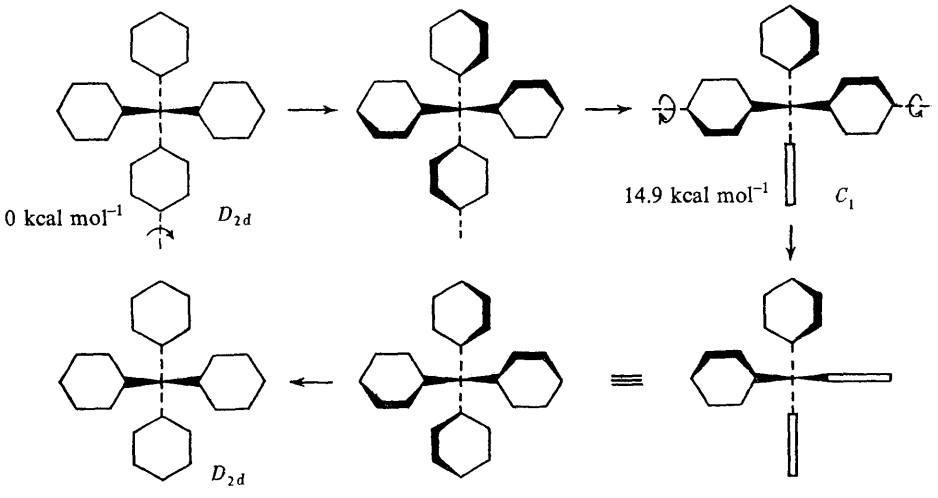

Figure 3. Internal rotation pathway in tetraphenylmethane.[15]

corresponds to the conformation of allylsilane with a torsional angle of rotation round the central bond equal to ~100°; the values of the *cis*- and *trans*-barriers differ slightly, and according to the data obtained using the MMM (in agreement with quantum-chemical calculations) are equal to 2.09 kcal mol^{-1} and 2.75 kcal mol^{-1} respectively.

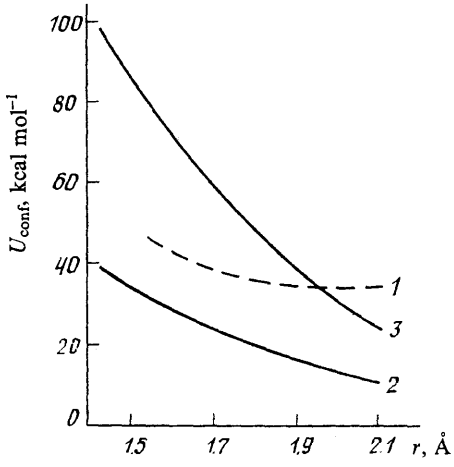

Figure 4. Calculated energies of the transition state for different mechanisms of the stereo-isomerisation of $Z(Mes)_3$ molecules: *1*, rotation of one mesityl substituent; *2*, two substituents; and *3*, three substituents (r is the $Z-C_{Mes}$ bond length).[14]

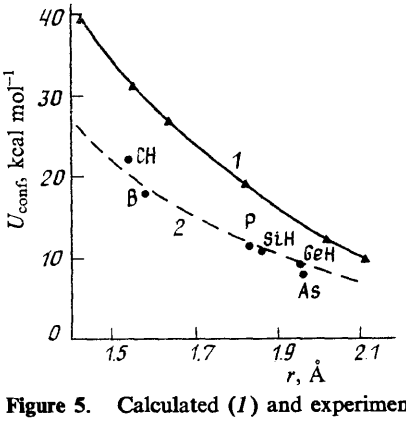

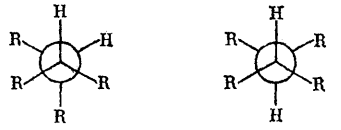

Figure 5. Calculated (*1*) and experimental (*2*) values of the energy of stereo-isomerisation for $Z(Mes)_3$ molecules (r is the length of the $Z-C_{Mes}$ bond).[14]

A parametrisation which makes it possible to carry out conformational calculations for molecules containing chains of several Si atoms was described by Mislow and co-workers[24] and developed in later studies.[25] The simplest representatives of this series are the alkyl-substituted disilanes $(R_2HSi)_2$, where R = Me, t-Bu, and Cy (cyclohexyl).[26] For the compound with R = Me, the energies of the *gauche*- and *anti*-conformations

according to the calculations, differ by 0.2 kcal mol^{-1}, but the barriers to the transformations $G \rightleftarrows G^-$ and $G \rightleftarrows A$ are fairly small: 0.97 kcal mol^{-1} and 1.34 kcal mol^{-1} respectively. The dependence of U_{conf} on the angle of rotation about the Si–Si bond in the $[(t\text{-Bu})_2HSi]_2$ molecule is shown in Fig. 6. In this case the barriers to the corresponding conformational transformations are significantly larger: 24.9 kcal mol^{-1} for $G \rightleftarrows G^-$ and 15.1 kcal mol^{-1} for $G \rightleftarrows A \rightleftarrows A^- \rightleftarrows G^-$; the last value is close to the experimental value obtained by NMR ($\Delta G^{\neq}$ = 13.8 ± 0.3 kcal mol^{-1}). For $(Cy_2HSi)_2$, for which the number of possible conformers is appreciably greater than in the previous cases (45 *gauche*- and 27 *anti*-forms), the most favourable conformer was again found to be one of the *gauche*-conformers, whose structure shows good agreement with that found in the crystal by XRD.

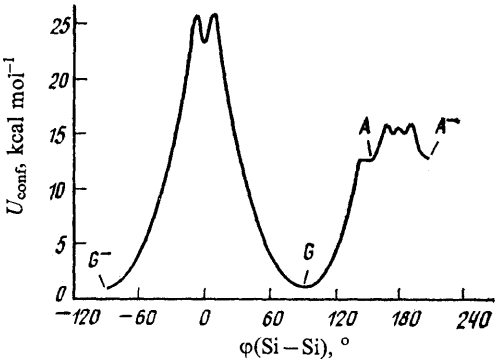

Figure 6. Dependence of U_{conf} on the angle of rotation about the Si–Si bond in the $[(t\text{-Bu})_2HSi]_2$ molecule.[26]

The stereochemistry of similar tetra-aryl-substituted disilanes has been studied[27] using the MMM, XRD, and NMR. For the $(Ph_2HSi)_2$ molecule, the energies of five *G*- and *A*-conformers are similar (the energies of the most favourable C_2– and C_i-conformers are –7.12 kcal mol^{-1} and –6.68 kcal mol^{-1} respectively). For the $(Mes_2HSi)_2$ molecules (in contrast to the alkyl derivatives described above), the *anti*-conformation becomes much more favourable [$U_{conf}(A)$ = 10.55 kcal mol^{-1}, $U_{conf}(G)$ = 13.08 kcal mol^{-1}]. The results of the calculation for the two molecules show good agreement with NMR data (in solution, the Ph-derivative exists as a mixture of conformers, whereas for the Mes-derivative the *anti*-form with C_2 symmetry predominates) and with XRD data for these compounds, according to which both derivatives are present in the crystals as the *anti*-conformers.

Molecules containing chains of several Si atoms have been examined.[24,25] The study of these molecules is a necessary stage in the determination of the structure of polymeric silane molecules. The parametrisation used in the works cited, and hence the results of the calculations, differ slightly. Table 1 compares the results of the calculations with the available experimental data for the molecules studied. The results obtained with the parametrisation proposed by Hönig and Hassler[25] show better agreement with the experimental data (Table 1). This last feature apparently explains why this version of the parameters was used to calculate the conformation of the polymer chains of polysilane $H(H_2Si)_nH$ and polydimethylsilane $Me(Me_2Si)_nMe$.[29] In the work cited, a calculation of the conformations of polysilane molecules containing n = 30, 10, and 5 units was used to analyse the dependence of the qualitative results obtained on the length of the chain being studied. The minimum chain length making it possible to model all its possible conformations was found to be that with n = 5. The data obtained for the chain with n = 5 can be used to obtain a sufficiently full description of the conformtion of longer chains. This made it possible, in the study of the conformation of polydimethylsilane, to consider only a fragment of the chain with n = 5. These calculations were repeated by Welsh and co-workers[30] with slight restrictions, in that account was taken of only the non-valence and torsional components of the energy, and also by Tashiro and co-workers,[31] where the parametrisation for the silanes (for the program MM2) was calibrated from the results of quantum-chemical calculations for model molecules.

**According to a non-empirical quantum-chemical calculation,[28] the relative energies of the *S*- and *E*-conformers are 0.0 and 3.8 kcal mol^{-1} respectively.

The results of the calculations for a chain with n = 5, carried out by Damewood and West[29] and Welsh and co-workers[30] (Table 2), and also by Tashiro and co-workers,[31] agree well with one another, and indicate that the *GG*-conformer is the most favourable. The differences, given below, in the conformational energies of the *anti*- (planar zigzag) and *gauche*- (spiral) conformers for alkane and silane chains[31] indicate an increase in the energetic advantage of the *gauche*-conformer for the silane and of the anti-conformer for the alkane with increase in the chain length:

n	4	5	7	13	17	21	30

*Large quantity, not calculated.

A statistical analysis of the conformational stability of polysilane chains has been carried out.[30] The calculation showed that the characteristic ratio

$$C_\infty = \lim_{n\to\infty} \langle r^2\rangle_0/nL^2,$$

where $<r^2>_0$ is the mean-square distance between the ends of the chain, n the number of units, and L the length of the unit in the chain, is 4.02 for polysilane, and 12.2−15.0 for polydimethylsilane (depending on the method used to calculate the conformational energy). Comparison of these values with the values of C_∞ for polyethylene (6.7) and polydimethylsiloxane (6.4) indicates that the polydimethylsilane molecule is less flexible than these polymers.

The influence of lateral substituents on the conformation of a polysilane chain has not been studied by calculation, but it can be followed from experimental studies of the structure of polymers of the type $R-(SiR_2)_n-R$. The polymer with R = n-pentyl has a spiral chain conformation (7/3 spiral), and that with R = n-hexyl has a planar zigzag conformation, which is apparently stabilised by the regular packing of the lateral substituents.[32,33] In the opinion of the authors cited,[32] the existence of extended chain fragments with the *trans*-conformation is responsible for the unusual spectral properties of the hexyl-derivative (the displacement of the absorption band to the low-wavenumber range 370−380 nm), not observed for its homologues with n < 6.

The fluorescence of the n-hexyl-derivative in the near ultraviolet range (λ_{max} = 300−400 nm) has also been attributed to the presence of planar *trans*-fragments.[34] Experimental data and quantum-chemical calculations indicate that the chain in this macromolecule effectively breaks down into a number of planar chromophores separated by sections with the *gauche*-conformation, between which rapid exchange of energy takes place.[34]

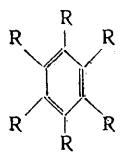
No experimental data have yet been published on the stucture of diphenyl-substituted polysilanes $R-(SiPh_2)_n-R$, but their conformation can be characterised from XRD data for the oligomers with

chain length $n = 4-7$.[35,36] The conformation of the phenyl-substituted polysilanes changes from planar to spiral with increase in the length of the oligomer chain. This last feature (and the fact that, as shown above, the chain with $n = 5$ repeats the conformation of the corresponding polymer) indicates that the corresponding polymers also contain chain fragments with the spiral conformation.

2. Organoelemental molecules containing cyclic fragments

A number of authors[12,37-41] have examined the influence of organoelemental substituents on the conformation of saturated cyclic hydrocarbons, and also the relative advantage of different arrangements of the substituents in them, in particular the equatorial (*e*) and axial (*a*) arrangements. Calculation has shown[12] that in mono-substituted cyclohexanes containing organoelemental substituents, as in those containing organic substituents, the equatorial arrangement is most favourable; its energetic preference compared with the axial arrangement (ΔE) for different substituents is given below:

R	Me	SiH_3	Me_2CH	Me_2SiH	Me_3C	Me_3Si
ΔE, kcal mol^{-1}	1.77	1.26	2.05	1.94	5.41	3.41



In this case, equatorial substituents have practically no influence on the conformation of the ring, whereas axial substituents lead to slight flattening.

In 1,2-disubstituted cyclohexanes[37] with comparatively small substituents (Me, SiH_3), the di-equatorial *trans*-arrangement is most favourable, as indicated both by calculations using the MMM and by non-empirical quantum-chemical (QC) calculations[37] (Table 3). For bulky substituents, the di-axial conformation is more favourable (Table 3). For $SiMe_3$ this is the only favourable conformation, but for CMe_3 the twist conformation has a similar energy. The results of the calculation show good agreement with NMR data,[36] which show that the solution of the first compound contains one conformer, whereas the solution of the second contains a mixture of two conformers.

Table 3. Relative energies of 1,2-disubstituted cyclohexanes (kcal mol^{-1}) from MMM data and QC calculation.

Conformation	Me		SiH_3		CMe_3	$SiMe_3$
	MMM	QC	MMM	QC	MMM	MMM
e,a-cis	1.62	1.96	0.78	1.16	5.29	1.80
a,a-trans	2.44	2.76	0.70	1.69	0.0	0.0
e,e-trans	0.0	0.0	0 0	0.0	6.73	1.70
twist-trans	5.40	8.15	5.80	6.50	0.41	2.34

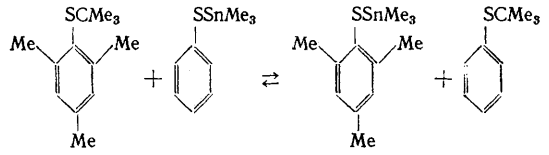
The influence of bulky substituents, including group IV elements, on the conformation of the aromatic ring in hexa-substituted benzenes, and also the possibility and the mechanism of the internal rotation of these substituents, have been studied by Mislow and co-workers.[38-41] The problem was solved by a combination of experimental methods (NMR, XRD) and calculations. The following series of compounds was studied:

(I)—(VI)

(I): R = CH_2Me (Ref.38),
(II): R = $CHMe_2$ (Ref.39),
(III): R = $SiHMe_2$ (Ref.40),
(IV): R = CMe_3 (Ref.41),
(V): R = $SiMe_3$ (Ref.41),
(VI): R = $GeMe_3$ (Ref.41).

According to the calculations, which show good qualitative agreement with XRD data, the ethyl, isopropyl, and dimethylsilyl substituents do not distort the planar structure of the aromatic ring. These distortions are detected, however, when the bulkier trimethylgermyl substituent is introduced. The C—C bond length in the benzene ring is increased considerably (to 1.418 Å) relative to the value 1.384 Å in non-substituted benzene, the ring acquires a flattened chair conformation, and the arrangement of the $GeMe_3$ substituents, which are displaced considerably from the average plane of the central ring, is described as a "superchair" conformation. The average value of the torsional angles Ge—C—C—Ge is 57.1° (XRD), in good agreement with the results of the calculation. The same trend in the distortion of the benzene ring was found from the results of the calculation for molecules (IV) and (V).

The conformation corresponding to the energy minimum for all three molecules with substituents XMe_3 [(IV)—(VI)] has D_3 symmetry. A second possible conformation for these molecules, with S_6 symmetry, is much less favourable (by 16—18 kcal mol^{-1}).



Molecules (I)—(III) have a large number of conformers [8 for (I) and 9 for (II) and (III)]. Calculation of their relative energies showed that for molecule (I), the most favourable conformation is that with D_{3d} symmetry (Me groups arranged alternately above and below the plane of the benzene ring), and for molecules (II) and (III) the C_{6h} conformation is most favourable (the H atoms of the substituent lie in the plane of the ring and occupy the space between the groups of neighbouring substituents). The calculation also made it possible to reach conclusions about the mechanism of internal rotation of the substituents in molecules (I)—(III). Two possibilities were examined—coupled (correlated) and "stepwise" (non-correlated) rotation of the ethyl, isopropyl, and dimethylsilyl groups. The second version of the rotation makes it possible to select the conformational transformation route with the lowest barrier. For example, for molecule (III), according to the calculations, the coupled rotation of the substituents can take place with an energy barrier of ~90 kcal mol^{-1}, whereas for stepwise rotation the barrier is ~35 kcal mol^{-1}. NMR data¶ for this compound give for the barrier the value $\Delta G \geqslant 22$ kcal mol^{-1}. Much better agreement is observed for the barriers to rotation of the substituents in molecules (I) and (II): 11.8 and 15.7 (calculation) and 11.5 and 14.2 (experiment) kcal mol^{-1} respectively. This proves the stepwise mechanism of internal rotation in molecules (I)—(III).

The optimum orientations and the barriers to internal rotation of the substituent R in molecules ArSR (R = CH_3, CMe_3, $SnMe_3$ and $SnPh_3$) have been compared.[42] The calculations showed that the substituent R usually does not lie in the plane of the aromatic

¶The energy of the internal rotation was measured by a dynamic NMR method for π-complexes of compounds (I)—(III) with $Cr(CO)_3$.[41] The authors cited[41] consider that the steric influence of tricarbonylchromium is slight, and that the conclusions about the mechanism of rotation in the isolated molecules C_6R_6 are unaffected.

fragment (the dihedral angle C–C–S–R is 80–90°). For Ar = Ph, internal rotation is possible for all the substituents except CMe_3. For Ar = Mes, this rotation is unlikely for all types of substituent.

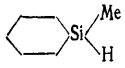
The conformational energies of the starting materials and reaction products have also been calculated[42] for the exchange reaction:

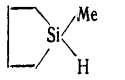
The replacement of the t-butyl group, which experiences greater steric hindrance, by the trimethylstannyl group is accompanied by a decrease in the sum of U_{conf} for the reaction products compared with the sum for the starting materials by ~8 kcal mol^{-1}, that is the equilibrium should be displaced to the right.

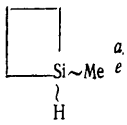
The conformational characteristics of saturated molecules with one or several X atoms in the ring have been studied.[11,12,43,44] It is fairly obvious that these molecules should differ from the corresponding cycloalkanes, primarily because of the non-equivalence of the bond lengths in the ring. For silacyclopentane, the relative advantage of the conformers decreases in the order:[44]

half-chair (C_2) 8.42 kcal mol^{-1} → envelope (C_s) 11.77 kcal mol^{-1} →
→ planar conformation (C_{2v}) 14.23 kcal mol^{-1}

and the calculated values of the geometric parameters of the most stable conformer (C_2) agree with experimental data on its structure in the gas phase.[45] The introduction of methyl substituents into different positions in silacyclopentane (1-; 1,2-*cis*-; 1,2-*trans*-) does not lead to a significant change in its conformation.[44] When the ring does not contain a heteroatom (cyclopentane), the conformations C_2 and C_s are energetically equivalent.







For silacyclohexane, the energy difference between the most favourable chair conformation and the next most favourable twist conformation (according to different data) is 3–4 kcal mol^{-1}.[11,43] For silacyclohexane, in contrast to cyclohexane, the ring is flattened slightly in the region of the Si atom and "wrinkled" in the region of the C atom lying opposite (according to calculation,[44] the endocyclic angles at these atoms are 104.2° and 113.5° respectively).

Comparison of the energies of mono-substituted silacyclohexanes[44] showed that for the 2-, 3-, and 4-methyl-derivatives, the equatorial isomers are more favourable (their energies are lower than those of the axial isomers by 1.87, 1.66, and 1.27 kcal mol^{-1} respectively). For 1-methylsilacyclohexane, the data on the relative advantage of the isomers differ slightly; Cartledge[44] considers the axial isomer to be more favourable, whereas Ouelette and co-workers[12] consider the equatorial isomer to be more favourable (difference in the energies 0.2 kcal mol^{-1} and 0.3 kcal mol^{-1} respectively). Both results indicate, however, that these isomers have similar energies.

For cyclic compounds of the type being considered, the calculations effectively reproduce the barriers to inversion of the ring. Thus for 1,1-dimethylsilacyclohexane, calculation gives the value 5.46 kcal mol^{-1}, and experiment gives the value 5.5 kcal mol^{-1} (in the analogous hydrocarbon, the corresponding values are slightly higher, 8.99 kcal mol^{-1} and 10–11 kcal mol^{-1}).

It has been shown[44] that the MMM can be used to establish the relationship between the structure and reactivity of compounds. The calculations were carried out for a series of cyclic and polycyclic molecules with one Si atom in the ring. It was previously assumed that in these compounds, the hydrolysis of the Si–H bond under basic catalysis conditions depends on the degree of strain of the coordination site including the Si atom, that is, in the language of molecular mechanics, on the contribution of U_{ang}(Si) to the total conformational energy. To verify this suggestion, the correlation between U_{ang}(Si) for several molecules and the hydrolysis rate constant was analysed (the corresponding data are given in Table 4 and Fig. 7). The graph in Fig. 7 shows that the strain in the angle at the Si atom is linearly dependent on lg k_{rel}, and the correlation coefficient (0.991) indicates that this relationship is not accidental.

Table 4. Strain in the angles at the Si atom and reactivity of a series of silanes in hydrolysis.[44]

	94.3 94.3 102.2	6.2	4
 *a* *e*	75.0 75.7	10.3 9.9	5.5

The study by experimental methods and calculations of the structure of cyclic and more particularly macrocyclic polysilanes is to a large extent determined by their unusual properties: the formation of charge-transfer complexes, radical-anions and radical-cations, and absorption in the ultraviolet range.[46]

A series of conformational calculations has been carried out[25,47] for cyclic silanes $(SiR_2)_n$ with small rings (n = 4–6) and different substituents, in particular with R = H, Me, Cl, Br, I. The authors cited compared the results of the calculations with earlier results obtained by calculations and experimental studies. The data obtained[25,47] are summarised in Table 5. Table 5 shows that for four-membered silane rings (as for cyclobutane), the folded conformation is more favourable. A similar result for $(SiH_2)_4$ was obtained by a non-empirical quantum-chemical calculation,[48] according to which the relative advantage of the D_{2d} conformation

Table 5. Relative conformational energy of cyclic silanes $(SiR_2)_n$, $n = 4-6$ (kcal mol^{-1}).

*Calculation carried out with allowance for the electrostatic component.

compared with the D_{4h} conformation is 0.54–0.74 kcal mol^{-1} (calculations in different basis sets). This difference in energy indicates conformational non-rigidity of the four-membered silane rings. The conformational non-rigidity of four-membered silane rings is also indicated by experimental data. Thus according to XRD data, the molecules of $(SiMe_2)_4$ [49] and $[Si(SiMe_3)_2]_4$ [50] are planar, and the molecules of $[Si(i\text{-}Pr)_2]_4$,[51] $[SiMe(Bu\text{-}t)]_4$,[52] and $(SiPh_2)_4$ [53] are folded; the angles of bending in the last three molecules are 37.1, 37.0, and 12.8° respectively. For the last two molecules, calculation using the MMM [47] led to good agreement between the experimental and calculated geometric parameters.

For cyclopentasilanes with different substituents, as for cyclopentane, the two conformers C_s and C_2 have similar energies. For the Ph-derivative, whose structure was studied in the crystal, an intermediate conformation was found.[54]

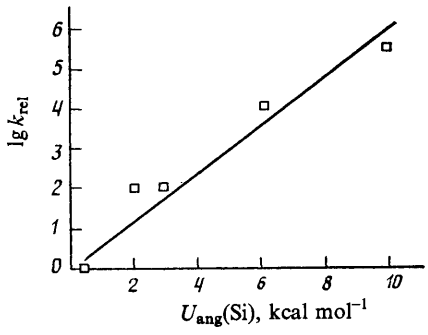

Figure 7. Dependence of lg k_{rel} for the hydrolysis of the SiH group on the strain in the valence angles at the Si atom.[44]

The optimum conformation of cyclohexasilane and its derivatives is the chair conformation, in agreement with experimental data for $(SiH_2)_6$ (GED),[55] $(SiMe_2)_6$ (XRD),[56] and $(SiMePh)_6$ (XRD).[57] According to calculations[24,58,59] and GED data,[55] the cyclohexasilane molecule is less flattened than the cyclohexane molecule [the valence angles in the $(SiH_2)_6$ and $(CH_2)_6$ rings are 111.4° and 110.3° respectively, and the torsional angles are 54.9° and 57.9°]. This is understandable, since the bonds in the ring in the $(SiH_2)_6$ molecule are appreciably longer than those in the $(CH_2)_6$ molecule, so that the repulsion of the groups occupying the *gauche*-positions will be smaller in $(SiH_2)_6$ than in $(CH_2)_6$ (by analogy with the non-cyclic tetrasilane).

For the seven-membered cyclosilane $(SiMe_2)_7$, according to XRD data and calculation,[60] the characteristic conformation is the twisted chair (*TC*) conformation. The same conformation is also the most favourable for cycloheptane. The calculation showed, however, that the relative advantage of other conformers† (Table 6), and also the conformational transformation routes, are different for $(SiMe_2)_7$ and its hydrocarbon analogue.

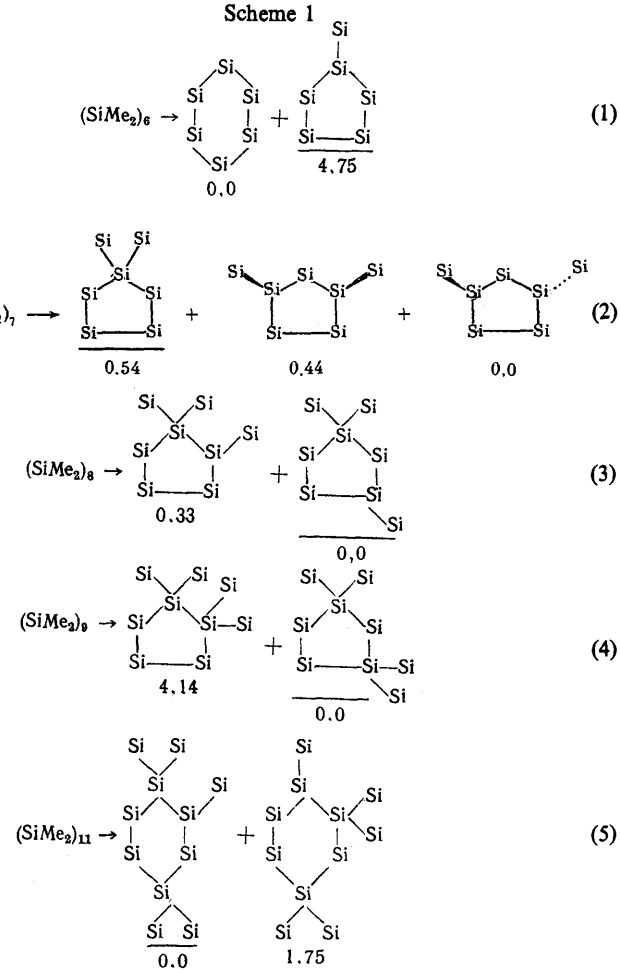
Even greater structural and energetic differences compared with the hydrocarbon analogues were observed[61] for the $(SiMe_2)_8$ molecule. This is obvious from a comparison of the conformational energies (kcal mol^{-1}) of a number of conformers:

	TCC	*CC*	*CR*	*TBC*	*BC*	*TB*	*TC*	*C*	*BB*	*B*
$(SiMe_2)_8$ (Ref.61)	0.0	0.4	0.9	2.3	2.6	3.7	4.3	6.3	9.2	10.7
$(CMe_2)_8$ (Ref.62)	—	—	1.22	2.37	0.0	—	9.96	9.51	1.67	12.13

†The torsional angles and the generally accepted notation for the conformers of cyclic molecules (*C* = chair, *B* = boat, *TC* = twisted chair, *TB* = twisted boat, *CR* = crown, *BB* = boat–boat, *CC* = chair–chair, *TCC* = twisted chair–chair, *TBB* = twisted boat–boat, etc.) have been described in detail.[63]

The authors cited[61] also noted a significant increase in the valence angles in the ring at the Si atoms (118–123°), which exceed the equilibrium value (111.7°); the same was previously observed for $(SiMe_2)_7$.[60] Thus with increase in the size of the ring, the differences in the structures and conformational behaviour of the molecules of cyclic silanes and the corresponding hydrocarbons increase.

Table 6. Relative energy (kcal mol^{-1}) of the conformers of $(SiMe_2)_7$ and $(CH_2)_7$.[60]



Conformer	$(SiMe_2)_7$	$(CH_2)_7$ *
TC	0.0	0.0
C	0.9	0.63–1.58
TB	2.6	2.40–5.64
B	4.2	2.60–5.66
TT	2.9	8.1–9.6

*The scatter in the data of different authors cited by Shafiee[60] are given.

Molecules with larger ring dimensions have been less extensively studied. Data have been published[64] on the structures of the molecules $(SiMe_2)_{13}$ and $(SiMe_2)_{16}$ in the crystals. Comparison of their conformations with those of their hydrocarbon analogues, in which the ring most frequently can be "placed" in the diamond lattice, shows appeciable differences in both cases. A calculation of the geometric characteristics of hypothetical conformers of the $(SiMe_2)_{13}$ molecule with the "pentagonal" or "trigonal" conformations (the conformer consists of five or three approximately planar fragments), observed for the hydrocarbons $(CR_2)_{13}$, showed that these conformations cannot be produced in the case of the cyclosilane, since they lead to shortened contacts between the methyl groups. The values of the torsional angles in the $(SiMe_2)_{13}$ and $(SiMe_2)_{16}$ rings differ considerably from the values corresponding to the *trans*- and *gauche*-arrangements of the units, indicating again that the silanes have a greater conformational flexibility than the hydrocarbons.

In the standard version of the MMM, electronic effects (for example conjugation) are not taken into account in explicit form. This makes it possible to use the mechanical model to detect those cases where the part played by electronic effects (irrespective of their nature) is considerable. An example of this use of the MMM is provided by studies[58,59] of a large group of alkyl-substituted penta- and hexasilanes. These compounds are products of the isomerisation of permethylated cyclic silanes $(SiMe_2)_n$ with $n = 5-11$, and a characteristic feature of the reaction, which takes place in the presence of the catalyst $AlFeCl_6$, is that the isomerisation of each of the rings usually gives a product consisting of a single isomer (Scheme 1). Scheme 1 shows only the energetically most favourable isomers (the Me groups are not shown). The values of ΔU_{ster} (kcal mol^{-1}) are given. The isomers whose yields are 95% are underlined.

Scheme 1

It is suggested that in these reactions, decrease in the ring size leads to a gain in the so-called σ-conjugation energy‡. The σ-conjugation energy for the molecules being considered can be estimated as follows. The gain in free energy for the isomer formed is written as the sum

$$\Delta H = \Delta H_{ster} + \Delta H_{bd} + \Delta H_{\sigma}.$$

Data on the ratio of the isomers (reaction products) make it possible to estimate ΔH, the MMM can be used to calculate ΔH_{ster}, and the value of ΔH_{bd} (a characteristic of the bonds in the molecules) is assumed[58,59] to be the same for all the isomers. These quantities can then be used to calculate ΔH_{σ}.

For $(SiMe_2)_6$ (Scheme 1), the ratio of the initial and final isomers is 99:1, which gives for ΔH the value 2.7 kcal mol^{-1}. With allowance for the difference ΔH_{ster} indicated in the Scheme, ΔH_{σ} for this pair of isomers is 7.4 kcal mol^{-1}, that is in this case the formation of the product with the five-membered ring is determined by not steric but electronic factors. The same is characteristic of the isomers obtained from $(SiMe_2)_7$; in this case, ΔH_{σ} is 3.2 kcal mol^{-1}.

For the products of the isomerisation of 8-, 9-, and 11-membered cyclosilanes, the preference for the formation of a given isomer is determined by steric factors. Summarising the results of calculations

‡The concept of σ-conjugation has been discussed in detail.[65]

and the experimental study of the ratio of the quantities of isomers obtained, the authors cited[58,59] point out that in the formation of cyclic isomers with the same number of silicon atoms in the ring and different arrangements of the $SiMe_3$ substituents, a decisive role in the "choice" of product is played by steric factors [see reactions (3)–(5) in Scheme 1]. When the numbers of silicon atoms in the ring or the positions of the substituents are different [reactions (1) and (2)], the electronic σ-conjugation effect predominates.

In the opinion of the present authors, however, no absolute significance should be given to the separation of the contributions into steric and electronic (this is indicated by a detailed quantum-chemical analysis of these contributions in four- and five-membered cyclosilanes[48]). These conformational calculations also lead to the conclusion that the force field suitable for the description of cyclosilanes with $n \geqslant 6$ should not be extended automatically to the description of smaller rings.

The range of substances which have now been examined using the MMM includes compounds containing the bonds X–O, X–N, X–S, etc., such as organoelemental peroxides, siloxanes, and silazanes.

Siloxanes. The MMM has been applied to the organosiloxanes,[66,67] an extensive class of compound with wide practical applications in polymer chemistry.[68] The selection of the required parameters of the potentials describing the siloxane bond has been carried out for various simple linear and cyclic siloxanes: $(H_3Si)_2O$, $(Me_3Si)_2O$, $(Me_2SiO)_3$, $(H_2SiO)_4$, and $(Me_2SiO)_4$.[66] These parameters supplement the set of parameters proposed by Allinger and Tribble[11] for the description of the molecules of silanes and carbosilanes.

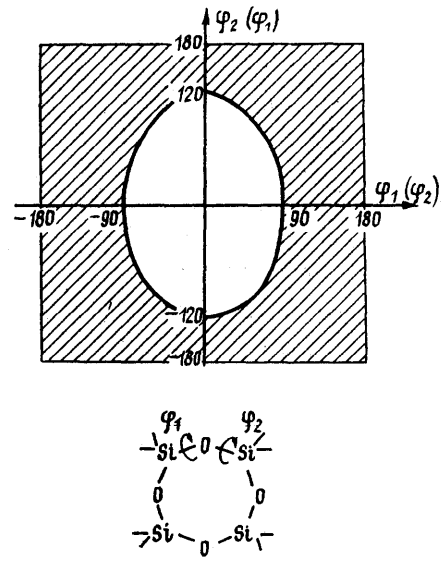
A detailed analysis of the conformational possibilities of the tetrasiloxane ring, which is the basic structural fragment of a number of polymers, has been carried out.[67,69] An eight-membered ring with fixed bond lengths and valence angles has two degrees of freedom,[70,71] namely two torsional angles, and the values of the remaining six torsional angles are determined by the ring closure conditions.[72] A calculation for non-substituted cyclotetrasiloxane[69] showed that in the space of the two independent torsional angles (φ_1 and φ_2), the extensive range shown in Fig. 8 is allowed (within the isoenergetic line 10 kcal mol^{-1}). The values of the remaining torsional angles also lie in this range.

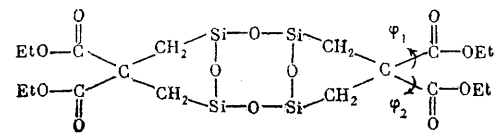
The tetrasiloxane ring is much more flexible than the cyclo-octane ring;[69] a typical value of the difference between the energies of the symmetrical conformers§ is 0.1–0.2 kcal mol^{-1}, and the least favourable planar conformer differs from the most favourable conformer by only 3.4 kcal mol^{-1}. It was also shown that for a given conformation, a smooth change in the torsional angles without an appreciable change in energy is possible. The small difference in the conformational energies is associated with a large variety of unsymmetrical structures of the tetrasiloxane ring observed in the crystals;[74] these structures can be represented approximately as the superposition of the symmetrical canonical forms of the eight-membered ring. The conformational non-rigidity of the siloxane molecules is apparently one of the reasons for the greater "friability" of siloxane crystals compared with organic molecular crystals.[75]

A smaller siloxane ring (cyclotrisiloxane) compared with the tetrasiloxane ring is characterised by the single energetically most favourable planar conformation.[66]

§The canonical symmetrical forms of the eight-membered rings according to Hendrickson[63,73] were examined.

According to XRD data[76] and calculation,[76] in the carboxysiloxane six-membered ring of the $CH_2CH(COOH)CH_2SiMe_2OSiMe_2$ molecule the siloxane fragment CSiOSiC also remains planar, whereas the CCC angle deviates from this plane by 57°, that is the ring as a whole has the "sofa" conformation.





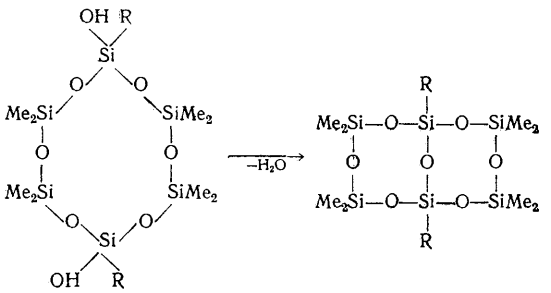


Figure 8. Range of existence of cyclotetrasiloxane in the space of the torsional angles φ_1 and φ_2 (the forbidden region is hatched).[69]

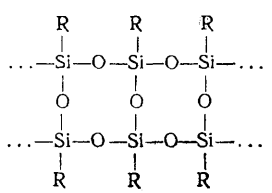
For various organosiloxanes, calculations have established the relationship between the conformational characteristics of the molecules and their chemical behaviour. Thus in the tricyclic molecule



the pseudo-equatorial ester group can undergo practically free rotation (angle φ_1), whereas for the pseudo-axial group there are two ranges of allowed values of φ_2 close to ~60° and ~240°, separated by a high barrier.[77] The orientation of the pseudo-axial group in the crystal (φ_2 = 60°[77]) lies in one of the allowed ranges, and should not change on transfer to solution. This ester group occupies a shielding position relative to the carboxysiloxane group and, partly, the siloxane ring, and this (together with the redistribution of charges on the atoms of the ring, taking place under the influence of the ester substituent) probably explains the lowered reactivity of this compound in ionic splitting reactions.

The possibilities of change in the conformation of a twelve-membered siloxane ring on dehydration, taking place with the formation of a bicyclic product, have been examined.[78,79]

According to the calculation, in the ring with the *cis*-arrangement of the OH groups the approach of these groups is possible without a significant change in U_{conf} for the molecule to a distance corresponding to the formation of an H-bond between them (O...O ~ 2.94 Å). Dehydration at this bond apparently gives the bicyclic product. For the *trans*-isomer, this approach is impossible, and the formation of a cyclic product can take place only with rupture of the bonds in the ring at intermediate stages of the reaction. The conformation of the molecule of the *cis*-isomer predicted in the work cited[78] showed good agreement with that subsequently found in the crystal,[80] where the ring again has the boat form, and the OH groups are joined by an intramolecular H-bond (O...O 2.71 Å).

The bicyclic product obtained in the reaction is the simplest fragment of the cyclic–linear ladder polymer

A calculation[67] carried out for the bicyclic molecule showed that for it, at least two conformations with similar energies are possible (in the first, the molecule has C_2 symmetry, and both rings have the *BB* conformation, and in the second, one ring has the *CB* conformation, and the other the *LC* conformation), differing from the conformation found in the crystal.[81]

For the molecules of oligomers containing three cyclic fragments, where the side rings are joined in *cis*- and *trans*-fashion to the central ring, the calculated geometric parameters (particularly for the central ring) show fairly good agreement with those obtained by XRD.[74,82] These results indicate that introduction into the bicyclic molecule does not restrict the mobility of the eight-membered siloxane rings, whereas tricyclic (and hence polycyclic) connection makes this ring fairly rigid.

The calculation also showed slight energetic preference for *trans*-connection for the tricyclic molecule, compared with *cis*-connection (8.17 kcal mol^{-1} and 7.55 kcal mol^{-1} respectively). This indicates that for the ladder polymer, the *trans*-connection of the rings (Fig. 9*a*) is more favourable than alternate *trans*- and *cis*-connection (Fig. 9*b*).

In the above studies, the structure of the polymer chain was estimated from the results of calculations for its fragments represented by oligomer molecules. Other authors[83–85] examined the structure of infinite linear siloxane chains $(R_2SiO)_n$ in the isolated state and in the crystalline regions of the polymer. The calculation for the isolated chains $(R_2SiO)_n$, where R = Me, Et, Pr,[83] and Ph [85] showed that the spiral conformation is energetically most favourable. For polydimethylsiloxane, several possible conformations were examined, corresponding to the planar zigzag and the spirals 4_1 and 6_1 (with four and six units in each period). The spiral 4_1 version was found to be energetically most favourable, but the difference between its energy and that of the next most favourable version 6_1 is small (energy difference ~0.1 kcal mol^{-1}), while the production of the planar zigzag conformation is unlikely. For the molecules of polydiethyl- and polydipropylsiloxanes, several conformations of similar energy were detected, having approximately the same spiral step (~2.35 Å) but differing in the orientation of the substituents and the angle of rotation about the virtual bond O...O characterising the connection of the chain units. The final selection of the most favourable conformation in these cases made it possible to carry out a search for the optimum packing of the molecules in the crystal, corresponding to a minimum value of $U_{conf} + U_{interm}$, where the last term characterises the intermolecular non-valence interactions.[84] The search for this packing was carried out using the space groups and unit cell parameters obtained in an X-ray diffraction study of the crystalline polymers. For the tetragonal polydipropylsiloxane and the monoclinic polydiethylsiloxane, the most favourable conformation in the crystal is the spiral with 4_1 symmetry.

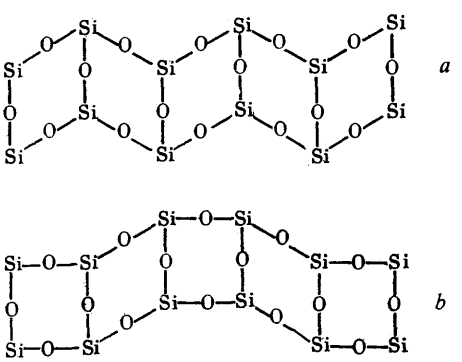


Figure 9. Cyclic–linear polyorganosiloxanes with *trans*- (*a*) and *cis*–*trans*- (*b*) connection of the rings.

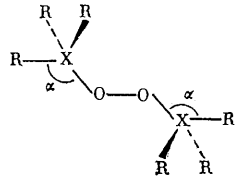
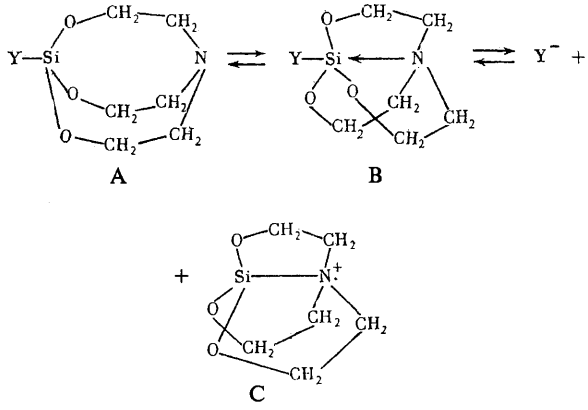


The same conformation is characteristic of polydiphenylsiloxane in the free state and in the crystal.[85] In the last case the authors cited note that the conformation is the same in the two states mentioned. Thus for all the polyorganosiloxanes examined (at least in the crystalline state), the most favourable conformation is the spiral 4_1, with slight differences which are due to the increase in the volume of the substituents and which correspond to an increase in the spiral step and in the valence angles at the O atoms.

Peroxides. The conformational characteristics of organosilicon and organic peroxides with similar structures have been examined.[86–89] A common feature of the molecules of simple peroxides is the "half-opened book" conformation with torsional angle ω about the O–O bond equal to 90–150°. For molecules

with bulky organoelemental and organic substituents, this angle may reach 180°, that is the molecule as a whole has the *trans*-conformation.

The conformations of a series of peroxides $Me_2RSiOOSiRMe_2$, where R = Me, CH_2Ph, and *p*-C_6H_4Cl, have been calculated.[86] The values of the angle ω in these compounds are 143.5° (GED),[90] 180°, and 180° (XRD)[88] respectively. The aim of the calculation was to determine whether the *trans*-conformation in the last two compounds is due to the effect of the crystalline environment, or whether it is characteristic of these molecules in the free state. It was found that for the molecule with R = Me, the optimum angle is ω = 140°; for the molecule with the slightly larger substituent R = CH_2Ph, two ranges of favourable conformations corresponding to angles ω = 140° and 180° were detected, the energy of the first being lower by 0.7 kcal mol^{-1}; and, finally, for the molecule with R = *p*-C_6H_4Cl the only favourable conformation is the *trans*-conformation (ω = 180°). Thus the molecule of the peroxide with R = CH_2Ph apparently adopts the *trans*-conformation under the influence of the crystal field. With more bulky substituents, this conformation is also characteristic of the isolated molecule. The same regularities were found in calculations for the molecules of organic peroxides R_3COOCR_3.[87,89]



The MMM does not reproduce all the characteristics of the structure of peroxide molecules. X-Ray diffraction[87–89] has shown that in organic and organoelemental peroxides

the value of the valence angle O–X–R (α), including the X–R bond in the *trans*-orientation to the O–O bond, is always smaller than the tetrahedral value, and equal to ~100°. It has been shown[89] that the tendency for this angle to decrease is not reproduced satisfactorily in calculations using the MMM, but is effectively described by the semi-empirical CNDO/2 quantum-chemical method, indicating that this effect is predominantly electronic.

In the molecules of $Me_3COOCMe_3$ and $Me_3SiOOSiMe_3$, GED [90] did not detect a decrease in the angle α, whereas X-ray gave for the first molecule a value of α equal to 100.7°.[89] This difference is due to the fact that the GED refinement was carried out using a model with fixed symmetry of the Me_3X groups (C_{3v}),[90] which could not have led to a decreased value of one of the valence angles.

Silatranes. As noted in the Introduction, the range of applicability of the MMM is usually restricted to those cases of change in the structure of molecules where there is no rupture or formation of chemical bonds. Earlier, however, attempts had already been made to modify the mechanical model in order to examine processes of molecular rearrangement accompanied by a change in the coordination of various atoms, that is essentially not conformational but chemical transformations. An example from organoelemental compounds is provided by studies[91–94] in which a method for carrying out these calculations was developed for the case of the 1-methylsilatrane molecule. The last of the works cited,[94] in which the most fully developed calculation procedure was used, can be considered in more detail. The authors cited examined the hypothetical conversion of the energetically unfavourable *exo*-form of the silatrane A into the ionic product C, which is also unfavourable, via the *endo*-form B, which is the only one to actually exist:

The authors cited[94] regard this process as a model substitution reaction of the S_N2 type. To take account of the change in the coordination number of the silicon atom, the dependence of the equilibrium values and force constants of the valence angles on the bond orders (*P*) at the Si atom was introduced into the model. The nature of the change in the bond orders in this reaction was the subject of a special study;[95] in particular, in the *exo*-form $P_{Si-N} = 0$, and in the *endo*-form $P_{Si-N} = P_{Si-Y}$.

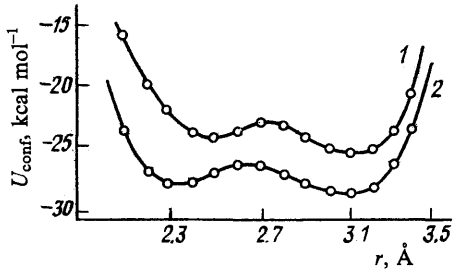


Figure 10. Dependence of the conformational energy on the distance Si...N for the molecules of 1-methylsilatrane (*1*) and 1-chlorosilatrane (*2*).

The calculated dependence of the energy (U_{conf}) on the distance Si–N (reaction coordinate) for the molecules with Y = Me and Cl is shown in Fig. 10. Curves *1* and *2* have minima corresponding to the *endo*-form which actually exists, and to the *exo*-form which has not been detected; the geometric parameters of the first show good agreement with those found for molecules of this kind by GED and XRD. The calculation showed that with the usual parametrisation (tetrahedral coordination of the silicon atom), these curves will have only one minimum, corresponding to the *exo*-form.

The authors cited[95] point out that the differences in the energies of the forms and the barriers to the transformation calculated for both molecules do not explain the fact that the silatrane molecules

exist only in the *endo*-form and the fact that quantitative agreement between calculation and experiment can be achieved only by taking account of the energy of the hypervalent bonding Y—Si ← N. In spite of these shortcomings, the results obtained are fairly encouraging, since they make it possible to obtain geometric parameters of the molecules which are close to the actual values, at the point corresponding to the minimum on the reaction coordinate.

IV. Conformational calculations for organometallic molecules

The previous section examined molecules in which the atom X has a definite (most frequently four-fold) coordination, analogous to the coordination of the C atom (sp^3) in organic molecules; this made possible an exhaustive description of its immediate environment using the X—R bond lengths and valence angles. The examination of structural data on the nature of the ligand environment of a metal atom (M) in organometallic complexes (mononuclear and polynuclear π-complexes and metal clusters) shows that in these compounds there is no rigidly fixed coordination of the M atom,[96,97] so that it cannot be described in terms of ideal values of the valence angles at the M atom. This feature, and also the widely encountered view that the structure of these molecules is determined chiefly by electronic factors, apparently explain why, until recently, there has been practically no application of the mechanical model to the examination of organometallic molecules¶.

1. Mononuclear metal complexes

Until recently, the only example of the application of the MMM to π-complexes was that described by Dashevskii and co-workers.[98] For molecules of the type $(C_5H_5)_2M$, the authors cited calculated the dependence of the energy of the non-valence inter-ligand interaction on the angle of relative rotation of the parallel cyclopentadienyl (Cp) rings. In agreement with the experimental data, it was shown that the barrier to this rotation is low, and that, depending on the M—C(Cp) distance, the molecule may have the staggered ($\varphi = 36°$, $d \lesssim 2.05$ Å) or eclipsed ($\varphi = 0°$, $d > 2.05$ Å) conformation of the ligands. A calculation has also been carried out for the $(C_5H_5)_2TiCl_2$ molecule, assuming ideal tetrahedral coordination of the Ti atom.[98] The minimisation of U_{conf} gave a ligand arrangement agreeing with that obtained by electron diffraction (the angle Cl—Ti—Cl is 105° or 102°, and the dihedral angle between the Cp ligands 125° or 121°, according to calculation and GED respectively).

Later, a simplified version of the MMM was proposed,[100–102] which makes it possible to predict fairly reliably the geometric characteristics of π-complexes. This model of a mononuclear π-complex ("hinge" model) is based on the view that the coordination sphere of the metal is uniformly occupied by the ligands,[99,103] and the criterion of uniform filling is the attainment of a minimum energy of the non-valence inter-ligand interaction. In this case the geometric characteristics of each of the organic ligands are calculated using the usual MMM scheme; the constants characterising the rigidity of the valence angles at the metal atom are taken as zero, and the metal—ligand distances are fixed by specifying high values of the deformation constants of the bond lengths M—L.

For a comprehensive verification of the proposed model, π-complexes of three main types were examined:[101,102,104] a, the half-sandwich compounds $CpM(CO)_3$ (Fig. 11*a*); b, the sandwich compounds $(C_5R_5)_2M$ with R = H or Me (Fig. 11*b*); and c, wedge-sandwich compounds with additional ligands $(C_5R_5)_2ML_n$, where L = H, Cl, CO (Fig. 11*c*). For the half-sandwich molecules, the calculation was carried out for values of the bond lengths M—Cp (centre of gravity of the Cp ligands) equal to 1.730 Å and 1.957 Å, and values of the M—CO bond lengths equal to 1.826 Å and 1.894 Å, characteristic of metals of the first and second transition series. The calculated values of the inter-ligand angles α (Fig. 11*a*), equal to 95.2—96.4° for the first set of distances and 98.7—99.7° for the second, show good agreement with XRD data for $CpMn(CO)_3$ [105] (M—Cp 1.79 Å, M—CO 1.79 Å, α = 91—94°), $[CpFe(CO)_3]^+PF_6^-$ (M—Cp 1.68 Å, M—CO 1.82 Å, α = 92—95.6°), and $CpRe(CO)_3$ (M—Cp 1.96 Å, M—CO 1.90 Å, α = 89.9—90.5°). Increase in the covalent radius of the atom M leads to a decrease in the steric strain in the coordination sphere and to slightly less satisfactory quantitative agreement between the calculated and experimental values of the angles α, although qualitatively the geometry of the "piano stool" is reproduced correctly.

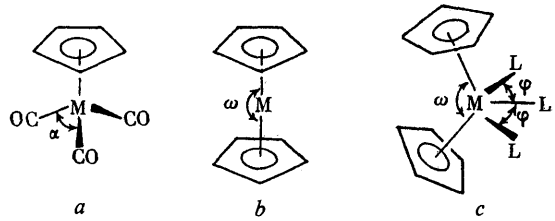

Figure 11. Types of π-complex studied:[101,102] *a*, half-sandwich $CpM(CO)_3$; *b*, sandwich $(C_5R_5)_2M$; and *c*, wedge-sandwich with additional ligands $(C_5R_5)_2ML_n$.

A calculation[102] carried out for the half-sandwich complex $(\eta^4\text{-}C_4H_6)Fe(CO)_3$ (Fig. 12) effectively reproduced all the experimentally observed structural characteristics.

In sandwich molecules with the parallel arrangement of the CP ligands, the inter-ligand contacts C...C are usually close to the normal van der Waals distances, so that regular filling of the coordination sphere of the metal atom is observed. At the same time, the structures of a number of bis-cyclopentadienyl derivatives Cp_2M, where M = Si, Ge, Sn, Pb, As,[106–109] have molecules with a wedge-sandwich configuration. According to quantum-chemical calculations, this arrangement of the Cp rings is due to the presence of a localised lone pair of electrons of the atom M in the equatorial plane of the wedge-sandwich.[106] An alternative explanation of the

¶The MMM is applied fairly extensively[7] to the molecules of coordination compounds in which the values of the valence angles at the M atoms are fixed. At the same time, in coordination chemistry, use is also made of models in which the most favourable arrangement of the ligands is determined by the minimum of the energy of interaction of points arranged on a sphere and approximating the ligands.[99]

wedge-shaped arrangement of the rings[101,102] takes account of only the non-valence inter-ligand interaction, and corresponds to the mutual attraction of the Cp ligands, where the non-valence contacts between the ligands when M has a large radius correspond to an attractive van der Waals interaction.

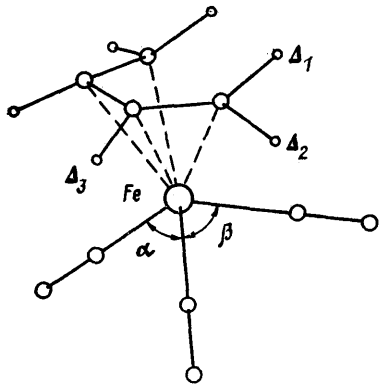

Figure 12. Structure of the $(\eta^4\text{-}C_4H_6)Fe(CO)_3$ molecule; the geometric parameters have the following values: α = 93.7° and 92.0°, β = 98.3° and 100.0°; Δ_1 = 0.65 Å and 0.50–0.65 Å, Δ_2 = −0.14 Å and from −0.15 Å to −0.20 Å, Δ_3 = −0.48 Å and from −0.05 Å to −0.15 Å from calculation and experiment respectively (Δ is the deviation of the hydrogen atom from the average plane of the ligand).[102]

A calculation[101] of the optimum configuration of metallocenes, characterised by the angle ω (see Fig. 11*b*), in the range of distances M–Cp from 1.6 Å to 2.5 Å at intervals of 0.05 Å showed preference for the wedge-sandwich configuration for the molecules Cp_2M and $(C_5Me_5)_2M$ for distances M–Cp greater than 1.80 Å and 2.05 Å respectively. Qualitative agreement was observed between the calculated and experimental values of the geometric parameters in these molecules (Fig. 13). The slight quantitative differences[101,102] are attributed to the appreciable conformational flexibility of the wedge-shaped sandwich, and hence to the influence of the crystal field on its geometry, found by XRD. This effect is illustrated, for example, by the difference in the angles ω in the Cp_2Sn molecule in the gas phase (GED) and in the crystal (XRD) and by the coexistence in the $(C_5Me_5)_2Si$ crystal[109] of two symmetrically independent molecules with markedly different angles ω, equal to 180° and 154.7°. The model used also effectively explains the increase in the angle ω when bulky substituents are introduced; the experimental values of this angle in Cp_2Sn[106] (GED), $(C_5Me_5)_2Sn$,[105] and $(C_5Ph_5)_2Sn$[110] are 125, 144, and 180°; and in Cp_2Ge[108] and $[C_5H_2(SiH_3)_3]_2Ge$[111] 129.6° and 171° respectively. Thus in the approximation used (and in agreement with experiment) it has been shown that with increase in the radius of the atom M, the structure of the metallocene molecule changes from parallel to wedge-sandwich under the influence of van der Waals forces.

For wedge-sandwich metallocene derivatives with additional ligands, where there is more "compact" filling of the coordination sphere of the metal by the ligands, better agreement between the calculated and experimental values of the angles at the central atom M should be expected. This is confirmed by the data in Table 7, where the calculated and experimental values of the angles ω and φ are compared (see Fig. 11*c*). The experimentally observed decrease in the angle φ on going from the complexes with the d^0 electron configuration of the atom M to the d^1 and d^2 complexes is satisfactorily explained in the MMM by steric factors, although usually this change in the geometry is interpreted on the basis of the molecular-orbital model as the result of the electrostatic repulsion of the ligands in the bisector plane and the electrons localised in the "rear" orbitals of the metal atom.[112] Here, the difference between the calculated and experimental values of the angles is small for φ, and slightly greater for ω. This result shows that calculations using the MMM can be used to reproduce qualitatively fairly fine structural effects previously attributed to electronic factors.

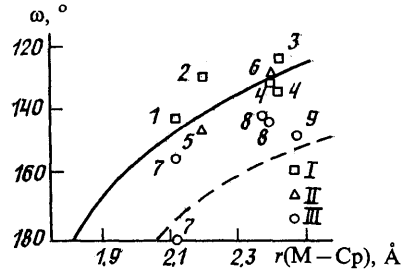

Figure 13. Calculated dependence of the angle ω on the distance M–Cp in Cp_2M (continuous line) and $(C_5Me_5)_2M$ (broken line); I, experimental values for Cp_2M molecules; II, the same for $(C_5H_4Me)_2M$; III, the same for $(C_5Me_5)_2M$; *1*, Cp_2As (XRD);[107] *2*, Cp_2Ge (XRD);[108] *3*, Cp_2Sn (GED);[106] *4*, Cp_2Sn (XRD, two independent molecules);[106] *5*, $(C_5H_4Me)_2Ge$ (GED);[106] *6*, $(C_5H_4Me)_2Sn$ (GED);[106] *7*, $(C_5Me_5)_2Si$ (XRD, two independent molecules);[109] *8*, $(C_5Me_5)_2Sn$ (XRD, two independent molecules);[106] *9*, $(C_5Me_5)_2Pb$ (XRD).[106]

These results[101,102,104] show the possibilities provided by the study of organometallic π-complexes by the MMM method, whose development should apparently take the direction of a search for an improved parametrisation.

Here, mention may be made of another purely geometric model, whose conceptual basis is similar to that of the method examined above, and which also makes it possible to obtain the characteristics of the coordination environment of the metal atom in the molecules of π-complexes. This model is based on Tolman's approach,[113] which makes it possible to describe the filling of the coordination sphere of the metal atom using the body (conical) angles characterising the projection of the ligand on to the coordination sphere of the metal. An analysis[114] of a large number of examples, including lanthanide π-complexes, was used to formulate the "packing centre" rule, according to which the sum of the products of the fraction of the body angle corresponding to the ligand and the length of the vector characterising the relative position of the ligand is close to zero. This rule makes possible an *a priori* quantitative description of the relative arrangement of the ligands in mono- and

dinuclear complexes with a sufficiently high accuracy. The authors cited point out that this rule is analogous to the requirement of a minimum energy for the non-valence interaction of the ligands in their optimum arrangement.

the immediate environment of the metal atom but the relative arrangement of the parts of the complex or the orientation of the substituents in the ligands. In these cases, when carrying out a conformational analysis, the coordination environment is most frequently fixed, and only a limited number of the parameters being considered are varied. Examples of such calculations, which were begun only recently, have been published.[115,116]

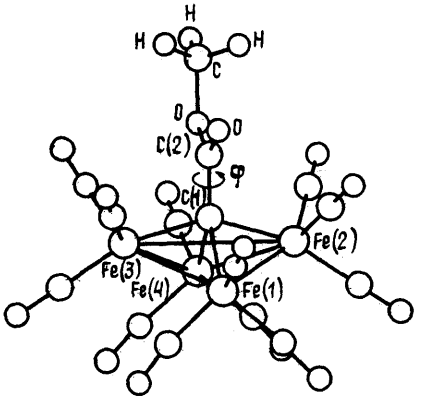

Figure 14. Structure of the $Fe_4(CO)_{12}CC(O)OCH_3$ molecule.[115]

In the opinion of the present authors, this rule should be fulfilled effectively only for sufficiently "compact" filling of the coordination sphere by ligands (for example, for the molecules MCp_3, where M represents a lanthanide, examined in the work cited[114]). It is fairly obvious that in the wedge-shaped sandwich molecules of the same lanthanides (for example for the wedge-sandwich $SmCp_2$ and $EuCp_2$) this rule is not fulfilled, but the conformation of these molecules is effectively described using the hinge model mentioned above.

In a number of cases, in the examination of the conformation of the molecules of mononuclear and polynuclear π-complexes, the feature of particular interest is not the arrangement of the ligands in

In the first of the works cited, U_{conf} was calculated to establish the relationship between the nature of the substituent R = COOMe, CH_2, and Me and the reactivity of the iron cluster $Fe_4(CO)_{12}CR$, which has the "butterfly" shape (Fig. 14). For R = COOMe (the structure of this cluster has been established experimentally by XRD[115]), the calculated orientation of the substituent showed good agreement with experiment. A similar position of the substituent was found in the model molecule with R = CH_2. For the cluster with R = Me, the total conformational energy is many times greater than that for R = CH_2, because of the short contacts between the hydrogen atoms of the CH_3 group and the carbonyl ligands. This

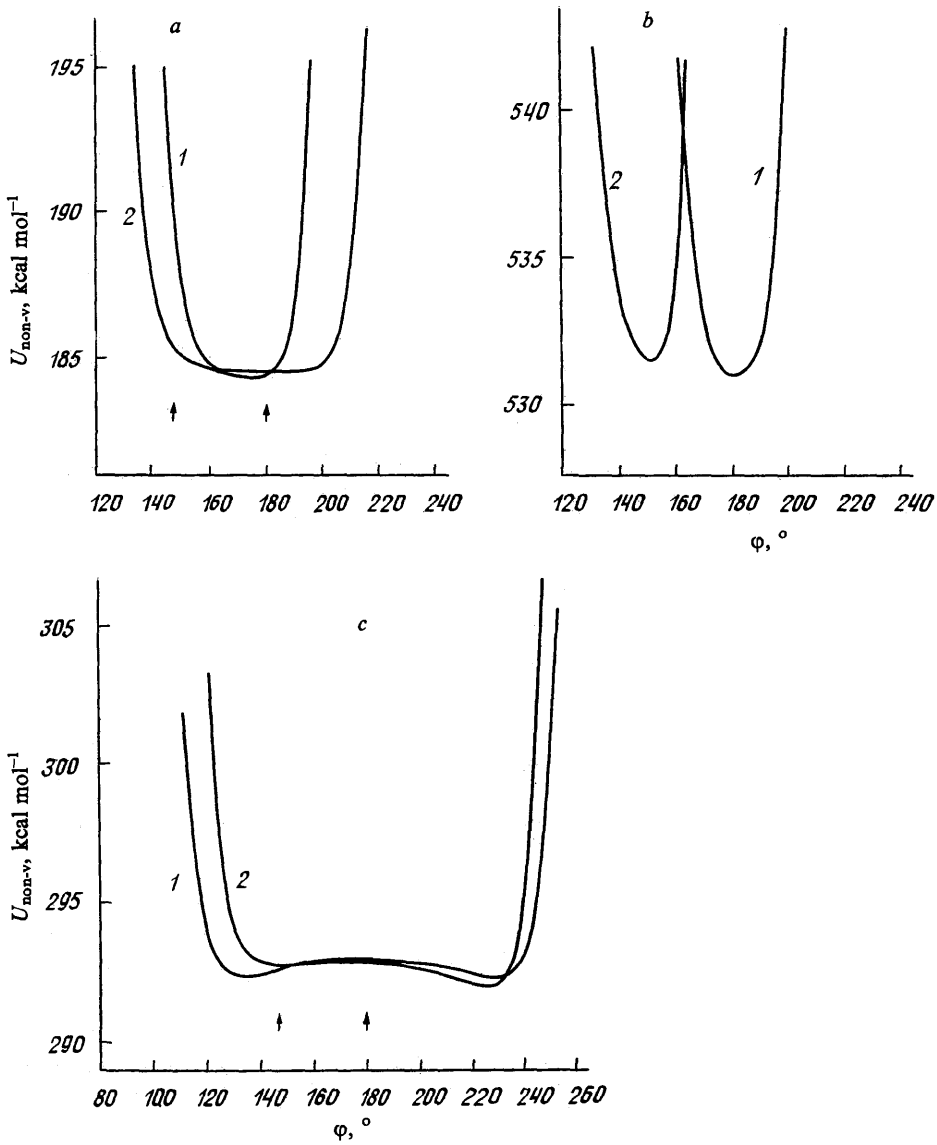

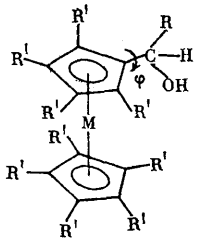

Figure 16. Dependence of the energy of the van der Waals interaction on the pseudo-torsional angle (Mo—S...S—Mo) in the molecules $[C_5R_5Mo(\mu\text{-}S)]_2$ with R = H (*a*) and Me (*b*) and in the molecule $[(C_2H_4S_2)MoS(\mu\text{-}S)]_2$ (*c*); the arrows indicate the values of φ found experimentally in the crystal; *1*, *anti*-isomer; *2*, *syn*-isomer.[116]

last feature led the authors cited to the conclusion that the addition of any group to this cluster through the sp^3 hybridised C atom cannot take place without a change in the structure of the cluster itself.

The same approach was used to study the possibility of variation in the relative arrangement of the parts of the molecules in the dinuclear complexes $[LMoS(\mu\text{-}S)]_2$, where L = $C_2H_4S_2$, C_5H_5, and C_5Me_5.[116] The *syn*- and *anti*-isomers, in which, for a fixed ligand environment of each of the metal atoms, the relative arrangement of these atoms was varied by changing the pseudo-torsional angle Mo—S...S—Mo (φ) (Fig. 15), were examined. The graphs giving the dependence of U_{conf} on φ (Figs. 16*a*—16*c*), including only the non-valence component, show that in the non-crowded molecules with L = $C_2H_4S_2$ and C_5H_5 the angle φ changes over a fairly wide range, which also includes the values of these angles for the corresponding isomers in the crystal. For both of these molecules, the *syn*- and *anti*-isomers have similar energies. The energy difference between these isomers is appreciable only for the complex with the bulkier ligand C_5Me_5. This complex is characterised by narrow ranges of allowed values of the angle φ. At present, only the energetically most favourable *anti*-isomer of this complex has been detected.[116] The slight difference in the energies of the *syn*- and *anti*-isomers (0.59 kcal mol^{-1}), however, does not exclude the existence of the second isomer.

To investigate unusual intramolecular hydrogen bonds, Shubina and co-workers[117–119] undertook a combined spectral, X-ray

diffraction, and calculation study of various carbinol derivatives of metallocenes

U

where M = Fe, Ru; R = H, Me, Ph, Mes, etc.; and R' = H, Me. The conformational calculation in this case should have revealed the steric predisposition of these molecules to the formation of H-bonds of different types: OH...M (involving the metal atom) or OH...π (involving the π-electron system of the cyclopentadienyl ligand). Fig. 17 shows several possible orientations of the carbinol group relative to the metallocene ring. From geometric criteria, an O–H...M bond can be formed in case (*A*), an O–H...π bond can be formed in cases (*B*) and (*C*), neither of these bonds is formed in case (*D*).

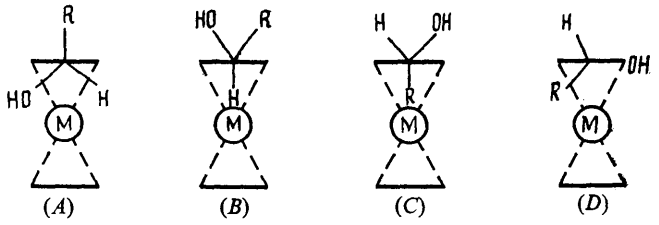

Figure 17. Schematic representation of possible orientations of the carbinol group in metallocenes.

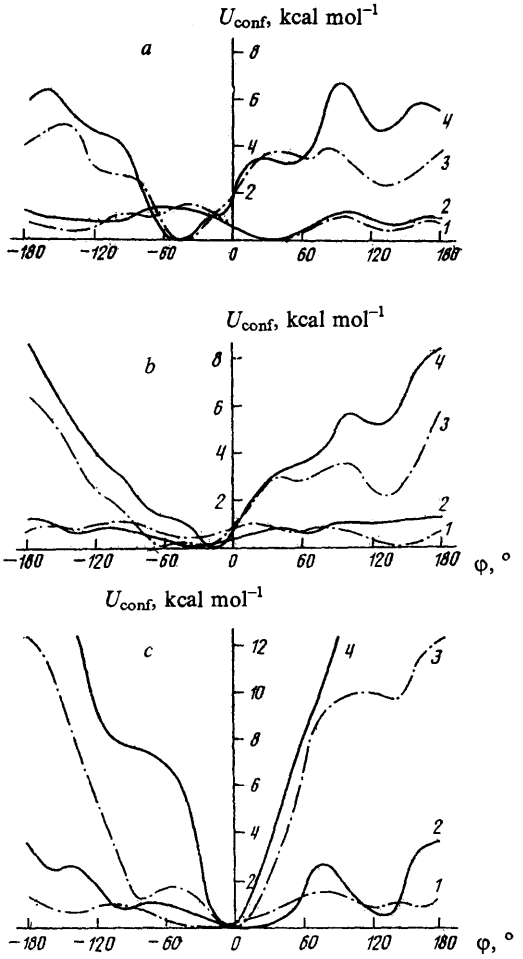

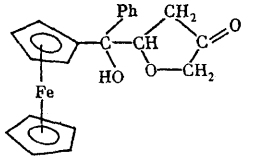

Figure 18. Dependence of the conformational energy of carbinol derivatives of metallocenes on the angle of rotation φ of the carbinol group (M = Fe—continuous line, M = Ru—dot–dash line): *a*, R = Me; *b*, R = Ph; *c*, R = Mes; curves *1* and *2* characterise the molecules with R = H, and curves *3* and *4* the molecules with R = Me.

The dependence of U_{conf} on the angle of rotation φ (C–C–C–O) of the carbinol group has been calculated. The angle φ has negative values for orientation of the OH group towards the metal, and positive values for the arrangement of the OH group above the Cp ring. The calculation showed that for carbinol-substituted metallocenes and nonamethylmetallocenes (M = Fe, Ru) with R = H, there are no ranges of preferential orientation of the OH group. For R = Me, Ph, and Mes (Figs. 18*a*–18*c*), these ranges are distinguished sufficiently clearly only for the nonamethylmetallocene derivatives. For R = Me, the OH group is orientated towards M when M = Fe, and has two orientations when M = Ru; when R = Ph, the OH group is oriented towards the M atom for both metals, but the probability of approach of the OH group to the metal is greater for M = Ru; when R = Mes, the OH group may be turned towards the metal (M = Ru) or may lie in the plane of the Cp ligand (M = Fe), which does not favour the formation of intramolecular H-bonds. In the last case, the calculation shows good agreement with XRD data,[117] according to which the torsional angle φ is 7°.

For the molecule $(C_5Me_5)Fe(C_5Me_4CH(OH)Bu\text{-}t)$ with one bulky substituent on the carbinol group and the molecule

V

with two bulky substituents on the carbinol group, the calculation[118] (Fig. 19) indicates that the OH group is oriented towards the metal (negative range of values of the angles φ); this orientation is fairly "rigid" for the first molecule, and less "rigid" for the second. This is in good agreement with the results of a study of the second complex in the crystal[120] (φ = −50.5° from the calculation, and φ = −42.9° from the experiment). The arrangement of the OH group in these molecules makes probable only the formation of the O–H...M bond.

The results of all the calculations are consistent with the infrared spectra of the complexes, which show that they contain O–H...M bonds in those cases where, from steric considerations, only the orientation of the OH group towards the metal is possible, and that two types of bond, O–H...M and O–H...π, are present when there is no steric hindrance.

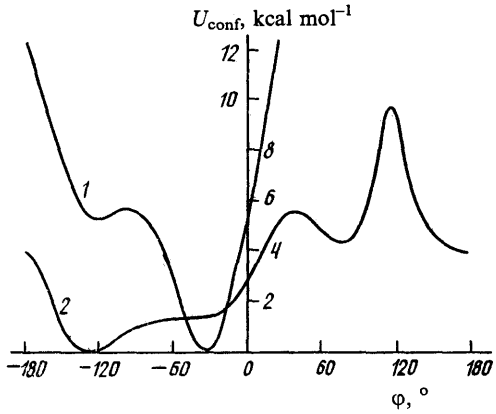

Figure 19. Dependence of the conformational energy on the angle of rotation of the carbinol group φ in the molecules of $(C_5Me_5)Fe[C_5Me_4CH(OH)(Bu\text{-}t)]$ (*1*) and $(C_5H_5)Fe[C_5H_4CPh(OH).(C_4H_5O_2)]$ (*2*).

The orientation of substituents on an asymmetric atom plays an important role in stereoselective reactions. Conformational calculations revealing the role of this factor for organic molecules have been described in detail.[4] Similar calculations were recently carried out[121] for a large number of organometallic complexes containing carbonyl, cyclopentadienyl, phosphine, and acyl ligands on an asymmetric metal atom. The aim of these calculations was to establish the relative orientation of the acyl ligands assuming rigidly fixed coordination (square planar, octahedral, etc.) of the metal atom and a fixed arrangement of the other ligands. The calculations were carried out with allowance for only the energy of the non-valence interaction in the model molecules, which contained the phosphine groups PH_2Ph, and the acyl groups C(O)Me. Fig. 20 shows the Newman projections of complexes of different types, in which the position of the C(O)Me group corresponds to the energy minimum. Complexes ML_4 with square planar, tetrahedral, and pseudo-octahedral (for complexes with Cp ligands) coordination, complexes ML_5 with square-pyramidal and trigonal-bipyramidal coordination, and complexes ML_6 with octahedral coordination were examined.

For all these complexes, the dependence of U_{conf} on the angle of rotation of the C(O)Me group for different filling of the coordination sphere by bulky (PPh_3, Cp) and less bulky (CO) ligands was analysed.[121] The introduction of bulky ligands in most cases does not change the optimum arrangement of the substituents, but it makes the range of allowed orientations narrower, and in some cases decreases the number of such ranges.

The calculation showed a similarity in the orientations of the acyl group in the octahedral and pseudo-octahedral complexes, where one of the faces of the coordination polyhedron is occupied by a Cp ligand replacing three CO groups. The authors cited[121] consider that this similarity [for example in the complexes (4) and (11), and (5) and (12), in Fig. 20] illustrates the so-called isolobal analogy between octahedral and pseudo-octahedral complexes.

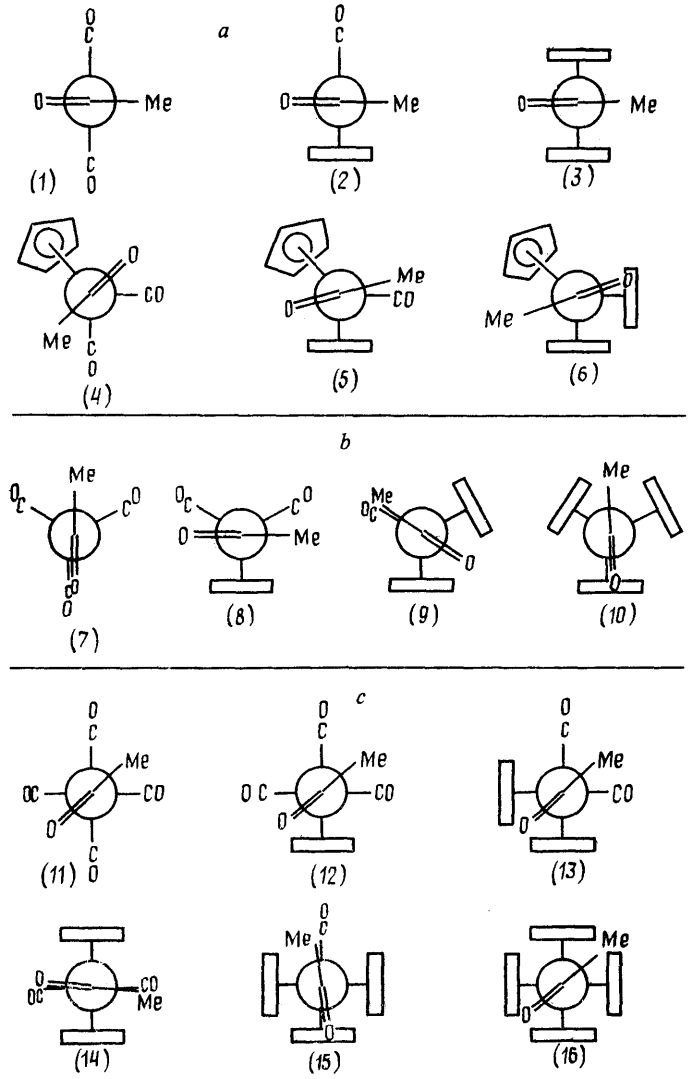

Figure 20. Newman projections of acyl complexes of metals along the line [Me(O)]C–M–CO, corresponding to the minimum energy in complexes ML_4 (*a*), ML_5 (*b*), and ML_6 (*c*); *1–3*, square planar; *4–6*, pseudo-octahedral (tetrahedral); *7–10*, trigonal-bipyramidal; *11–16*, octahedral; the rectangle denotes the ligand PPh_3; in complexes *1–3* and *7–16* the CO group under the plane of the diagram is not shown.

The most interesting and complex conformational calculations for organometallic molecules known at present are the calculations for the molecular complexes of cyclodextrins with ferrocenylacrylic esters

with the 1 : 1 composition, carried out simultaneously by two groups of authors.[122,123] The aim of these calculations was to find the conformation of the clathrate and to establish the mechanism and conformation of the product of the acylation of β-cyclodextrin by ferrocene derivatives (Fig. 21).

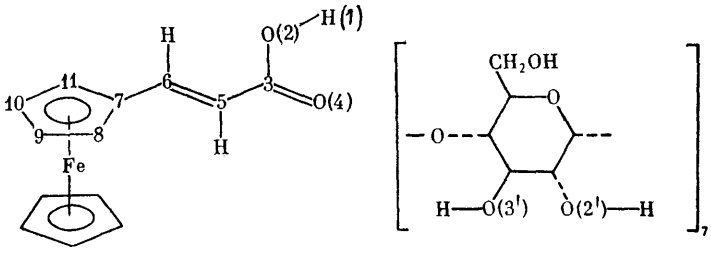

Figure 21. Structure of the molecule of the ferrocenylacrylic ester and the elementary unit of the β-cyclodextrin molecule.

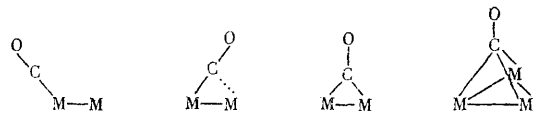
In the first stage of the calculation, the conformations of the isolated molecules forming the complex were determined. It was found, in particular, that the substituent in the ferrocene derivative† has an almost planar structure, and that the *cis*- and *trans*-conformers with respect to the C(3)–C(5) bond have similar energies (with slight preference for the latter). The second stage of the calculation involved the search for the optimum arrangement of the molecule of the ferrocenylacrylic ester in the cavity of the β-cyclodextrin molecule. In this search, in each of the molecules, account was taken of all the components of the conformational energy and the non-valence and electrostatic components of the intermolecular interaction.



The calculation showed the existence of the three most favourable orientations of the molecule of the ferrocenylacrylic ester in the β-cyclodextrin cavity.[122] In the first of the orientations, the C(3) atom of the ferrocenylacrylic ester approaches the O(2′) atom of β-cyclodextrin, and in the second and third orientations it approaches the O(3′) atom (see Fig. 21). Their relative advantage has the values 0.0, 3.0, and 5.0 kcal mol^{-1} respectively. Calculation of the conformational energy of the acylation products (with allowance for the different arrangements of the parts in the unreacted complex) revealed a slight preference for the product corresponding to the first of these orientations. Evidence in support of the first product is also provided by the fact that the conformation of the acylating agent in this case [acylation at the O(2′) atom] undergoes the smallest change. These conclusions were confirmed by an independent calculation.[123]

2. Metal clusters

The most complex organometallic materials for which the MMM is used at present are cluster molecules. The arrangement of the ligands on the surface of metal clusters, like that round a single M atom, is not rigidly fixed, and may change when the molecule is transferred from the crystal to solution, and in solution the ligands can migrate over the surface of the cluster, that is many clusters are stereochemically non-rigid.[124,125] These features obviously make it difficult to use the ordinary version of the MMM in calculations of the ligand environment of clusters. Earlier, however, it was suggested that the nature of the ligand environment of the metallic nucleus of a cluster is determined by the closest packing of the ligands on its surface.[126] The development of this suggestion has led in recent years to modified versions of the MMM which make it possible to calculate the geometric characteristics of the ligand environment of clusters, using (as in the case of mononuclear complexes) the criterion of the minimum energy of the inter-ligand van der Waals interaction.[127,128]

Thus the authors cited[127,128] developed a model in which the ligands were regarded as points on a sphere approximating the surface of the cluster, between which only the repulsion interaction was specified. The proposed model provides a qualitatively correct description of clusters with CO ligands, but does not reproduce all the details of their structure. It is understandable that the carbonyl ligand can be approximated satisfactorily by a point on a sphere, but this can hardly apply to larger π-bonded hydrocarbon or phosphine ligands, so that the application of this model is restricted considerably.

A more complex version of the MMM, free from the above limitations, has also been developed[125] for carbonyl clusters. The main complication in the description of the ligand environment of the molecules of metal clusters lies in the fact that for the M–L bonds it is difficult to specify the ideal values of the bond lengths and their force constants, since the actual concept of a bond in these molecules is somewhat indefinite. For example, the CO ligand may be terminal, half-bridging, or bridging between two or three metal atoms:

It is considered[125] that in cluster molecules of this type the ligands are joined not to one or several M atoms but to the entire metallic nucleus of the cluster. It is clear that the angle characteristics are also indefinite in this case. Here, therefore, as in mononuclear metal complexes, the non-valence inter-ligand interactions predominate.

The following model has been proposed[123] to take account of these difficulties. All the metal atoms are regarded as spheres with a radius r_m equal to half the length of the M–M bond (usually, in clusters, $r_m \simeq 2.6/2 = 1.3$ Å). Around the centres of the metal atoms, spheres are described with radius r_t equal to the "ideal" (corresponding to the energy minimum) length of the M–C bond with a terminal CO group (1.75 Å). Assuming a definite length r_b for the "ideal" bond M–C with a bridging CO group (in the present case 2.0 Å), the radius of the so-called "trial" sphere r_p (the significance of the notation is clear from Fig. 22) is calculated. As the trial sphere is moved over the surface of the metal core of the cluster, an equipotential surface is constructed from the points of contact; all the points of the surface correspond to a minimum energy of the metal–carbonyl interaction. Examples of these equipotential surfaces for di- and trinuclear clusters are shown in Fig. 23. A similar representation of the surface was adopted for protein molecules[129] in an examination of their solvate layer, from

† The parameters of the potentials for ferrocene derivatives, which make it possible to use the program MM2 for their calculation, have been published.[122,123]

which a mathematical description of this surface was obtained. The movement of a carbonyl ligand arranged at right angles to the equipotential surface is regarded as equally energetically favourable in all directions over the metal cluster.

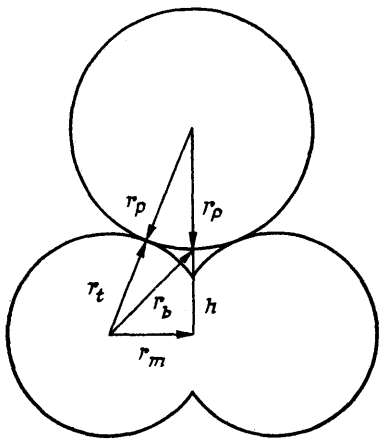


Figure 22. Diagram (section) of the relative arrangement of the metal atoms and the "trial" sphere in a dinuclear cluster.[123]

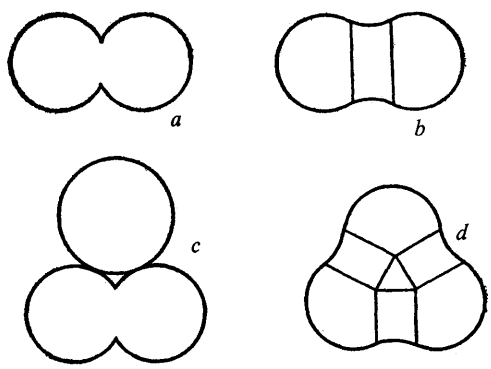

Figure 23. Construction of the equipotential surface of clusters: *a*, metal cores M_2 with intersecting (at a distance r_m) spheres of radius r_t; *b*, the same with a trial sphere of radius r_p touching the fragment M_2; *c*, the equipotential surface of a dinuclear cluster; *d*, the equipotential surface of a trinuclear cluster.[123]

The energies of bond stretching and valence angle deformation are written with allowance for the position of the carbonyl group.

For a terminal CO group, the bond stretching energy is given by

$$E_s = 71.94\, K_s (r - r_t)^2 [1 - 2.0 (r - r_t)],$$

where r is the M–C distance, and K_s the force constant of the bond.

For bridging bonds

$$E_s = 71.94\, K_s (r' - r_p)^2 [1 + 2.0 (r' - r_p)],$$

where r' is the distance from the C atom to the centre of the trial sphere.

The dependence of the energy on the angle of slope of the ligand is given by the expression:

$$E_\theta = 0.021941\, K_\theta (\theta - \theta_0)^2 [1 + 7.0 \cdot 10^{-8} (\theta - \theta_0)^4],$$

where θ is the angle between the C–O bond and the normal to the surface of the cluster, and θ_0 is the ideal value, equal to 0. The angle constant K_θ is small, and the values of the C–M–C angles are determined almost entirely by van der Waals interactions. The geometry of the metal core is not varied in the calculation.

The proposed model[125] was used to carry out calculations for a large number of carbonyl clusters containing from one to four metal atoms. Good agreement between the calculated and experimentally determined coordination was observed for the mononuclear complexes $M(CO)_n$ (n = 4–7). For n = 7, the isomers with coordination of different types (singly-capped octahedron, singly-capped trigonal pyramid, pentagonal bipyramid) have similar energies. In the dinuclear molecules $M_2(CO)_n$ (n = 8, 9), a large number of isomers is detected for the complexes with the less extensively filled coordination layer (n = 8), in agreement with the experimental data. The trinuclear clusters $M_3(CO)_{12}$ are characterised by the existence of three most favourable types of ligand coordination with overall symmetry of the molecules D_{3h}, D_3 (all CO groups terminal), and C_{2v} (two CO groups bridging). For tetranuclear clusters $M_4(CO)_n$ (n = 12–14, 16) with a small number of ligands in the coordination sphere, several versions of the environment corresponding to an energy minimum are possible, whereas increase in the number of ligands usually gives one most favourable type of ligand environment.

The author cited[125] considers that a promising development of the model which he proposed involves the inclusion in it of ligands of different types; this requires the selection of new metal cluster–ligand interaction parameters. The parameters describing the geometry of the organic ligands themselves can be taken, for example, from papers by Allinger and co-workers.[4] The calculation of the ligand environment using this model requires special fairly complex programs.

Mention may be made of another recently published calculation[130] of the geometric characteristics of the molecule of a tetrahedral cluster $M_4(CO)_{14}$ by the usual version of the MMM method with parameters proposed by the authors cited for the interactions including the metal atoms. The calculation was carried out to investigate the influence of steric crowding on the increase in the lengths of the M–M bonds relative to the same bond lengths in the non-crowded molecules. The calculation showed that a definite contribution to the additional elongation of the M–M bonds is made by the C...C non-valence interactions of adjacent CO ligands, but it was not possible to reproduce the values of the M–M bonds characteristic of the cluster $[Fe_3Cr(CO)_{14}][(PPh_3)_2N]_2$, studied by XRD by the same authors.[130]

Brief mention may be made of the possibilities provided by calculations of the conformations of isolated clusters without a ligand environment, which have been described in sufficient detail.[131,132] The atom–atom approximation has for long been used successfully for their description. The calculation of the optimum configuration of clusters of any size, consisting of inert gas atoms, was carried out by minimising the energy of the system using the hard-spheres potential, the Lennard–Jones potential, the Morse potential, etc.[131] The use of long-range potentials gives a significantly smaller number of possible isomers. For small clusters, the number

of isomers with similar energies is fairly large, and decreases with increase in the number of atoms in the aggregate. The same conclusions also apply to metal clusters for which calculations have recently been carried out using special potentials.[133]

The above data, together with the extensive experimental material on the structure of the molecules of metal clusters characterised by different types of arrangement of the metal atoms,[124,134] indicate that the ligand environment may have a significant influence on the metallic core of the cluster. For a complete description of the structure of cluster molecules, it is apparently necessary to develop a model involving the combined calculation of the optimum configuration of the metallic core and the ligand environment with allowance for their constant mutual influence. At the present level of computer technology, this model should be developed in the near future.

V. Summary

The material presented leads to various conclusions about the present possibilities provided by conformation analysis by calculation in the study of organoelemental and organometallic molecules.

It is fairly obvious that for organoelemental molecules in which the coordination of the atom of the element is analogous to that of the carbon atom, the working instrument of conformational analysis by calculation, namely the mechanical model of the molecule, has a sufficiently well developed methodological base (parametrisation and programs). This makes it possible to analyse the conformations of a large number of acyclic, cyclic, and polycyclic organoelemental molecules (mainly organosilicon molecules), and to compare their conformations with those of the corresponding hydrocarbons. It has been found that in spite of the similarity in the coordination of the atoms of carbon and the element, quantitative differences between organic and organoelemental molecules are observed in the values of the barriers to internal rotation and in the ratio of the energies of the conformers, together with qualitative differences in the optimum conformations corresponding to the energy minimum.

The existing level of development of calculation methods for molecules of this class makes it possible to solve for these molecules not only stereochemical problems (the search for the most favourable conformers and the optimum stereo-isomerisation paths) but also the problems of establishing the relative reactivity of molecules and distinguishing the dominant factors (steric or electronic) in chemical transformations. In the near future, the fields of application of the MMM for organoelemental molecules should be as varied as that for organic compounds.

For organometallic molecules and metal clusters, for which conformational calculations have been actively carried out only in the last few years, the situation is different. It has now been shown possible to apply the MMM to molecules of this type, but the parametrisation for mononuclear complexes has not yet been sufficiently developed, and apparently requires improvement. The same applies to the molecules of metal clusters, where in addition to improvement of the parametrisation it is also necessary to continue the search for models making possible the simultaneous description of the arrangement of the atoms in the metallic core and in the ligand environment.

The above results of calculations for organometallic molecules and their comparison with the results of experimental studies for molecules of this type indicate unambiguously the complete qualitative agreement between the results and indicate that the use of the MMM in the stereochemistry of organometallic compounds is promising.

Carbon dioxide in coordination chemistry and catalysis

I S Kolomnikov, T V Lysyak
Mendeleev Moscow Institute of Chemical Technology

ABSTRACT. All aspects of the fixation of carbon dioxide in the presence of catalytic systems based on transition metals have been reviewed. The results of calculations to determine the nature of the complexes of the CO_2 molecule with transition metal atoms and complexes have been described. The progress made in new fields such as the electrocatalytic, photoelectrocatalytic, photocatalytic, and radiation-catalytic fixation of carbon dioxide has been examined.

The bibliography contains 252 references.

I. Introduction

The problem of the utilisation of carbon dioxide, that is its use as a source of carbon for organic synthesis, is extremely important.[1–8] The solution of this problem is closely related to the solution of the fuel problem (the use of CO_2 to prepare hydrocarbons, methanol, and other compounds), and also to the production of synthetic food. Here it should be borne in mind that carbon dioxide, which is a waste product from various industries, can provide a practically unlimited source of carbon. The fixation of carbon dioxide is of practical interest in connection with the development of waste-free technology and the accumulation of CO_2 in isolated systems such as submarines, spacecraft, etc. The utilisation of carbon dioxide is also of considerable importance for understanding the nature of photosynthetic and chemical synthetic processes. The most important stage in the transformation of carbon dioxide in catalytic processes is the activation of the CO_2 molecule, brought about by its coordination to transition metal compounds acting as catalysts. The most promising method of utilising carbon dioxide involves the use of systems in which the CO_2 molecule can be activated by the combined use of physical (radiation of different kinds, electrolytic reduction, etc.) and catalytic (catalysis by transition metal compounds with cocatalysts of different types) methods. Of particular interest is the fixation of carbon dioxide in aqueous solutions, when water acts as a source of hydrogen; this is related to problems of bioinorganic chemistry.

About 20 years have passed since the publication of the first papers on the preparation of stable complexes of transition metals with carbon dioxide, which have led to the achievements associated with the introduction of this molecule into catalytic processes. In this time, considerable progress has been made in the development of catalytic systems for obtaining organic compounds using carbon dioxide as the source of carbon, and this work has been fairly fully reviewed.[1–8] The present review differs from earlier reviews in its complete coverage of all aspects of CO_2 fixation.

II. Estimation of the stability of the complexes of transition metals with carbon dioxide

As noted in early reviews,[1,2] the coordination of a CO_2 molecule to a transition metal atom (M) can give not only M–O bonds but also M–C bonds. The preparation and determination of the structure of stable complexes of transition metals with CO_2 stimulated the development of methods for calculating the coordination of the CO_2 molecule to metals. In principle, when one CO_2 molecule is coordinated to a metal atom, the following structures may be produced:

(I) (II) (III) (IV) (V)

A virial-statistical method has been used to calculate the stability of structures (I)–(V) for the adducts $M.CO_2$, where M = Cu, Hg, and Tl.[9–14] Adducts of this type have been observed (as ions) in mass-spectrometric studies of the corresponding carboxylates (see the references in the paper by Nekrasov and co-workers[13]). According to the data obtained by mass-spectrometry and calculation, the thallium adducts are the most stable. In the series of structures (I)–(IV), the most stable for all the metals was found to be structure (IV), in which the CO_2 molecule is coordinated through oxygen and carbon atoms simultaneously;[12] the stability of the structures decreases in the order (IV) $\geqslant$ (III) $\gg$ (I) > (II) for copper and (IV) > (III) $\gg$ (I) > (II) for thallium. The results of calculations on these structures made it possible to put forward a mechanism for the fragmentation of copper and thallium carboxylates in the gas phase under the influence of electron impact; the mechanism suggests that the rupture of the C–C bond of the carboxylate gives adducts $M.CO_2$ in which the CO_2 molecule is coordinated to the metal with the formation of a metal–carbon bond.[5,10–12] According to later calculations, the formation of structure (V) is not excluded.[14] In this case, however, difficulties arise, associated with the destabilisation of the adduct as a result of the repulsion of the lone pairs of electrons of the oxygen atoms with the bending of the CO_2 molecule.

It was found by the CNDO-2 method that the stability of the copper adducts $M.CO_2$ decreases in the order (II), (IV) ≫ (III) ≫ (I).[15,16] In the opinion of the authors cited,[15,16] the coordination of a CO_2 molecule to give structure (IV) is favourable because the formation of an M—C bond leads to an increase in the strength of the M—O bond, and vice versa. In the case of titanium (in contrast to copper), the highest stability is shown by the adduct with structure (III), due, in the opinion of the authors cited,[16] to the increase in the separation between the donor levels of the atom of this metal and the unoccupied $2\pi_u$-orbital of the CO_2 molecule on formation of the complex. When there is a high charge on the metal, structure (IV) becomes unfavourable, and coordination of type (I), when the electron density is displaced from the $1\pi_g$-level to an unoccupied *d*-orbital of the metal, is preferred.

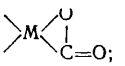
The *ab initio* method has been used to determine the nature of the coordination of CO_2 to the metal in the hypothetical complexes $(H_3P)_2Ni(CO_2)$ and $(H_3P)_2Cu(CO_2)^+$.[17] According to the data obtained by the authors cited,[17] who examined only structures of types (I) and (IV), the positively charged copper atom forms structure (I) preferentially, whereas for zerovalent nickel, the formation of structure (IV) is more probable. It is suggested that the coordination of carbon dioxide to nickel to give structure (IV) is brought about by the reverse displacement of electron density from the metal to the ligand, whereas the fact that structure (I) is preferred for copper(I) is due to the strong electrostatic interaction of the metal with the negatively charged oxygen atom. The authors cited do not exclude the possible formation of structure (III) for nickel, if for some reason (the non-availability of a coordination position, etc.) structure (IV) cannot be produced.

Calculation of the stability of the hypothetical complexes $(H_3P)_2Ni(CO_2)$ and $(H_3P)_2Cu(CO_2)^+$ by the extended Hückel method confirmed that structure (IV) is fairly stable for nickel, although its energy advantage over structure (I) is small.[18] The CNDO method was previously used to calculate the stability of the complex $(H_3P)_2Pt(CO_2)$, for which the coordination of CO_2 to the metal to give structure (IV) was found to be most favourable.[19]

The results of a calculation by the CNINDO method indicate that the adduct $Ag.CO_2$, obtained by the co-condensation of the products of the reaction of silver atoms with carbon dioxide, is stable in form (IV).[20] According to data obtained by various authers,[17—20] the CO_2 molecule coordinated to the metal is bent (problems related to the bending of CO_2 on excitation have been examined[1,2]).

Overall, the results of calculations of the stability of the complexes of transition metals with carbon dioxide by different methods indicate that the CO_2 molecule tends to coordinate to a metal atom through oxygen and carbon atoms simultaneously. Coordination to give structure (I) is most probable, however, for a positively charged metal, when the formation of the complex is essentially the result of the first stage of the reaction of the metal of the complex, acting as a Lewis acid, with carbon dioxide. Thus according to a calculation of the stability of the adducts of Zn^{2+} with carbon dioxide, the preferred structure is structure (I) with an equilibrium M—O distance of 1.85 Å.[21] According to calculations and spectral data, the adducts of CO_2 with the alkali metals have structures (I) (C_s) or (II) (C_{2v}) [22,23] (see also the next section).

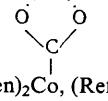
Structure (I) tends to undergo conversion into structures (III) and (IV) containing an M—C bond, whose formation in existing complexes has been confirmed by X-ray diffraction (see next section). This tendency in turn is the result of the transition from the primary act of activation of the CO_2 molecule in its reaction with the metal atom to give structure (I) to the formation of more stable adducts in which CO_2 is coordinated to the metal not only through an oxygen atom but also through the carbon atom [structures (III) and (IV)].



III. Complexes of transition metals with carbon dioxide

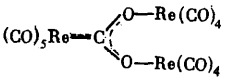
1. Stable complexes

Since carbon dioxide is a better acceptor than donor of electron density, it has been suggested that for this molecule, the formation of coordination compounds with the complexes of metals in a low oxidation stable is most characteristic.[2—4] In fact, compounds of this type have now been obtained by the direct action of carbon dioxide on complexes of metals with a low oxidation number, M^0 (Ni, Pt, Rh) or M^+ (Cu, Ag, Rh, Ir). Stable complexes have also been obtained by indirect methods.



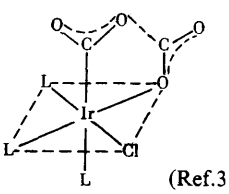
a. Direct method

The direct preparation of complexes of transition metals with CO_2 is of fundamental importance, since it is by this means that the CO_2 molecule can be introduced into catalytic processes. The first stable complex of CO_2 with rhodium(I) was obtained in 1969.[24] Since then, new complexes of various metals have been synthesised, fundamental problems associated with the use of CO_2 as a source of carbon for obtaining organic compounds have been solved, and the principal directions of study in the field of CO_2 fixation have been clearly defined. The number of complexes obtained by the direct method is small, since various side reactions take place. The difficulties associated with the preparation and identification of complexes of metals with CO_2 have been reviewed.[25] X-Ray diffraction has shown that a CO_2 molecule coordinated to a transition metal atom forms an M—C bond:



The following complexes have been obtained by the direct method:

$[(C_6H_{11})_3P]_2NiCO_2$ (Ref.26); $(\eta\text{-}C_5H_4Me)_2Nb(CH_2SiMe_3)(\eta^2\text{-}CO_2)$ (Ref.27);



(n-Pr-Salen)$_2$Co, (Ref.28) where Salen = salicylidene-ethylenediamine;

(Ref.29)

$[HOs_3(CO)_{10}CO_2Os_6(CO)_{17}]^-$ (Ref.30);

L = PMe_3

(Ref.31).

A recently prepared complex of rhodium with carbon dioxide is $(diars)_2Rh(\eta^1\text{-}CO_2)Cl$, where diars = $Me_2AsCH_2CH_2AsMe_2$, in which, as shown by X-ray diffraction, the CO_2 molecule is

coordinated to the metal atom only through an oxygen atom, that is to give structure (I) (see previous section).[7] Since X-ray diffraction data are not available, it is impossible to reach an unambiguous conclusion about the mode of coordination of CO_2 in the complex $(dppe)_2RhCl.CO_2$, where dppe = $Ph_2PCH_2CH_2PPh_2$.[32] In the opinion of Areste and Nobile,[33] the action of the phosphines $EtPPh_2$ and $n\text{-}Bu_3P$ on the complex $[Rh(C_2H_4)_2Cl]_2$ and CO_2 gives adducts of two types: $L_3RhCl.CO_2$ and $L_2RhCl.CO_2$. The formation of these adducts was confirmed only by infrared spectroscopy.

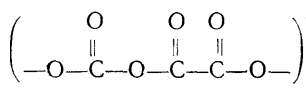
According to the same authors,[34] for the nickel complexes $L_2Ni.CO_2$, where L = Et_3P and $n\text{-}Bu_3P$, the bands in the infrared spectrum corresponding to the antisymmetric and symmetric stretches and deformations of the coordinated CO_2 molecule are displaced from 1740 (br., s), 1150 (v.s), 1094 (v.s), 845 (s), and 730 (med) [for $(C_6H_{11})_3P$] to 1660, 1203, 1009, 823, and 750 (for Et_3P) and 1660, 1003, 825, and 750 (for $n\text{-}Bu_3P$).

The reaction of carbon dioxide with the anionic complexes $[(Salen)_2Co]^-$ gives adducts of cobalt with CO_2.[28] From X-ray diffraction data it was concluded that these compounds are complexes of carbon dioxide with cobalt, and that the K^+ cation brings about additional specific coordination of the CO_2 molecule as a result of its reaction with two oxygen atoms of carbon dioxide. Without X-ray diffraction data it is difficult to determine whether the products of the reaction of CO_2 with $NaRe(CO)_5$ or $CpFe(CO)_2MgBr$ are complexes of the metals with carbon dioxide or salts of the metal-carboxylic acids.[34–36] For example, the insertion product obtained by the reaction of CO_2 with $CpFe(CO)_2MgBr$ (an organometallic analogue of the Grignard reagent) is readily alkylated by methyl iodide to give the ester of the iron-carboxylic acid:[35]

$$CpFe(CO)_2MgBr + CO_2 \rightarrow \{CpFe(CO)_2(CO_2MgBr)\} \xrightarrow{MeI} \longrightarrow CpFe(CO)_2CO_2Me.$$

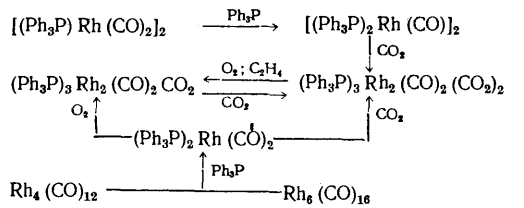
The problems associated with complex formation of this type have been examined in detail[36] (see also the next section). At the present time, because of the lack of X-ray diffraction data, it is difficult to determine the nature of the coordination of the CO_2 molecule in these compounds. Moreover, although in the complexes $[(Salen)_2Co]K$ the insertion of CO_2 is reversible,[28] the insertion of CO_2 into the rhenium and iron complexes[35,36] is irreversible.

The reaction of carbon dioxide with the complex $(dmpe)_2IrCl$, where dmpe = $Me_2PCH_2CH_2PMe_2$, gives the adduct $(dmpe)_2IrCl.CO_2$, which on heating is readily converted into a carboxylate complex of iridium:[37]



$$(dmpe)_2IrCl \cdot CO_2 \rightleftarrows Me_2PCH_2CH_2P(Me)CH_2CO_2(dmpe)IrCl.$$

If the ligand is not dmpe but diars (diars = $Me_2AsCH_2CH_2.AsMe_2$), the only product is $(diars)_2IrCl.CO_2$, whose infrared spectrum contains bands at 1550 cm^{-1} and 1220 cm^{-1}. The reaction of CO_2 with $(Me_3P)_3IrCl$, however, gives a complex containing two carbon dioxide molecules per metallic centre;[31] one CO_2 molecule is coordinated to the metal through an oxygen atom [structure (I)], and the other through the carbon atom [structure (III)], and the two CO_2 molecules are joined to one another by a C–O bond. It has also been suggested[38] that in the unstable adduct of molybdenum with carbon dioxide $(Me_3P)_3Mo.(CO_2)_2$, the two CO_2 molecules form a similar ring (the infrared spectrum of the adduct of iridium with two CO_2 molecules contains bands at 1725, 1680, 1648, 1605, 1280, 1008, and 790 cm^{-1}). The molybdenum complex readily disproportionates according to the scheme



$$2(Me_3P)_3Mo(CO_2)_2 \rightarrow [(Me_3P)_3Mo(CO_3)(CO)]_2,$$

(see also the next section).

The reaction of CO_2 ligands at a metallic centre is an important process for the activation of this molecule, and it determines to a large extent the nature of the final products. The study of the nature of the coordination of several molecules at a metallic centre is of considerable interest for an understanding of the processes involved in the chemisorption of carbon dioxide on the surface of heterogeneous catalysts or on the electrode surface in the electrocatalytic reduction of CO_2. An interesting result is the preparation of an adduct containing three CO_2 molecules per metallic centre, $Mg(CO_2)_3^{2-}$.[39] The adduct was obtained in an inert-gas matrix by the co-condensation of Mg vapour with carbon dioxide. Analysis of the chemical reactions and the infrared spectroscopic data indicates that oxalate and carbonate units are combined in its structure:

The synthesis of the paramagnetic rhodium complex $(Ph_3P)_3Rh_2.(CO)_2(CO_2)_2.C_6H_6$ has been described.[40,41] This complex can be obtained by different methods:

b. Indirect methods

The first complex of a transition metal with CO_2 to be obtained by an indirect method was $(Ph_3P)_3Rh_2(CO)_2.CO_2.C_6H_6$.[42] It was obtained by oxidising a carbonyl group on the metal with oxygen. Reactions of this type have been reviewed.[8] The same complex was synthesised by another method, via an unstable rhodium-carboxylic acid:[41]

$$L_2Rh(CO)OH + CO \rightarrow L_2Rh(CO)CO_2H,$$

$$L_2Rh(CO)CO_2H + L_2Rh(CO)OH \rightarrow L_3Rh_2(CO)_2CO_2 + H_2O + L,$$

$$L = Ph_3P.$$

This complex can be regarded as the rhodium salt of a rhodium-carboxylic acid. The role of metal-carboxylic acids in the preparation of complexes with CO_2 by this method has been examined.[36] In particular, the reaction of a platinum-carboxylic acid with a phosphine complex of zerovalent platinum gives polynuclear complexes with carbon dioxide:[43]

$$2L_2Pt(Cl)CO_2H + L_3Pt \rightarrow [L_2Pt(Cl)CO_2]_2PtL_2 + 2H^+ + L,$$

$$L = Ph_3P.$$

The polynuclear complexes of rhenium[29] and osmium[30] are also probably formed via metal-carboxylic acids. Thus the rhenium complex is formed via the intermediate $(CO)_5ReOH$, which may be present in equilibrium with $(CO)_4ReCO_2H$. In connection with the

preparation of complexes of metals with carbon dioxide via metal-carboxylic acids, mention may be made of the formation of an ester of an iridium-carboxylic acid from a complex with CO_2:[44]

$$dmpe_2\,IrCl\cdot CO_2 + MeSO_3F \rightarrow [dmpe_2Ir(Cl)\,CO_2Me]^+\,SO_3F^-.$$

The existence of the stable rhenium-, iron-, and iridium-carboxylic acids described in the literature extends considerably the possibilities for obtaining transition metal complexes.[36] The use of metal-carboxylic acids is also important because it gives complexes with carbon dioxide in which the M–C bond is fixed on a definite metal.

2. Unstable complexes

The formation of unstable adducts of carbon dioxide with transition metals takes place in the solid, liquid, and gas phases. Thus the co-condensation of silver atoms with CO_2 in a matrix gives the adduct $Ag.CO_2$.[20] From the similarity in the infrared and ultraviolet spectra of this adduct and the corresponding spectra of the complex of nickel with CO_2, whose structure has been determined,[26] it was concluded that the CO_2 molecule is π-coordinated to Ag. Adducts of CO_2 with other metals have been obtained in matrices.[45] It has been suggested that the formation of CO_3 by the ultraviolet irradiation of mercury in a carbon dioxide atmosphere involves the intermediate $Hg.CO_2$.[2] The formation of the adduct $Tl.CO_2$ in the solid phase during the thermal decomposition of thallium(I) carboxylates has been reported.[46]

The formation of unstable adducts $M.CO_2$ in solution has been examined.[1,2] In the formation of the complexes of carbon dioxide with hydride complexes of cobalt and iron, the initial stage of the reaction is the insertion of CO_2 at an M–H bond.[47,48] The existence of the equilibrium

$$(Ph_3P)_3\,Ru\,(H)\,O_2\,CH \rightleftarrows (Ph_3P)_3\,Ru\,(CO_2)\,H_2,$$

and the formation of an intermediate adduct of ruthenium with CO_2 were discussed in a study of the kinetics of the reduction of alkenes by formic acid in the presence of phosphine complexes of ruthenium.[1,8,49] ^1H NMR has been used to study the transformation of ruthenium formates into a complex of ruthenium with carbon dioxide in solution.[50,51] The formation of unstable complexes with CO_2 may take place in the decarboxylation of the fragment $[Ir]O_2CR$,[37] and also copper carboxylates.[52,53] Carbonate and hydrogen carbonate complexes are also formed via unstable intermediates formed by the metals with CO_2 (see next section). The formation of an adduct of cobalt with CO_2 has been noted in the electrolytic reduction of Co^{3+} complexes.[36]

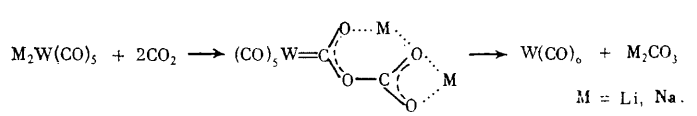
Adducts with CO_2 are formed in the reaction of N-bases with metal-carboxylic acids:[36]

$$[M]\,CO_2H + R_3N \rightleftarrows [M]\,CO_2^- + R_3NH^+.$$

The study of the behaviour of transition metal formates and metal-carboxylic acids in solution is extremely important for an understanding of the mechanism of the preparation of "synthetic gas":[7,36]

$$CO + H_2O \rightleftarrows CO_2 + H_2.$$

Different groups of workers have observed the formation of the following unstable adducts of metals with CO_2 in the gas phase (mass-spectrometric data): $Cu(CO_2)^+$,[54–57] $Cu_2O(CO_2)^+$,[55] $Cu(CO_2)_2^+$,[56] $Cu(O_2CR)(CO_2)^-$,[55] $Cu_2(CO_2)(O_2CR)^+$,[55] $Cu_4(CO_2)_2(CO)^+$,[55] $Cu_4(CO_2)_2(CO)_2^+$,[55] $Cu_4O_2(CO_2)_2^+$,[55] $Re(CO_2)^+$,[58] $(CO)_5Re(CO_2)Re(CO)_4^+$,[29] and $Tl(CO_2)^+$.[11–14,59,60]



A noteworthy feature is the selective formation of the adduct $Tl.CO_2^+$ from Tl^I carboxylates, which opens up the possibility of studying the mode of coordination of the CO_2 molecule to the metal in the gas phase and its behaviour in chemical reactions.[11–14] The reaction of nickel vapour with CO_2 gives Ni(CO).[61]

3. The formation of carbonate and hydrogen carbonate complexes in the reaction of CO_2 with transition metal compounds

The formation of carbonate and hydrogen carbonate complexes by the reaction of carbon dioxide with transition metal compounds is a side reaction in the preparation of complexes with CO_2, and in most cases takes place under mild conditions.[1,2,26] The formation of the carbonate ion and carbon monoxide can be represented as the result of the reaction of two radical-anions $CO_2^{\cdot-}$ at a metallic centre:[2]

$$2CO_2^{\cdot-} \rightarrow CO_3^{2-} + CO.$$

Thus the final product of the reaction of $(Me_3P)_4Fe$ with CO_2 is $(Me_3P)_3Fe(CO_3)(CO)$.[62] According to the data obtained,[62] this reaction involves the formation of an intermediate unstable adduct of iron with carbon dioxide. The formation of molybdenum carbonate from an adduct containing two CO_2 molecules per metallic centre was noted in section 1. Carbonates are readily formed by the reaction of CO_2 with hydride complexes of ruthenium, cobalt,[1,26] and rhodium,[26,63] and with alkyl derivatives of cobalt and palladium.[26] In the reaction of CO_2 with anionic complexes of transition metals under mild conditions, disproportionation of carbon dioxide to CO_3^{2-} and CO takes place.[26,64–70] Na_2CO_3 and CO were identified in the reaction of CO_2 with $CpFe(CO)_2Na$.[64] The rate of the reaction of carbon dioxide with anionic complexes of iron, nickel, tungsten, and manganese changes in the same sense as the relative nucleophilic character of the metals. The reaction of CO_2 with the complexes formed by the action of organic derivatives of Li, Mg, and Al on the hydrides $CpMH_2$, where M = Mo or W, has been studied.[65–67] The formation of the carbonate ion and CO involves the insertion of CO_2 at the M–Li, M–Mg, or M–Al bonds respectively. It has been suggested that in the reaction of the tungsten dianion with CO_2, an adduct with two CO_2 molecules is formed as an intermediate:[70]

The unstable adduct $[Ir]CO_2[Al]$ is probably liberated in the hydrolysis of an ester of an iridium-carboxylic acid in the presence of $AlCl_3$.[71]

The CO_2 molecule, which is a heterocumulene, contains nucleophilic and electrophilic centres, so that it can be activated extremely effectively by coordination to metals with different electron-donor and electron-acceptor properties (bifunctional catalysis). Catalysis of this type reveals most clearly the role of the catalytic centre containing the transition metal, to which carbon dioxide is able to coordinate to give an M–C bond, and also the role of metals of groups I–III, capable of forming M–O bonds (see next section).

IV. The insertion of carbon dioxide at an M–X bond

1. The insertion of carbon dioxide at an M–H bond

The problems associated with the insertion of a CO_2 molecule at an M–H bond have been reviewed in detail.[1,7,47,48] The insertion can take place in two ways:[1,7]

$$[M]-H + CO_2 \begin{cases} \longrightarrow [M]O_2CH \\ \longrightarrow [M]CO_2H \end{cases}.$$

The insertion products may be formed at an intermediate stage in the reduction of carbon dioxide to HCO_2H, etc. For example, the reaction of carbon dioxide with $(Ph_3P)_2Cu.BH_4$ [72] or with $(dppe)ReH_3$ [73] gives $L_2Cu(\eta^2\text{-}O_2CH)$ and $(dppe)ReO_2CH$ respectively. The reaction of the cluster $(Ph_3PCuH)_6$ with CO_2 has been studied.[74] The main product is formate, but the authors cited suggest that an unstable copper-carboxylic acid is formed in one of the stages. Carbon dioxide can be selectively reduced to MeO^- by treatment with the hydride complex of zirconium $Cp_2Zr(H)Cl$.[75] In the $TiCl_4-Mg-CO_2-THF$ system, the formate complex $Ti(O_2CH)_2.MgCl_{1.5}.THF$ is formed.[76] The source of hydrogen (moisture or the solvent) is not indicated, but it is stated that in the reaction of $TiCl_4$ with Mg in THF it is possible to isolate a complex which gives titanium formate when treated with CO_2:

$$2TiCl_4.2THF + 6Mg + 2THF \xrightarrow{Ar} (TiMg_2Cl_2.THF)_2 + 2MgCl_2.THF \xrightarrow{CO_2} Ti(O_2CH)_2MgCl_{1.5}.THF.$$

The presence of traces of moisture in the solvent or the addition of water may have a significant influence on the nature of the catalytic processes involving carbon dioxide.[1,7,8] Thus the reduction of CO_2 by molecular hydrogen in $C_6H_6-H_2O$ solution in the presence of basic additives and phosphine complexes of palladium, rhodium, ruthenium, and iridium gives formic acid.[77] A significant feature is that when these systems contain hydrogen carbonate, HCO_2H is also formed in the absence of CO_2. In this connection it should be noted that transition metal compounds are able to activate water with the formation of hydride complexes. In the presence of phosphine complexes of palladium and copper as catalysts, and of alcohols and amines as additives, methane is formed in addition to derivatives of formic and oxalic acids.[78] The formation of CH_4 from CO_2 and H_2 has also been observed in the presence of ruthenium compounds deposited on an Al_2O_3 surface.[79]

A phosphine complex of ruthenium or its hydride cluster have been used for the hydrosilylation of carbon dioxide.[80,81] This reaction takes place with the intermediate formation of ruthenium formates.

2. The insertion of carbon dioxide at an M–C bond

The solution of the fundamental problems associated with the insertion of CO_2 at a transition metal–carbon bond[1] stimulated the appearance of a large number of publications on this topic. From the wide range of studies it is necessary to distinguish those involving the investigation of the mechanism of the reactions leading to the formation of the M–C bond and the preparation of organic products by the carboxylation of intermediates produced, for example, by the oligomerisation or polymerisation of unsaturated compounds in the presence of catalysts. Of particular importance is the formation of organic products as a result of the carboxylation, by carbon dioxide, of organometallic compounds produced by the activation of C–H bonds by transition metal complexes. Thus acetonitrile, acrylonitrile, and phenylacetylene are carboxylated in the presence of phosphine complexes of rhodium and iridium ML_4^+, where L = a trialkyl- or triarylphosphine:[82]

$$L_4M^+ + RH \rightleftarrows L_4M(R)H \underset{-CO_2}{\overset{+CO_2}{\rightleftharpoons}} L_4M(O_2CR)(H).$$

It has also been shown that it is possible in principle to carry out the carboxylation of cyclohexene in the presence of H_2 and of amines to the corresponding acid amides on complexes of iridium, rhodium, platinum , and palladium.[83]
